Relationship Between NK Cell Count and Important Safety Events in Rheumatoid Arthritis Patients Treated with Tofacitinib. R. van Vollenhoven[1], Y. Tanaka[2], R. Riese[3], M. Lamba[3], T. Kawabata[3], T. Hirose[4], S. Toyoizumi[4], A. Hazra[3] and S. Krishnaswami[3]. [1]The Karolinska Institute, Stockholm, Sweden, [2]University of Occupational and Environmental Health, Kitakyushu, Japan, [3]Pfizer Inc, Groton, CT, [4]Pfizer Inc, Tokyo, Japan.

Background/Purpose: Tofacitinib is an oral Janus kinase (JAK) inhibitor for the treatment of rheumatoid arthritis (RA). Cytokines (e.g. interleukin [IL]-2, -4, -7, -15, -21) involved in lymphocyte development, function and homeostasis are known to signal through JAK. Objectives were to characterize changes in natural killer (NK) cell counts following tofacitinib treatment and evaluate the relationship between NK counts and rates of infection and malignancy.

Methods: Lymphocyte subset data, enumerated by flow cytometric analyses, were pooled from 3 double-blind, placebo-controlled, Phase 2 (P2) studies (two monotherapy and one background methotrexate [MTX]) in MTX inadequate responders, and from a sub-study of an ongoing long-term extension (LTE) study (study is ongoing; database not locked). RA patients (pts) received tofacitinib (1 to 30 mg twice-daily [BID]) or placebo for 6 to 24 weeks in P2 and tofacitinib 5 or 10 mg BID for 22 months (median) in LTE. 928 and 161 pts contributed NK cell data in P2 and LTE, respectively. Correlations between baseline or nadir NK cell count and serious infection (SIE, any infection that requires hospitalization for treatment or parenteral antimicrobial therapy), herpes zoster (HZ) and malignancy (excluding non-melanoma skin cancer) were assessed by sub-dividing NK cell data into deciles and calculating incidence rate (events/100 pt years) of adverse events for each decile.

Results: Following tofacitinib administration, NK cell counts decreased in a dose-dependent manner by Week 2 (Figure 1). Median NK cells counts returned to baseline 2 to 6 weeks after treatment discontinuation (dc). At the 5 mg BID dose, pts with the largest (>90th percentile) decrease in NK cell counts recovered from ~70% below baseline to ~18% by 6 weeks after treatment dc (n=4). The estimated median decrease for 5 mg BID at Week 24 was ~35%. Cross-sectional analyses in different groups of pts showed similar median NK cell count in the LTE (141 cells/μL) compared to pre-treatment baseline (135 cells/μL). No clear association between baseline or nadir NK cell counts (predominantly collected within first 6 months of treatment) and the incidence of SIE, HZ or malignancy (Figure 2) was seen over the period of observation (median duration 1.9 years).

Conclusion: Tofacitinib treatment is associated with a dose-dependent decrease in NK cell counts. No association between baseline or nadir NK cell counts and the incidence of SIE, HZ or malignancy was observed. Long-term lymphocyte subset data are being collected in the ongoing LTE study to confirm these relationships.

Figure 1: Time course of NK cell counts in Tofacitinib or Placebo Treated RA Patients

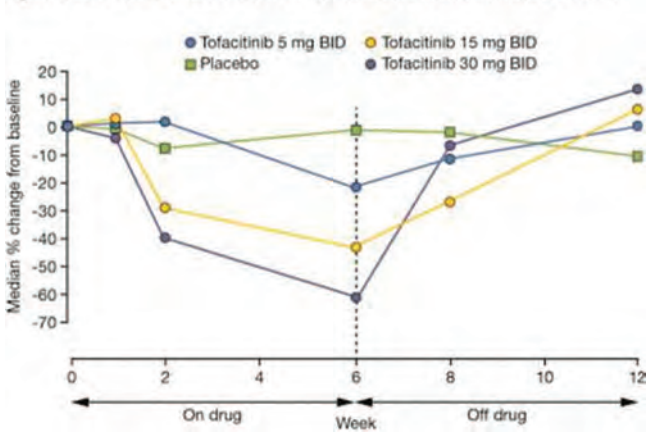

Figure 2: Lack of correlation between NK cell counts and Malignancy excluding non-melanoma skin cancer

Etanercept Have Better Drug Survival Than Monoclonal Antibodies in Rheumatoid Arthritis: Results of Single Center Hur-BIO Registry. Umut Kalyoncu[1], Murat Torgutalp[2], Hakan Babaoglu[2], Sadettin Kilickap[2], Sedat Kiraz[3], Ali Akdogan[1], Omer Karadag[1], Abdulsamet Erden[2],

Sule Apras Bilgen[2] and Ihsan Ertenli[1]. [1]Hacettepe University Faculty of Medicine, Ankara, Turkey, [2]Hacettepe University, Faculty of Medicine, Ankara, Turkey, [3]Hacettepe Unv.Tip Fakultesi-Romatoloji Servis, Ankara, Turkey.

Etanercept have better drug survival than monoclonal antibodies in Rheumatoid Arthritis: Results of single center HÜR-BÝO registry

Background/Purpose: In routine practice, observational registries may show retention rates of TNFi drugs in rheumatoid arthritis (RA). The objective of this study was to compare TNF inhibitors regarding the drug survival rate in RA patients.

Methods: HÜR-BIO (Hacettepe University Rheumatology Biologic Registry) is a single center biological registry since 2005. Data collected includes demographic data, switch ratio, baseline and follow-up disease activity parameters (if available). Patients with regularly follow-up status were recorded systematically. Patients with lost of follow-up searched regarding to last TNFi prescription date either local computer system or national social security institution database. Inition and last date of TNFi were noted from those systems. First TNFi drug switch date (either advers event or inefficacy) was accepted as main variable for drug survival. Kaplan-Meier plots and log rank tests were used to assess drug survival. HÜR-BIO is not sponsored by any pharmaceutical company.

Results: HÜR-BIO includes 815 RA patients, however 156 of 815 patients excluded because of other biological agents such as rituksimab, abatecept and golimumab. Of 659 patients 77,7% was female. Mean age was 50±13 years and mean disease duration was 11±8 years. TNFi drug duration was 3,2±2,8 years and 176 (26,7%) patients were used TNFÝ drugs more than 5 years. Positive ACPA and RF were 216/356 (60,6%) and 353/601 (58,7%), respectively. First TNFi drugs were etanercept 321 (48,7%), adalimumab 223 (33,8%) and infliximab 115 (17,5%). TNFi switch was found in 246 (37,3%) patients. Patients were divided as regularly follow-up (either first biological drugs or another biological drugs) 487 (73,9%), lost of follow-up 114 (17,3%), drug cessation 35 (5,3%), exitus 15 (2,3%) and not first control performed 8 (1,2%). Patients with etanercept had better drug retention than monoclonal antibodies (log rank p=0.014), figure 1.

Conclusion: In this single center observational registry, etanercept had better drug retention rate than monoclonal antibodies. Our result is similar with another registry such as DANBIO (1). On the other hand, certain confounder factors such as baseline disease activity, functional status, socioeconomic status were not known in whole patients, thus our results should evaluate in this limitation.

Similar Short Term Survival on Drug for Patients with Rheumatoid Arthritis Treated with Subcutaneous and Intravenous Abatacept - Results from the National Swedish Rheumatology Quality Register. Carl Turesson[1], Leszek Stawiarz[2], Staffan Lindblad[2] and Saedis Saevarsdottir[3]. [1]Section of Rheumatology, Department of Clinical Sciences, Malmö, Lund University, Malmö, Sweden, [2]Karolinska Institutet, Stockholm, Sweden, [3]Rheumatology Unit, Department of Medicine, Karolinska institutet and Karolinska University Hospital, Stockholm, Sweden.

Background/Purpose: Abatacept is a biological anti-rheumatic drug used in Rheumatoid Arthritis (RA). Data on patient characteristics, diagnosis, previous treatment and outcomes of abatacept have been collected in the Swedish Rheumatology Quality register (SRQ) which comprises the Swedish Biologics (ARTIS; Arthritis Treatment In Sweden) register, since the drug was approved in 2006. In early 2013, subcutaneous treatment with abatacept became available. The objective of this study was to investigate baseline characterstics and drug survival probability in clinical practice for patients with RA treated with subcutaneous (sc) vs. intravenous (iv) abatacept, using a national register.

Methods: Observational data from the SRQ for the period when both iv and sc abatacept were available, January, 2013 to May 20, 2014, were obtained. Kaplan-Meier survival analysis with right censoring and log-rank test of equality across strata were performed and Šidák multiple-comparison adjustments applied.

Results: A total of 371 patients with RA were started on their first treatment with abatacept during the study period (252 with sc administration and 119 with iv treatment). Age (mean 58.7 vs 59.7 years), RA duration at treatment initiation (median 12.8 vs 13.2 years) and sex distribution (79 % vs 81 % women) were similar in the two groups, and there was no major difference in baseline disease activity (DAS28; mean 5.10 vs. 4.98). Among those receiving sc treatment, 21 % were bio-naïve, 26 % had previously been exposed to one biologic drug, and 53 % to ≥ 2 biologics. The corresponding figures among those treated with iv abatacept were 17%/ 30%/ 53 %. There was no significant difference in the survival on drug for those on sc, compared to iv treatment (p=0.19). The estimated survival rates at 6 months were 76 % (sc) and 81 % (iv). Furthermore, there were no significant differences in drug survival in analyses stratified by previous exposure to biologics (p=0.73 for bio-naïve patients, p=0.19 for those with 1 previous biologic, and p=0.32 for those with ≥ 2 previous biologics).

Conclusion: In this observational study of a real-life national cohort, the majority of patients with RA started on abatacept since the subcutaneous administration form became available received that form of treatment. There were no major differences in baseline characteristics or short term survival on drug between patients treated with subcutaneous or intravenous abatacept. This supports clinical trials that have demonstrated similar efficacy and safety for the two routes of administration of abatacept.

First and Second Line Continuation Rates of Non Anti-TNF-α Biological DMARD for the Treatment of Rheumatoid Arthritis. Tristan Pascart[1], Rene-Marc Flipo[2], Xavier Deprez[3] and Eric Houvenagel[4]. [1]Saint-Philibert Hospital, Lille, France, [2]University Hospital Lille, Lille, France, [3]Ch De Valenciennes, Valenciennes, France, [4]Saint-Philibert Hospital, LOMME, France.

Background/Purpose: The 2013 update of the EULAR recommendations for the management of RA with synthetic and biological DMARDs set non-anti-TNF- α as first-line biological treatments. Yet, available data regarding treatment after rituximab, abatacept and tocilizumab failure is weak. The objective of this study was to compare continuation rates of second line non-anti-TNF- α treatments after a first non-anti-TNF- α failure.

Methods: This retrospective multicentre study included patients treated for RA with rituximab, abatacept or tocilizumab after having received in a previous line abatacept, tocilizumab or rituximab from 2002 to 2013. Data were collected from patients' file including baseline and final DAS28-ESR and DAS28-CRP for both lines of treatment, motives for treatment introduction and discontinuation. Follow-up of the second line of treatment was one year. The primary endpoint was the continuation rate at the end of the first year of treatment.

Results: A total of 100 patients were included. Patients had previously received an average of 2.6 (+/− 0.9) biological DMARDs. Patients were aged 55.4 (+/− 11.5) years and disease duration was 14.3 (+/− 9.4) years. In first line, 29 patients were treated with tocilizumab, 26 with abatacept and 45 received rituximab. In second line of treatment, 49 patients were treated with abatacept, 36 received tocilizumab and 15 rituximab. Methotrexate was associated in 36% of cases. The first line of treatment was continued for 15.6 (+/− 14.4) months. At baseline, DAS28-ESR was 5.57 (+/− 1.19) and DAS28-CRP was 5.25 (+/− 1.15) for the first line and DAS28-ESR was 5.00 (+/− 1.41) and DAS28-CRP was 4.84 (+/− 1.22) for the second line of treatment. Treatment continuation rates at the end of the first year was 45.9% in first line and 58.6% in second line of treatment (p=0.10). In patients without Methotrexate, continuation rates at the end of the first year was 37.5% for the first line of treatment and 64.3% in the second line (p=0.009). In the first line of treatment, 66.6% of patients that interrupted their treatment for a reason of intolerance in the first year of treatment versus 15.5% in the second line of treatment.

Conclusion: After a first non-anti-TNF- α biological DMARD failure, continuation rates at one year are similar in the second line of non-anti-TNF-α treatment. Association to Methotrexate does not seem to bring any benefits in the second line of treatment.

Effect and Safety of Concomitant Methotrexate and Tacrolimus on Clinical Response of Abatacept in Rheumatoid Arthritis Patients with Prior Use of Biological Dmards. Nobunori Takahashi[1], Toshihisa Kojima[1], Yuji Hirano[2], Yasuhide Kanayama[3], Koji Funahashi[1] and Naoki Ishiguro[1]. [1]Nagoya University Graduate School of Medicine, Nagoya, Japan, [2]Toyohashi Municipal Hospital, Toyohashi, Japan, [3]Toyota Kosei Hospital, Toyota, Japan.

Background/Purpose: Abatacept (ABT) is a new class of biologic agents for the treatment of rheumatoid arthritis (RA) that inhibits T cell activation by binding to CD80/86. It has been reported that ABT was less effective in the patients with previous biological DMARDs and concomitant MTX had only little enhancing effect on ABT efficacy. Tacrolimus (TAC) was approved in Japan for the treatment of RA (oral dosage of ≤ 3 mg/day). It down-regulates the synthesis of inflammatory cytokines activated by T cells mainly via inhibition of a calcineurin. In this study, we investigated whether concomitant TAC had enhancing effect on ABT efficacy in the patients with previous biological DMARDs, using data from a Japanese multicenter registry system (TBCR).

Methods: The present study included all patients who had previous biological DMARDs and were initiated intravenous ABT and prospectively observed for longer than 52 weeks at TBCR-affiliated institutes (n = 121). Demographic data and the following parameters of disease activity were collected; tender joint count (TJC) and swollen joint count (SJC), patient global assessment (VAS), ESR, and serum CRP at baseline, 4, 12, 24, and 52 weeks. We compared these clinical data between the patients treated without concomitant MTX or TAC (ABT-mono, n=42), those treated with concomitant MTX (ABT-MTX, n=56), and those treated with concomitant TAC (ABT-TAC, n=18). The last observation carried forward (LOCF) method was used in each analysis.

Results: In the baseline characteristic data, the ABT-mono group had higher pulmonary comorbidity rate (23.8%, p = 0.030) compared to the ABT-MTX (5.4%) and ABT-TAC (16.7%) group while no other clinical parameters showed significant difference including all disease activity indices such as DAS28-ESR (5.10, 5.30, and 5.30, p = 0.949). The ABT-TAC group demonstrated significantly lower f¢% of DAS28 score compared to the ABT-mono group while no difference between the ABT-mono and ABT-MTX group (Left panel). The patients taking 3 mg/day dosage of TAC demonstrated apparently lower f¢% of DAS28 score compared to those taking < 3 mg/day (Middle panel). Kaplan-Meier analysis demonstrated that the ABT-MTX group showed significantly higher discontinuation rate due to adverse events compared to the ABT-mono group while no difference between the ABT-TAC and ABT-mono group (Right panel).

Conclusion: We clearly demonstrated that concomitant TAC treatment had dose-dependent enhancing effect on the ABT efficacy, while there seemed to be little combinational effect of ABT and MTX. Since both ABT and TAC are the agents targeting T cells, there is concern regarding safety issue when used in combination. However, in our results, the ABT-TAC group did not show increased discontinuation due to adverse events. We would suggest that combination of ABT and TAC treatment should be helpful when we treat the patients with previous biological DMARDs history.

Analysis of Shoulder Joint Destruction in Rheumatoid Arthritis Patients Treated with Biologics. Yukio Yonemoto, Koichi Okamura, Tetsuya Kaneko, Chisa Okura and Kenji Takagishi. Gunma University Graduate School of Medicine, Maebashi, Japan.

Background/Purpose: The assessment of joint destruction in rheumatoid arthritis (RA) patients being treated with biologics is normally mainly carried out for small joints. There are a few reports that have so far assessed joint destruction of large joints, and no reports that assess joint destruction of the shoulder joint. The aim of this study was therefore to assess the risk factors for shoulder joint destruction in RA patients being treated with biologics based on the findings of both the magnetic resonance imaging (MRI) and 18F-fluorodeoxy glucose positron emission tomography (PET).

Methods: Twenty-nine shoulders (5 male shoulders, 25 female shoulders; 16 right shoulders, 14 left shoulders) in 30 patients with RA were assessed using PET and MRI before starting biologics and then again six months later. The mean age (range) was 54 (18–72) years and the mean disease duration was 7 (0.8–30) years. The XP findings were assessed before starting biologics and then again three years later. The CRP, ESR and MMP-3 levels, and the DAS28-ESR, DAS28-CRP, CDAI and SDAI scores were also assessed. We compared these parameters between the progression of joint destruction group (P group) and the no progression group (N group).

Results: The SUV max, the rates of synovitis and the rates of rotator cuff tear on MRI before biologics treatment were significantly higher in the P group than in the N group. The SUV max and synovitis detected by MRI after biologics were also significantly higher in the P group. The CRP, ESR and MMP-3 levels and disease activity showed no significant differences between the two groups. RA patients who had severe joint destruction (Larsen grade ≧ III) before starting biologics demonstrated a significantly greater progression of shoulder joint destruction than the patients who had mild joint destruction (Larsen grade ≦ II) before starting biologics.

Conclusion: The detection of synovitis by PET or MRI is thus considered to be more important than the disease activity and serum inflammation markers when assessing the potential for a progression of shoulder joint destruction. In addition, a previous history of joint destruction and rotator cuff tears is also an important factor for the evaluation of shoulder joint destruction in RA patients.

Methotrexate Reduces the Frequency of Prediabetes in Patients with Rheumatoid Arthritis or Psoriatic Arthritis. Katja Perdan-Pirkmajer[1], Sergej Pirkmajer[2], Alojzija Hocevar[1], ŽIga Rotar[1], Natasa Gaspersic[1], Sonja Praprotnik[1], Matija Tomsic[3] and Ales Ambrozic[1]. [1]University Medical Centre Ljubljana, Ljubljana, Slovenia, [2]Faculty of Medicine Ljubljana, Ljubljana, Slovenia, [3]University Medical Centre Ljubljana, Ljubljana, Slovenia, Ljubljana, Slovenia.

Background/Purpose: Rheumatoid arthritis (RA) and psoriatic arthritis (PsA) are associated with an increased risk of diabetes mellitus (DM). Disease-modifying anti-rheumatic drugs, including methotrexate (MTX), may exert protective metabolic effects conducive to reduced incidence of DM. Whether MTX mitigates metabolic risk factors in non-diabetic RA and PsA patients has not been determined unequivocally. In this study we assessed metabolic parameters in RA or PsA patients during the first six months of MTX therapy.

Methods: Newly diagnosed, MTX-naïve RA (2010 ACR/EULAR criteria) and PsA (CASPAR criteria) patients were included between December 2012 and June 2013. Patients with DM or hypothyroidism were excluded. The initial assessment included DAS28ESR, BMI, fasting plasma glucose and insulin, HbA_{1c}, TSH, triglycerides, HDL, LDL and urate. Disease activity and the metabolic parameters were followed 1, 2, 3 and 6 months after MTX initiation. Uninterrupted MTX treatment with dose escalation according to the treat to target approach was required. HOMA-IR (glucose (mM) × insulin (μU/ml)/22.5), HOMA-B (20 × insulin (μU/ml)/[glucose (mM)-3.5]) and QUICKI ($[\log_{10}$glucose (mg/dl) + $\log_{10}$insulin (μU/ml)$]^{-1}$) were used as surrogate indices of insulin sensitivity and β-cell function. ANOVA or the Kruskal-Wallis test, followed by an appropriate *post hoc* test was used to establish statistical significance.

Results: Inclusion criteria were fulfilled by 16 RA and 10 PsA patients (16 female, 10 male). Mean age was 52.5±12.2 (range: 27–76), BMI 28.4±4.8 kg/m^2 (range: 19.7–39.4) and the initial DAS28ESR 5.23±1.27 (range: 2.95–7.71). Eighteen patients had prediabetes according to the American Diabetes Association criteria (HbA_{1c}: 5.7–6.4%), while 11 patients had insulin resistance as assessed by HOMA-IR (>2.5). After six months of MTX (±methylprednisolone) therapy remission or low disease activity (DAS28ESR<3.2) was achieved in 76%. BMI, fasting plasma glucose, insulin, triglyceride, cholesterol or urate levels remained unaltered. Conversely, HbA_{1c} (%) decreased in a time-dependent manner from the baseline value of 5.80±0.29% to 5.55±0.31% (n=26, P=0.017) at 6 months. HbA_{1c} (%) was reduced in 17 out of 26 patients. The decrease in HbA_{1c} (%) was especially pronounced in patients without insulin resistance at inclusion (5.82±0.35% vs. 5.42±0.32%, P=0.013, 12 out of 14 patients). Overall, the number of patients with prediabetes was reduced from 18 to 8. HOMA-IR, HOMA-B and QUICKI remained unaltered in patients receiving MTX or MTX and methylprednisolone, indicating co-therapy with methylprednisolone did not impair insulin sensitivity.

Conclusion: MTX reduces serum HbA_{1c} in non-diabetic RA or PsA patients during the initial 6 months of treatment. As assessed by HbA_{1c} MTX also reduces the prevalence of prediabetes, consistent with the notion that MTX protects against the development of DM. According to recent data HbA_{1c} is not only an established predictor of CV risk in diabetic patients, but also an independent CV risk predictor in non-diabetics. Taken together, our findings support a possible role of MTX in reducing DM and CV risk in RA as well as PsA patients.

Dosing of Intravenous Tocilizumab in a Real-World Setting—Analyses from a US RA Registry. Dimitrios A. Pappas[1], Ani John[2], Jeffrey R. Curtis[3], George W. Reed[4], Chitra Karki[5], Robert Magner[6], Joel M. Kremer[7], Ashwini Shewade[2] and Jeffrey D. Greenberg[5]. [1]Columbia University, New York, NY, [2]Genentech, Inc, South San Francisco, CA, [3]University of Alabama at Birmingham, Birmingham, AL, [4]Corrona, LLC., Southborough, MA, [5]Corrona, LLC, Southborough, MA, [6]University of Massachusetts Medical School, Worcester, MA, [7]Albany Medical College and The Center for Rheumatology, Albany, NY.

Background/Purpose: In the US, the recommended starting dose of intravenous tocilizumab (TCZ) in combination with DMARDs or as monotherapy is 4 mg/kg every 4 weeks and increased to 8 mg/kg based on clinical response for patients with moderate to severe rheumatoid arthritis (RA)[1]; however, data on actual dose escalation patterns are limited. The objective of this analysis was to evaluate how intravenous TCZ is dosed in a real-world setting using data from the Corrona registry.

Methods: All patients enrolled in the comparative effectiveness substudy (CERTAIN) nested within Corrona who initiated TCZ and had 3- and 6-month follow-up data available were eligible for inclusion in this analysis. Data were collected from patients who remained on their initial TCZ dose of 4 mg/kg at 3 months (Group 1) and patients who had their TCZ dose escalated to 8 mg/kg by or at 3 months (Group 2). Unadjusted efficacy response data were provided for patients at 3 and 6 months, including Disease Activity Score in 28 joints using C-reactive protein (DAS28-CRP), Clinical Disease Activity Index (CDAI), CRP, modified Health Assessment Questionnaire, patient pain, patient fatigue and EULAR response.

Results: Of the 196 patients included in this analysis, 56.1% (95% CI, 48.9% to 63.2%) escalated their TCZ dose by or at 3 months (Group 1, n = 86; Group 2, n = 110). Baseline characteristics were similar between dosing groups, except patients in Group 2 were older (58.3 vs 54.0 years) and a lower proportion were female (75.5% vs 89.4%) compared with patients in Group 1. At baseline, the mean (SD) CDAI was 32.4 (13.9) and 31.3 (12.9), mean (SD) DAS28-CRP was 5.1 (1.1) and 5.0 (1.2) and mean (SD) CRP was 10.4 (15.1) mg/L and 13.0 (20.2) mg/L in Group 1 and Group 2, respectively. The median (IQR) number of prior biologics was 2.0 (1.0, 4.0) and 2.0 (1.0, 3.0) in Group 1 and Group 2, respectively, suggesting a rather refractory disease. Unadjusted disease activity response outcomes at 3 months were mostly

similar between the 2 groups, except median (IQR) decrease from baseline in CRP was significantly greater in Group 2 vs Group 1 (−3.4 [-12.8, -0.8] mg/L vs -1.0 [-5.0, 1.0] mg/L; $P = 0.001$). At 6 months, efficacy outcomes remained similar between the 2 groups (**Table**); however, a numerically higher proportion of patients in Group 2 achieved EULAR good responses, CDAI low disease activity and DAS28-CRP low disease activity and remission vs Group 1, and median decrease from baseline to 6 months in CRP was significantly greater in Group 2 vs Group 1.

Conclusion: Real-world data show that physicians escalate the dose of TCZ at varying frequencies. In slightly more than one half of TCZ initiators in this refractory to therapy population, the TCZ dose was escalated by 3 months. The majority of patients in both groups achieved moderate or good EULAR response.

The Safety and Treatment Efficacy of Abatacept in Rheumatoid Arthritis Patients with Pulmonary Complications: From the Tsurumai Biologics Communication Registry (TBCR) Multicenter Study.

Shinya Hirabara[1], Toshihisa Kojima[2], Nobunori Takahashi[2], Yuji Hirano[1], Atsushi Kaneko[3], Daihei Kida[4], Yasuhide Kanayama[5] and Naoki Ishiguro[2]. [1]Toyohashi Municipal Hospital, Toyohashi, Japan, [2]Nagoya University Graduate School of Medicine, Nagoya, Japan, [3]Nagoya Medical Center, Nagoya, Japan, [4]Nagoya Medical Center, National Hospital Organization, Nagoya, Japan, [5]Toyota Kosei Hospital, Toyota, Japan.

Background/Purpose: Roughly 10–30% of rheumatoid arthritis (RA) patients reportedly develop pulmonary complications. These patients are at increased risk of MTX or biologics-induced damage, which often becomes problematic for RA treatment. Abatacept (ABT) has been reported to have relatively few adverse events, and is often used in clinical settings in patients with pulmonary complications. Given the paucity of studies on the safety of ABT, however, accumulation of safety data under actual clinical settings is warranted. In the present study, we examined the persistence rates and treatment effects of ABT in patients with pulmonary complications.

Methods: We divided 250 RA patients registered in the Tsurumai Biologics Communication Registry who used ABT for ≥52 weeks according to whether they had pulmonary complications (L group: n=32) or not (N group: n=218). We then compared the persistence rates, incidence of adverse events, and disease activity between the two groups.

Results: No significant differences were found between groups with regard to mean age (L group, 67.7±6.9; N group, 64.0±12.8), disease duration (L group, 12.6±9.8; N group, 11.8±8.8), concomitant use rates of steroid (L group, 62.5%; N group, 60.5%), CRP (L group, 2.6±2.9; N group, 2.1±2.8), DAS28-CRP (L group, 4.7±1.5; N group, 4.4±1.3), or SDAI (L group, 28.8±16.5; N group, 24.5±14.0) at the time ABT was initiated, but significant differences were found in the percentage of women (L group, 65.6%; N group, 83.5%) and concomitant use rates of MTX (L group, 25%; N group, 53.2%). The persistence rates for 52 weeks were 73.1% and 74.3% in the L and N groups, respectively (Figure 1a). Adverse events occurred in 1 (3.13%) and 7 (3.83%) patients in the L and N groups, respectively. No pulmonary complications occurred after ABT administration in the L group, but 2 patients in the N group had interstitial pneumonia. Treatment was discontinued due to insufficient response in 6 (18.8%) and 29 (15.9%) patients in the L and N groups, respectively. None of these were significantly different by group. Mean DAS28-CRP significantly improved in both groups (Figure 1b), from 4.7 at ABT initiation to 3.2 at 52 weeks in the L group (P<0.01), and from 4.4 to 3.1 in the N group (P=0.034). Achievement of those with low disease activity also increased, from 9.4% at ABT initiation to 53.3% at 52 weeks in the L group, and from 8.3% to 47.7% in the N group.

Conclusion: The safety, treatment effects, and persistence rates of ABT were similar among RA patients with and without pulmonary complications. Use of ABT is beneficial even in patients with pulmonary complications, under close consideration of the risks involved.

Real-World Use of Tocilizumab in Rheumatoid Arthritis Patients in Canada: Interim Results. Boulos Haraoui[1], Shahin Jamal[2], Vandana Ahluwalia[3], Tarang Manchanda[4] and Majed Khraishi[5]. [1]Centre Hospitalier de l'Université de Montréal, Montréal, QC, [2]University of British Columbia, Vancouver, BC, [3]William Osler Health Center, Brampton, ON, [4]Hoffmann-La Roche Canada, Mississauga, ON, [5]Nexus Clinical Research, St John's, NF.

Background/Purpose: Tocilizumab (TCZ) has been approved for the treatment of adults with rheumatoid arthritis (RA) either as monotherapy or as combination with disease-modifying antirheumatic drugs (DMARDs). However, to date, data on its real-world utilization and durability are limited. The aim of this analysis is to describe the pattern of TCZ use at baseline (BL) and after 6 months (mos) of treatment in Canadian patients enrolled in ACT-UP, a multi-national observational study in moderate-to-severe RA patients treated with TCZ.

Methods: ACT-UP is an ongoing, multi-national, observational study with TCZ. As of June 2014, 1,375 patients have been enrolled from 14 countries. In this analysis, data from the 200 Canadian patients participating in ACT-UP were used. Descriptive statistics were produced and between-group comparisons were performed with the independent samples t-test (continuous variables) and the chi-square test (categorical variables).

Results: Among the 200 patients included, 67 (33.5%) started TCZ as monotherapy and 133 (66.5%) in combination with DMARD(s) (mean methotrexate dose: 19.9 mg/week). BL age (55.2 vs 55.6 years, respectively), gender (79.1% vs 80.5% females) and disease duration (13.8 vs 12.0 years) were similar in the two groups. No difference in the initial TCZ dose was observed between groups with 91.0% in each receiving 8 mg/kg and the remaining receiving <8 mg/kg. Similarly, concomitant use at BL of a corticosteroid (38.8% vs 36.1%; mean prednisone dose: 10.7 vs 9.2 mg/day) and prior exposure to a biologic (80.6% vs 82.0% in monotherapy vs combination therapy) were also comparable in TCZ monotherapy vs combination therapy. Lack of efficacy (70.4% vs 68.2%) and intolerance (12.2% vs 10.9%) were the most common reasons for stopping a previous biologic in both treatment groups. However, a significantly higher proportion of patients in the monotherapy group had been previously treated with >1 traditional DMARD (90.8% vs 66.9%; P<0.001). Overall, BL disease parameters were statistically comparable between treatment groups with the exception of patient global assessment which was significantly higher in the TCZ monotherapy group (68.1 vs 60.6 mm; P=0.017).

Upon 6 mos of treatment, 86.6% of patients in the monotherapy group and 85.0% in the combination therapy group were still on TCZ. Over that period no change in TCZ dose was reported in 80.6% patients (76.9% vs 82.5% in mono- vs combination therapy), while the TCZ dose was down-titrated in 14.7% patients (18.5% vs 12.7%, respectively). Seven of 67 (10.4%) patients in the TCZ monotherapy group added a concomitant DMARD to TCZ within 6 mos. Regardless of treatment group significant improvements were observed over 6 mos in all disease parameters examined (BL vs 6 mos DAS28: 5.3 vs 3.4; P<0.001).

Conclusion: In this real-world observational study, TCZ was used as monotherapy in 33.5% of patients. Despite the fact that 81.5% of patients had been previously treated with a biologic, more than 85% of patients remained on TCZ treatment after 6 mos of treatment. TCZ treatment alone or in combination with DMARD(s) over 6 mos was effective in inducing significant improvements in all disease parameters studied.

Risk of Infection Associated with Subsequent Biologic Use Following Rituximab—Results from a National RA Patient Registry. Leslie R. Harrold[1], George W. Reed[2], Chitra Karki[3], Robert Magner[1], Ashwini Shewade[4], Ani John[4], Joel M. Kremer[5] and Jeffrey D. Greenberg[3]. [1]University of Massachusetts Medical School, Worcester, MA, [2]Corrona, LLC., Southborough, MA, [3]Corrona, LLC, Southborough, MA, [4]Genentech, Inc, South San Francisco, CA, [5]Albany Medical College and The Center for Rheumatology, Albany, NY.

Background/Purpose: Rituximab is a chimeric monoclonal antibody for the treatment of rheumatoid arthritis (RA). Prolonged B-cell depletion from repeated doses of rituximab may be associated with increased risk of infection during subsequent biologic use; however, there are limited data on rates of infection in patients (pts) with RA who switched to a subsequent biologic following rituximab. [1–3] The objectives of this analysis were to assess whether time between last rituximab infusion and switching to a biologic with a different mechanism of action and intensity of rituximab use influenced risk of infection in a large, national RA pt registry (Corrona).

Methods: Pts with RA who newly initiated rituximab within Corrona were included if they switched to a (non-rituximab) biologic and had ≥ 1 follow-up visit within 12 months of switching. Pts were followed from the time they switched to a subsequent biologic to either the first infectious event or 12 months. The primary outcome was time to the first infectious event. Pts were categorized by the duration of time between their last rituximab infusion and switching to a subsequent biologic (≤ 5 months, 6–11 months and ≥ 12 months). Additionally, the number and rate of rituximab retreatments prior to starting the subsequent biologic were evaluated. Cox regression models estimated the association between time to starting a subsequent biologic and infection, and were adjusted for potential confounders.

Results: A total of 215 pts who switched to a subsequent biologic following rituximab use were included in this analysis (≤ 5 months [N = 104], 6–11 months [N = 67] and ≥ 12 months [N = 44]). Baseline characteristics were similar between the groups except for higher tender joint count and rate of rituximab retreatment in those pts who switched to a subsequent biologic earliest. Fewer than 50% of patients experienced an infection; of those patients who had an infection during the 12-month follow-up, the median (IQR) time to infection was 4 (2, 5) months. The overall rates of infection (95% CI) per person-year were 0.34 (0.22, 0.52), 0.30 (0.17, 0.52) and 0.41 (0.22, 0.77) in the ≤ 5 months, 6–11 months and ≥ 12 months groups, respectively. After adjusting for potential confounders, time to switch to a subsequent biologic was not associated with infection, which remained unchanged when including the number and rate of rituximab retreatments in the models (**Table**).

Conclusion: Duration of time between last rituximab infusion and switching to a biologic with a different mechanism of action was not associated with an increased rate of infection in pts with RA. Additionally, the number and rate of rituximab retreatments did not influence the risk of infection associated with the subsequent biologic.

519

Patterns of Tocilizumab Use and Safety in Patients with Rheumatoid Arthritis: Interim Results from a Multinational Observational Study. Boulos Haraoui[1], Gustavo Casado[2], Elke Theander[3], Laszlo Czirják[4], Andrew Taylor[5], Peter Button[6], Lykke Hinsch Gylvin[7] and Roberto Caporali[8]. [1]Centre Hospitalier de l'Université de Montréal, Montréal, QC, [2]Hospital Militar Central, Buenos Aires, Argentina, [3]Skane University Hospital Malmö, Lund University, Malmö, Sweden, [4]University of Pécs, Pécs, Hungary, [5]Royal Perth Hospital, Perth, Australia, [6]Roche Products Pty Limited, Dee Why, Australia, [7]F. Hoffmann-La Roche, Basel, Switzerland, [8]Division of Rheumatology, University of Pavia, IRCCS Policlinico San Matteo, Pavia, Italy.

Background/Purpose: Tocilizumab (TCZ) is indicated for the treatment of patients with RA who have had inadequate responses to DMARDs either as monotherapy (Mono) or in combination with DMARDs (Combo). ACT-UP is an umbrella project with data pooled from several international, observational, postmarketing studies investigating intravenous TCZ use in patients with RA in routine care. Interim observations of patterns of TCZ use, adherence to label recommendations, and safety are reported.

Methods: Adult patients with moderate to severe RA who started TCZ within 8 wk of enrollment were observed in clinical practice for 6 mo. There were no specified dosing regimens (concomitant RA treatments were permitted) and no interventional procedures, clinic visits, or laboratory analyses outside routine practice.

Results: Of 961 patients who received their first TCZ dose by June 30, 2013, 352 (37%) started Mono and 609 (63%) started Combo; 94% and 95% of Mono and Combo patients, respectively, started TCZ at 8 mg/kg, and 93% and 94% of patients, respectively, who received TCZ at 6 mo received 8 mg/kg. TCZ dose changes were reported for 34 (10%) Mono patients (7 increased, 11 decreased, 16 both increased and decreased) and 68 (11%) Combo patients (13 increased, 20 decreased, 35 both increased and decreased). Reasons for dose changes were AEs for 4% of Mono and 5% of Combo patients and lack of efficacy for 2% of Mono and 1% of Combo patients. Median MTX dose for Combo patients was 15.0 mg/wk. Sixty-three patients changed MTX dose during the study at a median dose change of –5.0 mg/wk. Twenty-eight (8%) patients who started TCZ Mono added a DMARD during the study. Corticosteroids were used by 57% of Mono and 70% of Combo patients (median prednisone-equivalent dose of 7.5 and 5.0 mg/d, respectively, at baseline). At 6 mo, 72% of Mono and 84% of Combo patients were still receiving TCZ. Overall, 100 (10%) patients discontinued TCZ in the first 3 mo and another 94 (10%) discontinued in the next 3 mo. Reasons for discontinuations included lack of efficacy (11% Mono; 27% Combo), adverse events (AEs; 27% Mono, 29% Combo), and other (62% Mono, 44% Combo). Regarding safety, AEs occurred in 53% of patients in each group. AEs classified as infections were less common in Mono than Combo patients (Table). No gastrointestinal perforations were reported in either group. Among patients for whom an AE required TCZ dose modification or an abnormal laboratory test result required follow-up, the investigator reported that local label/protocol recommendations were followed for 98% of Mono and 95% of Combo patients.

Conclusion: In this multinational observational study, 37% of patients started TCZ as monotherapy in clinical practice. Most patients continued TCZ treatment 6 mo after initiation whether they started it as monotherapy or in combination with DMARDs. TCZ was well tolerated in both groups, and adherence to local label recommendations was high.

Table. Safety

	TCZ Mono n = 352	TCZ Combo n = 609	All Patients n = 961

Background/Purpose: Development of non-Hodgkin lymphoma (NHL) is one of the most severe complications of pSS. It occurs in 5–10% of the patients. A more accurate detection of the high risk patients is mandatory to enable a more individualized approach. Presence of ectopic germinal center (GC) in salivary glands biopsy has been shown to be a predictor of NHL occurrence in pSS patients[1]. Interestingly, 2 single nucleotide polymorphisms (SNPs) located within *CCL11 (Eotaxin)*gene are associated with GC structures in pSS patients[2]. CCL11 is a chemokine that plays a role in chemotaxis of eosinophils and in allergy. In this study, we decided to assess the role of CCL11 both at the genetic and proteic level in the occurrence of pSS-associated NHL.

Methods: Genotyping of the 2 SNPs (rs3091328 and rs1860184, located on chromosome 17) known to be associated with GC structures was performed in 562 pSS cases (ASSESS cohort and Paris-Sud teaching hospital cohort) and 435 healthy controls, both of them of European ancestry as assessed by 47 ancestry informative markers. Among patients, 25 had a history of NHL. CCL11 serum levels at inclusion in the ASSESS cohort were evaluated in 385 pSS patients by multiplex assay. Among them, 21 patients had a NHL (history or future). Case-only associations (i.e., pSS patients with vs. without lymphoma) were tested with logistic regression adjusting for the top two Immunochip principal components. Association between CCL11 levels and genotype was assessed with the Kruskal-Wallis test. Levels of

CCL11 were compared in the different subsets of patients with a Mann-Whitney test.

Results: The 2 *CCL11* SNPs were not significantly associated with risk of pSS. However, we found a significant association between the rs1860184A located within the first intron of *CCL11*and pSS complicated by NHL: OR 1.87 CI95% [1.07–3.27], p= 0.03 compared to pSS patients without NHL and OR 1.84 CI95% [1.02–3.31], p= 0.04 compared to healthy controls. The median [range] serum level of CCL11 was 106.5 [13.2–283.5]pg/ml in the 385 pSS patients from the ASSESS cohort. We did not find any association between the CCL11 levels and the rs1860184 genotype (p=0.36). We found a trend for an association between CCL11 levels and the occurrence of NHL: (median [range]): 105 [13.23–283.5] in patients without NHL vs 141.3 [46.76–211] in patients with NHL (p=0.053). Interestingly we found a significant increased serum level of CCL11 in patients with an active disease defined by an ESSDAI ≥ 5 vs patients with inactive disease (112.2 pg/ml [13.23 – 283.5] vs 103.1 pg/ml [14.13 – 281.5] respectively, p=0.01). Last, we found significant correlations between CCL11 serum levels and B cells biomarkers (RF titer: p=0.01; free light chain kappa/lambda ratio: p=0.02 and β2-microglobulin level: p=0.0003).

Conclusion: This study highlights the potential implication of CCL11 in the occurrence of NHL in pSS patients. We show that the rs1840186 SNP is associated with NHL occurrence. An increased serum level of CCL11 tends to be associated with NHL occurrence and is associated with increased disease activity and B cells bio-markers. Further studies will be mandatory to determine the functional role of CCL11 in this phenomenon.

Background/Purpose: Development of non-Hodgkin lymphoma (NHL) is one of the most severe complications associated with pSS. It affects 5–10% of the patients. Definition of predictive factors is mandatory to enable a more individualized approach. CXCL13 is a chemokine also known as B lymphocyte chemo-attractant (BLC) involved in the homing of B cells within germinal centers. High CXCL13 serum levels have been shown to be predictive of NHL occurrence in the general population outside the context of autoimmunity [1]. Given this association with NHL in the general population, we decided to assess a possible association between CXCL13 serum levels and lymphoma and B-cell biomarkers in our cohort of pSS patient.

Methods: CXCL13 serum levels at inclusion were evaluated in 385 pSS patients included in the ASSESS cohort by multiplex assay. Among them, 21 patients had a NHL (history of or future). Levels of CXCL13 were compared in the different subsets of patients with a Mann-Whitney test. Association between CXCL13 levels and B cells markers was assessed by the Pearson's r correlation test.

Results: The median [range] levels of CXCL13 was 108 [6.33–4040] pg/ml in the 385 pSS patients from the ASSESS cohort. We found an increased CXCL13 serum level in pSS patients with NHL vs pSS patients without NHL (191.1 [43.7–3251] vs 105 [6.33–4040], p=0.008). CXCL13 was also increased in patients with active disease (ESSDAI ≥5) compared to patients with inactive disease (ESSDAI < 5) (98.5 [6.3–3251] vs 66.9 [11.1–4040], p=0.009). Last we found significant correlations between CXCL13 serum levels and B cells biomarkers such as gammaglobulinemia (r=0.11, p=0.04), β2-microglobulin level (r=0.22, p< 0.0001), BAFF serum level (r=0.18, p=0.0006), free light chain kappa/lambda ratio (r=0.21, p<0.0001) and rheumatoid factor titer (r=0.22, p<0.0001) and an increased level in patients with anti-SSA vs patients without (138.3 [7.2–4040] vs 76.5 [6.3–1515], p<0.0001).

Conclusion: This study demonstrates that CXCL13 may be involved in lymphomagenesis in pSS patients. We demonstrated that CXCL13 serum level is increased in pSS patients with NHL, in patients with active disease and is associated with B cells markers. Further studies will be needed to investigate the functional role of this chemokine in the disease.

Whole Blood microRNA Signature for Primary Sjögren's Syndrome-Related Lymphoma.

Jessica Tarn[1], Simon Cockell[1], Colin Gillespie[1], Shereen Al-Ali[2], Katherine James[1], James Locke[1], Simon Bowman[3], Bridget Griffiths[4], David Young[1] and Wan-Fai Ng[1]. [1]Newcastle University, Newcastle upon Tyne, United Kingdom, [2]University of Basrah, Basrah, Iraq, [3]University Hospital Birmingham, Birmingham, United Kingdom, [4]Freeman Hospital, Newcastle Upon Tyne, United Kingdom.

Background/Purpose: Micro RNAs (miRNAs) are 18–25nt non-coding RNAs that bind target/complementary sequences within the 3'UTR of RNA molecules steering them towards degradation or translational repression, and play a key role in the regulation of gene expression. Better understanding of the expression pattern of miRNAs in diseases may improve our understanding of the biological basis of the disease and identify potential biomarkers. The role of miRNAs in primary Sjögren's syndrome (PSS) and PSS-related lymphoma remains poorly understood. The aim of this project is to identify a miRNA signature for PSS-related lymphoma.

Methods: We profiled the expression of miRNAs in whole blood (PaxGene) total RNA preparations using the Exiqon miRCURY LNA array which encompasses >1400 miRNAs and other small non-coding RNAs. A discovery cohort comprised of 36 samples from the United Kingdom Primary Sjögren's Syndrome Registry (UKPSSR) (12 PSS patients with lymphoma, 12 PSS patients without lymphoma, 12 healthy controls) were used in the initial analysis. We also explored different normalisation strategies and developed an approach which we considered most appropriate for analysing these data. Real-Time PCR was used to validate the most highly differentially expressed miRNAs between groups. A miRNA signature for PSS-related lymphoma was identified using cluster analysis followed by validation with a second independent cohort of 36 patients and controls.

Results: The initial miRNA array profiling revealed a clear clustering of the 3 subject groups. Between the 'High Function' and 'Lymphoma' patient groups, 44 miRNAs were found to be differentially expressed. The differential expressions of these miRNA were validated by RT-PCR in 3 out of 9 miRNAs with the highest fold-changes between the two groups. Indeed, based on the expression levels of these 3 miRNAs were sufficient to distinguish PSS patients with lymphoma from those without. Two out of these 3 miRNAs were also differentially expressed between the same two groups in the validation cohort.

Conclusion: We have identified 2 miRNAs that are differentially expressed in peripheral blood between PSS patients with lymphoma and those without lymphoma. Identifying the mRNA targets of these miRNAs in PSS may improve our understanding of the pathogenesis of PSS-related lymphoma. Furthermore, miRNAs may be useful biomarkers for PSS-related lymphoma.

Serum CXCL4 Is Increased in Patients with Primary Sjögren's Syndrome and Is Associated with Features of Microvascular Impairment. Rosaria Irace[1], Antonella Riccardi[1], Daniela Iacono[1], Luciana Pellecchia[1], Lucia Vicedomini[1], Gabriele Valentini[2] and Serena Vettori[1]. [1]Second University of Naples, Naples, Italy, [2]Second University of Naples, Napoli, Italy.

Background/Purpose: CXCL4 is a pleiotropic antiangiogenic and immunomodulatory chemokine. We aimed to investigate CXCL4 serum levels in primary Sjögren's syndrome (pSS) and looked for associations with disease features, with a focus on parameters of microvascular involvement.

Methods: Thirty-nine consecutive pSS patients meeting the 2012 classification criteria for the disease were enrolled and underwent clinical assessment, nailfold videocapillaroscopy (NVC), and autoantibody profiling. Additional serum to measure levels of CXCL4 and soluble E-selectin (sE-selectin) was available from 36 pSS patients and 30 healthy controls (HC). At NVC, enlargement, density, and tortuosity of capillaries, and microhemorrhages were scored on a 0 to 3 scale (0 = normal, 3 = high grade). Plexus visualization and neoangiogenesis were also considered as present/absent. Autoantibodies were assayed by ELISA, while CXCL4 and sE-selectin were measured by multiplex suspension immunoassay.

Results: Serum levels of CXCL4 were increased in pSS patients (median 1.79 ng/ml [0.2–11.18], vs 1.023 ng/ml [0.02–14.45] in HC, $p < 0.05$), the highest found in anti-La/SSB autoantibody-negative patients (2.89 mg/ml [1.01–11.18] vs 1.69 [0.2–2.72] ng/ml, $p < 0.05$), and correlating with a longer disease duration ($r = 0.35$, $p < 0.05$). Most interestingly, we found a higher prevalence of CXCL4 levels above the 95° percentile of the HC group (10.91 ng/ml) in pSS patients with Raynaud's phenomenon (RP) (11/14 vs 4/18, $p < 0.001$). This prompted us to look for associations of serum CXCL4 with microvascular abnormalities at NVC and/or correlations with serum levels of sE-selectin, a marker of endothelial activation. Indeed CXCL4 positively correlated with sE-selectin ($r = 0.45$, $p < 0.01$), but was not associated with any NVC finding. However, a reduced capillary density and high grade enlarged capillaries were more prevalent in patients with RP (14/15 vs 6/21 and 16/16 vs 8/23, respectively; both $p < 0.0001$). An NVC "scleroderma pattern" was observed only in 3 patients (megacapillaries), and neoangiogenesis in 2 (both $p > 0.05$).

Conclusion: Here we show for the first time that pSS patients have increased serum CXCL4 levels, which correlate with disease duration and serum sE-selectin levels, and are associated with the presence of RP. These data suggest that CXCL4 might be implicated in microvascular/endothelial impairment in pSS. Actually, our pSS patients with RP had microvascular damage, as a reduced capillary density and high grade enlarged capillaries showed. Lastly, we detected higher CXCL4 levels in anti-La/SSB autoantibody-negative patients. This negative association might be related to the role played by pSS specific autoantibodies in promoting pathological angiogenesis in human salivary glands. Taken together this data provide preliminary evidence of a role for circulating CXCL4 as a marker of microvascular damage in pSS on larger cohorts of patients.

Distinct Patterns of DNA Methylation in Labial Salivary Gland Tissue Based on Sjögren's Syndrome Disease Status. Michael Cole[1], Xiaorong Shao[1], Diana Quach[1], Hong L. Quach[1], Lisa F. Barcellos[1] and Lindsey A. Criswell[2]. [1]University of California, Berkeley, Berkeley, CA, [2]University of California, San Francisco, Rosalind Russell / Ephraim P. Engleman Rheumatology Research Center, San Francisco, CA.

Background/Purpose: Sjögren's Syndrome (SS, OMIM #270150) is a chronic, multi-system autoimmune disease characterized by progressive destruction of the exocrine glands, with subsequent mucosal and conjunctival dryness. A growing body of evidence indicates that epigenetic changes contribute to the development of this complex disease. In particular, altered patterns of DNA methylation may modulate both risk and severity.

Methods: We report an expanded case-control study of DNA methylation differences within labial salivary gland tissues, using biopsies sampled from 12 primary SS cases, 2 secondary SS cases, and 14 controls in the Sjögren's International Collaborative Clinical Alliance (SICCA; http://sicca.ucsf.edu/; HHSN268201300057C) collection. These subjects are part of a larger, 36-subject study group for which blood, gland tissue, and cell-sorted blood samples have been methylotyped (110 samples total). We generated genome-wide DNA methylation profiles using Illumina HumanMethylation450 BeadChips and further characterized full genome SNP profiles using the Illumina HumanOmni2.5-Quad platform. All methylation results were background subtracted via out-of-band normal-exponential convolution (NOOB) and normalized via all sample mean normalization (ASMN) and beta-mixture quantile normalization (BMIQ).

Results: Multidimensional Scaling (MDS) applied to the 360,546 CpG sites passing strict QC criteria visibly separates primary SS cases from controls within the first 2–3 components, and this clustering changes substantially with the inclusion of a subset of 9 symptomatic SICCA control subjects (control status based on SICCA's extensive clinical and serologic data). We demonstrate significant gene-centered mean hypomethylation across *IL10* and *IRF5* in SS cases (False Discovery Rate $\leq .05$). Mean methylation levels within 15 other putative SS-associated genes were similar between cases and controls. We report median methylation levels in specific *BLK* and *KLHL24* CpGs that are 15–25% hypermethylated in primary SS cases versus controls; other sites in *IRF5* and *BLK* display 10–20% hypomethylation. Single-site methylation differences across 7 of the 17 genes retain significance after multiple-testing correction, with 6 of the 7 genes exhibiting hypomethylation at a majority of sites.

Conclusion: Our results emphasize the utility of DNA methylation as a potential biomarker of disease status. Additional research, including studies of pathway-specific gene expression will be required to fully define the role of DNA methylation in SS-affected salivary glands.

The Genetic Basis of Sjögren's Syndrome (SS) Clinical Manifestations from Genome-Wide Association Analysis of Subphenotype Extremes in an International Cohort. Lindsey A. Criswell[1], Kimberly E. Taylor[1], Quenna Wong[2], David M. Levine[2], Caitlin McHugh[2], Cathy Laurie[2], Kimberly Doheny[3], Mi Y. Lam[4], Alan N. Baer[5], Stephen Challacombe[6], Yi Dong[7], Hector Lanfranchi[8], Morten Schiødt[9], M. Srinivasan[10], Susumu Sugai[11], Hisanori Umehara[11], Frederick B. Vivino[12], Zhao Yan[13], Stephen Shiboski[4], Troy Daniels[4], John S. Greenspan[4], Caroline H. Shiboski[4] and Sjögren's Syndrome Collaborative Clinical Alliance (SICCA)[4]. [1]University of California, San Francisco, Rosalind Russell / Ephraim P. Engleman Rheumatology Research Center, San Francisco, CA, [2]University of Washington, Biostatistics, Seattle, WA, [3]Center for Inherited Disease Research, Baltimore, MD, [4]University of California San Francisco, San Francisco, CA, [5]Johns Hopkins University School of Medicine, Baltimore, MD, [6]Kings College London, London, United Kingdom, [7]Peking Univ Med Coll Hospital, East City Beijing, China, [8]University of Buenos Aires, Buenos Aires, Argentina, [9]Rigshospitalet, Copenhagen, Denmark, [10]Aravind Eye Hospital, Madurai, India, [11]Kanazawa Medical University, Ishikawa, Japan, [12]Penn Presbyt Med Ctr, Philadelphia, PA, [13]Peking Union Medical College Hospital, Beijing, China.

Background/Purpose: Our goal is to define the contribution of genetic factors to two hallmark manifestations of SS, keratoconjunctivitis sicca (KCS) and focal lymphocytic sialadenitis (FLS), in an international cohort.

Methods: We studied 3,334 participants in the Sjögren's International Collaborative Clinical Alliance (SICCA; contract # HHSN 268201300057C) registry who were characterized for the Illumina HumanOmni 2.5-Quad marker set. SICCA participants were enrolled according to standardized protocols at 9 international sites, including Argentina (n=428), China (n=304), Denmark (n=583), India (n=127), Japan (n=367), the UK (n=296) and the US (total n=1229 from 3 sites). QC measures included filters based on SNP and sample missingness ($\geq 2\%$), unexpected relatedness, non-Mendelian inheritance, and chromosomal regions of anomaly (> 10Mb). SICCA participants were assessed for presence and severity of FLS defined by focus score (FS, positive ≥ 1) on minor salivary gland biopsy and degree of KCS based on ocular staining pattern measured by ocular staining score (OSS, positive ≥ 3). In order to investigate the genetic basis of these manifestations, we compared patients with high values (OSS ≥ 7, FS ≥ 2.5) to patients with normal values (OSS < 3, FS < 1) via logistic regression. Principal components analysis (PCA) was used to characterize each participant for genetic ancestry, and PCs 1 – 5 were included as covariates in all

association analyses. We analyzed the entire group and also the two largest strata by ethnicity (European and Asian, with outliers removed outside of PCA clusters).

Results: Out of 3284 unrelated subjects with post-QC genotypes and sufficient clinical data, patients were categorized for analysis as follows: high FS (n=636), normal FS (n=1968), high OSS (n=1333), normal OSS (n=857). A total of 1,550,200 SNPs with MAF ≥ 1% passed all QC filters and were fully analyzed. Not surprising in autoimmunity, the MHC was the most significantly associated with both traits in the full dataset (FS p=3e-22; OSS p=6e-12) and in Europeans (FS 375 SNPs p<5e-8, lowest 3e-17; OSS 60 SNPs p<5e-8, lowest p=4e-11). However, in Asians the MHC appears to have much less importance. There was only one suggestive MHC SNP (p=8e-6) for FS; the most associated FS gene in Asians was *PTPRD*, with 12 SNPs p<5e-6 (lowest p=1.8e-7). Outside of the MHC, some genes appear to influence both phenotypes while others are trait-specific. For example, *IRF5* is the highest-associated region for FS (p=2e-7) but not suggestive for OSS. The *XYLT1* region is the highest-associated region for OSS (p=1e-6) but is not implicated in FS. On the other hand, *STAT4* is among the most-associated regions for both FS (p=1e-6) and OSS (p=3e-6).

Conclusion: These results demonstrate that the ocular (OSS) and oral (FS) manifestations of SS are influenced by both shared and trait-specific genetic factors. Furthermore the genetic profile appears to be quite different for both depending on ancestry, in particular when comparing European and Asian SS patients. Additional work including imputed genetic data and more extensive ancestry analysis will provide more power for extending these findings and fully characterizing the genetic contribution to SS.

A Descriptive and Comparative Study of the Transcriptome from Salivary Exosomes of Sjögren's Syndrome Patients Using RNA-Seq. Alessia Gallo[1], Mayank Tandon[2], Shyh-Ing Jang[2], Ana Paola Cotrim[1] and Ilias Alevizos[3]. [1]NIH, Bethesda, MD, [2]NIDCR, Bethesda, MD, [3]NIDCR/NIH #10 1N110, Bethesda, MD.

Background/Purpose: Saliva is a biofluid secreted by the salivary glands (SGs) that is critical for the health of the oral cavity. In Sjögren's Syndrome (SS), changes in salivary biomarkers are not only useful for diagnosis, but may also elucidate the mechanisms underlying SG dysfunction. The RNA content of saliva has been shown to be useful for monitoring the health of oral tissue and the oral microbiome. Next-Generation Sequencing (NGS) offers a high throughput method for comparing the salivary transcriptomes of SS patients and healthy volunteers (HV). We have previously shown that RNA is protected within exosomes and we focused this study in using salivary exosomes isolated from the parotid. Parotid saliva has the advantage of being pure without the contamination generated from all type of cells found in the whole saliva.

Methods: Total RNA was extracted from exosomes isolated from parotid saliva from 4 healthy volunteers and 4 primary SS patients. The amount and the quality of the RNA were assessed using Nanodrop, Qubit and Bioanalyzer. The Ion Torrent Proton sequencer was used sequencing according to manufacturer protocols. Reconstructed reads were aligned using the TMAP (Torrent Mapper) algorithm sequentially to miRBase 19, hg19, viral, and bacterial genomes, i.e. reads left unmapped were used as input for each subsequent step. The bacterial reference included 14,549 contigs representing 1,132 genomes retrieved from the Human Oral Microbiome Database, and the viral reference included 1,741 viruses retrieved using the NCBI assembled genomes FTP website. Read counts were generated using the HTSeq python module, and differential expression analysis was done in R using the DESeq2 package. Ingenuity Pathway Analysis (IPA) was used to analyze pathway enrichment and visualization. Microbial expression and taxonomy were analyzed used Pathosystems Resource Integration Center (PATRIC).

Results: Overall the percentage of all reads mapping to each reference were similar between SS and HV: miRBase (5.96% in HV, 5.427% in pSS), hg19 (81.82% HV, 81.96% pSS), viral (6.94% HV, 3.26% pSS), and bacterial (1.121% HV, 1.737% pSS). On average, 4.14% of the input was left unmapped in HVs and 7.62% in pSS patients after all mapping. The differences between percent input reads in patients and HVs was only significant for the bacterial reference, and for unmapped reads. Expression pairing between miRNAs and their target genes using IPA showed significant enrichment for canonical pathways for pancreatic adenocarcinoma signaling, and estrogen-mediated S-phase Entry. Top differentially regulated bacterial genera (fold-change greater than or less two and FDR-corrected p-value less than 0.01) include Streptococcus, Selenomonas, and Actinomyces. Notable upregulated viruses include Tomato yellow leaf curl virus and streptococcus phage Cp-1. Human papillovirus, type 41 was found to be significantly downregulated in pSS patient saliva.

Conclusion: This is the first known effort to compare the transcriptome of SS patients' salivary exosomes versus healthy controls. Using RNA-Seq, we were able to identify important human genes as well as alterations in the salivary microbiome that could shed light on the mechanisms of salivary dysfunction in pSS.

Salivary Expression of S100A7/Psoriasin and Oral Damage in Primary Sjögren's Syndrome and Overlapping Disorders. Francesca Sernissi[1], Chiara Baldini[1], Daniela Martini[1], Leonardo Lorenzini[1], Laura Bazzichi[1], Antonietta Raffaella Maria Sabbatini[1], Giada Marchi[1], Camillo Giacomelli[1], Marta Mosca[2] and Stefano Bombardieri[2]. [1]Rheumatology Unit, Pisa, Italy, [2]Rheumatology Unit, University of Pisa, Pisa, Italy.

Background/Purpose: S100A7/psoriasin, a 11.4kDa protein belonging to the S100A family of Ca2+-binding proteins, is known to exhibit an antimicrobial activity at skin level, but has also been implicated in the regulation of cell proliferation, differentiation, invasion and metastasis. By using a proteomic approach, S100A7/psoriasin has been recently identified in the whole saliva of patients with Systemic Sclerosis as a potential disease biomarker. The aims of the present study were (1) to compare the expression of salivary S100A7/psoriasin in patients with Sjögren's Syndrome associated to anti-centromere antibodies (ACA) positive Systemic Sclerosis (SS-SSc), versus patients with primary Sjögren's Syndrome (pSS), and (2) to explore any correlation between salivary S100A7/psoriasin and oral damage.

Methods: Unselected pSS and SS-SSc patients (AECG 2002) were consecutively recruited in the study. Unstimulated salivary flow (USF) rate were measured according to the sialometry protocol, and saliva samples were collected on ice, centrifuged and stored at -80°C. S100A7/psoriasin levels were determined by CircuLex S100A7/psoriasin ELISA kit (MBL International Corporation), according to manufacturer's instructions. All subjects had a standardized evaluation for pSS which included oral and ophthalmologic examinations, laboratory testing and a rheumatologic evaluation.

Results: Eighteen SS-SSc and 33 pSS female patients were included in the study. SS-SSc patients had a mean age ± standard deviation (SD) of 65.6 ± 11.3, which did not differ from that of pSS (59.8 ± 11.3). S100A7/psoriasin levels were significantly higher in SS-SSc subjects (p=0.02). S100A7/psoriasin salivary levels negatively correlated with the USF rate (r=−0.27, p<0.05), particularly in pSS subjects (r=−0.508, p=0.003), and were significantly higher in patients with a USF <1.5 ml/15 minutes (p=0.006). Regarding the relationship between S100A7/psoriasin and patients' oral damage, we found that the salivary expression of the protein was significantly associated with the Sjögren's Syndrome disease damage index (SSDDI) (p<0,05) and specifically with the complete loss of teeth (p=0.02).

Conclusion: Salivary S100A7/psoriasin might be useful in differentiating pSS from SS-SSc and seems to be able to reflect oral damage in both pSS and SS overlapping disorders. The potentially predictive value of this biomarker for oral damage accrual in SS calls for further studies.

Calcium-Calcineurin-NFAT Signaling Pathway Regulates AQP5 Expression in Primary Salivary Gland Acinar Cells. Shyh-Ing Jang[1], Hwei Ling Ong[1], Indu Ambudkar[2] and Illias Alevizos[1]. [1]NIDCR, Bethesda, MD, [2]NIH, Bethesda, MD.

Background/Purpose: Aquaporin (AQP) 5 belongs to a family of small integral membrane proteins which function as a water channels in cells. AQP5

plays a critical role in mediating the secretion of fluid in salivary gland. Decrease or no saliva flow is one of the key symptoms in Sjögren's syndrome patients. Towards understanding the molecular basis of the loss of salivary secretion, here we have studied the regulation of AQP5 expression in primary human salivary gland epithelial cells (phSG).

Methods: cell culture, Western blot, qPCR, siRNAs, site-directed mutagenesis, chromatin immunoprecipitation.

Results: We observed that the phenotype of the cells depended largely on the calcium levels in the culture conditions. AQP5 transcript showed more than 3-fold increase in phSG cells grown in high calcium (0.8 mM) medium compared to that in low calcium (0.05 mM) condition. This was confirmed by both immunofluorescence staining and Western blot studies. Evaluation of expression transcripts of calcium signaling proteins in phSG cells revealed that NFAT1 expression was dependent on calcium in a dose-response manner. Furthermore, when cells were switched to a high calcium medium pGFP-NFAT1 was translocated from the cytoplasm into the nucleus. Expression of AQP5 was also reduced when phSG cells were treated with cyclosporine A confirming the involvement of calcineurin-NFAT1 signaling pathway in regulation of AQP5 expression. Since NFAT activation has been linked to calcium influx, we examined the role of the calcium entry regulatory proteins STIM1 and STIM2 as well as the channel protein Orai1. Knockdown of NFAT1 and STIM1, but not STIM2 or Orai1, resulted in 70% decrease of AQP5 expression. Further analysis revealed that several NFAT binding motifs were identified in the AQP5 promoter and these were validated using AQP5-promoter-luciferase assays. Mutagenesis of putative NFAT-binding regions as well as chromatin immunoprecipitation analyses revealed the presence of functional NFAT binding sites within the proximal AQP5 promoter region.

Conclusion: These data demonstrate that AQP5 expression in phSG cells is regulated by a calcineurin-NFAT-dependent signaling pathway. Importantly, STIM1, but not Orai1 is involved in this mechanism. We propose that external Ca^{2+}-dependent Ca^{2+} entry triggers activation of AQP5 expression in phSG cells. Thus alterations in calcium signaling could lead to alterations in AQP5 expression and function in pSS. Further studies are being directed towards determining the status of calcium signaling in pSS salivary glands.

IP3R3 Deficit Underlies the Loss of Fluid Secretion in Salivary Glands from Sjögren's Syndrome Patients. Leyla Y Teos[1], Bill Swaim[2], Margaret Grisius[1], Ana Paola Cotrim[1], Shyh-Ing Jang[3], Lolita Bebris[1], David Yule[4], Gabor G. Illei[5], Indu Ambudkar[1] and Ilias Alevizos[6]. [1]NIH, Bethesda, MD, [2]NIH/NIDCR, Bethesda, MD, [3]NIDCR, Bethesda, MD, [4]University of Rochester, Rpochester, NY, [5]NIDCR/ NIH, Bethesda, MD, [6]NIDCR/ NIH #10 1N110, Bethesda, MD.

Background/Purpose: Sjögren's syndrome (SS) is a chronic autoimmune disease with unknown etiology. Affecting from 0.2% to 3.0% of the total population, with a 9:1 female to male ratio, Sjögren's patients suffer from a reduction in salivary flow which leads to tenacious dry mouth and dry eyes symptoms causing debilitating oral complications, in addition to extraglandular systemic manifestations. Our focus has been to assess the possible mechanism(s) underlying the reduction in salivary flow by examining cellular volume regulation and the trigger to this regulation which is calcium signaling. Saliva is an orchestrated process initiated by neurotransmitter stimulation which is critically regulated by an increase in cytosolic calcium. This increase in calcium triggers ion channel activities, leading to the secretion of fluid which can be detected as a decrease in cell volume. We hypothesized that alterations in calcium signaling in acinar cells (where secretion is produced) accounts for the reduction in salivary flow seen in SS.

Methods: A non-enzymatically dispersed organotypic tissue preparation was used to maintain the microenvironment. Human minor salivary gland biopsies were finely minced (0.5mm) to obtain cell clusters which were loaded with cytosolic calcium indicator (Fluo-2AM) or cell-volume indicator, calcein. The loaded cell clusters were then used for live-cell imaging using confocal microscopy. In addition we performed immunoflourescence to label key proteins involved in calcium and volume regulation in salivary glands such as AQP5, STIM1, and IP3 receptor 3 (IP3R3).

Results: Acinar cells from SS patients displayed significant attenuation of agonist-stimulated cytosolic calcium increases when compared to the function in cells from normal healthy volunteers. Both intracellular release and Ca^{2+} influx were substantially reduced. This was correlated with a loss of agonist stimulated decrease in cell volume. Decrease in cell volume is indicative of fluid secretion and is completely dependent on increase in $[Ca^{2+}]_i$. There was a significant correlation between agonist – induced volume decrease and saliva secretion within the patient population. Together these data demonstrate that the reduced salivary secretion in the SS patients is due to reduced Ca^{2+} signaling in acinar cells. To further determine underlying factors causing the functional defect we examined the expression of critical components involved in calcium mobilization and fluid secretion; AQP5, STIM1, and IP3R. Within the area of infiltration, there was cell damage and all proteins were disrupted. In the area around the infiltrate there was no change in AQP5. STIM1 was reduced in cells around the infiltrate, but not in areas further away infiltrating site. Importantly, IP3R was uniformly decreased in all areas of the gland.

Conclusion: Our findings reveal an underlying defect in IP3R in acinar cells that can account for loss of salivary secretion in patients with low levels of lymphocytic infiltration and minimal tissue damage. Further studies are required to determine what causes loss of IP3R.

Downregulation of Microrna-183 in Sjogren's Syndrome Minor Salivary Glands. Implications in Control of Ezrin Expression and Salivary Gland Function. Paola Perez Riveros[1], Mayank Tandon[1], Salman Kazmi[2], Alessia Gallo[2], Gabor G. Illei[3] and Ilias Alevizos[4]. [1]NIDCR, Bethesda, MD, [2]NIH, Bethesda, MD, [3]NIDCR/ NIH, Bethesda, MD, [4]NIDCR/ NIH #10 1N110, Bethesda, MD.

Background/Purpose: Sjogren's syndrome (SS) is an exocrinopathy, which is mainly characterized by salivary glands (SG) hypofunction. SGs from SS patients present dilated lumen in acini and loss of microvilli in the acinar cell SG. Previously, we reported that these changes correlate with an **aberrant location in the basal pole of the acinar cells** and **an overexpression of ezrin**. Ezrin is a cytoplasmic peripheral membrane protein that regulates the microvilli organization and secretion of exocrine cells. The mechanism of gene expression and specific function of ezrin in SG is unknown. We also proved that microRNA hsa-miR-183 is down regulated in SG from SS patients and it can modify the expression of ezrin SG cell culture in 3D. Here we are further confirming the function of hsa-miR-183 in vivo, its implication in saliva secretion and exploring a mechanism by which ezrin mislocalization produce saliva hyposecretion.

Methods: LNA-antimir-183 was transfected into mice parotid SG. The effect of the blockage of hsa-mir-183 was assessed evaluating the volume of saliva secretion after stimulation with isoproterenol and ezrin protein expression. Proximity ligation assay was performed to determine the interaction of ezrin with three possible targets: Sodium-hydrogen antiporter 3-regulator1 (SLC9A3R1), Anotacmin1 (ANO1) and Rab27A.

Results: The *in vivo* transfection of the LNA-antimir produced an increase of protein levels of ezrin and a decrease in the saliva secretion. ANO1 did not appear to form complex with ezrin in human SG. The complex ezrin/SLC9A3R1 was decreased in apical pole acinar cells of SS patient. A similar change was observed for ezrin/Rab27.

Conclusion: These experiments suggest that in SG of SS patients the overexpression of ezrin is produced by the down regulation hsa-miR-183 and propose a role of ezrin in the mechanism of SG hyposecretion. In this mechanism the mislocalization of ezrin affect the localization of the sodium-hydrogen antiporter 3-regulator1, altering the activation of the SLC9A3R1 and the electrolyte balance to regulate water secretion. Additionally, the change in the interactionof ezrin- Rab27A would affect the fusion of the secretory granules with apical plasma membrane.

Expression of Indoleamine 2,3 Dioxygenase-1 and -2 in Focal Sialoadenitis of Patients with Sjögren's Syndrome. Claudio Vitali[1], Antonina Prafioriti[2], Domenico Sambataro[2], Andrea Di Bernardo[2], Elisabetta Admiraglio[2], Saba Nayar[3], Francesca Barone[3] and Nicoletta Del Papa[2]. [1]Istituto San Giuseppe, Como, Italy, [2]Istituto G.Pini, Milan, Italy, [3]University of Birmingham, Birmingham, United Kingdom.

Background/Purpose: The role of indoleamine 2,3 dioxygenase 1 and 2 (IDO1-IDO2) enzymes in modulating the immune response has not been so far completely clarified. IDO1 may induce immune-tolerance by suppressing antigen-specific T-cell response, directly or by activating T-reg cells, as shown in some cancer cells and in the placental tissue. IDO1 and IDO2 function in autoimmune diseases is controversial. In collagen-induced arthritis of DBA/1 mice, IDO1 limits the arthritis phenotype, as suggested by arthritis worsening after IDO1 inhibition. Conversely, IDO2 is critical for arthritis development in K/BxN transgenic mice, since IDO2-null mice display less aggressive joint inflammation.

This study was aimed at investigating whether IDO1/IDO2 are expressed in focal sialoadenitis of Sjögren's syndrome (SS), and possibly at identifying the inflammatory cells where these enzymes are active.

Methods: Minor salivary gland biopsies from 22 patients (21 F) with SS (according to the AECG classification criteria) were examined for IDO1 and IDO2 expression by using monoclonal antibodies, and immunohistochemical (IH) and immuno-fluorescence (IF) methods. In IH-stained sections the prevalence (or number) of CD3+T-cells, CD20+B-cells, CD123+dendritic cells (DC), IDO+cells was semi-quantitatively scored. Co-localization of IDO+cells and of the other inflammatory cells was investigated by IF methods.

Results: IH studies showed that IDO1 was notably expressed within the focal infiltrates. Correlations were found between the amount of IDO1+cells and the focus score ($R=0.52$, $p<0.02$), the prevalence of B-cells ($R=0.79$, $p<0.0005$), and the number of DCs ($R=0.64$, $p<0.005$). IDO2 was expressed in the vessel walls and ductal cells surrounded by infiltrates, but not in the CD3+T-cell area.

In germinal centre-like foci, IF studies showed that IDO1+cells were noticed around the B-cell area, at the boundaries of the T-cell zone. IDO2 was expressed only in a part of samples within the B-cell area, and in both CD138+plasma cells and CD68+macrophages.

Conclusion: In focal infiltrates of patients with SS, different areas and different cells may express IDO1 and IDO2 enzymes, thus suggesting that activity and function of these molecules in this context could be different.

Adipose Tissue Is Prominent in Salivary Glands of Sjögren's Syndrome Patients and Appears to Influence the Autoimmune Microenvironment in These Organs. Kathrine Skarstein[1], Lara Adnan Aqrawi[1], Roland Jonsson[1] and Janicke Cecilie Liaaen Jensen[2]. [1]University of Bergen, Bergen, Norway, [2]University of Oslo, Oslo, Norway.

Background/Purpose: A positive salivary gland (SG) biopsy with a focus score of ≥1 is the only widely accepted pathological finding confirming the salivary gland component of Sjögren's syndrome (SS). SG biopsies can yield important information about the autoimmune activity and severity of the disease process including identification of germinal centers that may be possible predictors of lymphoma development. Moreover, adipocytes can occupy a large percentage of the gland area, and at present, little is known about their significance in SS lesions. The aim of the present study was to characterize adipose tissue infiltration in labial SG biopsies of patients under evaluation for SS.

Methods: 3–5 SGs were excised from the lower lip following a standard procedure. Evaluation of the glands was performed by one oral pathologist and included area assessment and counting of foci (dense aggregates of 50 or more mononuclear cells), as well as evaluation of acinar atrophy, fatty replacement, interstitial fibrosis, nonspecific chronic inflammation, and scattered or focal infiltrates of mononuclear cells adjacent to tissue not appearing normal. Patients were classified according to the AECG classification criteria and included 28 SS patients and 28 subjects evaluated for SS but not fulfilling the criteria (non-SS controls). IL-6 (rabbit polyclonal, Abcam-ab6672) expression was assessed by immunohistochemical staining of paraffin embedded salivary gland biopsies from SS patients and non-SS controls.

Results: Fatty replacement was evident in all SS patients possessing autoantibodies (RoSS-A and/or LaSS-B) as well as a positive SG biopsy (focus score ≥1), whereas 62% of the SS patients having autoantibodies but a negative biopsy showed fatty infiltration. Less than one third of the non-SS controls demonstrated fatty replacement. Overall, the SS group (mean age 53.0 years) had a significantly higher degree (p-value 0.0003) of fatty infiltration than the non-SS controls (mean age 54.8 years). Interestingly, adipocytes were located in IL-6 rich areas, and scattered IL-6 positive adipocytes were detected.

Conclusion: Our observations indicate that although fatty infiltration may occur in the repair process of glandular epithelium, fat deposition seems to be more extensive in salivary glands affected by SS. The important finding of IL-6 positive adipocytes supports the notion that adipocytes have the potential to secrete IL-6, thus being active contributors to immune reactions. Further analysis to delineate possible roles of adipocytes in the autoimmune salivary gland microenvironment is needed. Moreover, assessing the adipose tissue replacement may be helpful for diagnostic accuracy in SS.

Predictive Significance of CCL21 and CXCL13 Levels in the Minor Salivary Glands of Patients with Sjögren's Syndrome. Kyung-Eun Lee, Dong-Jin Park and Shin-Seok Lee. Chonnam National University Medical School, Gwangju, South Korea.

Background/Purpose: Chemokines, which control inflammatory cell migration, have been shown to play important roles in the inflammatory processes associated with Sjögren's Syndrome (SS). CCL21 and CXCL13 within the lymphocytic infiltrate characteristic of the condition have been reported to contribute to ectopic lymphoneogenesis. In the current study, we investigated whether the laboratory and clinical manifestations of SS patients were associated with CCL21 and CXCL13 expression levels in the minor salivary gland.

Methods: We obtained sociodemographic data on a total of 106 SS patients, documented glandular and extraglandular manifestations of the disease, performed minor salivary gland biopsies, and analyzed laboratory findings. EULAR index values of SS disease activity (ESSDAI values) at the time of biopsy, and SS disease damage index (SSDDI) values, were also noted. An immunohistochemical approach was used to (semiquantitatively) measure the expression levels of CCL21 and CXCL13 in the minor salivary glands.

Results: The minor salivary glands of SS patients stained positively for CCL21 and CXCL13 in 46.2% (49/106) and 70.7% (75/106) of all cases, respectively. Higher-level expression of CCL21 was associated with an elevated ESR, an increased IgG level, elevated anti-SS-A and -SS-B titers, a higher focus score, and a greater ESSDAI value at the time of biopsy. Higher-level expression of CXCL13 was associated with an elevated ESR, an increased IgG level, elevated anti-SS-A and -SS-B titers, a rise in the level of rheumatoid factor, a higher focus score, and a greater ESSDAI value at the time of biopsy. In patients with extraglandular manifestations of SS, the prevalence of lymphadenopathy tended to rise with an increase in the level of CCL21.

Conclusion: The expression levels of CCL21 and CXCL13 within the lymphocytic infiltrates of SS patients were associated with several laboratory features of the disease, lymphadenopathy, and the extent of clinical disease activity. CCL21 and CXCL13 levels should serve as useful markers predicting SS disease activity and prognosis.

Serum Biomarkers of Inflammation and Fibrosis in Advancing Diagnosis, Prognosis and Treatment of Anti-Ro Associated Congenital Heart Block. Amit Saxena, Peter M. Izmirly, Sung Won Han, Andrew Markham, Robert M. Clancy and Jill P. Buyon. New York University School of Medicine, New York, NY.

Background/Purpose: Women with Sjogren's Syndrome (SS) and anti-Ro antibodies face the risk of a pregnancy complicated by fetal congenital heart block (CHB). Identification of maternal and fetal biomarkers which associate with development and morbidity of CHB should provide clues to pathogenesis with translational implications for management. Several candidates were chosen based on potential roles in cardiac disease, inflammation and fibrosis: 1) C-reactive Protein (CRP), elevated in fetal sepsis and hypoxia 2) NT-proBNP, elevated in neonates with congenital heart disease 3) Matrix Metalloproteinase-2 (MMP2), a proinflammatory/profibrotic factor associated with heart failure in adults 4) Urokinase plasminogen activator, its receptor and plasminogen (UPA, UPAR, PGN), proteins in a cascade induced by anti-Ro binding to apoptotic cardiocytes, resulting in TGFb activation 5) Vitamin D, negative regulator in TGFb signaling and fibrosis.

Methods: Sera from anti-Ro positive mothers and cord blood from their CHB and unaffected children in the Research Registry for Neonatal Lupus

were analyzed. Cord CRP and NT-proBNP were assessed on Luminex and MMP2, UPA, UPAR and PGN by ELISA. Maternal vitamin D 25-OH was analyzed by LC-MS. Logistic regression was applied to identify predictors of CHB, fetal echo endocardial fibroelastosis (EFE) and hydrops, need for and age at pacemaker (PM) placement, and requirement of B-Blocker, digoxin, and/or ACE-I on long term follow up. Confounders were added stepwise, including maternal steroid, HCQ and IVIg use, race, maternal SS/lupus, child's gender, gestational week (GW) of delivery, and GW of greatest disease vulnerability during winter. Skewed data were log transformed for normalization.

Results: Log transformed levels of cord CRP positively associated with CHB and hydrops in 50 affected and 62 unaffected cases (adjusted OR 1.65, p=0.02, OR 3.7, p=0.02). Log cord NT-proBNP positively associated with CHB and hydrops in 57 affected and 65 unaffected (OR 2.24, p<0.001, OR 2.46, p=0.02). Log cord MMP2 positively associated with CHB in 36 affected and 28 unaffected (OR 20.23, p=0.01). Cord UPA (OR 45.42, p<0.001), UPAR (OR 12.99, p=0.03) and log PGN (OR 38.28, p=<0.001) were positively associated with CHB in 27 affected and 22 unaffected. UPA and log PGN (OR 1.22, p=0.02, OR 1.27, p=0.03) were positively associated with cardiac meds (mean age at follow-up 7.34 ± 4.93 y) in 18 affected cases. Other cord biomarkers did not associate with PM, timing of PM or cardiac meds. Although maternal vitamin D at GW 20 of CHB and healthy pregnancies were equivalent (34.3 ± 11.8 in 50 CHB and 34.1 ± 14.5 ng/mL in 81 unaffected), levels were negatively associated with fetal EFE (OR 0.89, p=0.03), and positively associated with later age at PM (p=0.01) in CHB cases.

Conclusion: Elevated inflammatory markers in neonates with CHB and extranodal disease support close follow up to identify worsening heart function. The association of NT-proBNP supports consideration of this maker as a diagnostic during amniocentesis. Elevations of MMP2, UPA, UPAR and PGN in CHB children suggest therapies aimed at decreasing fibrosis. Optimizing maternal vitamin D levels could become routine in the management of all anti-Ro positive pregnancies.

Secukinumab, a Monoclonal Antibody to Interleukin-17A, Significantly Improves Signs and Symptoms of Active Ankylosing Spondylitis: Results of a Phase 3, Randomized, Placebo-Controlled Trial with Subcutaneous Loading and Maintenance Dosing. Joachim Sieper[1], Jürgen Braun[2], Xenofon Baraliakos[2], Dominique L. Baeten[3], Maxime Dougados[4], Paul Emery[5], Atul A. Deodhar[6], Brian Porter[7], Mats Andersson[8], Shephard Mpofu[8] and Hanno Richards[8]. [1]Charité Universitätsmedizin Berlin, Berlin, Germany, [2]Rheumazentrum Ruhrgebiet, Herne, Germany, [3]Department of Clinical Immunology and Rheumatology and Department of Experimental Immunology, Academic Medical Centre/University of Amsterdam, Amsterdam, Netherlands, [4]INSERM (U1153): Clinical Epidemiology and Biostatistics, PRES Sorbonne Paris-Cité, Paris, France., Paris, France, [5]University of Leeds, Leeds, United Kingdom, [6]Oregon Health and Sciences University, Portland, OR, [7]Novartis Pharmaceuticals Corporation, East Hanover, NJ, [8]Novartis Pharma AG, Basel, Switzerland.

Background/Purpose: Previous data indicate that interleukin (IL)-17, a key pro-inflammatory cytokine, might play a role in the pathogenesis of ankylosing spondylitis (AS). We assessed the efficacy and safety of two different doses of secukinumab, a fully human anti–IL-17A monoclonal antibody, in a randomized, multicenter, double-blind, placebo (PBO)-controlled, phase 3 trial in patients with AS (MEASURE 2; NCT01649375).

Methods: Adults with active AS fulfilling modified New York Criteria and a BASDAI ≥ 4, despite adequate NSAID therapy, were randomized to receive weekly subcutaneous (s.c.) secukinumab 75 mg, 150 mg, or PBO for 4 weeks followed by dosing every 4 weeks. Subjects naïve to anti-TNF agents (61.6%) and subjects with prior intolerance or inadequate response to anti-TNF agents (TNF-IR; 38.4%) were included. The primary endpoint was the proportion of subjects achieving an ASAS20 response at Week 16. Secondary endpoints included ASAS40, hsCRP, BASDAI, ASAS 5/6, SF-36, ASQoL, and ASAS partial remission. Statistical analyses used non-responder imputation and followed a pre-defined hierarchical hypothesis testing strategy to adjust for multiplicity.

Results: 219 subjects were randomized. Demographics and baseline disease characteristics were comparable between study arms: mean age 43.3 years, mean time since diagnosis 6.2 years and mean BASDAI 6.65. The primary endpoint was met with secukinumab 150 mg at Week 16: ASAS20 response rate was 61.1% vs. 27.0% with PBO ($P < 0.001$; Figure), with significant improvements seen as early as Week 1. Secukinumab 150 mg also significantly improved hsCRP, ASAS40, ASAS 5/6, BASDAI, SF-36 PCS and ASQoL compared with PBO. Efficacy of secukinumab 150 mg vs. PBO was observed in both TNF-naïve and TNF-IR subjects for ASAS20 (68.9% vs. 31.1% and 48.1% vs. 20.7%, respectively; both $P < 0.05$) and ASAS40 (44.4% vs. 17.8% and 22.2% vs. 0%, respectively; both $P < 0.05$). Secukinumab 75 mg provided numerically greater responses than PBO at Week 16, but these did not reach statistical significance for any of the pre-specified primary or secondary endpoints based on hierarchical testing. Similar adverse event (AE) rates were reported up to Week 16 for secukinumab 75 mg (57.5%), 150 mg (62.5%), and PBO (63.5%). Serious AEs were reported in 5.5% of subjects in the secukinumab 75 mg group, compared with 5.6% in the secukinumab 150 mg group and 4.1% in the PBO group.

Conclusion: Secukinumab 150 mg s.c. was effective at rapidly reducing the signs and symptoms of disease and improving health-related quality of life in subjects with active AS, regardless of prior anti-TNF exposure. Secukinumab was well tolerated, with no unexpected safety findings.

Secukinumab, a Human Anti–Interleukin-17A Monoclonal Antibody, Significantly Reduces Psoriasis Burden in Patients with Psoriatic Arthritis: Results from a Phase 3 Randomized Controlled Trial. Alice B. Gottlieb[1], Philip Mease[2], Iain B. McInnes[3], Bruce Kirkham[4], Arthur Kavanaugh[5], Proton Rahman[6], Peter Nash[7], Luminita Pricop[8], Jiacheng Yuan[8], Hanno Richards[9] and Shephard Mpofu[9]. [1]Tufts Medical Center, Boston, MA, [2]Swedish Medical Center and University of Washington, Seattle, WA, [3]University of Glasgow, Glasgow, United Kingdom, [4]Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom, [5]UCSD School of Medicine, La Jolla, CA, [6]Memorial University of Newfoundland, St. John's, NF, [7]University of Queensland, Brisbane, Australia, [8]Novartis Pharmaceuticals Corporation, East Hanover, NJ, [9]Novartis Pharma AG, Basel, Switzerland.

Background/Purpose: Reducing the burden of skin manifestations of psoriatic arthritis (PsA) is an important aspect of disease management. Secukinumab, a human anti–IL-17A monoclonal antibody, has demonstrated rapid and sustained efficacy in the treatment of psoriasis in phase 3 trials, including in the subset of patients (pts) with PsA. Here we present the effect of secukinumab on dermatological parameters in pts enrolled in FUTURE 1 (NCT01392326), the first phase 3 trial to evaluate the efficacy of IL-17A inhibition in pts with PsA.

Methods: Adults with moderate to severe PsA according to ClASsification of Psoriatic ARthritis criteria were randomized to a secukinumab 10 mg/kg intravenous (i.v.) loading dose at baseline (BL), Week (Wk) 2, and Wk 4, then either 75 mg subcutaneously (s.c.; 10 IV→75 SC) or 150 mg s.c. (10 IV→150 SC) every 4 wks from Wk 8, or placebo (PBO) on the same i.v. and s.c. schedules. Assessments of psoriasis burden included 75% and 90% improvement in Psoriasis Area and Severity Index (PASI 75/90), Investigator's Global Assessment (modified 2011) score of 0 or 1 (IGA 0/1), target lesion score (TLS), modified Nail Psoriasis Severity Index (mNAPSI), and the Dermatology Life Quality Index (DLQI). The effect of treatment on high-sensitivity C-reactive protein (hsCRP) levels, a marker of skin and joint inflammation, was also monitored.

Results: From the full analysis set (FAS) of 606 pts, 325 (53.6%) had psoriasis affecting ≥ 3% of body surface area at BL (psoriasis subset), 510 (84.2%) had a psoriatic target lesion ≥ 2 cm in diameter (TLS subset) and 435 (71.8%) had nail involvement (nail subset). Improvements in dermatology parameters with secukinumab vs. PBO at Wk 24 are presented in the table. In the psoriasis subset, 10 IV→75 SC and 10 IV→150 SC significantly improved the proportion of PASI 75, PASI 90, and IGA 0/1 responders vs. PBO at Wk 24, and provided clinically meaningful improvement (≥ 4-point change from BL) in DLQI, with most pts having a decline in DLQI score from > 10 (severe) at BL to < 4 at Wk 24. Pts in the TLS subset experienced a rapid (from Wk 1) and significant improvement in TLS with secukinumab vs. PBO at Wk 24, while mNAPSI was significantly improved with secukinumab in the nail subset. hsCRP values were significantly lower with secukinumab vs. PBO from Wk 1 through Wk 24 (FAS).The improvements in dermatological parameters observed with secukinumab at Wk 24 were sustained through Wk 52.

Table. Effect of treatment on skin and involvement at Week 24

BL and Wk 24 Data	Secukinumab10 mg/kg IV → 75 mg SC	Secukinumab10 mg/kg IV → 150 mg SC	Placebo
[a]PASI Responses	6.4	9.2	8.9

Secukinumab, a Monoclonal Antibody to Interleukin-17A, Significantly Improves Physical Function and Quality of Life in Subjects with Active Ankylosing Spondylitis: Results of a Phase 3 Randomized, Placebo-Controlled Trial with Intravenous Loading and Subcutaneous Maintenance Dosing. Atul A. Deodhar[1], Dominique L. Baeten[2], Jürgen Braun[3], Xenofon Baraliakos[3], Joachim Sieper[4], Maxime Dougados[5], Paul Emery[6], Brian Porter[7], Ruvie Martin[7], Shephard Mpofu[8] and Hanno Richards[8]. [1]Oregon Health and Sciences University, Portland, OR, [2]Department of Clinical Immunology and Rheumatology and Department of Experimental Immunology, Academic Medical Centre/University of Amsterdam, Amsterdam, Netherlands, [3]Rheumazentrum Ruhrgebiet, Herne, Germany, [4]Charité Universitätsmedizin Berlin, Berlin, Germany, [5]Descartes University, Cochin Hospital, Paris, France, [6]University of Leeds, Leeds, United Kingdom, [7]Novartis Pharmaceuticals Corporation, East Hanover, NJ, [8]Novartis Pharma AG, Basel, Switzerland.

Background/Purpose: Ankylosing spondylitis (AS) can have a profound negative effect on an individual's physical functioning, health status and quality of life (QoL), affecting the ability to work (Sieper J et al. Ann Rheum Dis. 2002). Since interleukin (IL)-17A is implicated in the pathogenesis of AS (Dougados M, Baeten, D. Lancet 2011), inhibition of this cytokine with secukinumab, a fully human anti-IL-17A monoclonal antibody, may help reduce the burden of disease. Here we present the impact of high-dose intravenous (i.v.) loading with secukinumab followed by subcutaneous (s.c.) maintenance dosing on patient-reported outcomes (PROs) in a phase 3 trial (MEASURE 1; NCT01358175) over 52 weeks.

Methods: 371 adults with active AS fulfilling modified New York Criteria and Bath Ankylosing Spondylitis Disease Activity Index ≥ 4 were randomized to receive i.v. secukinumab 10 mg/kg (Week 0, Week 2, Week 4) followed by s.c. secukinumab 75 mg every 4 weeks (10 IV → 75 SC); i.v. secukinumab 10 mg/kg (Week 0, Week 2, Week 4) followed by s.c. secukinumab 150 mg every 4 weeks (10 IV → 150 SC); or i.v. placebo (Week 0, Week 2, Week 4) followed by s.c. placebo every 4 weeks (placebo group; PBO). PBO subjects were re-randomized to either 75 mg or 150 mg s.c. secukinumab based on ASAS20 response at Week 16, with non-responders switched to secukinumab at Week 16 and responders at Week 24. PROs were measured every 4 weeks using the following questionnaires: short form 36 (SF-36), EuroQoL (EQ-5D), AS QoL (ASQoL), Functional Assessment of Chronic Illness Therapy — Fatigue (FACIT-Fatigue) and Work Productivity and Activity Impairment — General Health (WPAI-GH). PROs to Week 16 are reported using a mixed-effect model repeated measures (MMRM) analysis, except WPAI-GH domains which are observed data.

Results: Demographics and disease severity were comparable among the three groups with subjects experiencing moderate to severe levels of fatigue and impaired health-related QoL at baseline. Secukinumab 10 IV →75 SC and 10 IV → 150 SC significantly improved scores on the SF-36 physical and mental component summaries, ASQoL, EQ-5D and FACIT-Fatigue vs. PBO at Week 16 (Table), with significant differences in these parameters seen with both doses in all assessments starting at Week 4. Mean changes from baseline at Week 16 were greater than the minimum clinically important difference (MCID) for SF-36

PCS, MCS, ASQoL and FACIT-Fatigue (Table). Reductions in the impact of disease on work productivity (WPAI-GH) were observed with secukinumab vs. PBO at Week 16. Improvements in PROs observed with secukinumab were sustained or increased beyond Week 16 through Week 52.

Conclusion: In subjects with active AS, selective inhibition of IL-17A with secukinumab provided rapid and sustained improvements in PROs, including fatigue, general and AS-specific QoL measures, and illness-associated reductions in work productivity.

Efficacy and Safety of Ustekinumab in Psoriatic Arthritis Patients with Spondylitis and Peripheral Joint Involvement: Results from a Phase 3, Multicenter, Double-Blind, Placebo-Controlled Study. Arthur Kavanaugh[1], Lluís Puig Sanz[2], Alice B. Gottlieb[3], Christopher T. Ritchlin[4], Yin You[5], Yuhua Wang[5], Alan M. Mendelsohn[5], Michael Song[5], Proton Rahman[6] and Iain B. McInnes[7]. [1]University of California San Diego, La Jolla, CA, [2]Universitat Autònoma de Barcelona, Barcelona, Spain, [3]Tufts Medical Center, Boston, MA, [4]University of Rochester Medical Center, Rochester, NY, [5]Janssen Research & Development, LLC., Spring House, PA, [6]Memorial University of Newfoundland, St. John's, NF, [7]University of Glasgow, Glasgow, United Kingdom.

Background/Purpose: IL-23 may be implicated in spondylitis. A substantial number of pts with spondylitis and peripheral joint involvement were enrolled in PSUMMIT. We evaluated the efficacy of SC UST 45/90 mg in a subgroup of psoriatic arthritis (PsA) pts with physician diagnosed spondylitis and peripheral joint involvement through wk108, from PSUMMIT 1.

Methods: Adult PsA patients (n=615) with active disease (≥5 SJC and ≥5 TJC;CRP≥0.3mg/dL) despite DMARD and/or NSAIDs were randomized to UST45mg, 90mg, or PBO at wks 0, 4, and q12wks. Pts treated with prior anti-TNF agents were excluded. Stable concomitant MTX was permitted but not mandated. At wk16, pts with <5% improvement in TJC & SJC entered blinded early escape (PBO→UST45mg; UST45mg→90mg; 90mg→90mg). PBO pts subsequently crossed over to UST45mg at wk24. Pts received q12w dosing to wk88, with final efficacy evaluation at wk100 and safety assessment at wk108. Pts with spondylitis and peripheral joint involvement as their primary arthritis presentation of PsA also had BASDAI assessments at wks12 and 24.

Results: 186 randomized pts (70 PBO, 116 UST combined) had spondylitis with peripheral joint involvement at baseline (30% of overall population); mean baseline characteristics were similar to the overall population (age 45.6yrs, weight 82.8kg, PsA duration 6.3yrs, SJC/TJC 14.3/24.1, HAQ-DI 1.3; BASDAI 6.5, and 26% were HLAB27 positive. Mean baseline scores among pts with dactylitis (n=100), enthesitis (148), and skin disease (147) were 8.3, 5.6, and PASI 14.2, respectively. At wk24, greater proportions of combined UST45/90mg treated pts had improvements in dactylitis/enthesitis measurements, HAQ-DI and ACR20/50/70 responses than PBO (Table). Clinical improvements were generally maintained through wk100. A significantly higher proportion of UST-treated pts achieved BASDAI20/50/70 responses vs. PBO at wk24 (54.1%/27.9%/14.4% vs. 26.2%/13.1%/0.0%). Peripheral structural damage assessed by total vdH-S mean change from baseline also showed improvement in the UST groups vs PBO at wk24. Of the 135 patients with ≥3% BSA involvement and spondylitis with peripheral arthritis at baseline, PASI75 responses were also maintained through wk100. During the PBO-controlled period, the proportion of pts with AEs were comparable between the PBO and combined UST-treated groups (AEs 32.9% vs 24.1%; SAEs 1.4% vs 0.9%; discontinuations due to AEs 2.9% vs 0.9%; serious infections 14.3% vs 7.8%). Through 2yrs, safety observations were consistent with the overall PsA population.

Conclusion: In this post-hoc subgroup analysis, UST significantly improved signs and symptoms, and demonstrated improvements in BASDAI and peripheral radiographic progression compared with PBO through wk24; efficacy was maintained through wk100. UST was well-tolerated and demonstrated a safety profile similar to that observed in the overall PsA study population.

Two Years Sacroiliac Radiographic Progression Rate and Influence of Baseline Markers of Inflammation in Recent Onset Spondyloarthritis. Maxime Dougados[1], Christophe Demattei[2], Rosaline van den Berg[3], Viet Vo Hoang[4], Fabrice Thévenin[5], Monique Reijnierse[3], Damien Loeuille[6], Antoine Feydy[7], Pascal Claudepierre[8] and Désirée van der Heijde[9]. [1]INSERM

(U1153): Clinical Epidemiology and Biostatistics, PRES Sorbonne Paris-Cité, Paris, France., Paris, France, [2]CHU, Nimes, France, [3]Leiden University Medical Center, Leiden, Netherlands, [4]Department of radiology, Lyon, France, [5]Paris Descartes University, Côchin Hospital, APHP, Paris, France, [6]CHU Nancy, Vandoeuvre Les Nancy, France, [7]Paris Descartes University, Radiology B department, Cochin Hospital, paris, France, [8]Paris-Est University; LIC EA4393; APHP, Henri Mondor Hospital, Creteil, France, [9]LUMC, Leiden, Netherlands.

Background/Purpose: According to the ASAS axial spondyloarthritis (SpA) criteria, patients suffering from inflammatory back pain (IBP) can be recognized as suffering from axial SpA even in the absence of structural damage of the sacroiliac joints (SIJ) but the natural history of these patients is not well known.The objective of this study was to evaluate 1) the rate of SIJ structural progression over a 2 years period and 2) the influence of baseline objective signs of inflammation on this progression rate in patients suffering from recent onset inflammatory back pain suggestive of SpA.

Methods: *Patients:* IBP < 3 years duration suggestive of axial SpA according to the treating rheumatologist (DESIR cohort) *Outcome measures:* **Pelvic X-rays** collected both at baseline and at the 2 year follow up visit and **MRI of the SIJ** collected at baseline were stored after anonymizing and blinding for the visit. Radiographic structural damage was defined as the fulfillment of the modified New-York (mNY) criteria and inflammation on MRI ("positive MRI") was defined according to the ASAS criteria. The radiographs and MRIs were read centrally by two pairs of well calibrated central readers blinded for clinical, laboratory and other imaging data. In case of disagreement, images were adjudicated by an experienced radiologist. **CRP**at baseline was defined as abnormal if >6mg/l.

Results: Of the 708 enrolled patients, 449 had a complete radiological data set (34 + 9 years old, 53 % females, HLA B27 positive: 61%). At baseline, 123 of 449 (27%) fulfilled the mNY criteria. Of the remaining 326 patients, 16 (4.9%) progressed (fulfilling the mNY criteria at the 2 year visit). Among these 326 patients, baseline MRI, CRP and both MRI and CRP were available in 307, 314 and 303 patients respectively. The table summarizes the main findings of this study. MRI positivity, CRP abnormality and either MRI positivity or CRP abnormality was observed in 14/15 (93%) *versus* 67/292 (23%), 7/15 (46%) *versus* 61/299 (20%) and 14/15 (93%) *versus* 111/288 (39%) of the patients with *versus* without a radiographic progression after the 2 year follow-up visit. A normal MRI and CRP at baseline almost excluded the development of sacroiliitis according to the mNY criteria after two years.

Table: SIJ structural progression among the 326 patients not fulfilling SIJ mNY criteria at baseline

		SIJ structural progression		
Baseline Variable		**mNY Positive at year 2**	**mNY negative at year 2**	
MRI	positive	14*	67	OR: 47.0[6.1–364.1] PPV: 0.17
	negative	1	225	NPV:0.004
CRP	abnormal	7	61	OR:3.4[1.2–9.8] PPV:0.10
	normal	8	238	NPV:0.033
Inflammation**	presence	14	111	OR:23.3[2.9–172.1] PPV:0.11
	absence	1	177	NPV: 0.006

*values given are the number of patients and OR []: Odds ratio [95% confidence interval]; PPV: positive predictive value; NPV: negative predictive value.
**baseline inflammation: either MRI positive or abnormal CRP

Conclusion: These data suggest that 1) SIJ structural progression to fulfillment of mNY criteria in this cohort was low after a two years follow-up period 2) the presence of objective signs of inflammation are a predisposing factor of structural progression keeping in mind that the majority of patients with baseline signs of inflammation did not progress.

Collagen II Neo-Epitopes in Spondyloarthritis. Heidi Lausten Munk[1], Natasja Staehr Gudmann[2], Anne Friesgaard Christensen[3], Leif Ejstrup[4], Grith Lykke Sørensen[5], Anne Gitte Loft[3], Anne C. Bay-Jensen[2], Anne Sofie Siebuhr[2] and Peter Junker[1]. [1]Department of Rheumatology, Odense University Hospital, Odense, Denmark, [2]Cartilage Biomarkers and Research, Nordic Bioscience, Herlev, Denmark, [3]Department of Rheumatology, Vejle Hospital, Vejle, Denmark, [4]Department of Rheumatology, Esbjerg Hospital, Esbjerg, Denmark, [5]Institute of Molecular Medicin, University of Southern Denmark, Odense, Denmark.

Background/Purpose: Spondyloarthritis (SpA) is characterized by aseptic inflammation of the axial skeleton which may ultimately lead to irreversible deformities due to bony ankylosis. Occasionally, peripheral joints and extraskeletal sites are also involved. The etiology is unknown, but there is a well-established association with HLA-B27. Intervertebral discs and diarthrodial joints of the spine are targeted by the disease, and studies on cartilage have indicated increased turnover of several extracellular matrix components, mainly collagen, in active ankylosing spondylitis (AS). Thus, C2M, a matrix metalloproteinase derived collagen type II fragment has been found to be increased in AS. Procollagen IIA, an alternatively spliced collagen II variant, is preferentially expressed during embryogenic skeletal patterning where it is supposed to participate in the regulation of chondro- and osteogenesis. In adults PIIANP is present in damaged cartilage and osteophytes.

The aims of this investigation were to assess collagen II turnover in SpA by studying C2M and PIIANP concomitantly in patients treated with or without TNF inhibitors (TNFi).

Methods: One hundred and ten patients (age 18–63 years) with SpA according to the ASAS criteria were recruited from two secondary and one tertiary center. Demographic and clinical disease measures were recorded. Ninety six volunteer blood donors served as healthy controls. C2M and PIIANP were quantified in serum by ELISA. Mann–Whitney U test for intergroup comparisons and Spearman's rank test for correlations were applied. The discriminative power of the serum markers between healthy and diseased was calculated by receiver-operator characteristics (ROC) and expressed by the area under the curve (AUC).

Results: The serum level of C2M was higher in SpA patients compared to healthy controls ($p<0.01$)(table). The PIIANP level did not differ between SpA patients and controls. There was no correlation between C2M and PIIANP. C2M correlated negatively with smoking ($r=-0.22$;$p=0.02$) and PIIANP correlated positively with sex ($r=0.31$;$p=0.001$), CRP ($r=0.31$; $p=0.001$), HLA-B27 ($r=0.21$;$p=0.03$) and negatively with treatment ($r=-0.23$;$p=0.02$). Patients were categorized according to TNFi treatment (TNFi-/TNFi+). PIIANP and C2M were increased in TNFi- patients compared to controls ($p<0.05$–0.001). Using ROC calculation for C2M AUC was estimated to 0.67.

Characteristics	**SpA (n=110)**	**TNFi- (n=57)**	**TNFi+ (n=53)**

#Denotes SpA vs. controls *Denotes TNFi- vs. TNFi+

Conclusion: These findings indicate that active SpA is associated with enhanced cartilage turnover as reflected by increased collagen II degradation and repair. Conversely, this sero-marker profile was normal during TNFi treatment. In addition, C2M discriminates well between healthy subjects and SpA.

Predictors for Cardiovascular Events in Patients with Psoriatic Arthritis – a Cohort Study. Lihi Eder[1], Arane Thavaneswaran[1], Vinod Chandran[1], Hua Shen[2], Richard J. Cook[2] and Dafna D. Gladman[1]. [1]University of Toronto, Toronto Western Hospital, Toronto, ON, [2]University of Waterloo, Waterloo, ON.

Background/Purpose: The prevalence of cardiovascular (CV) morbidity is increased in patients with psoriatic arthritis (PsA). CV risk is only partially explained by traditional CV risk factors. We aimed to identify predictors for CV events in a cohort of patients with PsA.

Methods: A retrospective cohort analysis was conducted in patients attending a large PsA clinic from 1978 to 2013. Patients were assessed at 6–12 month intervals according to a standard protocol. The collected information included demographics, lifestyle habits, medical history and disease-related outcomes. The following factors were assessed as candidate predictors of CV events: traditional CV risk factors, measures of PsA disease activity and laboratory biomarkers of inflammation. The primary outcome was the time to the first major CV event that comprised myocardial infarction (MI), ischemic stroke, re-vascularization or CV death. The secondary outcome was the time to any first CV event that included major CV events, angina, transient ischemic accident (TIA) and congestive heart failure (CHF). Each event was confirmed by reviewing hospital records and death certificates. Cox proportional hazard model, with time-dependent explanatory variables and date of birth as the time of origin, was used to compute the multivariate relative risk (RR) for incident CV events adjusting for sex and duration of PsA.

Results: The analysis included 1103 patients with PsA for a combined follow-up time of 10,751 person-years, during which 104 cardiovascular events occurred (57 MI, 9 stroke, 19 revascularization, 2 CV death, 10 angina, 1 TIA and 6 CHF). The mean follow-up period was 9.8±8.5 years. The mean age at the first visit was 44±12.9 years and 56.3% of the patients were males. The incidence rate of CV events did not change significantly across the three decades from 1978 to 2013 (p=0.65). The following variables were associated with a higher incidence rate of major CV events: diabetes (RR 2.7, p=0.002), hypertension (RR 1.93 p=0.003), high triglycerides (RR 1.95 p=0.005), high cholesterol (RR 1.58 p=0.05), erythrocyte sedimentation rate (ESR) (RR 1.36 p=0.009), leukocyte count (RR 2.19 p=0.007) and tender joint count (RR 1.34, p=0.01). The variables that were associated with a higher incidence rate of any CV event were: diabetes (RR 2.68 p=0.0007), hypertension (RR 1.99, p=0.0008), high triglycerides (RR 1.71 p=0.02), ESR (RR 1.3 p=0.02) and tender joint count (RR 1.34 p=0.007). Achieving a minimal disease activity state was associated with a lower incidence rate of major CV events (RR 0.56, p=0.009) and any CV event (RR 0.62, p=0.02). No association was found between the use of non-steroidal anti-inflammatory drugs, disease modifying anti rheumatic agents or TNFα blockers and CV events.

Conclusion: Cardiovascular morbidity in patients with PsA is explained by the combined effect of elevated inflammatory burden and traditional CV risk factors. The achievement of a minimal disease activity state may decrease CV risk in patients with PsA.

Disease Activity and Clinical Response Early in the Course of Treatment Predict Long-Term Outcomes in Axial Spondyloarthritis Patients Treated with Certolizumab Pegol. Désirée M. van der Heijde[1], Atul A. Deodhar[2], Owen Davies[3], Tommi Nurminen[4] and Martin Rudwaleit[5]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]Oregon Health and Science University, Portland, OR, [3]UCB Pharma, Slough, United Kingdom, [4]UCB Pharma, Monheim, Germany, [5]Endokrinologikum, Berlin, Germany.

Background/Purpose: Early response to anti-TNF therapy has been shown to be a strong predictor of good long-term outcomes in ankylosing spondylitis (AS). [1] However, early identification of patients (pts) unlikely to achieve good long-term disease control by anti-TNF therapy has been less well characterized, although identifying such pts may help avoid unnecessary exposure, increase cost-effectiveness and improve the chance of achieving long-term treatment goals. Here we aim to assess the association between disease activity (DA) during the first 12 weeks (wks) of treatment, and attainment/lack of attainment of treatment targets at Wk48 in axial spondyloarthritis (axSpA) pts, including AS and non-radiographic (nr-) axSpA pts, receiving certolizumab pegol (CZP).

Methods: The relationship between DA during the first 12 wks of treatment and achievement of the Wk48 treatment targets: ASDAS Inactive Disease (ID) or BASDAI <2 with or without CRP levels equal to or below the upper limit of normal (ULN=7.9mg/L), was assessed post hoc using CZP data from the RAPID-axSpA trial (NCT01087762). [2] DA state was defined for ASDAS as: ID, moderate (MD), high (HD) or very high DA (vHD), and for BASDAI as Low (<2), Moderate (≥2 to <4), High (≥4 to ≤6) or Very High (>6). BASDAI thresholds have not been validated. Analyses are based on all pts randomized to CZP (200mg Q2W or 400mg Q4W) in the overall axSpA population and also the AS and nr-axSpA subpopulations. Predictability analyses for a given wk are based on all pts continuing treatment at that wk. For these pts, LOCF was applied for withdrawals before, or missing evaluation at, Wk48.

Results: ASDAS DA state at Wk2 was associated with likelihood of achieving ID at Wk48, with 71% (22/31) of pts with ID at Wk2 achieving ID at Wk48, compared with 0% (0/27) of pts with vHD at Wk2 achieving ID at Wk48. A similar trend was observed at Wk12, although fewer pts had HD and vHD, and more pts had ID at this time point (Table A). BASDAI Very High DA also successfully predicted the lack of attainment of the treatment target BASDAI <2 + CRP ≤ULN (Tables B and C), and results were not altered if only BASDAI <2 (and not CRP level) was the target. Lack of clinical response (CR) to CZP was also an effective negative predictor of Week 48 DA (Table C), with 3/45 (6.7%) pts with Wk12 BASDAI improvement <1 achieving Wk48 DA of BASDAI <2, and 12/65 (18.5%) pts with Wk12 ASDAS improvement less than clinically important improvement (<CII) achieving Wk48 ASDAS ID. Similar trends were observed in the AS and nr-axSpA subpopulations (Table C).

Conclusion: Using ASDAS or BASDAI DA state or CR during the first 12 wks of CZP treatment, it was possible to identify a subset of pts who are unlikely to achieve long-term treatment goals. This approach may enable physicians adopting a treat-to-target strategy to determine early on when to change therapy in pts not responding to CZP.

Observed Incidence Rates of Uveitis over 96 Weeks of Certolizumab Pegol Treatment in Patients with Axial Spondyloarthritis. James T. Rosenbaum[1], Martin Rudwaleit[2], Robert B. M. Landewé[3], Helena Marzo-Ortega[4], Joachim Sieper[5], Désirée M. van der Heijde[6], Owen Davies[7], Christian Stach[8], Tommi Nurminen[8] and Atul A. Deodhar[9]. [1]OHSU, Portland, OR, [2]Endokrinologikum, Berlin, Germany, [3]Amsterdam Rheumatology Center, Amsterdam, Netherlands, [4]University of Leeds and NIHR Leeds Musculoskeletal Biomedical Research Unit, Leeds, United Kingdom, [5]University Hospital Charité, Berlin, Germany, [6]Leiden University Medical Center, Leiden, Netherlands, [7]UCB Pharma, Slough, United Kingdom, [8]UCB Pharma, Monheim, Germany, [9]Oregon Health and Sciences University, Portland, OR.

Background/Purpose: Axial spondyloarthritis (axSpA) is characterized by inflammation in the spine and sacroiliac joints, but can also manifest as inflammation at extra-spinal sites, most commonly inflammation of the uvea (uveitis).[1] Here we aim to estimate the incidence of uveitis flares in patients (pts) with axSpA following certolizumab pegol (CZP) treatment in the RAPID-axSpA trial.

Methods: RAPID-axSpA (NCT01087762)[2] was double-blind and placebo (PBO)-controlled to Week (Wk) 24, dose-blind to Wk48 and open-label to Wk204. Pts fulfilled ASAS criteria and had active axSpA, including ankylosing spondylitis (AS) and non-radiographic (nr-)axSpA. Pts were randomized 1:1:1 to either CZP 200mg Q2W, 400mg Q4W (following 400mg loading dose [LD] at Wks 0, 2, 4) or PBO. PBO pts entering dose-blind phase were re-randomized to CZP LD followed by CZP 200mg Q2W or 400mg Q4W after Wk24 or, for non-responders, Wk16. Uveitis events were recorded on extra-articular manifestation forms or adverse event forms (preferred term "Uveitis"). Events were analyzed in pts with or without a history of uveitis (defined using standard medical history, ASAS classification criteria screening assessment and baseline extra-articular assessment). At Wk24, combined CZP dosing regimens were compared with PBO; for Wk96 analyses all pts exposed to CZP were considered. Incidence rates (IR) are reported per 100 pt-yrs (PY) with censoring at time of event. No analyses of statistical significance were carried out on these data.

Results: At baseline, 38/218 (17.4%) CZP-randomized pts had a history of uveitis, as did 31/107 (29.0%) PBO-randomized pts. The proportion of pts with history of uveitis was similar in AS (20.8%) and nr-axSpA (21.1%) subpopulations. During the 24-wk double-blind phase, overall IR of uveitis flares (regardless of previous history) was lower in CZP pts (IR=2.0/100 PY) than PBO pts (IR=10.6/100 PY). There were no *de novo* cases of uveitis flares observed to Wk24 – ie. all cases were observed in pts with history of uveitis; in these pts, IR was 11.9/100 PY for CZP and 42.1/100 PY for PBO (Table A). To Wk96, 22 uveitis flares occurred in 19 pts, 11 in AS pts and 11 in nr-axSpA pts. The IR of uveitis flares (regardless of prior history of uveitis) remained low to Wk96 in CZP-treated pts (IR=4.0/100 PY; Table B). The incidence of uveitis flares in CZP-treated pts (IR=4.0/100 PY) was comparable to rates observed for other anti-TNFs in AS pts including adalimumab (IR=6.9/100 PY)[3] and etanercept (IR=6.7/100 PY).[4]

Conclusion: The IR of uveitis flares was lower for axSpA pts treated with CZP than with PBO during the randomized controlled phase, and was comparable to the rate reported for AS pts receiving anti-TNF therapy.

Long-Term Safety and Efficacy of Certolizumab Pegol over 96 Weeks in Patients with Psoriatic Arthritis with and without Prior Tumor Necrosis Factor Inhibitor Exposure. Philip Mease[1], Roy Fleischmann[2], Jurgen Wollenhaupt[3], Atul A. Deodhar[4], Dafna D. Gladman[5], Bengt Hoepken[6], Luke Peterson[7] and Désirée M. van der Heijde[8]. [1]Swedish Medical Center and University of Washington, Seattle, WA, [2]University of Texas Southwestern Medical Center and Metroplex Clinical Research Center, Dallas, TX, [3]Schoen-Klinik Hamburg-Eilbek Teaching Hospital of the University of Hamburg, Hamburg, Germany, [4]Oregon Health and Sciences University, Portland, OR, [5]University of Toronto, Toronto Western Hospital, Toronto, ON, [6]UCB Pharma, Monheim, Germany, [7]UCB Pharma, Raleigh-Durham, NC, [8]Leiden University Medical Center, Leiden, Netherlands.

Background/Purpose: Previous reports of RAPID-PsA (NCT01087788) demonstrated efficacy and safety of certolizumab pegol (CZP) over 48 weeks (wks) in psoriatic arthritis (PsA) patients (pts), including pts with prior anti-TNF therapy.[1] Here, we report the efficacy and safety of CZP in PsA from a 96-wk interim data cut of RAPID-PsA.

Methods: RAPID-PsA[1] is double-blind and placebo (PBO)-controlled to Wk24, dose-blind to Wk48 and open-label (OL) to Wk216. Pts had active PsA and had failed ≥1 DMARD. Pts originally randomized to CZP (200mg Q2W/400mg Q4W, following 400mg loading dose [LD] at Wks 0, 2, 4) continued on assigned dose in the OL phase; PBO pts entering dose-blind phase were re-randomized to CZP LD followed by CZP 200mg Q2W or 400mg Q4W after Wk24 or, for non-responders, Wk16. We present efficacy data for pts originally randomized to CZP (combined dose regimens). Primary clinical endpoint was Wk12 ACR20 response.[1] Other endpoints included ACR and PASI responses, HAQ-DI, pain and minimal disease activity (MDA)[2] at Wk96, and ACR responses in pts with/without prior anti-TNF exposure. Data are shown as observed case and with imputation (NRI for categorical measures; LOCF for continuous measures). Safety set consists of pts treated with ≥1 dose of CZP to Wk96.

Results: 409 pts were randomized and 273 received CZP from Wk0. 54 (19.8%) CZP pts had prior anti-TNF exposure with similar baseline (BL) characteristics to pts without. Of CZP-randomized pts, 91% completed Wk24, 87% Wk48 and 80% Wk96. ACR and MDA responses were maintained in both dosing regimens from Wk24 to Wk96 (Figure). ACR responses were similar in pts with/without prior anti-TNF exposure (Figure). Pts randomized to PBO who switched to CZP displayed rapid clinical improvements that were maintained to Wk96. In pts with ≥3% skin involvement at BL (N=166, 60.8% CZP pts) PASI responses were maintained to Wk96 (Table). Improvements in PROs were maintained to Wk96 (Change from BL at Wk24 and Wk96: HAQ-DI: -0.48 vs -0.52; pain: -28.5 vs -31.3). In the safety set (N=393) total CZP exposure was 606 pt-yrs. Adverse events (AEs) occurred in 345 pts (87.8%; event rate [ER] per 100 pt-yrs=329.8) and serious AEs (SAEs) in 67 (17.0%; ER=14.5). SAEs included malignancies in 4 pts (1.0%; ER=0.7) (2 cases of breast cancer, 1 lymphoma, 1 stage 0 *in situ* cervix carcinoma) and serious infections in 16 pts (4.1%; ER=3.3). 6 deaths were reported in the overall 96-wk period (1.5%) (2 cardiac disorders, 1 sudden death, 1 infection, 1 breast cancer, 1 lymphoma).

Conclusion: Clinical efficacy of CZP was maintained through both the dose-blind and OL phases of RAPID-PsA. Efficacy was maintained in both dosing regimens and in both TNF-naïve and TNF-experienced pts. The safety profile was in line with previous reports from RAPID-PsA, with no new safety signals observed with increased exposure.

Psoriatic Arthritis Mutilans: Characteristics and Radiographic Progression. Deepak R. Jadon[1], Gavin Shaddick[2], William Tillett[1], Graham Robinson[3], Charlotte Cavill[1], Nicola Waldron[1], Eleanor Korendowych[1] and Neil J McHugh[4]. [1]Royal National Hospital for Rheumatic Diseases, Bath, United Kingdom, [2]University of Bath, Bath, United Kingdom, [3]Royal United Hospital, Bath, United Kingdom, [4]Department of Pharmacy and Pharmacology, University of Bath, Bath, United Kingdom.

Background/Purpose: Psoriatic arthritis mutilans (PAM) is a rare extreme subtype of psoriatic arthritis (PsA). Our objectives were to: (1) compare clinical characteristics of PsA patients with PAM and without PAM (non-PAM); (2) determine the rate of PAM radiographic progression.

Methods: A retrospective cohort study was conducted of all PsA patients attending a teaching hospital. Clinical characteristics were recorded. Most recent radiographs of hands and feet were evaluated for PAM, defined as osteolysis affecting ≥50% of the articular surface on both sides of the joints. All available radiographs (earliest to most recent) were quantitatively scored for osteolysis, erosion, joint space narrowing, and osteoproliferation. Radiographic progression was analysed using random effects models to allow for patient differences, and additive models for all joints.

Results: 610 PsA cases fulfilling CASPAR criteria were screened: 36 PAM (35 with serial radiographs); 483 non-PAM; 91 had insufficient radiographs to determine PAM.

PAM cases were younger at diagnosis of PsA than non-PAM cases (33 *vs.* 40 years; p=0.04). Psoriatic nail dystrophy was more prevalent in PAM than non-PAM cases (83.33 *vs.* 47.95%; p=0.0002). At most recent assessment, PAM cases had a higher HAQ than non-PAM cases (median 1.25 *vs.* 0.63; p=0.05), especially in domains relating to hand / feet function: HAQ-grip (p=0.02); HAQ-eating (p=0.03). In cases with ACPA serology available, PAM cases were no more likely to be ACPA positive (0/16) than non-PAM cases (8/226; p=0.44). 16/28 PAM cases had radiographic sacroiliitis, often bilateral (14/16) and of grade ≥3 (15/16). During their disease course, PAM cases were more likely than non-PAM cases to have used a DMARD (91.67 *vs.* 50.21%; p<0.0001), but no more likely to have used a Biological (p=0.53). 87.50% of PAM cases had used a DMARD before PAM-occurrence.

A median of 5 radiographs were scored for each PAM case (IQR 3–7). 22/35 patients developed PAM during the course of their follow-up. PAM was most commonly monoarticular (21/35) at first observation, and polyarticular most recently (28/35). The most frequently affected joints were: feet IPJ1, MTPJ2–5; hand DIPJ2, PIPJ5, MCPJ1. Significant changes in osteolysis scores over time were observed for all joints (p<0.008). There was strong indication of differences in the patterns of deterioration over time for different joints (p<0.001). An initial increase in score, followed by a slower rate of deterioration was seen (effective degrees of freedom; edf 2.82), with the change in rate more marked for hands (edf 2.84) than feet (edf 2.08) (*Figure 1*).

Conclusion: PAM is associated with worse physical function, more prevalent nail dystrophy, high-grade bilateral sacroiliitis, greater DMARD use and earlier diagnosis when compared to cases without PAM. Osteolysis progresses most rapidly in early disease, slowing in established disease.

Figure 1. **Osteolysis progression over time in PAM cases**

Comparison of Clinical and Imaging Characteristics of Axial Psoriatic Arthritis and Axial Spondyloarthritis. Neha Garg[1], Abhijeet Danve[2], Kiana Vakil-Gilani[3] and Atul A. Deodhar[4]. [1]Oregon Health and Sciences University, Portland, OR, [2]Oregon Health & Science University, Portland, OR, [3]OHSU, Portland, OR, [4]Oregon Health and Science University, Portland, OR.

Background/Purpose: Few studies have compared the clinical and imaging (x-ray and MRI) characteristics between axial psoriatic arthritis (axPsA) and axial spondyloarthritis patients without psoriasis (axSpA). We compared the clinical and imaging characteristics in these two groups.

Methods: AxSpA patients were identified by searching electronic medical records of our university, and axPsA patients were identified from our existing cohort. Demographic and clinical data were collected by chart review. Disease activity was measured using BASDAI and RAPID3. For

imaging comparisons, the patients were divided into 2 gender and disease duration matched subgroups – 1) AS: ankylosing spondylitis patients without psoriasis fulfilling mNY criteria 2) axPsA: PsA patients fulfilling mNY criteria. Symmetry of sacroiliitis was defined as having same grade of sacroiliitis on each side. Bilateralism was defined as having any grade sacroiliitis on either side. Categorical and continuous variables were reported using proportions and means. Statistical significance was estimated using Mann-Whitney, two mean comparison t-tests, and two sample proportion comparison tests as applicable.

Results: Of 168 SpA patients, 135 axSpA patients were compared with 33 axPsA patients (Table1). Mean age, symptom duration, BMI were similar between the two groups. axSpA had lesser number of females compared to axPsA (33% vs. 57%, $p<0.01$), higher prevalence of uveitis (29% vs. 12%, $p<0.04$), higher HLA B27 (80% vs. 50%, $p<0.007$) and higher BASDAI and RAPID3 scores (BASDAI 4.4 vs 3.8, RAPID3 4.3 vs 3.6, p = ns). These scores were numerically higher in HLA-B27 positive compared to HLA-B27 negative patients (4.3 vs. 3.7, and 4.4 vs. 3.6, respectively; p = ns). Eighteen patients with axPsA were gender and disease duration matched with 86 patients with AS. Radiographic grading of sacroiliitis, symmetry or bilateralism were not significantly different between AS and axPsA. RAPID 3 and BASDAI scores did not correlate with radiographic grading in any group. No significant clinical or imaging differences were found between patients positive and negative for HLA B27.

Conclusion: In this comparative study between axPsA and axSpA patients, we found a higher prevalence of female gender, uveitis and positive HLA-B27 in the axSpA group. Our findings do not confirm the previous reports of more symmetry and more severe disease in AS compared to axPsA patients.

Table 1: Demographic and clinical characteristics of axSpA and axPsA patients

	All patients N=168 % or means (standard deviation)	axSpA N=135 (80.4%) % or means (standard deviation)	axPsA N=33 (19.6%) % or means (standard deviation)	P value

Apremilast, an Oral Phosphodiesterase 4 Inhibitor, Is Associated with Long-Term (52-Week) Improvement in Measures of Disease Activity in Patients with Psoriatic Arthritis: Results from 3 Phase 3, Randomized, Controlled Trials.

Arthur Kavanaugh[1], Maurizio Cutolo[2], Philip Mease[3], Dafna D. Gladman[4], Adewale O. Adebajo[5], Juan Gomez-Reino[6], Jürgen Wollenhaupt[7], Georg A. Schett[8], Eric Lespessailles[9], ChiaChi Hu[10], Randall M. Stevens[10], Christopher Edwards[11] and Charles A. Birbara[12]. [1]University of California San Diego, La Jolla, CA, [2]Research Laboratory and Academic Division of Clinical Rheumatology, Department of Internal Medicine, University of Genova, Genoa, Italy, [3]Swedish Medical Center and University of Washington, Seattle, WA, [4]University of Toronto, Toronto Western Hospital, Toronto, ON, [5]University of Sheffield, Sheffield, United Kingdom, [6]Hospital Clinico Universitario de Santiago, Santiago de Compostela, Spain, [7]University of Hamburg, Hamburg, Germany, [8]University of Erlangen-Nuremberg, Erlangen, Germany, [9]University of Orléans, Orléans, France, [10]Celgene Corporation, Warren, NJ, [11]NIHR Wellcome Trust Clinical Research Facility, University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom, [12]University of Massachusetts Medical School, Worcester, MA.

Background/Purpose: Apremilast (APR) is an oral phosphodiesterase 4 inhibitor that helps regulate the immune response that causes inflammation and skin disease associated with psoriatic arthritis (PsA). The PALACE 1, 2, and 3 trials compared the efficacy and safety of APR with placebo (PBO) in patients with active PsA despite prior conventional disease-modifying antirheumatic drugs (DMARDs) and/or biologics, including biologic failures. We evaluated the impact of APR over 52 weeks on PsA disease activity.

Methods: Patients were randomized (1:1:1) to receive PBO, APR 20 mg BID (APR20), or APR 30 mg BID (APR30) stratified by baseline DMARD use (yes/no). Patients whose swollen and tender joint counts had not improved by ≥20% at Week 16 were considered non-responders and were required to be re-randomized (1:1) to APR20 or APR30 if they were initially randomized to PBO, or continued on their initial APR dose. At Week 24, all remaining PBO patients were re-randomized to APR20 or APR30. This analysis reports data over 52 weeks. Disease activity was evaluated using a modified American College of Rheumatology 20 (ACR20) response, 28-joint count Disease Activity Scale (DAS-28; C-reactive protein [CRP]), Maastricht Ankylosing Spondylitis Enthesitis Score (MASES), dactylitis count, and 75% reduction from baseline Psoriasis Area and Severity Index (PASI-75) response.

Results: At Week 16, a significantly greater proportion of patients treated with APR achieved a modified ACR20 response vs PBO (primary endpoint). In patients initially randomized to APR and completing 52 weeks, ACR20 response was sustained over 52 weeks. APR20 and APR30 demonstrated improvement in disease activity vs PBO at Week 16, as measured by the

mean change in DAS-28 (CRP), achievement of DAS-28 <2.6, median percent changes in MASES/dactylitis score, and PASI-75 response. Among patients who were continuously treated with APR through 52 weeks, sustained improvements were observed at Week 52 (Table). The most common adverse events reported during the PBO-controlled period (PALACE 1–3; pooled) were diarrhea (12.2%), nausea (10.1%), and headache (8.0%). The safety profile of APR through 52 weeks was similar to that observed with APR for up to 24 weeks of treatment (PBO-controlled period). Marked laboratory abnormalities generally were infrequent and returned to baseline with continued treatment or were associated with a concurrent medical condition.

Conclusion: APR demonstrated sustained clinically meaningful improvements in measures of PsA disease activity through Week 52. APR demonstrated an acceptable safety profile and was generally well tolerated through 52 weeks.

Reliability and Construct Validity of the Psoriasis Symptom Inventory in Subjects with Psoriatic Arthritis. Philip Mease[1], Mark C. Genovese[2], Alex Mutebi[3], Hilary Wilson[4], Dennis Revicki[4], Ngozi Erondu[3], Ajay Nirula[3], JingYuan Feng[3] and Hema Viswanathan[3]. [1]Swedish Medical Center and University of Washington, Seattle, WA, [2]Stanford University Medical Center, Palo Alto, CA, [3]Amgen Inc, Thousand Oaks, CA, [4]Evidera, Bethesda, MD.

Background/Purpose: The Psoriasis Symptom Inventory (PSI) is an 8-item patient-reported outcome measure of psoriasis symptom severity. Data from a Phase 2 study of Brodalumab in subjects with plaque psoriasis demonstrated that the PSI has good reliability, validity, and ability to detect change. Psoriasis related symptoms are an important component of psoriatic arthritis (PsA). However, the measurement properties of the PSI have not been evaluated in the PsA population. This analysis sought to evaluate the reliability and construct validity of the PSI in subjects with PsA.

Methods: This was a secondary analysis of pooled data from treatment arms of a Phase 2 clinical trial (NCT01516957) evaluating the efficacy of Brodalumab, an anti-IL-17 R monoclonal antibody in subjects with PsA. Confirmatory factor analysis (CFA) and Rasch analysis were used to assess the dimensionality of the PSI. Item evaluation and internal consistency (Cronbach's α) were conducted on baseline PSI data. Test-retest reliability was assessed using intraclass correlation coefficients (ICC) between PSI scores at week 2 and week 4 in stable subjects (i.e., -1≤ change ≤1 on the subject global assessment of disease [SGA]). Construct validity was evaluated based on correlations between PSI scores and body surface area (BSA) affected by psoriasis, and selected domains of the SF-36. Known groups validity was explored based on BSA severity categories (<5%, 5–10%, >10%) using analysis of variance. Ability to detect change was explored using t-tests comparing mean PSI scores in subjects reporting ≥30% versus <30% improvement from baseline to week 12 on the SGA.

Results: The analysis sample included 154 subjects; 93.5% White, 63.0% females, mean (SD) age was 52.2 (11.47) years. Mean (SD) duration of PsA and BSA at baseline was 8.8 (7.84) years and 10.4% (15.61%) respectively. At baseline, 12% of subjects had no skin involvement and 63% had ≤5% skin involvement. Mean (SD) PSI total score at baseline was 12.2 (7.89). CFA and Rasch analysis supported unidimensionality. Rasch analysis also indicated good item fit and correctly ordered categories. The PSI had excellent internal consistency (α=0.95) and good test-retest reliability (ICC=0.70 for total scores and ranging from 0.67 to 0.81 for items). Convergent validity was supported by moderate correlations with BSA (r=0.50). Discriminant validity was supported by small correlations (r<−0.3) for SF-36 domains of mental health and role emotions. Known groups validity was supported by significantly lower mean PSI scores ($p<0.001$) between subjects with BSA<5% compared to those with BSA >10%). Mean change in PSI score was significantly greater ($p<0.001$) in subjects with ≥30% SGA improvement than subjects with <30% SGA improvement.

Conclusion: This study provides evidence that the PSI is unidimensional, with excellent internal consistency, good test-retest reliability, construct validity, and ability to detect change in subjects with PsA. Based on the findings, the PSI is a robust yet simple and practical measure of psoriasis-related symptoms for use in PsA clinical trials.

Secukinumab, an Anti–Interleukin-17A Monoclonal Antibody, Improves Physical Function, Quality of Life and Work Productivity in Patients with Active Psoriatic Arthritis: Results from a Phase 3, Randomized, Controlled Trial. Vibeke Strand[1], Philip Mease[2], Iain B. McInnes[3], Bruce Kirkham[4], Arthur Kavanaugh[5], Proton Rahman[6], P. Nash[7], Luminita Pricop[8], Jiacheng Yuan[8], Hanno Richards[9] and Shephard Mpofu[9]. [1]Stanford University, Palo Alto, CA, [2]Swedish Medical Center, Seattle, WA, [3]University of Glasgow, Glasgow, United Kingdom, [4]Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom, [5]University of California San Diego, La Jolla, CA, [6]Memorial University of Newfoundland, St. John's, NF, [7]Rheumatology Research Unit, Nambour Hospital, Sunshine Coast and Department of Medicine, University of Queensland, Queensland, Australia, [8]Novartis Pharmaceuticals Corporation, East Hanover, NJ, [9]Novartis Pharma AG, Basel, Switzerland.

Background/Purpose: Psoriatic arthritis (PsA) has a significant adverse effect on patients' health-related quality of life (HRQoL), affecting their physical and emotional functioning and psychological health. Here we present the impact of treatment with secukinumab on patient-reported outcomes (PROs) in patients enrolled in FUTURE 1 (NCT01392326), the first phase 3 trial to evaluate interleukin (IL)-17A inhibition in subjects with PsA.

Methods: Adults with active, moderate to severe PsA were randomized to secukinumab 10 mg/kg i.v. at baseline, Weeks 2 and 4, then either 75 mg s.c. (10 IV → 75 SC; n = 202) or 150 mg s.c. (10 IV → 150 SC; n = 202) at Week 8 and every 4 weeks until end of study, or placebo (PBO; n = 202) on the same i.v. and s.c. schedules. PROs were measured using: Health Assessment Questionnaire – Disability Index (HAQ-DI); Short Form-36 Health Survey (SF-36); EuroQoL (EQ-5D); PsAQoL; Functional Assessment of Chronic Illness Therapy – Fatigue (FACIT-F); and Work Productivity and Activity Impairment – General Health (WPAI). PROs were reported using a mixed-effect model repeated measures analysis, except WPAI and SF-36 domains which were assessed using an observed analysis.

Results: At baseline, dose groups were comparable with respect to demographics and disease activity; subjects had moderate to severe physical impair-

ment, fatigue levels and impaired HRQOL. Secukinumab 10 IV → 75 SC and 10 IV → 150 SC significantly improved HAQ-DI ($P < 0.0001$), SF-36 physical component summary [PCS] score ($P < 0.0001$), EQ-5D ($P < 0.001$ and $P < 0.0001$) and PsAQoL ($P < 0.0001$) vs. PBO at Week 24; only 10 IV → 150 SC significantly improved FACIT-F ($P < 0.05$). Mean changes from baseline reported in HAQ-DI, PCS, mental component summary (MCS) and all domains of SF-36 and FACIT-F exceeded minimum clinically important differences (MCID; Table, in bold): physical functioning (PF), role physical (RP), bodily pain (BP), general health (GH), vitality (VT), social functioning (SF), role emotional (RE), and mental health (MH). Various aspects of work productivity, as assessed by WPAI, were also improved with secukinumab vs. PBO. Improvements in all PROs were sustained or further increased over 52 weeks.

Table. Mean baseline scores and mean change from baseline (BL) in patient-reported outcomes (PROs) at Week 24 by treatment group

PROs		Secukinumab 10 mg/kg i.v. → 75 mg s.c. n = 202	Secukinumab 10 mg/kg i.v. → 150 mg s.c. n = 202	Placebo n = 202

Predictors Associated with Rheumatologist Referral Time in Patients with Ankylosing Spondylitis. Atul A. Deodhar[1], Manish Mittal[2], Patrick Reilly[2], Yanjun Bao[2], Shivaji Manthena[2], Jaclyn K. Anderson[2] and Avani D. Joshi[2]. [1]Oregon Health and Sciences University, Portland, OR, [2]AbbVie Inc., North Chicago, IL.

Background/Purpose: Average delay between symptom onset and diagnosis of ankylosing spondylitis (AS) has been reported as 8–12.8 years[1,2]. This study assessed delay in AS diagnosis following diagnosis of back pain (BP), and sought to identify factors affecting time from BP diagnosis to rheumatologist referral in AS patients (pts).

Methods: This longitudinal study used claims data from the large US MarketScan® commercial insurance claims databases (total number of pts n = 127,137,195 between Jan 2000–Dec 2012). Pts aged 18–64 years with diagnosis of BP in a non-rheumatology setting followed by AS diagnosis in any setting were selected. Pts with a rheumatologist visit on/before AS diagnosis were considered to have been referred. A time-dependent Cox proportional hazard model was used to determine factors associated with referral time after adjusting for age, sex, comorbidities, physician specialty, drug therapy and imaging procedures.

Results: Out of 3,336 pts diagnosed with AS after a diagnosis of BP, 1,244 (37%) were referred to and diagnosed by rheumatologists; remaining were diagnosed in a primary care (PCP; 25.7%), chiropractor/physical therapy (7%), orthopedic (3.8%), pain (3.6%), acute care (3.4%) or other (19.2%) setting. More referred pts were prescribed NSAIDs, DMARDs, corticosteroids and anti-TNF prior to diagnosis of AS, suggesting potentially more severe AS (**Table 1**). In the time between the diagnoses of BP and AS, 75 (6%) of referred patients were prescribed anti-TNF therapy by rheumatologists and 42 (2%) of non-referred patients were prescribed anti-TNFs by PCPs. Referred pts were also more likely to have had spinal/pelvic imaging procedures (x-ray, MRI, CT scan). Median time from BP diagnosis to rheumatologist referral was 307 days and median time from first rheumatologist visit to AS diagnosis was 28 days. Referred pts were more likely to be younger, male, diagnosed with uveitis, referred by PCPs, prescribed NSAIDs, DMARDs, and anti-TNF prior to referral, and to have had spinal/pelvic x-ray **(Table 2)**.

Conclusion: During 2000–2012, the majority of AS patients who presented with BP were diagnosed without rheumatologist referral. Among those referred, there was a delay of approximately 10 months before a rheumatologist referral was made. After a rheumatologist visit, diagnosis of AS generally followed within a month. Predictors of referral time included young age, male sex, presence of uveitis, use of drug therapy and imaging procedures, and referring physician specialty.

Sustained Improvement in Physical Function, Health-Related Quality of Life, and Work Productivity with Adalimumab Treatment in Non-Radiographic Axial Spondyloarthritis. Désirée van der Heijde[1], Manish Mittal[2], Naijun Chen[2], Aileen L. Pangan[2] and Avani D. Joshi[2]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]AbbVie Inc., North Chicago, IL.

Background/Purpose: In the ABILITY-1 trial, adalimumab (ADA) treatment for 12 weeks was associated with improved clinical and health-related quality of life (HRQOL) outcomes among patients with nonradiographic axial spondyloarthritis (nr-axSpA). [1] We aimed to evaluate physical function, HRQOL and work productivity over 3 years of ADA treatment in ABILITY-1.

Methods: ABILITY-1 was a 3-year, phase 3, multicenter, randomized, controlled trial of ADA vs placebo in patients with nr-axSpA (classified using the Assessment of SpondyloArthritis international Society axial SpA criteria). After a 12-week double-blind phase, all patients switched to open-label ADA for an additional 144 weeks (156 total). This post hoc analysis evaluated patient-reported outcomes through year 3 among 185 patients overall and among subgroups of 142/43 patients with/without elevated C-reactive protein (CRP) and/or MRI evidence of inflammation at baseline. Physical function was assessed using the disability index of the Health Assessment Questionnaire for Spondyloarthropathies (HAQ-S) and HRQOL using the Short Form 36 Health Survey (SF-36) Physical Component Summary (PCS) score. Productivity was assessed using the Work Productivity and Activity Impairment Questionnaire (WPAI). Changes in HAQ-S, SF-36 PCS, and WPAI from baseline to years 1, 2, and 3 were reported for the ITT populations (LOCF).

Results: No significant differences were observed between patient cohorts in baseline HAQ-S, SF-36 PCS, or WPAI domain scores. Mean change from baseline in HAQ-S indicated sustained improvement over time among patients in the overall population at years 1, 2, or 3 (−0.39, -0.40, and -0.39, respectively); a majority of patients (56%, 55%, and 54%, respectively) achieved the minimum clinically important difference (MCID) of -0.26[2] (**Table**). Trends were similar for SF-36 PCS score; approximately 68% of patients achieved the MCID of 3.0[3] at each time point; mean scores were 41.8, 41.9, and 41.9 at years 1, 2, and 3, respectively, compared to the US general population norm of 50[4]. Mean changes from baseline in overall work impairment and activity impairment were stable over time, and >60% of patients achieved the MCID of -7.0%[5] at each time point. Improvements were sustained among patients with and without elevated CRP and/or positive MRI, and in observed case analysis.

Mean Change From Baseline Through Week 156 in HAQ-S, SF-36 PCS, and WPAI Domain Scores Among nr-axSpA Patients[a], Mean ± SD, MCID (%)

	Overall Population (n=185)			MRI+/elevated CRP at baseline (n=142)			MRI- and normal CRP at baseline (n=43)		
	Year 1	Year 2	Year 3	Year 1	Year 2	Year 3	Year 1	Year 2	Year 3
HAQ-S[b]	−0.39 ± 0.50 55.7%	−0.40 ± 0.54 55.1%	−0.39 ± 0.55 54.1%	−0.40 ± 0.49 57.8%	−0.41 ± 0.53 57.8%	−0.40 ± 0.54 55.6%	−0.36 ± 0.55 48.8%	−0.35 ± 0.58 46.5%	−0.36 ± 0.58 48.8%
SF-36 PCS[c]	8.3 ± 10.0 69.2%	8.4 ± 10.3 68.1%	8. 5 ± 10.7 68.1%	9.1 ± 9.9 73.9%	9.2 ± 10.2 72.5%	9.1 ± 10.8 71.1%	5.6 ± 9.8 53.5%	5.5 ± 10.2 53.5%	6.2 ± 10.3 58.1%
Overall Work Impairment[d]	−18.9 ± 31.8 60.8%	−17.3 ± 35.0 59.8%	−16.0 ± 37.4 59.8%	−20.1 ± 32.5 62.2%	−17.1 ± 34.5 57.3%	−16.8 ± 37.3 59.8%	−14.8 ± 29.6 56%	−18.1 ± 37.5 68%	−13.5 ± 38.4 60%
Activity Impairment[d]	−24.3 ± 29.5 75.3%	−23.5 ± 28.9 72.5%	−23.7 ± 29.6 73.1%	−24.6 ± 30.2 75%	−23.0 ± 29.3 70.7%	−23.9 ± 29.8 71.4%	−23.3 ± 27.6 76.2%	−25.0 ± 28.0 78.6%	−23.1 ± 29.3 78.6%

[a]ITT population. Missing data were imputed using last observation carried forward (LOCF).
[b-d]MCID = −0.26, 3.0, and −7.0%, respectively.

Conclusion: Treatment of nr-axSpA with ADA was associated with significant and sustained improvements in physical function, HRQOL, and work productivity over 3 years of the ABILITY-1 trial among patients with and without elevated CRP and/or positive MRI as well as the overall nr-axSpA population.

Comparison of Baseline Extra-Articular Manifestations, Comorbidities, and Long-Term Safety in Patients Treated with Adalimumab for Ankylosing Spondylitis and Non-Radiographic Axial Spondyloarthritis. Joachim Sieper[1], Désirée van der Heijde[2], Nupun A. Varothai[3] and Jaclyn K. Anderson[3]. [1]Charité Universitätsmedizin Berlin, Berlin, Germany, [2]Leiden University Medical Center, Leiden, Netherlands, [3]AbbVie Inc., North Chicago, IL.

Background/Purpose: To compare 1) extra-articular manifestations, 2) baseline comorbidities, and 3) adverse event (AE) rates with long-term adalimumab (ADA) therapy in patients (pts) treated in clinical trials for established ankylosing spondylitis (AS) and non-radiographic axial spondyloarthritis (nr-axSpA).

Methods: This *post hoc* analysis was performed in 3 studies: 1) ATLAS, a phase 3, randomized, double-blind (DB), multicenter study in US and Europe in pts with active AS who had inadequate response, or were intolerant to ≥1 nonsteroidal anti-inflammatory drug (NSAID); 2) M03–606, conducted in Canada with the same study design as ATLAS, and 3) ABILITY-1, a phase 3, multinational, randomized, DB, multicenter study in pts with active nr-axSpA (pts with past/present diagnosis of psoriasis were excluded). Pts were randomized to receive ADA 40 mg every other week (wk) or placebo for 24 wks followed by open-label ADA for up to 260 wks in ATLAS and M03–606, and up to 156 wks in ABILITY-1. Pts who received ≥1 dose of

ADA at any time during the study were analyzed (Any ADA set). AE frequency and events/100 patient-years (E/100 PY) of ADA exposure were summarized by study indication with the AS studies combined.

Results: The Any ADA population in the ATLAS/M03–606/ABILITY-1 studies was n=311/82/183, respectively. The Any ADA safety population was n=393 for AS and n=190 for nr-axSpA. Mean age was similar in AS and nr-axSpA pts, ranging from 37–42 yrs and about 80% of both AS and nr-axSpA pts were HLA-B27 positive. AS pts were predominantly male and had longer duration of disease diagnosis compared to nr-axSpA pts. Mean duration of SpA symptoms was >10 yrs in the nr-axSpA study; however, it was not collected in the AS studies (Table 1). At BL uveitis and IBD were less frequent in nr-axSpA pts compared to AS pts. Among pts exposed to ADA (1543.9 PY of exposure in AS, 412.2 PY in nr-axSpA), the incidence of serious AEs was similar in both populations (10.8 vs. 10.9 E/100 PY, AS vs. nr-axSpA). The malignancy rate in AS studies was 0.8 E/100 PY and 0 in nr-axSpA. There was 1 death in the AS studies (<0.1 E/100 PY) and 2 in nr-axSpA pts (0.5 E/100 PY); none were considered related to ADA. (Table 2)

Psychiatric Disorders	7.8	9.9
Gastrointestinal Disorders	27.0	33.7
Liver Events	0.8	0.5
Inflammatory bowel disease (new onset or worsening)[c]	0.6	0.5
Psoriasis (new onset or worsening)	2.7	0.5
Uveitis (new onset or worsening)[d]	3.0	1.5
Deaths	<0.1	0.5

[a]ATLAS + M03-606 studies. [b]ABILITY-1 study. [c]Includes inflammatory bowel disease, Crohn's disease and colitis ulcerative. [d]Includes uveitis, iritis and iridocyclitis. Any ADA = patients who received ≥1 dose of ADA at any time during the study. Not all events within larger system organ categories are reported in this table. MedDRA version 15.1. ADA, adalimumab; AE, adverse event; AS, ankylosing spondylitis; E, event; nr-axSpA, non-radiographic axial spondyloarthritis; PY, patient-year.

Conclusion: Enrolled pts with AS and nr-axSpA were generally similar in terms of demographics and BL disease activity. Although the SpA-related comorbidities of IBD and uveitis were more commonly reported in AS pts as compared to nr-axSpA pts at BL, reported AE rates were generally similar between pts with AS and nr-axSpA. This indicates a similar safety profile for ADA treatment in all pts with axial SpA.

Myocardial Infarction Risk with Diclofenac Use in Spondyloarthropathy Versus Non-Inflammatory Low Back Pain. Maureen Dubreuil. Boston VA HealthCare System, Boston, MA.

Background/Purpose: Spondyloarthropathies (SpA) have been associated with increased risk of myocardial infarction (MI), however it remains unclear if the risk is related solely to the underlying inflammatory disease, or also due to use of medications that increase MI risk, such as certain non-steroidal anti-inflammatory drugs (NSAIDs). Alternatively, NSAIDs may reduce MI risk through reduction in systemic inflammation. Although diclofenac is commonly prescribed for treatment of SpA symptoms, its effect on MI in the SpA population has not been well quantified. By comparing risk of MI with diclofenac use in the SpA population with that in non-inflammatory back pain, we aimed to determine if the increased MI risk is solely due to the inflammatory disease or also the result of NSAID use.

Methods: We performed a cohort study assessing the effect of diclofenac on MI risk using 1995–2013 data from The Health Improvement Network, a medical record database from the United Kingdom, comprising records of over 11 million patients from over 600 general practitioners. We included adults with at least 1 year enrollment in the database, followed by a diagnosis of ankylosing spondylitis or psoriatic arthritis (combined SpA population) or who had a low back pain (LBP) diagnosis without any prior SpA history. From the SpA and LBP populations.we identified subjects who used either diclofenac or naproxen after SpA or LBP diagnosis and followed them until diagnosis of MI, death or end of the study period. We divided subjects into four categories: SpA/diclofenac, SpA/naproxen, LBP/diclofenac, and LBP/naproxen. We used Cox proportional hazards models with adjustment for potential confounders. The risk of MI in each cohort was compared to that in the LBP/naproxen cohort to estimate the effects of diclofenac and SpA on MI independently.

Results: We identified 2590 naproxen users and 3573 diclofenac users with SpA, as well as 147510 naproxen users and 280442 diclofenac users with LBP. SpA subjects tended to be younger, and less commonly female than LBP subjects. In all cohorts, baseline smoking, obesity, hypertension and use of cardioprotective medications was common. After adjustment for potential confounders, relative to the LBP/naproxen cohort, hazard ratios were 1.02 (985% CI 0.91–1.14) for LBP/diclofenac, 1.26 (0.71–2.23) for SpA/naproxen, and 1.50 (1.02–2.22) for SpA/diclofenac (Table).

Conclusion: Diclofenac use among SpA patients was associated with 50% increased risk of MI, while naproxen use did not significantly increase risk relative to its use in LBP patients. Notably in LBP patients, diclofenac use did not increase MI risk, potentially reflecting different patterns of use among LBP and SpA populations (eg- dose, frequency). These findings suggest that diclofenac use in SpA increases MI risk beyond any potential risk conferred by the underlying inflammatory disease.

Table. Risk of Myocardial Infarction (MI) according to low back pain or spondyloarthropathy diagnosis and use of naproxen or diclofenac.

Cohort	Subjects, N	MI, N (%)	Follow-up time (PY)	Incidence rate (/1000 PY)	Crude RR (95% CI)	Age-sex adjusted HR (95% CI)	Multivariable adjusted HR* (95% CI)
LBP/Naproxen	147510	1156 (0.8%)	518282	2.23	1.0 (Ref)	1.0 (Ref)	1.0 (Ref)
LBP/Diclofenac	280442	3797 (1.4%)	1798810	2.11	0.93 (0.87,1.00)	1.03 (0.96,1.10)	1.02 (0.91,1.14)
SpA/Naproxen	2590	27 (1.0%)	10375	2.60	1.16 (0.79,1.70)	1.30 (0.89,1.91)	1.26 (0.71,2.23)
SpA/Diclofenac	3573	61 (1.7%)	23498	2.60	1.14 (0.88,1.48)	**1.34 (1.04,1.74)**	**1.50 (1.02,2.22)**

LBP= low back pain, SpA=spondyloarthropathy, PY=person-years, RR=risk ratio, HR=hazard ratio, CI=confidence interval. *Adjusted for presence of hypertension, diabetes, gastrointestinal bleeding, kidney disease, hyperlipidemia and ischemic heart disease within 1 year prior to study entry; use of ACE inhibitors, aspirin, beta-blockers and lipid-lowering drugs within 2 years prior to study entry, and most recent value of body mass index, smoking status and alcohol use within 5 years prior to study entry.

Urinary Excretion of Type II Collagen C-Telopeptide and Glucosyl-Galactosyl-Pyridinoline As Prognostic Biomarkers in Early Spondyloarthritis. Elisa Trujillo[1] and Maria del Mar Trujillo[2]. [1]Hospital Universitario de Canarias, La Laguna, Tenerife, Spain, [2]Servicio Canario de la Salud, Tenerife, Spain.

Background/Purpose: The search for biomarkers in spondyloarthritis (SpA) is of great interest because of their diagnostic and prognostic role in the treatment of these diseases. In recent years cartilage has been shown to be a major target organ in spondyloarthritis. In other diseases of the joints, elevated levels of urinary CTX-II (C-telopeptide fragments of type II collagen) and Glc-Gal-PYD (glucosyl-galactosyl-pyridinoline) have been associated with progression of radiological damage. *Objectives:* 1. To compare the level of urinary CTX-II and Glc-Gal-PYD in patients with early-stage SpA with urinary levels in healthy people of similar age and gender. 2. To analyze the association between the level of urinary CTX-II and Glc-Gal-PYD with patient variables and diagnosis at 3 years of follow up.

Methods: We included 68 patients aged <45 years who came to the service with some of the suggestive information of ESP of the table and who later completed three years of follow-up and they fulfill nowadays criteria for the Classification of Spondyloartropathy of The European Spondyloarthropathy Study Group (ESSG):

- inflammatory back pain,
- asymmetrical arthritis especially in lower limbs, dactylitis,
- raquialgia or arthralgia, plus one of the following; psoriasis, enthesitis, IBD, anterior uveitis, family history of spondyloarthritis, radiographic sacroiliitis, HLA-B27+, cervicitis/urethritis/diarrehea in the previous month.

Urine samples were taken from all patients attending for the first time with suspected early SpA. Urinary excretion of CTX-II was determined by immunoassay (ELISA). Urinary excretion of Glc-Gal-PYD was determined by High performance liquid chromatography. We also determined CTX-II and Glc-Gal-PYD urinary excretion in a healthy control group (n = 25) of similar age and sex.

Association analysis was performed with the following variables at 3 years: final diagnosis, HLA-B27, SpA axial / peripheral ASAS, early involvement of large joints (hips/knees), presence of extra-articular manifestations (anterior uveitis, psoriasis or IBD) and anti-TNF therapy.

Results: Urinary excretion of CTX-II and Glc-Gal-PYD in patients presenting for the first time with suspected early SpA was significantly higher than in the healthy control group matched for age and sex ($p < 0.001$).

The levels of urinary excretion of CTX-II and Glc-Gal-PYD in patients presenting for the first time with suspected early SpA were significantly higher in those who had predominantly peripheral involvement (SpA peripheral ASAS) versus axial involvement and in those due to high clinical activity and functional deficits (BASDAI and BASFI) required biological treatment at 3 years follow up. Urinary excretion of CTX-II was also significantly higher in patients developed early large joint involvement at 3 years follow up.

Conclusion: Urinary excretion of CTX-II and Glc-Gal-PYD in patients with early SpA may be a prognostic biomarker since in our series it was associated with peripheral involvement and early large joint involvement, and the need for biological treatment in the first three years of follow-up.

Defining Flare in Spondyloarthritis: Thresholds of Disease Activity Variations. Marie Godfrin-Valnet[1], Marc Puyraveau[1] and Daniel Wendling[2]. [1]CHRU, Besançon, France, [2]CHU J Minjoz, Besancon, France.

Background/Purpose: Spondyloarthritis (SpA) activity varies with time and treatment, but to date no clear definition of a flare of the disease is available.

The aim of this study was to evaluate thresholds of disease activity variations using validated composite indexes.

Methods: SpA patients fulfilling ASAS criteria and prospectively followed with at least two visits were evaluated using BASDAI, ASDAS-CRP and ASDAS-ESR. Patients and physician answered at each visit the question: "do you consider your SpA in a state of flare ?". Variations of BASDAI and ASDAS between visits were assessed and associated to the change of perception of a flare (yes/no). ROC curves were built to assess thresholds of variation in BASDAI and ASDAS associated with the change Flare: no to yes between visits.

Results: The patients were issued from a prospective series of 250 SpA. 99 situations with at least 2 visits were analyzed. The main characteristics of this cohort were: 67 % men, mean age 45 ± 12 years; disease duration: 16 ± 10 y; 84 % HLA-B27 positive; purely axial SpA: 81 %; PASS at baseline: 56 %; mean CRP: 8.6 ± 13.5 mg/l. Mean BASDAI and ASDAS-CRP at baseline were 4.3 ± 2.2 and 2.5 ± 1.1 respectively. The kappa coefficient of agreement between patient and physician for considering a flare was 0.68. The main results of the ROC curves are reported in the table:

Variation of the activity score	Flare considered by Patient and physician	Flare considered by Physician	Flare considered by Patient
BASDAI	**2.1**	**2.1**	2.1
Number of 2 visits	67	97	76
AUC	0.715	0.671	0.694
Specificity %	83	82	83
Sensitivity %	59	53	55
ASDAS-CRP	**1.3**	**0.7**	**1.3**
Number of 2 visits	30	45	34
AUC	0.74	0.698	0.682
Specificity %	100	72	100
Sensitivity %	47	59	40
ASDAS-ESR	**0.8**	**0.8**	**0.8**
Number of 2 visits	28	28	31
AUC	0.779	0.779	0.759
Specificity %	91	91	92
Sensitivity %	56	56	50

Conclusion: According to these results, an increase from a non-flare state of at least 2.1 units in BASDAI, 0.8 units in ASDAS-ESR or 1.3 units in ASDA-CRP is associated to (and may define) a flare, as considered by the patient and the physician.

This is the first study assessing, in current practice, thresholds of variation of activity score associated with a flare in SpA. This may help physicians in the evaluation and management of the patients with SpA.

Background/Purpose: The ASAS Health Index (ASAS HI) is a unidimensional questionnaire measuring health and impairment in functioning in patients with spondyloarthritis (SpA). The ASAS HI is accompanied by a multidimensional item set aiming at measuring environmental factors (EF Item Set). These two disease-specific questionnaires are the first questionnaires which have been developed based on the International classification of functioning, disability and health (ICF). The ASAS HI contains 17 dichotomous items addressing categories of pain, emotional functions, sleep, sexual function, mobility, self care, and community life and the EF Item Set contains 9 dichotomous items addressing categories of support/relationships, attitudes and health services. The objective is to translate and adapt the ASAS HI and

the EF Item Set cross-culturally into 15 languages with 17 versions and to field test the new versions in patients with axial SpA (axSpA).

Methods: Translation and cross-cultural adaptation was done in 20 countries according to published recommendations (forward-backward procedure) in 5 steps: translation, synthesis of translation, back translation, expert committee review and pre-testing in a field test. The field test was conducted in patients with axSpA to test its applicability in patients with all forms of SpA.

Results: The ASAS HI and EF Item Set was translated into Arabic, Chinese, Croatian, Dutch/Flemish, French, German, Greek, Hungarian, Italian, Korean, Portuguese, Russian, Spanish (Colombia, Mexico, Spain), Thai, and Turkish. 206 patients (approximately 10 patients/country, 59.7% male, mean (SD) age 42.4 (13.9) years, mean (SD) BASDAI 3.8 (2.3)) with axSpA underwent qualitative interviews during field testing in 23 countries (19 non-English speaking countries, 4 English-speaking countries). 65% of the patients were diagnosed with AS, 35% with non-radiographic axSpA and 33% of the total sample size suffered from peripheral involvement. Interviews showed the English questionnaire and the translations to be clear, relevant and comprehensive. All versions were accepted with minor modifications. The total sum of the ASAS HI (range 0–17, with a lower score indicating a better health status) was 7.1 ± 4.4 (mean ± SD). Completion times for ASAS HI and for EF Item Set were respectively, 2.6 ± 1.6 and 2.1 ± 1.5 (mean ± SD) minutes.

Conclusion: The ASAS HI and the EF Item Set were successfully translated into 15 languages with 17 versions. This study showed the ASAS HI items to be readily adaptable throughout countries, indicating the concepts covered may be meaningful in many cultures. In the other hand, more difficulties were experienced with the contextual factors indicating these concepts may be more culture-dependent. The field test suggested that the English and the non-English versions have high face and content validity. By investigating patients with axSpA with and without peripheral manifestations it could be shown that the ASAS HI and the EF Item Set are valid to be applied in patients with all forms of SpA. Further validation is underway to test the psychometric properties of this new disease-specific questionnaire.

Therapeutic Response in Adalimumab-Treated Patients with Non-Radiographic Axial Spondyloarthritis Is Similar Regardless of Body Mass Index.

Philip Mease[1], Denis Poddubnyy[2], Su Chen[3] and Jaclyn K. Anderson[3]. [1]Swedish Medical Center and University of Washington, Seattle, WA, [2]Charité Universitätsmedizin Berlin, Berlin, Germany, [3]AbbVie Inc., North Chicago, IL.

Background/Purpose: C-reactive protein (CRP), an objective measure of active inflammation, has been associated with obesity, with both overweight and obese individuals more likely to have elevated CRP levels than their normal-weight counterparts. The objective of this analysis was to assess the relationship of elevated CRP with clinical response in non-overweight and non-obese subgroups of non-radiographic axial SpA (nr-axSpA) patients (pts).

Methods: This *post hoc* analysis was performed in ABILITY-1, a phase 3, randomized, double-blind, multicenter study in pts with active nr-axSpA. Pts were randomized to receive adalimumab (ADA) 40 mg every other week (wk) or placebo (PBO) for 12 wks followed by open-label (OL) ADA for up to 156 wks. The MRI+/elevated CRP subpopulation included pts with a positive baseline MRI (Spondyloarthritis Research Consortium of Canada [SPARCC] score ≥2 for either the sacroiliac joints or spine) and/or elevated baseline CRP. Pts with BMI ≥25 kg/m^2 were considered overweight; pts with BMI ≥30 kg/m^2 were considered obese. Clinical response variables were analyzed by BMI subgroups at wk 12.

Results: BMI was <25 in 85/185 (45.9%) pts in the overall population (PBO/ADA, n=43/42) and in 57/142 (40.1%) in the MRI+/elevated CRP subpopulation (PBO/ADA, n=30/27); BMI was <30 in 149/185 (80.5%) pts in the overall population (PBO/ADA, n=70/79) and in 110/142 (77.5%) in the MRI+/elevated CRP subpopulation (PBO/ADA, n=52/58). In the overall population CRP was elevated in 43/100 (43%) pts with BMI ≥25 and in 22/36 (61.1%) pts with BMI ≥30. BMI and CRP were weakly correlated (0.23, P=0.002); however, in pts with elevated CRP, mean BMI was significantly higher than in pts with normal CRP (28.8 vs 25.0; P<0.0001). ASAS40 response at wk 12 was similar in the overall population and when excluding overweight and obese pts. (Table 1) A comparable effect was seen in the MRI+/elevated CRP subpopulation with the exception of a slightly higher ASAS40 response in the MRI+/elevated CRP subgroup with BMI <25; however, this should be interpreted with caution due to small sample size. (Table 2) ASAS40 response for the subgroup BMI ≥25 for the overall and MRI+/elevated CRP populations was consistent with the overall population (PBO 15.7% vs ADA 34.7%, and PBO 16.3% vs ADA 33.3%, respectively).

[a]Non-responder imputation. [b]Mean (standard deviation). [c]Observed case analyses. ADA, adalimumab; ASAS, Assessment of SpondyloArthritis international Society; BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; BMI, body mass index; HAQ-S, Health Assessment Questionnaire modified for the Spondyloarthropathies; hs-CRP, high sensitivity C-reactive protein; MRI, magnetic resonance imaging; PBO, placebo; PR, partial remission; SI, sacroiliac; SPARCC, Spondyloarthritis Research Consortium of Canada; SF-36v2 PCS, Short Form-36 Health Status Survey Version 2 Physical Component Summary.

Conclusion: In ABILITY-1, ADA showed similar clinical responses in subgroups excluding overweight and obese pts compared to the overall study population. These data suggest nr-axSpA pts have a general inflammatory

state which is unrelated to obesity-related CRP elevations and that response to ADA is not driven by CRP elevations related to obesity.

Ultra Sonographic Evaluation of the Anterior Chest Wall in Spondyloarthritis. a Prospective Study. Frank Verhoeven[1], Xavier Guillot[2], Marie Godfrin-Valnet[3], Clément Prati[4] and Daniel Wendling[4]. [1]CHU jean Minjoz, Besançon, France, [2]rheumatology, Besançon, France, [3]CHRU, Besançon, France, [4]CHU J Minjoz, Besancon, France.

Background/Purpose: Anterior chest wall (ACW) involvement is a characteristic feature of spondyloarthritis (SpA), even in early stages, but its paraclinic exploration is not standardized.The aim of this study was to evaluate prevalence and type of ultrasonic (US) ACW involvement in SpA, and to look for factors associated to this involvement.

Methods: This prospective monocentric study included consecutive SpA (ASAS criteria) patients and a control group (healthy subjects, discal sciatica). Clinical (pain, swelling) and US evaluation (synovitis, joint effusion, erosion, joint space narrowing, ankylosis, power Doppler activity) were performed on manubrio sternal and sternoclavicular joints. The main characteristics of SpA were recorded (disease duration, biologic features, BASDAI, ASDAS, radiographic and extra articular involvement). Patients were compared to controls (C).

Results: 131 SpA and 49 control patients (same age and sex ratio) were included. Clinical and US ACW involvement was found respectively in 36 and 39 % of SpA and 10 and 15 % of controls ($p< 0.01$). US findings were:synovitis (9 SpA vs 2 C), joint space narrowing (12 vs 0), erosions (34 vs 0), manubrio sternalankylosis (24 vs 3), power Doppler activity (12 vs 2). US involvement in SpA is associated to smoking ($p< 0.05$), history of ACW pain ($p < 0.05$), to radiographic changes of sacro iliac joint ($p = 0.05$), to age (45 vs 41 y, $p = 0.004$), disease duration (14.9 vs 11.1 y, $p = 0.04$) and presence of inflammatory bowel disease ($p = 0.03$). US involvement is not associated to HLA-B27, enthesitis, psoriasis or uveitis, whereas clinical ACW involvement is associated with higher BASDAI (47 vs 32; $p = 0.0009$) and ASADAS (2.9 vs 2.2; $p = 0.006$). There is only a weak correlation between clinical and US involvement of ACW in these patients and controls.

Conclusion: US involvement of ACW is frequent in SpA, associated to disease duration, smoking and bowel involvement.

High Sensitivity of the ASAS Classification Criteria in Patients with HLA-B27 Positive Undifferentiated Spondyloarthritis with Onset of Disease after Age 45. Ignazio Olivieri[1], Michele Gilio[1], Salvatore D'Angelo[1], Angela Padula[1], Pietro Leccese[1], Silvana Di Bello[1], Norullah Akkoc[2], Nicola Ferrara[3] and Carlo Palazzi[1]. [1]Rheumatology Department of Lucania, San Carlo Hospital of Potenza and Madonna delle Grazie Hospital of Matera, Potenza, Italy, [2]Department of Internal Medicine, Division of Rheumatology, Dokuz Eylul University School of Medicine, Izmir, Turkey, [3]Department of Translational Medical Sciences, Federico II University, Naples, Italy.

Background/Purpose: The spondyloarthritis (SpA) complex also includes forms that do not meet criteria for the definite forms and are called undifferentiated SpA (uSpA). Recently the Assessment in SpondyloArthritis international Society (ASAS) suggested criteria for axial and peripheral SpA that have substituted the Amor and the European Sondylarthropathy Study Group (ESSG) criteria for all forms of SpA. In the ASAS criteria for axial disease the entry criterion is chronic low back pain in a patient with an age less than 45 years. Only 15% of the patients included in the study for the ASAS criteria for peripheral disease were older than 45 years. The objective of our study was to evaluate the sensitivity of the ASAS criteria for axial and peripheral SpA in a cohort of consecutive patients with HLA-B27-positive uSpA with onset of disease after the age of 45 (late onset uSpA) consecutively recruited in a 12-year period in comparison with a cohort of consecutive patients with HLA-B27-positive uSpA with onset before age 45 (ordinary onset uSpA) recruited in the same period.

Methods: Patients HLA-B27-positive with at least one clinical manifestation of SpA and not meeting the New York criteria for ankylosing spondylitis (AS) and with a negative personal history for psoriasis, inflammatory bowel disease and preceding infection seen since January 2001 were entered in a special register and were followed prospectively. Each patient was examined at 6-month interval even if asymptomatic.

Results: During the 12-year recruitment period, 93 patients (35 M, 58 F; age 58.4±9.8) with late onset uSpA were seen. The first 93 consecutive patients (54 M, 39 F; age 29.6 ± 8.6) with ordinary onset uSpA seen in the same period were evaluated for comparison. Compared to the 93 patients with ordinary onset uSpA, the 93 patients with late onset uSpA were more frequently females (62.4% *vs.* 41.9 %, $p < 0.05$) had a significant shorter diagnostic delay (time elapsed between the day of onset and the day of diagnosis) (24.2 ± 45.6 *vs.* 65.1±97 months, $p < 0.05$) and showed more frequently increased levels of ESR (Erythrocite Sedimentation Rate)(57% *vs.* 33.3%, $p < 0.05$) and CRP (C-reactive proteine) (62,4% vs. 48,4%, p=0,07). In addition, patients with late onset uSpA developed more frequently inflammatory extremity swelling with pitting edema (IESPE) over the dorsum of hands and/or of the feet (25.8% *vs.* 4.3%, $p < 0.01$) and peripheral enthesitis (48.4% *vs.*31.2%, $p < 0.05$). In contrast, patients with ordinary onset uSpA showed more frequently acute anterior uveitis (20.4% vs. 7.5%, $p <0.05$). The sensitivity of the ASAS criteria was similar in the ordinary onset (90.3%) and the late onset (91.4%) cohorts of patients with uSpA.

Conclusion: The ASAS classification criteria for axial and peripheral SpA showed a similar high sensitivity in patients with ordinary and late onset uSpA. In addition, this study confirms that some clinical and laboratory features of SpA may differ with the age at onset of the disease.

A Psychometric Analysis of Outcome Measures in Trials of Peripheral Spondyloarthritis. Sofia Ramiro[1], Maureen C. Turina[2], Dominique L. Baeten[3], Philip Mease[4], Jacqueline E. Paramarta[2], In-Ho Song[5], Aileen L. Pangan[6] and Robert Landewé[2]. [1]Amsterdam Rheumatology Center/University of Amsterdam, Amsterdam, Netherlands, [2]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands, [3]Department of Clinical Immunology and Rheumatology and Department of Experimental Immunology, Academic Medical Centre/University of Amsterdam, Amsterdam, Netherlands, [4]Swedish Medical Center and University of Washington, Seattle, WA, [5]AbbVie Deutschland GmbH & Co. KG, Ludwigshafen, Germany, [6]AbbVie Inc., North Chicago, IL.

Background/Purpose: We assessed the discriminatory aspects of disease activity measures and response criteria between adalimumab (ADA) and placebo (PBO) in 2 studies of patients (pts) with peripheral spondyloarthritis (pSpA).

Methods: ABILITY-2 is an ongoing randomized controlled trial of ADA in pts with pSpA fulfilling ASAS peripheral SpA criteria. Primary endpoint was peripheral SpA response criteria (PSpARC)40 at wk 12, defined as ≥40% improvement from baseline (BL) (≥20 mm absolute improvement on a visual analog scale) in Patient Global Assessments of Disease Activity (PGA) and Pain (PGA-pain) and ≥40% improvement in ≥1 of the following: swollen joint (SJC) and tender joint counts (TJC); enthesitis count; or dactylitis count. In an investigator-initiated study (AMC) in the Netherlands, pts fulfilling ESSG and/or AMOR criteria for SpA for ≥3 months but not criteria for ankylosing spondylitis or psoriatic arthritis were randomized to ADA or PBO. Primary endpoint was change in PGA at wk 12. Analyses to determine the discriminatory capacity of disease activity measures between ADA and PBO groups included standardized mean difference (SMD) of the mean change from BL; for categorical response criteria Pearson's χ^2 between treatments were calculated. The higher the SMD and χ^2, the higher the discriminatory capacity. Variables evaluated included PGA, PGA-pain, Physician's Global Assessment of Disease Activity (PhGA), CRP, TJC, SJC, BASDAI, SF-36, HAQ-S, ASDAS, PSpARC40/50/70, ACR20/50/70, ASDAS major improvement/inactive disease, and BASDAI50.

Results: ABILITY-2 randomized 165 pts (ADA 84, PBO 81); AMC enrolled 40 pts (ADA 20, PBO 20). Among the continuous variables, ASDAS

discriminates better than BASDAI or individual measures such as CRP as shown by higher SMD values (Table). For clinical response criteria, PSpARC40, PSpARC50, ASDAS inactive disease and BASDAI50 performed well in differentiating between ADA vs. PBO treatment as shown by the χ^2 in the table. ACR20 and ACR50 performed better than ACR70 in differentiating between ADA vs. PBO.

Discrimination between patients on adalimumab vs. placebo at week 12

	ABILITY-2				AMC

ACR50	28 (34)	8 (10)	13.66	<0.001	7 (37)	0 (0)	8.58	0.008
ACR70	15 (18)	2 (3)	10.75	0.001	4 (21)	0 (0)	4.47	0.105

Observed analyses. SMD: Standardized Mean Difference

Conclusion: Composite indices (ASDAS and BASDAI) outperformed individual measures (TJC, SJC, CRP) in sensitivity to change and discriminatory properties. The PSpARC response criteria developed for pSpA, as well as ACR20 and ACR50, have good discriminatory ability in patients with pSpA. Although the ASDAS and to some extent BASDAI, which were developed for AS, performed reasonably well in being able to discriminate between active treatment and placebo in patients with peripheral SpA, there may be problems regarding face validity.

Clinical Response and Remission in Patients with Non-Radiographic Axial Spondyloarthritis after Three Years of Adalimumab Therapy.

Désirée M. van der Heijde[1], Joachim Sieper[2], Walter P. Maksymowych[3], Dominique L. Baeten[4], Yinglin Xia[5], Jaclyn K. Anderson[5] and Aileen L. Pangan[5]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]Charité Universitätsmedizin Berlin, Berlin, Germany, [3]University of Alberta, Edmonton, AB, [4]Department of Clinical Immunology and Rheumatology and Department of Experimental Immunology, Academic Medical Centre/ University of Amsterdam, Amsterdam, Netherlands, [5]AbbVie Inc., North Chicago, IL.

Background/Purpose: Adalimumab (ADA) has been previously shown to be effective for the treatment of non-radiographic axial spondyloarthritis (nr-axSpA) patients (pts) in the ABILITY-1 trial. [1] Week (wk) 12 results were further supported by sustained clinical response and remission data through Year 2 of the study. [2] We evaluate the final Year 3 long-term response/ remission and durability of response with ADA in pts with nr-axSpA.

Methods: ABILITY-1 was a phase 3, double blind (DB), randomized, controlled trial in pts with nr-axSpA who had an inadequate response, intolerance, or contraindication to NSAIDs. A 12-wk DB period of ADA 40 mg every other week (eow) or placebo was followed by an open-label period in which pts could receive ADA 40 mg eow for up to an additional 144 wks. This *post hoc* analysis evaluated the final Year 3 (wk 156) efficacy and safety results for both the overall population and the MRI+/elevated CRP subpopulation defined as those with a positive MRI at baseline (BL) (SPARCC score ≥2 for either the SI joints or spine) or an elevated CRP at BL. ASAS, BASDAI and ASDAS responses were calculated. Clinical remission was defined by ASDAS inactive disease (ASDAS ID, ASDAS <1.3) or by ASAS partial remission (ASAS PR).

Results: Of the 185 pts enrolled in ABILITY-1, 122 (66%) had data available at wk 156 and 97 of 142 (68%) from the MRI+/elevated CRP sub-population. Clinical responses and remission rates were generally sustained between Year 2 and Year 3 of the study (Table). Through 412.2 patient-years (PYs) of exposure to ADA, the serious infection rate observed was 2.4 events/100 PYs, including 1 case of disseminated TB. There were 2 deaths – 1 due to suicide and another due to opiate toxicity. There were no malignancies reported.

Table. Long-term clinical response and remission at Years 2 and 3

	Overall Population				MRI+/elevated CRP Sub-population			
	Year 2		Year 3		Year 2		Year 3

Evaluation of Clinical Parameters and Quality of Life in Smokers with Ankylosing Spondylitis: Results from the Scotland Registry for Ankylosing Spondylitis.

Linda E. Dean[1], Fabiola Azeni[2], Tiara Ratz[1], Alan G. MacDonald[3], Roger D. Sturrock[4], John Hunter[5], David Marshall[6], Gary J. Macfarlane[1] and Gareth T. Jones[1]. [1]University of Aberdeen, Aberdeen, United Kingdom, [2]Rheumatology Unit, L.Sacco University Hospital, Milan, Italy, [3]Aberdeen Royal Infirmary, Aberdeen, United Kingdom, [4]Glasgow Royal Infirmary, Glasgow, United Kingdom, [5]Gartnavel General Hospital, Glasgow, United Kingdom, [6]Inverclyde Royal Hospital, Greenock, United Kingdom.

Background/Purpose: Several studies have shown that smoking is associated with increased disease activity, worse physical function and poor quality of life in ankylosing spondylitis (AS). However, other than as part of general health advice, recommendations on smoking cessation are not commonly given by physicians, nor perceived as of high importance by AS

patients. The aim of the current study was to examine the effect of smoking cessation on various clinical and patient-reported parameters in AS.

Methods: SIRAS collects data on clinically diagnosed AS patients in Scotland. Clinical measures are obtained from medical records, and postal questionnaires provide patient-reported data, including smoking status and quality of life. Differences between current and ex-smokers were assessed using linear regression models, adjusted for potential confounders (age, sex, education, socio-economic status, and alcohol consumption). **Results** are given as regression coefficients with 95% Confidence Intervals.

Results: SIRAS includes clinical and patient-reported information on 959 AS patients: 73% male; mean age 52yrs; 22% current smokers and 38% ex-smokers. Compared to current smokers, ex-smokers initially reported significantly lower disease activity (BASDAI) and physical function (BASFI) scores (−0.7 (−1.2, -0.2) and -0.4 (−0.95, 0.2), however, after adjusting for potential confounders this was no longer statistically significant (although still lower): -0.4 (−0.98, 0.1), and -0.4 (−0.97, 0.3), respectively. Additionally, ex-smokers reported significantly better quality of life: ASQoL score -1.4 (−2.5, -0.4). There were no other statistically significant differences between current and ex-smokers with any other clinical or patient-reported outcome.

Conclusion: Ex-smokers with AS, in comparison to smokers, have lower disease activity and function in addition to better disease-related quality of life. For comparison, the difference in disease activity is around 30% of the expected effect one might achieve with intensive physiotherapy, and 16% that of biologic therapy. Rather than being part of generic health advice, clinicians should actively promote smoking cessation as an adjunct to usual therapy.

Cardiovascular Events in Ankylosing Spondylitis. an Updated Meta-Analysis. Sylvain Mathieu[1] and Martin Soubrier[2]. [1]Hopital Gabriel Montpied, Clermont Ferrand, France, [2]CHU G.-Montpied, Clermont-Ferrand, France.

Background/Purpose: Rheumatoid arthritis is associated with increased cardiovascular risk. In the guidelines, ankylosing spondylitis (AS) is considered to have an equally high cardiovascular risk. The literature findings remain controversial. Objectives of this study were to assess the risk of myocardial infarction (MI) and stroke in AS patients in 2013.

Methods: An updated meta-analysis with a new systematic literature review using PubMed was conducted up to December 2013. Incidence of MI or stroke was calculated by metaproportion.

Results: In addition to the eleven previously included studies, five new studies assessed the occurrence of MI or stroke in AS patients.

1. MI. 726 MI were reported in AS patients (N=18,916) over mean follow-up of sixteen years: incidence 5.5% [3.9%, 7.4%], i.e. 0.44/100 pyrs. Seven studies revealed 17,410 MI (2.5% (95% CI [1.8%, 3.4%])) in the control group (N=1,349,964). Meta-analysis of the seven longitudinal studies showed a significant increase in MI (RR=1.46 [1.33, 1.60]) in AS patients. **2. Stroke.** In ten longitudinal studies (N=43,374), 1,370 strokes were reported in AS patients over 18.5 years of follow-up: incidence 3.4% [1.2%, 6.8%], i.e. 0.1/100 pyrs. Three studies reported 22,899 strokes in controls (N=1,239,041), giving an incidence of 1.78% [1.75%, 1.80%]. A significant increase in stroke (RR=1.50 [1.39, 1.62]) in AS patients was found.

Conclusion: AS patients appear to have a higher risk of MI and stroke. Management of cardiovascular risk factors and control of systemic inflammation should be taken into account in AS.

Effect of Certolizumab Pegol over 96 Weeks of Treatment on Inflammation of Spine and Sacroiliac Joints Measured By Magnetic Resonance Imaging in Patients with Axial Spondyloarthritis. Jürgen Braun[1], Walter P. Maksymowych[2], Robert B. M. Landewé[3], Christian Stach[4], Owen Davies[5], Tommi Nurminen[4] and Desiree van der Heijde[6]. [1]Ruhr-University Bochum, Herne, Germany, [2]University of Alberta, Edmonton, AB, [3]Amsterdam Rheumatology Center, Amsterdam, Netherlands, [4]UCB Pharma, Monheim, Germany, [5]UCB Pharma, Slough, United Kingdom, [6]Leiden University Medical Center, Leiden, Netherlands.

Background/Purpose: Previous results from RAPID-axSpA (NCT01087762) demonstrated that certolizumab pegol (CZP) reduced inflammation in the sacroiliac joints (SIJ) and spine, as assessed by Magnetic Resonance Imaging (MRI), after 12 weeks (wks) of therapy in patients (pts) with axial spondyloarthritis (axSpA) and in both ankylosing spondylitis (AS) and non-radiographic (nr-) axSpA subpopulations. [1] The objective of this report is to present MRI outcomes from RAPID-axSpA to Wk96.

Methods: RAPID-axSpA,[2] a Phase 3 study in axSpA pts, is double-blind and placebo-controlled to Wk24, dose-blind to Wk48 and open-label (OL) to Wk204. Pts originally randomized to CZP (200mg Q2W or 400mg Q4W, following 400mg loading dose at Wks 0, 2, 4), continued on their assigned dose in dose-blind and OL phases. MRI scans of the SIJ and spine,[3] using short-tau-inversion recovery sequences, were performed at baseline (BL) (±3 days), Wk12, Wk48 and Wk96. MRI endpoints were change from BL in the Spondyloarthritis Research Consortium of Canada (SPARCC) SIJ score for inflammation and in the Berlin modification of AS spine MRI score for disease activity in the spine (ASspiMRI-a). MRIs were recorded in a subset of pts, and results reported for pts randomized to CZP using all observed MRI measurements.

Results: 218 pts were randomized to receive CZP, of which 109 were included in the MRI set. 27 pts (24.8%) reported inflammation of SIJ (SPARCC≥2), but no spinal involvement (ASspiMRI-a≤2); 17 (15.6%) reported spine inflammation without SIJ involvement; and 31 (28.4%) reported inflammation of spine and SIJ. Mean BL SPARCC was similar between AS and nr-axSpA pts (7.2 in both groups), but mean BL ASspiMRI-a score was higher in AS pts (AS: 5.3 vs nr-axSpA: 2.8). Rapid improvement in SPARCC SIJ and ASspiMRI-a scores was observed at Wk12 and sustained to Wk96 (Table). Similar results were observed for both CZP dose regimens (data not shown). Similar improvement in SPARCC SIJ score was observed in AS and nr-axSpA pts. While improvement in spinal inflammation was observed in both AS and nr-axSpA pts, nr-axSpA pts had a lower mean ASspiMRI-a score at all time points.

Conclusion: Previously reported improvements in MRI scores at Wk12 were maintained to Wk96 in axSpA, AS and nr-axSpA pts.

Structural Progression of the Spine Measured By X-Ray in Patients with Axial Spondyloarthritis Treated with Certolizumab Pegol over 96 Weeks, Including Ankylosing Spondylitis and Non-Radiographic Axial Spondyloarthritis. Désirée M. van der Heijde[1], Walter P. Maksymowych[2],

Robert B. M. Landewé[3], Christian Stach[4], Owen Davies[5], Tommi Nurminen[4] and Jürgen Braun[6]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]University of Alberta, Edmonton, AB, [3]Amsterdam Rheumatology Center, Amsterdam, Netherlands, [4]UCB Pharma, Monheim, Germany, [5]UCB Pharma, Slough, United Kingdom, [6]Ruhr-University Bochum, Herne, Germany.

Background/Purpose: The impact of certolizumab pegol (CZP) on clinical and Magnetic Resonance Imaging outcomes in patients (pts) with axial spondyloarthritis (axSpA), including ankylosing spondylitis (AS) and non-radiographic (nr-) axSpA, has been described previously.[1] However, structural progression in these pts measured by X-ray has not been previously reported. The objective of this report is to present structural progression, assessed using X-ray, over 96 weeks (wks) of CZP treatment in the RAPID-axSpA study (NCT01087762).[2]

Methods: RAPID-axSpA, a Phase 3 study in axSpA pts, is double-blind and placebo-controlled to Wk24, dose-blind to Wk48 and open-label (OL) to Wk204. Pts had adult-onset active axSpA. Pts originally randomized to CZP (200mg Q2W or 400mg Q4W, following 400mg loading dose at Wks 0, 2, 4), continued on their assigned dose in dose-blind and OL phases. X-ray assessment of the anterior vertebral edges of the cervical and lumbar spine was conducted using the modified Stokes Ankylosing Spondylitis Spine Score (mSASSS) at baseline (BL) and Wk96. X-rays were recorded in a subset of pts, and results reported for pts initially randomized to CZP with both available BL and Wk96 X-ray measurements (observed case). Definite mSASSS progression was defined as an mSASSS increase ≥2 units, and was assessed over 96 wks. Unadjusted descriptive analyses investigated mSASSS disease activity and response in subgroups of pts.

Results: 218 pts were randomized to receive CZP, of which 109 were included in the imaging set, and 89 had both BL and Wk96 X-rays available for analysis. 22.2% of CZP pts in the imaging set had evidence of structural changes in the spine (mSASSS≥2, with ≥1syndesmophyte) at BL (32.3% of AS and 8.7% of nr-axSpA pts). Mean mSASSS at BL was 8.0 in axSpA pts. As expected, BL damage was more severe in AS pts compared to the nr-axSpA population (11.1 vs 3.2, Table). Over 96 wks of CZP treatment, mean mSASSS score of the axSpA population increased by 0.4 units, and 9.0% of pts experienced definite mSASSS progression ≥2 units. Radiographic progression was greater in AS pts compared to nr-axSpA pts (change from BL: 0.6 vs 0.2, definite mSASSS progression 13.0% vs 2.9%). A number of BL characteristics appeared to influence mSASSS progression over 96 wks (Table). However, these are unadjusted analyses, therefore further investigation is underway to determine whether these observations are influenced by confounding BL factors.

Conclusion: Limited radiographic progression was seen over 96 wks in CZP-treated pts. Further analyses are needed to confirm which subgroups of pts have an increased risk of progression.

Use of Monotherapy Anti-Tnf Agents in Ankylosing Spondylitis Patients from the rhumadata® Registry: 8-Year Comparative Effectiveness of Adalimumab, Etanercept and Infliximab.

Denis Choquette[1], Louis Bessette[2], Isabelle Fortin[3], Boulos Haraoui[1], Jean Pierre Pelletier[1], Jean-Pierre Raynauld[1], Diane Sauvageau[1], Edith Villeneuve[1] and Louis Coupal[1]. [1]Institut de rhumatologie de Montréal (IRM), Montréal, QC, [2]Centre d'ostéoporose et de rhumatologie de Québec (CORQ), Québec, QC, [3]Centre de rhumatologie de l'est du Québec (CREQ), Rimouski, QC.

Background/Purpose: Anti-TNF agents namely adalimumab (ADA), etanercept (ETA) and infliximab (INF) are approved for the treatment of signs and symptoms of ankylosing spondylitis. Their efficacy has been demonstrated in randomized controlled trials against placebo. They have also been shown effective in the treatment of extra-articular features such as enthesitis, inflammatory bowel entities such as Crohn's disease and ulcerative colitis and uveitis. Antibodies and soluble receptors may have a different efficacy profile. Our objective is to assess the retention rates of adalimumab (ADA), etanercept (ETA) and infliximab (INF) in patients diagnosed with ankylosing spondylitis (AS) and to compare patient reported response over time.

Methods: Data of AS patients who had been prescribed adalimumab (ADA), etanercept (ETA) or infliximab (INF) in monotherapy on or after January 1st 2004 was extracted. Baseline demographics included age, gender, disease duration, HAQ-DI, fatigue and pain visual analog scale evaluations (VAS), morning stiffness, BASDAI, BASFI, ASDAS and HLA-B27. Eight-year drug retention rates were estimated and compared using Kaplan-Meier survival estimates. BASDAI improvement over time was assessed using proportional hazard model adjusted for age and disease duration at TNF initiation. Other differential measures of effectiveness were tested using general linear models (GLM). For these analyses, patients with baseline BASDAI of 4 or more were included. Statistical analysis was performed using SAS version 9.3. RHUMADATA® is a clinical database and registry used in daily clinical practice at the IRM, CORQ and CREQ.

Results: Data from 170 patients diagnoses with AS was extracted and no significant differences in baseline characteristics were observed between treatment groups except for age and disease duration. The 8-year retention rate of ADA, ETA and INF were 62%, 55% and 54% respectively and were not statistically different (Log-Rank p=0.90). Seventy-five patients were used to analyse time required to reach a BASDAI of 2 and compare rates of response. At baseline, ADA, ETA and INF BASDAI were 6.6, 6.2, 6.5 respectively. The adjusted hazard ratio for reaching a BASDAI of two was found to be 0.77 (95% CI = [0.32, 1.87]) and 0.92 (95% CI = [0.40, 2.14]) when comparing ETA and INF to ADA respectively. Overall 42%, 61% and 64% of ADA, ETA and INF patients reached a target BASDAI of 2 in average adjusted times of 9.6, 19.0 and 15.6 months (p-value=0.31).

Conclusion: Monotherapy adalimumab, etanercept and infliximab in AS patients show similar 8-years retention rates and similar improvement in BASDAI. They all represent good options for the treatment of AS in monotherapy.

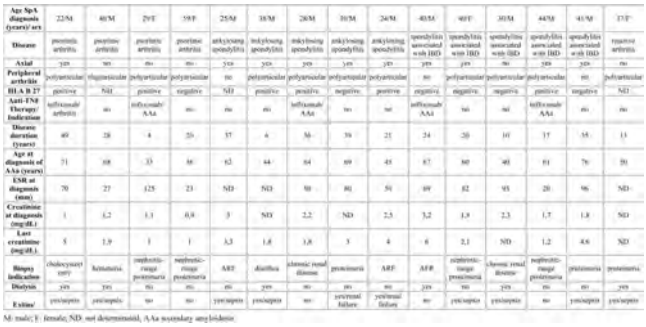
Secondary Amyloidosis Complicating Spondyloarthritis: Still Present after All These Years. Samantha Rodriguez-Muguruza[1], Melania Martínez-Morillo[1], Susana Holgado[1], Maria Lourdes Mateo[1], Juana Sanint[1], Anne Riveros-Frutos[2], Jeronima Cañellas[1], Xavier Tena[1] and Alejandro Olivé Marqués[1]. [1]Hospital Universitari Germans Trias i Pujol, Barcelona, Spain, [2]Hospital Universitario Germans Trias i Pujol, Badalona, Spain.

Background/Purpose: Secondary amyloidosis (AA) is a disorder caused by deposition of insoluble amyloid A fibrils in different tissues and organs. It is a rare and serious complication of rheumatic diseases including spondyloarthropathies (SpA).

The aim of this study was to determine the clinical features, laboratory data, treatment and clinical outcome of patients with SpA who developed AA amyloidosis.

Methods: Design: retrospective (1984–2013). Hospital: academic tertiary hospital. Referral area: 850,000 inhabitants. We reviewed the medical records of 1125 patients with SpA: 509 (45%) psoriatic arthritis (PsA), 263 (23%) ankylosing spondylitis (AS), 128 (11.3%) spondylitis associated with inflammatory bowel disease (IBD), 190 (16.8%) undifferentiated spondyloarthropathies, and 35 (3.1%) reactive arthritis. We selected patients who had a histological diagnosis of AA amyloidosis. Patients with comorbidities that might be associated with AA amyloidosis were excluded.

Results: Fifteen (1.3%) patients with AA amyloidosis were recruited: 11 (73.3%) males and 4 (26.7%) females. Five (33.3%) AS, 5 (33.3%) spondylitis associated with IBD, 4 (26.7%) PsA, and 1 (6.7%) reactive arthritis. Mean age at SpA and AA amyloidosis diagnosis: 35.13 and 57.7 years, respectively. Mean disease duration: 23.9 years. Eleven patients with AA amyloidosis were diagnosed in 1984–2000 and 4 in 2001–2013. Amyloid deposits were observed on biopsy of: rectum (6 cases), kidney (3 cases), subcutaneous fat (4 cases) and bladder (1 case). In one case diagnosis was made incidentally (gallbladder), in the others diagnosis was symptomatic and suspected due to nephrotic syndrome (4), acute renal failure (ARF) (3), non-nephrotic-range proteinuria (3), chronic renal failure (CRF) (2), diarrhoea (1) and macroscopic haematuria (1). The mean values of erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) at diagnosis of amyloidosis were 65.4 mm and 25.22 mg/L, respectively. Five patients were treated with infliximab: three showed a clinical improvement, with decreased proteinuria and improved renal function. Ten patients did not receive an anti-TNF treatment, 9 of whom died (2 of CRF, 7 of sepsis). Mortality at one and five years was 30 and 50% respectively. Clinical and analytical parameters are described in Table 1.



Conclusion: The frequency of clinically apparent AA amyloidosis in our patients was 1.3%. There was a marked male predominance. Clinical AA amyloidosis was diagnosed at a relatively late stage in SpA. The predominant clinical picture was nephrotic syndrome. The frequency of AA amyloidosis decreases between decades, reflecting better control of the disease with novel therapies. Mortality is high.

Better Outcomes in Ankylosing Spondylitis: The Synergistic Association Between Exercise and Tumor Necrosis Factor Inhibitors. Sarah L. Patterson[1], John D. Reveille[2], MinJae Lee[2], Michael M. Ward[3], Mohammad H. Rahbar[4], Matthew A. Brown[5], Michael H. Weisman[6] and Lianne S. Gensler[1]. [1]University of California, San Francisco, San Francisco, CA, [2]University of Texas Health Science Center at Houston, Houston, TX, [3]NIAMS/NIH, Bethesda, MD, [4]The University of Texas Health Science Center at Houston, Houston, TX, [5]University of Queensland Diamantina Institute, Brisbane, Australia, [6]Cedars-Sinai Medical Center, Los Angeles, CA.

Background/Purpose: Exercise is an important component of Ankylosing Spondylitis (AS) management. The purpose of this study was to determine if the amount patients exercise associates with better functional outcomes and to assess if medication use contributes to this relationship.

Methods: This is a prospective cohort of 623 AS patients, meeting modified New York criteria followed up to 4 years. We collected demographic, clinical and self-reported outcomes every 6 months. Participants were queried about exercise habits including number of days per week and minutes per time exercised. A moderate exercise dose was defined as ≥120 minutes per week. Using a mixed effects Poisson regression model, we assessed multivariable associations between independent variables and the Bath Ankylosing Spondylitis Functional Index (BASFI). This accounted for correlation of repeated measures over time. Potential confounding, including baseline function, and effect modifications were examined and addressed while developing a final longitudinal multivariable model.

Results: The mean age of patients was 43 ± 14.0 years. The cohort was 72% male and 78% of patients were white. Mean disease duration was 19 ± 13.4 years. Findings from our final multivariable model indicated BASFI scores for the moderate exercise group were significantly lower than those who exercised less than 120 minutes per week at 1, 2, 3, and 4 years of follow-up (Table 1). Additionally, there was a significant interaction between exercise and Tumor Necrosis Factor (TNF) inhibitor use on function ($p=0.046$). When we looked at the effect based on level of exercise, there was a significant association between TNF inhibitor use and better function regardless of exercise status, but a greater benefit in function in those who were both on a TNF inhibitor and exercising above the defined threshold (Figure 1).

Conclusion: AS patients who exercise for at least 120 minutes per week have significantly better long-term function than those who do not. Additionally, there is a greater likelihood of functional improvement in those on both a TNF inhibitor and moderate exercise program compared to those using a TNF inhibitor alone.

Table 1. Adjusted Associations of Exercise and Other Covariates on Function (BASFI)

Independent Variable	Adjusted Rate Ratio[a]	95% Confidence Interval	P-value
Exercise & Time Interaction			0.0349
Exercise > 120[b]			
Baseline	1.00	0.96–1.05	0.96
Year 1	0.93	0.90–0.96	<0.0001
Year 2	0.95	0.91–0.99	0.01
Year 3	0.93	0.88–0.97	<0.001
Year 4	0.95	0.90–1.00	0.04
Exercise & TNF inhibitor Interaction			0.0464
Exercise > 120			
TNF inhibitor Use	0.99	0.93–1.06	0.83
No TNF inhibitor	1.04	0.97–1.11	0.32
TNF inhibitor Use			
Exercise > 120	0.87	0.84–0.91	<0.0001
Exercise < 120	0.91	0.88–0.95	<0.0001
BASFI at Baseline	1.03	1.03–1.03	<0.0001
Age at least 50 years	1.12	1.05–1.19	0.0003
Male	1.01	0.91–1.13	0.85
Postgraduate Education	0.96	0.84–1.10	0.58
BASDAI score at least 40	1.33	1.29–1.36	<0.0001
Total CES-D score at least 8	1.14	1.11–1.16	<0.0001
Current Smoker	0.93	0.79–1.08	0.32
At least 1 comorbidity	1.04	0.93–1.18	0.48
Disabled	0.91	0.76–1.08	0.28
NSAID Use	1.07	1.04–1.09	<0.0001

Sleep Disturbances in Korean Patients with Ankylosing Spondylitis Are Associated with Increased Disease Activity.

Hye-Jin Jeong[1], Yun Sung Kim[2], Chang-Nam Son[3], Ji-Min Kim[3] and Sang-Hyon Kim[3]. [1]Keimyung University Dongsan Medical Center, Daegu, South Korea, [2]Chosun University Hospital, Gwangju, South Korea, [3]Keimyung University School of Medicine, Daegu, South Korea.

Background/Purpose: Sleep problems have been reported to be more frequent in rheumatic disease than normal population. Other studies indicate various sleep problems have been reported in ankylosing spondylitis (AS). Inadequate sleep in AS patients is associated with multiple factors including pain, fatigue, disease activity and depression. In this study, we evaluated the prevalence of sleep disturbance in Korean patients with ankylosing spondylitis, and its association with disease activity and depression.

Methods: Forty patients with AS and eighty healthy controls were included in the study. Participants completed questionnaires. Sleep quality was assessed using the Korean version of the Pittsburgh sleep quality index (PSQI). Depression was assessed by the Korean version of the Beck depression inventory second edition (BDI-2). The Bath ankylosing spondylitis disease activity index (BASDAI) and ankylosing spondylitis disease activity score-C-reactive protein (ASDAS-CRP) were used to evaluate disease activity. Patients were dichotomized into a good sleeper group ($PSQI \leq 5$) and a poor sleeper group ($PSQI > 5$).

Results: The mean total PSQI score of patients with AS was 7.23 ± 3.84. It was higher than that of control subjects ($p < 0.001$). AS patients had higher scores in the subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbance and daytime dysfunction components. 60% of the AS patients classified as poor sleeper group. The mean ASDAS-CRP and BDI-2 score of poor sleeper group were higher than that of good sleeper group. Significantly, higher disease activity according to ASDAS-CRP was associated with poor sleep quality and depression. Stepwise multiple regression analysis revealed that duration of morning stiffness and depression were independent risk factors that influenced poor sleep quality.

Conclusion: Sleep disturbances are prevalent amongst Korean patients with AS. Lower quality of sleep is significantly associated with higher disease activity and depression. Morning stiffness and depression were independent risk factors that influenced poor sleep quality. Therefore, evaluation and optimal management of morning stiffness and depression to improve sleep quality in patients with AS is important.

Unraveling the Familial Tendency for Ankylosing Spondylitis in Korea.

Hye Won Kim[1], Hye Rim Choe[2], Won Ik Chang[2], Yong-Gil Kim[3], Bin Yoo[3], Jin Wook Hur[1], Tae-Hwan Kim[4], Sungim Lee[5] and Eun Young Lee[2]. [1]Eulji University of Medicine, Eulji General Hospital, Seoul, South Korea, [2]Seoul National University College of Medicine, Seoul, South Korea, [3]University of Ulsan College of Medicine, Asan Medical Center, Seoul, South Korea, [4]Hanyang University Hospital for Rheumatic Diseases, Seoul, South Korea, [5]Dankook University, Yongin, South Korea.

Background/Purpose: Despite of the evidence of familial aggregation of ankylosing spondylitis (AS), familial tendencies are not fully explored. The purpose of this study was to examine the recurrence risk (RR) ratios in different degrees of relatives for Korean AS patients.

Methods: 526 consecutive unrelated AS probands (101 female, 425 male, mean age 35.5 years, mean disease duration 12.3 years, 88.7% HLA-B27 positive) fulfilling the modified New York criteria were face-to-face-interviewed by physicians, with elaborated questionnaire to investigate AS in other family members by the same criteria. A total of 12,051 relatives (2284, 5342 and 4425 for first, second and third-degree relatives (TDR), respectively) were included. The RR ratios for different degrees of relatives were elicited and subsequently stratified by gender and HLA-B27 status. The prevalence of AS among Korean in 2013 was estimated by the Korean National Health Insurance Service at 0.07%.

Results: The RR ratio was 53.8 for first-degree relatives (FDR) followed by 10.8, 9.0 for second-degree relatives (SDR) and TDR, respectively, indicating strictly decreasing in familiality. Among FDRs, siblings were more frequently affected than offspring or parents. For male probands, the overall RR ratio for FDR was 55.5, and 65 for female, implying higher familiality of female over male. Remarkably, all of affected SDRs and beyond were relatives of HLA-B27 positive probands.

Conclusion: We demonstrated strongest familiality of AS in FDRs, particularly in siblings. Despite of similar sharp decline pattern of familiality beyond SDR, lower RR ratio in FDR in our study, compared to previous Caucasian reports, indicates ethnic difference in inheritance of the same disease. This study suggests familial tendency for AS can be explained by degrees of relationship, gender and HLA-B27, warranting further studies.

Table. The relative recurrence risk ratio by gender in Korean AS patients

	Female		Male		All	
Korean population prevalence (%)	0.04		0.09		0.07	
	RR % (95% CI)	RR ratio	RR % (95% CI)	RR ratio	RR % (95% CI)	RR ratio
Overall familial AS	0.8 (0.5–1.0)	19.3	1.8 (1.4–2.1)	19.5	1.3 (1.1–1.5)	18.3
First degree	2.6 (1.7–3.5)	65.0	5.0 (3.8–6.3)	55.5	3.8 (3.0–4.5)	53.8
Parent	1.8 (0.6–3.0)	45.0	3.7 (2.0–5.3)	41.1	2.7 (1.7–3.8)	39.2
Offspring	2.5 (0.1–4.9)	62.5	5.1 (1.9–8.4)	56.6	3.9 (1.8–5.9)	55.3
Sibling	3.3 (1.7–4.8)	82.5	6.6 (4.3–8.9)	73.3	4.8 (3.4–6.1)	68.1
Second degree	0.4 (0.2–0.7)	10.0	1.1 (0.7–1.5)	12.2	0.8 (0.5–1.0)	10.7
Third degree	0.2 (0.0–0.4)	5.0	1.0 (0.6–1.4)	11.1	0.6 (0.4–0.9)	9.0

Figure. Recurrence risk ratios of familiality in different countries. It shows familial tendencies are decreasing as familial degree extends in order, though with lesser risk for FDR in our study.

Objective Evaluation of Physical Functioning after TNFi Therapy in Ankylosing Spondylitis Patients; A Selection of Three Feasible Performance-Based Tests. Salima F.E. van Weely[1], Joost Dekker[2], Martijn P.M. Steultjens[3], Christiaan J. Van Denderen[1], Mike T. Nurmohamed[1], Ben A.C. Dijkmans[4] and Irene E. van der Horst-Bruinsma[4]. [1]Reade, centre for Rehabilitation and Rheumatology, Amsterdam, Netherlands, [2]VU University Medical Center, Amsterdam, Netherlands, [3]Glasgow Caledonian University, Glasgow, Scotland, [4]VU University Medical Centre, Amsterdam, Netherlands.

Background/Purpose: Physical functioning is considered an important outcome domain for the evaluation of the effectiveness of therapy and the course of the disease. In an effort to find objective outcome measures that assess limitations in physical functioning in Ankylosing Spondylitis (AS) patients, eight performance-based tests based on items of the Bath AS Functional Index (BASFI) were developed. However, in research and clinical practice it is important to eliminate redundant testing in order to safe energy, time and money. Therefore, this study aimed (i) to select a limited number of performance-based tests that are reliable, show improvement in physical functioning after TNFi therapy and generate the equivalent information as the full set of tests and (ii) are feasible for use in daily clinical practice.

Methods: Eight performance-based tests were evaluated ((1) climbing stairs, (2) bending, (3) reaching up, (4) putting on socks, (5) rising up and sitting down on a chair, (6) getting up from the floor, (7) looking over the shoulder and (8) a physically demanding activity). The tests that showed adequate reliability, highest Standardized Response Means (SRM) and the largest proportion of patients with an improved performance-based physical functioning were selected. The selected tests were combined into a new criterion for improvement in physical functioning (AS Performance-based Improvement, ASPI). The number and percentage improved patients identified with the ASPI and identified with the full set of performance tests were compared.

Results: Reliability for all tests was adequate to excellent (Intraclass Correlation Coefficients 0.73–0.96). The tests for bending, putting on socks and getting up from the floor had the highest SRM's (0.52–0.74) and showed the largest proportion of improved patients after TNFi therapy. The combination of these three tests is feasible in daily clinical practice and showed improved physical functioning after TNFi therapy in 67% of the patients.

Conclusion: The tests for bending, putting on socks and getting up from the floor are recommended for use in daily practice, because they generate comparable information as the full set and are feasible for use in daily clinical practice. A new criterion, the ASPI, using a combination of these three tests showed an improved physical functioning after TNFi therapy in 67% of the patients. By performing only three instead of all performance-based tests, redundant testing is eliminated. In future, evaluations of the effectiveness of TNFi therapy in AS patients might be improved by adding these tests to other outcome measures.

Three-Year Course and Prediction of Physical Functioning in Ankylosing Spondylitis Patients Treated with TNF-Inhibitors. Salima F.E. van Weely[1], Eva L. Kneepkens[1], Mike T. Nurmohamed[1], Joost Dekker[2] and Irene E. van der Horst-Bruinsma[3]. [1]Reade, centre for Rehabilitation and Rheumatology, Amsterdam, Netherlands, [2]VU University Medical Center, Amsterdam, Netherlands, [3]VU University Medical Centre, Amsterdam, Netherlands.

Background/Purpose: Currently, only limited information is available on the long-term course of limitations in physical functioning and spinal mobility in Ankylosing Spondylitis (AS) patients receiving TNF inhibiting (TNFi) therapy in daily clinical care. Therefore this study aimed (i) to examine the 3-years course of physical functioning and spinal mobility impairments in patients routinely treated with TNFi; (ii) to predict the 3-years level and (iii) to predict the 3-years course of physical functioning and spinal mobility.

Methods: AS patients eligible for TNFi were followed in a prospective observational cohort for 3 years. Prediction models were developed with linear mixed modelling using 18 baseline variables. The Bath AS Functional Index (BASFI) and Bath AS Metrology Index (BASMI) were used as outcome measures for physical functioning and spinal mobility, respectively.

Results: At baseline 257 patients were included and treated with etanercept (n=174) or adalimumab (n=83). Physical functioning improved significantly during the first 24 weeks after the start of TNFi. The BASFI score decreased from 5.4±2.4 to 3.3±2.6 in week 24, and stabilised thereafter (BASFI 3-years 3.6±2.5; see figure-1). The BASMI showed a stable course over time. Lower baseline BASFI and BASMI-scores predicted a better physical functioning and spinal mobility after 3-years of TNFi therapy. Other predictors for a higher 3-years level and better 3-years course of physical functioning included absence of comorbidity, physical activity, younger age and lower body mass index (BMI) at baseline. However, large between-patient variations were observed.

Conclusion: Improvement of physical functioning in TNFi treated AS patients continues up to 24-weeks and stabilises thereafter. Therefore, the efficacy of treatment should be determined at 6 months. Predictors for the level and course of physical functioning and spinal mobility after 3-years of TNFi treatment include baseline BASFI, BASMI, absence of comorbidity, physical activity and BMI.

Do Extra-Articular Manifestations Influence Outcome in Ankylosing Spondylitis? a 12 Year Follow-up Study. Ivette Essers[1], Sofia Ramiro[2], Carmen Stolwijk[1], Marc Blaauw[3], Robert Landewé[4], Désirée M. van der Heijde[5], Filip van Den Bosch[6], Maxime Dougados[7] and Astrid van Tubergen[8]. [1]Maastricht University, Maastricht, Netherlands, [2]Amsterdam Rheumatology Center/University of Amsterdam, Amsterdam, Netherlands, [3]Catharina Hospital, Eindhoven, Netherlands, [4]Atrium Medical Center, Heerlen, Netherlands, [5]Leiden University Medical Center, Leiden, Netherlands, [6]Department of Rheumatology Ghent University Hospital, Ghent, Belgium, [7]Hopital Cochin, Descartes University, Paris, France, [8]Maastricht University Medical Center, Maastricht, Netherlands.

Background/Purpose: Extra-articular manifestations (EAMs), such as acute anterior uveitis (AAU), inflammatory bowel disease (IBD), and psoriasis contribute to diagnosis, classification criteria, and choice of treatment in patients with ankylosing spondylitis (AS). Therefore, the aim of the present study is to assess whether the presence of EAMs is associated with more functional disability, worse quality of life (QoL), and more radiographic damage in patients with AS over time.

Methods: Twelve-year follow-up data from all patients included in the Outcome in Ankylosing Spondylitis International Study (OASIS) were used. The presence of EAMs was extracted from medical charts by two independent extractors. Function was assessed by the Bath AS Functional Index (BASFI), and the physical component of the Short Form-36. QoL was assessed by the ASQoL, and EuroQoL. Radiographic damage was assessed by the modified Stoke AS Spinal Score. Time adjusted univariable and multivariable generalized estimating equations analyses were performed to assess whether prevalent and incident EAMs, respectively, were associated with functional disability, QoL, and radiographic damage over time. Patients with prevalent EAMs were excluded from the analysis involving incident EAMs.

Results: 216 Patients were included (154 (71%) men, mean age 43.6 years (SD 12.7), mean symptom duration 20.5 years (SD 11.7), and mean follow-up 8.3 years (SD 4.1)). At baseline, 39 (18%) patients had AAU, 15 (7%) IBD, and 9 (4%) psoriasis (prevalent cases). During follow-up, 19 patients developed AAU, 9 IBD, and 5 psoriasis (incident cases). Psoriasis was excluded from further analyses, because of a low prevalence and incidence in this cohort. Prevalent AAU was univariably associated with more radiographic damage (B=7.19, 95%-Confidence Interval [CI] 0.19 to 14.19, p=0.04) over time, but in a multivariable model this association was no longer significant (B=1.22, 95%-CI -3.81 to 6.26, p=0.64). Prevalent IBD was not associated with any of the clinical outcomes over time. Incident AAU was also not associated with clinical outcomes over time. Incident IBD, however, showed a trend towards worse function (BASFI) over time in a univariable model (B=1.86, 95%-CI -0.08 to 3.80, p=0.06), and also in a multivariable model (B=1.40, 95%-CI -0.04 to 2.84, p=0.06).

Conclusion: Prevalent AAU and IBD at baseline were not associated with a worse course of QoL, function, or radiographic damage over time. However, patients with new-onset IBD tended to have more functional disability over time in comparison with patients who do not develop IBD.

Disease Activity Strongly Influences Work Productivity and Physical Health Related Quality of Life in Early Axial Spondyloarthritis: Data from the SPACE-Cohort. A Roeterink[1], M de Hooge[1], R. van den Berg[1], H Dagfinrud[2], R Landewé[3], M. van Oosterhout[4], R Ramonda[5], D. van der Heijde[1] and F van Gaalen[1]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]Diakonhjemmet Hospital, Oslo, Norway, [3]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands, [4]Groene Hartziekenhuis, Gouda, Netherlands, [5]University of Padova, Padova, Italy.

Background/Purpose: In early onset axial spondyloarthritis (axSpA), not much is known about the relationship between disease activity and work productivity loss (WPL) or disease activity and health-related quality of life (HRQoL) In this study we assessed the relationship between disease activity and WPL and HRQoL in early axSpA.

Methods: The SPACE cohort recruited patients (n=345) with chronic back pain (≥3 months, ≤2 years, onset <45 years) in 5 European centres. In patients fulfilling the ASAS axSpA criteria (n=131), the following assessments were done: ASDAS and BASDAI (disease activity), BASFI (functional ability), SF-36 (HRQoL) and Work Productivity and Activity Impairment (WPAI). Patients were grouped according to ASDAS: inactive disease (<1.3), moderate disease (1.3–2.1), high disease (2.1–3.5) and very high disease activity (>3.5). BASDAI and BASFI scores ≥4 were considered as high disease activity and impaired function, respectively. HRQoL was reported as the SF-36 physical (PCS) and mental component summary (MCS) scores. Lower scores indicate decreased quality of life compared to the general population. Impact of disease on work productivity (WP) was defined as percentage of absenteeism and presenteeism and WPL (combines absenteeism and presenteeism) with greater scores indicating greater impairment.

Results: Figure 1 shows that physical health-related quality of life (PCS) decreased significantly with increasing ASDAS. For example, in patients with inactive disease, the PCS was 42.5 compared to 17.3 in patients with very high disease activity. Moreover, absenteeism, presenteeism and WPL increased as ASDAS increased (figure 1b). MCS was not influenced by disease activity. PCS and WPL had a similar association with BASDAI (not shown) and BASFI (low vs.high BASFI; PCS 46.3 vs. 47.2, P=0.76; WPL; 30.9% vs. 66.7%; absenteeism; 7.1% vs. 24.9%; presenteeism; 28.9% vs. 61.1%, all P <0.001).

Conclusion: In early axial SpA, disease activity highly influences physical health-related quality of life and work productivity. These findings support aiming for clinical remission in patients with early axial SpA.

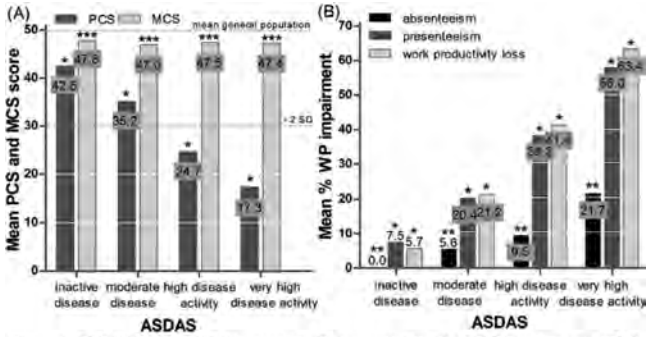

Figure 1. PCS, MCS (A) and WPAI components (B) in association with ASDAS in patients with axSpA. * $P < 0.001$ ** $P = 0.02$ *** $P = 0.97$.

Dikkopf-1 (Dkk-1) Serum Levels in Axial Spondyloarthritis (axSpA) Are Related to Disease Duration. Victoria Navarro-Compán[1], Enrique Melguizo-Madrid[2], Concepción González-Rodríguez[2], Federico Navarro-Sarabia[2] and Rafael Ariza-Ariza[2]. [1]University Hospital La Paz and Leiden University Medical Center, Madrid, Spain, [2]University Hospital Virgen Macarena, Sevilla, Spain.

Background/Purpose: Tumor necrosis factor (TNF) alpha is responsible for induction of dkk-1 which down-regulates bone formation. Therefore, it was expected that TNF-blocker therapy would inhibit radiographic progression in patients with axSpA but this effect has not been observed yet. Nevertheless, most of the studies have included patients with long disease duration and it is unknown whether or not this effect would be the same in patients with an early stage of the disease. The objective of this study was to investigate if disease duration influences on the serum levels of dkk-1 in patients with axSpA.

Methods: Observational study including consecutive patients with axSpA according to ASAS criteria visiting a tertiary hospital between January 2011 and June 2013. All patients were receiving NSAIDs and none of them was under biologic therapy. The following characteristics were recorded at one visit: Demographic (age, gender), symptoms duration, HLA-B27, disease activity indices (BASDAI, CRP, ESR) and function (BASFI). Blood samples to determine dkk-1 serum levels by enzyme immunoassay were collected at the same visit too. Patients were classified as early axSpA (symptoms duration ≤ 5 years) and established axSpA (>5 years) and the characteristics enumerated above were compared between both groups. Univariate and multivariate linear regression models were employed to identify the characteristics related to dkk-1 serum levels.

Results: Fifty one patients (31 with early axSpA and 21with established disease) were included this study. Patients with early axSpA were younger (32.6 ± 9.3 vs 41.0 ± 10.2 years; p<0.01), had lower degree of disease activity (BASDAI: 4.6 ± 2.7 vs 6.6 ± 1.9; p<0.01 and ESR: 7.7 ± 9.2 vs 18.1 ± 15 mmHg; p<0.05) and worst function (3.2 ± 2.9 vs 5.8 ± 2.5; p<0.01) compared with patients with established disease. Serum levels of dkk-1 were significantly higher in patients with early disease (25.9 ± 11.5 vs 13.9 ± 13.5; p<0.001 ng/dl). No statistically significant differences were found between both groups for the rest of characteristics. In the univariable analysis, symptoms duration and BASDAI were inversely related to dkk-1 levels (std β: -0.435; p<0.01 and Std β: -0.283; p<0.05, respectively). However, only the relationship with symptoms duration remained statistically significant in the multivariable analysis (std β: -0.415; p<0.01).

Conclusion: Serum Dkk-1 levels in patients with axSpA depend on disease duration, being higher in patients with recent onset of the disease. The effect of TNF-blocker therapy on radiographic progression may be different in patients with an early stage of the disease compared with patients with established disease.

A Substantial Decrease in Work Productivity and Physical Health-Related Quality of Life in Chronic Back Pain of Recent Onset: Data from the SPACE-Cohort. A Roeterink[1], M de Hooge[1], R. van den Berg[1], H Dagfinrud[2], M Turina[3], M. van Oosterhout[4], D. van der Heijde[1] and F van Gaalen[1]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]Diakonhjemmet Hospital, Oslo, Norway, [3]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands, [4]Groene Hartziekenhuis, Gouda, Netherlands.

Background/Purpose: Ankylosing spondylitis is associated with work productivity (WP) loss and a decreased health-related quality of life (HRQoL). Little is known about WP loss and HRQoL in early axial spondyloarthritis (SpA). Aim of the study was to determine the impact of chronic back pain (CBP) of recent onset on HRQoL and work productivity in young patients.

Methods: The SPACE-cohort includes patients with CBP (≥3 months, ≤2 years, onset <45 years) in 5 European centers (n=345). Patients who met the ASAS axial SpA criteria were classified as axSpA (n=131). Patients with 1 SpA feature were defined as possible SpA (n=167), and those with no SpA features as no SpA (n=47). The 36-item Short-Form (SF-36) and Work Productivity and Activity Impairment (WPAI) surveys were used to assess HRQoL and WP. SF-36 physical (PCS) and mental component summary (MCS) scores were compared to the general population (a score of 50±10 SD represents the general population). Impact of disease on WP was defined as percentage of absenteeism, presenteeism and WP loss (which combines absenteeism and presenteeism) with greater scores indicating greater impairment.

Results: 304 patients completed the SF-36 and 230 the WPAI. Figure 1 shows a significant reduction of ≥2 SD in mean physical component scores (PCS) in all subgroups compared to the general population (25.9 in no SpA, 23.5 in possible SpA and 28.3 in axial SpA). Mental components scores (MCS) were not significantly reduced in patients with CBP compared to the general population. Considerable absenteeism and presenteeism was present in all subgroups with CPB. Absenteeism was highest in no SpA and possible SpA (21.6% and 18.5%; compared to axSpA (10.3%) (p=0.10 and p=0.05, respectively),. Presenteeism was highest in no SpA and possible SpA (46.9% and 44.7%), compared to axSpA (34.7%). Total WPL was highest in no SpA and possible SpA (55.2% and 48.3%) compared to axSpA (37.5%).

Conclusion: Work productivity and physical health-related quality of life are already greatly reduced in young patients with chronic back pain of less than two years duration.

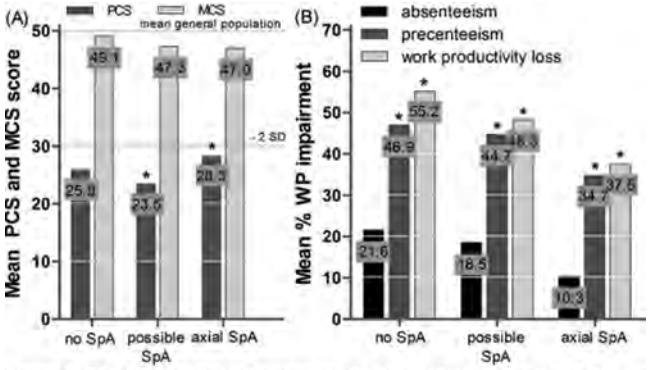

Figure 1. PCS, MCS (A) and WPAI components (B) in patients with chronic back pain ≥3 months but ≤2 years and <45 years of age. * *P*<0.05 axSpA vs. possible SpA and axSpA vs. no SpA.

Female Patients but Not Male Patients with Ankylosing Spondylitis Are at Increased Risk of Developing Ischemic Heart Disease: A Population-Based Cohort Study. Ivette Essers[1], Carmen Stolwijk[1], Annelies Boonen[2], Marie L. De Bruin[3], Marloes Bazelier[3], Frank de Vries[1] and Astrid Van Tubergen[1]. [1]Maastricht University, Maastricht, Netherlands, [2]Maastricht University Medical Center, Maastricht, Netherlands, [3]Utrecht Institute for Pharmaceutical Sciences, Utrecht, Netherlands.

Background/Purpose: It is well recognized that rheumatoid arthritis is an independent risk factor for cardiovascular disease. For ankylosing spondylitis (AS), the literature on this risk is relatively scarce, and shows conflicting results. Furthermore, these studies did not explore the role of non-steroidal anti-inflammatory drugs (NSAIDs) use on this risk. Therefore, the aim of the present study was to investigate the incidence and risk of ischemic heart disease (IHD) and acute myocardial infarction (AMI), including the role of NSAIDs, in patients with AS compared with matched population controls.

Methods: All patients with newly diagnosed AS from the British Clinical Practice Research Datalink (1987–2012) were matched with up to 7 persons without AS by year of birth, gender and practice. Incidence rate ratios (IRRs) and hazard ratios (HR) for development of IHD and AMI were calculated. Stepwise analyses were performed adjusting for age, gender, comorbidity, and drug use, including NSAIDs.

Results: In total, 3,809 patients with AS were matched with 26,196 population-based controls. The number of men (70.5% vs 70.7%), and the mean age (43.7 years vs. 43.3 years) were comparable for patients with AS and controls. The mean duration of follow up for patients and controls was 6.6 years. At baseline, 4.3% of the patients had a history of IHD, and 1.8% had a history of AMI, compared with 3.4% and 1.4% of the controls, respectively (p<0.01 and p=0.02, respectively). After excluding subjects with pre-existing cardiovascular disease, the overall IRR for IHD was 1.18 (95%-confidence interval [CI] 0.96–1.46) and for AMI 0.91 (95%-CI 0.65–1.27). Compared with controls, the age-gender adjusted HR for developing IHD was 1.20 (95%-CI 0.97–1.48), and for AMI 0.91 (95%-CI 0.65–1.28) for patients with AS. In female patients, the increased risk of developing IHD was statistically significant (HR 1.81, 95%-CI 1.18–2.79), but after adjustment for all possible risk factors only a non-significant trend towards increased risk was found (HR 1.36, 95%-CI 0.86–2.14). In particular, recent NSAID use explained the change in risk (female HR IHD adjusted for age-gender-NSAID use 1.47, 95%-CI 0.93–1.36). After stratification for the use of NSAIDs, the overall risk of IHD in patients with AS was 1.36-fold (95%-CI 1.00–1.87) increased with recent use of NSAIDs. This was particularly increased in female patients (HR fully adjusted 2.52, 95%-CI 1.41–4.51), but not in male patients (HR fully adjusted 1.13, 95%-CI 0.78–1.64).

Conclusion: Female patients with AS are at increased risk of developing IHD, but this effect is associated with recent NSAID use. However, it cannot be excluded that NSAID use is (partly) a reflection of active disease.

Disclosure: I. Essers, None; **C. Stolwijk**, None; **A. Boonen**, None; **M. L. De Bruin**, None; **M. Bazelier**, None; **F. de Vries**, None; **A. Van Tubergen**, None.

Patients with Ankylosing Spondylitis Do Not Adapt to Their Disease: Evidence from the 'then Test' in Patients Treated with TNF-Inhibitors. Ivette Essers[1], Astrid Van Tubergen[1], Jurgen Braun[2], Xenofon Baraliakos[2], Frank Heldmann[2] and Annelies Boonen[3]. [1]Maastricht University, Maastricht, Netherlands, [2]Rheumazentrum Ruhrgebiet, Herne, Germany, [3]Maastricht University Medical Center, Maastricht, Netherlands.

Background/Purpose: Although never formally studied, rheumatologists feel that patients with ankylosing spondylitis (AS) tend to adjust to their disease. Response shift is one of the theories to demonstrate that adaptation takes place and makes use of the 'then test'. A 'then test' asks patients to re-rate their past health in a situation where change in health occurred. This theory states that patients with a treatment response would re-rate their former health as worse as initially thought, and that the magnitude of treatment response is associated with a larger gap between the initial and retrospective assessment of health. The aim of the present study was to understand whether patients with AS adapt to their disease, using the 'then test', in patients in whom infliximab (INF) was started. It was hypothesized responders to therapy would re-rate retrospectively their initial health as worse.

Methods: Data were used from 103 European patients who participated in the AS Study for the Evaluation of Recombinant INF Therapy (ASSERT) and continued in the European AS INF Cohort (EASIC). The Bath AS Global Score (BAS-G) last week was used to assess patient global well-being. A BAS-G 'then test' was integrated in EASIC, and asked patients to re-rate their initial well-being (i.e. before the start of INF in ASSERT). Treatment response between ASSERT and EASIC was assessed with the Assessment of SpondyloArthritis International Society 20 (ASAS20) response criteria. The baseline BAS-G of ASSERT and retrospective BAS-G of ASSERT were compared using paired t-test. Limits of agreement were calculated. A linear regression analysis was performed to identify whether response influenced the difference between the initial and retrospective BAS-G of ASSERT (i.e. gap) after adjusting for other covariates.

Results: 86 Patients contributed to the current analyses (mean age 39.6 years (SD 10.6); mean disease duration 9.7 years (SD 8.1), and 68/96 (79.1%) patients had an ASAS20 response). At baseline, the BAS-G in ASSERT was 7.0 (SD 1.6), and patients retrospectively re-rated their BAS-G, using the 'then test', at 7.2 (SD 2.3), revealing a non-significant and non-relevant gap of 0.2 (SD 2.7) ($p=0.45$). Limits of agreements show that the gap varied between -5.1 and 5.5. In a multivariable model, the difference between the baseline BAS-G of ASSERT and retrospective BAS-G of ASSERT was irrespective of treatment response, and was only associated with the baseline BAS-G of ASSERT ($p<0.01$) and the BASDAI ($p=0.02$) before the start of INF.

Conclusion: Patients with AS were able to retrospectively judge their well-being, even if substantial time relapsed between the start of the treatment and this retrospective assessment, and irrespective of treatment response. In this setting, the 'then test' could not prove adaptation by response shift in AS.

MRI Is Often Negative in Clinically Suspected Non-Radiographic Axial Spondyloarthritis. M.L. John[1], M.a.C. van der Weijden[2], C.M.a. van der Bijl[1], S.T.G. Bruijnen[1], C.J. van der Laken[1], M.T. Nurmohamed[1] and I.E. van der Horst-Bruinsma[1]. [1]VU University Medical Center, Amsterdam, Netherlands, [2]Jan van Breemen Research Institute Reade, Amsterdam, Netherlands.

Background/Purpose: The diagnosis of ankylosing spondylitis (AS) is based on disease specific bone damage seen on plain radiography of the pelvis. Recent developments in magnetic resonance imaging (MRI) techniques have demonstrated that active inflammation in the sacroiliac joints (SIJ) and/or spine is detectable by MRI and might even be visible before the appearance of chronic changes on plain radiography. However, the current literature discussing the actual diagnostic properties of MRI in early spondyloarthritis (SpA)/non-radiographic axial SpA remains controversial and its prognostic value regarding the future development of AS has yet to be determined.

Methods: In this cross-sectional study, we recruited 70 patients with chronic inflammatory back pain (mean disease duration of 5 years) and high disease activity (BASDAI$\geq$4) who had to be either HLA-B27 positive with $\geq$1 SpA-feature or HLA-B27 negative with $\geq$2 SpA-features. All patients underwent MRI of the SIJ and 50 patients underwent additional MRI of the spine on baseline. A positive MRI was defined by the presence of either BMO and/or osteitis, a negative MRI by the absence of both. Patients with a negative baseline MRI were asked to undergo a second MRI after 6 months. Eventually, 29 out of 49 patients with a negative baseline MRI SIJ and 22 out of 47 patients with a negative baseline MRI spine were willing and eligible to undergo the second MRI. Additionally, all patients were tested for CRP and ESR levels, X-rays of the pelvis were made and several patient features were recorded. Correlation analysis was performed between the different collected variables.

Results: At baseline, only 21 of the 70 patients (30%) showed signs of inflammation on MRI: 18 had sacroiliitis, 2 had spinal involvement and one patient had both. In total, only 4 patients presented with inflammation of the spine at baseline and six months, of which 2 also suffered from sacroiliitis. Comparison of the two consecutive MRIs revealed that, in two patients, the inflammatory process spread from the SIJ to the spine or the other way around. Only one patient with a negative baseline MRI SIJ developed apparent sacroiliitis over time. Furthermore, three patient characteristics were significantly associated with a positive MRI outcome at any point in time: raised CRP-level ($p=0.032$), family history of uveitis ($p=0.028$) and the number of swollen joints (SJC, $p=0.023$). We also observed a slight difference regarding HLA-B27-status and medical history of uveitis, in favor of the positive MRI-group.

Conclusion: Only a small number of patients with clinically suspected non-radiographic axial SpA showed signs of inflammation on MRI SIJ and/or spine, questioning the sensitivity and with this the value of this new imaging tool in early SpA. Even though, some patient characteristics seem to be positively associated with MRI outcome, defining the right place of MRI in the diagnosis of early SpA remains difficult. The diagnostic properties of MRI in this particular patient group should be weighted carefully because patients with a negative MRI might also have severe complaints.

Evaluation of the Nonsteroidal Anti-Inflammatory Drug-Sparing Effect of Etanercept in Axial Spondyloarthritis: Results of a Multicenter, Randomized, Double-Blind, Placebo-Controlled Trial. Maxime Dougados[1], Emily Wood[2], Bernard Combe[3], Corinne Miceli-Richard[4], Francis Berenbaum[5], Nandan Koppiker[6], Arnaud Dubanchet[7] and Isabelle Logeart[7]. [1]Université Paris René Descartes and Hôpital Cochin, Paris, France, [2]Quanticate, Hitchin, England, [3]Hôpital Lapeyronie, Montpellier, France, [4]Université Paris-Sud 11, Bicêtre Hospital, Kremlin Bicêtre, France, [5]Saint-Antoine Hospital, Paris, France, [6]Pfizer PGRD, Sandwich, United Kingdom, [7]Pfizer, Paris, France.

Background/Purpose: Nonsteroidal anti-inflammatory drugs (NSAIDs) are first-line pharmacotherapy in axial spondyloarthritis (axSpA) but are recommended for use at the lowest effective dose for the shortest possible time due to safety concerns. Although NSAID discontinuation is common in clinical practice after response to biologic therapy in axSpA patients, its impact has not been evaluated in prospective controlled trials. The SPARSE trial was conducted to assess the effects of etanercept (ETN) on NSAID intake as measured by the ASAS-NSAID score[1]and conventional clinical outcomes in axSpA.

Methods: In the initial 8-week, double-blind (DB), placebo (PBO)-controlled period, patients with active (mini BASDAI $\geq$4) axSpA (ASAS criteria) despite optimal NSAID intake were randomized to ETN 50 mg or PBO once weekly for 8 weeks. All patients were advised to taper/stop their NSAID intake (self-reported diary) during the study treatment period. Completers were eligible for ETN 50 mg in the subsequent 8-week open-label (OL) period. ASAS-NSAID scores were calculated according to ASAS recommendations. [1] The primary endpoint, the change from baseline (BL) to week 8 in the ASAS-NSAID score, was analyzed using an analysis of covariance (ANCOVA).

Results: In 90 randomized patients at BL, mean age ($\pm$SD) was 38.9$\pm$11.8 years; disease duration, 5.7$\pm$8.1 years; 62% were male; 66% were HLA-B27 positive; and 50% were MRI sacroiliitis positive. Mean ASAS-NSAID scores at BL (ETN vs PBO: 98.2$\pm$39.0 vs 93.0$\pm$23.4), BASDAI (6.0$\pm$1.7 vs 5.9$\pm$1.5), and BASFI (5.2$\pm$2.1 vs 5.1$\pm$2.2) were similar between groups. A between-group difference in changes in ASAS-NSAID scores of -27.3 ($P=0.002$) favoring ETN was observed at week 8 (table). Significantly more patients in the ETN vs PBO group achieved BASDAI50 and ASAS40 at week 8. Significant reductions in ASAS-NSAID scores were seen in the ETN/ETN group from BL to week 16 and in the PBO/ETN group from week 8 to 16 (table); response rates increased in the ETN/ETN and PBO/ETN groups for most clinical endpoints in the OL period.

Table. Effects of ETN vs PBO in patients with axSpA (ITT).

	Wk 8 (DB), N/n (%)		Wk 16 (OL), N/n (%)	
Endpoint	**ETN (n=42)**	**PBO (n=48)**	**ETN/ETN (n=39)**	**PBO/ETN (n=44)**

Non-Steroidal Anti-Inflammatory Drugs in Axial Spondyloarthritis: A Cochrane Review. Féline Kroon[1], Lennart van der Burg[1], Sofia Ramiro[2], Robert Landewé[3], Rachelle Buchbinder[4] and Désirée van der Heijde[1]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]Amsterdam Rheumatology Center/University of Amsterdam, Amsterdam, Netherlands, [3]Academic Medical Center, University of Amsterdam, Amsterdam, Netherlands, [4]Monash Department of Clinical Epidemiology at Cabrini Hospital, Department of Epidemiology and Preventive Medicine, Monash University, Malvern, Victoria, Australia.

Background/Purpose: We performed a Cochrane systematic review to determine the benefits and harms of non-steroidal anti-inflammatory drugs (NSAIDs) in axial spondyloarthritis (axSpA).

Methods: We included all published randomised controlled trials (RCTs) of NSAIDs versus any comparator in adult patients with axial SpA identified by searches in MEDLINE, EMBASE and CENTRAL (until April 2014). The comparisons investigated were traditional NSAIDs versus placebo, COX-2 NSAIDs versus placebo, traditional NSAIDs versus COX-2 NSAIDs, NSAIDs in low versus high dose and NSAIDs versus NSAIDs. Main efficacy outcomes were pain, Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), Bath Ankylosing Spondylitis Functional Index (BASFI), Bath Ankylosing Spondylitis Metrology Index (BASMI) and radiographic progression. Main safety outcomes were number of withdrawals due to adverse events and number of serious adverse events. Risk of bias of included studies was assessed according to the Cochrane risk of bias tool.

Results: Forty-one trials (n=6073) with a median duration of 12 weeks (range 1 week to 2 years) met inclusion criteria. Thirty-one studies (n=5317) with a median duration of 12 weeks (range 2 to 26 weeks) could be included in quantitative data-analysis. Most studies were at unclear risk of selection bias, although blinding was adequate in most trials and many trials had low risk of attrition and reporting bias.

In 5 RCTs (n=1165), comparing conventional NSAIDs versus placebo (duration 2 to 12 weeks), there was a consistent significant effect in all efficacy variables favouring NSAIDs, for example pain on VAS: mean difference (MD) -16.5 (95% CI -20.8 to -12.2) in 4 trials (n=850). There were no significantly more (serious or any) adverse events or withdrawals due to adverse events, except for more gastrointestinal adverse events in patients taking NSAIDs (RR 1.92 (95% CI 1.41 to 2.61), 5 trials, n=1289). We found similar results in the comparison COX-2 versus placebo (3 studies, n=669). When comparing conventional NSAIDs to COX-2 we found no difference in either efficacy or safety (4 studies, n=995). In general we found no clear dose-effect on efficacy or safety. When comparing different NSAIDs to each other, no important difference in efficacy could be determined. However, 11 studies (n=1135) showed that indomethacin resulted in more adverse events than other NSAIDs (RR 1.25 (95% CI 1.06 to 1.49)), in particular neurological adverse events like headache and dizziness (RR 1.96 (95% CI 1.06 to 3.57), 9 trials, n=963), although there were not more withdrawals due to adverse events.

Conclusion: In patients with axial SpA, overall high quality trials indicate that traditional and COX-2 NSAIDs are consistently more efficacious than placebo, without a significant difference between the two NSAIDs classes. Various NSAIDs do not differ in efficacy in low to moderate quality trials, although indomethacin seems to result in more, mainly neurological, adverse events, even though this did not lead to more withdrawals. Results of this review support current recommendations for treatment of axial Spa with NSAIDs.

What Is the Correlation of Individual HAQ and Basdai Questions with Disease Activity Measures in Ankylosing Spondylitis? Implications for Instrument Reduction. Proton Rahman[1], Michel Zummer[2], Wojciech Olszynski[3], Majed Khraishi[4], Dalton Sholter[5], Rafat Faraawi[6], William Bensen[7], Milton Baker[8], Andrew Chow[9], Julie Vaillancourt[10], John S. Sampalis[10], Francois Nantel[11], Allen J Lehman[11], Susan Otawa[11] and May Shawi[11]. [1]Memorial University of Newfoundland, St. John's, NF, [2]Université de Montréal, Montreal, QC, [3]University of Saskatchewan, Saskatoon, SK, [4]Nexus Clinical Research, St John's, NF, [5]University of Alberta, Edmonton, AB, [6]McMaster University, Hamilton, ON, [7]Division of Rheumatology, McMaster University, Hamilton, ON, [8]University of Victoria, Victoria, BC, [9]Credit Valley Rheumatology, Mississauga, ON, [10]JSS Medical Research, Montreal, QC, [11]Janssen Inc., Toronto, ON.

Background/Purpose: Despite the importance of the Health Assessment Questionnaire (HAQ) and Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) in assessing patient-reported functional status and disease activity, they have been critiqued for being time-consuming, not convenient on a daily-basis and thus not contributing to decisions in routine care. The aim of this analysis was to describe the correlation of individual HAQ and BASDAI questions with patient and physician reported measures used in ankylosing spondylitis (AS) and to examine whether the instruments could be reduced to better reflect routine clinical practice.

Methods: BioTRAC is an ongoing prospective registry of patients initiating infliximab or golimumab as first biologics or after <6 months of biologic treatment. Data from AS patients treated in 2005–2014 were used. The correlation of individual HAQ and BASDAI questions with patient (pain, BASDAI, HAQ and BASFI) and physician (MDGA) reported measures was described with the Pearson's correlation coefficient. The impact of each question on the need for help in each HAQ domain was assessed with logistic regression. Factor analysis was used to assess the variability due to each individual question in HAQ and BASDAI.

Results: A total of 413 AS patients with 1660 BASDAI and 1654 HAQ assessments were included. HAQ and BASDAI questions correlated at different extents with each AS measure (Table 1). Questions related to "eating" and "gripping" showed the lowest correlation with patient and physician reported measures. All HAQ questions had higher correlations with patient reported measures than with MDGA. The BASDAI question on "fatigue and tiredness" showed the highest correlation with BASFI, while the question on "other joints pain/swelling" showed the lowest correlation with MDGA. None of the HAQ and BASDAI questions were associated with needing help for eating. All other HAQ individual questions were significantly associated with the need for help within their corresponding category, with the exception of Q5C and Q7A. BASDAI question on level of discomfort was significantly associated with the need for help in all HAQ categories, with the exception of "eating" and "walking". Q2A and Q7C accounted for 59.6% of the HAQ variance. The level of morning stiffness accounted for 73.8% of the BASDAI variance. When combining the HAQ and BASDAI, Q2A and Q3A from HAQ and Q1 from BASDAI accounted for 63.5% of the variance.

Conclusion: Variability exists in the correlation of HAQ and BASDAI questions with patient and physician reported AS measures. The results suggest that "standing up straight from an armless chair" and "turning faucets on/off" are the main drivers of HAQ, while the level of morning stiffness drives the BASDAI. Three questions were found to drive the combined HAQ and BASDAI which may have implications in the design of self-report instruments.

Table 1. Correlation between Individual HAQ / BASDAI Questions and Disease Activity Measures

HAQ Questions	Pain	BASDAI	BASFI	MDGA
Dressing and Grooming (Q.1 A/B)	0.56/0.41	0.53/0.45	0.68/0.52	0.47/0.37

Flare in Spondyloarthritis: Proposal of a Meaningful Change in Symptomatic Outcome Measures in Axial Spondyloarthritis. Maxime Dougados[1], Emily Wood[2], Laure Gossec[3], Désirée van der Heijde[4] and Isabelle Logeart[5]. [1]Université Paris René Descartes and Hôpital Cochin, Paris, France, [2]Quanticate, Hitchin, England, [3]UPMC GRC08, Paris 06 University, Pitié Salpétrière Hospital, Paris, France, [4]Leiden University Medical Center, Leiden, Netherlands, [5]Pfizer, Paris, France.

Background/Purpose: Recognition of flare is important in both daily practice and clinical trial setting. However, there is no clear definition of flare in patients with axial spondyloarthritis. SPARSE was a randomized controlled trial evaluating the NSAID-sparing effect of etanercept in axial spondyloarthritis. All patients had to be on NSAIDs prior to screening and were requested to discontinue their NSAID therapy at screening. The objective of this post-hoc analysis was to evaluate the threshold in the changes in symptomatic outcome measures in case of a restart of NSAID, which was considered as a flare.

Methods: Patients: Axial spondyloarthritis (ASAS criteria) with active disease (BASDAI $\geq$ 4) refractory to NSAIDs and justifying anti-TNF therapy. Design: Prospective randomized controlled trial. Study period of interest: This analysis was focused on the period between screening and baseline. During this period, patients were requested to stop their NSAID therapy and to restart the NSAID only if they experienced clinical deterioration. In this case, patients were asked to complete a diary. Analysis: The proposal of a meaningful change in symptomatic outcome measures was based on the 75th percentile technique. The 75thpercentiles of the change in the evaluated outcome measures between screening and re-starting NSAIDs were examined for the subgroup of patients who were able to stop NSAID therapy for at least 2 consecutive days and subsequently had to restart their NSAID therapy (i.e. those patients who flared). Evaluated outcome measures: The BASDAI score and each component of the BASDAI.

Results: Of the 128 screened patients, 91 (71.1%) had an available BASDAI at the screening visit and 45 (35.2 %) were able to stop their NSAID therapy for at least 2 consecutive days. Of these 45 patients, 32 optimally completed their diary the day they had to restart their NSAID. The table summarizes the observed values for the study variables at screening and flare (time of NSAID restarting) in these 32 patients.

			Changes from Screening to Flare	
Variable		**Screening**	**Absolute**	**Percentage**
BASDAI total score	Mean ± SD	5.8 ± 1.2	0.7 ± 1.2	13 ± 21
	(Median)	(5.8)	(0.8)	(14)
	75th Percentile [95% CI]		1.5 [1.2, 1.9]	28 [20, 38]
BASDAI question #1 (fatigue)	Mean ± SD	6.7 ± 1.6	0.8 ± 1.9	23 ± 54
	(Median)	(7.0)	(1.0)	(13.0)
	75th Percentile [95% CI]		2.0 [1.0, 3.0]	25 [17, 67]
BASDAI question #2 (axial)	Mean ± SD	6.6 ± 1.5	0.8 ± 1.6	16 ± 27
	(Median)	(7.0)	(1.0)	(14)
	75th Percentile [95% CI]		2.0 [2.0, 2.0]	33 [29, 43]
BASDAI question #3 (peripheral)	Mean ± SD	4.3 ± 2.8	0.1 ± 2.5	16 ± 80
	(Median)	(5.0)	(0.0)	(0)
	75th Percentile [95% CI]		2.0 [1.0, 3.0]	50 [13, 100]
BASDAI question #4 (enthesitis)	Mean ± SD	5.0 ± 2.3	0.9 ± 2.5	43 ± 128
	(Median)	(5.0)	(1.0)	(17)
	75th Percentile [95% CI]		2.0 [1.0, 3.0]	43 [25, 100]
BASDAI question #5/6 (morning stiffness)	Mean ± SD	6.5 ± 1.7	0.6 ± 1.3	12 ± 23
	(Median)	(6.5)	(0.5)	(7)
	75th Percentile [95% CI]		1.5 [1.0, 2.5]	27 [11, 43]

Conclusion: This study suggests that there is no universal change that is applicable to all variables. However, an absolute change of at least 2 on a scale of 10 or a relative change of 30% is indicative of a meaningful symptomatic deterioration for most of the symptomatic variables included in the BASDAI score.

Optimism Levels Are Moderate and Similar in Patients with Axial Spondyloarthritis and Chronic Low Back Pain, and Are Related to Mental Quality of Life but Not Physical Quality of Life. a Cross Sectional Study of 277 Patients. Sarah Kreis[1], Anna Molto[1], Florian Bailly[1], Sabrina Dadoun[2], Stephanie Fabre[3], Christophe Hudry[2], Franck Zenasni[4], Sylvie Rozenberg[1], Edouard Perthuiset[3], Bruno Fautrel[2] and Laure Gossec[2]. [1]Pitié-Salpêtrière Hospital, AP-HP, Rheumatology department, paris, France, [2]Sorbonne Universités, UPMC Univ Paris 06, GRC-08, Institut Pierre Louis d'Epidémiologie et de Santé Publique, paris, France, [3]Pontoise University Hospital, pontoise, France, [4]Institut de Psychologie, Laboratoire de Psychopathologie et Processus de Santé EA4057, Université Paris Descartes, Paris, France, Boulogne-Billancourt, France.

Background/Purpose: Axial Spondyloarthritis (AxSpA) and chronic low back pain (LBP) are very different chronic rheumatic diseases in terms of physiopathology and prognosis but both have a strong impact on patients' health-related quality of life (HRQoL). Dispositional optimism is defined as a stable personality trait consisting of a general positive mood or attitude about the future with a tendency to expect favorable outcomes in life situations. It has been shown in some chronic disease groups (e.g cancer) that dispositional optimism is related to both physical and psychological outcomes and seems to lead to better HRQoL. The objective of this study was to explore the relationship between optimism and HRQoL in both chronic diseases: AxSpA and LBP.

Methods: A cross-sectional study was performed in two tertiary care hospitals and two private practices in France. Patients were diagnosed with definite AxSpA or chronic LBP according to the rheumatologist. HRQoL was collected using a generic HRQoL questionnaire (Short Form, SF-12) with physical and mental composite scores (PCS and MCS respectively) and optimism was collected using the Life Orientation Test-revised (LOT-R) questionnaire. Analyses included descriptive statistics, non-parametric correlations and multiple regression analyses to study the effect of optimism on physical and mental HRQoL.

Results: In all, 277 patients (188 AxSpA and 89 LBP) were included: mean age, 47.3±11.9 years, 49.1% were males. BASDAI in AxSpA was 3.8±2.0 and the LBP patients' pain visual analog scale was 4.3±2.3. HRQoL was similarly altered in both diseases, for both physical and mental composite scores (mean PCS: 43.4±8.4 vs. 41.9±7.1; mean MCS: 45.7±7.9 vs. 46.7±8.1 for AxSpA and LBP respectively). Optimism was moderate and similar in both populations. Optimism was positively correlated to MCS in both diseases (r=0.57 vs. 0.54, for AxSpA and LBP respectively, both $p<0.0001$) and these relations persisted in multivariate analyses (beta=0.77 vs. 1.21, both $p<0.0001$).

Conclusion: Optimism was similar in these two chronic diseases and was an explanatory factor of mental HRQoL, but not physical HRQoL. Physical HRQoL may reflect more the disease process than character traits.

Helplessness in Coping Is Associated with Worse Patient Reported Outcomes Among Patients with Ankylosing Spondylitis: A Longitudinal Multi-Country Cohort Study. Walter P Maksymowych[1], Annelies Boonen[2], Helena Marzo-Ortega[3], Marina N. Magrey[4], Manish Mittal[5], Michael Halpern[6], Jeannette Renaud[6], Yanjun Bao[5] and Avani D. Joshi[5]. [1]University of Alberta, Edmonton, AB, [2]Maastricht University Medical Center, Maastricht, Netherlands, [3]LMBRU, Chapel Allerton Hospital, and University of Leeds, Leeds, United Kingdom, [4]Case Western Reserve University, MetroHealth Medical Center, Cleveland, OH, [5]AbbVie Inc., North Chicago, IL, [6]RTI International, Washington, DC.

Background/Purpose: Ankylosing spondylitis (AS) causes pain, joint damage and reduced function, which contribute to a substantial burden on affected patients and their families. A feeling of helplessness (self-perceived lack of control over the disease) can have an impact on coping[1,2]. We aimed to understand associations between helplessness in coping with AS and patient-reported outcomes, including depression, work productivity, disease activity, functional impairment and health-related quality of life (HRQoL).

Methods: A prospective Patient Reported Outcomes Survey of Employment in Patients with AS (PROSE-AS) was conducted at rheumatologists' clinical practice sites in Canada (n=234), the Netherlands (n=131), the

United Kingdom (n=144) and the United States (n=46). Patients ≥18 years of age completed surveys at baseline, 3, 6, 9 and 12 months. Helplessness was assessed using the helplessness subscale of the Rheumatology Attitudes Index (RAI; scale 5–25), and patients were stratified according to low (RAI <11), moderate (RAI 11–19) or high (RAI ≥20) helplessness for analysis[3]. Depression was assessed using the Center for Epidemiological Studies Depression (CES-D) scale. Work outcomes were assessed using the Work Productivity and Activity Impairment (WPAI) questionnaire. Disease activity and functional impairment were assessed using the Bath AS Disease Activity Index (BASDAI) and Bath AS Functional Index (BASFI) scales, respectively. HRQoL was assessed using the Physical Component Summary (PCS) and Mental Component Summary (MCS) of the Short Form 36 Health Survey (SF-36) and the AS Quality of Life (ASQoL) questionnaires. Associations between helplessness and outcome variables over time were analyzed using multivariable generalized estimating equations (GEE), with adjustment for baseline patient socio-demographics, disease characteristics, medication use and country.

Results: Mean AS duration among 553 patients was 13.9 years; 194 (35.1%), 317 (57.3%) and 42 (7.6%) were classified with low, moderate and high helplessness, respectively. Patients with moderate and high helplessness were significantly more likely than patients with low helplessness to be depressed, unemployed and exhibit overall work and activity impairment (**Table**). High helplessness was also significantly associated with greater clinical severity as measured by BASDAI and BASFI, and with greater HRQoL impairment as measured by ASQoL, SF-36 PCS and MCS scores, compared with low helplessness.

Association Between RAI Helplessness Category and Outcome Variables Over Time[a]

Outcome Variables (Categorical)	Moderate vs Low Helplessness (OR, 95% CI)	High vs Low Helplessness (OR, 95% CI)
CES-D (scale 0–60) (a) Depressed (≥16, n=182) vs Not Depressed (<16, n=371)	3.56 (2.72 to 4.64)	12.91 (8.20 to 20.32)
Work Status (a) Unemployed (n=177) vs Employed (n=376)	1.14 (0.99 to 1.33)	1.69 (1.30 to 2.21)
WPAI (a) Absenteeism (n=60) vs no absenteeism (n=312) (b) Presenteeism (n=287) vs no presenteeism (n=86) (c) Overall work impairment (n=286) vs no overall work impairment (n=83) (d) Activity impairment (n=317) vs no activity impairment (n=59)	3.41 (2.07 to 5.62) 2.49 (1.86 to 3.34) 2.54 (1.89 to 3.41) 2.93 (2.06 to 4.17)	5.16 (2.35 to 11.33) 4.57 (1.76 to 11.86) 4.65 (1.75 to 12.35) 4.46 (1.33 to 14.91)
Outcome Variables (Continuous)	**Moderate vs Low Helplessness (β, 95% CI)**	**High vs Low Helplessness (β, 95% CI)**
BASDAI Score (n=553, scale 0–10)	1.01 (0.85 to 1.16)	2.28 (1.98 to 2.58)
BASFI Score (n=552, scale 0–10)	0.88 (0.73 to 1.02)	2.01 (1.74 to 2.28)
SF-36 PCS Score (n=553, scale 0–100)	−4.40 (−5.04 to −3.75)	−8.31 (−9.56 to −7.07)
SF-36 MCS Score (n=553, scale 0–100)	−4.03 (−4.88 to −3.17)	−9.92 (−11.57 to −8.28)
ASQoL Score (n=552, scale 0–18)	2.77 (2.47 to 3.07)	5.34 (4.76 to 5.92)

[a]Adjusted for age, sex, race, country, education, comorbidities, NSAIDs, DMARDs, anti-TNF, and AS duration. CI, confidence interval; DMARD, disease-modifying antirheumatic drug; MCS, Mental Component Summary; OR, odds ratio; PCS, Physical Component Summary; β, regression coefficient

Conclusion: High helplessness in coping with AS was associated with depression, poor work productivity and employment outcomes, greater disease activity and functional impairment, and worse HRQoL. Helplessness should receive more attention in clinical care.

Clinical Characteristics of Nonradiographic Axial Spondyloarthritis in Korea: A Comparison with Ankylosing Spondylitis. Hyungjin Kim[1], Hyemin Jeong[2], Seulkee Lee[1], Inyoung Kim[1], Jiwon Hwang[3], Jaejoon Lee[2], Jinseok Kim[4], Eun-Mi Koh[2] and Hoon-Suk Cha[2]. [1]Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, South Korea, [2]Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, South Korea, [3]Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, South Korea, [4]Jeju National University Hospital, Jeju, South Korea.

Background/Purpose: To evaluate the clinical characteristics and outcomes of nonradiographic axial spondyloarthritis (nr-axSpA) in Korean patients.

Methods: A retrospective analysis evaluated 155 patients with nr-axSpA at a single tertiary hospital between January 2001 and January 2011. Baseline characteristics and clinical courses were reviewed and compared with those of patients with ankylosing spondylitis (AS).

Results: The mean age at disease onset was 29.5 ± 10.8 years, and 52 (33.5%) patients were female. The mean age at symptom onset was older (29.5 ± 10.8 vs. 25.9 ± 9.2, respectively, $p < 0.001$) and the male to female ratio was lower (2:1 vs. 5:1, respectively, $p = 0.001$) in patients with nr-axSpA compared with patients with AS. The proportion of females was higher among patients with late onset-SpA than early-onset nr-axSpA (55.0 vs. 30.1%, respectively, $p = 0.029$). Among 74 patients with nr-axSpA, whose follow-up duration was more than 1.5 years, 29 (39.2%) patients progressed to AS during the follow-up period. The proportion of females was lower in progressors that that of non-progressors (13.8 vs. 44.4%, respectively, $p = 0.010$). Presence of syndesmophyte and minimal X-ray changes at baseline were frequently observed in progressors compared with non-progressors (26.7 vs. 0.0 %, $p = 0.006$ and 69.0 vs. 35.6%, $p = 0.005$, respectively).

Conclusion: The predominance of male patients is more prominent among Korean patients with SpA compared with Caucasians. Female nr-axSpA patients had late symptom onset and less progression to AS. X-ray changes at baseline were associated with radiographic progression.

Blacks with As Have Greater Disease Severity Than Whites. Farokh Jamalyaria[1], Michael M. Ward[2], MinJae Lee[1], Lianne S. Gensler[3], Laura A. Diekman[4], Mohammad H. Rahbar[4], Amirali Tahanan[4], Shervin Assassi[1], Michael H. Weisman[5] and John D. Reveille[1]. [1]University of Texas Health Science Center at Houston, Houston, TX, [2]NIAMS/NIH, Bethesda, MD, [3]University of California, San Francisco, San Francisco, CA, [4]The University of Texas Health Science Center at Houston, Houston, TX, [5]Cedars-Sinai Medical Center, Los Angeles, CA.

Background/Purpose: To compare clinical parameters in African American (AA) patients with ankylosing spondylitis (AS) to white patients.

Methods: 539 AS patients (47 B, 492 W), meeting the modified New York criteria f enrolled in a longitudinal outcome study were assessed cross-sectionally at the baseline visit. Disease activity was defined by the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), functional outcomes by the Bath Ankylosing Spondylitis Functional Index (BASFI) and radiographic severity by the Bath Ankylosing Spondylitis Radiographic Index (BASRI) and the modified Stokes Ankylosing Spondylitis Scoring System (mSASSS). Univariable comparisons of clinical characteristics for African-American and White patients were done using Chi-square test and Student t test and their non-parametric counterparts when necessary in both cohorts. We compared the baseline BASRI total score for African-American and White patients by constructing multivariable mixed effect models to account for intra-family correlation (539 patients from 449 families). Possible confounders were examined by identifying variables that were significantly associated with race and effect modifications were also tested while developing a final multivariable model. Analyses were performed using SAS 9.3 (SAS Institute Inc, Cary, NC) at a statistical significance level of 0.05.

Results: Blacks had greater radiographic severity as seen by higher BASRI scores (9.12 versus 6.41, $p=0.0001$), greater functional impairment as measured by the BASFI (53.65 versus 31.94, $p=0.0001$) and higher disease activity as determined by the BASDAI (5.52 versus 4.11, $p=0.007$) compared to whites. There was no difference between disease duration or age. A significant interaction effect was found between race and disease duration. Table 1 shows the associations between baseline BASRI score and race at different levels of disease duration from the unadjusted and adjusted mixed effect model. Sex, B27+, study site and comorbidities (heart attack and diabetes) were adjusted in the final multivariable model. Subjective disease activity (BASDAI) and functional impairment (BASFI) were not included

because data for African-American subjects were missing n some subjects. BASRI scores for African-American subjects were higher than those for Whites and this association got stronger as disease duration increased in both unadjusted and adjusted models.

Table 1. Associations between Baseline BASRI Score and Race at Different Levels of Disease Duration

Outcome=BASRI	Disease Duration	Beta coefficient	SE	p
		unadjusted model		
Black vs. White	5 years	**1.2907**	**0.9859**	**0.2046**
	15 year	**2.5696**	**0.6331**	**0.0006**
	25 year	**3.8484**	**0.7087**	**<.0001**
	40 year	**5.7666**	**1.3842**	**0.0004**
		adjusted model		
Black vs. White	DD=5 year	**0.8247**	**1.0393**	**0.4408**
.DD=15 year		**1.923**	**0.7758**	**0.0265**
.DD=25 year		**3.0213**	**0.8555**	**0.0033**
.DD=40 year		**4.6688**	**1.4379**	**0.0058**
Male vs. Female			2.6606	0.3535	<.0001
B27+ vs. B27 -			0.07704	0.4337	0.8616
Heart attack vs. no			2.5047	0.9595	0.0206
Diabetes vs. no			1.5079	0.6768	0.0428

Conclusion: Although we cannot rule out the possibility that the more severely affected AA with AS are properly diagnosed and/or volunteer for study, these data confirm and extend prior subjective assessments of greater disease severity in African Americans using objective clinical and radiographic measurements and validated outcome tools.

Patients with Nr-Axspa Show a Statistically Higher Disease Burden in Clinical Practice Compared with Patients with Radiographic Axial Spa. Lennart TH Jacobsson[1], Tomas Husmark[2], Elke Theander[3], Kenneth Henriksson[4], Katharina Büsch[5] and Martin Johansson[5]. [1]Department of Rheumatology and Inflammation Research, Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden, [2]Falu Hospital, Falun, Sweden, [3]Skane University Hospital Malmö, Lund University, Malmö, Sweden, [4]Rheumatology city clinic, Stockholm, Sweden, Stockholm, Sweden, [5]AbbVie AB, Stockholm, Sweden, Stockholm, Sweden.

Background/Purpose: The ASAS axial SpA classification criteria was published in 2009 but so far there has been limited research on axial SpA patients in clinical practice. There is no diagnose code for non-radiographic axial SpA (nr-axSpA) and it is unclear which diagnosis these patients receive in clinical practice. Characterization of nr-axSpA patients in clinical practice is lacking in comparison with radiographic axial SpA (rad-axSpA). The aim of this study was to characterize patients with axial SpA in clinical practice and to investigate similarities/differences between radiographic and non-radiographic axial SpA.

Methods: This is a prospective, cross-sectional, multi-center cohort study from Sweden. SpA patients (diagnosed with Psoriatic Spondylitis (M07.2), Ankylosing Spondylitis (M45), Spinal entesopathy (M46.0), Sacroiliitis, not elsewhere classified (M46.1), Other specified inflammatory spondylopathies (M46.8), or Inflammatory spondylopathy, unspecified (M46.9)) were consecutively recruited from the clinical settings of the participating study centers. Patients were followed for three months via an online questionnaire. At baseline, the rheumatologist assessed the ASAS axial SpA criteria and registered information on disease history, extra articular manifestations, and treatments. The patients answered online questionnaires capturing patient demographics, disease activity and function (BASDAI, BASFI, HAQ-S, etc.), QoL (EQ-5D, AS-QoL), health care resource use, and work ability (WPAI). P-values, unadjusted for covariates, were calculated using chi-square tests for categorical variables and t-tests for continuous variables.

Results: 251 patients were included of whom 197 (78%) were classified as axial SpA. Of those, 125 (63%) were classified as rad-axSpA and 72 (37%) were classified as nr-axSpA according to the ASAS axial SpA criteria. The nr-axSpA patients were diagnosed with AS (35%), other specific inflammatory spondylopathies (31%), inflammatory spondylopathy unspecified (19%), psoriatic spondylitis (11%), and sacroilitis, not elsewhere classified (4%). Time between symptom onset and diagnosis was 9.0 (8.4) years for rad-axSpA and 6.7 (7.1) years for nr-axSpA. The nr-axSpA patients showed a higher disease burden compared with rad-axSpA patients, e.g. higher BASDAI (4.1 vs. 2.7), VAS global (4.3 vs. 2.9), VAS pain (4.4 vs. 2.9), and ASDAS(CRP) (2.3 vs. 1.9) (Table).

Variable	Radiographic Axial SpA N = 125	Non-radiographic Axial SpA N = 72	p-value
BASDAI, mean, n (%)	2.7 (65)	4.1 (61)	<0.001
BASDAI >4.0, %, n (%)	28 (65)	55 (61)	0.004
BASFI, mean, n (%)	2.5 (65)	3.0 (61)	0.29
VAS global, mean, n (%)	2.9 (65)	4.3 (61)	0.006
VAS pain, mean, n (%)	2.9 (65)	4.4 (61)	0.003
ASDAS CRP, mean, n (%)	1.9 (58)	2.3 (57)	0.03
ASDAS ESR, mean, n (%)	1.8 (58)	2.3 (56)	0.007
Current NSAID use, %, n (%)	60 (100)	71 (100)	0.13
Current MTX or SSZ use, %, n (%)	28 (100)	22 (100)	0.37
Current anti-TNF use, %, n (%)	50 (100)	40 (100)	0.17

Conclusion: In this study, from Swedish clinical practice, we included patients from rheumatology clinics with pre-specified diagnoses most likely to be classified as axial SpA. The results show that the nr-axSpA patients have a statistically higher burden of disease than patients with rad-axSpA.

Factors Associated with a Poor Functional Prognosis in Early Inflammatory Back Pain: Results from the DESIR Cohort. Cédric Lukas[1], Maxime Dougados[2] and Bernard Combe[1]. [1]Hopital Lapeyronie, Montpellier, France, [2]Descartes University, Cochin Hospital, Paris, France.

Background/Purpose: Spondyloarthritis is a heterogeneous disease, with various and hardly predictable potential courses. We aimed at determining prognostic factors of a bad functional outcome at 2 years in patients with early inflammatory back pain.

Methods: Data from patients included in the French multicenter DESIR cohort, i.e. suffering from inflammatory back pain (IBP) starting before 50 years of age and lasting for between 3 months and 3 years, were used in this work. A bad functional outcome was defined as an increase in BASFI superior to 75th percentile of observed progression in the cohort from inclusion visit to 24-months assessment, or a BASFI at 2 years higher than 75th percentile at this latter timepoint. Demographic, clinical, biological andradiological data collected at inclusion were compared in patients with bad functional outcome versus others, first by Chi2 test (numeric data were dichotomized according to observed median values), then by multivariate logistic regression model with stepwise selection of relevant factors.

Results: 513 patients (54.4% females, mean age 34±8.8 years, 72.2% fulfilling ASAS criteria) were assessed. Of those, 130 (25.3%) fulfilled the aforementioned criteria of a bad functional outcome (with BASFI increase of at least 4 units or value at 2 years ≥6). A bad outcome was more frequently observed in "older" patients aged over 33 years at disease onset, or with educational level lower than college (both $p<0.0001$). Smoking patients ($p<0.001$) and female patients ($p<0.008$) also had more frequently an unfavourable course of disease. Patients not fulfilling ASAS criteria, having negative X-Rays or MRI of sacroiliac joints, with a history or active peripheral arthritis were also more prone to have poor functional outcome (all $p<0.05$). A high disease activity at baseline (ASDASCRP >3.5 and BASDAI >45) was also associated with a bad functional evolution ($p<0.0001$). Multivariate analysis revealed that not fulfilling ASAS criteria, a female sex, an age >33 years, a lower educational level, an active smoking status and a high disease activity according to BASDAI at baseline were independently associated with a bad functional outcome at 24 months follow-up (Table).

Factors associated with a bad functional outcome at 24 months

	OR [95% confidence interval]	p
ASAS criteria fulfilled	0.59 [0.34–0.99]	0.049
Female sex	1.94 [1.16–3.23]	0.012
Age>33 years	2.27 [1.37–3.77]	0.002
Education > college	0.33 [0.20–0.55]	0.0001
Active smoking	3.20 [1.89–5.39]	0.0001
Baseline BASDAI>45	3.74 [2.21–6.32]	0.0001

Conclusion: We confirmed, in a large prospective cohort of early IBP patients, bad prognostic factors formerly described in ankylosing spondylitis, especially a low educational level, a (relatively) older age and a high disease

activity at onset, and revealed that an active smoking status was also independently associated with a poor outcome. Fulfilment of ASAS criteria on the other hand was predictive of a better outcome, likely due to more consensual management of a defined disease. Female sex however, usually regarded as a protective factor in AS, was related with a (self-assessed) poorer functional outcome after 2 years of follow-up.

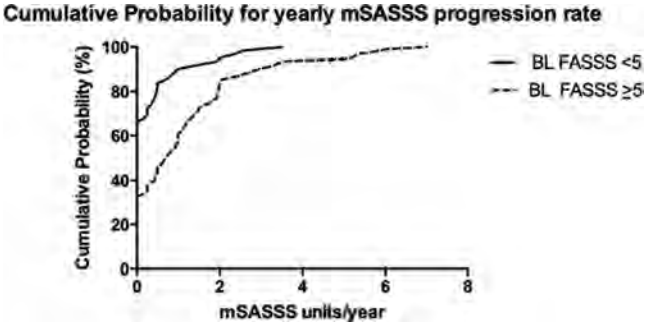
The Fat Spondyloarthritis Spine Score (FASSS) Independently Predicts Radiographic Progression in Patients with Ankylosing Spondylitis. Susanne Juhl Pedersen[1], Stephanie Wichuk[2], Praveena Chiowchanwisawakit[3], Zheng Zhao[4], Robert GW Lambert[2] and Walter P. Maksymowych[2]. [1]Copenhagen University Hospital at Glostrup, Copenhagen, Denmark, [2]University of Alberta, Edmonton, AB, [3]Mahidol University, Bangkok, Thailand, [4]PLA General Hospital, Beijing, China.

The Fat Spondyloarthritis Spine Score (FASSS) independently predicts radiographic progression in patients with ankylosing spondylitis.

Background/Purpose: Vertebral corner fat lesions have been shown to be associated with later development of new syndesmophytes in the same vertebral corners[1,2]. The aim of this study was to investigate the association between fat lesions and radiographic progression at the patient level using the novel Fat Spondyloarthritis Spine Score (FASSS)[3]. This could lead to an important target for therapeutic intervention.

Methods: 157 patients with AS (N (%) male sex: 121 (77%); receiving TNFα inhibitor: 93 (59%); mean (SD) age: 39.4 (11.7); symptom duration: 15.9 (10.2)) had MRIs and X-rays performed with a mean (SD) follow-up of 2.3 (0.7) years and 2.2 (0.68) years. Status and change in fat lesions were assessed with FASSS and radiographic progression with the modified Stoke AS Spine Score (mSASSS). Two readers independently read MRIs scans and radiographs, and an adjudicator re-assessed discrepant cases according to pre-specified rules. Multivariate stepwise regression analysis included variables significant in univariate analyses (age, sex, symptom duration, baseline CRP, baseline mSASSS) and treatment.

Results: When mSASSS progression was dichotomized (mSASSS progression yes/no), baseline FASSS scores were significantly higher in the progression group as compared to the non-progression group (20.0 (21.6) vs. 12.9 (22.5), $p<0.001$). When a pre-specified FASSS cut-off of 5 was used, which has been suggested as a definition of a "positive spine MRI"[4], higher rates of radiographic progression were seen in patients with score ≥ 5 vs. <5 (1.19 (1.52) vs 0.34 (0.72), $p<0.001$). In the regression analyses baseline FASSS score was the only independent predictor of radiographic progression ($\beta=0.008$, $p=0.0004$). Figure 1 shows patients with a baseline FASSS scores ≥ 5 had a higher cumulative probability of radiographic progression.



Conclusion: A positive spine MRI for fat assessed with FASSS, and the degree of spinal fat are significantly associated with radiographic progression in patients with AS.

Clinical and Psychological Correlates of Sleep Difficulties in Patients with Spondyloarthropathies Compared to Patients with Rheumatoid Arthritis. Konstantinos Kotsis[1], Thomas Hyphantis[2], Paraskevi V. Voulgari[3], Andre F. Carvalho[4] and Alexandros A. Drosos[5]. [1]Department of Psychiatry, Medical School, University of Ioannina, 45110, Ioannina, Greece., Ioannina, Greece, [2]Department of Psychiatry, Medical School, University of Ioannina, Ioannina 45110, Greece., Ioannina, Greece, [3]Associate Professor of Rheumatology, Ioannina, Greece, [4]Department of Clinical Medicine, Faculty of Medicine, Federal University of Ceará, Fortaleza, Ceará, Brazil., Fortaleza, Brazil, [5]Professor of Medicine/Rheumatology, Ioannina, Greece.

Background/Purpose: Sleep difficulties are common in patients with rheumatological disorders. Patients with Rheumatoid Arthritis (RA) report frequently poor quality sleep, numerous night awakening and difficulty falling asleep; complaints of patients with Spondyloarthropathies (SpA) often include poor sleep quality, sleep-onset insomnia and difficulty awakening. The aim of the present study was to test whether the clinical and psychological factors associated with sleep difficulties are different in patients with SpAs compared to RA patients.

Methods: In 138 consecutive SpA patients (55 with Ankylosing Spondylitis (AS) and 83 with Psoriatic Arthritis) we assessed disease's parameters, pain, depressive symptom severity (PHQ-9), Illness Perceptions (B-IPQ) and sleep difficulties (SCL-90-R). One hundred and ninety-nine consecutive RA patients served as disease control group. Multiple regression models determined the associations of clinical and psychological variables with sleep difficulties separately for each disease-group.

Results: SpA patients reported more waking up early in the morning ($p=0.012$) and less difficulties in falling asleep ($p<0.001$) and restless sleep ($p=0.002$) compared to RA patients. Depressive symptoms were associated with sleep difficulties in both disease-groups. In RA, older age ($p=0.038$) and female gender ($p=0.016$) were associated with more difficulties in falling asleep; female gender was correlated with waking up early in the morning ($p=0.028$), and disease activity, as measured by the DAS-28, was associated with restless sleep ($p=0.004$). However, pain was associated with troubles falling asleep ($p=0.009$) and sleep restlessness ($p<0.001$) only in patients with SpA. In addition, in patients with SpA, the higher the number of bodily symptoms attributed to the illness (illness identity), the greater the waking up early in the morning ($p=0.05$).

Conclusion: Apart from early recognition and treatment of depressive symptoms in both SpA and RA, addressing pain issues should be considered a priority in patients with SpA, as axial pain and stiffness in the latter half of the night are an important characteristic of the inflammatory back pain in those patients with AS, resulting in sleep disturbances, as the present findings showed. Attention to patients' illness perceptions and their concerns about numerous bodily symptoms attributed to the illness may also enable rheumatologists to identify and manage treatable aspects of sleep difficulties in patients with SpA.

The Clinimetric Outcomes of Two Bath Ankylosing Spondyltis Metrology Indices in Treatment with TNF-á Blockers. Eon Jeong Nam[1], Jeong Soo Eun[1], Sang Hoon Kwon[1] and Young Mo Kang[2]. [1]Kyungpook National University School of Medicine, Daegu, South Korea, [2]Kyungpook National Univ Hosp, Daegu, South Korea.

Background/Purpose: Bath Ankylosing Spondyltis Metrology Index (BASMI) was developed to quantify the accurate axial status and to assess the clinical changes in spinal movement. The original BASMI was a 3-point scale (range 0–2; $BASMI_2$), which was refined to an 11-point scale, $BASMI_{10}$ (range 0–10) to increase the sensitivity to changes of axial status in ankylosing spondylitis (AS). In this study, we compared these BASMI scoring methods in AS patients who were treated with TNF-α blockers.

Methods: A retrospective study was conducted in a total of 116 patients who were treated with TNF-α blockers (137 cases; 96 patients with single agent, 19 patients with two, and 1 patient with three). Clinical efficacy was assessed using Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), ASAS20, ASAS40, ASAS5/6, BASDAI50, and acute phase reactants including ESR and CRP at baseline and month 3, and then every six months up to 27 months. Metrology outcome was also evaluated by chest expansion, $BASMI_2$ and $BASMI_{10}$ methods at the same time.

Results: Three TNF-α blockers including etanercept (60 cases), adalimumab (62 cases), and infliximab (15 cases) showed a similar clinical efficacy. ASAS20 response rate was 87.3%, 91.3%, 91.9%, 90.3%, and 90.9% at months 3, 9, 15, 21, and 27, respectively. ASAS20 responders at month 3 (3MoASAS20) showed a significant improvement of $BASMI_2$ and $BASMI_{10}$ scores and chest expansion, compared to those of baseline, while 3MoASAS20 non-responders did not show a significant change until month 27. $BASMI_2$ scores at baseline and months 3, 9, 15, 21, and 27, were not significant different from those of $BASMI_{10}$ scores at the same time points. Both $BASMI_2$ and $BASMI_{10}$ scores were significantly correlated with components of ASAS20 response criteria including Bath Ankylosing Spondylitis Functional Index (BASFI), BASDAI-spinal inflammation (BASDAI-SI), patient's global assessment, and pain. The change of $BASMI_2$ and $BASMI_{10}$ in 3MoASAS responders was most prominent from baseline to month 3, but still significant from month 3 to month 9. The change of lumbar flexion and lumbar side flexion components of both $BASMI_2$ and $BASMI_{10}$ in 3MoASAS20 responders were statistically significant until month 9, while that of other components was only significant until month 3. The improvement of both $BASMI_2$ and $BASMI_{10}$ was significantly associated with changes of BASDAI-SI, BASFI, and pain at month 3, 9, 15, 21, and 27.

Conclusion: The $BASMI_2$ method showed similar sensitivity to changes in range of axial motion in patients with AS who were treated with TNF-α blockers. Further studies are required to determine whether $BASMI_2$ method is as sensitive as $BASMI_{10}$ method for assessment of axial involvement in AS patient with TNF-α blocker treatment.

Do Bone Marrow Edema Lesions in the Sacroiliac Joint Change into Fatty Lesions over a 1-Year Period in Patients with Axial Spondyloarthritis or Possible Spondyloarthritis. Pauline Bakker[1], Rosaline van den Berg[1], Manouk de Hooge[1], Floris van Gaalen[1], Monique Reijnierse[1], T.W.J. Huizinga[1] and Désirée van der Heijde[2]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]Diakonhjemmet Hospital, Oslo, Norway.

Background/Purpose: Bone marrow edema (BME) lesions in the sacroiliac joint (SIJ) may change into fatty lesions over time. Fatty lesions are regarded as the earliest sign of chronic changes as a consequence of inflammation but are sometimes also found healthy controls.[1] At the moment, there is little information on the course over time in patients without treatment of TNF-inhibitors. The aim is to investigate whether BME lesions in the sacroiliac joint change into fatty lesions over 1 year time in patients with axial SpondyloArthritis (axSpA) or possible SpA and to evaluate the volatility of both lesions general.

Methods: Patients in the SPACE cohort (back pain: $\geq$ 3 months, $\leq$ 2 years, onset $<$ 45 years) with (suspicion of) axSpA underwent MRI of the SIJ at baseline and 1-year follow-up (n=76). MRIs were scored independently by 3 well-calibrated readers, blinded for time sequence and patient characteristics (STIR and MRI T1-weighted sequences viewed simultaneously). The presence of BME and fatty lesions was scored. Both lesions were defined present if 1 lesion was seen on $\geq$2 consecutive slices or if $>$1 lesion was seen on a single slice and scored in 4 quadrants per SI joint. For the two readers individually, scores of baseline and 1 year were compared on quadrant level (Q). The sum of all 8 Qs was calculated to obtain total scores per patient.

Results: 76 patients were completed in the analyses (number of Q=608); of which 39 (51%) were classified axSpA at baseline (ASAS classification criteria), and 37 (49%) as possible SpA. BME or fatty lesions at any time point was found in 27/76 (36%) and 20/76 (26%) patients respectively (reader 1, reader 2). Reader 1 indicated no lesions at baseline or follow-up in 519/608 Qs (85%) and in 45/608 Qs (7%) a change in lesions was visible (new lesions occurred, former lesions disappeared or the type of lesions changed over time). Similar trends were visible amongst the two readers (table). In both readers, fatty lesions newly occurred in 8/76 patients (11%) over 1 year time with agreement on 5 patients. In 3 patients, a transition of BME to fat occurred. On the other hand, fatty lesions disappeared in 2/76 patients (3%, reader 1) and in 5/76 patients (7%, reader 2). In reader 2, concomitant occurrence and disappearance of fatty lesions was observed in 2/76 (3%) of patients. In reader 1, this was not seen.

Conclusion: About one third of the patients showed BME/fatty lesions in the SIJ at any time point. There was not much change in site and/or type of lesions visible over 1-year period of time. Fatty lesions occurred more frequently de novo than in quadrants with previous BME and fatty lesions and can also resolve over time. The incremental value of fatty lesions in the SIJ needs to be further re-evaluated.

Radiographic Sacroiliitis Progression in an Early Axial Spondyloarthritis Cohort. Concepcion Castillo-Gallego[1], Jesus Sanz[2], Carmen Martin-Hervas[3], Mireia Moreno[4], Victoria Navarro-Compán[5], Diana Peiteado[1], Jorge Gratacos-Masmitja[6], Eugenio De Miguel[7] and Emilio Martín-Mola[1]. [1]Hospital La Paz - IdiPaz, Madrid, Spain, [2]Hospital Puerta de Hierro Majadahonda, Madrid, Spain, [3]Hospital Universitario La Paz, Madrid, Spain, [4]University Hospital Parc Taulí, Sabadell, Spain, [5]Rheumatologist, Madrid, Spain, [6]Hospital Parc Tauli, Sabadell, Spain, [7]Department of Rheumatology, Hospital Universitario La Paz, Madrid, Spain.

Background/Purpose: The current concept of axial Spondyloarhtritis (axSpA) considers non-radiographic axSpA (nr-axSpA) and Ankylosing Spondylitis (AS) as two stages of one disease. There are limited data available regarding rate of radiographic progression of the sacroiliac joints (SIJ) and the rate of transition from nr-axSpA to AS. The aim of the current study was to investigate radiographic progression in the SIJ in an early axSpA cohort.

Methods: Patients included in the study came from an early SpA cohort, from three centers of the ESPERANZA programme, a Spanish nationwide health management programme designed to provide excellence in care for early SpA. One of the inclusion criteria was symptom duration between 3 and 24 months. Every patient had a complete examination at baseline that included ESR, CRP, ASDAS-CRP, ASDAS-ESR, BASDAI, HLA-B27, pelvis x-Rays and Magnetic resonance (MRI) of SIJ. Pelvis x-Rays at baseline and at follow up were performed for every patient. These x-Rays were centrally digitized, anonymised and the SIJ were scored independently by two trained readers, according to the grading system of the modified New York criteria (mNYc). The readers scored images of both time points randomly and were blinded for all clinical data. MRI of SIJ were assessed independently and blinded by two trained readers, according to ASAS definition for bone marrow oedema (BME). Descriptive analysis was performed using SPSS program v.21.0. Cohen's kappa coefficients were also calculated to assess agreement between the two readers (mNYc for x-Rays and ASAS definition for a positive MRI).

Results: Forty four patients (52% male) were included. Mean age was 34.4 years (range: 21–45) and 52.3% were HLA-B27 positive. Mean time since symptoms onset until baseline visit was 10.4 months (range: 3–24). Mean (SD) follow up period (between baseline x-Ray and last follow up x-Ray) was 3.6 (1.4) years (median 4 years). All patients fulfilled ASAS criteria for axSpA and 16 of them had AS according to mNYc at baseline, in the opinion of both readers. Interobserver agreement for the x-Ray reading at baseline visit (44 x-Rays) was at the limit between moderate and good (kappa 0.62), but it increased to very good agreement (kappa 0.90) at the x-Rays reading corresponding to the follow-up visit. Regarding MRI, data from 27 images were available for analysis and the kappa value for the ASAS definition of BME was 0.76 at baseline. Progression of sacroiliitis over follow up period by at least one grade at one side was found in 43.2% (19/44), in the opinion of both readers. Among the 28 nr-axSpA patients at baseline, 3 of them (11%) progressed to AS according to NYmc in the opinion of both readers. We also analyzed the possible association between all variables

collected at baseline with radiographic progression but we did not find any statistically significant association for any of them.

Conclusion: Progression of radiographic sacroiliitis by at least one grade after a mean time of follow-up of 3.6 years occurs in almost half of the patients. The rate of progression from nrax-SpA to AS was 11%. The inter-reader reliability of pelvis x-Ray improves as disease progresses. Regarding to these results, pelvis x-Ray has a limited utility at early stages of axSpA.

Monte Naranco, Oviedo, Spain, [18]Complexo Hospitalario de Ourense, Ourense, Spain, [19]Hospital Reina Sofía, Córdoba, Spain, [20]Abbvie, Madrid, Spain.

Background/Purpose: The ASDAS (ankylosing spondylitis disease activity score) was developed to overcome some of the deficiencies of BASDAI (Bath Ankylosing Disease Activity Spondyltis Index). In this prospective study merits of both scores are compared.

Methods: Patients with AS according to mNY criteria and BASDAI≥4 were enrolled at 23 Spanish centers and followed during 1 year. Follow-up visits were scheduled every 4 months. Physical examination, CRP and ESR, Patient Global disease activity visual analogue scale (PG-VAS), pain due to AS (VAS), BASDAI, BASMI, BASFI, ASDAS, patient acceptable symptom state (PASS), SF-36, ASQoL, work productivity and activity impairment (WPAI) questionnaire data were recorded at each visit.

Results: A total of 127 evaluable patients, 75.6% men, with median age of 48 years and median time from diagnosis of 10 years, were recruited. *Criterion validity*: across follow-up correlations between ASDAS and PG-VAS ranged from 0.560 to 0.736, and from 0.758 to 0.840 between BASDAI and PG-VAS. *Convergent validity*: ASDAS correlation with BASDAI (0.733 to 0.781), BASMI (0.275 to 0.552), BASFI (0.476 to 0.591), lumbar pain VAS, (0.691 to 0.702) and lumbar night pain VAS (0.648 to 0.702) were found. *Discriminant validity*: mean ASDAS and mean BASDAI were significantly higher in patients with non-acceptable PASS than in patients with acceptable PASS. Patients below median PG-VAS showed significantly lower mean ASDAS and BASDAI than patients above median PG-VAS. ASDAS, but not BASDAI, distinguishes between patients below and above median CRP. Patients in different ASDAS categories showed significant differences in CRP, PG-VAS, BASMI, BASDAI, BASFI and pain VAS across follow-up, but significant differences in TJC and SJC were not found at any visit. *Sensitivity to change*: significant reductions in mean ASDAS and BASDAI were observed in patients changing from non acceptable PASS at baseline to acceptable PASS across the follow-up, and a significant proportion of patients had a reduction in disease activity level according to their ASDAS categories. ASDAS was sensitive to patients achieving a 50% reduction in BASDAI. Concerning treatments, ASDAS and BASDAI were sensitive to changes in PASS in patients treated with biological therapies, but only BASDAI was sensitive to changes in patients treated with DMARDs. An inverse relationship was detected between ASDAS and physical and mental subscales of SF36, and changes in ASDAS were significantly related with changes in ASQoL. Concerning WPAI, the work time missed increased as ASDAS score increased.

Conclusion: ASDAS has shown good metric properties in patients with AS, performing as well as BASDAI, but with higher sensitivity to inflammatory signs. Patients' quality of life and impairment of productive activity are associated with ASDAS scores.

Inflammatory Burden in Recent-Onset Axial Spondyloarthritis. Juan Jose Aznar Sánchez, Raul Veroz Gonzalez, Adela Gallego Flores, Tamara Libertad Rodriguez Araya, Piter José Cossio Jimenez and Eugenio Chamizo Carmona. Hospital de Mérida, Mérida, Spain.

Background/Purpose: Patients with Non-Radiographic Axial Spondylarthritis (non-Rx AxSpA) don't presnt with different clinical manifestations than patients with Ankilosing Spondylitis (AS), although the inflammatory burden measured by ASDAS and CPR is higher in the latter. Stydies have still yet to discover any difference in inflammatory burden between patients with non-Rx SpA classified by ASAS criteria by the pathway of imaging (active inflammatory lesions in sacroiliac joints detected by MRI) and that classified by the clinical pathway (HLA-B27). The aim of this study is to analyze the clinical characteristics and the inflammatory burden of patients classified of Axial Spondylorarthritis (AxSpA) by ASAS criteria attended in recent-onset Spondyloarthritis Unit (RSpAU).

Methods: We included adult patients younger than 45 years old attended the RSpAU of the General Hospital in Mérida (Spain) between May 2008 and May 2014 with inflammatory low back pain more than 3 months and less than 2 years, asymmetric arthritis and/or mechanical low back pain/arthralgias accompanied by, at least, one of the following: psoriasis, uveitis, inflammatory bowel disease (IBD), entesytis, sacroiliitis on imaging, HLA-B27(+) or familiy history of SpA. Patients with previous diagnosis of SpA were however excluded.

Results: We studied 132 patients, 36 patients fulfilled ASAS criteria for SpA. Of this group, 8 patients fulfilled NY criteria for EA, and 28 were diagnosed with non-Rx SpA. Of the patients with non-Rx SpA, 16 entered through the clinical pathway (HLA-B27) and 12 through the pathway of imaging (MRI of sacroiliac joints with active inflammatory lesions or bone marrow edema). The age at the diagnosis was 29.5 year for both EA and non-Rx SpA. In the group of non-Rx SpA we found female predominance (16 women/12 men), in particular in the group with MRI positive and HLA-B27 negative (4 women/2 men). The measures of BASDAI and BASFI indexes were higher in the group of non-Rx SpA, but without stadistically significance. In patients with non-Rx SpA, the medium level of CRP was higher in patients with positive MRI than patients that entered by the clinical pathway, but without sadistically significance.

Conclusion: In the non-Rx SpA there is a female predominance and a lower rate of HLA B27 (+) than in radiological EA. We didn't find any significant differences in the indexes used to measure the inflammatory burden between both groups. There is a trend to higher inflammatory burden measured by CRP and ASDAS in EA than in non-Rx SpA and in the last group, higher in patients with active inflammatory lesions in sacroiliac joints by MRI.

Anti-Drug Antibodies As a Predictor for the Discontinuation of Anti-TNF Agents in Patients with Spondyloarthrtis. Jiwon Hwang, In young Kim, Seulkee Lee, Hyemin Jeong, Hyungjin Kim, Jaejoon Lee, Eun-mi Koh and Hoon-Suk Cha. Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, South Korea.

Background/Purpose: Tumor necrosis factor (TNF) blocking agent has shown to be effective in patients with axial spondyloarthritis (SpA) including ankylosing spondylitis (AS) as up to 60–70%. However, the other 30–40% of patients fails to respond. This non-responsiveness to TNF blocking agent has been suggested as the result of the development of antibodies against it, anti-drug antibodies (ADA), which have been described well in patients with rheumatoid arthritis and Crohn's disease. The aim is to assess whether ADA is related to the clinical efficacy in SpA patients on anti-TNF agents.

Methods: According to the Assessment of SpondyloArthritis international Society (ASAS) classification criteria for axial SpA, consecutive patients were recruited at a single tertiary hospital who received treatment with adalimumab (Ada) or infliximab (Ifx): 86 AS, 11 inflammatory bowel disease associated SpA, 3 psoriatic SpA and 2 undifferentiated SpA. Serum samples were collected at the enrolment for the drug and ADA levels, which were measured by ELISA. Disease activity was assessed by the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) at baseline (at the beginning of the current anti-TNF agents), at 3 month and then every 6 months. The reactivation of tuberculosis infections, side-effects or infusion reactions, and the cause for discontinuation of therapy were assessed prospectively.

Results: A total of 102 patients were studied (89.2% male; mean age at sampling 35.2 $\pm$ 18.0 years; mean disease duration 11.3 $\pm$ 7.9 years). HLA-B27 was positive in 65 of 76 patients (85.5%). Among 102 patients, 74 were treated with Ada and 28 with Ifx. Eighteen patients (17.6%) had switched from other kinds of anti-TNF agents including Ada, Ifx and etanercept. Latent tuberculosis (TB) infection was detected in 22 patients (21.6%) before starting anti-TNF agents and the treatment regimen with isoniazid and rifampin was commenced by a TB expert. ADA was demonstrated in 8 patients (7.8%) (5 of Ada and 3 of Ifx) and all of them were anti-TNF naïve patients. Patients who developed ADA had lower levels of the corresponding drugs (Ada level: 0.45 $\pm$ 0.68 vs 4.42 $\pm$ 2.12, $p < 0.0001$; Ifx level 0.91 $\pm$ 1.36 vs 3.38 $\pm$ 2.24, $p = 0.076$). At baseline, no differences in BASDAI were found in patients with or without ADA, and neither ESR nor CRP was different. The median period under prospective observation was 15 months (range 0 – 17, mean 12.7 $\pm$ 7.8). ADA-positive patients had a significantly higher cumulative drug discontinuation rate due to inefficacy and adverse events (37.5% vs 6.4%, $p = 0.022$). There was no reactivation of tuberculosis during anti-TNF treatment.

Conclusion: Our result suggests that in SpA patients the presence of ADA to current Ada or Ifx can predict the drug discontinuation in future due to inefficacy or adverse events.

Is There Any Gender Specific Difference in the Cut Off Values of Ankylosing Spondylitis Disease Activity Score (ASDAS) in Patients with Axial Spondyloarthritis? Erkan Kilic, Gamze Kilic and Salih Ozgocmen. Erciyes University, Faculty of Medicine, Kayseri, Turkey.

Background/Purpose: Axial spondyloarthritis (ax-SpA) consisted patients with advanced axial SpA or ankylosing spondylitis (AS) and non-radiographic axial SpA (nr-axSpA). Evaluation of disease activity in axSpA is complex due to the phenotypic heterogeneity of the disease. Assessment in Spondyloarthritis international Society (ASAS) endorsed the cut off values for ASDAS-CRP. The aim of this study was to assess the validity of AS Disease Activity Score (ASDAS)-CRP and ASDAS-ESR as clinical tools for assessing disease activity in axSpA and to estimate the cut-off values of ASDAS-CRP and ASDAS-ESR for male and female patients with axSpA.

Methods: Patients with axSpA were recruited from Erciyes Spondyloarthritis Cohort (ESPAC) and assessed for BASDAI, ASDAS, BASFI, BASMI, Ankylosing Spondylitis Quality of Life (ASQoL), and VAS-pain. Patients were grouped into low and high disease activity according to the physician's (DrG) and patient's global (PtG) assessment score (>6/10 vs <4/10), ASAS partial remission criteria, treatments and presence of peripheral arthritis. The discriminant ability of ASDAS-CRP and ASDAS-ESR was assessed using standardized mean differences. Receiver operating characteristic (ROC) curves were used for comparisons. Optimal cut-off values of ASDAS-CRP and ESR were calculated for both genders and for the whole group.

Results: Three hundred fifty-eight patients with axSpA (138 F, 220 M) were included in this study. One hundred sixty two patients met criteria for non-radiographic axSpA (nr-axSpA) and 196 for ankylosing spondylitis. Two ASDAS versions and BASDAI had good correlations with PtG and DrG in both groups, however correlation coefficients were relatively higher in men. Women had significantly higher VAS-pain, BASDAI item scores, PG and DrG and ESR. Discriminant ability of ASDAS-CRP, ASDAS-ESR and BASDAI were similar in men and women when patients were assigned into low and high disease activity based on the ASAS partial remission, PtG and DrG scores (assessed by comparing AUC of ROC curves). ASDAS cut-off values are quite similar in all groups indicating that ASDAS-CRP works similarly well in male and female patients with axSpA. The calculated ASDAS-CRP cut-offs in both genders were very similar to predefined values by ASAS except the cut off for in-active to moderate disease activity. The cut-off values for ASDAS-ESR seem to be lower than predefined values and women tent to have higher cut-offs compared to males.

Conclusion: The construct validity of ASDAS-CRP to discriminate low and high disease activity and cut off values are similar in male and female patients with axSpA, however cut offs for ASDAS-ESR need to be redefined.

	ASDAS-CRP			ASDAS-ESR		
	In-active-moderate	Moderate-High	High-Very high	In-active-moderate	Moderate-High	High-Very high

Differing Patterns of Axial Spondyloarthritis in Females and Males. Ibrahim Almaghlouth[1], Arane Thava[1], Nigil Haroon[2] and Robert D. Inman[3]. [1]Toronto Western Hospital, Toronto, ON, [2]Toronto Western Research Institute, Toronto, ON, [3]Department of Medicine, University of Toronto, Toronto, ON.

Background/Purpose: Sex effects have been noted in axial spondyloarthritis (AS) however controversy still exists regarding male and female clinical manifestations of AS. This includes uncertainty regarding pattern of spinal disease, peripheral joint involvement, and clinical burden of disease. Prior studies have often been limited by numbers and lack of contemporaneous comparators. In this study we examine sex effects on a longitudinal observation cohort of AS.

Methods: A systematic review of 950 AS patients (671 male and 279 female) followed in a longitudinal clinic which entails regular clinic visits using a standardized protocol. Patients were stratified by sex. Descriptive characteristics using means (sd) and frequencies (%) can be seen in Table 1. Tests were used to compare continuous variables and Chi-Squared tests for categorical variables. P-value <0.05 was used to define statistical significance.

Results: We observed that age of onset of back pain was higher in females, and that there was a significant longer delay in diagnosis in females. CRP levels were lower among female patients. This finding parallels previous reports of lower CRP among female with non-radiographic axSpA. We noticed no difference between both sex in terms of affected joints, nor with respect to key extra-articular manifestations (iritis, psoriasis, inflammatory bowel disease). Significant differences in BASMI indicate less impairment of spinal mobility, which may reflect both lower levels of CRP and lower rates of smoking, both of which have been previously associated with structural progression of AS. The use of biologic agents as a surrogate marker of symptomatic burden of disease did not differ between females and males but comparative ASQOL scores reflected greater impact on quality of life in females.

Conclusion: Our large cohort documents later onset of AS symptoms and longer delay in diagnosis in female AS patients compared with males. Difference in inflammatory markers might be a reflection of different disease pathogenesis but environmental factors such as smoking also contribute to the difference in clinical expression of the disease.

TABLE 1: Comparison of Baseline Demographic and Disease Characteristics by Sex (n=950)

	Frequency (%) or Mean(sd)		
Variable	Males n=671	Females n=279	p-value
Age	38.2 (14.1)	37.5 (12.3)	0.45
Age at Joint Pain	23.6 (11.3)	25.8 (11.8)	0.02
Age at Back Pain	24.0 (10.2)	25.7 (10.7)	0.03

Age at diagnosis of AS	29.7 (12.2)	32.2 (11.2)	0.004
Duration of AS	14.5 (11.8)	12.1 (10.6)	0.002
Ever smoked (Yes)	283 (42.2%)	85 (30.5%)	0.0007
Employment status	332 (61.9%)	153 (62.2%)	<0.0001

Combined Hip Abduction Angle Measured By Using Iphone Compass Application; A Novel Measurement Tool to Asses Hip Mobility. Handan Yarkan, Berrin Zengin, Gokce Kenar, Pinar Cetin, Ismail Sari, Fatos Onen and Nurullah Akkoc. Dokuz Eylul University School of Medicine, Izmir, Turkey.

Background/Purpose: Intermalleolar distance (IMD) is a component of the Bath ankylosing spondylitis metrology index (BASMI) and measures abduction of the hips. New generations of smartphones are equipped with a gyroscope and an accelerometer which in combination with a smartphone's operating system or specific software applications can be used for various inclinometric functions. The purpose of this study was to estimate the intra and inter-rater reliability of using iphone built in compass application, as compared to IMD in the assessment of hip abduction in patients with AS.

Methods: The study sample included 20 AS patients (6 females, 14 males) with a mean age of 47.8 (± 10.2). BASMI scores were obtained from patient charts. Two examiners measured intermalleolar distance as the standard method at two different time points with the patient lying in a supine position. Then combined abduction of the hips angle (CAHA) was measured by iPhone compass application twice. To stabilize the iphone's position during measurements an iphone case and an elastic bandage with velcro patches were used. Intra-rater and inter-rater reliability were examined with intra-class correlation coefficients (ICC). The validity was assessed by Pearson Correlation analysis.

Results: The mean BASMI score was 43 (±22.7). The mean scores for BASDAI, ASDAS and BASFI were 3.7 (± 19.9), 2.9 (± 0.96) and the 3.5 (± 24.02), respectively. The mean IMD was 83.6 cm (± 24.4) for rater 1 and 83.4cm (SD: 23.1) for rater 2. The mean CAHA was 51.2° (±18.3) for rater 1 and 55.6°(±20.5) for rater 2. We observed almost an excellent intra and inter-rater reliability for both methods (Table 1). CAHA measurements showed a strong correlation with IMD (r=0.74)

Conclusion: The results of this study suggest that measurement of combined hip abduction angle using iphone, which is not to be affected by patients' height, can be used as a novel hip mobility measure.

Table: Intra-rater and inter-rater reliability of the two methods to asses the hip mobility

	Intrarater reliability		Interrater reliability
	Rater 1 ICC (95% CI)	Rater 2 ICC (95% CI)	ICC (95% CI)
Intermalleolar distance	0.99 (0.98–0.99)	0.85 (0.66–0.94)	0.93 (0.85–0.97)
Combined hip abduction Angle	0.94 (0.85–0.97)	0.84 (0.64–0.93)	0.94 (0.85–0.97)

A Phase 3, Randomized, Controlled Trial of Apremilast, an Oral Phosphodiesterase 4 Inhibitor, for Treatment of Psoriatic Arthritis: Long-Term (52-Week) Improvements in Physical Function. Alvin Wells[1], Jacob A. Aelion[2], Adewale O. Adebajo[3], Alan Kivitz[4], Paul Bird[5], ChiaChi Hu[6], Randall M. Stevens[6] and Christopher J. Edwards[7]. [1]Rheumatology & Immunotherapy Center, Franklin, WI, [2]West Tennessee Research Institute, Jackson, TN, [3]University of Sheffield, Sheffield, United Kingdom, [4]Altoona Center for Clinical Research, Duncansville, PA, [5]Combined Rheumatology Practice, Kogarah, Australia, [6]Celgene Corporation, Warren, NJ, [7]University Hospital Southampton, Southampton, United Kingdom.

Background/Purpose: Apremilast (APR) is a phosphodiesterase 4 inhibitor that helps regulate the immune response that causes inflammation and skin disease associated with psoriatic arthritis (PsA). PALACE 4 compared APR efficacy and safety with placebo in patients with active PsA who were DMARD-naïve. We evaluated the impact of APR over 52 weeks on physical function among PALACE 4 patients.

Methods: Patients were randomized (1:1:1) to placebo, APR 20 mg BID (APR20), or APR 30 mg BID (APR30). Patients whose swollen and tender joint counts had not improved by ≥20% at Week 16 were considered non-responders and were required to be re-randomized (1:1) to APR20 or APR30 if they were initially randomized to placebo, or continued on their initial apremilast dose. At Week 24, all remaining placebo patients were re-randomized to APR20 or APR30. This analysis reports data for Weeks 0 to 52. Physical function was evaluated using the Health Assessment Questionnaire-Disability Index (HAQ-DI) and 36-item Short-Form Health Survey version 2 (SF-36v2) Physical Function (PF) domain and physical component summary (PCS) scores. Proportions of patients initially randomized to APR achieving minimum clinically important difference (MCID) thresholds at Week 52 for HAQ-DI (≥0.13 or ≥0.30)[1,2] and SF-36v2 PF and PCS (both ≥2.5)[3] were determined.

Results: At Week 16, a significantly greater proportion of patients treated with APR achieved a modified ACR20 response vs placebo (primary endpoint). Mean changes in HAQ-DI at Week 16 (key secondary endpoint) were 0.03 (placebo), -0.17 (APR20; $P=0.0008$), and -0.21 (APR30; $P<0.0001$). Among patients who were treated with APR continuously through 52 weeks, sustained improvement in HAQ-DI was observed. Mean change in HAQ-DI was -0.32 (APR20) and -0.39 (APR30) at Week 52, exceeding MCID thresholds of ≥0.13 or ≥0.30 (Table). At Week 52, 56.8% (APR20) and 59.0% (APR30) achieved HAQ-DI MCID ≥0.13 and 48.5% and 48.9% achieved MCID ≥0.30, respectively. Week 52 mean changes from baseline in SF-36v2 PF (APR20: 4.61; APR30: 6.41) and PCS (APR20: 5.55; APR30: 6.67) exceeded the MCID threshold (≥2.5). At Week 52, 57.6% of APR20 and APR30 patients achieved SF-36v2 PF MCID, and 60.6% (APR20) and 69.1% (APR30) achieved SF-36v2 PCS MCID. The most common adverse events reported during the placebo-controlled period were nausea (12.6%), diarrhea (9.4%), and headache (6.0%). The safety profile of APR for up to 52 weeks was similar to that observed with APR for up to 24 weeks of treatment (placebo-controlled period).

Conclusion: Over 52 weeks, APR continued to demonstrate clinically meaningful improvements in physical function in active PsA patients who were DMARD-naive. APR demonstrated an acceptable safety profile and was generally well tolerated for up to 52 weeks.

Physical Function at Week 52 in Patients Receiving APR From Baseline

	APR20 n=132	APR30 n=139
HAQ-DI*		
Baseline, mean	1.12	1.09
Mean change from baseline	−0.32	−0.39
Patients achieving MCID ≥0.13‡, %	56.8	59.0
Patients achieving MCID ≥0.30‡, %	48.5	48.9
SF-36v2 PF$^{\mu}$		
Baseline, mean	35.8	35.6
Mean change from baseline	4.61	6.41
Patients achieving MCID ≥2.5‡, %	57.6	57.6
SF-36v2 PCS$^{\mu}$		
Baseline, mean	35.6	36.4
Mean change from baseline	5.55	6.67

Periostin May Have a Role in Ankylosing Spondylitis and It Is Associated with Wnt Signalling Pathway Regulators. Servet Akar[1], Saadettin Uslu[2], Leyla Didem Kozaci[3], Gercek Can[4], Neslihan Karaca[5], Emine Figen Tarhan[4], Mustafa Ozmen[4] and Dilek Solmaz[6]. [1]Izmir Katip Celebi University School of Medicine, Izmir, Turkey, [2]Izmir Katip Celebi University School of Medicine, Izmir, Turkey, [3]Adnan Menderes University School of Medicine, Aydin, Turkey, [4]Izmir Ataturk Education and Reseach Hospital, Izmir, Turkey, [5]Adnan Menderes University, Science Thecnology Research and Application Center, Aydin, Turkey, [6]Namik Kemal University School of Medicine, Tekirdag, Turkey.

Background/Purpose: Ankylosing spondylitis (AS) is a chronic rheumatic disease characterized by sacroiliac and spinal inflammationand new bone formation (syndesmophyte). Molecular mechanisms underlying this process have not been yet fully understood however differentiation of mesenchymal cells into bone-forming osteoblasts appears to be a key pathogenic event. Periostin is an extracellular matrix protein and primarily secreted by osteoblasts. It was shown that periostin has a role in bone anabolism by the regulation of Wnt-β-catenin signaling, therefore it may be one of the pathogenic mechanisms in syndesmophyte formation in AS. To evaluate the serum periostin levels in patients with AS. We also assessed the relationship among periostin levels and other biomarkers of bone formation and the role of periostin in disease outcomes, radiographic changes in particular.

Methods: In total 98 consecutive AS patients (77 males [79%]; with a mean age of 39.3 ± 10.0years) according to the modified New York criteria and 49 healthy controls (37males [76%]; with a mean age of 39.0 ± 5.9 years) from two centers were included in the study. Serum periostin, interleukin (IL)-8, dickkopf-1 (Dkk-1) and sclerostin levels were measured by commercially available ELISA kits. We also determined the serum high-sensitivity C-reactive protein(hs-CRP) levels. Disease related characteristics of patients were assessed by using BASDAI, BASFI, BASMI. Radiographs of the pelvis, cervical and lumbar spine were scored by using the modified New York and modified Stokes ankylosing spondylitis spinal score (mSASSS).

Results: As expected hs-CRP levels and erythrocyte sedimentation rate were higher in AS patients in comparison with controls. Serum periostin and Dkk-1 levels were significantly lower in AS patients compared with controls. Moreover periostin level was particularly lower in patients with active (35.4 ± 25.8 vs 53.9±42.1 ng/mL and P=0.014) disease (BASDAI >4). There was also a trend towards higher periostin levels in patients with syndesmophyte, hip involvement and sacroiliac ankylosis however these were not reached statistical significance. Regression analysis showed that serum periostin levels were independently predicted by Dkk-1, IL-8 levels.

Conclusion: Our results suggested that periostin may be down regulated in AS patients with active disease and the increase in periostin in inactive phase may contribute to the new bone formation along with the Wnt signalling.

	AS patients (n=98)	Controls (n=49)	P

Characterisation of Mucosal-Associated Invariant T (MAIT) Cells in Ankylosing Spondylitis Patients. Ibrahim Almaghlouth[1], Eric Gracey[2], Zoya Qaiyum[2], Robert D. Inman[3] and Ammepa Anton[4]. [1]Toronto Western Hospital, Toronto, ON, [2]University of Toronto, Toronto, ON, [3]Department of Medicine, University of Toronto, Toronto, ON, [4]University Health Network, Toronto, ON.

Background/Purpose: Ankylosing spondylitis (AS) is chronic inflammatory disease of unknown origin. Studies into the molecular basis of AS have demonstrated exaggerated innate and adaptive immune responses mediated though various cytokines. Over-expression of cytokines such as TNFα and IL-17 has provided a rationale for targeted biologic agents for suppressing the disease activity. Identifying the cellular sources of these cytokines is crucial to understand the pillars of inflammation in AS. Recently, mucosal associated invariant T (MAIT)-cells have been implicated in various autoimmune diseases. Their effectors phenotype and preferential localization to peripheral tissue makes them possible contributor in the pathogenesis of AS. Thus we hypothesized that MAIT cells may be increased in AS patients compared to normal controls.

Methods: Peripheral blood mononuclear cells (PBMC) and synovial fluid (SF) mononuclear cells (SFMC) from the AS patients (N=17) and controls (n=11) were isolated. Healthy controls were used for the MAIT cells in the in PBMC while RA and OA were used as controls for the SF MAIT cells. Flow cytometry was used to identify MAIT cells, which were defined as CD3+CD161^{hi}V.α 7.2+CCR6+, with the majority being CD8+. Cytokine production by respective cell populations was assessed indirectly by intracellular straining for IL-4, IL-17, TNFa, IFNg and granzyme B.

Results: The percentage of MAIT cells in PBMC of AS patients and control groups were similar. Whereas CD69+ (activation marker) and CCR6+(homing marker) MAIT cells were comparable in AS and HC, CCR6+ MAIT showed a tendency to be higher in AS PBMC. It was noted that in PBMC, activated MAIT cells (CD69+) represented a small proportion of the total MAIT cells in. In contrast, almost all SF MAIT cells from AS patients were activated (CD69+). We also noticed that the percentage of CD4+ MAIT to total MAIT cells in AS SF is higher than peripheral blood. Similar results were seen in paired patient blood-synovial fluid analysis. In this analysis, IL17 production was similar while an increased granzyme B production and reduction of IL4, IFNγ and TNFα were detected in SF MAIT cells compared to MAIT cells in PBMC.

Conclusion: To our knowledge, this study is the first to look at MAIT cells in both blood and SF of AS patients. Interestingly MAIT cells in the inflamed joints in AS are predominantly activated. This suggests that examining the microenvironment of the joint to define the activating signals for local MAIT cells would be productive.

Decreased Frequencies of Circulating Follicular Helper T Cell Counterparts and Plasmablasts in Ankylosing Spondylitis Patients Naïve for TNF Blockers. M. Belén Bautista-Caro[1], Irene Arroyo-Villa[1], Concepcion Castillo-Gallego[1], Eugenio de Miguel[2], Diana Peiteado[1], Chamaida Plasencia-Rodriguez[1], Alejandro Villalba[1], Paloma Sanchez-Mateos[3], Amaya Puig-Kröger[4], Emilio Martín-Mola[1] and Maria Eugenia Miranda-Carus[1]. [1]Hospital La Paz - IdiPaz, Madrid, Spain, [2]University Hospital La Paz - IdiPaz, Madrid, Spain, [3]Hospital Gregorio Marañon, Madrid, Spain, [4]Hospital General Universitario Gregorio Marañón, Instituto de Investigación Sanitaria Gregorio Marañón, Madrid, Spain.

Background/Purpose: Follicular helper T cells (Tfh), localized in lymphoid organs, promote B cell differentiation and function. Circulating CD4 T cells expressing CXCR5, ICOS and/or PD-1 are counterparts of Tfh. Three subpopulations of circulating CD4+CXCR5+ cells have been described: CXCR3+CCR6- (Tfh-Th1), CXCR3-CCR6+ (Tfh-Th17) and CXCR3-CCR6- (Tfh-Th2). Only Tfh-Th17 and Tfh-Th2 function as B cell helpers.

Our objective was to study the frequencies of circulating Tfh (cTfh), cTfh subsets and plasmablasts (CD19+CD20-CD27+CD38^{high} cells), and the function of cTfh cells, in patients with Ankylosing Spondylitis (AS).

Methods: Peripheral blood was drawn from healthy controls (HC) (n=50), AS patients naïve for TNF blockers (AS/nb) (n=25) and AS patients treated with TNF blockers (AS/b) (n=25). The frequencies of cTfh and plasmablasts were determined by flow cytometry. Cocultures of magnetically sorted CD4+CXCR5+ T cells with autologous CD19+CD27- naïve B cells were established from 3 AS/nb patients and 3 HC, and concentrations of IgG, A and M were measured in supernatants.

Results: AS/nb but not AS/b patients, demonstrated decreased frequencies of circulating CD4+CXCR5+ICOS+PD-1+ cells and plasmablasts together with a decreased (Tfh-Th17+Tfh-Th2)/Tfh-Th1 ratio. The amounts of IgG and IgA produced in cocultures of CD4+CXCR5+ T cells with CD19+CD27- B cells of AS/nb patients were significantly lower than observed in cocultures established from HC.

Conclusion: AS/nb but not AS/b patients, demonstrate a decreased frequency of cTfh and plasmablasts, and an underrepresentation of cTfh subsets bearing a B helper phenotype. In addition, peripheral blood CD4+CXCR5+ T cells of AS/nb patients showed a decreased capacity to help B cells ex vivo.

The Immunological Basis of the Sex-Bias in Ankylosing Spondylitis: Th17 Expansion Is Restricted to Male Patients and Correlates with Sex-Related Alteration in Vitamin D Metabolism. Eric Gracey[1], Blerta Green[1], Paul Yip[1], Renise Ayearst[1], Ammepa Anton[1], Aifeng Lin[1] and Robert D. Inman[2]. [1]University Health Network, Toronto, ON, [2]University of Toronto and Toronto Western Hospital, Toronto, ON.

Background/Purpose: Ankylosing spondylitis (AS) is an inflammatory arthritis of the spine, which has a major impact on function and quality of life. AS is known to have a sex-bias with a M:F ratio of 3:1. In addition, females have a delayed onset and reduced radiographic severity compared to males. Genetic and immunologic studies have implicated the Th17-axis in AS pathogenesis, and recent clinical trials suggest efficacy of anti-IL-17A therapy. Prior studies have demonstrated a suppressive effect of vitamin D_3 on Th17 cells. In the present study we examine whether there is a sex-bias in the Th17-axis, and its possible relationship to vitamin D metabolism in AS.

Methods: Serum IL-6 and IL-17A were measured by ELISA and 25(OH) vitamin D_3 by mass-spectrometry in a cohort of 39 male AS patients, 36 female AS patients and 34 age- and sex-matched healthy controls. Whole blood gene expression for vitamin D_3-associated and Th17-associated genes was measured by RT-PCR. Th17 cells were measured by flow cytometry of peripheral blood mononuclear cells (PBMC) in a second, overlapping cohort of 14 female AS patients, 24 male AS patients and 30 age- and sex-matched healthy controls. Data was analyzed by Mann-Whitney tests and correlations with Spearman tests.

Results: AS patients had an elevated Th17-axis when compared to healthy controls as demonstrated elevated IL-6 ($p<0.01$), IL-17A ($p=0.06$) and Th17 cell levels ($p<0.05$). When stratified for sex, the elevated Th17-axis was restricted to male patients, as exemplified by higher Th17 cell levels in male AS *vs* female AS (Figure 1). A trend was seen for lower serum 25(OH) vitamin D_3 in male AS patients and healthy controls relative to their respective female counterparts. Gene expression of *VDR* and *CYP27B1* (vitamin D_3 activating enzyme) were equivalent in male and female AS patients, whereas *CYP24A1* (vitamin D_3 degrading enzyme) expression was significantly elevated in male AS patients. This was not seen in male *vs* female healthy controls. In male AS patients, serum 25(OH) vitamin D_3 was inversely proportional to whole blood *IL23R* expression ($r=-0.43$, $p<0.05$) and Th17 cell level ($r=-0.014$, $p=0.085$).

Conclusion: This is the first demonstration that elevated levels of Th17 cells in AS are restricted to male patients, which could inform targeted therapy with anti-IL17 agents. This may be due to a sex-related alteration in the biochemistry of vitamin D_3 which functions as an important inhibitory factor to the Th17 axis. This work demonstrates a biological basis for the observed sex-bias in incidence and in disease expression in AS.

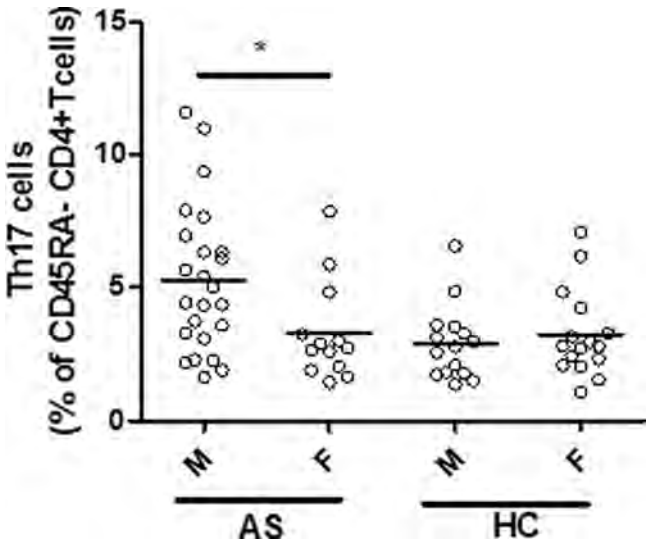

Figure 1: Male AS patients have higher circulating Th17 levels than female AS patients and healthy controls (HC). Results displayed as scatter plot with mean and analyzed by Mann-Whitney test.

The HLA-B27 Peptidome in Vivo in Transgenic Rats. Joel D. Taurog[1], Yael Haimovich[2], Eilon Barnea[2], Michal Bassani-Sternberg[2], Shira Yair-Sabag[2], Martha L. Dorris[1], Nimman Satumtira[1], Mylinh Nguyen[1], Robert E. Hammer[1], Tri M. Tran[3], Robert A. Colbert[3] and Arie Admon[2]. [1]UT Southwestern Medical Center, Dallas, TX, [2]Technion-Israel Institute of Technology, Haifa, Israel, [3]NIAMS/NIH, Bethesda, MD.

Background/Purpose. In all current hypotheses for the association of B27 with SpA, the B27 peptide repertoire (peptidome) is likely to play a key role. ERAP1 directly influences the MHC-I peptide repertoire and has strong genetic association with AS. The B27 peptidome has previously been reported only in cell lines. We used mass spectrometry to characterize the in vivo B27 peptidome in spleen cells from rats transgenic (TG) for B27 and human beta-2-microglobulin (hb2m).

Methods. B27 TG rats that develop SpA (males only), the protective Dazl-knockdown (kd) transgene, and rats TG for a B27 C67S mutant have been described (A&R 54,1317, 2006; 64:2518, 2012). ERAP1 knockout (ko) rats were produced by microinjection of LEW rat zygotes with a zinc finger nuclease targeting ERAP1. In ERAP1-ko spleen, absence of ERAP1 protein was confirmed by immunoblotting, and ERAP1 mRNA abundance was 18±3% of wild type. One B27/hb2m/ERAP1-ko male was available for peptide analysis. Frozen spleens were solubilized with 1% octyl-glucoside, B27 molecules were immunoaffinity-purified, and peptides were dissociated in 0.1% TFA and isolated by capillary reverse–phase chromatography. Peptides were analyzed by Orbitrap tandem mass spectrometry and data analyzed for peptide identities and relative intensities by MaxQuant, Sequest and Mascot software.

Results. A total of 20,096 unique peptides fitting the B27 peptide motif were identified, of which 10,587 were shared by all genotypes. The data are summarized in the table. The C67S mutant rats showed fewer B27-motif peptides and had a higher proportion of unique peptides, compared with the groups with wild type B27. The Dazl-kd rats, which have no disease manifestations, carried fewer unique peptides than the other groups.

B27-bound peptides isolated from male rat spleens

Group (all B27/hb2m TG)	Age (d)	Phenotype	No. spleens	No. B27 motif peptides	No. group specific peptides
Wild type B27, Dazl, ERAP1	72–109	EO	4	9,808	1,238
	223–236	EO, SpA	4	10,029	
Dazl-knockdown	72–109	healthy	4	9,911	360
	223–236	healthy	4	9,994	
B27 C67S mutant	163–218	EO	12	7,610	1,896
ERAP1 knockout	57	*	1	9,808	781

EO = epididymo-orchitis; *phenotype not yet known

The peptidome from the ERAP1 ko rat was skewed toward longer peptides, compared with the young wild type and Dazl-kd rats (Figure).

Conclusion. HLA-B27 in TG rat spleen carries large numbers of peptides conforming to the B27 peptide motif identified in human cell lines. Rats with disease show more unique B27-bound peptides than healthy rats, suggesting that disease itself alters the B27 peptidome. Whether either specific peptides or the peptidome as a whole play a role is disease initiation is not yet clear, but the data are consistent with alterations in the peptidome playing a role in disease perpetuation. ERAP1 deletion leads to binding of longer peptides, and the effect of the deletion on disease should be known soon.

Identification of Novel Autoantibodies in Patients with Ankylosing Spondylitis Using Human Protein Microarray. Matthew Presby[1], Mark J. Soloski[1], John A. Flynn[1], Clifton O. Bingham III[1], Michael M. Ward[2] and Grant H. Louie[1]. [1]Johns Hopkins University, Baltimore, MD, [2]NIAMS/NIH, Bethesda, MD.

Background/Purpose: Ankylosing spondylitis (AS) is an immune-mediated disease for which the search for autoantibodies has been elusive. Conventional immunoserological approaches are slow and limited to the analysis of several dozen proteins at a time. In this pilot study, we used large-scale, high-throughput, protein microarrays to identify potential autoantibodies in AS.

Methods: Sera from patients who fulfilled the 1984 modified New York criteria for AS (N=20) were profiled using a human protein array composed of ~17,000 human proteins (CDI Laboratories, MD) and compared with healthy controls (N=18). Proteins were purified from *Saccharomyces cerevisae*, N-terminus tagged with GST-HisX6, spotted in duplicate on the array, imaged using a GenePix 4000B microarray scanner (Molecular Devices, CA), and analyzed using GenePix Pro software. Signal intensity, referred to as an A-score, was computed.

Results: AS patients were age (mean ± SD) 53.5 ± 12.1 years, 80% men, 100% HLA-B27 positive, with a disease duration (mean ± SD) of 28.6 ± 12.8 years. Healthy controls were age 55.7 ± 14.4 years and 50% men. Among 146 potential autoantigens detected in AS patients but not in healthy controls, we identified 6 with the highest frequency and signal intensity. These proteins were microtubule-associated serine/threonine-protein kinase 4 (MAST4), centriole, cilia and spindle-associated protein (CCSAP), SNF related kinase (SNFRK), calcium-binding protein 4 (CaBP4), protein MTG8 (MTG8), and eukaryotic elongation factor 2 kinase (EEF2K). The 3 most frequently targeted autoantigens were the serine/threonine kinases SNFRK, EEF2K, and MAST4. SNFRK and EEF2K were positive in 4/20 patients (20%). Three patients (15%) were positive for autoantibodies against MAST4. Two patients (10%) had antibodies to both MTG8 and CCSAP. The highest A-score observed was reactivity to CaBP4 by 1 patient (5%) (Figure 1). This was the lowest frequency autoantigen observed; however, CaBP4 reactivity was higher in the overall AS population compared to healthy controls. The images of each autoantigen were inspected and can be seen in Figure 2 for the patients with the five highest A-scores.

Conclusion: Using a high-throughput, protein microarray system, we have identified 6 novel autoantigens (SNFRK, EEF2K, MAST4, MTG8, CCSAP, and CaBP4) in AS patients, with an overall frequency of 5–20%. The detection of these AS-specific antibodies may allow for better understanding of disease pathogenesis and potential therapeutic targets. Further validation studies in larger numbers of patients are currently underway.

Induced Pluripotent Stem Cells (iPSCs) As a Tool for Unraveling the Role of Different Cell Types in the Disease Process of Spondyloarthritis Pathogenesis. Gerlinde Layh-Schmitt, Shjia Lu, Fatemeh Navid, Massimo Gadina and Robert A. Colbert. NIAMS/NIH, Bethesda, MD.

Background/Purpose: Many genetic factors and cell types contribute to the axial inflammation, trabecular bone loss, and aberrant bone formation that result in ankylosing spondylitis. The functional consequences of genetic variants may be manifest in specific cell types and in many cases affected cell types are not readily accessible for evaluation. In order to obtain these cell types we examined the feasibility of reprogramming fibroblasts from patients

with axial spondyloarthritis (AxSpA) into induced pluripotent stem cells (iPSCs) and subsequent re-differentiating iPSCs into various lineages.

Materials and Methods: Dermal fibroblasts from 7 AxSpA patients and 3 healthy controls (HC) were reprogrammed using a Sendai virus vector encoding Oct4, Sox2, Klf4 and Myc. One AxSpA and one HC fibroblast line were reprogrammed in two different labs to assess technical reproducibility. Virus-free iPSCs were differentiated into mesenchymal stem cells (MSCs) using a TGF-β inhibitor. MSCs were differentiated into osteoblasts, chondrocytes, and adipocytes; defined cytokine cocktails were used to differentiate iPSCs into monocytes. IPSC derived monocytes were treated with RANKL to induce osteoclastogenesis. IPSC gene expression patterns were established by RNAseq. Gene expression during MSC-osteoblast differentiation was monitored by Nanostring. Flow cytometry was conducted to evaluate the expression of iPSC, MSC and monocyte specific markers.

Results: All iPSC lines expressed pluripotency markers (OCT4, TRA-1, SSEA-4) and stem cell specific genes. IPSC derived MSCs proved positive for CD105, CD73, CD90 and CD44, but lacked CD45, CD34, CD11b, CD19, and HLA-DR. MSCs exhibited the capacity to induce differentiation of peripheral blood monocytes into osteoclasts in co-culture as demonstrated by tartrate resistant acid phosphatase staining. MSCs could be differentiated into mineralizing osteoblasts, as confirmed by expression of osteogenic genes and Alizarin-Red staining, into chondrocytes (proteoglycan staining with Alcian-Blue), and into adipocytes (lipid staining with Oil Red O). iPSC-derived monocytes/macrophages expressed HLA-DR, CD14, CD86, CD80 and CX3CR1 and CD45, and were capable of phagocytosing beads and differentiating into osteoclasts. Preliminary comparison of mineralization potential revealed that MSCs from AxSpA patients (n=3) exhibited 3-fold higher mineralization than the HC as determined by Alizarin Red staining. Independently-derived iPSC lines behaved similarly.

Conclusion: We have successfully derived iPSCs from AxSpA patient fibroblasts. The iPSCs can be differentiated into functional MSCs capable of differentiating into mature osteoblasts, chondrocytes, and adipocytes, as well as inducing monocytes to become osteoclasts. We have also successfully generated hematopoietic cells that can differentiate into monocytes, macrophages and osteoclasts. Notably, MSCs from AxSpA patients demonstrated greater mineralization capacity. This was observed repeatedly in independently iPSC derived MSCs from the same patient. These cells may provide a powerful system to examine the molecular functional consequences of genetic differences that predispose to SpA.

Functional Implications of the Endoplasmic Reticulum Aminopeptidase 2 (ERAP2) Association with Ankylosing Spondylitis and Crohn's Disease: Impact on the Unfolded Protein Response. Zhenbo Zhang[1], Francesco Ciccia[2], Kirby Yee[3], Giuliana Guggino[2], Hasan Abdullah[4], Ricardo Alessandro[5], Stefania Raimondo[5], Giovanni Triolo[5] and Nigil Haroon[1]. [1]Toronto Western Research Institute, Toronto, ON, [2]Rheumatology Unit, University of Palermo, Palermo, Italy, [3]McMaster University, Hamilton, ON, [4]University of Toronto, Toronto, ON, [5]University of Palermo, Palermo, Italy.

Background/Purpose: Endoplasmic Reticulum Aminopeptidase 2 (*ERAP2*) has found to be associated with AS and Crohn's Disease (CD). The functional implications of this association have not been explained to date. We tested levels of HLA-B27 and MHC-I Free Heavy Chain (FHC) in AS patients with the ERAP2 null allele. We further tested if ERAP2 suppression in an *in vitro* system results in changes in B27 misfolding and UPR.

Methods: A total of 40 B27-positive AS patients were typed for the rs2248374 polymorphism. Peripheral Blood Mononuclear Cells (PBMC) were isolated and stained with antibodies to CD19 (B cells) and CD14 (Monocytes). Staining with HC10 antibodies to assess MHC-I FHC expression and ME-1 antibody for intact HLA-B27 was performed. Mean Fluorescence Intensities (MFI) for FHC and B27 expression was assessed by flow cytometry.

C1R-B27, a human B lymphoblastoid cell line stably transfected with HLA-B27, were treated with 2 separate shRNAs to suppress endogenous ERAP2. Changes in UPR were assessed by PCR for BiP, CHOP and PERK. Protein expression of CHOP was assessed by western blot and semi-quantitative XBP-1 splicing assay was done by PCR.

Results: AS patients with no ERAP2 expression (homozygous for the minor allele of rs2248374) had higher FHC expression on the surface of PBMCs (P=0.019). When corrected for ME1 expression there was significantly lower ratio of intact-B27:FHC ratio in PBMC as well as specifically on monocytes.

PCR showed more than 20-fold increase in CHOP levels with ERAP2 suppression and between 1.2–1.5 fold increase in BiP and PERK. CHOP protein levels increased more than 3 fold while XBP1s increased 20-fold.

Conclusion: This is the first study showing a functional relevance of the ERAP2 association with AS and Crohn's Disease. ERAP2 deficiency in AS patients are associated with higher MHC-I FHC expression on PBMCs. Suppression of ERAP2 in an *in vitro* system led to significant increase in UPR markers. Changes in ERAP2 expression could influence the pathogenesis of AS and CD.

Autophagy and Unfolded Protein Response: A Fine Balance That Can Influence the Pathogenesis of Ankylosing Spondylitis and Inflammatory Bowel Disease. Nigil Haroon[1], Giuliana Guggino[2], Zhenbo Zhang[1], Kirby Yee[3], Hasan Abdullah[4], Ricardo Alessandro[5], Stefania Raimondo[5], Giovanni Triolo[5] and Francesco Ciccia[2]. [1]Toronto Western Research Institute, Toronto, ON, [2]Rheumatology Unit, University of Palermo, Palermo, Italy, [3]McMaster University, Hamilton, ON, [4]University of Toronto, Toronto, ON, [5]University of Palermo, Palermo, Italy.

Background/Purpose: We have shown an increase in the unfolded protein response (UPR) with decreased ERAP1 or ERAP2 function in an *in vitro*system. Similarly UPR has been demonstrated to correlate with onset of disease in the HLA-B27 rat model. UPR has been difficult to demonstrate in the gut of AS patients but autophagy is upregulated. ERAP2 is associated with both AS and inflammatory bowel disease (IBD). Here we explore the moderating effect of autophagy on UPR.

Methods: Lamina Propria Mononuclear cells (LPMC) were isolated from terminal ileal biopsies of 10 AS patients. Autophagy was suppressed with 2 agents anisomycin and 3-MA. In parallel an in vitro system was established with C1R-B27 cells (B-lymphoblastoid cells with stable HLA-B27 expression) and the presence of autophagy in these cells were established with electron microscopy as well as by transfecting these cells with LC3-RFP followed by confocal microscopy. Autophagy was suppressed in C1R-B27 cells using 3-MA.

In both LPMC and C1R B27 cells, suppression of autophagy was demonstrated by RT-PCR of appropriate markers. Changes in MHC-I free heavy chain (FHC) expression were tested by HC10 staining and flow cytometry. Changes in UPR following inhibition were tested by XBP1 splicing assay and RT-PCR for BiP, CHOP, PERK, GADD34 and PDIA6.

Results: Electron and confocal microscopy demonstrated autophagy in C1R-B27 cells. Autophagy was in a dynamic state in the C1R cells as demonstrated by changes with rapamycin a stimulator of autophagy. Significant suppression of autophagy was noted in both LPMCs and C1R-B27 cells. Following autophagy suppression there was a significant increase in FHC expression in both C1R cells and LPMCs. In parallel we demonstrated increase in UPR markers in both LPMCs and C1R cells.

Conclusion: The inability to demonstrate UPR in some in vivo studies could be due to compensation by autophagy. Inhibition of autophagy led to significant increase in UPR in both LPMC and C1R cells. Autophagy and UPR regulate each other and perturbations of this fine balance can influence the pathogenesis of AS and IBD.

Association of Platelet Endothelial Cell Adhesion Molecule-1 and beta1 Integrin Gene Polymorphisms with Uveitis Development in Ankylosing Spondylitis. Seong-Wook Kang[1], Seung-Taek Song[1], Su-Jin Yoo[1], Mi-Kyoung Lim[2], Dong-Hyuk Sheen[2], In-Seol Yoo[1], Jinhyun Kim[1] and Seung-Cheol Shim[1]. [1]Chungnam National University School of Medicine, Daejeon, South Korea, [2]Eulji University Hospital, Daejeon, South Korea.

Background/Purpose: Genetic factors provide over 90% of the overall susceptibility to ankylosing spondylitis (AS) and recent studies have focused on non-major histocompatibility complex genes. The etiology of uveitis in AS has been suggested to involve two adhesion molecules including intercellular adhesion molecule (ICAM)-1 and leukocyte functional antigen (LFA)-1.

Platelet-endothelial cell adhesion molecule 1 (PECAM1) is a member of the immunoglobulin superfamily which is expressed on endothelial cells. There is emerging evidence to suggest that PECAM1 may be an important regulator of antigen induced cell activation of lymphocytes. The β1 integrin (ITGB1) can associate with different membrane proteins and cause signal transduction by interactions in the extracellular and trans-membrane domain. Therefore, we examined the association of PECAM1 and ITGB1 gene polymorphisms with development of uveitis in patients with AS.

Methods: We conducted a case–control study where 223 AS patients who met the Modified New York criteria and 239 ethnically matched controls were genotyped for 9 single nucleotide polymorphisms (SNPs) in the PECAM-1 promoter and gene. Genomic DNA was isolated from peripheral blood leukocytes by a standard phenol–chloroform method and a Golden Gate assay (Illumina, http://www.illumina.com) was used for genotyping.

Results: Conditional logistic regression was used to evaluate the association between the PECAM1 or ITGB1 SNPs with susceptibility to AS, and no significant association was found on both genes. However, in the subgroup analyses between AS patients with uveitis and those without, seven SNPs in PECAM1 gene were associated with the presence of uveitis, including rs1050382 (dominant model (DM), p=0.022), rs2812 (recessive model (RM), p=0.013), rs4968721 (DM, p=0.016), rs6808 (DM, p=0.011), rs6809 (DM, p=0.013), rs9899806 (DM, p=0.013) and rs9913080 (DM, p=0.019). In addition, seven polymorphisms in ITGB1 gene including rs11009147 (DM, p=0.012; co-dominant model (CDM), p=0.034), rs17468 (DM, p=0.012; CDM, p= 0.019), rs2153875 (CDM, p= 0.030), rs2230396 (DM, p=0.012; CDM, p=0.034), rs2488330 (DM, p=0.004; CDM, p=0.017), rs3780871 (DM, p=0.031) and rs7079624 (RM, p=0.004; CDM, p=0.017) were associated with uveitis development.

Conclusion: This is the first analysis of the PECAM1 and ITGB1 gene polymorphisms in AS, demonstrating a clear association with uveitis in AS. Given the functional role of PECAM-1 and ITGB1 variants in the immune system, larger studies are now warranted to elucidate the association of PECAM-1 and ITGB1 in the pathogenesis of uveitis in AS.

Table 1. Logistic analysis of PECAM1 polymorphisms and the risk of uveitis among AS patients

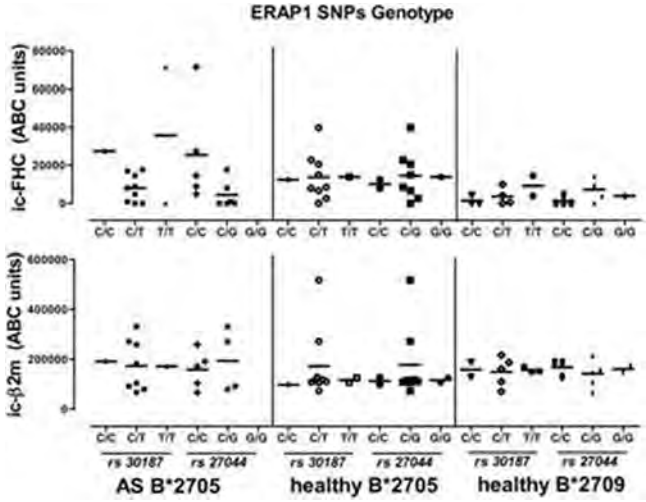
The Amount of Free Heavy Chain and β2-Microglobulin in the Cytoplasm of B*2705 Ankylosing Spondylitis Patients Compared to B*2705 and B*2709 Healthy Subjects Does Not Support the UPR Theory. Influence of ERAP1 Polymorphisms. Alberto Cauli, Grazia Dessole, Giovanni Porru, Matteo Piga, Alessandra Vacca and Alessandro Mathieu. Unit and Chair of Rheumatology, University Hospital of Cagliari, Cagliari, Italy.

Background/Purpose: Ankylosing Spondylitis (AS) is a chronic inflammatory disease of the spine strongly associated with the majority of HLA-B27 alleles, with the exception of B*2709 and B*2706. Genome wide association studies (GWAS) have revealed that besides HLA-B27, other genes are involved in AS pathogenesis, such as ERAP1, an ER aminopeptidase that is implicated in peptide trimming thus influencing B27-peptide-β2microglobulin (β2m) complex stability. Several theories have been proposed to explain the B27 association with AS. Among them, the unfolded protein response (UPR) theory suggests that the tendency of B27 trimeric complex to misfold determines free heavy chain (FHC) accumulation in the endoplasmic reticulum, leading to a stress response and activation of pro-inflammatory pathways.To our knowledge this is the first *ex vivo* study investigating the intracellular (ic) level of FHC and β2m in peripheral blood mononuclear cells (PBMC) and the possible influence of ERAP1 allelic variance in HLA-B27 positive AS patients and healthy subjects (HSs) bearing the AS-associated (B*2705) and the non-AS-associated (B*2709) allele.

Methods: The ic amount of FHC and β2m in CD14+ cells from *ex vivo* PBMC was evaluated in 12 HLA-B*2705 patients with AS, 12 HLA-B*2705 HSs and 12 HLA-B*2709 HSs by flow cytometry analysis. HC10 (gift of Dr. Chella David) and TU99 clone (BD Biosciences, USA) monoclonal antibodies were used to detect FHC and β2m, respectively, and quantified by comparison with standard beads (antibody binding capacity ABC units, Dako Denmark). Cells were fixed and permeabilized by the Intraprep Permeabilization technique (Beakman Coulter, USA) according to standard procedure. Patients and controls were also genotyped for two ERAP1 SNPs associated with AS (rs27044 C/G and rs30187 C/T). Optimized allelic discrimination assays were purchased from Applied Biosystem (Life Technologies, Italy). Values were expressed as mean ± standard deviation. Differences between AS patients and healthy subjects were analyzed by Mann-Whitney U test.

Results. FHC expression in AS patients was 37486 ± 30346 compared to B*2705 HSs 35673 ± 16723 and B*2709 HSs 26683 ± 10592 ABC units (p=ns). β2m quantity was also not significantly different in AS patients 174930 ± 90441 compared to B*2705 HSs 156471 ± 123855 and B*2709 HSs 153478 ± 42117 ABC units (p=ns). The majority of AS patients and HSs were heterozygous for both rs27044 (C/G) and rs30187 (C/T) SNPs; the intracellular amount of FHC and β2m in the PBMC of the analysed cohorts appeared not influenced by ERAP1 allelic distribution, as shown in the figure below:



Conclusion: This study shows equal amount of FHC and β2m in the cytoplasm of B*2705 AS patients compared to B*2705 and B*2709 healthy controls, regardless of ERAP1 allelic variance. These data, therefore, do not provide support to the UPR theory in the pathogenesis of AS.

The Association of PPM1A with Inflammasome Activation in Ankylosing Spondylitis. Soo Min Ahn, Seung-Hyeon Bae, Seokchan Hong, Eun-Ju Lee, Eun-Jin Lee, Eun-Ju Chang, Doo-Ho Lim, Yong-Gil Kim, Chang-Keun Lee and Bin Yoo. University of Ulsan College of Medicine, Asan Medical Center, Seoul, South Korea.

The Association of PPM1A with Inflammasome Activation in Ankylosing Spondylitis

Background/Purpose: Ankylosing spondylitis (AS) is a chronic inflammatory disorder usually affecting axial skeleton and joints. The pathogenesis and mechanism of inflammatory response in AS, however, remains not fully under-

stood. Recently, it has been suggested that AS could be associated with autoinflammatory responses, which are driven by innate immunity through inflammasome activation. We have reported that immunity to protein phosphatase magnesium-dependent 1A (PPM1A), which regulate BMP and Wnt signaling, are associated with AS. In this study, we try to investigate the association of PPM1A with inflammatory response in AS and its role in the inflammasome activation.

Methods: The concentration of PPM1A was measured in the plasma from AS, rheumatoid arthritis (RA) and healthy control (HC) subjects by enzyme-linked immunosorbent assay (ELISA), and addressed the association with inflammatory burden including disease activity in AS patients. Next, the expression of intracellular PPM1A was evaluated in the synovia from patients with AS, RA and osteoarthritis and in peripheral blood mononuclear cells (PBMCs) from patients with AS, RA and HC. To know the role of PPM1A in the inflammasome activation, the production of IL-1β and expression of active caspase-1 were measured with or without PPM1A knockdown in the macrophage. The expression of PPM1A was evaluated after stimulation with various cytokines.

Results: The levels of PPM1A were significantly higher in the plasma of AS patients compared with RA or HC subjects. In addition, there was significant correlation between the levels of PPM1A in plasma and the values of BASDAI, ESR and CRP in AS patients (Figure 1). The expression of PPM1A in the synovia and PBMCs were elevated in AS. Further, IL-1β secretion and activation of caspase-1 was significantly decreased by knockdown of PPM1A. Finally, the expression of PPM1A was enhanced by stimulation with TGF-β in the macrophage.

Conclusion: Our present study suggested that inflammasome activation could be regulated by intracellular PPM1A, which contribute to the pathogenesis of inflammatory responses in AS.

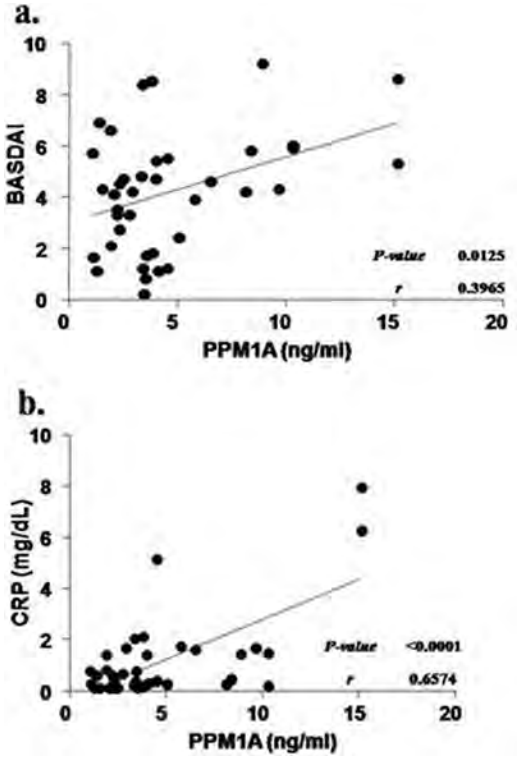

Figure 1. Correlation between BASDAI (a), CRP (b) and the levels of PPM1A in the plasma of patients with AS

Analysis of the Gut Transcriptome in HLA-B27 Transgenic Rats By RNA-Seq Reveals Prominent Interferon and IL-23/IL-17 Axis Signatures. Tejpal Gill[1], Mark Asquith[2], Steve Brooks[1], James T. Rosenbaum[2] and Robert A. Colbert[1]. [1]NIAMS/NIH, Bethesda, MD, [2]OHSU, Portland, OR.

Background/Purpose: Expression of HLA-B27 and human beta 2-microglobulin (hb_2m) in rats induces a spontaneous inflammatory disease resembling human spondyloarthritis (SpA). SpA overlaps with IBD in genetic predisposition, pathogenic mechanisms and clinical manifestations. While key components of rat SpA have been studied in great detail, a complete understanding of the associated inflammatory bowel disease (IBD) has not been established. The goal of this project is to determine how HLA-B27 alters gut transcriptome in transgenic rats that develop SpA-like disease. HLA-B27 and hb_2m transgenic (TG) rats (33–3 transgene locus) on a Lewis (LEW), Fischer (F344), and Dark Agouti (DA) background from two different animal facilities are being studied along with strain-specific controls. TG LEW and F344 rats develop SpA beginning with colitis at about 8 weeks of age, while TG DA rats are disease free. Arthritis develops later in LEW and F344 TG animals, and is more variable.

Methods: To assess colitis, tissue samples from colon were assessed by H&E staining and scored for histological differences. Samples were also assessed for transcriptome differences using RNA-Seq. Total poly (A) enriched RNA was reverse transcribed into double stranded complementary DNA (dscDNA) and sequenced on Illumina HiSeq 2000. Raw reads were mapped to Rat rn5 genome using Tophat (2.0.8). Transcript expression levels in Reads per Kilobase Million (RPKM) and ANOVA comparisons were calculated using Partek GS (6.6/6.14.0514). A minimum fold change of 50% (p value $\leq$ 0.05% and q value $\leq$0.2) with Max Mean ≥ -3.3 was used as cutoff criteria for identifying differentially expressed genes between TG and WT animals on LEW, F344 and DA background at 2, 3 and 6 months. These genes were subjected to pathway exploration by Ingenuity Pathway Analysis (IPA) software.

Results: Inflammation in the colon was documented by histopathological analysis. Transcriptome analysis revealed that LEW and F344 TG animals exhibit up-regulation of the genes for IFN response (e.g. *Tap1, Tap2, Irf1, Cxcl10, Oas1 Gbp-2, Stat1*). The *Il17* pathway is highly up regulated at all age groups whereas *Il23* up regulation became statistically significant at 6 months of age. Apoptotic signaling and *iNos* (*Nos2*) pathways as well as the oxidative stress (*Gpx2, Nox1, Duox2*) pathway in colon were up-regulated as compared to their age matched WT controls. Susceptibility genes (*Card9, Nod2*) as well as IBD associated genes (*Tnf, Ltb, Reg3*γ*, Ccl2, Ccr7*) were up regulated in TG F344 and LEW animals. DA background had a protective affect since TG DA did not exhibit significant gene expression changes consistent with the fact that they do not develop either SpA or IBD.

Conclusion: Transcriptome analysis of the TG inflamed colon depicts upregulation of interferon and Il23/Il17 pathways suggesting a shift in the immune microenvironment in the colon. The interferon signature contrasts results recently obtained from isolated dendritic cells, and underscores the role of interferon in this disease process. These results increase our understanding of SpA associated IBD and may lead to the identification of potential biomarkers for use in diagnosis and treatment.

In Situ Analysis of Mechanisms of New Bone Formation in Zygapophyseal Joints from Patients with Ankylosing Spondylitis. Janine Bleil[1], Joachim Sieper[2], Rene Maier[3], Uwe Schlichting[4], Axel Hempfing[5], Heiner Appel[6] and Uta Syrbe[7]. [1]Charité Medical University, Campus Benjamin Franklin, Berlin, Germany, [2]Charité Universitätsmedizin Berlin, Berlin, Germany, [3]Deutsches Rheumaforschungszentrum, Berlin, Germany, [4]Charite, Berlin, Germany, [5]Werner-Wicker-Klinik, Bad Wildungen, Germany, [6]Rheumatology and Nephrology Practice, Hamm, Germany, [7]Charité, Berlin, Germany.

Background/Purpose: Osteoproliferation leading to joint ankylosis is a characteristic feature of ankylosing spondylitis (AS). In general, there are two ways of bone formation: a) endochondral bone formation via generation of collagen X scaffolds requiring hypertrophic chondrocytes and b) membraneous or direct bone formation mediated by osteoblasts without primary cartilage synthesis.

Using zygapophyseal joints of AS patients (and zygapophyseal joints from autopsy controls and from OA patients for comparison), we determined whether chondrocytes acquire signs of chondrocyte hypertrophy upon joint remodeling or whether direct ossification by osteoblasts could be involved in the process of new bone formation in AS.

Methods: 17 zygapophyseal, i.e. facet joints from 14 patients with AS fulfilling the modified New York Criteria, 22 zygapophyseal joints from 12

patients with OA and 11 zygapophyseal joints of 10 non-AS control patients were included in the study.

The percentage of hypertrophic chondrocytes was determined by immunohistochemistry according to Runx2, MMP13 and collagen X expression in the cartilage of zygapophyseal joints. Activation of the wingless (wnt) pathway controlling chondrocyte hypertrophy was analyzed according to beta-catenin expression. Osteoblasts were identified according to CD56 staining.

Results: The percentage of hypertrophic chondrocytes expressing Runx2, COL10 and MMP13 was significantly increased in OA (mean ± SEM: Runx2 = 55.03 ± 11.83%, COL10 = 8.79 ± 8.88%, MMP13 = 14.55 ± 8.77%) but not in AS joints (Runx2 = 38.49 ± 22.84%, COL10 = 2.71 ± 3.05%, MMP13 = 1.80 ± 2.53%) compared to CO joints (Runx2 = 33.06 ± 17.27%, COL10 = 4.87 ± 4.66%, MMP13 = 1.43 ± 0.87%). Beta-catenin expression was low in AS (0.54 ± 0.84%) and CO zygapophyseal joints (1.83 ± 2.85% of chondrocytes) while in OA joints the number of beta-catenin positive chondrocytes was significantly increased (18.84 ± 18.31%).

Osteoblasts were observed at their typical location, i.e. within the bone marrow, lining the trabecular bone. However, CD56-positive cells were also found at the edges of fibrous tissue which is often observed at subchondral bone marrow sites in AS and OA joints and which invades the subchondral bone. Runx-2 and weak osteocalcin expression of these lining cells further supports their osteoblastic nature. Ossification of cartilage was predominantly found at contact zones between the fibrous tissue and the cartilage in AS joints; i.e. in 71% of AS joints and 27% of OA joints with fibrous tissue-cartilage contacts.

Conclusion: The lack of chondrocyte hypertrophy as an indicator of endochondral bone formation but co-localization of osteoblasts with fibrous tissue and bony transformation at contact zones to cartilage in AS joints suggest that direct ossification is involved in joints ankylosis in AS.

Shared HLA Class I and II Alleles in Susceptibility to Ankylosing Spondylitis Among Three Ethnic Groups. Mark Hwang[1], Xiaodong Zhou[1], Michael H. Weisman[2], Michael M. Ward[3], Jiucun Wang[4], Lianne S. Gensler[5], Hejian Zou[4], Dongyi He[6], Matthew A. Brown[7], Paul Scheet[8] and John D. Reveille[1]. [1]University of Texas Health Science Center at Houston, Houston, TX, [2]Cedars-Sinai Medical Center, Los Angeles, CA, [3]NIAMS/NIH, Bethesda, MD, [4]Huashan Hospital, Shanghai, China, [5]University of California, San Francisco, San Francisco, CA, [6]Shanghai Guanghua Hospital, Shanghai, China, [7]University of Queensland Diamantina Institute, Brisbane, Australia, [8]MD Anderson Cancer Center, Houston, TX.

Background/Purpose: The purpose of this study is to examine associations of HLA class I and class II alleles with AS in different patients populations of whites of European ancestry (EA) and African-American (AA) ethnicities, as well as HLA-B locus associations in Han Chinese (HC).

Methods: HLA-A, -B, -C, -DRB1, -DQB1 and -DPB1 alleles were examined by DNA typing in unrelated patients from the Prospective Study of Outcomes in Ankylosing Spondylitis cohort, the North American Spondylitis Consortium and Australo-Anglo-American Spondyloarthritis Consortium. For the HLA-B locus analyses, an additional 578 British and Australian AS patients from the Australo-Anglo-American Spondylitis Consortium and 360 HC AS patients were also analyzed. Included therefore in the study were 1829 EA, 62 AA patients and 360 HC who met modified New York criteria for AS. Controls were North American white and African American as well as Han Chinese subjects without history of rheumatic disease. To remove an associated effect of HLA-B*27 due to linkage disequilibrium, analyses were also conducted on HLA-B*27 non-carriers only. Statistical analysis was done by construction of 2x2 tables and testing the proportion of alleles in cases vs. controls with Fisher's exact test. Other analyses included permutation-based omnibus testing and "relative predispositional effects" (RPE) analysis.

Results: HLA-B27 occurred in 88.7% of EA, 61% of AA, and 93% of HC patients compared to 7.5%, 2% and 7.6%, respectively, of ethnicity matched controls. HLA-B*07 was negatively associated with AS in all three ethnic groups (6.2 % versus 14.9% in EA, p $3.655 \times 10^{-26,}$ 3.2% versus 14% in AA(p=0.02), and 1% versus 12% in HC (p=0.0018). Among EA AS patients, HLA-B27 noncarriers showed positive associations with HLA-B*38 (OR=2.94, p =0.0008) and DRB1*04:04 (OR= 3.02 p = 0.0065) and negative associations with HLA-B*07 and HLA-DRB1*03, HLA-DRB1*15:01 and their respective linked alleles DQB1*02:01 and DQB1*06. Additional associations with HLA-B*14(OR = 1.74, p < 0.001) and HLA-B*40 (OR = 1.32, p = 0.02) were observed via RPE analysis, which excludes the HLA-B*27 alleles. No associations were seen with HLA-DPB1 alleles or with HLA-A*02 (the latter seen in a much larger study where HLA alleles were imputed but not directly genotyped). Among AA patients, positive associations were seen in HLA-B*27 (OR = 75.11, p <0.0001), HLA-B*40 (OR = 8.33, p = 0.01) and HLA-DRB1*13:02 (OR = 2.43, p = 0.02). No statistically significant associations were seen in HLA-DQB1, HLA-DPB1 alleles. In the HC, no association was seen with B*40:01 (B60) although an association was seen by a covariate via logistic regression analysis (p=0.02, OR=2.3) and by RPE analysis (p=0.01, OR=1.56). Negative associations were also demonstrated with HLA-B*13, B*15, B*46 and B*51.

Conclusion: This is the largest directly genotyped HLA study to date. These data, analyzing the largest number of AS patients in three patient populations examined to date, suggest other HLA alleles to be operative in AS predisposition in addition to HLA-B*27. The shared association of certain alleles in all three groups suggests a direct role in AS pathogenesis

A Gender Bias in Gut Microbiota of SKG Mice Colonized with a Limited Bacterial Consortium Associated with Severity of Spondyloarthritis and Ileitis Triggered By Beta-Glucan. Linda Rehaume, Olga Zbarskaya, Alicia Kang, Helen Benham, Paraic O Cuiv, Mark Morrison and Ranjeny Thomas. University of Queensland Diamantina Institute, Brisbane, Australia.

Background/Purpose: Beta-glucan (curdlan)-treated BALB/c ZAP-70^{W163C}(SKG) mutant mice develop IL-23-dependent spondyloarthritis, and curdlan promotes ileitis in SKG mice housed under specific pathogen-free (SPF) but not germ-free (GF) conditions. When GF SKG mice were recolonized with altered Schaedler flora, a limited bacterial consortium known as altered Shaedler microbiota (ASM), SKG mice developed spondyloarthritis and ileitis. Relative to SPF conditions, ASM-SKG mice developed spondyloarthritis and ileitis with reduced severity, and incidence of ileitis was reduced. Relative to female mice, disease severity in male SKG mice was reduced. Our aim was to study SKG mice recolonized with ASM to understand the mechanisms by which certain gut micro-organisms drive SpA-like disease, and their relationship to gender and the curdlan inflammatory trigger.

Methods: GF SKG mice were recolonized at the Walter and Eliza Hall Institute of Medical Research with ASM (*Eubacterium plexicaudatum*, *Lactobacillus murinus*, *Mucispirillum schaedleri*, 2 *Clostridium* sp., *Lactobacillus* sp., *Parabacteroides* sp., *Firmicutes* bacterium) then injected with curdlan or saline. Fecal samples were collected following recolonization and then serially after injection. The microbiota community profile was analyzed by real-time PCR. Arthritis, spondylitis and ileitis were assessed histologically in ASM-SKG mice or SPF SKG-DTR mice depleted or not of regulatory T cells (Treg).

Results: After colonization and before injection, four bacterial strains were detectable in male ASM-SKG mice (*Clostridium* sp, *Lactobacillus murinus*, *Mucispirillum schaedleri*, *Parabacteroides* sp.) with *Parabacteroides* the dominant species. In female ASM-SKG mice before curdlan, this same bacterial profile was observed except that the *Clostridium* species was not detected. After injection, the *Clostridium* species increased in female mice treated with curdlan but not saline-treated mice, and was maintained at similar levels in male mice. Depletion of Treg from curdlan-treated SKG mice under SPF conditions resulted in rapid and severe disease development.

Conclusion: Similar to non-obese diabetic mice, microbiota of ASM-SKG mice show a gender bias. Furthermore, these preliminary data suggest that the absence of a *Clostridium* species in naive female mice and outgrowth of the same species associated with curdlan-induced inflammation correlate with greater disease severity in females. *Clostridium* species derived from mouse and human microbiota have been shown to induce Treg in mouse colon. Together our data suggest a link between gender, microbial environment, mucosal Treg induction and propensity to disease severity, where either a lack of *Clostridium* species in SpA-prone mice or a lack of Treg in mice developing SpA promotes disease severity. Analysis by next generation sequencing methods will further explore gender and treatment differences in mouse gut microbiota associated with phenotype.

Effect of ERAP1 Knockdown on Conformation of HLA-B27 and Other HLA Class I Molecules in Human Monocytic Cells. Tri M. Tran[1], Sohee Hong[1], Jehad H. Edwan[2] and Robert A. Colbert[1]. [1]NIAMS/NIH, Bethesda, MD, [2]NIAMS NIH, Bethesda, MD.

Background/Purpose: Polymorphisms in endoplasmic reticulum (ER) aminopeptidase 1 (ERAP1) are associated with ankylosing spondylitis, Behcet's disease, and psoriasis/psoriatic arthritis, where HLA class I alleles are also implicated in susceptibility. The mechanism by which ERAP1 influences disease is unknown, although ERAP1 trims peptides that are presented by HLA class I. To better define the functional interaction between ERAP1 and HLA-B27 we examined the effect of knocking down ERAP1 (ERAP1 KD) on the conformation of HLA-B27 in human monocytic U937 cells (U937.B27) that also express HLA-A3/31, HLA-B18/51, HLA-C1/7).

Methods: U937.B27 cells stably expressing shRNA for ERAP1 showed a 65% reduction in ERAP1 protein expression. The unfolded and folded forms of HLA class I molecules (including HLA-B27) were assessed by immunoprecipitation with antibodies HC10 and W6/32, respectively, followed by either isoelectric focusing to separate HLA class I heavy chains, or SDS-PAGE under non-reducing or reducing conditions, to assess disulfide-linked (misfolded) complexes of HLA-B27. HLA proteins were visualized by immunoblotting with 3B.10.7. Flow cytometry was employed to measure expression of folded forms of HLA-B27 (HLA.ABC.m3 or ME1), unfolded and folded forms of HLA class I (HC10 and W6/32, respectively), on the cell surface or after permeabilization (cell surface and intracellular). MARB4, which recognizes a subset of HLA-B27 containing longer peptides and also dimers was also used.

Results: The HLA-B27-transfected U937 cells express approximately equal amounts of HLA-B27 and B51 heavy chains, which is greater than the HLA-B18 allele. At steady state, ERAP1 KD resulted in 47% more folded HLA-B27 accumulating on the cell surface (HLA-ABC.m3) and 30% more in total (extra- plus intracellular), whereas there was only an 11% increase in total folded HLA class I (W6/32). When other alleles were examined by focusing, there was no increase in folded forms of HLA-B51 or B18. MARB4-reactive HLA-B27 was increased by 24% on the cell surface in ERAP1 KD cells. ERAP1 KD caused a 53% increase in unfolded HLA class I (B/C) on the cell surface, and led to a 39% increase in the accumulation of high molecular weigh disulfide-linked complexes of HLA-B27 (immunoblots) ($P < 0.05$ for all comparisons).

When cells were treated with IFNg, ERAP1 KD caused a 25% increase in total unfolded HLA-B27 compared to sc shRNA, but no increase in HLA-B51 or B18. High molecular weigh disulfide-linked complexes of HLA-B27 were also increased.

Conclusion: These data demonstrate that reduction of ERAP1 expression significantly increases both folded and unfolded/misfolded forms of HLA-B27. IFNg treatment further increased all forms of HLA-B27 when ERAP1 expression was limited. It is of interest that the effects of ERAP1 KD on HLA-B allele conformation were substantially greater for HLA-B27 than for Behcet's disease associated HLA- B51.

Innate Immune Stimulation Triggers Altered IL-1a/b Gene Expression and Experimental Spondyloarthritis in HLA-B27/huβ2m Transgenic Rats. Melissa N. van Tok[1], Leonie M. van Duivenvoorde[1], Nimman Satumtira[2], Martha L. Dorris[2], Joel D. Taurog[2] and Dominique L. Baeten[1]. [1]Department of Clinical Immunology and Rheumatology and Department of Experimental Immunology, Academic Medical Centre/University of Amsterdam, Amsterdam, Netherlands, [2]UT Southwestern Medical Center, Dallas, TX.

Background/Purpose: Spondyloarthritis (SpA) does not display typical features of autoimmune diseases such as female predominance, presence of autoantibodies, or clinical response to T- and/or B cell targeting biologicals. Despite the strong association with MHC class I, CD8 T cells are not required for disease induction in the HLA-B27/huβ2m transgenic rat model. Moreover, the capability of HLA-B27 to misfold and thereby induce endoplasmatic reticulum stress and the direct recognition of HLA-B27 homodimers by NK cells suggest pathogenic mechanisms which may be independent of classical acquired immune responses. Therefore, we and others propose that SpA may be primarily driven by an innate immune response. Using the HLA-B27/huβ2m transgenic rat model,[1] we investigated this hypothesis by studying the effect of innate immune stimulation on ex vivo cytokine expression and in vivo development of arthritis and spondylitis.

Methods: Splenocytes and bone marrow cells isolated from HLA-B27/huβ2m tg rats and controls were stimulated for 6 hours with 50 ng/ml LPS, 5 μg/ml zymosan or 5 μg/ml heat-inactivated *Mycobacterium tuberculosis*. TNF, IL-1, IL-6, IL-10 and IL-23p19 expression was measured by qPCR. In vivo, six week old male and female HLA-B27/huβ2m tg were immunized with a low dose of *M. tuberculosis*in incomplete Freund's adjuvant. Rats were followed up for 60 days and scored clinically for arthritis and spondylitis. At day 60 hind limbs and tails were analysed for inflammation, destruction and new bone formation by histology.

Results: In vitro stimulation of splenocytes with zymosan and with *M. tuberculosis*, but not with LPS, strongly induced gene expression of pro-inflammatory cytokines such as TNF, IL-1a, IL-1b and IL-6 in all 3 groups of rats. IL-1a and IL-1b, but not TNF or IL-6, were increased in the HLA-B27/huβ2m transgenic cells as compared to both HLA-B7/huβ2m tg and wild-type controls upon ex vivo stimulation. IL-10 and IL23p19 expression could not be detected in any of the groups after stimulation. In vivo, non-immunized HLA-B27/huβ2m tg males spontaneously develop arthritis and spondylitis after 4–6 months of age with an incidence of 70% and 40%, respectively, whereas female rats do not develop disease. Immunization of male HLA-B27/huβ2m tg rats with 30 μg of *M. tuberculosis* was sufficient to induce arthritis and spondylitis within 2–3 weeks with an incidence of 80–100%. Moreover, HLA-B27/huβ2m tg females developed similar disease when immunized with 60 μg of *M. tuberculosis*. Control rats were less sensitive to low doses of *M. tuberculosis*. Histologically in both male and female HLA-B27/huβ2m tg rats inflammation, destruction and new bone formation was detected in both peripheral and axial joints.

Conclusion: The transgenic expression of HLA-B27/Hub2m increases the sensitivity to innate immune stimulation as evidenced by increased IL-1a and IL-1b expression ex vivo and development of arthritis and spondylitis in vivo. These data suggest that the B27/Hub2m expression lowers the threshold for innate immune activation of the IL-1 pathway, and this alone may be sufficient to trigger experimental SpA.

ERAP1 Knockdown Affects HLA-B27 Misfolding and Endoplasmic Reticulum Stress in HLA-B27 Transgenic Rat Macrophages. Sohee Hong and Robert A. Colbert. NIAMS/NIH, Bethesda, MD.

Background/Purpose: Endoplasmic reticulum aminopeptidase 1 (ERAP1) is a multifunctional enzyme involved in the processing of peptide cargo for major histocompatibility complex (MHC) class I complexes, and can have significant effects on peptide repertoire, and cell surface expression and stability of MHC class I molecules. ERAP1 variants are associated several MHC class I-associated inflammatory diseases, such as ankylosing spondylitis (AS), Behcet's disease, and psoriasis/psoriatic arthritis, with evidence for epistasis with MHC class I susceptibility alleles. Since peptide supply is a critical determinant of MHC class I folding and assembly, we asked whether ERAP1 knockdown would affect HLA-B27 misfolding and endoplasmic reticulum (ER) stress in HLA-B27 transgenic (Tg) rats.

Methods: Bone marrow derived macrophages from HLA-B27 Tg, HLA-B7 Tg and wild type (WT) rats were transduced with lentiviral ERAP1 shRNA or scrambled shRNA as a control. Protein expression including folded, unfolded, and misfolded forms of HLA-B27 was evaluated using immunoblotting of whole cell lysates and immunoprecipitates. To evaluate the effects of cytokines, macrophages were treated without or with IFNg (100 ng/ml) or IFNg and TNFa (30 ng/ml) for 24–48 hr. ER stress was assessed using real time PCR and XBP-1 splicing.

Results: ERAP1 protein expression was reduced 55–77% by ERAP1 shRNA as measured by immunoblotting blotting in several experiments, before and after treatment with cytokines. ERAP1 knockdown led to

increased accumulation of aberrant disulfide-liked HLA-B27 complexes in whole cell lysates and HC10 immunoprecipitates. Interestingly, HLA-B7 heavy chains, which do not misfold under normal conditions, could be detected forming dimers with prolonged exposure in ERAP1 KD cells, although quantitatively much less than for HLA-B27. Expression of Bip and CHOP mRNA and XBP1 splicing were elevated in ERAP1 KD cells compared to sc shRNA. With cytokine stimulation, the there was increased UPR target gene expression and XBP1 splicing consistent with accumulation of aberrant HLA-B27 complexes.

Conclusion: In summary, these results suggest that ERAP1 loss-of-function impacts HLA-B27 misfolding and may affect the pathogenesis of AS via the aberrant biology of HLA-B27 and ER stress.

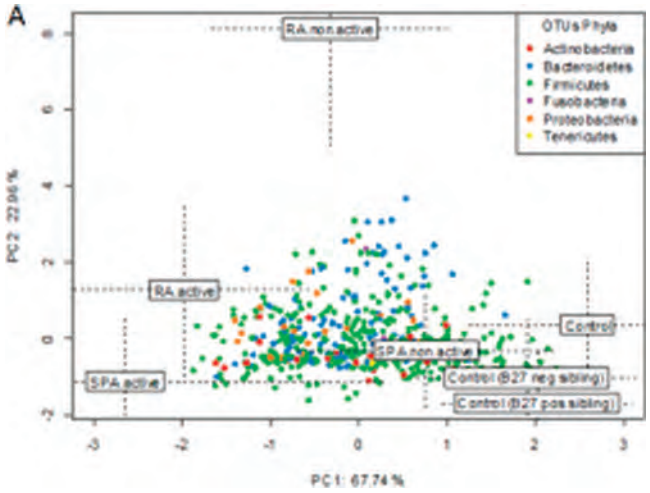
Gut Microbiota Variations Correlate with Disease Activity in Spondyloarthritis (SpA) and Rheumatoid Arthritis (RA). Julien Tap[1], Jad Abou-Ghantous[1], Ariane Leboime[2], Roula Said Nahal[2], Philippe Langella[1], Henri-Jean Garchon[3], Gilles Chiocchia[4], Jean-Pierre Furet[1] and Maxime Breban[2]. [1]UMR INRA-AgroParisTech 1319, Equipe ProbiHote, MICALIS Institute, National Institute for Agronomical research (INRA), Jouy-en-Josas, France, [2]Service de Rhumatologie, Hopital Ambroise Pare, Boulogne-Billancourt, France, [3]INSERM U987, Faculté des Sciences de la Santé Simone Veil, Montigny-le-Bretonneux, France, [4]INSERM U987, UFR des Sciences de la Santé, Montigny-le-Bretonneux, France.

Background/Purpose: Inflammatory bowel diseases (IBD) are associated with changes in microbiota which may be responsible for sustained gut inflammation and/or a consequence of it. Whether variations in microbiota also play a role during the course of inflammatory rheumatic disorders such as SpA or RA, remains to be addressed.

Methods: Targeted metagenomic profiles were established by deeply sequencing the 16S rRNA-encoding bacterial genes amplified by PCR in stools from 97 SpA and 33 RA patients, and 72 healthy controls (including 46 siblings of SpA patients). After pyrosequencing and a denoizing step to remove artefactual reads, bacterial operational taxonomic units (OTUs) were attributed to the remaining sequences (>1.5M reads, 8,000 sequences per sample in average). Supervised analysis (between class co-inertia analysis and L1-regularized logistic machine learning procedure) was carried out to identify factors associated with OTUs variations. Age, gender, disease status and activity (SpA: BASDAI; RA: DAS28) and concomitant treatments (NSAIDs, corticosteroids, DMARDs, biotherapies) were the considered variables.

Results: Neither SpA nor RA status correlated with discrete OTUs variations. Using 600 OTUs represented in at least 1% of the reads mass per sample, disease activity was the main clinical factor explaining variations in OTUs composition, similarly in SpA and RA. Concomitant treatments, and particularly corticosteroids, had also significant impact but of lesser magnitude.



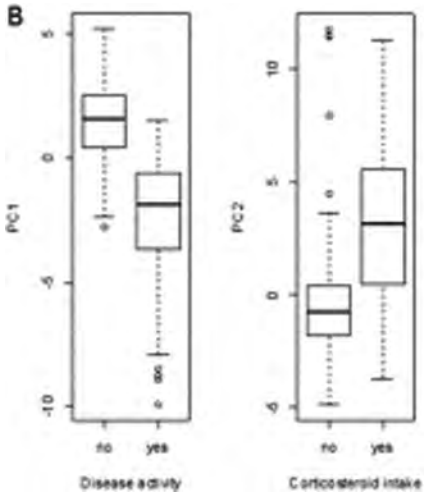


Figure 1: Supervised co-inertia analysis between clinical metadata and microbial OTUs variation as function of health status. A) Health statuses are plotted according the two main components. Monte Carlo test showed that health statuses were significantly linked with clinical metadata and microbiota OTUs variations (colored according their phylum assignation). B) Principal components allowed to significantly separate patients according to disease activity and corticosteroid intake.

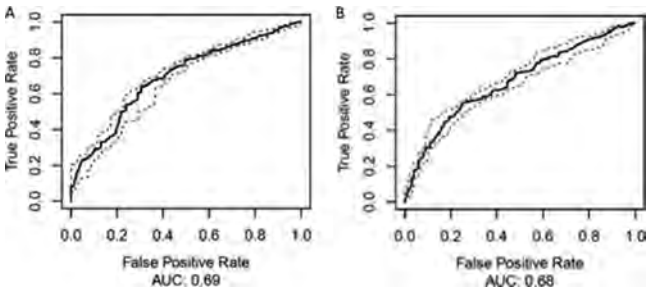

Figure 2: A. Complementary to this signal, SpA and RA could be distinguished from controls by combining 16 OTUs, yielding a statistically significant ROC curve (AUC = 0.69). B. The best model to predict disease activity included 110 OTUs and yielded a statistically significant ROC curve (AUC = 0.68).

Conclusion: Variations in OTUs were found both in SpA and RA, as compared to healthy controls that primarily correlated with disease activity. Whether such variations are cause or consequence of chronic joint inflammation remains to be determined.

Epigenetic Studies in Maternally Versus Paternally Transmitted Psoriatic Disease. Darren D. O'Rielly[1], Remy Pollock[2], Yuhua Zhang[3], Nayef Al Ghanim[1], Sean Hamilton[1], Dafna D. Gladman[2], Vinod Chandran[2], Rose Ardern[1], Guangju Zhai[3] and Proton Rahman[1]. [1]Memorial University of Newfoundland, St. John's, NF, [2]University of Toronto, Toronto Western Hospital, Toronto, ON, [3]Discipline of Genetics, Faculty of Medicine, Memorial University of Newfoundland, St. John's, NF.

Background/Purpose: Epidemiological studies have noted excess paternal transmission in psoriasis and psoriatic arthritis. To date, there has been no molecular explanation to account for this observation. Differential methylation patterns have long been implicated as a potential mechanism to account for excess paternal transmission. In this pilot study, we investigated the differential methylation pattern among paternally and maternally transmitted PsA.

Methods: Twenty-four (24) patients with maternally transmitted PsA were compared with 24 paternally transmitted PsA cases. For maternally transmitted PsA, the proband's mother had either psoriasis or PsA, and for

paternally transmitted PsA, the proband's father had either psoriasis or PsA. Genome-wide DNA methylation profiling was performed on all these 48 samples by using Illumina HumanMethylation450k Beadchip, which measures up ~480,000 different CpG sites per sample and covers 96% of RefSeq genes. The methylation level at each CpG site was measured by β values varying from 0 (no methylation) to 1 (100% methylation).

Results: Maternally transmitted PsA cases were predominantly females (19/24) with mean age of onset of PsA at 30.6 years. For paternally transmitted PsA, there were slightly more females (13/24) and age of onset of PsA was 22.2 years. Methylation data were normalized using BMIQ method and no batch effects were detected by PCA analysis. Methylation analysis was performed on 382,024 of the 485,512 CpG sites after filtering and revealed 90 significant CpG sites ($p<0.05$). The three most significant CpG sites were hypermethylated regions located on chromosome 8 that did not reside on or adjacent to a gene, with p values ranging from $9x10^{-7}$ to $5x10^{-6}$. Many genes of interest based on current understanding of psoriatic disease were identified including hypermethylation of CPG sites on *MICA* (diff 10.22%; p=0.014), *IRIF1* (diff 10.3%; p=0.016), *PSORS1C3* (diff 11.1%; p=0.005); and *TNFS4* (diff 15.2%; 0.004). Excess hypomethylation at CPG sites was noted on *PSORS1C1* (18.9% diff. p=0.027).

Conclusion: These preliminary results demonstrate that the global DNA methylation pattern in paternally transmitted PsA differs from maternally transmitted PsA. High priority candidate regions and genes identified in this study need further validation.

Genome-Wide Methylome Investigation Reveals New Candidate Genes Associated with Arthritis Mutilans. Vinod Chandran[1], Darren O'Reilly[2], Amir Haddad[1], Yuhua Zhang[3], Guangju Zhai[3], Dianne Codner[2], Arane Thavaneswaran[1], Proton Rahman[2] and Dafna D. Gladman[1]. [1]University of Toronto, Toronto Western Hospital, Toronto, ON, [2]Memorial University of Newfoundland, St. John's, NF, [3]Discipline of Genetics, Faculty of Medicine, Memorial University of Newfoundland, St. John's, NF.

Background/Purpose: Arthritis mutilans is a severe form of psoriatic arthritis (PsA). Why some patients develop this rapidly progressive destructive disease remains unclear. We hypothesized that the epigenetic signature may be different between PsA patients with and without arthritis mutilans. The aim of this study was to investigate DNA methylation in PsA patients with and without arthritis mutilans.

Methods: Arthritis mutilans was defined using the modified Steinbrocker scoring (mSS) method which classifies each of a total of 42 joints on a 0–4 scale where grade 0=normal, 1= juxta-articular osteopenia or soft tissue swelling, 2=erosion, 3=erosion and joint space narrowing and 4=total destruction (severe osteolysis, subluxation, ankylosis, pencil-in-cup change). Patients with at least 1 joint with grade 4 damage were classified as having arthritis mutilans and those with no damage following similar duration of follow up were classified as PsA patients without mutilans. All patients were Caucasians of Northern European Ancestry. Genome-wide DNA methylation profiling was performed on the blood DNA samples from 24 PsA patients with mutilans and 24 patients without arthritis mutilans. The methylation profiling was performed using Illumina HumanMethylation450k Beadchips, which measures up ~480,000 different CpG sites per sample and covers 96% of RefSeq genes. The methylation level at each CpG site was measured by β values varying from 0 (no methylation) to 1 (100% methylation).

Results: PsA patients with arthritis mutilans (50% males) had mean of disease onset at age 31.8 (10.7) years and age at time of assessment was 42.8 (11.4) years Meanwhile, PsA patients with no evidence of arthritis mutilans (50% males) had mean of disease onset at age 32.7 (16.1) years and age at time of assessment was 41.8 (15.1) years. Methylation data were normalized using BMIQ method and no batch effects were detected by PCA analysis. Methylation analysis was performed on 332,530 autosomal CpG sites after applying quality control filtering. Two outliers were identified and excluded in the subsequent analysis. Methylation profiling analysis revealed 37 CpG locations where there was at least 10% difference in β values between patients with and without arthritis mutilans. The three locations that differentiated the most after correction for multiple testing included CpG sites in *WNT3A* (hypermethylated; $p=3.74x10^{-5}$); *NRXN2* (hypomethylated; $p=6.02x10^{-5}$) and an agenic region (hypomethylated; $p=4.53x10^{-5}$). Based on functional relevance to PsA pathology, particularly antigen presentation, cytokine signalling, and bone remodeling, 5 candidate genes (2 hypomethylated; 3 hypermethylated) emerged: *PELI2* (β diff=−0.1249; p=0.001), *SEEK1* (β diff=0.1834; p=0.002), *COL11A1* (β diff=0.1085; p=0.006), *ADAMTS1* (β diff=−0.1030; p=0.005), and *WNT3A* (β diff=0.0752; $3.74x10^{-5}$).

Conclusion: These preliminary results demonstrate that the DNA methylation signature in PsA patients with arthritis mutilans is distinct compared with PsA patients without mutilans. High priority candidate genes identified in this study warrants further validation.

Elder[4], Paul IW. de Bakker[12] and Soumya Raychaudhuri[13]. [1]Tokyo Medical and Dental University, Tokyo, Japan, [2]Broad Institute of MIT and Harvard, Cambridge, MA, [3]University of Michigan, Ann Arbor, MI, [4]University of Michigan Medical School, Ann Arbor, MI, [5]Christian-Albrechts-University of Kiel, Kiel, Germany, [6]University of Toronto, Toronto Western Hospital, Toronto, ON, [7]University of Toronto, Toronto, ON, [8]Imperial College, London, United Kingdom, [9]University of Utah, Salt Lake City, UT, [10]Memorial University of Newfoundland, St. John's, NF, [11]The Feinstein Institute for Medical Research, Manhasset, NY, [12]University Medical Center, Utrecht, Netherlands, [13]Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Background/Purpose: Psoriasis vulgaris (PsV) risk is strongly associated with genetic variation within the major histocompatibility complex (MHC) region, although its fine genetic architecture has not been elucidated.

Methods: To fully characterize and fine-map the MHC associations of PsV, we conducted a large-scale fine-mapping study of PsV risk in the MHC region in 9,247 PsV cases and 13,589 controls of European descent. We also evaluated risk of two major clinical subtypes of PsV, psoriatic arthritis (PsA; n = 3,038) and purely cutaneous psoriasis (PsC, defined as 10 years of psoriasis without developing PsA; n = 3,098). We imputed class I and II HLA gene variants by applying SNP2HLA software to the SNP genotype data. In addition, we newly constructed an imputation reference panel of sequence variants for *MICA*, an HLA-like gene within the MHC region that has been implicated for PsA risk. We applied MICA variant imputation to the SNP genotype data and evaluated their risk as well.

Results: As previously described, we observed that *HLA-C*06:02* demonstrated the most significant impact on overall PsV risk (odds ratio [OR] = 3.38, 95% confidence interval [95%CI]: 3.18–3.60, $P = 1.7x10^{-364}$). Stepwise conditional analysis revealed multiple independent risk variants of both class I and class II HLA genes for PsV susceptibility independent of *HLA-C*06:02* (*HLA-C*12:03*, HLA-B amino acid positions 67 and 9, HLA-A amino acid position 95, and HLA-DQα1 amino acid position 53; $P < 5.0x10^{-8}$), but no apparent independent risk conferred by *MICA*. Strikingly, we found that risk heterogeneity between PsA and PsC may be driven by one amino acid position at *HLA-B* (Glu at HLA-B amino acid position 45; OR = 1.46, 95%CI: 1.31–1.62, $P = 2.9x10^{-12}$), which demonstrated much more significant association signals compared to classical *HLA-B* alleles including *HLA-B*27* and *HLA-B*39:01* ($P > 1.0x10^{-4}$).

Conclusion: These results indicate that multiple class I and II HLA genes (*HLA-C*, *HLA-B*, *HLA-A*, and *HLA-DQA1*) contribute to development of PsV, and suggest that different genetic factors, most evident at *HLA-B*, underlie for the differential risk of specific PsV sub-phenotypes. Our study illustrates the value of high-resolution HLA and *MICA* imputation for fine-mapping causal variants in the MHC.

The Impact of the Interaction Between Human Leukocyte Antigen Alleles and Obesity on Psoriatic Arthritis Risk. Lihi Eder[1], Fatima Abji[1], Cheryl Rosen[1], Proton Rahman[2], Vinod Chandran[1] and Dafna D. Gladman[1]. [1]University of Toronto, Toronto Western Hospital, Toronto, ON, [2]Memorial University of Newfoundland, St. John's, NF.

Background/Purpose: Human Leukocyte Antigen (HLA) class I alleles and obesity are risk factors for psoriatic arthritis (PsA). We aimed to assess whether there is an interaction between HLA risk alleles for PsA and obesity in susceptibility to PsA.

Methods: The study comprised two parts: 1) a case-only design that included patients with early PsA (<2 years) from 2 PsA cohorts, 2) a case-control design in which patients with early PsA were compared to those with psoriasis alone (PsC). Body Mass Index (BMI) at the first visit was stratified to normal (<25), overweight (25≤BMI<30) and obese (≥30). HLA genotyping was performed by sequence-specific oligonucleotide probes. The following alleles that were independently associated with PsA were analyzed: HLA-B*08, B*18, B*27, B*38, B*39 and C*06. Due to low frequency and similar structure, the effect of HLA-B*08, B*18, B*39 and B*38 was assessed in conjunction (termed "combined HLA-B alleles"). The interaction between obesity and HLA alleles was assessed by comparing the distribution of the various alleles across the three BMI categories in patients with PsA using trend test (case-only design). The interaction between HLA alleles and obesity was further investigated (case-control design) by assessing a departure from multiplicative combined effect of risk using logistic regression analysis after adjusting for age and sex and by assessing a departure from additivity by calculating the attributable proportion (AP).

Results: 637 Caucasians patients were analyzed (262 PsA, 375 PsC). Obesity was more frequent in patients with PsA compared to those with PsC (p=0.005). In addition, HLA-B*27 (p=0.0001) and the combined HLA-B alleles (p=0.03) were associated with PsA vs. PsC. A differential distribution of HLA-B alleles was observed across the 3 BMI categories in patients with PsA (case-only design) suggesting an interaction. The frequency of B*27 was higher in patients with normal weight compared to those with higher BMI (p^{trend}=0.005). In contrast, PsA patients who carried one of the combined HLA-B alleles tended to be heavier (p^{trend}=0.03). Similar findings were observed in the case-control analysis (Figure 1). A multiplicative interaction was found for the combined effect of B*27 and obesity in logistic regression analysis (OR 0.1 p=0.01) as well as for the joint effect of combined HLA-B alleles and obesity (OR 2.7 p=0.03). A significant additive interaction of combined HLA-B alleles and obesity was found with the proportion of risk due to additive interaction (AP) of 0.62 (95% CI 0.38, 0.93, p=0.0001). No interaction was found between obesity and HLA-C*06 allele.

Conclusion: An interaction was found between HLA-B alleles and obesity in PsA risk thus the effect of obesity on PsA risk may depend on the presence of HLA-B alleles.

Figure 1 - The frequency of HLA alleles in PsA vs. PsC by BMI category

HLA Markers for Disease Severity Are Associated with a Higher Burden of Atherosclerosis in Patients with Psoriatic Disease. Lihi Eder, Fatima Abji, Cheryl Rosen, Vinod Chandran and Dafna D. Gladman. University of Toronto, Toronto Western Hospital, Toronto, ON.

Background/Purpose: Recent evidence supports the link between the extent of inflammation and cardiovascular risk in patients with psoriatic disease (PsD). We aimed to investigate the association between Human-Leukocyte Antigen (HLA) markers of severe phenotype and the extent of atherosclerosis in PsD.

Methods: Consecutive Caucasian patients with Psoriatic arthritis (PsA) and psoriasis alone (PsC) were recruited from two large cohorts. Patients with PsA met the CASPAR criteria. Patients with PsC were examined by a rheumatologist to exclude the presence of arthritis. Information about the participants' demographics, co-morbidities and skin and joint disease activity was obtained from the cohorts' database. An ultrasound of the carotid arteries was performed and the presence of atherosclerotic plaques was recorded. The size of each plaque was measured and the resulting score, the total plaque area (TPA), represented the extent of atherosclerosis. TPA was classified to 4 categories (No plaques, mild, moderate and severe atherosclerosis). HLA genotyping was performed by sequence-specific oligonucleotide probes. Haplotype information was inferred using an expectation–maximization algorithm. Ten HLA alleles that were previously reported to be associated with severe phenotype of PsD were analyzed. The association between each HLA allele and the severity of atherosclerosis was assessed by ordinal logistic regression models adjusted for age, sex and traditional cardiovascular risk factors.

Results: 411 patients with PsD (273 PsA, 138 PsC) were analyzed. Their mean age was 55.5±11.5 years and 55.7% were males. 254 (61.8%) had at least one atherosclerotic plaque. HLA-B*1302 and HLA-C*0602 were associated with more severe atherosclerosis (age- and sex-adjusted Odds Ratio (OR) 2.31 (95% Confidence Interval (CI) 1.23, 4.32) and OR 1.68 (95% CI 1.12, 2.52), respectively). The haplotype HLA-B*1302-C*0602 was also associated with more severe atherosclerosis (OR 2.49, 95% CI 1.32, 4.72). The association between HLA-C*0602 and B*1302 and atherosclerosis severity remained statistically significant after adjusting for traditional cardiovascular risk factors (OR 1.63 (95% CI 1.08, 2.45) and OR 2.21 (95% CI 1.17, 4.16), respectively). Lower extent of atherosclerosis was found in carriers of HLA-B*3801 allele and the HLA-B*3801-C*1203 haplotype (age- and sex-adjusted OR 0.49 (95% CI 0.28, 0.86) and OR 0.45 (95% CI 0.26, 0.80), respectively). Higher levels of erythrocyte sedimentation rate over time were associated with HLA-B*1302 (p=0.02) and HLA-C*0602 (p=0.0007). No association was found between these alleles and traditional cardiovascular risk factors. No interaction was found between the HLA alleles and disease status.

Conclusion: HLA-C*0602 and B*1302 are markers of more severe atherosclerosis, while HLA-B*3801 is associated with lower burden of atherosclerosis in patients with PsD.

Disclosure: L. Eder, None; **F. Abji**, None; **C. Rosen**, None; **V. Chandran**, None; **D. D. Gladman**, None.

The Predictive Value of Cardiovascular and Metabolic Biomarkers for Progression of Atherosclerosis in Psoriatic Disease. Lihi Eder, Fatima Abji, Cheryl Rosen, Vinod Chandran and Dafna D. Gladman. University of Toronto, Toronto Western Hospital, Toronto, ON.

Background/Purpose: The pathophysiologic mechanisms underlying the accelerated atherosclerosis in patients with psoriatic disease (PsD) are unknown. We aimed to investigate candidate pathways involved in this process by identifying biomarkers that predicted progression of atherosclerotic plaques in patients with PsD.

Methods: A prospective cohort study was conducted in patients with psoriatic arthritis (PsA) and psoriasis alone (PsC) from 2010 to 2014. Patients with PsA met the CASPAR criteria. Patients with PsC were examined by a rheumatologist to exclude the presence of arthritis. Information about demographics, co-morbidities and disease manifestations was collected. The following serum cardiovascular and metabolic biomarkers were assessed at baseline by enzyme-linked immunosorbent assay (ELISA): insulin, adiponectin, leptin, vascular cell adhesion molecule 1 (VCAM-1), intracellular adhesion molecule 1 (ICAM-1), plasminogen activator inhibitor 1 (PAI-1), myeloperoxidase (MPO) and lipoprotein-associated phospholipase A2 (Lp-PLA2). The homeostatic model assessment (HOMA) was calculated using insulin and glucose levels to estimate insulin resistance. Ultrasound assessment of the carotid arteries was performed and Total Plaque Area (TPA) was measured at baseline and after 3 years. This measure represented the extent of atherosclerosis and was considered the outcome of interest. TPA at baseline was classified to 4 categories (No plaques, mild, moderate and severe atherosclerosis). A significant progression in atherosclerosis was defined as an increase in TPA of $> 0.1\ cm^2$ at 3 years (top quartile of TPA progression from baseline). The association between the log-transformed levels of the various biomarkers and TPA at baseline and atherosclerosis progression at 3 years was assessed using logistic regression models adjusted for age, sex and cardiovascular risk factors.

Results: A total of 235 patients with PsD (121 PsA, 114 PsC) were scanned at baseline, 129 of them were re-scanned at 3 years. The mean age of the study population was 52.5 ± 11.9 years and 54% were males. Patients with more severe atherosclerosis at baseline had higher levels of VCAM-1 ($p=0.0002$), ICAM-1 ($p=0.03$), leptin ($p=0.03$) and HOMA ($p=0.0002$), however in the age- and sex-adjusted model only HOMA remained significantly associated with more severe atherosclerosis (Odds Ratio (OR) 1.6, 95% Confidence Interval (CI) 1.2, 2.3, $p=0.006$). 31 of 129 patients had a significant progression of atherosclerosis at 3 years. Higher levels of Lp-PLA2 ($p=0.03$), PAI-1 ($p=0.05$) and HOMA ($p=0.01$) and lower levels of adiponectin ($p=0.04$) predicted progression of atherosclerosis. In the multivariate regression model adjusted for age, sex and cardiovascular risk factors, Lp-PLA2 (OR 5.5, 95% CI 1.4, 22.5, $p=0.02$), adiponectin (OR 0.3, 95% CI 0.1, 0.8, $p=0.008$) and HOMA (OR 2.2, 95% CI 1.1, 4.4, $p=0.03$) predicted progression of atherosclerosis in patients with PsD. No interaction was found between disease status (PsA vs. PsC) and any of the biomarkers.

Conclusion: Biomarkers involved in lipid and glucose metabolism and other metabolic pathways play a role in progression of atherosclerosis in patients with PsD.

Disclosure: L. Eder, None; **F. Abji**, None; **C. Rosen**, None; **V. Chandran**, None; **D. D. Gladman**, None.

Biomarkers of Chondrocyte Activity Are Increased in Psoriasis Arthritis and Spondyloarthritis. Natasja Stæhr Gudman[1], Heidi Lausten Munk[2], Anne Friesgaard Christensen[3], Leif Ejstrup[4], Grith Lykke Sørensen[5], Anne Gitte Loft[3], Morten A. Karsdal[1], Anne C. Bay-Jensen[6], Yi He[7], Anne Sofie Siebuhr[1] and Peter Junker[2]. [1]Nordic Bioscience, Biomarkers and Research, Herlev, Denmark, [2]Department of Rheumatology, Odense University Hospital, Odense, Denmark, [3]Department of Rheumatology, Vejle Hospital, Vejle, Denmark, [4]Department of Rheumatology, Esbjerg Hospital, Esbjerg, Denmark, [5]Institute of Molecular Medicin, University of Southern Denmark, Odense, Denmark, [6]Cartilage Biomarkers and Research, Nordic Bioscience, Herlev, Denmark, [7]Nordic Bioscience, Herlev, Denmark.

Background/Purpose: Psoriasis arthritis (PsA) and spondyloarthritis (SpA) are both inflammatory joint diseases in which the pathogenesis is not fully understood. However, both pathologies are associated with extracellular matrix (ECM) remodeling favoring cartilage formation and calcification (type II and X collagen formation) in the affected joints. Treatment of the diseases has improved within recent years, but the therapeutic response at the level of the individual cannot be adequately predicted. Hence, there is an increasing interest in diagnostic and prognostic biomarkers to further characterize the patients to achieve personalized medicine. The biomarker ProC2 measures the level of propeptide type II collagen and C-Col10 measures type X collagen. Collagen type X is exclusively expressed by hypertrophic chondrocytes and is a measure of hypertrophic cartilage. The aim of this study was to evaluate the level of two novel biomarkers of cartilage formation (ProC2) and hypertrophy (C-Col10) in SpA, PsA and healthy controls, and to investigate whether these markers would have diagnostic potential.

Methods: 99 PsA patients, 94 SpA patients and 120 age-matched healthy controls were included in the study. Demographic and clinical disease measures were recorded. ProC2 and C-Col10 were quantified in serum by newly developed and specific competitive ELISAs based on monoclonal antibodies. One way analysis of variance and Tukeys multiple comparison test were performed on log-transformed data. Receiver operator characteristics (ROC) curve analysis was carried out to evaluate the discriminative power of the biomarkers.

Results: The serum levels of P2BNP had a mean level of 0.59ng/ml for healthy controls, but were significantly increased in patients with either SpA (mean 1.25ng/ml) or PsA (mean 1.35) compared to controls ($p<0.001$). When segregating between patients and healthy controls by mean of ROC curves the AUC was 0.78 for SpA (Cl 95% 0.71 to 0.84) and 0.79 (CI 95% 0.73–0.85) for PsA as listed at the table below. Furthermore SpA had a slightly, but significantly increased level of type X collagen (mean 0.60ng/ml) compared the controls (mean 0.56ng/ml) ($p=0.035$). None of the two markers correlated with age, sex, BMI and the markers did not correlate with each other.

Conclusion: These findings indicate that both SpA and PsA arthritis have enhanced cartilage formation reflected by increased levels of PIIBNP levels in serum compared to healthy controls. In addition, an increased level of the hypertrophic chondrocyte collagen X marker was found in SpA only, indicating a difference in cartilage turnover between the two diseases. This difference could aid in the differentiation between SpA and PsA.

Biomarkers of Bone Remodeling Are Elevated in Psoriatic Arthritis. Fatima Abji, Arane Thavaneswaran, Vinod Chandran and Dafna D. Gladman. University of Toronto, Toronto Western Hospital, Toronto, ON.

Background/Purpose: Psoriatic arthritis (PsA) is an inflammatory arthritis that develops in about a third of patients with cutaneous psoriasis (PsC). The identification of biomarkers to aid in the early diagnosis of PsA in patients with PsC may prevent disability and improve the quality of life for those affected. Inflammation in peripheral and/or axial joints in PsA is associated with abnormal bone metabolism, including erosions and bone formation. The goal of the current study was to determine if markers of bone remodeling are associated with PsA patients with active disease compared to patients with PsC only.

Methods: PsA patients with active disease (≥ 3 tender and swollen joints) and PsC patients were identified from the cohort of patients followed prospectively. Patients were matched for age, sex, PASI score and psoriasis duration and were not receiving treatment with biologic agents. PsA patients

satisfied CASPAR criteria and PsC patients were examined by a rheumatologist to exclude arthritis. Patients were not receiving treatment with methotrexate for a minimum of two years before the sampling date. Serum biomarkers measured included DKK1, FGF23, IL-6, IL-1β, leptin, osteocalcin, osteoprotegerin, osteopontin, sclerostin and TNFα. All proteins were measured simultaneously using the Millipore Milliplex MAP human bone magnetic bead panel, according to the manufacturer's instructions. Data was acquired using the Luminex 200 system and analyzed with the Biorad Bio-Plex Manager software. Significant differences were determined by performing paired t-tests between the PsA and PsC cohorts ($p<0.05$).

Results: The levels of bone biomarkers were measured in 60 PsA patients (mean age 51 years, 50% males, psoriasis duration 18 years, PASI 4.24, 11.4 tender joints, 6.3 swollen joints) and 60 PsC patients (mean age 52 years, 50% males, psoriasis duration 20 years, PASI 3.7). DKK1, leptin, osteoprotegerin, osteopontin, and sclerostin were significantly elevated in PsA patients compared to PsC patients (Table 1, paired student's t-test). TNFα levels were significantly reduced in PsA (3.7 pg/ml) patients compared to those with psoriasis only (10.6 pg/ml). Elevation in markers of bone resorption (DKK1, OPN, SOST) and ossification (leptin, OPG) in PsA relative to PsC were found, reflecting the balance in both synthesis and degradation that is disrupted in PsA. Using a reduced conditional logistic regression model that included all markers tested, IL-6, osteopontin, sclerostin and TNFα were independently associated with PsA.

Conclusion: Serum markers of bone remodeling were elevated in PsA patients with active disease compared to patients with PsC only. Future studies will focus on validating these markers in a large, independent cohort, to determine whether these genes can serve as biomarkers of PsA susceptibility.

Table 1: Expression of bone biomarkers ($p<0.05$) in serum of PsA and PsC patients

			Mean (sd) levels (pg/ml)		
Protein	**Description**	**Function**	**PsA Cohort**	**PsC Cohort**	**P-Value**
DKK1	dickkopf WNT signaling pathway inhibitor 1	Resorption	**1940.7 (627.6)**	**1750.6 (483.7)**	**0.045**
FGF23	Fibroblast growth factor 23	Resorption	113.7 (262.7)	76.3 (35.4)	0.28
IL-6	Interleukin-6	Resorption	37.0 (139.5)	49.1 (197.3)	0.71
IL-1β	Interleukin-1 beta	Resorption	2.1 (2.7)	4.1 (10.8)	0.18
LEP	Leptin	Ossification	**22347.5 (22503.2)**	**11279.1 (10508.0)**	**0.002**
OC	Osteocalcin	Ossification	10332.4 (6360.4)	8099.3 (4985.9)	0.05
OPG	Osteoprotegrin	Ossification	**443.4 (218.6)**	**374.3 (162.1)**	**0.04**

Joint and Bone Related Pathways Discriminate Psoriatic Arthritis Lesional Skin from Psoriasis vulgaris Lesional Skin. Jennifer Belasco[1], James S. Louie[2], Nicholas Gulati[1], Nathan Wei[3], Kristine Nograles[1], Hiroshi Mitsui[1], Mayte Suarez-Farinas[1] and James G. Krueger[1]. [1]The Rockefeller University, New York, NY, [2]UCLA School of Medicine, Los Angeles, CA, [3]Arthritis & Osteoporosis Center of MD, Frederick, MD.

Background/Purpose: It is preferable to start therapy as early as possible in psoriatic arthritis (PsA) because of the destructive nature of the arthritis. Starting treatment promptly is complicated because the arthritis component can occur years after the psoriatic skin disease (psoriasis vulgaris, PsV), and the arthritis may not be diagnosed until it is more established. Many patients with PsV are seen in dermatology clinics where early arthritis symptoms may not be diagnosed. Given these issues, it would be useful to have a predictive model that would allow the identification of patients with PsV that will go on to have PsA, possibly even before clinical symptoms of arthritis are apparent. Since the psoriasis lesions of the skin are often the first detected symptom of psoriatic disease, molecular profiles of the skin may provide prognostic value to predict the onset of joint inflammation, We conducted a comprehensive genomic and molecular comparison of lesional skin from subjects with PsA and PsV.

Methods: Lesional psoriatic skin samples were obtained from subjects with PsA (n=6) and PsV (n=10). PsA subjects were diagnosed by Moll and Wright criteria by a rheumatologist. PsV samples were chosen after a retrospective chart review was done to assure subjects denied joint complaints at all visits. Gene expression analysis was conducted using Affymetrix HGU133 2.0+ arrays. Differentially expressed genes (DEGs) were evaluated with a cut-off of fold change >2.0 and false discovery rate <0.01. **Results** were validated using RT-PCR. Ingenuity Pathway Analysis (IPA) was utilized to identify canonical pathways among DEGs.

Results: A comparison of PsA and PsV lesional skin revealed 1569 genes were upregulated and 1838 genes were downregulated. While there are a variety of differences in gene expression, it is notable that genes typically associated with bone formation and cartilage were in the top 50 upregulated genes. These include cartilage oligomeric matrix protein (COMP), secreted frizzled-related protein 1 (SFRP1), and proteoglycan 4 (PRG4). In addition, IPA showed differential expression of several pathways related to joint destruction and dysregulated bone metabolism. These include the "Role of Macrophages, Fibroblasts, and Endothelial Cells in Rheumatoid Arthritis", the "BMP Signaling Pathway", the "Wnt/β-Catenin Signaling Pathway" and "RANK Signaling in Osteoclasts". RT-PCR confirmed a significant difference in BMP2.

Conclusion: In this pilot study we show differences in gene expression of lesional skin from subjects with PsA and PsV. To our knowledge, this is the first study to show that markers linked to the joint and dysregulated bone metabolism could be identified in skin biopsies. This could be useful as both an early predictor of PsV patients who will go on to have PsA and help to guide therapies at a very early stage of disease diagnosis to prevent destructive arthritis. In addition, this could lead to the discovery of key pathogenic molecules in skin that may affect joints and/or entheses, thus suggesting new therapeutic targets.

IL-23 Mediates Psoriasis-like Inflammation in the SKG Mouse Model of Spondyloarthropathy. Helen Benham[1], Linda Rehaume[1], Athan Baillet[1], Zaied Bhuyan[1], Jaclyn Bowman[1], Dimeng Pang[1], Kristine Kikly[2], Geoffrey Strutton[3], Matthew Brown[1] and Ranjeny Thomas[1]. [1]University of Queensland Diamantina Institute, Brisbane, Australia, [2]Biotechnology Discovery Research, Eli Lilly and Co, Indianapolis, IN, [3]Department of Pathology, Princess Alexandra Hospital, Brisbane, Australia.

Background/Purpose: Psoriasis (Ps) is a common immune-mediated inflammatory skin disease and is a well- recognised extra-articular manifestation of the spondyloathopathies (SpA). Genetic studies implicate IL-23 signalling in the pathogenesis of both Ps and SpA. Spondyloarthritis and psoriasis-like disease develop in an IL-23-dependent fashion in ZAP70-mutant SKG mice, which have deficient T cell receptor signaling. We characterized curdlan (1,3-D β-glucan) induced psoriasis-like inflammation in SKG mice, investigating the role of IL-23, IL-22/IL-17, regulatory T cells (Tregs) and microbiota.

Methods: SKG mice, IL-17A-deficient SKG mice, Germ Free SKG mice and Foxp3-DTR SKG mice were injected intraperitoneally with curdlan (1,3-D β-glucan) to induce disease. Anti-mouse IL-22, anti-IL-23 or isotype control antibodies were given i.p one day before curdlan, and weekly until sacrifice. Recombinant IL-23 or PBS was administered intra-dermally into ear skin. Outcomes were measured by clinical and histological scoring; cytokines and by qRT-PCR and in supernatants of cultured tissue explants by ELISA and CBA.

Results: Curdlan induced psoriasis-like inflammation in addition to spondyloarthritis in 100% of SKG mice. SKG skin lesions showed a histological phenotype similar to human Ps with elevated constitutive levels of *IL-23a(p19)* and increased secretion of both IL-17 and IL-22, 7 days after curdlan. Neutralisation of both IL-23 and IL-22 suppressed development of skin inflammation, in contrast IL-17A-deficient SKG mice were only partially spared. Germ Free (GF) SKG mice failed to develop significant skin inflammation after curdlan, however colonization of GF-SKG mice with a limited microbiota induced mild psoriasis-like inflammation. Tregs modulated the severity of skin inflammation through the suppression of IL-23 secretion. Intradermal injection of IL-23 induced IL-22 mediated, microbiota dependent psoriasis-like inflammation in naïve SKG mice.

Conclusion: In curdlan-treated SKG mice IL-23-driven psoriasis-like inflammation is induced in the setting of spondyloarthritis. The skin inflammation recapitulates several features of human Ps and is dependent on the relative contributions of IL-17, IL-22, microbiota and the balance of Tregs and T effector cells.

Immunological and Clinical Relationships of Synovial IL-17+ T Cells in Psoriatic Arthritis. Bruce Kirkham[1], Bina Menon[2] and Leonie S. Taams[3]. [1]Guy's & St Thomas NHS Foundation Trust, London, United Kingdom, [2]Guy's and St. Thomas' Foundation Hospital NHS Trust, London, United Kingdom, [3]King's College London, London, United Kingdom.

Background/Purpose: We recently reported elevated numbers of synovial fluid IL-17+CD4- T cells (mainly CD8+ (Tc17) cells) in Psoriatic Arthritis (PsA), correlating with clinical, serological and imaging measures of disease activity (1). These relationships are not found with CD4+ IL-17+ (Th17) synovial cells. Here we report the relationship of synovial fluid T cell cytokine expression with PsA clinical patterns, and the relationships between synovial fluid cytokine-expressing T cells.

Methods: Mononuclear cells from synovial fluid (SF) and peripheral blood (PB) samples from 22 patients with PsA were isolated and stimulated for three hours in vitro with PMA and ionomycin in the presence of GolgiStop. CD3+ T cells were investigated for cytokine expression (IL-17A, IFN-γ, TNF-α, IL-22, IL-21, IL-10) by flow cytometry. Clinical measures and Power Doppler Ultrasound (PDUS) of the affected joint were made at the time of joint aspiration.

Results: Of 22 subjects, 16 (73%) had an oligoarthritis (<5 involved joints) and 6 (27%) a polyarticular pattern of PsA, with 9 (41%) having co-existing axial disease. 2 subjects had a history of dactylitis, 8 of enthesitis and 5 of nail disease.

All clinical subgroup patients had elevated synovial IL-17+CD4- and IL-17+CD4+ T cells compared to PB, which was significant in the oligo ($p=0.001$ and $p=0.02$ respectively) and axial groups ($p=0.01$ for both), with the polyarthritis group increase not statistically significant ($p=0.06$ for both), most likely due to low numbers.

TNF-α+CD4- T-cell frequency positively correlated with DAS28 ($r=0.51$, $p=0.02$) with a trend for TNF-α+CD4+ T-cells and DAS28 ($r=0.43$, $p=0.07$). In contrast to IL-17+CD4- T cells, there was no correlation between TNF-α+ T-cells and ESR, CRP or PDUS. IL-22+CD4- cells correlated with PDUS. No other T cell cytokine expression pattern correlated with clinical measures.

Relationships of cytokine expressing T cells were assessed for the percentages of IL-17+CD4- T cells and IFN-γ+, TNF-α+, IL-22+, IL-21+ and IL-10+ CD4- T-cells in PsA SF. Only TNF-α+ cells positively correlated with IL-17+ cells in the CD4- T-cell compartment ($r=0.55$, $p=0.01$). This relationship may be partly explained by the finding that 60% of IL-17+CD4- cells co-express TNF-α. IL-22 was co-expressed in 22% of IL-17+ CD4- T cells.

Conclusion: These data suggest that IL-17 expressing CD4- (CD8+) T cells are found in all articular patterns of PsA. The correlation of IL-17+ and TNF-α+ CD4- cells suggests that IL-17 and TNF-α may be related in expression as well as synergy of function.

Characterization of $CD4^+$ T Cell Response and Effects of Regulatory T Cells in Pristane Induced Lupus (PIL). Harald Leiss, Barbara Schwarzecker, Irina Gessl, Antonia Puchner, Birgit Niederreiter, Carl-Walter Steiner, Josef Smolen and Georg H. Stummvoll. Medical University of Vienna, Vienna, Austria.

Background/Purpose: $CD4^+$ T cells and the Th1 and Th17 subsets in particular play a pivotal role in SLE. Regulatory T cells (Treg) are essential for maintaining peripheral tolerance, but their number and function in SLE is decreased. We herein characterize CD4+T cell and Treg homeostasis and severity of organ involvement in a murine model of SLE and analyze the effects of *in vitro* –induced iTreg.

Methods: Mice were injected i.p. with 0.5ml of pristane or PBS as control and killed after 8 months. Naïve $CD4^+$ thymocytes were cultured under specific conditions and tested for $CD4^+Foxp3^+$ expression by FACS. Cell suspensions with >80% purity for $CD4^+FoxP3^+$ iTreg were injected intravenously either once at start of experiments (iTreg-boost) or monthly (1xiTreg-repeated).

Animals were monitored for clinical signs of arthritis and, in order to analyze and compare disease severity, histological features of arthritis and pneumonitis were quantified by an image analysis system. Lungs were scored for the severity of perivascular inflammation by analyzing the numbers of affected vessels and the area of the inflammatory infiltrate.

Lymphocytes were isolated from granulomas (intraperitoneal ectopic lymphoid tissue), lymph nodes (LN) and spleens and were analyzed separately by FACS. For analyzes of the Th1, 2 and 17 subsets, cells were restimulated in vivo plate bound with anti-CD3 and anti-CD28abs.

Results: PIL mice presented with involvement of inner organs, most frequently affected were the lungs (100% pneumonitis); 52% of PIL developed arthritis, both clinically and histologically. Monthly iTreg-injection significantly decreased clinical signs of arthritis and histological lung and joint parameters. 66% of treated mice did not show any signs of arthritis at all. (Fig. 1A-F)

The iTreg-boost did not prevent joint manifestations or pneumonitis, but appeared to have a retarding effect (Fig.1A-F) indicated by a delayed onset of clinical symptoms and by a significantly decreased erosive area at the end of observation (Fig.1B).

Intraperitoneal granuloma typical for PIL appeared to be the hotspots of inflammation showing a significantly elevated Teff/Treg ratio of 1.3. Upon re-stimulation, CD4+ cells showed a pronounced Th1 response (27% IFNγ producers) compared to cells from LN and spleens from both PIL and HC (with Th1 percentages ranging from 9–16%). In addition, frequencies of Th2 and Th17 cells were elevated in PIL, again with the highest yield in granuloma. The repeated application of iTreg reduced the Teff/Treg ratio in PIL granuloma to 0.7.

Conclusion: Repeated injections of iTregs reduce severity of pneumonitis and arthritis as well as the T_{eff}/T_{reg} ratio. A single injection of iTregs is not effective, but appears to retard onset of symptoms and progression of arthritis and pneumonitis. Thus, iTreg have significant effects on lupus symptoms, which may have consequence for future therapeutic considerations.

Mir-663 Impairs the Effects of Bone Marrow-Derived Mesenchymal Stem Cells on MRL/Lpr Mice. Linyu Geng, Xuebing Feng and Lingyun Sun. The Affiliated Drum Tower Hospital of Nanjing University Medical School, Nanjing, China.

Background/Purpose: Previously we have shown that miR-663 was increased in bone marrow derived mesenchymal stem cells (BMSCs) from SLE patients and involved in the functional deficiency of BMSCs through inhibiting transforming growth factor β1 (TGF-β1) production. This study was undertaken to explore whether the modulation of miR-663 in BMSCs could affect their therapeutic effects on MRL/lpr mice.

Methods: Negative-control-miR-663 (miR-663-C), mimics-miR-663 (miR-663-M) and inhibitor-miR-663 (miR-663-I) eukaryotic expression vector were artificially transfected into BMSCs and intravenous injected (1°Á10^6) into 20 weeks old female MRL/lpr mice. 8 weeks later, mice were sacrificed, with kidneys, lymph node harvested and spleen weighed. Their serum and urinary samples were collected for the measurement of autoantibodies (including IgG, ds-DNA and ANA) and cytokines (TGF-β1, IL-4, IFN-¡Ã, IL-17A and so on) by ELISA, and proteinuria by coomassie blue staining assay. Immune complex deposition including IgG and complement 3 (C3) in kidney sections was performed by immunofluorescence staining. The percentages of Th1, Th2, Th17, regulatory T cells (Treg) and follicular T helper (Tfh) cells in splenic mononuclear cells were detected by flow cytometry.

Results: Compared to the miR-663-C and miR-663-M group, miR-663-I transfected BMSCs displayed enhanced therapeutic effects on MRL/lpr mice, as shown by significantly declined spleens and lymph nodes size as well as reduced serum IgG and anti-dsDNA levels. Compared to miR-663-C and miR-663-I group, mice treated with miR-663-M transfected BMSCs presented enlarged glomerulus with hyper cellularity and meningeal expansion, and greater amounts of immune complex deposition including IgG and C3 in the meningeal and peripheral capillary loops. Meanwhile, Treg cell percentages were increased in miR-663-I group compared with those in miR-663-M and miR-663-C group (13.3±1.12% vs. 6.90±0.82% and 8.25±1.07%, overall $p < 0.05$), while Tfh cell percentages were decreased (8.58±1.09% vs. 22.9±4.24% and 12.40±1.61%, overall $p < 0.05$).

Conclusion: Inhibition of miR-663 in MSCs enhanced the therapeutic effects of MSC transplantation on MRL/lpr mice.

Liposomal-Glucocorticoids: A Novel Approach to the Therapy of SLE. Yaakov Naparstek, Eli Moallem, Rina Ulmansky, Erez Koren and Yechezkel Barenholz. Hadassah - Hebrew University Medical Center, Jerusalem, Israel.

Background/Purpose: Glucocorticoids (GCs) have been known for years to be the most effective therapy in SLE. Their use is however limited by the need of high doses due to the unfavorable pharmacokinetics and biodistribution of the drug. A possible approach to overcome this obstacle is to use liposomal formulation that has a different biodistribution than that of the free GCs. We have previously developed a new liposomal GC formulation and demonstrated its specific accumulation in inflamed tissues, as well as superior therapeutic efficacy over that of free GC in the autoimmune adjuvant arthritis model. In the present study we have tested the effect of the liposomal GC formulation in the murine SLE model of MRL/lpr/lpr mice.

Methods: We used 80 nm sterically stabilized nanoliposomes which were remote-loaded with an amphipathic weak acid GC methylprednisolone hemisuccinate (liposomal GC). Six-weeks old MRL/lpr/lpr mice were injected subcutaneously with either the liposomal GC 25 mg/kg weekly, or free MPS 5 mg/kg daily, or the appropriate solvents and their clinical course, kidney damage and serology, followed until the age of 24 weeks.

Results: No mortality was observed in mice treated with the liposomal GC up to 24 weeks, as compared to 20% and 30% mortality in the free MPS and the solvent-treated groups. Anti-dsDNA levels (OD) were 0.49±0.05 in the liposomal GC group, compared to 1.21±0.22 and 1.7±0.12 in the two other groups. Significant reduction of spleen size was observed in the liposomal GC-treated group, 1.09±0.43 cm^2, compared to 2.98±0.65 cm^2 and 2.82±0.51 cm^2 in the two other groups. A significant improvement in renal histopathology was achieved in the liposomal GC treatment, and mean urea levels were 8.8±1.05 nM/L in the liposomal GC group compared to 18.9±3.86 nM/L and 22.5±2.69 nM/L in the two other groups.

Conclusion: Liposomal GC has significant superiority over daily injections of free MPS in suppressing murine lupus. These results make our liposomal GC formulation a good candidate for the treatment of human SLE.

Decreased Inflammatory Dendritic Cells in Lupus-Prone Estrogen Receptor Alpha Knockout (ERαKO) Mice Correlate with Increased Survival. Melissa A. Cunningham[1], Jena R. Wirth[2], Jackie G. Eudaly[1], Jennifer L. Scott[1], Osama S. Naga[1] and Gary S. Gilkeson[1]. [1]Medical University of South Carolina, Charleston, SC, [2]MUSC, Charleston, SC.

Background/Purpose: SLE is a disease that disproportionately affects females. The etiology of the sex bias in this disease is unclear. We previously showed that a functional knockout of estrogen receptor alpha (ERαKO) resulted in significantly reduced renal disease and increased survival in murine lupus. Subsequently, we demonstrated a role for ERα in modulating Toll-like receptor (TLR)-induced inflammation, partially explaining the protected phenotype. The mechanism of this effect, however, is not known. Dendritic cell development, which requires both estrogen and ERα is impacted, as is activation status and cytokine production. Due to altered feedback loops, the hormonal milieu of ERα mutant mice is significantly different from WT. ERαKO mice have hypergonadism and partial endocrine sex reversal (elevated estrogen and testosterone levels), and decreased prolactin levels. These hormones may have immunomodulating effects in concert with other intact hormone receptors. Therefore, we investigated the phenotype of the NZM/ERαKO mouse following ovariectomy (OVX) and estrogen pellet (to preserve a physiologic hormonal state).

Methods: ERαKO and Ex3a (ERα null) strains were backcrossed onto the NZM2410 lupus-prone background. Subsets of mice were ovariectomized (at 4 or 8 weeks). Urine and blood were collected at 2–4 week intervals starting at 10 weeks, and mice were sacrificed at 32 weeks, or earlier if they had high proteinuria and >10% weight loss. Bone marrow was isolated and cultured for 7 days with Flt3L to enrich for dendritic cells. Spleen and kidney cells were also isolated. Flow cytometry was utilized to determine number of cDCs (CD11c+/CD11b+) and activated cDCs (CD11c+/CD11b+/MHCII+) from cultured BM-DCs, as well as from *ex vivo* spleen and kidney cells.

Results: Survival at 32 weeks: NZM/ERαKO – OVX + E2: 8/8 (100%) vs. NZM/ERαKO – OVX: 5/9 (56%) vs. NZM/WT – OVX 8/14 (57%) vs. NZM/Ex3a 7/7 (100%) vs. NZM/Ex3a – OVX 3/6 (50%) vs. NZM/Ex3a – OVX + E2 5/8 (63%). Proteinuria (dipstick) correlated with survival as did total and activated cDCs (BM-DCs) which were significantly reduced in NZM/ERαKO – OVX + E2 vs. both NZM/WT – OVX ($p<0.001$) and NZM/ERαKO – OVX ($p<0.05$). To date, analyzed numbers of activated cDCs from both spleen and kidney of NZM/ERαKO mice were also significantly reduced.

Conclusion: Consistent with previous experiments, NZM/ERαKO mice were protected from lupus disease expression (no early deaths; no proteinuria at 32 weeks). This was only true if they were either unmanipulated, or both ovariectomized *and* E2-repleted. These mice had fewer inflammatory and activated cDCs from bone marrow, spleen and kidney, which correlated with increased survival in this group. The protective phenotype was lost after ovariectomy if no E2 pellet was administered, suggesting that the effect requires E2 in the system (despite the lack of a full length ERα). A protective effect was not observed in lupus-prone Ex3a mice (ER$\alpha-/-$) that were OVX'ed and E2-repleted, suggesting that the A/B domain mutant in ERαKO mice potentially modulates disease in the presence of estrogen, rather than ERα deficiency alone being protective.

Commensal Microbiota Influence Systemic Autoimmune Responses. Jens Van Praet[1], Erin Donovan[2], Michael Drennan[1], Fons Van de Loo[3], Sylvie Rabot[4], Jeroen Raes[5], Tom Van De Wiele[1], Carl Ware[6] and Dirk Elewaut[7]. [1]Ghent University Hospital, Ghent, Belgium, [2]Ghent University Hospital, ghent, Belgium, [3]Raboud University Medical Center, Utrecht, Netherlands, [4]AgroParisTech, Micalis, Jouy-en-Josas, France, [5]Rega Institute, KU Leuven, Leuven, Belgium, [6]Sanford-Burnham Medical Research Institute, La Jolla, CA, [7]Department of Rheumatology Ghent University Hospital, Ghent, Belgium.

Background/Purpose: Antinuclear antibodies are a hallmark feature of generalized autoimmune diseases, including systemic lupus erythematosus and systemic sclerosis. However, the processes underlying the loss of tolerance, particularly the role of lymphoid organs, against nuclear self constituents remains largely unresolved.

Methods: We generated mice lacking all secondary lymphoid organs including spleen by intercrossing lymphotoxin beta receptor deficient mice with HOX11 deficient animals. LTbR-Fc was administered intrauterine and postnatally at various stages of development. *Ltb*$^{-/-}$, T-*Ltb*$^{-/-}$, B-*Ltb*$^{-/-}$ and Rorγt-*Ltb*$^{-/-}$ were generated by crossing LTβ-floxed mice with CD4-cre, mb1-cre, RORgt-cre mice respectively. Thymi were isolated from newborn LTbR$^{-/-}$ or wildtype mice and transplanted under the kidney capsule of adult nude mice. 16S rRNA profiling and analysis was conducted on mucosal, luminal and faecal samples. Germfree versus conventionalized mice were treated with LTbR-Fc intrauterine and postnatally. Germfree mice were monocolonized with SFB or E. Coli species and treated with LTbR-Fc. We screened for autoantibodies using a validated immunodetection system for a broad range of ANA, including anti-U1RNP, anti-Sm, anti Scl70/Topoisomerase-I, anti-Centromere protein B, anti-SSA/Ro52 and anti-Jo1 (INNO-LIA ANA Update, Innogenetics NV).

Results: We found that approximately 25% of mice lacking secondary lymphoid organs spontaneously develop specific antinuclear antibodies. Interestingly, we find this phenotype is not caused by a defect in central tolerance. Rather, cell-specific deletion and *in vivo* lymphotoxin blockade link these systemic autoimmune responses to the formation of gut associated lymphoid tissue in the neonatal period of life. We further demonstrate antinuclear antibody production is influenced by the presence of commensal gut flora, in particular increased colonisation with segmented filamentous bacteria, IL-17 receptor signalling, and IgA production, which appears to have a protective role against autoantibody formation.

Conclusion: Together, these data indicate that neonatal colonization of gut microbiota influences generalized autoimmunity in adult life.

Lack of Response Gene to Complement-32 Impairs Th17 Differentiation and Attenuates Lupus-like Chronic Graft Versus Host Disease. Vinh Nguyen[1], Cosmin Tegla[1], Cornelia Cudrici[2], Tudor Badea[3], Horea Rus[1] and Violeta Rus[1]. [1]University of Maryland School of Medicine and Veteran Affairs Medical Center, Baltimore, MD, [2]University of Maryland School of Medicine, Baltimore, MD, [3]NIH, National Eye Institute, Bethesda, MD.

Background/Purpose: Response Gene to Complement (RGC)-32 was cloned and characterized by our group as one of the genes induced by complement activation. It encodes an intracytoplasmatic protein that promotes cell cycle activation via cyclin B1-CDC2 activation and Akt phosphorylation in vascular smooth muscle and endothelial cells. RGC-32 is also a downstream target of TGF-β in fibroblasts and renal proximal tubular cells and plays a role in renal fibrogenesis. The expression and function of RGC-32 in immune cells has not been studied. As Th17 and induced T regulatory cells (iTreg) differentiate under the control of TGF-β, we determined whether RGC-32 plays a role in Th17/Treg balance using RGC-32 KO mice generated in our lab. In addition, using two established models of chronic graft versus host disease (cGVHD), we assessed whether absence of RGC-32 on either donor CD4 cells or host B cells alters autoimmune parameters of disease.

Methods: Naïve CD4$^+$ cells purified from WT or RGC-32 KO splenocytes were cultured under Th1, Th2, Th17 and Treg conditions. The expression of IFN-γ, IL-4, IL-17A, FoxP3, T-bet, RORγt, and GATA-3 were determined by flow cytometry, ELISA and RT-PCR. Lymphocytes isolated from the large intestine lamina propria of WT and RGC-32$^{-/-}$mice were stained for IL-17A. Phosphorylation of STAT3, Smad2 and 3 were assessed by Western blot.

Parent-into-F1 cGVHD was induced with 12x10^6 WT or RGC-32$^{-/-}$ CD4 cells injected into B6D2F1 recipients. Bm12-into-B6 cGVHD was induced by injecting 100x10^6 Bm12 splenocytes into WT or RGC-32$^{-/-}$hosts. In both models, parameters of cGVHD including donor CD4, host B cell number and activation, anti-ssDNA autoAb production were assessed at two weeks after disease induction.

Results: RGC-32$^{-/-}$ CD4$^+$ T cells failed to differentiate normally to Th17 lineage as demonstrated by a significant reduction in IL-17 and RORγt mRNA and protein expression in vitro and a decreased proportion of IL-17$^+$ cells in lamina propria lymphocytes in vivo. Decreased phosphorylation of Smad2 but not of STAT3 and Smad3 was noted in RGC-32$^{-/-}$ CD4$^+$ cells. A trend for increased iTreg differentiation was also noted while Th1 and Th2 differentiation did not differ between WT and RGC-32$^{-/-}$CD4 cells.

In P-into-F1 cGHVD mice, RGC-32$^{-/-}$ donor CD4 cells displayed decreased expansion and proliferation compared to WT donor cells**.** Consistent with the in vitro data, RGC-32$^{-/-}$ donor CD4 cells displayed lower proportion of IL-17$^+$ cells. Bm12-into- B6 cGVHD induced in RGC-32$^{-/-}$ mice was characterized by decreased anti-dsDNA titers versus WT B6 recipients.

Conclusion: RGC-32 is a novel mediator of Th17 differentiation. In cGVHD expression of RGC-32 on CD4 cells is critical for their proliferation, expansion and IL-17 differentiation while expression of RGC-32 on B cells is critical for optimal autoantibody production. These data support the idea that RGC-32 blockade has the potential to attenuate autoimmune parameters of cGVHD and possibly reverse abnormalities in the Th17 and Treg cell pathways that contribute to lupus pathogenesis. These observations provide a compelling rationale for further investigating the therapeutic potential of RGC-32 blockade in murine and human lupus.

A Peptide Mimic Inhibits the Cross Reaction of Anti-DNA Antibodies with Glomerular Antigens. Yumin Xia, Ertan Eryilmaz, Rahul Pawar, David Cowburn and Chaim Putterman. Albert Einstein College of Medicine, Bronx, NY.

Background/Purpose: Systemic lupus erythematosus (SLE) is an autoimmune disease characterized by high titers of multiple autoantibodies. Of those, anti-DNA antibodies play a key role in the pathogenesis of lupus nephritis by cross reacting with renal antigens. Previously, we generated a panel of anti-DNA antibodies from the murine PL9–11 anti-DNA mAb (IgG3), which share identical variable regions of both heavy and light chains but differ in their heavy chain constant region. We demonstrated that the binding affinity of the PL9–11 mAbs to self-antigens (including renal antigens) is isotype-dependent. The present study was designed to further investigate the cross reaction between anti-DNA antibodies and renal antigens, by identifying a peptide mimic that can bind to multiple anti-DNA isotypes.

Methods: A phage display library was used for peptide selection, and identified a 12-mer peptide, ALWPPNLHAWVP or "ALW". The specificity and kinetics of binding affinity of ALW to anti-DNA isotypes were determined by ELISA and surface plasmon resonance. Inhibition and cell surface ELISAs, flow cytometry, and glomerular binding assays were performed to evaluate how well ALW inhibits murine and human anti-DNA antibodies in binding to glomerular antigens in vitro and ex vivo.

Results: The ALW peptide exhibits differential binding affinity to the PL9–11 anti-DNA antibodies in the order of IgG2b >IgG2a >IgG3=IgG1. Pre-incubation with the ALW peptide significantly reduced the binding of anti-DNA IgGs to dsDNA, laminin, matrigel, mesangial cells, and isolated glomeruli. Moreover, the inhibition by ALW of anti-DNA binding was isotype-dependent. Alanine replacement studies and phage binding assays confirmed the specificity of the amino acid sequence in the binding of ALW to the PL9–11 panel. Finally, ALW significantly inhibited the binding of sera from MRL/lpr and B6.Sle1/3 mice and patients with active SLE to nuclear and glomerular antigens.

Conclusion: The ALW peptide significantly inhibits the binding of nephritogenic anti-DNA antibodies and human/mouse lupus sera to multiple self-antigens, presumably by mimicking their antigenic properties. The ALW peptide or its derivatives may potentially be a useful approach in the treatment of lupus nephritis and other autoantibody-mediated disease manifestations, by

inhibiting the binding of polyclonal anti-DNA antibodies to their in vivo targets.

Peptidylarginine Deiminase Inhibition Mitigates NET Formation and Protects Against Kidney, Skin, and Vascular Disease in Lupus-Prone MRL/Lpr Mice. Jason S. Knight[1], Venkataraman Subramanian[2], Alexander A. O'Dell[1], Srilakshmi Yalavarthi[1], Wenpu Zhao[3], Carolyne K. Smith[3], Jeffrey B. Hodgin[1], Paul Ryan Thompson[2] and Mariana J. Kaplan[3]. [1]University of Michigan, Ann Arbor, MI, [2]The Scripps Research Institute, Jupiter, FL, [3]National Institutes of Health, Bethesda, MD.

Background/Purpose: An imbalance between neutrophil extracellular trap (NET) production and NET degradation has been observed in systemic lupus erythematosus (SLE), potentially contributing to autoantigen externalization, type I interferon production, and endothelial dysfunction. We have previously demonstrated that peptidylarginine deiminase (PAD) inhibition can mitigate NET formation and protect against vascular damage in the New Zealand Mixed model of lupus. However, another strategy for disrupting NET formation—knockout of *NOX2*—accelerates lupus in a different mouse model, MRL/*lpr*. Here, we tested PAD inhibition in MRL/*lpr* mice in an attempt to clarify whether some NET inhibitory pathways may be consistently therapeutic across different models of SLE.

Methods: NET formation, autoantibodies to NETs, interferon signature, and endothelial function were characterized at baseline in MRL/*lpr* mice. MRL/*lpr* mice were also treated for six weeks (daily, from 8 to 14 weeks of age) with two different PAD inhibitors, Cl-amidine and the newly developed BB-Cl-amidine. NET formation, interferon signature, endothelial function, nephritis, and skin disease were examined in treated mice.

Results: Neutrophils from MRL/*lpr* mice demonstrate more NET formation than controls. MRL/*lpr* mice also form autoantibodies to NETs and have evidence of endothelial dysfunction. PAD inhibition with either Cl-amidine or BB-Cl-amidine markedly improves endothelial function, while downregulating expression of type I interferon-regulated genes. PAD inhibition also protects against proteinuria, immune complex deposition in the kidneys, and skin disease.

Conclusion: Chemical PAD inhibition reduces NET formation, while protecting against damage to the endothelium, kidneys, and skin in various lupus models. The strategy by which NETs are targeted will have to be carefully considered if human studies are to be undertaken.

Treatment with a Glycolipid Ameliorates Lupus Dermatitis and Expands Skin ãä T Cells That Promote the Migration of Langerhans Dendritic Cells. Ram Raj Singh, Anna Eriksson, Darshan Randhawa and Miguel-Angel Gutierrez. UCLA, Los Angeles, CA.

Background/Purpose: Self antigens are taken from tissues to local lymphoid organs to acquire ability to avoid self-reactivity. This important immune function is accomplished by dendritic cell (DC) populations that primarily reside in tissues. We posit that a defect in the migration of tissue-resident DCs may predispose to autoimmunity in a tissue-specific manner; and an improved migration of tissue-specific DC may ameliorate disease in the respective organ. We have previously reported that lupus dermatitis-prone MRL mice exhibit a profound defect in the migration of skin-resident DC. Here, we investigated the effect of improved skin-DC migration on lupus dermatitis and determined mechanisms that regulate the migration of tissue-resident DC from tissues to lymph nodes

Methods: Skin and cutaneous lymph nodes from MRL-lpr mice and MHC-matched control mice and $\gamma\delta$ T cell-deficient mice were analyzed for Langerhans DC and skin-resident invariant $\gamma\delta$ T cells before and after treatment with a glycolipid αGalCer that was previously shown to ameliorate lupus dermatitis, without affecting disease in other organs.

Results: MRL mice that exhibit reduced skin-DC migration had reduced skin-resident $\gamma\delta$ T cells, whereas treatment with αGalCer reduced the severity of lupus dermatitis and restored skin-$\gamma\delta$ T cells and skin-DC migration. This effect of αGalCer was independent of its effect on invariant natural killer T cells, but required the presence of lipid antigen presenting molecule CD1d. We further show that gd T cell-deficient mice had reduced skin-DC migration in vivo, and skin-gd T cells directly promoted the migration of skin-DC in vitro via CD40L–CD40 interaction.

Conclusion: Our data elucidate a new mechanism of regulation of skin-DC homeostasis whereby skin-gd T cells normally facilitate skin-DC migration from skin to cutaneous lymph node. Such 'local' control of migratory behavior of tissue-DC can regulate immune response in a tissue-specific manner. This mechanism of skin-DC homeostasis is disrupted in lupus dermatitis, but can be repaired by treatment with a glycolipid.

The Effect of TNF Inhibition on the Autoreactive B Cell Repertoire in SLE Prone Mice. Anne Davidson, Weiqing Huang and Ranjit Sahu. Feinstein Institute for Medical Research, Manhasset, NY.

Background/Purpose: TNF inhibitors are widely used for inflammatory diseases but often induce ANAs that sometimes progress to overt SLE. TNF deficient mice fail to generate germinal centers (GCs) but are still able to mount effective humoral responses to exogenous antigens. A similar loss of GCs occurs in the tonsils of RA patients treated chronically with TNF inhibitors. The goal of these studies was to analyze the mechanism of induction of ANAs by TNF inhibition and the nature of the checkpoint between ANA induction and clinical SLE in a mouse model.

Methods: TNF deficient autoimmune prone Sle1 mice were generated and the 3H9 IgVH transgene that confers anti-DNA and anti-cardiolipin specificity was introduced. Mice were followed clinically and sacrificed at the age of 52 weeks. Spleen cells were analyzed by single cell PCR for the repertoire of Vk light chains associated with the 3H9 heavy chain. Selected 3H9/Vk combinations were transfected into 293 cells and supernatants were tested for autoreactivity by ELISA.

Results: TNF deficient Sle1 mice did not spontaneously develop clinical SLE or proteinuria and survived until at least 52 weeks of age. Surprisingly, serum levels of both anti-chromatin and anti-dsDNA antibodies were decreased in TNF deficient mice compared with their TNF sufficient controls, with similar results in the 3H9 TNF deficient mice. By contrast, TNF deficient mice developed high titers of IgG anti-cardiolipin autoantibodies. Similar results were observed in Sle1.TNFR1 deficient but not Sle1.TNFR2 deficient mice. Single cell analysis of the follicular B cell repertoire of 3H9.Sle1 TNF deficient mice revealed a loss of 3H9/Vk12–46.Jk2 encoded B cells that can bind to histones and chromatin.

We have previously shown a preferential selection of Vk5 light chains into the GCs of 3H9 SLE prone mice; these light chains confer anti-chromatin activity in their germline configuration and acquire high affinity anti-DNA and anti-cardiolipin activity as a result of somatic mutations. Since GCs are not present in TNF deficient mice we analyzed the light chain repertoire of splenic class switched B cells and plasma cells. 3H9.Sle1 mice had marked overrepresentation of Vk5 encoded light chains among their class switched B cells and plasma cells. By contrast, 3H9.Sle1 TNF deficient mice had few Vk5 encoded plasma cells and instead had a vast overrepresentation of Vk4–57-1. Co-transfection of this light chain with 3H9 into 293 cells revealed that this combination had anti-cardiolipin but not anti-DNA or anti-chromatin activity. Further analysis of the Vk4–57-1 encoded light chains from class switched B cells of TNF deficient mice revealed that they were all germline encoded.

Conclusion: TNF deficiency has significant effects on the Ig repertoire of mature and antigen activated B cells. The loss of GCs in TNF deficient Sle1 mice alters the spontaneously autoreactive Ig repertoire and is associated with a decrease in somatic mutations in autoreactive B cells suggesting that these cells have matured in an environment that is not exposed to cognate T cell help. The data further suggest that a "second hit" that bypasses the germinal center defect is required for TNF inhibition to induce pathogenic autoimmunity.

HM-0523, a Novel Syk Inhibitor Blocks Glomerulonephritis and Extends Life Spans in Lupus Prone MRL/Lpr Mice. Yu Cai, Zhipeng Wu, Ping Ren, Xiaoming Dai, Jianlin He, Fang Yin, Wei Deng, Guangxiu Dai, Weiguo Su and Xiong Li. Hutchison Medipharma Limited, Shanghai, China.

Background/Purpose: Syk is a key mediator of signaling events downstream of a wide array of receptors important for immune functions, including the B cell receptor, immunoglobulin receptors bearing the Fcg or Fce chain. Therefore, modulation of Syk could provide a novel therapeutic approach for autoimmune diseases and cancers. HM-0523, a highly potent and selective, orally available Syk inhibitor, is currently in Phase I clinical trials. The aim of this study is to evaluate the efficacy of HM-0523 in a systemic lupus erythematous (SLE) model in lupus-prone (MRL/lpr) mice.

Methods: HM-0523 was orally administered to MRL/lpr mice before the disease onset. Key lupus features, including skin lesions, proteinuria and blood urea nitrogen levels were examined periodically. Overall survival and renal pathologic parameters were also assessed during the study (8–25 weeks).

Results: Lupus-prone (MRL/lpr) mice, commonly used as a SLE model, spontaneously develop autoimmune disorders that reflect pathologies of human SLE, including enlargement of lymph nodes, elevation of IgG levels, anti-nuclear antibody production, proteinuria, and kidney failure caused by inflammation of the glomeruli.

In this study, *in vivo* efficacy of the orally active HM-0523 was evaluated in the lupus-prone (MRL/lpr) mice. The mice, at the age of 8 weeks, were prophylactically administrated with HM-0523 at 0, 5 and 20 mg/kg (QD), respectively. HM-0523, at 20 mg/kg, significantly blocked skin lesions [skin lesion score: 1.0 ± 0.3 (vehicle control) vs. 0.0 ± 0.0 (HM-0523); $p< 0.05$], delayed the onset of proteinuria and reduced the immune organs to body weight ratios [for example, spleen: 1.744 ± 0.158 (vehicle control) vs. 0.426 ± 0.034 (HM-0523) $p< 0.05$]. HM-0523, at 20 mg/kg, also significantly suppressed production of anti-dsDNA antibodies [408.6 ± 172.6 KU/ML (vehicle control) vs. 156.3 ± 25.8 KU/ML (HM-0523) $p< 0.05$]. Histopathological investigation demonstrated that HM-0523, at 20 mg/kg, greatly alleviated the pathological changes in renal, including glomerulonephritis, interstitial nephritis, and perivascular infiltration. HM-0523, at 20 mg/kg, also significantly inhibited increase of serum BUN and creatinine. Overall survival rate at week 25 in the HM-0523 treated mice was 100% (at 20 mg/kg and 5 mg/kg) compared to 70.0% in controls ($p< 0.01$). These comprehensive data indicate that HM-0523 has significant activity against the development of lupus and could be developed as a novel therapeutic agent for the treatment of SLE.

Conclusion: Our data demonstrated that HM-0523, acting through selective inhibition of Syk activation, exhibited significant beneficial effects in a murine lupus model. HM-0523 is currently in Phase I clinical trials. These new data provided support that HM-0523 could potentially become a novel therapeutic agent for systemic lupus erythematous.

The Combination of Metformin and 2-Deoxy-D-Glucose Normalizes CD4 T Cell Metabolism and Functions, and Reverse Disease in Murine Models of Lupus. Laurence Morel, Yiming Yin, Seung-Chul Choi, Eric S. Sobel and Byron Croker. University of Florida, Gainesville, FL.

Background/Purpose: Autoreactive CD4 T cells are key effectors in Systemic Lupus Erythematosus (SLE). Cell metabolism is an important checkpoint for T cell activationand differentiation. Both Anaerobic glycolysis and mitochondrial oxidative phosphorylation are necessary for effector CD4 T cell differentiation and inflammatory cytokine production. We hypothesized that 1) SLE T cells have metabolic defects that impair their functions; 2) Targeting CD4 T cell metabolism may abrogate CD4 T cell inflammatory functions and reduce disease symptoms in SLE mice; 3) The functions of CD4 T cells from SLE patients can be normalized by treatment with metabolic inhibitors.

Methods: CD4 T cells from lupus-prone mice and controls, as well as CD4 T cells obtained from SLE patients and healthy controls were treated with metformin or 2-DG, or a combination of the two. Several models of lupus-prone mice were treated with these drugs, either before or after disease onset. Glycolysis (extracellular acidification rate; ECAR) and oxygen consumption rate (OCR) were measured in CD4 T cells with an Extracellular Flux Analyzer. CD4 T cell activation and effector subsets were analyzed by flow cytometry. Disease progression was assessed by measuring serum anti-dsDNA IgG and anti-nuclear autoantibodies by ELISA and immunofluorescence, as well as renal histopathology.

Results: CD4 T cells from lupus mice have a significantly higher metabolism with increase in both ECAR and OCR, as well as an enhanced mTOR activity as compared to control mice. To normalize T cell metabolism in these mice, we used metformin, which activates the AMPK pathway and inhibits mitochondrial oxygen consumption, and 2-DG, an inhibitor of glycolysis. *In vitro*, metformin blocked IFNγ production and enhanced Treg development. 2-DG also blocked IFNγ production, but only after T cell activation. *In vivo*, a combined treatment with metformin and 2-DG normalized T cell metabolism and reversed disease phenotypes, including T cell activation and effector functions, as well as autoantibody production in the B6.Sle1.Sle2.Sle3 and the NZB/WF1 spontaneous models, as well as the chronic graft-vs-host disease model. Renal pathology is pending. Neither treatment with metformin or 2-DG alone resulted in disease reversal. Further, CD4 T cells from SLE patients showed an enhanced metabolism as compared to healthy controls, and their excessive IFNγ production was significantly reduced by metformin.

Conclusion: The combination of a glucose inhibitor with metformin restores T cell functions and reverses disease in mouse models, while metformin treatment normalizes the function of T cells from lupus patients. We propose that T cell metabolism is a novel target for SLE treatment.

ONO-4059 - a Highly Potent and Dual Oral Inhibitor of Bruton's Tyrosine Kinase (Btk) and Tec Kinase: Improves Anti-Nuclear Antibodies–mediated SLE in Mice. Yuko Ariza, Toshio Yoshizawa, Yoshiko Ueda, Masayuki Murata and Kazuhito Kawabata. Ono Pharmaceutical Co., Ltd., Osaka, Japan.

Background/Purpose: Systemic Lupus Erythematosus (SLE) is a complex and heterogeneous autoimmune disease associated with the over production of high affinity autoantibodies, mainly raised against nuclear antigens and can be considered a B-cell disease. These autoantibodies mediate tissue injury affecting multiple organs such as skin and joints in mild forms of the disease to Central Nervous System (CNS) and kidney damage in severe forms that can be fatal. SLE is a chronic disease with a relapsing and remitting time-course of unknown etiology and the precise understanding of how these auto-antibodies contribute to the disease is still incomplete. However, overactivity of B-cell responsiveness to immune stimulation and direct activation of circulating FcR bearing cells are sufficient to initiate inflammatory responses, which may be an essential feature of SLE pathogenesis. ONO-4059 is a highly potent and dual oral Btk/Tec inhibitor with an IC_{50} in the sub-nmol/L range. We have previously shown that ONO-4059 strongly suppressed B-cell activation, FcγR-induced TNFα production in monocytes and FcεR-induced TNFα production in mast cells (ACR 2012). Given Btk/Tec play a critical role in B-cell development and function, we examined the potential efficacy of ONO-4059 using female NZB/WF1 mice in a model of spontaneous SLE.

Methods: Mice were randomized to two treatment groups and fed a diet containing 0.012% (equivalent to 20 mg/kg/day) and 0.0037% (6 mg/kg/day) ONO-4059 from 12 to 37 weeks. The mice were weighed weekly and the level of anti-dsDNA antibody was examined on weeks of 28, 32 and 37. The level of proteinuria and overall survival were recorded during the treatment period. A subset of mice was sacrificed at 37 weeks for histopathological analysis of the kidney and ELISpot assays for total Ig-secreting cells and anti-dsDNA-secreting B-cells were evaluated in spleens.

Results: The treatment with 0.012% and 0.0037% of ONO-4059 resulted in 100% and 90% survival respectively, while 60% survival was observed in untreated mice. The onset of proteinuria was markedly lower in ONO-4059-treated mice (untreated: 6570.2±2520.5 μg/mL vs 0.012% and 0.0037% of ONO-4059 treated: 366.2±19.2 and 358.3±18.4 μg/mL). ONO-4059 dramatically inhibited the production of anti-dsDNA in serum by 76% ($P<0.05$, 0.0037% diet) and 98.6% ($P<0.01$, 0.012% diet), compared with untreated mice at week 28. Furthermore, the observed inhibition was much stronger at week 37 (95.5% and 98.9% respectively). Significant reductions in the numbers of total IgG and anti-dsDNA-secreting B-cells were apparent in spleens from ONO-4059-treated mice. Germinal center B-cells and plasma cells were also significantly lower in ONO-4059 treated mice.

Conclusion: Recent studies indicate that the pathogenesis of SLE is associated with B-cell activation and circulating FcR bearing cells, in which Btk/Tec may play an important role. Our results demonstrate that treatment

with ONO-4059 may simultaneously target autoantibody producing and effector cells to prevent the spontaneous disease development in NZB/WF1 mice. These data suggest that ONO-4059 may provide promising therapeutic benefit in human lupus and related disorders.

Helminthes Derivative for Treating Lupus and Colitis in Mice Models. Miri Blank[1], Tomer Bashi[1], Dana Ben-Ami Shor[1], Mati Fridkin[2], Iris Barshack[3], Alexander Volkov[4] and Yehuda Shoenfeld[1]. [1]Zabludowicz Center for Autoimmune Diseases, Sheba Medical Center, affiliated to Sackler Faculty of Medicine, Tel-Aviv University, Ramat Gan, Israel, [2]Weizmann Institute for Sciences, Rehovot, Israel, [3]Institute of Pathology, Sheba Medical Center, affiliated to Sackler Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Tel-Aviv, Israel, [4]Institute of Pathology, Sheba Medical Center, affiliated to Sackler Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Tel-Aviv, Israel.

Background/Purpose: In areas where helminthes infections are common, autoimmune diseases are rare. Treatment with ova from helminthes, improved clinical findings of inflammatory bowel disease and other autoimmune diseases. The tolerogenic properties of the helminthes and their ova were attributed to the phosphorylcholine (PC) molecule. We aimed to decipher the tolerogenic potential of Tuftsin-PC (TPC) compound in experimental Lupus and Colitis.

Methods: 1. Lupus prone NZBXW/F1 mice received subcutaneously TPC (5μg/ml), 3 times a week using preventive protocol. Autoantibodies were tested by ELISA, T-regulatory-cells by FACS, cytokines by RT-PCR and R&D ELISA DuoSet. Glomerulonephritis was addressed by the presence of proteinuria, PAS staining and immunoglobulin deposition in the mesangium by immunofluorescence. 2. Colitis was induced by Dextran-Sodium-Sulfate (DSS) in drinking water. TPC was given by daily oral ingestion (500 μg/mouse or PBS) starting at day (−2). DAI score was followed daily and histology of the colon was performed by H&E staining.

Results: 1. **Lupus** mice treated with TPC attenuated the development of glomerulonephritis, illustrated by a significant diminished proteinuria ($p<0.02$), and reduced immunoglobulin deposits in the kidney mesangium. TPC enhanced expression of TGFbeta and IL-10 ($p<0.001$), and inhibited anti-inflammatory cytokines profile on the level of protein and RT-PCR. Significant enhancement of CD4+CD25+FOXP3+ T-regulatory cells phenotype was documented. 2. Chemically induced **colitic** mice, treated with TPC, developed a significant moderate colitis, in comparison to mice which received the vehicle. The DAI score of the TPC treated mice was 0.9, whereas DAI score of 2.6 was observed in colitis mice which received the vehicle, $p<0.02$. The reduced DAI score in the TPC group was associated with a significant colon shortening and prevention of colon destruction as observed by histological analyses.

Conclusion: TPC delayed lupus development in lupus prone mice and prevented a significant colitis induction in naïve mice.

Influenza A (H1N1) Virus Infection Triggers Severe Pulmonary Inflammation in Lupus-Prone Mice Following Viral Clearance. Samantha Slight-Webb, Harini Bagavant, Sherry Crowe, Jourdan R. Anderson and Judith A. James. Oklahoma Medical Research Foundation, Oklahoma City, OK.

Background/Purpose: Each year, up to one fifth of the United States population is infected with influenza virus. Although mortality rates are low, hundreds of thousands are hospitalized each year. Specific high risk groups, such as those with dysregulated immune systems, are in greater danger for complications from influenza. Further, infections are a common cause of hospitalizations and mortalities in patients with systemic lupus erythematosus (SLE). To understand the influenza immune response in SLE and the effect of infection on autoimmune disease in a controlled setting, we utilized the MRL-Fas(lpr) lupus-prone mouse model.

Methods: Female MRL-Fas(lpr) mice were infected with 200 EID^{50} influenza A virus PR/8/34 H1N1. Mice were weighed daily as a measurement of morbidity and viral burden was determined by quantitative RT-PCR of the influenza M1 gene. Further, lung, kidney, and spleen samples were collected at various time points post infection to analyze pathology by H&E and PAS staining, cytokines by ELISA, and cellular composition by flow cytometry. Total antigen-specific cells were determined by stimulated cells overnight with inactivated influenza virus and intracellular staining for cytokines. Serum was collected to determine autoantibody concentrations by ELISA. Apoptosis was examined in the spleen on paraffin-embedded spleen sections by TUNEL staining. Finally, the role of extrinsic apoptosis in influenza infected lupus-prone mice was examined by administration of 0.1 mM caspase-8 inhibitor (Z-IETD-FMK) and negative control (Z-FA-FMK) daily for six days.

Results: MRL-Fas(lpr) mice accumulated more CD8+ T cells and more TNF-a influenza A virus specific T cells with less neutrophil accumulation in the lung by day 7 post infection ($P<0.05$). Moreover, increased extrinsic apoptosis during influenza infection led to a reduction of autoimmune disease symptoms with decreased splenomegaly ($P<0.0005$) and kidney disease ($P<0.05$). Unlike acute infection, following clearance of the influenza A virus, MRL-Fas(lpr) mice had severe complications during the contraction and resolution phase with widespread severe pulmonary inflammation. Lupus-prone mice had an increased lung severity score ($P<0.05$) with significantly more CD4+ and CD8+ T cells and myeloid cells compared to MRL control mice at day 40 post infection ($P<0.005$). Further, the improvement of autoimmune disease symptoms ceased following clearance of the viral infection and by day 40 was similar to PBS treated MRL-Fas(lpr) mice.

Conclusion: Our findings suggest that autoimmunity drives an enhanced influenza-specific immune response to clear infection, but that severe complications can arise during the resolution of pulmonary inflammation. We propose that problems with pulmonary infection in lupus may arise not from an inadequate antigen-specific immune response, but from sustained pulmonary inflammation and defective cellular clearance causing prolonged symptoms in patients. Additionally, influenza infection diminishes autoimmune disease responses rather than exacerbate autoimmune pathology in mice during the acute infection as a direct result of virus induced apoptosis.

Enhance Translatability Using Multi-Modality Disease Evaluation Approach in Lupus Model. Jie Zhang-Hoover[1], Alan Byford[1], Mark Zielstorff[1], Robert Faltus[1], Joseph Eckman[1], Kimberly Bettano[1], Gain Robinson[1], Raquel Sevilla[1], Bindu Bennet[2], Lisa LaFranco-Scheuch[2], Franklin Vives[3], Michael Judo[3], Gulesi Ayanoglu[3], Weisheng Zhang[1] and Milenko Cicmil[1]. [1]Merck Research Laboratories, Boston, MA, [2]Merck Research Laboratories, West Point, PA, [3]Merck Research Laboratories, Palo Alto, CA.

Background/Purpose: Rodent models mimic some aspects of human lupus disease manifestations in various tissues, such as kidney, skin, joint, and CNS. NZB/NZW F1 and MRL/lpr models have been used extensively for gaining understanding of disease driving mechanism as well as pharmacological evaluation of new therapies. However, the translatability of therapeutic results from rodent lupus models to human lupus patients is limited. Here, we explored the feasibility of using a combination of clinically relevant methods, such as biochemistry analysis, terminal histology, and *in vivo* imaging modalities, to characterize and/or quantify specific inflammatory pathways/tissue damage and to evaluate treatment effect in MRL/lpr mice.

Methods: Female MRL/lpr mice were treated with cyclophosphamide (50 mg/kg i.p. qw) starting at 6–8 weeks of age. Disease development was monitored by gross skin lesion scoring, conventional blood (anti-dsDNA and blood urea nitrogen) and urine (proteinuria) biochemistry, and terminal skin and kidney H&E histology analyses. Disease phenotypes were also monitored longitudinally *in vivo* using multi-modality imaging. Changes in glomerular filtration rate (GFR) were tracked by contrast agent Omnipaque washout using micro-computed tomography (micro-CT). Myeloperoxidase-dependent reactive oxygen species (ROS) production by neutrophils/myeloid cells was quantified with luminol-bioluminescence imaging (luminol-BLI) to monitor skin and joint inflammation. Finally, changes in cerebral cortical thickness and ventricle size were measured by brain magnetic resonance imaging (MRI).

Results: MRL/lpr mice treated with cyclophosphamide had no detectable production of anti-nuclear antibodies and exhibited with minimal skin and kidney disease phenotype. Neutrophil activation and ROS production in the skin and hind limbs visualized by luminol-BLI was detectable at 12 weeks of age and preceded gross skin lesion observation at 14 weeks of age. MicroCT detected a GFR decrease as early as 14 weeks of age in MRL/lpr mice, compared to the blood urea nitrogen level increase at 16 weeks of age. Skin and kidney imaging

results correlated with the terminal tissue H&E histology evaluation. Furthermore, MRI of the brain detected cerebral cortical thinning as early as 10 weeks of age in MRL/lpr mice. Cyclophosphamide treatment resulted in reduced progression of the cerebral cortical thinning process in these mice.

Conclusion: Here for the first time we have successfully demonstrated that evaluation of disease progression and treatment effect can be achieved by a combination of *in vivo* imaging, blood biochemistry, and terminal histological analysis in MRL/lpr model. The novel non-invasive imaging approach in MRL/lpr model captured disease progression and treatment effect efficiently. This comprehensive approach of combined *in-life* and terminal inflammation pathway/tissue damage evaluation in a pre-clinical lupus model provides a potential platform for translatable biomarkers of lupus diagnosis and treatment evaluation in drug discovery.

Decreased Severity of Pristane Induced Lupus in miR155 Deficient Mice. Harald Leiss, Wilhelm Salzberger, Irina Gessl, Barbara Schwarzecker, Nicolas Kozakowski, Stephan Blüml, Antonia Puchner, Birgit Niederreiter, Carl-Walter Steiner, Josef Smolen and Georg H. Stummvoll. Medical University of Vienna, Vienna, Austria.

Background/Purpose: MicroRNAs (miRs) are an important class of regulators of gene expression that are associated with a variety of biological functions. Deregulation of endogenous miR155 was observed in many autoimmune conditions, including SLE. We herein examine the role of miR155 in the development of systemic manifestations in murine pristane induced lupus by evaluating the severity of organ involvement and assessing serum antibody-levels and T helper cell homeostasis.

Methods: MiR155-deficient (miR155-PIL) and C57/Bl6 (WT-PIL) mice were injected i.p. with 0.5ml of pristane or PBS as control (WT-PBS). In order to observe the effects of miR155 deficiency in fully developed SLE, we analyzed the mice 8 months after induction.

A blinded specialist appraised histological features of GN using the composite kidney biopsy score (KBS). Histological features of pneumonitis were quantified by an image analysis system: Lungs were scored for the severity of perivascular inflammation by analyzing the numbers of affected vessels and the area of the inflammatory infiltrate. In order to assess the composition of these infiltrates, specimens were stained with B220 (B), CD3 (T), Neu7/4 (neutrophils) and F4/80 (macrophages) and analyzed by cell-identification algorithms for nuclear segmentation (HistoQuest¨).

Lymphocytes were isolated from spleens and analyzed separately for each mouse by standard FACS procedures. For analysis of the Th1, 2 or 17 subsets, respectively, cells were re-stimulated *in vivo* with anti-CD3 and anti-CD28abs.

Results: Lungs were affected in both pristane-treated groups, but not in controls. MiR155-PIL had reduced lupus severity as indicated by significantly decreased perivascular inflammatory area with B cells being the most prominent inflammatory cell type in the HistoQuest analysis (Fig. 1A). Without showing clinical abnormalities WT-PIL had a more severe renal involvement in the kidney biopsy score than miR-PIL (Fig. 1B). Corresponding with reduced severity in organ involvement, miR155-PIL had lower serum levels of anti-dsDNA-abs (Fig. 1C), decreased frequencies of $CD4^+$ cells (14.24 ± 0.7587 vs. 18.04 ± 1.075, $p=0.01$) and slightly lower frequencies of activated $CD4^+CD25^+Foxp3^-$ cells (1.539 ± 0.1279 vs. 1.838 ± 0.2259, p=ns.). Interestingly, also frequencies of $CD4^+CD25^+Foxp3^+$ regulatory T cells were lower in Mir155-PIL (1.689 ± 0.1388 vs. 2.375 ± 0.2320, $p=0.03$). Upon restimulation, $CD4^+$ cells showed a more pronounced Th2 and Th17 response in WT-PIL, but no significant differences in Th1 phenotype (Fig. 1D).

Conclusion: MiR155 deficiency in PIL mice did not prevent the development of disease, but was associated with less severe lung and kidney involvement, lower serum auto-abs levels and lower Th17 and Th2 frequencies when analyzed in fully established PIL after 8 months. Thus, antagonisation of miR155 might be a beneficial future approach in treating SLE.

Inhibiting Tweak (TNF-like weak inducer of apoptosis) Signaling Improves Blood Brain Barrier Integrity and Protects from Neuronal Damage in Murine Neuropsychiatric Lupus. Jing Wen[1], Jessica Doerner[1], Ariel Stock[1], Jennifer Michaelson[2], Linda Burkly[2], Maria Gulinello[1] and Chaim Putterman[1]. [1]Albert Einstein College of Medicine, Bronx, NY, [2]Biogen Idec, Cambridge, MA.

Background/Purpose: While neuropsychiatric involvement in systemic lupus erythematosus (NPSLE) is relatively common and appears early, the underlying mechanisms are not fully understood. The disruption of the blood brain barrier (BBB) is believed to be one key pathological feature in NPSLE, allowing the passage of neurotoxic autoantibodies into the brain.

TWEAK is a cytokine member of the TNF superfamily; the TWEAK receptor, Fn14, is expressed in brain endothelial cells, astrocytes, microglia and neurons. We recently found that lupus prone MRL/lpr Fn14 knockout (KO) mice display a markedly attenuated neuropsychiatric phenotype, as revealed by a significant reduction in depressive-like behavior and improved cognitive function. Morever, NPSLE patients demonstrate high levels of TWEAK in the cerebrospinal fluid (CSF). We undertook the current studies to determine the mechanisms by which TWEAK signaling is involved in the pathogenesis of NPSLE.

Methods: Brains from female MRL/lpr Fn14WT and MRL/lpr Fn14KO mice at 20 weeks of age were prepared for qRT-PCR, Western blot and immunohistochemistry (IHC). Cellular infiltrates were quantified by hematoyxlin and eosin staining. To assess BBB integrity, extravascular fibronectin and IgG deposition, VCAM/ICAM, and iNOS expression was evaluated by Western blot, IHC and qPRT-PCR, respectively. Complement activation was assessed by measuring the expression of C3, C4a and C6 by qRT-PCR and Western blot. Fluoro Jade B and TUNEL staining were employed to analyze neuronal damage and apoptosis in the brain. Furthermore, gliosis, neuron loss, and neurogenesis were assessed by immunostaining with GFAP, NeuN and Ki-67, respectively.

Results: We found that MRL/lpr Fn14KO mice had significantly improved BBB integrity, as shown by a lower CSF albumin index, decreased fibronectin and IgG deposition, and reduced brain expression of VCAM, ICAM and iNOS. Furthermore, Fn14KO mice exhibited significantly fewer cellular infiltrates in the choroid plexus compared to the Fn14WT mice. At the same time, a significant reduction in C3, C4a and C6 expression was observed in brains of Fn14KO mice. Neuronal damage, an important pathological change present in lupus animal models, was also ameliorated by Fn14 deficiency. Fn14KO mice displayed reduced apoptosis in the cortex, as well as less neuron loss and less gliosis in the hippocampus. Interestingly, there were no differences in neurogenesis and in microglia activation between Fn14KO and Fn14WT mice.

Conclusion: Our studies indicate that TWEAK/Fn14 interactions can play a central role in the pathogenesis of NPSLE by improving BBB integrity

and reducing neuronal damage, suggesting this pathway as a novel target for therapeutic intervention in this disease.

Identification of Eat-2 As a Lupus Susceptibility Gene in New Zealand Black (NZB) Mice That Regulates Dendritic Cell Function. Nafiseh Talaei[1] and Joan E. Wither[2]. [1]Toronto Western Research Institute, Toronto, ON, [2]Toronto Western Research Institute, Toronto Western Hospital, University of Toronto, Toronto, ON.

Background/Purpose: We have previously shown that B6 mice with an introgressed homozygous NZB chromosome (c) 1 interval (70 to 100 cM) develop high titres of antinuclear antibodies and severe glomerulonephritis (GN), with approximately 40% of the mice dying by 8 months age. Using subcongenic mice with shorter intervals in this region we found that T cell and dendritic cell (DC) defects, derived from several genetic loci, synergize to convert the preclinical disease in c1(96–100) mice to fatal GN in c1(70–100) mice through expansion of pro-inflammatory T cell subsets. EAT-2, an adapter molecule in the SLAM signaling pathway that is located in the 70–96 cM region, has a promoter polymorphism in NZB mice that is predicted to lead to decreased expression. In this study we examine whether altered expression of this molecule leads to the abnormal DC function observed in these mice.

Methods: Expression levels of EAT-2 were evaluated in bone marrow derived DC from c1 congenic and B6 mice using *q*RT-PCR and Western blots. siRNAs targeting EAT-2 gene were introduced into B6 and c1 congenic DC. Subsequently, naïve OVA-specific TCR transgenic (OTII) T cells from B6 and c1 congenic mice were isolated and co-cultured with EAT-2 silenced or scrambled control treated DC in the presence of OVA peptide. In parallel DC were stimulated with anti-CD40 before and after knock-down of EAT-2. Production of cytokines (IL-12, IL-6, IFN-g) by DC and T cells were analyzed by flow cytometry.

Results: Expression of EAT-2 was reduced by ~70% in DC from c1(70–100) mice as compared to c1(96–100) and B6 mice. Silencing of the EAT-2 gene in DC from B6 and congenic mice resulted in increased production of IL-12 as compared to scrambled control and was associated with increased differentiation of OVA-specific T cells from both B6 and c1 congenic mice to a Th1 phenotype. Knock-down of EAT-2 in DC from all strains of mice did not affect IL-6 production when co-cultured with B6.OTII T cells, however augmented IL-6 production was seen for c1(96–100) and c1(70–100) DC when co-cultured with naïve T cells from c1 congenic mice. This was accompanied by somewhat enhanced production of IL-21, but not IL-17, by c1 congenic OTII T cells. SLAM/SLAM homotypic interactions inhibit production of IL-12 and IL-6 by CD40L-activated DCs. Consistent with a role for EAT-2 in this inhibition, knock-down of EAT-2 resulted in increased production of IL-12 by CD40-stimulated B6 and c1(96–100) DC. This was recapitulated in c1(70–100) DC, which demonstrated increased production of IL-12, and a trend to increased production of IL-6, as compared to B6 or c1(96–100) DC following CD40 stimulation.

Conclusion: EAT-2 negatively regulates cytokine production in DC downstream of the SLAM molecules and a genetic polymorphism leading to low levels of EAT-2 in c1(70–100) mice may contribute to the increased production of IL-12 we have previously observed for their DC.

Dermal Injury Promotes Nephritis Flare in Lupus-Prone NZM2328 Mice. Kaitlyn Clark, Tamra J. Reed, Jeffrey B. Hodgin and J. Michelle Kahlenberg. University of Michigan, Ann Arbor, MI.

Background/Purpose: Systemic lupus erythematosus is an autoimmune disease with pleotropic manifestations, including severe skin disease, hematologic abnormalities and nephritis. Clinically, lupus is characterized by episodes of flare and remission, and exposures such as UV light or viral infections have been proposed as flare triggers. However, induction of flare has been difficult to emulate in murine models. Here, we describe a system in which cutaneous injury is able to trigger the development of a lupus nephritis flare in lupus-prone mice.

Methods: 20-week old NZM2328 (NZM) female mice were depilated in a 2x4 cm area on the dorsal skin followed by 25 applications of duct tape under isofluroane anesthesia. NZM mice lacking the type I interferon (IFN) receptor (iNZM) were used as a non-lupus prone control. Skin biopsies were taken prior to and following tape-stripping, and gene expression changes were evaluated via quantitative PCR. Serial blood draws and urine collection were obtained following tape stripping, and anti-double-stranded DNA titers, C3 levels and urine albumin/creatinine ratios were measured via commercially available kits. Inflammatory cells were isolated from whole kidneys and cell populations were measured via flow cytometry. Renal immune complex deposition was assessed via immunofluorescent staining for IgG and C3. Renal inflammation was assessed on Hematoxylin and Eosin stained sections by a blinded renal pathologist.

Results: NZM mice subjected to tape stripping had a rapid dermal upregulation of type I IFN-mediated and inflammatory gene expression. Importantly, tape-stripped NZM mice developed onset of proteinuria and death within 3 weeks of skin injury whereas non-tape stripped littermates remained free of proteinuria. This was coupled with a drop in serum C3. Proteinuria induction did not occur in tape-stripped iNZM mice, suggesting the rapid death was not secondary to skin injury itself. In NZM mice, renal immune complex deposition was enhanced within two weeks of tape stripping, as was renal expression of the B cell chemokine CXCL13. Evaluation of renal inflammatory cell populations revealed an increased infiltrate of B cells in the kidney prior to proteinuria onset.

Conclusion: Cutaneous injury via tape-stripping induces a rapid flare of lupus nephritis that is preceded by enhanced renal immune complex deposition and B cell recruitment. This novel model provides a mechanism to study the communication between the dermal and renal immune systems and how crosstalk between these systems can lead to lupus flare, thus providing potential targets for prevention of flares in human disease.

Type I Interferon Induces the Depletion and Dysfunction of Endothelial Progenitor Cells in Gld. ApoE−/− C57BL/6 Mice. Linyu Geng, Shiying Wang, Xuebing Feng and Lingyun Sun. The Affiliated Drum Tower Hospital of Nanjing University Medical School, Nanjing, China.

Background/Purpose: To study whether the accelerated atherosclerosis in SLE is mediated by type I interferon (IFN-I) through the regulation of endothelial progenitor cells (EPCs) in gld. ApoE−/− C57BL/6 mice under normal chow diet.

Methods: The gld. ApoE−/− mice were generated through intercrossing and backcrossing of gld. and ApoE−/− mice on C57BL/6 background. At 20 weeks of age, female gld. ApoE−/− mice were injected with either saline vehicle, synthetic CPG-oligodeoxynucleiotides (CPG-ODN) IRS423 (TLR7/9 agonists) or IRS661 (TLR7 antagonists) twice a week. 4 weeks later, mice were euthanized. Quantitative PCR was applied to detect the mRNA expressions of IFN-I inducible genes. EPCs in peripheral blood and bone marrow were recognized as Sca-1+CD309+ cells by FACS. The capacities of EPC to differentiate into mature endothelial cells, to re-adherent and to form vascular-like structure were measured to determine EPC functions. To find out whether EPC function could be modulated by other cytokines, EPCs from 24 weeks old female gld. ApoE−/− mice were cultured in vitro in the presence of either IFN-α, IL-1β, TNF-α, IRS423 (1μM), IRS954 (1μM) or saline vehicle control for 24 hours.

Results: gld. ApoE−/− C57BL/6 mice displayed both aggravated lupus-like disease and atherosclerosis under normal diet. Decreased percentage of peripheral blood and bone marrow EPCs, impaired EPC functions and increased atherosclerotic lesion area were observed in gld. ApoE−/− mice. IRS661 treatment inhibited the expressions of IFN-I inducible genes (including IRF7, MX1, OAS1, OAS2 and IFIT-2), while IRS423 promoted the expressions of these genes. The number of EPCs and the ability of EPC to form normal endothelial cells monolayer, to form cavity structure and to re-adherent in gld. ApoE−/− mice were restored after IRS661 treatment, and deteriorated after IRS423 treatment. In vitro experiments showed that only recombinant IFN-α could affect EPC functions, while other interventions including IL-1β, TNF-α, IRS423 and IRS661 did not have a direct impact on EPC regulation.

Conclusion: IFN-I, activated through the upregulation of the TLR7/9 signaling, could induce the depletion and dysfunction of both peripheral and BM EPCs in gld. ApoE−/− C57BL/6 mice, thus may contribute to the development of atherosclerosis.

Hydroxycholorquine Is Cardioprotective in an *In Vivo* Rat Model of Myocardial Ischaemic Reperfusion Injury. Lauren Bourke[1], Valerie Taylor[2], James McCormick[3], Charis Pericelous[1], John Franklin[1], Daniel Stuckey[2], Mark Lythgoe[2], Anastasis Stephanou[4] and Yiannis Ioannou[5]. [1]Centre for Rheumatology Research, University College London, London, United Kingdom, [2]Centre for Advanced Biomedical Imaging (CABI), University College London, London, United Kingdom, [3]Clinical & Molecular Genetics Unit, University College London, London, United Kingdom, [4]Medical and Molecular Biology Unit (MMBU), University College London, London, United Kingdom, [5]Centre for Rheumatology Research, University College Hospital London, London, United Kingdom.

Background/Purpose: A significant amount of myocardial damage during a myocardial infarction (MI) occurs during the reperfusion stage which is known as ischaemic reperfusion (I/R) injury and can account for up to 50% of cell death. Systemic lupus erythematosus (SLE) is associated with increased cardiovascular morbidity and mortality. Many of these patients are treated with the drug Hydroxycholoroquine (HCQ) and whilst retrospective studies have suggested HCQ lowers the risk of suffering an MI, inevitably many still do. This study investigates the effects of HCQ on myocardial survival during reperfusion (I/R injury).

Methods: Male Sprague-Dawley rats (200–220g) were dosed by gavage with 200mg/kg of HCQ once a day for three days which yielded blood concentrations of HCQ in line with that seen in patients (1–2μg/ml). Rats underwent myocardial I/R injury by occlusion of the left anterior descending (LAD) coronary artery, with reperfusion after 40 mins. Twenty-four hours later animals were sacrificed, hearts excised, the LAD re-occluded and the hearts perfused with Evans Blue dye (to label perfused myocardium). Hearts were then cut into 1mm slices and stained with TTC to label viable myocardium). Infarct size (IS) was calculated as entire myocardium area - area of viable tissue. Area at risk (AAR) was then calculated from entire myocardium area - perfused myocardium from the area of viable myocardium. *In vitro* experiments were performed in neonatal rat cardiomyocytes isolated from 1–2 day old rat pups and exposed to simulated I/R injury using a hypoxic chamber. Protein lysates were collected and processed for use in western blot.

Results: *In vivo*, HCQ resulted in a significant reduction in infarct size (IS) presented as a percentage of area at risk (AAR) (area supplied by the LAD). Control rats had an IS/AAR of 20.36% (n=5)), which was significantly reduced in the presence of HCQ to 13.41% (n=5)(p=0.0159). When the hearts were probed for the protective kinase ERK, there was a significant increase in the phosphorylation of ERK in the presence of HCQ - control 0.11 for p-p42 and 0.14 for p-p44 versus HCQ 0.55 (p=0.029) for p-p42 and 0.52 (p=0.020) for p-p44. *In vitro* data has also shown that pre-treatment of neonatal rat cardiomyocytes with HCQ prior to simulated I/R injury was protective, specifically reducing apoptosis. This was observed by a reduction of 43.74% (p value <0.0001) in the number of TUNEL positive cells during reoxygenation and also confirmed thorough probing for cleaved caspase-3. A cell viability assay confirmed that HCQ caused a reduction in total cell death in cells exposed to simulated I/R injury of 57.85% (p value = 0.0213). Correlating with decreased cell death, enhanced ERK phosphorylation in HCQ treated cells was observed in a dose-dependent manner with no significant differences in p38, JNK nor Akt. Cells treated with HCQ and exposed to simulated I/R injury were incubated with the ERK inhibitor U1026 and protective effects of HCQ as assessed via caspase-3 cleavage were completely reversed.

Conclusion: HCQ is cardioprotective in this *in vivo* I/R injury model and phosphorylation of the pro-survival kinase ERK is enhanced in the presence of HCQ. Mechanistic experiments *in vitro* demonstrate that HCQ protection is ERK dependent.

Breach of B Cell Tolerance in New Zealand Black Chromosome 1 Congenic Mice. Kieran Manion[1], Nan-Hua Chang[2], Yuriy Baglaenko[1] and Joan Wither[2]. [1]University of Toronto, Toronto, ON, [2]Toronto Western Research Institute, Toronto Western Hospital, Toronto, ON.

Background/Purpose: Mapping studies in the lupus-prone New Zealand Black (NZB) mouse strain identified an interval from 170.8–181 Mb on chromosome 1 sufficient to induce B cell-intrinsic increases in B cell activation, germinal center formation and anti-ssDNA autoantibody production when introgressed onto a non-autoimmune C57BL/6 background. It was previously shown that B cells from these mice (denoted c1) expressing a transgene for hen egg lysozyme (HEL)-specific immunoglobulin in the presence of soluble HEL were able to breach anergy. The purpose of the current study was to determine if the autoimmune phenotype in c1 mice similarly resulted from a breach of anergy in DNA-reactive B cells.

Methods: To generate mice with a homogeneous, anergic B cell repertoire, genes for heavy (3H9) and light (Vκ8) chains specific for ssDNA were backcrossed onto the c1 strain (c1.Vκ8/3H9). Mice with both knock-in genes were aged to 8 months, at which time autoantibody production and B cell localization, activation and differentiation were assessed by ELISA and flow cytometry, respectively. Adoptive transfers were conducted by staining 10 million negatively isolated splenic B cells from 8–10 week old B6.Vκ8/3H9 or c1.Vκ8/3H9 mice with carboxyfluorescein succinimidyl ester (CFSE) and injecting them via tail vein into B6 or c1 mice. Splenic B cell subsets were analyzed by flow cytometry 7 days post-injection to assess survival, activation, plasma cell differentiation and germinal center recruitment. Germinal centers and plasma cells were further quantified by immunofluorescence microscopy.

Results: Surprisingly, analysis of autoantibody production and splenic B cell subsets in c1.Vκ8/3H9 mice revealed a reduced breach of tolerance to ssDNA as compared to c1 mice and a failure to recapitulate the cellular defects observed in the HEL model. To examine whether the preponderance of anergic B cells in the repertoire of c1.Vκ8/3H9 mice was suppressing the breach of tolerance that would otherwise occur, adoptive transfers of B6.Vκ8/3H9 and c1.Vκ8/3H9 B cells into recipients lacking the knock-in genes were performed. Supporting the previous observations of a breach of B cell tolerance in the c1 HEL model, transferred c1.Vκ8/3H9 B cells showed significantly increased activation compared to their B6 counterparts. Furthermore, increased marginal zone localization and a corresponding decrease in the size of the mature follicular subset for transferred c1.Vκ8/3H9 B cells were observed. Despite this, preliminary data did not reveal a difference between transferred B6.Vκ8/3H9 B cells and transferred c1.Vκ8/3H9 B cells with respect to recruitment to germinal centers in either B6 or c1 recipients, suggesting that the activation of transferred c1.Vκ8/3H9 B cells may be extra-follicular in nature.

Conclusion: The results reaffirm previous findings that c1 mice breach tolerance to nuclear self-antigen through an intrinsic B cell defect. There is also indication of an active role for anergic B cells in maintaining tolerance through immune suppression.

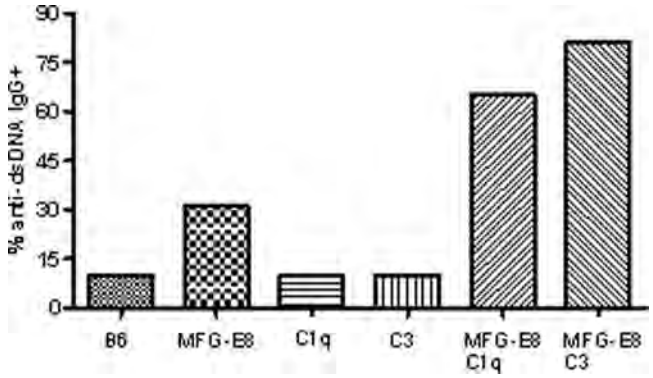
Distinct Contributions of C1q and C3 in Preventing Immunogenicity of Apoptotic Cells in Lupus. Clayton Sontheimer, Yenly Nguyen, Keith B. Elkon and YuFeng Peng. University of Washington, Seattle, WA.

Background/Purpose: Defective clearance of apoptotic cells (AC) and complement deficiency are important contributors to the pathogenesis of systemic lupus. Dead (sunburn) cells and complement activation are also observed in patients with cutaneous lupus. ACs are opsonized by several proteins including C1q, C3 and MFG-E8. MFG-E8 is a soluble milk protein that binds to phosphatidylserine on AC and facilitates their removal through its interaction with avb3 and avb5 integrins on phagocytes. In its absence, AC debris accumulates in germinal centers. In MFG-E8−/− B6 mice, we observed a C1q dependent increase of C3/IgG deposition on MZ B cell and FDCs, suggesting excessive self antigens can activate the classical pathway and be presented as antigen/immune complexes to autoreactive B cells in spleen. In this study, we determined how the interaction between AC and complement contribute to autoantibody production, nephritis and photosensitivity in lupus.

Methods: We introduced MFG-E8−/−, C1q−/− and C3−/− into SLE 1 congenic mice. We created MFG-E8−/−C1q−/− and MFG-E8−/− C3−/− double knock-out in the SLE1 background. We analyzed the titers of anti-chromatin and anti-dsDNA (n =15–20 in each group) by ELISA and confirmed the results by *Crithidia luciliae* staining. We examined T and B cell phenotypes by flow cytometry. Kidney damage was evaluated by blood urea nitrogen, immuno-fluorescence and PAS staining. We exposed respective strains to repeated UVB irradiation and followed development of nephritis and skin lesions.



Results: In 7 month old female B6.SLE1 mice, 10% of mice developed anti-dsDNA IgG. Neither C1q nor C3 deficiency alone changed the percentages of anti-dsDNA IgG+ mice. MFG-E8−/− SLE1 mice had a significantly higher number of germinal center B cells and 30% of females became anti-dsDNA IgG+. Combining MFG-E8−/− with either C1q−/− or C3−/− significantly accelerated the production of anti-dsDNA IgG and increased the percentage of anti-dsDNA IgG+ mice to 65% and 80%, respectively (Figure). Furthermore, 50% MFG-E8−/−C1q−/− but 0% FG-E8−/−C3−/− SLE1 mice showed early mortality due to spontaneous lupus nephritis. When exposed to UVB irradiation, 90% (8 out 9) MFG-E8−/−C3−/− developed either acute nephritis or persistent skin lesions. On the contrary, none of MFG-E8−/−C1q−/− mice (0 out 15) experienced similar symptoms.

Conclusion: Both C1q and C3 are essential in reducing the immunogenicity of apoptotic cells in lupus. The protective mechanisms they provide depend on availability of other opsonins and environmental factors such as sunlight exposure.

17β Estradiol Regulates VCAM-1 Expression during Glomerulonephritis. Neelakshi Jog and Roberto Caricchio. Temple University, Philadelphia, PA.

Background/Purpose: The immunomodulating roles of estrogens are not completely understood. Although 17β estradiol (E2) has been shown to promote systemic autoimmunity, it has also been shown to inhibit pro-inflammatory cytokine secretion. We showed previously that treatment of male mice with E2 led to improved survival in nephrotoxic serum induced nephritis (NTN). In this study we aimed at determining the effect of E2 on intrinsic renal cells and to understand the role of E2 in regulating inflammation in vivo in the kidney during nephritis. Vascular Cell Adhesion Molecule, VCAM-1, is an adhesion molecule for leukocytes that is upregulated in vivo in mice with autoimmune nephritis, and in vitro in tubular epithelial cells and mesangial cells (MCs) upon stimulation with tumor necrosis factor alpha (TNFα) and Interferon gamma (IFNγ). In this study we determined whether E2 regulates the extent of renal inflammation by regulating adhesion molecule expression by MCs.

Methods: We used nephrotoxic serum induced nephritis as a model of autoimmune nephritis. Mice were treated with E2 pellets prior to induction of nephritis. We determined the molecular mechanisms of VCAM-1 regulation by E2 using cell and molecular biology techniques such as flow cytometry, immunofluorescence, Chromatin immunoprecipitation (ChIP) assays, and quantitative PCRs in TNFα stimulated MCs.

Results: We show that E2 treatment inhibited VCAM-1 upregulation in kidneys in vivo during NTN in both male and female mice. E2 also inhibited upregulation of VCAM-1 in MC upon TNFα stimulation. The VCAM-1 upregulation in MCs was regulated by the transcription factor NFκB, since inhibition of NFκB inhibited the upregulation. We further determined the molecular mechanism of regulation of VCAM-1 by E2. We show that E2 does not regulate the nuclear translocation of p65 subunit. ChIP assays showed that although E2 does not inhibit p65 binding to the VCAM-1 promoter, it inhibits the recruitment of RNA polymerase II to the promoter, suggesting that E2 may inhibit the formation of pre-initiation complex at the promoter. We showed previously that absence of Poly (ADP-Ribose) Polymerase-1 (PARP-1) inhibited TNFα stimulated VCAM-1 upregulation in mouse MCs. PARP-1 has been shown to interact with estrogen receptor and we showed that E2 inhibits PARP-1 activity in macrophages. PARP-1 has been also proposed as a co-factor for NFkB activation. We therefore determined whether E2 regulates VCAM-1 upregulation through PARP-1. Indeed our data show that PARP-1 interacts with p65 upon TNFα stimulation and this interaction is inhibited in the presence of E2.

Conclusion: Our data show that E2 inhibits upregulation of VCAM-1 in nephritic kidneys. Using mesangial cells we further showed that E2 inhibits VCAM-1 upregulation by inhibiting the formation of pre-initiation complex at the VCAM-1 promoter. E2 inhibits PARP-1 recruitment to p65, further inhibiting the recruitment of RNA polymerase II and transcription at the VCAM-1 promoter. We propose that E2 plays an important role in regulating renal inflammation locally, which may explain why nephritis in systemic autoimmunity tends to be worse in males.

Breakdown of Tolerance at the Tissue Level in Systemic Autoimmunity: Role of Tissue-Resident Dendritic Cells. Jennifer K. King, Rachael Philips, Anna Eriksson and Ram Raj Singh. UCLA, Los Angeles, CA.

Background/Purpose: Systemic autoimmune diseases such as lupus affect multiple organs including skin and kidneys, usually in a diverse fashion where only certain organs are affected in individual patients. It is unclear whether the breakdown in tolerance manifested by global immune dysregulation can account for the tissue specificity in relation to heterogeneity of disease, or if local factors also contribute. We hypothesized that the local immune environment may regulate tissue specificity and chose to study skin tolerance within a systemic lupus disease model. Here, we investigated whether a subset of skin-resident dendritic cells, namely Langerhans cells (LC), maintain immune tolerance in skin versus other target organs in a model of SLE.

Methods: We used genetically lupus-prone MRL/MpJ-Fas$^{+/+}$ (MRL+/+) and MRL-lpr mice that develop lupus dermatitis, nephritis, arthritis, vasculitis, and dsDNA antibodies as models of systemic autoimmunity. To conditionally ablate LC in these mice, we introgressed the Langerin-DTR-EGFP knockin mutation from the stock B6 onto the MRL by backcrossing >10 generations, and injected diphtheria toxin in adult mice. Recombinant desmoglein 3 (Dsg3) was used as a skin autoantigen to assess tissue-specific tolerance using an epicutaneous tolerization assay. Thymidine uptake/Ki67 expression was used for cell proliferation and Western blot for measuring autoantibodies against skin lysate. Disease was assessed by clinical and histological scoring.

Results: We previously reported that MRL mice have reduced migration of langerin^{+}DC from the skin to the skin-draining lymph nodes (dLN), with a profound defect in the emigration of LC from their epidermis. This migration defect worsens with age and disease onset. We hypothesized that this impaired DC migration observed in MRL mice play a role in the loss of skin tolerance. Indeed, lymphocytes from dLN of MRL-lpr mice spontaneously proliferate to a skin autoantigen, desmoglein 3 (Dsg3), which can be reversed by the epicutaneous application of Dsg3. Such resumption of tolerance to skin antigen, however, is prevented upon a transient ablation of LC in these mice. We then asked that if reduced DC cell migration to the dLN contributes to lupus dermatitis, then the complete ablation of them would further exacerbate dermatitis. Indeed, an inducible LC ablation in adult MRL-lpr and MRL+/+, but not in B6 and B6-lpr mice, accelerated and exacerbated lupus dermatitis and increased circulating antibodies against skin antigens, along with reduced frequency of IL-10-producing CD4 T cells in dLN. However, LC ablation did not affect disease in other organs such as kidneys, lung, or liver, and serum levels of systemic autoantibodies such as anti-dsDNA.

Conclusion: These data indicate that LCs maintain skin tolerance in systemic lupus, and highlight the importance of the local immune milieu in regulating tissue-specific autoimmunity, without affecting systemic immunity. Such immune regulation at the local level may explain the heterogeneity of multiorgan involvement in SLE. Our data have implications for therapy at the local organ level, providing a target for therapy to correct a local breakdown in tolerance rather than attempting correction at a systemic level.

Microthrombotic Renal Vascular Lesions Are Associated to Increased Renal Inflammatory Infiltration in a Mouse Model of Lupus Nephritis.

María Galindo[1], Elena Gonzalo-Gil[1], Oscar Toldos[2], Carmen García-Herrero[1], Alicia Usategui[1], Sonia Pérez-Yagüe[3], Gabriel Criado[1], Domingo F. Barber[3] and Jose L. Pablos[1]. [1]Instituto de Investigación Hospital 12 de Octubre (I+12), Madrid, Spain, [2]Servicio de Anatomia Patologica, Hospital 12 de Octubre, Madrid, Spain, [3]Centro Nacional de Biotecnología (CNB-CSIC), Madrid, Spain.

Background/Purpose: In patients with lupus nephritis (LN), acute renal vascular and atherosclerotic lesions correlate with the degree of inflammation regardless the presence of antiphospholipid antibodies. The aim of this study was to confirm these results in MRL/lpr mice and to analyze the specific effect of blocking inflammatory factors and/or platelet aggregation.

Methods: The pattern of renal vascular disease, acute and chronic glomerular and tubulointerstitial lesions were specifically analyzed with histological staining (H&E, PAS) in 12–20-wk old female MRL/lpr mice with nephritis. Immunohistochemistry (IHC) techniques were used to detect CD41 (platelet aggregates), fibrinogen (FGN), periglomerular macrophagic F4/80 (quantified as the % of positive glomeruli), intraglomerular macrophage infiltration (Mac-2) and C3 deposition. Renal function was assessed by measuring proteinuria, serum creatinine and albumin (sCr, sAlb). Levels of a-dsDNA and anticardiolipin (aCL) antibodies were quantified by ELISA. The specific effect of treatment with steroids and antiaggregation (aspirin or clopidogrel) was analyzed. Association between categorical variables was tested by the X^2 test. For continuous variables, comparisons were carried out using *t*-test for two independent samples. A Spearman's rank was used for correlations among different study parameters. *P* values < 0.05 were considered significant.

Results: In the descriptive phase, 41 mice were analyzed. Histological, IHC and clinical characteristics of lpr mice with lupus nephritis are described in table 1.

Mice with microthrombotic renal vascular lesions showed a greater degree of periglomerular macrophage infiltration (p=0.002). All mice had detectable a-dsDNA or aCL IgG, irrespective of the presence of TMA or CD41+. Proteinuria positively correlated to the proportion of sclerotic glomeruli (r=0.4; p=0.01) and glomerular macrophage infiltration (r=0.46; p=0.004) and was higher in mice with diffuse proliferative glomerular lesions (340.8 vs110.8; p=0.02).

After two weeks of treatment, the specific effect of 15 mg/d dexamethasone, 10 mg/d aspirin or 1.5 mg/d clopidogrel, or combined therapy dexa+ antiaggregation was compared to PBS treatment in 52 mice, and results are detailed in table 2.

Table 1

	Mice (n=41)
Glomerular lesions:	–
Focal and segmental proliferative	53.70%
Diffuse proliferative	46.30%
Interstitial fibrosis	5%
Instertitial inflammation:	–
Medular	7.30%
Cortical	29.30%
Both	36.60%
Mice with sclerotic glomeruli (number of glomeruli)	46% (1–11)
Microthrombotic renal vascular lesions (thrombotic microangiopathy [TMA] or CD41+ microthrombi)	34%
Glomerular/extragomerular FGN (%)	–
Glomerular Mac-2 (%)	4.8 ± 3.6/ 0.8 ± 0.6
Periglomerular F4/80 (+ glom %)	3.9 ± 2.3
Mean sCr (mg/dl)	41.9 ± 21.4
Proteinuria (>300mg/dl)	0.5 ± 0.1
	13.20%

Conclusion: Presence of microthrombotic renal vascular lesions is associated to a higher degree of macrophage infiltration in MRL/lpr model of LN. Both dexamethasone and blockers of platelet aggregation reduce glomerular damage and inflammatory response, suggesting platelets involvement in inflammatory damage.

Dysfunction of Glycosphingolipid Metabolism in Lupus Nephritis.

Thirumagal Thiyagarajan[1], Leah Siskind[2], Jim Oates[1], Richard Drake[1] and Tamara K. Nowling[3]. [1]Medical University of South Carolina, Charleston, SC, [2]University of Louisville, Louisville, KY, [3]Medical University of South Carolina and Ralph H. Johnson VA Medical Center, Charleston, SC.

Background/Purpose: Lupus is a chronic autoimmune disease characterized by autoantibody production and aberrant activation and proliferation of lymphocytes. Subsequent deposition of immune complexes in target tissues leads to an inflammatory reaction and tissue damage. Glomerulonephritis (GN) is the most severe complication of lupus, lupus nephritis (LN) affecting up to two-thirds of lupus patients and is associated with high morbidity and mortality. LN is characterized by podocyte dysfunction, proteinuria and a decrease in renal function. Glycosphingolipids (GSLs) are a heterogeneous class of lipids in the sphingolipid family that play a role in the regulation of cellular processes. Highly abundant in the kidney, GSLs play a role in a variety of kidney diseases including GN, nephropathy, and polycystic kidney disease. GSLs are present in most cells and are thought to play roles in signal transduction, cell-cell adhesion and immune responses. GSLs are enriched in the kidney. Loss of sialic acid residues from the surface of podocytes is linked to proteinuria in GN. Neuraminidases (NEUs) remove sialic acids from gangliosides to generate lactosylceramide (LacCer) and glucosylceramide, (GlcCer) ganglioside precursors.

Methods: Kidney homogenates, serum and urine samples were prepared from 11, 14 and 18 week-old MRL/lpr lupus mice and human lupus patients and controls. GSL levels were measured by Supercritical Fluid Chromatography coupled with tandem mass spectrometry. NEU protein and activity were measured by western immunoblot and/or enzyme activity assays. Gene expression was analyzed by real-time RTPCR on RNA isolated from kidney cortex. Matrix-assisted laser desorption/ionization-imaging mass spectrometry (MALDI-IMS) and immunohistochemistry for LacCer was performed on frozen kidney sections.

Results: GlcCer and LacCer levels are significantly elevated 3–5-fold, NEU activity and Neu1 expression levels are significantly elevated 2-fold and

12-fold, respectively, in the kidney of lupus mice with nephritis compared to lupus mice without nephritis and/or normal, healthy controls. Levels of ceramide and other enzymes in the GSL metabolic pathway are unchanged. Urine LacCer levels appear to be significantly elevated prior to significant increases in proteinuria. Using MALDI-IMS, we also observed a striking decrease in the levels of gangliosides GM1 and GM3 in the LN mice compared to controls. Of translational significance, human LN patients compared to controls have a 1) significant 25-fold increase in urine LacCer levels, 2) significant increase in urine Neu1 levels, and 3) observed increased LacCer levels in the mesangial regions in renal biopsy sections. No significant differences were observed in serum LacCer levels in LN patients compared to controls.

Conclusion: Our results demonstrate that elevated LacCer is likely due to an upregulation of the GSL catabolic pathway in the kidney of lupus mice and patients with nephritis. Furthermore, the elevated LacCer levels in the urine of patients may be largely due to kidney rather than systemic contributions and our mouse studies suggest it may be an earlier marker than proteinuria of nephritis.

Interferon Regulatory Factor-5 Promotes Disease in the *MRL/Lpr* Mouse Model of Lupus. Amanda Watkins, Ramon Bonegio, Guneet Kochar, Gabriella Wilson, Bari Laskow, Christophe Richez, Ian Rifkin and Kei Yasuda. Boston University School of Medicine, Boston, MA.

Background/Purpose: Interferon regulatory factor 5 (IRF5) polymorphisms are strongly associated with an increased risk of developing Systemic Lupus Erythematosus (SLE). SLE is caused, in part, by the survival of self-reactive B cells which produce autoantibodies that can deposit in tissues such as the kidney leading to tissue injury and significant morbidity.

In murine lupus models, IRF5-deficiency has been shown to reduce disease severity, in part, by ameliorating immune complex-mediated kidney disease. IRF5 is highly expressed in B cells where it is involved in isotype switching to IgG2a and TLR-mediated activation. However, whether IRF5 contributes to lupus pathogenesis by promoting B cell differentiation or plasma cell survival is not fully understood. We hypothesized that IRF5 may contribute to disease in the MRL/lpr lupus mouse model by promoting B cell survival through regulation of B lymphocyte stimulator (BLyS).

Methods: We evaluated the effect of IRF5-deficiency in the MRL/lpr mouse lupus model by measuring splenomegaly, lymphadenophathy, severity of kidney disease, as well as total serum IgG and anti-Sm/RNP and anti-nuclear autoantibodies. In addition we analyzed the splenic and bone marrow lymphocyte populations and measured serum BLyS levels over the course of disease.

Results: We found that IRF5-deficient ($IRF5^{-/-}$) MRL/lpr mice developed much less severe disease compared to their IRF5-sufficient ($IRF5^{+/+}$) littermates. Despite markedly lower serum levels of anti-nuclear autoantibodies and reduced total splenocyte and $CD4^+$ T cell numbers, $IRF5^{-/-}$ MRL/lpr mice had similar numbers of all splenic B cell subsets compared to $IRF5^{+/+}$ MRL/lpr mice, suggesting that IRF5 is not involved in B cell development to the mature B cell stage. However, $IRF5^{-/-}$ MRL/lpr mice had greatly reduced numbers of splenic plasmablasts and bone marrow plasma cells. Despite the marked reduction in serum IgG and plasmablast numbers in $IRF5^{-/-}$ MRL/lpr mice, serum BLyS levels remained highly elevated with no difference observed between groups.

Conclusion: Overall our data demonstrate that IRF5 contributes to disease pathogenesis in the MRL/lpr lupus model and that this is due, at least in part, to the role of IRF5 in plasma cell formation and independently of BLyS production. Our data also suggest that combined therapy targeting both IRF5 and BLyS might be a particularly effective therapeutic approach in lupus.

STAT3 Inhibition Delays the Onset of Lupus Nephritis in MRL/*Lpr Mice*. Linsday Edwards[1] and Vasileios C. Kyttaris[2]. [1]Beth Israel Deaconess Medical Center, Boston, MA, [2]Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA.

Background/Purpose: The transcription factor Signal transducer and activator of transcription (STAT) 3 is overexpressed and aberrantly activated in patients with SLE as well as lupus-prone mice. More specifically, STAT3 plays a central role in T cell differentiation into pathogenic Th17 as well as T follicular helper cells, two T cell subsets that are thought to orchestrate autoimmune responses in SLE. Our previous studies have shown that STAT3 is also important in SLE T cell migration in response to chemokines. To better understand its role in SLE, we inhibited STAT3 in lupus-prone mice using the small molecule Stattic.

Methods: MRL/*lpr* mice were treated 3 times per week with 10 mg/kg of the STAT3 inhibitor Stattic or vehicle delivered intraperitoneally beginning at 6 weeks of age and continuing through 15 weeks of age. The kidney function was monitored weekly by urinalysis. Levels of anti-dsDNA antibodies, C3 and various cytokines were measured in the serum. At the conclusion of treatment, tissues were harvested for histology and phenotypic analysis. *In vitro* assessment of the effects of Stattic treatment on T cell function was also performed.

Results: Stattic treated mice exhibited a delay in the onset of proteinuria by approximately 3 weeks. Stattic treated mice had lower levels of anti-dsDNA production (mean=1771 U/ml in treated vs. 32174 U/ml in control) and inflammatory cytokine production (serum IL-17 levels approximately 2-fold higher in untreated mice). Inhibitor treatment reduced lymphadenopathy, and resulted in a decrease in the total number of T cells in treated mice. Absolute numbers of T cells were 3–4 fold higher in untreated mice. Furthermore, the numbers of T follicular helper cells were reduced in Stattic treated mice by 4-fold. Complimentary *in vitro* experiments showed that T cells treated with Stattic exhibited a dose dependent decrease in proliferation and an approximately 70% decrease in their ability to migrate in response to CXCL12 stimulation.

Conclusion: From the data generated in this study, we conclude that treatment of lupus prone mice with a STAT3 inhibitor delays the onset of autoimmunity and end-kidney damage. Our *in vivo* and *in vitro* findings suggest that STAT3 inhibition leads to the following: a. decreased T cell proliferation, b. decreased Tfh cells and decreased anti-dsDNA production, and c. decreased cell migration in response to chemokines. We propose that STAT3 inhibition represents a therapeutic target in SLE and in particular lupus nephritis.

The Pathogenesis of Neuropsychiatric Systemic Lupus Erythematosus Is Dependent on Brain Intrinsic Factors. Ariel Stock, Jing Wen, Jessica Doerner and Chaim Putterman. Albert Einstein College of Medicine, Bronx, NY.

Background/Purpose: Neuropsychiatric disease is a common manifestation of systemic lupus erythematosus (SLE). Frequent presentations include depression, anxiety, memory loss and cognitive decline. The pathogenesis of neuropsychiatric SLE (NPSLE), however, remains unclear; several potential mechanisms include thrombosis, complement deposition, brain reactive autoantibodies, and cytokine mediated inflammation. The MRL-*fas*$^{lpr/lpr}$ (MRL/lpr) mouse has proven quite valuable to the study of SLE in general, including NPSLE. This is due to development of a disease profile similar to humans including renal and cutaneous manifestations, as well as an early neuropsychiatric phenotype characterized by depression and spatial memory deficit. However, it is not clear whether the neuropsychiatric manifestations of SLE are secondary to systemic disease or a primary pathogenic process.

Methods: In order to distinguish between the relative contributions of the central nervous system (CNS) vs hematopoietic compartments, we generated three groups of bone marrow chimeras between MRL/lpr mice and the congenic control MRL/+ mouse (Table 1). We monitored systemic disease progression through titers of autoantibodies and levels of proteinuria. The mice underwent extensive behavioral testing to characterize their motor, cognitive and emotional states, including open field, object placement, object recognition and the forced swim tests.

Results: MRL/lpràMRL/lpr mice showed increasing autoantibody titers over time, consistent with untransplanted MRL/lpr mice. MRL/+àMRL/+

mice showed consistently low or undetectable levels of autoantibodies. MRL/+àMRL/lpr mice showed early increases in autoantibody titers that decreased over time, indicative of MRL/+ bone marrow engraftment and abrogation of the MRL/lpr systemic disease phenotype. Behaviorally, MRL/+àMRL/lpr mice displayed a phenotype remarkably consistent with MRL/lpràMRL/lpr (as well as untransplanted MRL/lpr) mice, including depression like behavior (Fig 1) and increased spatial memory deficits. MRL/+àMRL/+ mice displayed no behavioral deficits, consistent with untransplanted MRL/+ mice.

Conclusion: Previous studies have shown that MRL/lpr mice develop neuropsychiatric disease similar to human lupus, though have not determined whether this is a primary CNS manifestation or secondary to peripheral immune abnormalities and systemic disease. The data presented herein indicate that the MRL/lpr CNS is responsible for NPSLE development, which can occur absent hematopoietic contributions.

Table 1. Bone marrow transplant scheme

Donor	Host	Chimera	Source of CNS Cells	Source of Hematopoeitic Cells
MRL/+	MRL/+	MRL/+→MRL/+	MRL/+	MRL/+
MRL/lpr	MRL/lpr	MRL/lpr→MRL/lpr	MRL/lpr	MRL/lpr
MRL/+	MRL/lpr	MRL/+→MRL/lpr	MRL/lpr	MRL/+

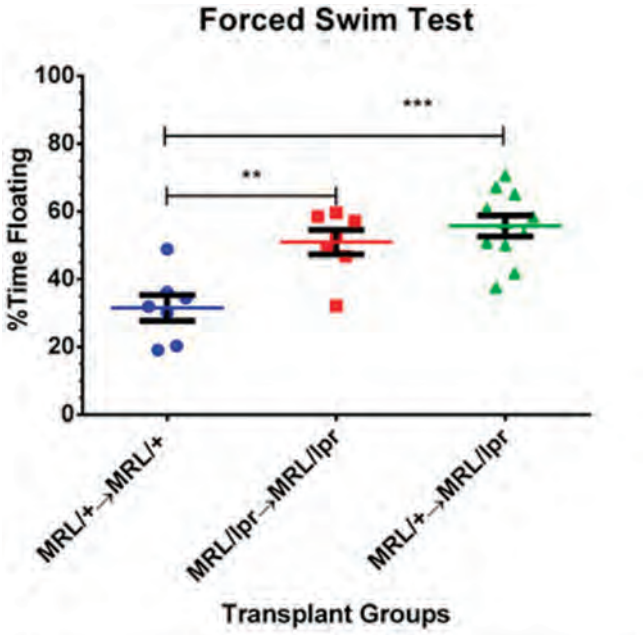

Fig 1. Despite the transplant of MRL/+ bone marrow and resultant resolution of systemic autoimmunity, MRL/+→MRL/lpr mice display depressive like behavior similar to MRL/lpr→MRL/lpr mice, as measured by forced swim test.

Safety and Efficiency of Low-Dose Interleukin-2 Treatment in Systemic Lupus Erythematosus. Jing He[1], Xia Zhang[1], Xiaolin Sun[1], Jianping Guo[1], Yunbo Wei[2], Zhaohua Hou[2], Yu Di[3] and Zhanguo Li[1]. [1]Peking University People's Hospital, Beijing, China, [2]Shandong Analysis and Test Center, Shandong Academy of Science, Shandong, China, [3]Monash University, Clayton, Austria.

Background/Purpose: Systemic lupus erythematosus (SLE) is an autoimmune disease characterized by loss of tolerance to nuclear self-antigens, production of pathogenic autoantibodies and damage tomultiple organs. While corticosteroids and immunosuppressive agents have improved the outcome of patients, there remains a significant unmet need for safe and more effective treatments. Low-dose Interleukin-2 (IL-2) therapy has recently been shown effective to treat autoimmune disease. We aimed to assess the safety and efficacy of low-dose IL-2 therapy in active SLE.

Methods: We conducted a clinical trail on active SLE patients (NCT02084238). A total of 40 patients were enrolled. Patients with SLE Disease Activity Index (SLEDAI) scores ≥8 received three courses of low dose recombinant human IL-2 (1 million IU every second day for 2 weeks followed by a 2-week hiatus). The primary end point was the response rate at week 10. Both the safety and efficiency of IL-2 therapy were evaluated.

Results: Total 36 patients (36/40, 90%) achieved an SLE Responder Index (SRI) improvement at week 6. No patients demonstrated high grad adverse events; mild injection-site reaction was observed in 5 patients (5/40, 12.5%). Better response was seen in patients with skin involvement (erythema, photo sensibility, Rdynolds, vasculitis), hematologic abnormities (leukopenia, Thrombocytopenia and anemia) and disease-related fever.Patients showed the improvement of major laboratory indicators, including reduced anti-dsDNA autoantibody titres and 24-hour proteinuria, and increased levels of the complement proteins C3 and C4. Immunological analysis showed significant increase of Treg cells and decrease of effector helper T cells after the therapy.

Conclusion: Our results showed that low-dose IL-2 therapy in active SLE was safe and achieved satisfactory efficacywith increasing Treg and decreasing effector helper T cells.

Approach to Discriminate Treatment Impact in Both Moderate and Severe SLE: The Atacicept Phase IIb Trial Design. Joan T. Merrill[1], Yong Li[2], Stephen D. Wax[3] and Christopher Tehlirian[4]. [1]Oklahoma Medical Research Foundation, Oklahoma City, OK, [2]R&D Global BioStatistics, EMD Serono, Billerica, MA, [3]Global Clinical Development Center - Immunology, EMD Serono Inc, Rockland, MA, [4]EMD Serono, Rockland, MA.

Background/Purpose: Increases in background treatment in SLE trials lead to high placebo group responses in patients with moderate but not those with high disease activity (1–3). The optimal allowance of background medication increase to ensure patient safety and still enable data interpretability over a range of disease severity remains unknown. Since even moderate lupus activity leads to organ damage, disability and poor quality of life (4–6), a goal of the ADDRESS II trial of atacicept (inhibitor of B cell stimulators BLyS and APRIL) is to discriminate treatment effects on both moderate and high SLE disease activity within one trial.

Methods: This 24 week study examines atacicept (75 or 150 mg/wk) versus placebo for the reduction of SLE disease activity. Similar to the Phase III belimumab (BLISS) program, study drug is added to standard of care. Unlike the BLISS design, which allowed temporary unlimited background steroids and permanent increases in immune suppressant doses, after the Week 4 study visit ADDRESS II restricts the corticosteroid dose to ≤ the dose at the Screening visit and ≤30 mg prednisone (or equivalent), and immunosuppressives must be stable from 2 months before screening throughout the duration of the study. Additional treatment defines a non-responder.

Results: The primary endpoint is similar to the BLISS trials as defined by the SRI (≥4 point reduction in SLEDAI-2K, <10% increase in PGA, no new BILAG A score and ≤1 new BILAG B score, at Week 24 compared to the Screening visit). A placebo response rate of 30% (lower than BLISS placebo rates due to more stringent background medication restriction) is predicted, enabling 80% power to detect a 20% absolute difference in proportion achieving an SRI response with 93 patients per arm and a 2-sided α=0.05 with a randomization ratio of 1:1:1. A steroid reduction endpoint, which includes a provision for lack of flare, will also be examined. Patients are stratified by level of disease activity (SLEDAI < 10 vs. ≥ 10), race, and use of mycophenolate at screening, enabling analysis of response in these subpopulations. A 2 year extension study will give all completer patients the option to receive active treatment (placebo patients will be switched to 150 mg atacicept), but the dose will be blinded, allowing longer term evaluation of responses.

Conclusion: Interpretation of SLE trials is hampered by confusing data in patients with moderate disease activity. The ADDRESS II study was

designed to discern treatment impact in both severe and moderate disease patients, who represent a large, underserved population with poor quality of life and progressive damage despite high response rates to increased standard of care in trials.

24-Month Outcomes Associated with Belimumab in Patients with Systemic Lupus Erythematosus in Clinical Practice Settings. Christopher E. Collins[1], Hong Kan[2], Maria Dall'era[3], Cynthia Macahilig[4], Ramesh Pappu[2], Charles T. Molta[5] and Volker Koscielny[6]. [1]MedStar Washington Hospital Center, Washington, DC, [2]GlaxoSmithKline, Research Triangle Park, NC, [3]UCSF, San Francisco, CA, [4]Medical Data Analytics, Parsippany, NJ, [5]GlaxoSmithKline, Philadelphia, PA, [6]GlaxoSmithKline, Brentford, United Kingdom.

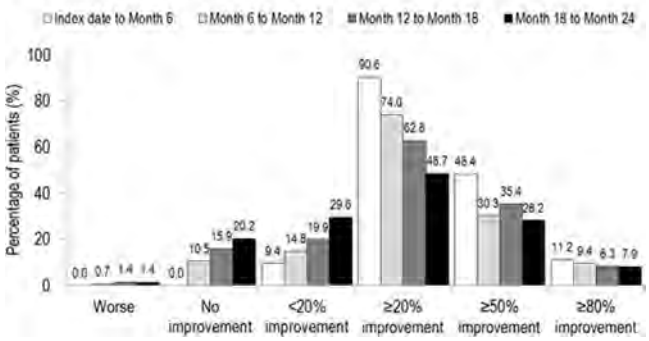
Background/Purpose: The clinical efficacy of belimumab in patients with systemic lupus erythematosus (SLE) has been demonstrated in large randomized clinical trials. We examined clinical outcomes following belimumab treatment in clinical practice settings in the US.

Methods: OBSErve US (evaluation **O**f use of **B**elimumab in clinical practice **SE**ttings in the US; GSK Study: BLM117295) was a multicenter, retrospective, medical chart review study. Rheumatologists from non-academic centers were randomly recruited from a national physician database. Physicians reported retrospective data from medical charts of randomly identified adult SLE patients in their care who had received ≥8 belimumab infusions as part of usual care. Data were reported for 6 months prior to index date (date of first belimumab infusion), and every 6 months thereafter for up to 24 months. The primary outcome measure was physician impression of change in SLE disease manifestations, relative to the previous time point. Here we report the final analyses of patients who had outcomes reported at Month 24.

Results: At index date, 501 patient charts were analyzed. By Month 24, 112 patients were lost to follow-up and 112 patients had discontinued. Most common reasons for discontinuation included patient request (n=44, 40.2%), medication not effective (n=33, 29.5%), disease progression (n=15, 13.4%), loss of insurance or reimbursement (n=14, 12.5%) and lack of patient compliance (n=11, 9.8%). The Month 24 completer analysis included 277 patients: female, 90.6%; mean age, 42.9 (standard deviation [SD]: 12.0) years; Caucasian, 52.7%; African-American, 24.9%; Hispanic, 15.5%; Other, 6.9%.

Of the 277 patients, 134 (48.4%) had ≥50% improvement in overall clinical response between index date and Month 6 according to the physicians' impression (**Figure 1**). Further improvements were observed during Months 6–12 and 12–18. At Month 24, 78 (28.2%) patients had improved by ≥50% since Month 18.

Figure 1. Clinical responses in completers (n=277), according to physicians' impression of overall change in SLE manifestations relative to the previous timepoint



At index date, 218/277 (78.7%) patients received concomitant steroids (mean [SD] dose: 18.0 [12.2] mg/day); by Month 24, the mean (SD) dose among these patients was 2.9 (3.4) mg/day and 95 (43.6%) patients had discontinued steroids. During the 24-month period six patients initiated steroid treatment.

Of the 277 patients who completed to Month 24, 69 (24.9%) had SELENA-SLEDAI scores available at index date and Month 24; the mean (SD) score at index date was 12.5 (3.0), with a reduction of 8.2 (3.8), to 4.4 (3.1) by Month 24.

Conclusion: Overall, physicians reported continued improvements in clinical outcomes throughout the study, among patients who had completed 24 months of treatment with belimumab 10 mg/kg plus usual care (≥8 belimumab infusions). Over 24 months, mean steroid dose among baseline users was reduced by 84%.

Evolution of Patients with Systemic Lupus Erythematous Treated with Belimumab in Clinical Practice Settings. Josefina Cortes[1], Carlos Marras[2], Jose Luis Andreu[3], Jaime Calvo-Alen[4], Angel M. Garcia-Aparicio[5], Elvira Diez Alvarez[6], Carlos Coronell[7], Elena Morejon[7], Alessandra Perna[8], Volker Koscielny[8] and Josep Ordi-Ros[1]. [1]Vall d'Hebron Hospital, Barcelona, Spain, [2]Virgen de la Arrixaca Hospital, Murcia, Spain, [3]Puerta de Hierro Universitary Hospital, Madrid, Spain, [4]Sierrallana Hospital, Torrelavega, Spain, [5]Virgen de la Salud Hospital, Toledo, Spain, [6]Leon Hospital, Leon, Spain, [7]GlaxoSmithKline, Madrid, Spain, [8]GlaxoSmithKline, Brentford, United Kingdom.

Background/Purpose: After the approval of belimumab for patients with systemic lupus erythematosus (SLE), the objective of this study is to describe the clinical outcomes associated with 6 months of belimumab treatment in clinical practice settings in Spain.

Methods: OBSErve (GSK 200883) is a multi-center and retrospective study from community-based rheumatology practices with high experience in SLE treatment. All adult SLE patients in their practices who had received belimumab (10mg/kg) as part of routine care were identified for chart abstraction. Baseline date is the date of belimumab initiation. The activity of the disease was classified as mild, moderate and severe according the perception of the disease manifestations by the physician or based on SELENA-SLEDAI index. The primary clinical outcome measure is the overall clinical response, reported as change from baseline in SLE disease manifestations, 6 months after belimumab initiation based on physician subjective assessment. Reasons for premature treatment discontinuation were collected as secondary variable of safety, and information about steroid use and dosage within the first 6 months of belimumab therapy was collected as secondary variables of efficacy.

Results: 64 eligible patient charts were included. The mean patient age was 42.7 years±12; 89% were female; 23% were diagnosed with SLE <5 years ago; 6%, 61% and 33% had mild, moderate and severe SLE respectively at baseline; 70% of patients had low C3 or C4, and 69% high anti-dsDNA at baseline. The most frequent reasons for initiating belimumab were an ineffective previous treatment regimen (78%), the intent to decrease steroid use (58%), and worsening patient condition (55%). The most frequent manifestation of SLE in these patients were musculoskeletal (arthritis=56.2%), Immunologic (low complement [C3, C4, or CH50]=53.13), Increased anti-dsDNA antibody levels=48.44%, and Mucocutaneous (Rash=26.56%). In general, belimumab appeared to be well-tolerated; two patients (3%) had discontinued belimumab within the first 6 months of therapy: one due to lack of efficacy, the other due to Pelvic inflammatory disease. After 6 months of belimumab therapy 72%, 52% and 27% of patients had an overall clinical improvement of >20%, >50% and >80% respectively. For the most frequent SLE manifestations, such as in arthritis (69%), low complements (47%), high anti-ds-DNA levels (48%), and fatigue (60%) a >50% improvement was observed. Additionally, the mean score of the SELENA-SLEDAI index decreased from 10.1 to 4.5 ($p<0.0001$) in the first 6 months. In 88% of the patients (n=57), a decrease SELENA-SLEDAI index was observed.

Oral steroids were used concomitantly in 95% of SLE patients at baseline. Patients had a mean reduction in steroid dose of 6.8mg/day from 14.8mg/day

at baseline after 6 months of treatment with belimumab ($p<0.0001$). 75% of patients (n=57) experienced a reduction in steroid use during the 6 months.

Conclusion: Among SLE patients treated with belimumab, clinical and serological improvement was observed in a majority of SLE patients over their first 6 months of routine treatment in a sample of clinical practices in Spain.

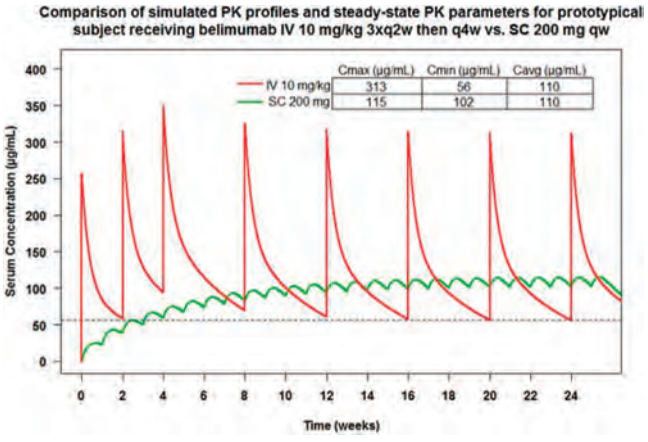
Predicted Chronic Exposure and Dose Selection for Belimumab Administered Subcutaneously to SLE Patients. Herbert Struemper[1], David Roth[2] and David Gordon[3]. [1]GlaxoSmithKline, Research Triangle Park, NC, [2]GlaxoSmithKline, Philadelphia, PA, [3]GlaxoSmithKline, King of Prussia, PA.

Background/Purpose: Monthly (q4w) intravenously (IV) administered belimumab 10 mg/kg is approved for the treatment of adults with active, autoantibody-positive SLE receiving standard therapy. The present analysis was conducted to predict a safe and efficacious weekly (qw) belimumab subcutaneous (SC) dose to be evaluated in a SC Phase 3 trial in adult SLE patients.

Methods: The belimumab IV Phase 3 clinical trials BLISS-52 and BLISS-76 indicated better efficacy with comparable safety for the 10 mg/kg versus the 1 mg/kg dose. A Phase 1 study (BEL114448: NCT#01583530) evaluated the pharmacokinetics (PK) of SC belimumab in healthy subjects as single or multiple doses up to 240 mg. IV and SC PK parameters were estimated using linear, 2-compartment PK models with NONMEM and Pharsight Phoenix modeling platforms, respectively, and chronic exposure profiles were simulated. The target steady-state SC exposure was set to an exposure level approximating the steady-state average belimumab serum concentration (Cavg) for 10 mg/kg IV q4w. Body-size dependent individual clearance values from the population PK analysis of the IV Phase 3 trials were used to predict the range of Cavg for the SC regimen.

Results: Simulation predicted that belimumab Cavg for 200 mg SC qw closely matched the corresponding Cavg for 10 mg/kg IV q4w. The simulated SC profile showed smaller fluctuations compared to the IV regimen, due to the slow absorption and more frequent dosing. At the end of the first month the trough concentration (Cmin) for 200 mg SC dosing is expected to exceed the steady-state Cmin for the 10 mg/kg IV regimen and therefore a loading dose was not deemed necessary.

The predicted body-size dependent steady-state Cavg values for the SC regimen, demonstrated that the Cavg ranges are similar between 10 m/kg IV q4w and 200 mg SC qw dosing. While for the IV regimen patients with large BMI experienced higher exposure, for the SC regimen higher weight patients are predicted to experience lower exposures.



Conclusion: 200 mg SC qw belimumab is predicted to result in a steady-state belimumab Cavg comparable to the Cavg for 10 mg/kg IV q4w dosing. The fixed SC dose is predicted to result in a similar range of Cavg values as compared to the weight-proportional 10 mg/kg IV dose, albeit with an inverse relationship between body size and exposure. This analysis supported the choice of the belimumab dose tested in the BLISS-SC Phase 3 trial.

Decreased Disease Activity and Corticosteroid Usage and No Renal Flares during Belimumab Treatment in Patients with Systemic Lupus Erythematosus. Ioannis Parodis[1], Elisabet Svenungsson[1], Magnus Axelsson[2] and Iva Gunnarsson[1]. [1]Department of Medicine, Rheumatology Unit, Karolinska Institutet, Stockholm, Sweden, [2]AlbaNova, Stockholm University, Stockholm, Sweden.

Background/Purpose: B cells have a central role in Systemic Lupus Erythematosus (SLE) and autoantibody production. B-Lymphocyte Stimulator (BLyS) is important for the activation and maintenance of B cells. Belimumab is a recombinant monoclonal antibody that specifically binds to soluble BLyS, and the only biologic agent approved for treatment of SLE. Its effects in patients with lupus nephritis (LN) are poorly known.

The aim of this study was to investigate the effects of belimumab given as an add-on to patients with active SLE despite standard-of-care therapy, with focus on patients with renal involvement.

Methods: Twenty-three patients (mean age 39.5 years) have been treated with belimumab at Karolinska University Hospital and have been included in this prospective observational study. Clinical data were acquired at baseline and at week 12, 26, 52 and 104. Disease activity was assessed using SLE Disease Activity Index 2000 (SLEDAI-2K) and Systemic Lupus Activity Measure (SLAM). C3 and C4 levels were determined by nephelometry. The predominant organ manifestations to motivate treatment with belimumab were mucocutaneous (n=14) and muskuloskeletal (n=14). Thirteen patients with history of LN, five of them having signs for nephritis and low-grade proteinuria, were included.

Results: At baseline, all but 2 patients received oral prednisolone (mean dose 9.1 mg/d, range 0–20 mg/d), 17 patients received antimalarials, 6 received azathioprine, 4 mycophenolate mofetil, 1 methotrexate, and 1 cyclosporine. The median SLEDAI and SLAM scores were 9 (range 2–24) and 12 (range 5–26), respectively.

Significant decreases of both SLEDAI-2K and SLAM were seen at week 12 ($p=0.018$ and $p=0.003$, respectively; n=18), 26 ($p=0.008$ and $p=0.002$, respectively; n=15), 52 ($p=0.003$ and $p=0.044$, respectively; n=12) and 104 ($p=0.042$ and $p=0.042$, respectively; n=5), as compared to baseline. Prednisolone dosages were significantly decreased compared to baseline at week 12 ($p=0.012$, n=18), 26 ($p=0.002$, n=16), 52 ($p=0.005$, n=12) and 104 ($p=0.043$, n=5). Eighteen patients had low complement at baseline. We observed no significant increases in C3 or C4 levels, with the exception of a significant increase of C4 levels at week 12 ($p=0.047$, n=18).

The patients with history of nephritis had at baseline a mean 24-h albuminuria of 0.25 g/d (range 0.01–1.16 g/d). No renal flare was observed during the study. The grade of proteinuria remained unchanged compared to baseline at all follow-up occasions.

One patient withdrew due to an allergic reaction. The treatment with belimumab was discontinued in 4 patients after 12 months follow-up due to inadequate or uncertain effect, and in 1 patient after 6 months follow-up due to plans for pregnancy. No severe adverse events were noted during the observation period. One male patient was diagnosed with prostate cancer (age at diagnosis 55 years) 15 months after discontinuation of belimumab.

Conclusion: Belimumab treatment decreased SLE disease activity and reduced corticosteroid usage. Despite the limited number of patients, our observations indicate that belimumab may prevent renal flares and may be used in patients with renal involvement and persistent low-grade proteinuria.

671

Belimumab Reduces the Frequency of Flares in Patients with Refractory SLE: DATA from Clinical Practice Setting. Andrea Doria[1], Luca Iaccarino[1], Silvano Bettio[1], Micol Frassi[2], Laura Andreoli[2], Rossella Reggia[2], Margherita Zen[1], Linda Nalotto[1], Mariele Gatto[1], Lara Pea[2], Leonardo Punzi[1] and Angela Tincani[2]. [1]University of Padova, Padova, Italy, [2]Rheumatology and Clinical Immunology, Spedali Civili and University of Brescia, Brescia, Italy.

Background/Purpose: To investigate the efficacy and safety of belimumab in patients affected with active systemic lupus erythematosus (SLE) refractory to standard therapy in the clinical practice setting.

Methods: Forty-one patients affected with active SLE (1997 ACR criteria), with low complement and high anti-double stranded DNA (dsDNA) antibody levels, unresponsive to corticosteroids, antimalarials and/or immunosuppressant were treated with belimumab (10 mg/kg at day 0, 14 and 28 and then every 28 days) for a median follow-up of 8.9 months (range 13.1–2.0). A total of 426 infusions of belimumab were performed. The median age of patients was 38.9 years (range 21–62) and mean disease duration 12.2 years (range 1–32). SLE Disease Activity Index 2000 (SLEDAI-2K), anti-dsDNA (tested by ELISA or Farr method), C3 and C4 serum levels, and corticosteroid daily dose were recorded at baseline and every 3 months thereafter. Disease flare was defined according to SLE flare index. Disease flare rate was evaluated in 23 patients prior and during treatment. Adverse events were carefully recorded at each clinical evaluation and were defined severe when hospitalization was required and/or death and/or life-threatening manifestations occurred.

Results: Refractory manifestations requiring belimumab were renal (41.4%), musculoskeletal (36.5%), mucocutaneous (36.5%), hematologic (21.9%), and serositic (4,8%). In the efficacy analysis we considered 34 patients followed for at least 6 months. Decrease in median SLEDAI-2K, anti-dsDNA, and corticosteroid daily dose and increase in C3 and C4 serum levels at baseline, 3, and 6 months of follow-up are reported in Table 1. Notably, a reduction in the frequency of flares was observed: 70 flare/100 patients in the 6 months before the start of belimumab and 18 flares/100 patients during the 6-month belimumab treatment ($p=0.02$).

Adverse events were analyzed in 23 patients. A total of 70 adverse events were obseved. Most frequent non infectious adverse events were fatigue (15%), hypertension (7%), and mild hair loss (5%). Infectious adverse events were 38 (54.2%), 34 were mild and 4 were moderate. Mild infusion reactions was observed in 2 patients (8.7%). No severe adverse events were observed.

Conclusion: These preliminary data confirm the efficacy and tolerability of belimumab in the treatment of patients with active SLE refractory to standard treatment in the clinical practice setting. Belimumab seem to reduce the number of disease flares and this suggest that it might be useful especially in those patients with relapsing remitting pattern of disease.

Table 1. SLEDAI-2K, anti-dsDNA antibody, C3, C4 and corticosteroid daily dose at baseline, 3, and 6 months of follow-up

	Baseline	3 months	P	6 months	P
SLEDAI-2K	8.9	5.4	0.002	5.9	0.004
Anti-dsDNA	459.8	142.6	0.001	140.4	0.003
- ELISA, KIU/L in 23 pts	76.0	37.3	n.s.	27.5	n.s
- Farr method, IU/mL in 18 pts					
C3 (g/l)	0.67	0.73	<0.0001	0.74	0.007
C4 (g/l)	0.11	0.14	<0.0001	0.18	<0.0001
Corticosteroid daily dose (mg/day)	12.1	8.2	0.015	6.0	<0.0001

Favorable Response to Belimumab in Pediatric-Onset Systemic Lupus Erythematosus. Joyce Hui-Yuen[1], Jennifer Taylor[1], Xiao Qing Li[1], Liza Mariel Bermudez[1], Josephine Isgro[1], Andrew H. Eichenfield[1], Amy J. Starr[1], Lisa F. Imundo[2], Jill P. Buyon[3], Richard Furie[4], Diane L. Kamen[5], Susan Manzi[6], Michelle Petri[7], Rosalind Ramsey-Goldman[8], Ronald van Vollenhoven[9], Daniel J. Wallace[10] and Anca Askanase[1]. [1]Columbia University Medical Center, New York, NY, [2]Pediatric and Adult Rheumatology Columbia University Medical Center, New York, NY, [3]New York University School of Medicine, New York, NY, [4]North Shore-LIJ Health System, Great Neck, NY, [5]Medical University of South Carolina, Charleston, SC, [6]Division of Rheumatology, University of Pittsburgh School of Medicine, Pittsburgh, PA, [7]Johns Hopkins University School of Medicine, Baltimore, MD, [8]Northwestern University and Feinberg School of Medicine, Chicago, IL, [9]Karolinska Institute, Stockholm, Sweden, [10]Cedars-Sinai Medical Center, Los Angeles, CA.

Background/Purpose: Belimumab (Benlysta) is a human monoclonal antibody that inhibits soluble B-lymphocyte stimulator. It was approved by the FDA in 2011 for treatment of active, autoantibody-positive, systemic lupus erythematosus (SLE) in adults. Patients with pediatric-onset SLE (pSLE) have more severe disease requiring more aggressive immunosuppression than adult SLE. To date, there have been no published data on the use of belimumab in pSLE.

Methods: Observational study of patients with SLE diagnosed before their 19thbirthday, and treated with belimumab, from 10 large academic centers. Data were collected on demographic and disease characteristics, clinical manifestations requiring treatment, concomitant medications, disease course, and treatment outcomes. The outcome was defined as the physician's impression of improvement in the initial manifestation(s) being treated without worsening in other organ systems. Chi-square and Student t-tests were used when appropriate.

Results: Of a cohort of 195 patients treated with belimumab, 38 patients had pSLE. The median age at diagnosis was 13.5 years old (range 4–18 years old); the median disease duration at initiation of belimumab was 12.5 years (range 2–43 years). Eighty-nine percent of the patients were female, 39% Black, 39% Caucasian, 11% Hispanic, 5% Asian. All patients were taking other background medications prior to initiation of belimumab (hydroxychloroquine 92%, prednisone 89% compared to 73% in the adult SLE patients, $p=0.005$, mycophenolate mofetil 47%, azathioprine 21%). The most common indications for initiation of therapy were inability to taper steroids (89%, mean prednisone equivalent dose 17.2mg/day compared to 27% in the adult SLE patients, $p<0.0001$), arthritis (61%), and rash (39%), accompanied by worsening serologic activity (increasing anti-dsDNA and hypocomplementemia). At 6 months, 71% of pSLE patients had responded clinically to belimumab compared to 48% of the entire patient population ($p=0.01$), and exhibited improvement in their laboratory abnormalities. Steroids were tapered in 63% of pSLE patients, and discontinued in 22%. Six months after initiation of belimumab, pSLE patients who responded clinically demonstrated an 86% decrease in anti-dsDNA ($p<0.0001$), 15% increase in C3 ($p=$NS), and 27% increase in C4 ($p=$NS). Of note, 100% of blacks with pSLE responded clinically ($p=0.0003$) with improvement in all serologic markers. Thirty-two of 38 pSLE patients tolerated infusions well, with only 6 patients discontinuing treatment.

Conclusion: This is the first study investigating the use of belimumab in pSLE. Our data demonstrate favorable clinical and laboratory outcomes across all ethnic groups: 71% of patients responded clinically within 6 months and steroids were tapered in 63% of our patients, suggesting a more important role for belimumab in pediatric-onset SLE.

A Comparison of Rheumatoid Arthritis and Systemic Lupus Erythematosus Trial Design: Ways to Improve Positive Trials in Systemic Lupus Erythematosus. Amy Miles[1] and Janet E. Pope[2]. [1]University of Western Ontario and U of Toronto, London, ON, [2]St Joseph Health Care, London, ON.

Background/Purpose: Recent SLE RCTs were examined and compared to rheumatoid arthritis (RA) RCT to suggest modifications to SLE RCTs that could improve the future success of SLE trials.

Methods: RA and SLE biologics RCTs published between 2005 and July 2013 were identified using PubMed. Inclusion criteria, study design, outcome measures, sample size calculations, baseline characteristics, steroid use and results were compared.

Results: Twenty-two RA RCTs and eight SLE RCTs were included. RA RCTs used composite scores (ACR response or DAS28). SLE RCTs used SLEDAI, BILAG, SLAM, SRI and BICLA. RA trials were larger (543 vs. 376 participants). RA measurements of response included patient reported outcomes, SLE trials did not. Concomitant corticosteroid use was stable in 100% of RA trials while all SLE RCTs allowed tapering. RA trials were mostly in methotrexate or DMARD inadequate responders whereas SLE trials allowed for the presence or absence immunosuppressives within all trials. Positive trials were found in 100% of RA RCTs and 25% of SLE RCTs. Table shows suggestions to improve SLE trials.

Conclusion: The potential insensitivity of SLE disease activity index (SLEDAI) to partial improvements may result in type II errors in SLE RCTs, whereas many BILAG flares were recorded with a significant number not considered as important flares by the physician (nonspecificity). Varying concomitant pharmacotherapy, especially corticosteroid use, in SLE may blunt observed treatment effects. Steroid dose must be accounted for within

SLE trials. Sample size calculations in SLE may be unrealistic in some SLE trials. Moving forward, clinical relevance in treatment could be considered by proportional responses similar to ACR20 such as in SLE inflammatory arthritis trials or per cent improvement for skin studies in SLE and/or time to improvement of active urinary sediment in nephritis studies and/or reduction of steroids. SLE trial experts may need to reassess what outcomes and what minimal degree of change should be necessary to consider a treatment effective.

Suggestions of Outcomes in SLE trials: Points to Consider

Organ specific trials in SLE

Inflammatory arthritis	If arthritis is being studied, the SJC and TJC should be the primary outcome and patients with fibromyalgia may need to be excluded.
Rash	If rash is the being studied, MD and patient global assessment of SLE rash and the CLASI (Cutaneous Lupus Erythematosus Disease Area and Severity Index) may be considered as outcomes.
Renal	In renal SLE, head to head comparisons of standard of care vs. the new treatment or add on to standard of care can be done with active urinary sediment (red blood cell [RBC] casts, total protein/day) and creatinine as the outcomes as well as time to normalizing urinary sediment. WBCs in the urine are not part of lupus nephritis and should not be included as an outcome (unless interstitial nephritis is being studied).
	Likewise, urinary RBCs may not be due to lupus nephritis.
	Many patients will do well on standard of care treatment so longer outcomes such as creatiniine, 24hr proteinuria at one and two years may be needed .
	Time to achieving a certain renal outcome, steroid sparing effect and safety may be the important outcomes.
Flares as an outcome	Flares in SLE patients within trials are frequent and a minimally important flare should be defined as relevant to the drug under study. A flare may need different defintions with a sensitivity analysis – such as MD reported major flare, a major increase in prednisone or a change in SLEDAI by at least 2 or 4 points.
Steroid sparing effects of treatment	A primary outcome could be a steroid sparing effect of a drug where steroids are not strictly mandated in their use and tapering but a suggested protocol of steroid tapering is given and only those with a certain minimum dose of steroids are allowed into the trial.
Head to head trial with active new comparator	The speed of improvement, ability to taper steroids and/or safety may be the primary outcomes or a non-inferiority design.

A Novel Strategy to Identify and Evaluate Approved Drugs and Treatments for Repositioning As Therapies for Systemic Lupus Erythematosus (SLE). Peter E. Lipsky, Matthew Ryals, Jacob Smearman, Victoria Soler and Amrie Grammer. AMPEL BioSolutions, Charlottesville, VA.

Background/Purpose: Development of new SLE treatments has been slow with only one new treatment approved in the past half century. One way to increase the availability of new therapies for SLE is to consider repositioning agents that have been approved for other indications. The goal of this project was to identify possible therapies that might be useful as therapies for lupus among the hundreds of agents approved for human use.

Methods: Initially, a comprehensive strategy was developed to identify all possible SLE therapies within FDA approved drugs and therapies. First, the lupus community was engaged via a social media site (www.linkedin.com/in/lrxlstat) and queried for recommendations. Secondly, the reported actions of all drugs approved for human used were cross-referenced with a database of known pathway abnormalities in SLE. Finally a comprehensive search of all drugs and therapies showing benefit in murine models of SLE was carried out. After the initial Lupus Treatment List (LRxL) was assembled, a structured research of the available literature on each drug and therapy was carried out focusing on mechanism of action, relevant experience in animals and humans, drug properties and adverse events. Finally, a comprehensive scoring system was developed and employed to score ten features of each drug or therapy on a 28 point scale. Face validity of this scoring system was assessed by ranking available lupus therapies and questioning rheumatologists for their response.

Results: Of the more than 1100 new chemical entities approved by the FDA for 6800 indications, 157 were identified as possible treatments for SLE. All drugs widely used for lupus or known to be in development for lupus by Pharma/Biotech were excluded. Of the 157 therapies initially screened, more than 25 have an appropriate set of characteristics to consider for testing in clinical trials in lupus, including drugs targeting cellular metabolism, kinases, cytokines, immune cell function and regulation, HDACs, complement as well as cellular therapies & non-drug/cell interventions.

Conclusion: This approach has demonstrated that there are numerous FDA-approved candidates for repositioning as new therapies for SLE. Not only have unique treatments that could be useful in SLE and possibly other autoimmune/inflammatory conditions been identified, but a rigorous evidence-based process has been delineated by which therapies can be objectively rated for possible clinical application to treat these conditions, thereby miti

Use of Rituximab in Systemic Lupus Erythematosus: A Single Center Experience. Renata Aguiar[1], Ana Carolina Araújo[2], Ana Luisa Papoila[3], Marta Alves[4] and David Isenberg[5]. [1]Centro Hospitalar do Baixo Vouga, E.P.E., Aveiro, Portugal, [2]Hospital de Curry Cabral, Centro Hospitalar Lisboa Central, Lisbon, Portugal, [3]Centro Hospitalar Lisboa Central, Lisbon, Portugal, [4]Centro Hospitalar Lisboa Central, Lisboa, Portugal, [5]Centre for Rheumatology Research, University College Hospital London, London, United Kingdom.

Background/Purpose: Rituximab (RTX), an anti-CD20 chimerical monoclonal antibody, has been used as an off-label in patients with systemic lupus erythematosus (SLE) refractory to standard treatment. Although some small, open label and retrospective studies suggest that RTX might be beneficial in SLE treatment, the two randomized controlled trials of RTX in SLE did not meet the primary endpoints.

The purpose of this work was to assess clinical efficacy and safety of RTX in a cohort of SLE patients treated at a single centre for a long period.

Methods: The authors undertook a retrospective in-depth analysis of all patients (>100) with SLE treated with RTX at a single center between June 2000 and December 2013 and followed for upto 14 years. Data collected included BILAG scores AT and 6, 12, 18 and 24 months after, RTX treatment; anti dsDNA antibody and C3 levels before and 6 months after RTX infusions; adverse events, including allergic/anaphylactic reactions, hypogammaglobulinemia, infections, cardiovascular and cerebrovascular events, and death.

Statistical analysis was performed using Wilcoxon and McNemar non-parametric tests.

Results: A total of 115 patients were reviewed; 93.9% female; 43.5% were Caucasian, 32.2% African and 17.4% South Asian; mean age at diagnosis was 26.39±11.90 years and mean disease duration at first RTX treatment was 91.96±84.80 months. The most frequent indications for RTX treatment were refractory musculoskeletal, renal and mucocutaneous involvement. Mean BILAG score before first RTX treatment was 18.29±10.62; after 6 months, 40% of patients had a complete response (loss of all A's and B′s and no new A's or B's) and 27% had a partial response (partial loss of some but not all A's or B's, no new ones.). At 6 months, there was a significant reduction in the BILAG score ($p<0.001$). Also, 6 months after the first treatment, 36,5% of patients had an increase in C3 levels of 25% and 33.5% had a decrease of over 50% from anti dsDNA antibody baseline level. Depletion of CD19+ cells was successfully achieved in 94% of patients. Hypogammaglobulinemia was detected in 14.9%, however, this reduction was only significant for IgM ($p<0.001$) and IgG ($p=0.001$); severe infections, infusion-related and hypersensitivity reactions occurred in 7%, 3.5% and 2.6% of patients, respectively. Of the 115 patients initially treated with RTX, 62 patients had further RTX treatments, maximum of 6, with an average number of 1.95±1.17 cycles per patient and a mean interval between infusions of 21.44±20.11 months. The reason that led to the second RTX treatment was different from the reason leading to the first one in 16 patients, and 25 of the 40 patients who had had partial or complete response at first administration remained partial or complete responders.

At the end of follow-up, 11 patients had died and 6 had cardiovascular events (2 deaths).

Conclusion: In this cohort, RTX treatment was effective in decreasing disease activity and had low incidence of adverse effects.

Background/Purpose: Published efficacy data for rituximab in SLE are complex with positive single-centre case series and negative randomised controlled trials. This may be due to heterogeneity of SLE or the populations, design and endpoints of trials. The BILAG Biologic Registry (BILAG BR) is a national, multicentre, prospective study of safety and efficacy of biologics in SLE patients refractory to standard immunosuppressive therapy. The objective of the present analysis was to describe clinical response to rituximab at three and six-months post therapy.

Methods: Patients with SLE (≥ 4 ACR 1997 criteria), ≥ 5 years old, refractory to conventional therapy and newly starting treatment with rituximab, from centres across the UK, were recruited into the BILAG BR. A comprehensive questionnaire collected information on concomitant medications, risk factors for infection, co-morbidities and SLE disease duration. Disease activity was measured using the BILAG 2004 Index and the SLEDAI2K at treatment initiation, 3 and 6 months post therapy.

Results: Baseline, 3 and 6 month disease activity were collected for 80 patients (92.5% women) starting therapy with rituximab. The cohort included 44 (60.3%) white British patients. The median (interquartile range [IQR]) age and disease duration at baseline were 39.5 years (IQR 30.0, 47.3) and 5.7 years (IQR 2.5, 11.6) respectively. The most commonly involved BILAG 2004 index systems were mucocutaneous (33 [41.25%]), renal (28 [35.0%]) and musculoskeletal (25 [31.0%]). The baseline SLEDAI2K was 8 (IQR 4, 13.5). At 3 months follow-up, 47 (58.75%) patients showed an improvement in their overall BILAG 2004 index, 16 (20.0%) had persisting active disease and 12 (15.0%) had deteriorating disease. The majority of patients (11/12 [91.7%]) who deteriorated, did so in one system only. In the same follow-up period, 56 (70.0%) had an improved SLEDAI2K, 15 (18.75%) had no change and 9 (11.25%) worsened. Data at 6 months showed 39 (48.75%) with improvement, 18 (22.5%) with persistent disease and 16 (20.0%) deteriorating. In addition, there was a trend towards steroid dose being reduced over the 6 month period (Table 1).

Conclusion: There was variability in the degree of response to rituximab with respect to both the magnitude and duration of response, in this cohort of SLE patients refractory to standard immunosuppression. Although nearly half of the cohort demonstrated significant reduction in disease activity across all systems at 6 months, there was a sub-group that worsened in either the original system involved, or developed activity in a new system. This may be explained some patients who initially responded to rituximab at 3 months, beginning to flare by 6 months post therapy. Further analysis will attempt to identify predictors of response in this cohort.

Pharmacokinetics, Safety, and Biological Activity of Intravenously or Subcutaneously Administered Tabalumab in Subjects with Rheumatoid Arthritis or Systemic Lupus Erythematosus. Jennifer Witcher[1], Ryan Hansen[1], Leijun Hu[1], David Radtke[1], James Voelker[1] and Juliet McColm[2]. [1]Eli Lilly and Company, Indianapolis, IN, [2]Eli Lilly and Company, Windlesham, United Kingdom.

Background/Purpose: B-cell activating factor (BAFF) promotes B-cell survival and maturation, and increased serum levels are associated with autoimmune disease and disease activity in systemic lupus erythematosus (SLE). Tabalumab is a human anti-BAFF monoclonal antibody that neutralizes both soluble and membrane-bound BAFF. The objectives of 2 Phase 1 studies were to evaluate the pharmacokinetics (PK), safety, and biological activity of tabalumab administered intravenously (IV) or subcutaneously (SC) in subjects with rheumatoid arthritis (RA) or SLE.

Methods: In Study A, subjects with stable RA (n=23) received a single dose of tabalumab ranging from 0.01 to 8.0 mg/kg (0.01, 0.04, 0.125, 0.5, 2.0, and 8.0 mg/kg) or placebo, and subjects with stable SLE (n=6) received 1 of 2 tabalumab doses (0.125 or 2.0 mg/kg) or placebo by IV infusion. In Study B, subjects with RA received a single tabalumab dose SC (20 mg) (n=12) or IV (10 mg infused over 30 min) (n=12). Serum tabalumab and peripheral CD20+ B-lymphocyte levels were evaluated for 36 weeks in Study A and 12 weeks in Study B with optional follow up to monitor B-lymphocyte recovery, if required. Safety was assessed throughout both studies.

Results: Tabalumab PK were nonlinear across the 0.01 to 8.0 mg/kg dose range (Figure A), with a slower clearance (CL) and longer half-life ($t_{1/2}$) at higher doses. The CL decreased from 2.9 to 0.1 L/day over the dose range, resulting in greater than dose-proportional increases in exposure. The terminal $t_{1/2}$ increased from 1.6 to 25 days over the dose range. PK parameters were similar between RA and SLE subjects. SC dosing had a slow absorption phase with time to maximal concentration (t_{max}) of approximately 5.5 days. The estimated bioavailability (F) for the 20-mg SC dose was 62%. Single-dose tabalumab was well tolerated, and the majority of treatment-emergent adverse events (TEAEs) were mild to moderate in severity in both studies. The rate of TEAEs was similar for IV and SC groups in Study B. TEAEs considered related to study drug included headache (n=1), back pain (n=1), dry mouth (n=1), dysgeusia (n=1) dysphagia (n=1), and nausea (n=3) in study A, and injection-site pain (n=1) and flushing (n=1) in the 20-mg SC group in Study B. In general, a tabalumab-dependent transient increase from baseline in CD20+ B lymphocytes followed by a progressive decrease below baseline levels was observed in both studies, with the decrease being significant (P<0.05; overall F-test) for the 2-mg/kg and 8-mg/kg doses. No increases in anti-tabalumab antibodies were detected post-treatment.

Conclusion: A single tabalumab dose administered IV or SC was well tolerated and had non-linear CL over the dose range investigated in subjects with RA and SLE. The non-linearity likely reflects target-mediated CL due to binding to BAFF. Tabalumab showed biological activity based on changes in peripheral CD20+ lymphocyte numbers in both subjects with RA and SLE.

Figure

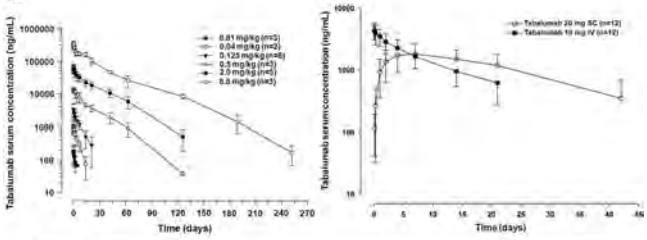

Figure legend: Tabalumab arithmetic mean (±SD) serum concentration-time profiles following a (A) single IV dose of tabalumab in subjects with stable RA or SLE (Study A) (data represent the combined data of RA and SLE groups, n=27) or (B) single IV (n=12) or SC (n=12) dose of tabalumab in subjects with RA (Study B)

The Effectiveness of Tacrolimus for Minor Flares of the Patients with Systemic Lupus Erythematosus. Haruki Watanabe[1], Ryutaro Yamanaka[2], Ken-ei Sada[1], Eri Katsuyama[1], Takayuki Katsuyama[1], Mariko Narazaki[1], Noriko Tatebe[1], Koichi Sugiyama[1], Katsue S. Watanabe[1], Hiroshi Wakabayashi[1], Tomoko Kawabata[1], Jun Wada[1] and Hirofumi Makino[1]. [1]Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama, Japan, [2]Himeji Red Cross Hospital, Himeji, Japan.

Background/Purpose: Although effectiveness of tacrolimus (TAC) for remission induction or maintenance treatment of patients with lupus nephritis has been reported, there are few reports about its efficacy for the flares of patients with systemic lupus erythematosus (SLE).

Methods: Medical records of 313 outpatients with SLE who fulfilled the revised ACR criteria in Okayama university hospital visited from 2006 to 2013 were assessed retrospectively. We recruited the patients treated with add-on TAC without the intensification of glucocorticoids (GC) for the minor flares (TAC group). The minor flare was defined as an increase of SLE disease activity index (SLEDAI) ranged from 3 to 11 in the patients maintained remission for over 3 months within 10 mg/day of predonisolone and/or immunosuppressants except calcineurin inhibitors. As controls, we also recruited the patients administered with the increased doses of GC for minor flares (GC group). We collected clinical and laboratory data at baseline, 1 month, 3 months, 6 months, and 12 months. We defined responders as the patients whose SLEDAI was improved to the level before the flares within 1 year. We also evaluated the development of the second flare in the responders. The second flare was defined as the reinforcement with other immunosuppressants or higher doses of GC.

Results: There were 14 eligible patients in the TAC group and 20 eligible patients in the GC group. Although SLEDAI at the flare was higher in the TAC group than the GC group (8.2 vs. 6.2, p<0.05), other baseline characteristics (sex, age, serological markers, and the dose of GC) were comparable between the two groups. The initial dose of TAC for the flare was 1.6 mg/day in the TAC group, while the dose of GC for the flare was 13.7 mg/day in the GC group. The proportion of responders was 79% in the TAC group and 75% in the GC group (p=0.92). In the responders, 2 of 11 (18%) patients in the TAC group and 4 of 16 (25%) patients in the GC group developed the second flare (p=0.68). The dose of GC was higher in the GC group than in the TAC group at 12 months (9.7 mg/day vs. 7.1 mg/day, p<0.05). Only 1 patient withdrew TAC because of fatigue after three months.

Conclusion: Adding TAC without increased dose of glucocorticoids may be an effective treatment option for minor flares of patients with SLE.

Hydroxychloroquine Dosing and Disease Activity in a Large Multi-Racial Lupus Cohort. Jennifer M. Grossman[1], Megan E. B. Clowse[2], Peter M. Izmirly[3], Diane L. Kamen[4], Alana B. Levine[5], Meggan Mackey[6], W. Joseph McCune[7], Jerry McGwin[8], David S. Pisetsky[2], Tammy Utset[9] and Jinoos Yazdany[10]. [1]UCLA David Geffen School of Medicine, Los Angeles, CA, [2]Duke University Medical Center, Durham, NC, [3]New York University School of Medicine, New York, NY, [4]Medical University of South Carolina, Charleston, SC, [5]Hospital for Special Surgery, New York, NY, [6]The Feinstein Institute, Mahasset, NY, [7]University of Michigan, Ann Arbor, MI, [8]UAB, Birmingham, AL, [9]UC Pritzker Schl of Medicine, Chicago, IL, [10]University of California, San Francisco, San Francisco, CA.

Background/Purpose: Treatment with hydroxychloroquine (HCQ) is recommended for all patients with lupus nephritis to prevent further damage and reduce disease manifestations. Some studies suggest that drug levels may be important in medication efficacy. In view of reports of an increased risk of ocular toxicity with HCQ, however, the American Academy of Ophthalmology (AAO) recommends more stringent screening for damage as well as changes in dosing. Specifically, the AAO recommends dosing by ideal and not actual weight, which would decrease the dose of HCQ for many patients. To assess the impact of these dosing recommendations, we explored the patterns of HCQ use in a large patient cohort and the effect of dose levels on the trajectory of disease activity. For this purpose, we analyzed data from the Lupus Clinical Trials Consortium, Inc. (LCTC) Lupus Data Registry, a prospective registry of 1506 patients with SLE from 16 lupus centers in the US and Canada.

Methods: Patients were consecutively enrolled into the Registry and followed at outpatient visits by participating rheumatologists. Medication use, disease activity, and patient global assessment were recorded at each visit. Baseline dose of HCQ was recorded as mg per kg and was analyzed as <4 mg/kg, 4–4.99 mg/kg, 5–5.99 mg/kg and

≥6 mg/kg, with approximately 25% of the cohort falling into each dose group. Associations between HCQ use, disease activity, and patient global assessments were evaluated.

Results: At the baseline visit, 1058 of the 1506 subjects (70.3%) were on HCQ. 80% of patients were on 400 mg daily, 15% on 200 mg daily with the mean dose 5.1 mg/kg. In the 400 mg group, the mean dose was 5.4 mg/kg while the mean dose in the 200 mg group was 3.2 mg/kg. 18% of all the patients on HCQ were on more than 6.5 mg/kg. There were no significant differences in change in disease activity among any of the different mg/kg groups compared to those not on HCQ even when adjusting for baseline disease activity or only evaluating those patients with a SLEDAI of ≥4. The dose of HCQ in mg/kg was not associated with flare risk using the SELENA-SLEDAI flare instrument. When evaluating patient global assessment of their worst score versus their baseline, those patients in the highest ≥6 mg/kg group had the smallest change in patient global assessment (p=0.02) compared to those not using HCQ suggesting better symptom control (table 1).

Conclusion: In this large observational cohort, there is significant variation in prescribed mg/kg dosing of HCQ. For patients on prevalent HCQ before the start of the study, the mg/kg dosing based on actual weight does not appear to impact the incidence of flare as measured by the SELENA flare instrument or overall SLE activity as measured by SLEDAI. Together, these results suggest efficacy with HCQ occurs with various drug dosing regimens although there is some indication for a greater subjective benefit at the higher dose range.

	No HCQ	HCQ <4 mg/kg	HCQ 4–4.99 mg/kg	HCQ 5–5.99 mg/kg	HCQ 6+ mg/kg
Any flare	59%	49%	57%	57%	58%
Severe flare	15%	10%	12%	18%	13%
Any flare in HCQ 400 mg		48%	56%	58%	58%
Severe flare in HCQ 400 mg		9%	11%	18%	18%
Decline in physician global worst-baseline	0.4	0.3	0.4	0.4	0.4
Decline in patient global worst-baseline	20	20	20	18	14

Influence of Antimalarial doesn′t Modify the Outcome of Cytopenias in Systemic Lupus Erythematosus. Eugenia Enriquez Merayo[1], Maria Galindo Izquierdo[2], Esther Rodriguez-Almaraz[3], Maria Martin Lopez[2], Otto Martin Olivas Vergara[2], Patricia E. Carreira[4] and Isabel Mateo[5]. [1]12 DE OCTUBRE, MADRID, Spain, [2]HOSPITAL 12 DE OCTUBRE, MADRID, Spain, [3]Department of Rheumatology. Hospital Universitario 12 de Octubre, Madrid, Spain, [4]Rheumatology Department. Hospital Universitario 12 de Octubre, Madrid, Spain, [5]Servicio De Reumatología, Hospital 12 De Octubre, Madrid, Spain.

Background/Purpose: To analyze the effect of antimalarials (AM) as preventive factor for the development of severe cytopenias and in their outcome after treatment in a large series of patients with systemic lupus erythematosus (SLE).

Methods: 253 SLE patients followed in rheumatology department (12 de Octubre hospital) between 1976–2014 were included. Demographic, clinical data and patients outcome were obtained from pre-existing databases and from the charts. SLE related cytopenias were defined as: autoimmune haemolytic anemia (AHA): hematocryt<35%, reticulocytes >5% or spherocytosis in peripheral blood smear; leukopenia:WBC<4000x106/l; neutropenia: neutrophils<1000x106/l; thrombocytopenia (TP):moderate 50–100x109/l and severe <50x109/l. The associations between categorical variables were tested using the chi-square or Fisher's exact test, where appropriate. The odds ratios with the corresponding 95% CIs were calculated. For continuous variables, the comparisons were carried out using the t-test for two independent samples. P-values<0.05 were considered significant. The analysis was performed using advanced SPSS software version 11.

Results: 253 patients were included (91.3% women), with a mean age at SLE onset of 30 ± 13 years. Globally, 74.3% of patients developed hematological involvement (HI): 37.2% TP(21% moderate, 21% severe); 26.1% AHA, 75% leukopenia, 68% lymphopenia and 11.2% neutropenia. Evans syndrome was present in 13 patients and secondary antiphospholipid syndrome (APS) was diagnosed in 19.4%. Among patients with severe haematological disease, aggressive treatments (bolus of methylprednisolone, cyclophosphamide, rituximab, intravenous immunoglobulin or esplenectomy) were needed in 9% of patients with TP and in 18% of AHA. Only 20% of the patients had received AM prior to the developement of HI. In 5.5% of cases life-threatening complications appeared because of HI. Relapses occurred in TP (9,1%) and in AHA (2.8%). In 3 cases of neutropenia colony stimulating factor was needed, all relapsed cases. TP was significantly associated with having positive aDNA (p0.035), antiB2GP1IgG, lupus anticoagulant AL +, with APS and venous thrombosis secondary to APS (all p<0.01). AHA was associated with malar rash and discoid lupus, and AL+, ACL IgG +, antiB2GP1IgG and IgM (all p<0,05) but not with APS. AHA was associated with exitus as a result of hematologic involvement (p0,039). Neutropenia was associated with arthritis (p 0.024). Hypocomplementemia (C3, C4) was associated with TP, AHA (all p<0.05) Treatment with hydroxychloroquine was associated with a tendency of complete response to therapy in AHA and a partial response in TP.

Conclusion: Up to 41% of patients had some kind of severe cytopenia. Only AHA was associated with increased mortality from this cause. All cytopenias were associated with hypocomplementemia except neutropenia. AM treatment tended with favorable therapeutic response in AHA and thrombocytopenia. In our series, treatment with antimalarial drugs not proved to be a protective factor for developing severe cytopenias LES related neither for prevent severe complications or to prevent recurrences, although further studies are needed.

Hydroxychloroquine Use Is Associated Independently with Improved Quality of Life in Systemic Lupus Erythematosus. Meenakshi Jolly[1], Winston Sequeira[2], Sarfraz Hasni[3], Zulfiqar Ali[4], Sergio Toloza[5], Ana M. Bertoli[6], Ivana Blazevic[7], Luis M. Vila[8], Ioana Moldovan[9], Karina D Torralba[10], Berna Goker[11], Josiane Bourré-Tessier[12], S. Navarra[13], Daniel Wallace[14], Michael H. Weisman[15], Ann E. Clarke[16] and Chi Chiu Mok[17]. [1]Rush University Medical Center, Chicago, IL, [2]Rush University, Chicago, IL, [3]NIH, BETHESDA, MD, [4]NIH, Bethesda, MD, [5]Hospital San Juan Bautista, San Fernando del Valle de Catamarca, Argentina, [6]Instituto Reumatológico Strusberg, Cordoba, Cordoba, Argentina, [7]University of Buenos Aires, Buenos Aries, Argentina, [8]University of Puerto Rico Medical Sciences Campus, San Juan, PR, [9]Beaver Medical Group, Redlands, CA, [10]University of Southern California, LA, CA, [11]Gazi University School of Medicine, Ankara, Turkey, [12]Division of Rheumatology, Centre Hospitalier de l'Université de Montréal, Montreal, QC, [13]University of Santo Tomas Hospital, Manila, Philippines, [14]UCLA, LA, CA, [15]Cedars-Sinai Medical Center, Los Angeles, CA, [16]University of Calgary, Calgary, AB, [17]Tuen Mun Hospital, Hong Kong, Hong Kong.

Background/Purpose: Hydroxychloroquine (HCQ) has been shown to be beneficial to patients with Systemic Lupus Erythematosus (SLE), however, its effects on the quality of life (QOL) of patients with SLE has not been evaluated. Interestingly, there is not a clear concordance between pharmacological amelioration of visceral organ damage in SLE and QOL, as reported by patients themselves. LupusPRO is a disease targeted QOL tool that is well validated in English and various other languages, and has two construct: health related quality of life (HRQOL) and non-HRQOL. Here, we test the hypothesis that treatment with HCQ has a beneficial effect on QOL as well as organ function in patients with SLE.

Methods: Cross sectional data from 1,037 SLE patients (USA, Canada, Argentina, Mexico, Philippines, Turkey, and China) was accumulated, after obtaining informed consent and IRB approval. Age, gender, LupusPRO scores, disease activity, and disease damage were analyzed. Disease activity was measured by SLEDAI (physician global assessment and Total), while damage was assessed using SLICC-ACR/SDI. We compared the QOL on the LupusPRO domains using nonparametric independent sample t tests, using two sided p values of ≤ 0.05 as significant. T tests were also used to compare disease activity and disease damage in patients where the data were available. Multivariate linear regression analysis for satisfaction with treatment domain of LupusPRO was performed as the dependent variable, and HCQ use, age, gender, disease activity (SLEDAI), damage (SLICC-ACR/SDI) and current steroid use as independent variables.

Results: 1,037 SLE patients (727 HCQ users and 310 non-HCQ users) data were analyzed. HCQ users and non-users were similar in age and gender (Mean age (SD) 40.1 (13.0 vs. 42.5 (12.9) yrs). SLICC-ACR/SDI was lower, while non-HRQOL was higher among HCQ users as compared to non-HCQ users (Table 1). Specifically non-HRQOL domain of satisfaction with treatment was significantly better among HCQ users than non-HCQ users. On multivariate analysis, HCQ use remained an independent predictor of satisfaction with treatment (non HRQOL LupusPRO domain), even after adjusting for age, gender, disease activity, damage and current steroid use.

Conclusion: Hydroxychloroquine use in SLE has clearly beneficial effects on QOL. This is in addition to the well-recognized ameliorative effects on cumulative damage. The QOL improvement appears to be related to non-HRQOL (satisfaction with treatment) independently. Longitudinal studies with disease targeted QOL tools with use of HCQ are indicated.

	HCQ (n=310)	No HCQ (n=727)	P value

Impact of Patient's Priorities on the Management of Systemic Lupus Erythematosus. Valérie Leclair[1], Holly O. Witteman[2], Carolyn Neville[3], Isabelle Fortin[4] and Paul R. Fortin[5]. [1]Laval University, Department of Internal Medicine, Quebec City, QC, [2]Laval University, Family and Emergency Medicine, Quebec City, QC, [3]Division of Clinical Epidemiology, Department of Medicine, McGill University Health Centre, Canada, Montreal, QC, [4]Centre de Rhumatologie de l'Est du Québec, Rimouski, QC, [5]Laval University, Division of Rheumatology, Centre de Recherche du CHU de Québec and Department of Medicine, Quebec City, QC.

Background/Purpose: Systemic Lupus Erythematosus (SLE) greatly reduces the quality of life (QoL) and satisfaction with life of affected patients. SLE patients can have numerous unmet needs and may feel misunderstood by their health care providers. The aim of this study was to explore what is important to SLE patients when it comes to their care.

Methods: Participants were adults satisfying the ACR classification for SLE, and were recruited by phone, letter or directly by their respective rheumatologist. A qualitative approach based on audio-recorded focus groups was used to collect data. Interview guides were prepared prior to the meetings by an expert panel including: a resident in internal medicine, a psychologist, a rheumatologist, and nurse. The open-ended questions covered SLE patient priorities, their means of conveying these priorities to their medical team, and the impact of these priorities on their disease management. The transcriptions were independently coded by 2 analysts using 2 techniques: 1) a qualitative data analysis software (NVivo 10) and 2) manual analysis. The analytic approach was based on grounded theory.

Results: Nineteen female participants attended 3 focus groups in 2 sites (university and community-based). Participants' ages ranged from 18 to >70 with the majority between 30 and 59 years of age. The average disease duration was 8.8 ± 7,7 years, ranging from 1 to 23 years. 68% were married/or cohabitating with a partner and 63% were employed. Five priorities (Figure 1) were identified: 1) management of disability, in particular, loss of energy that prevents full engagement in daily activities, relationships, and social roles; 2) management of the unpredictable nature of SLE including, preventing flares and worsening of their condition, employment and financial issues associated with chronicity; 3) management of side effects; 4) access to information about lupus and support resources, in particular, support groups; 5) access to health care (improved communication between physicians, shorter wait times and longer consultations with physicians).

Conclusion: SLE patients have multiple complex priorities and may have difficulty articulating them. Health care providers need to develop strategies and communication tools to help SLE patients identify their priorities and support them in the self-management of their disease.

Impact of Lupus on Work Productivity in Patients and Caregivers: Findings from a Cross-Sectional Online Survey in the United States. Sarah Al Sawah[1], R Paola Daly[2], Shonda Foster[1], April Naegeli[1], Katy Benjamin[3], Helen Doll[3], Greg Bond[3], Olga Moshkovich[3] and Graciela Alarcón[4]. [1]Eli Lilly and Company, Indianapolis, IN, [2]Lupus Foundation of America, Inc., Washington, DC, [3]ICON PRO, Bethesda, MD, [4]University of Alabama Birmingham, Birmingham, AL.

Background/Purpose: Lupus imposes a substantial burden on patients' work productivity[1]; however, little is known about its impact on the work productivity of those caring for individuals with lupus. In this study, we examined the impact of lupus on work productivity in a sample of patients with lupus and caregivers.

Methods: An online cross-sectional survey of English-speaking respondents aged ≥18 years with 1) self-reported diagnosis of lupus or 2) self-reported caregivers of individuals with lupus was conducted across the US in partnership with the Lupus Foundation of America between February and March 2014. Demographic and clinical information, as well as other self-reported measures, including the work productivity and activity index (WPAI), were collected. The WPAI is a 6-item, 4-domain questionnaire that measures respondents' levels of impairment in work and general activities over the past 7 days. [1]The four domains are: 1) absenteeism—time missed from work; 2) presenteeism—impairment of productivity while at work; 3) overall loss of work productivity—combination of absenteeism and presenteeism domains; and 4) activity impairment—impairment in activities of daily living outside of work. The responses for each of the four domains are expressed as impairment percentages, with higher numbers indicating greater impairment and reduced productivity.

Results: A total of 827 patients with lupus and 253 caregivers completed the survey. Almost all patients (97.5%) were females; 49.2% of all patient respondents reporting being employed, with 30.7% of them working part time. Around half of the caregivers (54.2%) were males; 68.8% of all caregiver respondents reported being employed, with 14.4% of them working part time. Patients who were employed missed an average of 16.6% of paid work time because of lupus, reported an almost 46.4% reduction in on-the-job effectiveness and a 36.6% impairment in overall work productivity. Caregivers who were employed missed an average of 12.8% of paid work time because of caregiving responsibilities, reported a 33.5% reduction in on-the-job effectiveness and a 27.4% impairment in overall work productivity. Overall, for those who were employed, there was no substantial difference between the number of hours missed from work during the past 7 days because of lupus 6.3 hours and the number of hours missed from work during the past 7 days because of taking care of an individual with lupus 5.2 hours. Overall, all patients reported an average of 64.8% of impairment in activities outside of work, whereas an average of 46.7% was reported by caregivers.

Conclusion: Lupus has a substantial impact on work productivity for not only patients, but also for caregivers. Understanding the extent to which lupus

impacts caregivers and patients will help healthcare professionals and policymakers expand their outreach to consider the well-being of caregivers.

Effects of Current Therapies for Lupus on Disease Activity and Renal Flares. Kenneth C. Kalunian[1], Jill P. Buyon[2], Cynthia Aranow[3], Mary Anne Dooley[4], Richard A. Furie[5], Ellen M. Ginzler[6], R. John Looney[7], Joan T. Merrill[8], Jerry McGwin[9] and Bevra H. Hahn[10]. [1]UCSD School of Medicine, La Jolla, CA, [2]New York University School of Medicine, New York, NY, [3]The Feinstein Institute, Manhasset, NY, [4]University of North Carolina at Chapel Hill, Chapel Hill, NC, [5]North Shore - Long Island Jewish Health System, Great Neck, NY, [6]SUNY-Downstate Medical Center, Brooklyn, NY, [7]University of Rochester, Rochester, NY, [8]Department of Clinical Pharmacology, Oklahoma Medical Research Foundation, Oklahoma City, OK, [9]UAB, Birmingham, AL, [10]UCLA David Geffen School of Medicine, Los Angeles, CA.

Background/Purpose: A paucity of data exists that delineates the effect of current medications for lupus on disease activity and the propensity for renal flares in these patients.

Methods: Data from a registry of SLE patients collected from 16 medical centers in the US and Canada in which patients are seen regularly to evaluate the association between specific medications and the incidence of renal flares over an average of 1.8 years of observation. The percentage of patients with low levels of disease activity (SLEDAI ≤ 4) at entry who maintained these same levels of low disease activity was calculated, as was the percentage of patients who entered at higher levels of disease activity (SELENA SLEDAI >4) but became inactive at 6 months and remained at that low level of disease activity during follow-up.

Results: Of the 1299 patients with any follow-up, 103 subjects were taking Azathioprine plus Hydroxychloroquine (AZA+HCQ), 312 were on Mycophenolate Mofetil (MMF) plus HCQ, 111 were on MMF alone, 502 were on HCQ without other immunosuppressant drugs and 271 were on none of these medications. Six-hundred and eleven had a history of renal disease at study entry; mean Prednisone dose did not significantly differ between the five medication groups and the SLEDAI score was significantly lower in the HCQ alone group. The incidence of renal flares ranged from 14%-37% with the lowest incidence in the HCQ group, but no statistically significant differences were noted. The incidence of severe renal flares varied from 7%-13% with the lowest in the MMF alone group and the highest in the MMF+HCQ group, though any differences were not statistically significant. Among subjects with a history of nephritis, the incidence of severe renal flares did not differ between those who were using Prednisone at enrollment compared with those who were not. Logistic regression was used to identify significant, independent risk factors for renal flares; only older age and higher baseline SLEDAI scores were associated with severe renal flares, while race/ethnicity, disease duration, gender and medications were not. Among patients who entered with low levels of disease activity (SLEDAI ≤ 4) and maintained these low levels of activity, the group using HCQ alone was significantly more likely to maintain low levels of disease activity (46% for HCQ group compared to 20%-27% for the other groups).

Conclusion: The results of this study suggest that over a period of almost two years, approximately one-third of SLE patients, even those with nephritis; can be maintained at a low level of disease activity with current maintenance therapies. Over that period, approximately 1/3 of patients have renal flares and approximately 10% have severe renal flares.

Successful Withdrawal and Discontinuation of Immunosuppressants in Lupus Patients: Outcomes and Predictors. Zahi Touma, Murray B. Urowitz, Dominique Ibanez and Dafna D. Gladman. University of Toronto, Toronto Western Hospital, Toronto, ON.

Background/Purpose: Physicians and patients (Pts) are hesitant to withdraw immunosuppressant (IS) in Pts in clinical remission as the consequences of this approach are unknown.

We aimed to determine the number of successful withdrawals of IS and their predictors in a large observational cohort study.

Methods: Analysis was conducted on all Pts seen in The Lupus Clinic, from 1987–2012, in whom IS was tapered and stopped. Pts who were in clinical remission and on prednisone (P) $\leq$7.5mg/day were included. Tapering start was defined as the date of the visit with a decrease $\geq$25% in IS dose. IS Stop was the day of IS discontinuation. Study end was the date of flare or last clinic visit following IS stop.

Flare was defined as the introduction of new IS or increase of P dose for active disease. Flare was evaluated within the first 2 years from IS stop and at any time after IS stop.

Kaplan-Meier curve was used to evaluate the time to flare after IS stop. Pts who flared after IS stop were compared to Pts who did not flare (t-test and χ^2 test) at the time of IS tapering start and IS stop.

Covariates evaluated in the univariate analysis were: sex, ethnicity, IS, DNA antibody level and DNA antibody [yes/no], C3/C4 level and low C3/C4 [yes/no], lupus duration, age at IS taper, length of time on IS, disease activity [SLEDAI-2K, AMS year 1 before IS taper] and steroids at IS stop [yes/no]. Forced and stepwise regression models were fitted with covariates with $p<0.1$ in addition to age, sex and ethnicity to predict flare in Pts who discontinued IS.

Results: Of the 1678 lupus Pts, 973 were ever on IS, 179 had tapering attempts and 99 Pts stopped IS. 91% were female and at tapering start age was 40.4$\pm$13.1 and disease duration was 11.4$\pm$9.4 years.

Of the 99 Pts, 25 flared within 2 years (16 AZA; 7 MTX and 2 MMF; p 0.31). The length of time from tapering start to IS stop was 1.8$\pm$1.8 years in the no flare and 0.9$\pm$0.9 years in the flare group; p 0.002.

46 of the 74 Pts who had not flared by 2 years had follow-up available beyond 2 years; 32 were followed beyond 3 years and 24 beyond 5 years. 17 Pts experienced a flared after year 2. Using Kaplan-Meier curve for time to flare showed that at 1, 2, 3, 4 and 5 years, the percent of Pts who flared was 17%, 30%, 46%, 49% and 51% respectively; Figure 1.

The percentage of Pts on P at the time of IS stop was greater among those who flared, 52% compared to 30%; p 0.04. At the time of IS tapering the models were not statistically significant for all studied covariates. At the time of IS stop, the results from the logistic regression showed that Pts off P are more likely not to flare; OR 2.99; 95% CI: 1.13, 7.89; p 0.03.

Conclusion: Within 2 years, successful stopping of IS was possible in about 75% of clinically stable Pts. Half were successful within 3 year and this proportion was stable up to 5 years. At the time of IS stop, Pts who discontinued IS slowly and who were off P were less likely to flare.

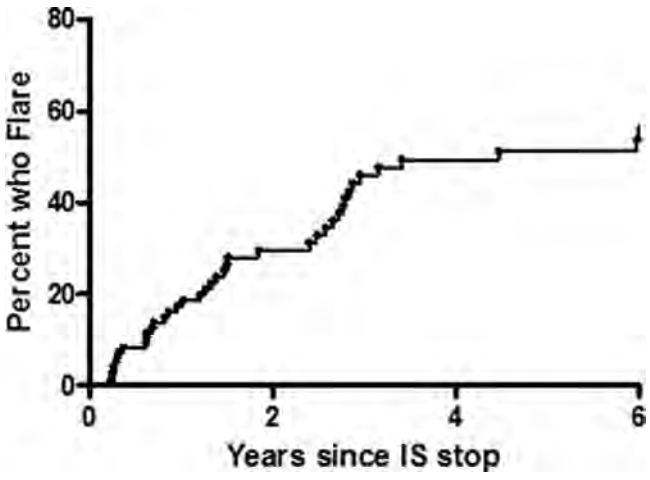

Figure 1: Percent Flared since IS stop

Clinicians Approaches to the Management of Background Therapy in SLE Patients in Clinical Remission: Results of an International Survey. Pintip Ngamjanyaporn[1], Ian Bruce[2], Ben Parker[1] and Jamie Sergeant[1]. [1]Arthritis Research UK Epidemiology Unit, University of Manchester, Manchester Academic Health Sciences Centre, Manchester, United Kingdom, [2]Arthritis Research UK Epidemiology Unit, Institution of Inflammation and Repair, University of Manchester, NIHR Manchester Musculoskeletal Biomedical Research Unit, Central Manchester University Hospitals, Manchester Academic Health Sciences Centre, Manchester, United Kingdom.

Background/Purpose: At present there is no consensus on what constitutes a remission in SLE. In particular it is not clear how background therapy should be interpreted in remission studies. We aimed to survey clinicians involved in the care of SLE patients to determine how background therapy is managed in patients in clinical remission and in particular to assess how previous severity, duration of remission and serological parameters influence therapy alterations.

Methods: We undertook an internet-based survey of clinicians involved in the management of SLE. Case scenarios were constructed to reflect different states of clinical remission; previous organ involvement, current serological abnormalities, duration of remission (1, 3 and 5 years) and current therapy (HCQ, steroids and/or immunosuppressives[ISS]). The survey link was sent to (1) the corresponding authors from Lupus Journal published between January 2013 and December 2013 (2) Lupus working groups e.g. BILAG, SLICC. Percentage of responses in each scenario was described and compared between different factors.

Results: 130 clinicians from 30 countries (Europe 54 [41.5%], Asia 53 [40.8%], North America 16 [12.3%]) responded including 113 (86.9%) rheumatologists. The median (range) duration of practice and number of SLE patients seen per month was 13 (2, 42) years and 30 (2, 200) respectively. There was variation in management decisions across all scenarios with increasing caution on therapy reduction with shorter duration of remission, extent of serological abnormalities and previous disease severity. Even with mild disease, normal serology and a 5 year clinical remission 104 (86.7%) clinicians would still continue HCQ, with only 16 (13.3%) stopping the drug. Similarly, when low dose steroid are co-prescribed in this scenario 78 (64.5%) would continue these and 116 (96.7%) would continue HCQ. When MTX is added to this scenario 85 (70.2%), 79 (67.8%), and 116 (96.7%) would continue all therapies. Of interest, persistent abnormal serology in the above scenario led to a higher proportion of respondents continuing HCQ 113 (96.6%). Similarly, 106 (89.1%) would continue steroid and 119 (100%) would continue HCQ when patients were prescribed both. Prescribing in remission scenarios varied geographically, particularly with regard to steroids. For example, in the scenario describing stable, mild disease for 5 years, steroids would be withdrawn by 24 (48%) European respondents, 4 (28.6%) North American respondents and 10 (19.6%) Asian physicians.

Conclusion: Clinicians approach to withdrawing or reducing therapy in patients with SLE in clinical remission varies substantially. Serological abnormalities, previous disease severity and duration of remission all influence a clinician's decision to reduce treatments and anti-malarials are not usually withdrawn. It is unusual for clinicians to withdraw all therapies, even after a very prolonged period of clinical remission and therefore any definition of remission needs to include the continued use of some background maintenance therapies.

Effect of Corticosteroid Use By Dose on the Risk of Developing Organ Damage over Time in Systemic Lupus Erythematosus—the Hopkins Lupus Cohort. Sarah Al Sawah[1], Xiang Zhang[1], Baojin Zhu[1], Laurence S. Magder[2], Shonda A Foster[1], Noriko Iikuni[1] and Michelle Petri[3]. [1]Eli Lilly and Company, Indianapolis, IN, [2]University of Maryland, Baltimore, MD, [3]Johns Hopkins University School of Medicine, Baltimore, MD.

Background/Purpose: Reduction of corticosteroid dose remains an important goal in the management of systemic lupus erythematosus (SLE). Current standard of care in SLE relies heavily on corticosteroids, despite what is known about the side effects of corticosteroids and their role in the development of new organ damage.

Methods: We used data from a longitudinal lupus cohort to understand the impact of different levels of exposure to corticosteroids on the risk of developing new irreversible organ damage, as measured by the Systemic Lupus International Collaborating Clinics/American College of Rheumatology Damage Index (SDI). Cox proportional hazard models were used to estimate the impact of predictors, including mean prednisone dose, on the risk of developing any new organ damage or any new organ damage by organ system (e.g., ocular, musculoskeletal, cardiovascular, and renal damage) over time.

Results: At cohort entry, the average age of SLE patients was 38 years and the average disease duration was 5.1 years. Patients were followed for an average of 6.2 years. The most frequent types of organ damage, occurring over time, were ocular damage (cataract) and musculoskeletal damage (osteoporotic fractures). Mean prednisone dose, disease activity score, and immunosuppressant use during the follow-up period, as well as SDI score at cohort entry, were significant predictors of the risk of developing any new organ damage. There was a dose-response relationship between mean prednisone dose during the follow-up period and the risk of developing any new organ damage (Models 1 and 2; Table 1). A 1-mg/day increase in prednisone dose increased the risk of developing any new organ damage by 2.8% ($p<0.001$). The risk more than doubled when patients were exposed to a prednisone dose during follow-up of $\geq$20 mg/day versus $<$7.5 mg/day (HR=2.51, 95% CI 1.98, 3.20; $p<0.001$). For individual organ systems, exposure to a mean prednisone dose during follow-up of $\geq$7.5mg/day versus $<$7.5 mg/day significantly increased the risk of developing cataracts (HR=2.41, $p<0.001$), osteoporotic fractures (HR=2.16, $p<0.001$), and cardiovascular damage (HR=1.54, $p=0.041$), but showed no significant difference for renal damage (HR=1.44, $p=0.163$).

Conclusion: Organ damage in SLE is multifactorial, with both corticosteroid treatment and disease activity playing a role. However, even a minimal change in corticosteroid dose (1 mg/day of prednisone) significantly affects the accrual of organ damage over time. These findings may be offset, to some degree, by the impact that prednisone has on damage through the reduction in disease activity.

Table 1. Time-dependent Cox proportional hazard model showing the effect of mean prednisone dose on the risk of any new organ damage in systemic lupus erythematosus

Variable	Model 1		Model 2	
	HR (95% CI)	p-Value	HR (95% CI)	p-Value
SELENA-SLEDAI score during follow-up ($\geq$6 vs. $<$6)	1.40 (1.17–1.67)	$<$0.001	1.37 (1.15–1.64)	$<$0.001
Mean prednisone dose, mg/day:				
($\geq$7.5 vs. $<$7.5)	1.74 (1.49–2.04)	$<$0.001	NA	
($\geq$7.5–$<$15 vs. $<$7.5)	NA		1.54 (1.28–1.84)	$<$0.001
($\geq$15–$<$20 vs. $<$7.5)	NA		1.80 (1.35–2.40)	$<$0.001
($\geq$20 vs. $<$7.5)	NA		2.51 (1.98–3.20)	$<$0.001

Abbreviations: CI = confidence interval; HR = hazard ratio; NA = not applicable; SELENA-SLEDAI = Safety of Estrogens in Lupus Erythematosus National Assessment version of the SLE Disease Activity Index.
Note: The only difference between Models 1 and 2 is that Model 1 uses mean prednisone dose as a binary variable, while Model 2 uses mean prednisone dose as a 4-level categorical variable. All HRs presented in the table are adjusted for age, race, ethnicity, and SDI score at cohort entry; calendar year of diagnosis; and time-dependent variables, including mean prednisone dose, SELENA-SLEDAI score, immunosuppressant use, and antimalarial use during follow-up.

Corticosteroids in Early Treatment Pathways in SLE. John G. Hanly[1], Amyn Sayani[2], Steve Doucette[1], Sandra Iczkovitz[2] and Jorge Alfonso Ross[2]. [1]Dalhousie University and Capital Health, Halifax, NS, [2]Medical Affairs, GlaxoSmithKline, Mississauga, ON.

Background/Purpose: The treatment algorithm for patients with new onset systemic lupus erythematosus (SLE) is more variable than that for other rheumatic diseases (e.g. rheumatoid arthritis). We examined the treatment

patterns, with a particular emphasis on corticosteroids (CS), in an inception cohort of SLE patients over the first 3 years of disease.

Methods: The study was conducted at a single academic center with a longitudinal lupus database. All patients fulfilled the ACR classification criteria for SLE within 12 months preceding their enrollment and completed at least 3 subsequent annual followup visits during which data since the previous assessment were recorded. Information was collected per protocol at each visit and included patient demographics, SLE manifestations, medications, SLE disease activity index-2K (SLEDAI-2K), SLICC/ACR damage index (SDI) and SF-36 for assessment of health related quality of life (HRQoL). Analysis included descriptive statistics and repeated measures mixed models.

Results: Seventy-nine patients, 86.1% female and 91.1% Caucasian were studied. At baseline the mean ± SD age was 39.8 ± 16.1 years, disease duration was 0.36 ± 0.28 years and SLEDAI-2K was 5.7 ± 4.6. Over 3 years the cumulative exposure to CS, antimalarials (AM) and immunosuppressive (IM) drugs was 53.2%, 77.2% and 40.5% respectively, and CS were virtually always used in combination with AM and/or IM. The use of CS fell between baseline and final assessments (44.3% vs. 15.2%) in contrast to the use of AM (55.7% vs. 70.9%) and IM (26.6% vs. 24.2%). Of the 44/79 (55.7%) patients who were not receiving CS at baseline 84.1% remained off CS for the duration of the study. Thirty-seven of 79 (46.8%) patients never received CS and only 5/79 (6.3%) of patients were taking corticosteroids at all 4 assessments. Patients exposed to CS at baseline had higher mean ± SD daily dose and cumulative dose of CS over 3 years compared to patients not on CS at baseline (9.0 ± 6.8 vs. 0.3 ± 1.3 mg; 10.8 ± 8.5 vs. 0.3 ± 1.2 gr.) The adjusted mean SLEDAI-2K over 3 years was higher in patients exposed to CS regardless of whether group assignment was determined by cumulative dose (none vs > 10 g: 2.7 ± 1.9 vs 6.5 ± 3.5; p=0.0001), CS at baseline visit (none vs present: 2.9 ± 2.1 vs 5.1 ± 3.9; p=0.006) or CS exposure at any time during the study (2.7 ± 1.9 vs 3.8 ± 0.6; p=0.002).Using the same group assignments CS exposure over 3 years was associated with a significant fall in SLEDAI-2K scores ($p<0.05$) compared to patients not exposed to CS. There was no consistent association with baseline SDI or HRQoL or change over time.

Conclusion: Exposure to CS occured in approximately half of the patients with new onset SLE, usually in association with AM and/or IM. It was associated with both higher disease activity, especially at baseline, and a subsequent fall in disease activity over time. In SLE patients who do not receive CS at disease presentation, the introduction of CS is very unlikely over the next 3 years.

Disclosure: J. G. Hanly, None; **A. Sayani**, GlaxoSmithKline, 3; **S. Doucette**, None; **S. Iczkovitz**, GlaxoSmithKline, 3; **J. A. Ross**, GlaxoSmithKline, 3.

Prednisone, Disease Activity and Hypertension Independently Predict Cataracts in Systemic Lupus Erythematosus (SLE). Khaled Alderaan[1], Vuk Sekicki[2], Laurence S. Magder[3] and Michelle Petri[4]. [1]King Fahad Specilaist Hospital, Dammam, Saudi Arabia, [2]Saint Agnes Hospital, Baltimore, MD, [3]University of Maryland, Baltimore, MD, [4]Johns Hopkins University School of Medicine, Baltimore, MD.

Background/Purpose: Cataract is the most common ocular damage in SLE. It is the second most frequent item in the SLICC/ACR Damage Index. Apart from cumulative corticosteroid doses, there are virtually no reports on other risk factors for cataract in SLE population. We report on a large prospective study of cataract risk factors in SLE.

Methods: The analysis was based on the follow-up experience prior to age 60 of 2109 SLE patients who had not had a cataract prior to cohort entry. Patients saw their ophthalmologist every 6 months. Cataract was defined by the SLICC/ACR Damage Index. The rate of incident cataract was calculated in subsets defined by patient characteristics and history. Multivariable logistic regressions were fit to identify predictors of cataract while controlling for potential confounding variables.

Results: The patients were 93% female, 54% Caucasian, and 39% African-American. The analysis was based on 11,887 persons-years of follow up, with median follow up time of 4.1 years per patient. During this follow-up we observed 157 new cases of cataract, for an incidence of 13.2 per 1000 persons-years. We estimated that the risk of being diagnosed with a cataract by age 60 was 28%. Table 1 shows the results of a multivariate regression model. Adjusting for other predictors, a cumulative prednisone dose equivalent to 10 mg/day for 10 years was a strong predictor of cataract (RR=3.1, P=0.0005). Disease activity measured by SLEDAI (P =0.0005) and higher systolic blood pressure (P =0.0006) were associated with cataract. Duration of SLE, diabetes mellitus, smoking, cholesterol, renal involvement, immunological profile and medication history, other than prednisone, were not associated with cataract.

Conclusion: Cataract development in SLE patients is multifactorial with cumulative prednisone doses, systolic blood pressure and disease activity all playing an independent role.

Table 1: Independent Predictors of Cataract Based on a Multivariable Model

Predictor	Comparisons	Rate Ratio (95% confidence interval)	P-value
Age	Per 10 year increase	2.0 (1.7, 2.4)	<0.0001
Mean Systolic BP during prior cohort visits > 140 mmHg	Yes vs. no	2.2 (1.4, 3.3)	0.0006
Mean total cholesterol	Per 50 mg/dl increase	1.1 (1.0, 1.2)	0.22
Diabetes mellitus	Yes/no	1.3 (0.9, 2.0)	0.22
Mean SELENA-SLEDAI	Per 2 point increase	1.3 (1.1, 1.5)	0.0005
Cumulative Corticosteroid Exposure[1]	<3649[2] mg vs. none	1.1 (0.5, 2.5)	0.77
	3650–10,949[3] vs. none	1.1 (0.5, 2.3)	0.87
	10,950–36,499[4] vs. none	2.3 (1.3, 4.3)	0.0065
	36,500[5] + vs. none	3.1 (1.6, 5.7)	0.0005

1 Includes prednisone history prior to cohort entry
2 Exposure equivalent to <10 mg/day for 1 year
3 Exposure equivalent to 10 mg/day for 1–3 years
4 Exposure equivalent to 10 mg/day for 3–10 years
5 Exposure equivalent to 10 mg/day for 10+ years

Disclosure: K. Alderaan, None; **V. Sekicki**, None; **L. S. Magder**, None; **M. Petri**, None.

690

Lupus Patients Requiring First Corticosteroid Intervention Late in Disease Course - a Phenotypic Description. Barry J. Sheane, Dominique Ibanez, Dafna D. Gladman and Murray B. Urowitz. University of Toronto, Toronto Western Hospital, Toronto, ON.

Background/Purpose: The University of Toronto Lupus Clinic (UTLC) recently described the phenotype of a group of inception patients with SLE who remained naïve of corticosteroid (CS-naïve) for the entire duration of follow-up at the Clinic. One third of those CS-naïve SLE patients accrued damage over time, yet developed less damage and at a slower rate than those exposed to CS.

We have identified a group of patients who remained CS-naïve for at least 3 years but who later required CS intervention. Below we describe the clinical features of this subset of patients.

Methods: Patients with SLE attending the UTLC satisfying the following criteria were included in the study: 3 years or more of follow-up from inception, no exposure to CS for the first 3 years from inception, no organ damage (as per the SLICC Damage Index (SDI) = 0) from inception and at least 5 follow-up visits. Two groups were identified from this cohort: those who remained entirely CS-naïve up to their last visit (CS-naïve) and those exposed to CS at some point after 3 years during follow-up (CS-late). Differences between the 2 groups were examined: in disease activity at inception (SLEDAI-2K) and over time (adjusted mean SLEDAI (AMS)), in the time to first incidence of organ damage (SDI ≥ 1), and the effect of exposure to anti-malarial (AM) medication on organ damage accrual (SDI ≥ 1).

Results: In the CS-late group, 31 patients were identified and 59 in the CS-naïve. The mean time to first CS exposure in the CS-late group was 9.0 ± 5.6 years.

Comparing the CS-late vs. CS-naïve groups, sex distribution (93.6% vs. 94.9% female), mean age at diagnosis (33.3 ± 11.9 vs. 37.8 ± 14.5 years; p = 0.15), years of follow-up (9.1 ± 5.6 vs. 11.0 ± 6.4 years; p = 0.15), mean SLEDAI at first visit (5.68 ± 3.31 vs. 5.25 ± 3.69; p = 0.59), AMS for the first 3 years, time to first damage (3.7 ± 3.9 vs. 4.8 ± 3.1 years; p = 0.36), damage scores over 10 years of follow-up, and the proportion eventually developing damage (11 (35.5%) vs. 23 (39%); p = 0.74) were similar between groups.

73.3% of the CS-late and 50.9% of the CS-naïve received a score on the SLEDAI for immunological activity (p = 0.04), with a mean immunological score of 2.00 ± 1.49 and 1.25 ± 1.38, respectively (p = 0.02). The CS-late had a lesser number with musculoskeletal (MSK) activity (16.1%) at first

visit, compared with the CS-naïve group (27.1%; p = 0.24) with lower MSK scores (0.65 ± 1.50 and 1.08 ± 1.79, respectively; p = 0.25). Arthritis and lupus rash were the cause of CS requirement in the CS-late group in most cases.

AM medication did not delay the onset of organ damage in the CS-late group.

Conclusion: A small group of patients with SLE remain steroid treatment naïve for more than 9 years and then develop a requirement for steroids usually because of arthritis and rash. Patients requiring late intervention with CS have greater immunological activity at baseline than patients who remain CS-naïve, yet accrue damage at similar rates to the CS-naïve. Early AM prescription is not protective of late CS requirement or development of organ damage.

Prevalence of Subclinical Echocardiographic Abnormalities in Patients with Systemic Lupus Erythematosus (SLE). Sergi Heredia[1], Javier Narváez[2], Andrea Zacarias[1], Eulalia Armengol[1], Gloria Albert[1], Alex Roset[1], Patricia Siguenza[1], Xavier Juanola[3], Manel Rubio Rivas[1] and Joan Miquel Nolla[1]. [1]Hospital Universitario de Bellvitge, Barcelona, Spain, [2]Hospital Universitario de Bellvitge. Barcelona. Spain, Barcelona, Spain, [3]University Hospital Bellvitge, Barcelona, Spain.

Background/Purpose: To determine the prevalence of unsuspected echocardiographic abnormalities (excluding pericardial effusion) and to identify associated clinical and laboratory features in a large SLE cohort.

Methods: The sample comprised 243 patients with SLE treated between 1980 and 2013 at a tertiary university hospital that does not attend pediatric populations. Patients were registered in a specific database (ACHILLES project). Ninety-one patients who were free of cardiovascular symptoms and had been examined at least once with a transthoracic Doppler echocardiogram (TTE) were selected for analysis. In patients with more than one TTE, only data from the last examination were included in the analysis. Each study investigated the presence of myocardial systolic dysfunction, diastolic myocardial dysfunction, valve disease, segmental wall motion abnormalities suggestive of ischemic heart disease and pulmonary arterial hypertension (PAH) defined as a systolic pulmonary artery pressure (PAP) of 40 mmHg and tricuspid regurgitation velocity (TRV) greater than 2.5 m/s.

Results: The mean age of patients (75 women) was 50 ± 12 years (range, 27–77) and median duration of disease at the time of the echocardiographic study was 83 months (range, 12 – 156). The main findings were:

- *Systolic dysfunction* in 1.1% (1/91) of patients.
- *Diastolic dysfunction* in 5.5% (5/91) of patients; all had arterial hypertension and two had positive antiphospholipid antibodies (aPL).
- *Segmental wall motion abnormalities suggestive of ischemic heart disease*: 3.3% (3/91) of patients.
- *Subclinical valve disease*: 46.2% (42/91) of patients, including 27 cases of tricuspid insufficiency (30%), 26 mitral regurgitation (29%), 5 aortic insufficiency (5.5%), 4 aortic stenosis (4.4%) and 1 verrucous Libman-Sacks endocarditis in mitral valve (1.1%). Some patients presented several different types of injury. Valve dysfunction was mild in all cases.
- *Pulmonary arterial hypertension*: 7.7% (7/91) of patients. Mean PAP was 46.8 ± 4 mmHg (range, 40–56) and mean TRV was 3 ± 0.3 m/s (range, 2.7–3.4). Pulmonale was observed in two patients; neither had dilated inferior vena cava or pericardial effusion. Six out of seven patients (86%) of patients with PAH also had some kind of valve disease.

Of the patients with subclinical valvular disease, 40.5% (17/42) were positive for one or more of the aPL (cardiolipin antibodies Ig or IgM, anti-beta2-glycoprotein IgG or IgM, lupus anticoagulant). Five out of seven patients with PAH (71.4%) were positive for aPL. In the comparative study of 49 SLE controls without valve disease or PAH, there were no statistically significant differences in aPL positivity (45% positivity in controls; p > 0.05). No significant differences were observed in the frequency of Raynaud's phenomenon between patients with PAH and controls.

Conclusion: Echocardiographic abnormalities were frequently detected in asymptomatic patients with SLE. Valve disease (46%) was the most common finding. TTE screening may be indicated in patients with SLE.

Circulating Anti-Ro/SSA Antibodies Are Associated with the Presence of Severe Mitral Regurgitation in Systemic Lupus Erythematosus. Violeta Higuera[1], Claudia Hübbe[2] and Luis M. Amezcua-Guerra[3]. [1]Instituto Nacional de Cardiologia Ignacio Chavez, Mexico City, Mexico, [2]Instituto Nacional de Cardiología, Mexico City, Mexico, [3]Mexican Board of Rheumatology, Mexico City, Mexico.

Background/Purpose: Systemic lupus erythematosus (SLE) is a complex autoimmune disorder involving multiple organ systems. The frequency of symptomatic heart disease ranges from 5 to 10%, but noninvasive imaging methods such as transthoracic echocardiography (TTE) may demonstrate subclinical cardiac involvement in up to 95% of SLE patients. In spite of this, intrinsic SLE factors conferring risk to develop cardiac valve involvement have not been adequately defined. Indeed, almost all available information about cardiac valve disease in SLE is related to both circulating antiphospholipid antibodies and the antiphospholipid syndrome.

A recent short study described that anti-Ro/SSA antibodies, one of the most commonly autoantibodies found in SLE (40–50%), could be associated with the presence of valvulopathy.

Objectives: To evaluate the association between anti-Ro/SSA and other antibodies and cardiac valve disease in SLE.

Methods: One-hundred patients fulfilling the ACR classification criteria for SLE were enrolled. Demographics and clinical data were collected and patients underwent to TTE. Also, serum antibodies against nuclear antigens, dsDNA, Sm, Ro/SSA, La/SSB, RNP, cardiolipin, and β2GP1 were measured.

Patients were grouped according to the presence or absence of anti-Ro/SSA antibodies, and clinical, serological and TTE data were compared by chi-square or Mann-Whitney tests as correspond.

Results: Eleven patients were excluded because rheumatic valve disease or congenital heart disorder. Eighty-nine patients were included for analyses, 36 patients (35 female, mean age 37.3±14 years) were positive and 53 negative (43 female,40.1±15) for circulating anti-Ro/SSA antibodies. There were no differences in age, disease duration or co-morbidities between groups. A difference was noted in the presence of anti-dsDNA (67% *vs* 45%; P=0.04) and anti-La/SSB (19% *vs* 2%; P=0.004) antibodies. In the cardiac abnormalities detected by TTE, there was a significant relationship between positive anti-Ro/SSA antibodies and severe mitral regurgitation (27% *vs* 5%; P=0.02). Indeed, anti-Ro/SSA antibodies confer an OR 6.5 (P=0.03) for the presence of severe mitral regurgitation. No other differences in the TTE findings were found.

Conclusion: In SLE, circulating anti-Ro/SSA antibodies are associated with the presence of severe mitral regurgitation.

Disclosure: V. Higuera, None; **C. Hübbe**, None; **L. M. Amezcua-Guerra**, None.

Acute Myocarditis in Patients with Systemic Lupus Erythematosus: Experience from Affiliated Hospitals of Catholic University of Korea. In-Woon Baek[1], Ki-Jo Kim[2], Yune-Jung Park[3], Chong-Hyeun Yoon[4], Wan-Uk Kim[5] and Chul-Soo Cho[1]. [1]Yeouido St. Mary's Hospital, The Catholic University of Korea, Seoul, South Korea, [2]St. Vincent's Hospital, The Catholic University of Korea, Suwon, South Korea, [3]St. Vincent's Hospital, The Catholic University of Korea, Suwon, South Korea, [4]Uijeongbu St. Mary's Hospital, The Catholic University of Korea, Uijeongbu, South Korea, [5]Seoul St. Mary's Hospital, The Catholic University of Korea, Seoul, South Korea.

Background/Purpose: To determine the factors associated with occurrence of acute myocarditis (AMC) and its outcomes in patients with systemic lupus erythematosus (SLE).

Methods: This was a retrospective study of hospitalized SLE patients with AMC from 2002 to 2014 at Catholic University affiliated hospitals. A diagnosis of AMC was made on the basis of clinical findings, electrocardiographic changes, elevated cardiac enzymes levels and echocardiographic abnormalities. Eighty-six SLE patients who showed no echocardiographic evidence of myocarditis were enrolled as a control group. The clinical and laboratory data from each patient were collected from the charts and compared between 2 groups.

Results: During these periods, 22 SLE patients were identified to have AMC (male 3, female 19). Patients with AMC, as compared with those without, were found to be associated with shorter disease duration and higher frequency of smoking (P<0.005, P<0.05, respectively). Moreover, they showed significantly higher SLE disease activity index score (P<0.001) and

C-reactive protein levels ($P<0.001$), but lower complement levels (C3, C4 and CH50, all $P<0.005$). Interestingly, antiphospholipid syndrome (APS) was more prevalent in patients with AMC compared with those without ($P<0.01$). In multivariate analysis, shorter disease duration, smoking and presence of APS were independent factors associated with AMC in SLE patients. All patients with AMC received high-dose corticosteroid and 2 of them received intravenous cyclophosphamide; 17 patients completely recovered, but 5 died.

Conclusion: AMC patients are more likely to have high disease activity and its occurrence is associated with shorter disease duration, smoking, and presence of APS.

Lupus Myocarditis: Clinical, Echocardiographic and Magnetic Resonance Characteristics. Maria del Carmen Zamora Medina[1], Hilda Fragoso-Loyo[2], Martha Morelos[3], Juan Jakez-Ocampo[3], Luis Llorente[4], Juan Rosas Saucedo[3] and Yemil Atisha-Fregoso[5]. [1]Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubiran, Mexico City, Mexico, [2]Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Mexico, Mexico, [3]Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, México, Mexico, [4]Instituto Nacional de Ciencias Medicas y Nutricion, Mexico City, Mexico, [5]Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Mexico City, Mexico.

Background/Purpose: Myocarditis is an uncommon manifestation with important morbidity and mortality in patients with Systemic Lupus Erythematosus (SLE). There are scant information about this manifestation that comes from case series, which include no more than 24 patients. Also, there are not a uniform definition about the criteria for the diagnosis of this manifestation in SLE, and only in few reports the diagnosis was supported by cardiac magnetic resonance (CMR).

Methods: Retrospective study of all cases of myocarditis seen in a single center between 2005 and 2014. Patients with diagnosis of SLE according to the updated 1982 ACR criteria, who met the expanded criteria for myocarditis and had CMR compatible with the diagnosis were included.

The objective of the study was to describe the clinical and laboratorial manifestations, and electrocardiographic, echocardiographic and CMR findings of these patients.

Results: Twenty five patients (24 women, 96%), with a mean age of 29.38 ± 11.36 years, and who presented 26 episodes of myocarditis were included. The mean time to development of myocarditis after SLE diagnosis was 11.5 months (IQR 0–31.2%). The main clinical and imaging findings are shown in tables 1 and 2.

During the episode of myocarditis the activity of SLE at diagnosis measured by SLEDAI was of 8.77 (IQR 4–12). Patients had a SLICC Damage Index at diagnosis of 1.43 ± 1.6. Nine of 26 patients (35%) required admission to the ICU and 6 of 26 (23%) patients were treated with inotropics. There were no deaths during the acute episode, but 4 patients died during the follow-up, three of them secondary to infections. All patients were treated with prednisone, mean dose 50 ± 12 mg/day.

Follow-up MRI was performed on 10 patients, the mean initial LVEF was 49.2% ± 9.2 vs 61% ± 8.1(p=0.007). The SLEDAI score at follow-up was of 2 points (IQR 0–6), and the SLICC Damage Index at follow-up was of 1.71 ± 1.82.

Conclusion: Myocarditis is a severe manifestation of SLE. CMR is a useful study in the diagnosis of myocarditis that can evaluate some parameters that are not detectable in echocardiography e.g., valvulitis, edema, hyperemia and myocardial fibrosis. Further studies are needed to determine the role of CMR and currently follow-up studies are undergoing at our Institute in SLE patients with myocarditis.

Osteonecrosis in Patients with Systemic Lupus Erythematosus: Risk Factors and Clinical Outcome. Andrea Zacarias[1], Javier Narváez[2], Sergi Heredia[1], Helena Borrell[1], Paula Estrada[1], Alex Roset[1], Nestor Arce Gonzalez[1], Carmen Gomez Vaquero[1], Olga Capdevila[1] and Joan Miquel Nolla[1]. [1]Hospital Universitario de Bellvitge, Barcelona, Spain, [2]Hospital Universitario de Bellvitge. Barcelona. Spain, Barcelona, Spain.

Background/Purpose: To study the prevalence of osteonecrosis (ON) in patients with systemic lupus erythematosus (SLE) and to identify the risk factors for development of this complication and predictors of total hip/knee arthroplasty.

Methods: The sample comprised 243 patients with SLE treated between 1980 and 2013 at a tertiary university hospital that does not attend pediatric populations. Patients were registered in a specific database. Patients with ON were selected for analysis. The diagnosis was confirmed in all cases with imaging techniques (conventional radiography and bone scan, CT scan or MRI). The variables associated with the occurrence of this complication were analyzed using a backward logistic regression model.

Results: During the follow-up period, 11 patients (4.5%) had 12 episodes of ON (one patient developed two). The mean age of the patients (nine women) was 52 ± 15 years and median time to progression of SLE at the time of diagnosis of ON was 149 months (range: 24–323). Three out of 11 cases of ON (27%) occurred within the first five years of the course of the disease.

The condition was monoarticular in eight episodes (66%) and multifocal in four (34%); in the latter case it simultaneously affected two or more joints (range 2–4). The most common site was the femoral head (75% of episodes), followed by the knee (33%) and the humeral head (8%). In 90% of the affected joints, ON presented with pain and functional impotence (the asymptomatic joints were detected in the scintigraphic study).

The mean dose of prednisone at the time of diagnosis of ON was 11 ± 8.2 mg/day and the total cumulative dose was 30.4 ± 16.7 g. Seven patients (64%) had received a prednisone dose of at least 0.5 mg/kg/day at some point of the disease; 5 (45%) of these had received a dose of 1 mg/kg/day for serious complications. However, at the time of ON diagnosis, disease was inactive or mild in all patients according to the SLEDAI score (mean 1.3, range 0–4).

Antiphospholipid antibodies were positive in two patients (18%); both were on antiplatelet therapy. We did not identify any other risk factors that have been associated with the development of ON in SLE.

Outcome was unfavorable in seven patients (64%), who required total hip/knee replacement. There was no increase in mortality.

Both in the comparisons between groups using univariate analysis and in the multivariate analysis, the only predictor of risk for development of this complication was the total cumulative prednisone dose (OR = 19.07 [95% CI: 2.7 – 133.7], p = 0.0002). No associations were found with the presence of antiphospholipid antibodies, immunosuppressive therapy, presence of arthritis or degree of disease activity according to the SLEDAI. In the Cox proportional hazards model, advanced radiological stage was the only statistically significant predictor for arthroplasty.

Conclusion: ON is a rare complication in patients with SLE (4.5%). In the majority of the cases it is symptomatic and occurs in advanced stages of the disease. The major risk factor associated with the development of this complication is the cumulative dose of glucocorticoids. ON was not associated with increased mortality, but it was associated with physical disability.

Clinical Characteristics and Outcome of Intestinal Pseudo-Obstruction in Patients with Systemic Lupus Erythematosus. Lingling Zhang, Mengtao Li, Dong Xu, Na Gao, Li Zhang, Yong Hou, Qian Wang and Xiaofeng Zeng. Peking Union Medical College Hospital, Chinese Academy of Medical Science & Peking Union Medical College, Beijing, China.

Background/Purpose: Intestinal pseudo-obstruction (IPO) is a rare clinical syndrome characterized by ineffective intestinal motility. IPO has been recently recognized as an uncommon complication of systemic lupus erythematosus (SLE). Though case series of patients with SLE-related IPO (SLE-IPO) have been reported, the epidemiology, characteristics, risk factors and prognosis for SLE-related IPO remain poorly understood.

Methods: To analyze the clinical characteristics and outcome of SLE-IPO, we retrospectively enrolled 68 SLE patients with IPO syndrome as the case group and 323 randomly matched SLE patients without any gastrointestinal manifestations as controls out of 3937 inpatients at Peking Union Medical College Hospital (PUMCH) from 2003 to 2013. IPO was diagnosed according to gastrointestinal symptoms, gaseous small bowel distension with air-fluid levels showed by radiographic signs or thickened gastric wall and dilated small or large bowels showed by CT scan, otherwise, patients were

excluded. The case-control study was conducted to compare the clinical and laboratory data. The outcome of SLE-IPO was also investigated.

Results: Within the last 10 years at PUMCH, the prevalence of IPO in SLE patients was 1.73% and the in-hospital fatality rate was 8.8%. 58.8% of the SLE-IPO manifested as the initial presentation of SLE. Ureterohydronephrosis was the most common complication (60.3%) in SLE patients with IPO and the incidence of biliary tract dilation was 7.9%. SLE patients with IPO were always diagnosed at earlier stage of SLE with higher frequency of hematological disturbance, polyserositis and hypocomplementemia than control patients. Ureterohydronephrosis (OR = 90.322, 95% CI 21.283–383.32, p = 0.000), hypocomplementemia (OR = 10.437, 95% CI 1.341–81.217, p = 0.025) and elevated CRP level in serum (OR = 5.143, 95% CI 1.401–18.876, p = 0.014) were independent risk factors for IPO in SLE disease. However, the positivity of anti-dsDNA antibody was a protective factor for SLE with IPO (OR = 0.222, 95% CI 0.061–0.8, p = 0.021). SLE-IPO patients with long IPO duration, diagnosed at late stage of SLE or concurrent with megacholedochus and ureterohydronephrosis always had unfavorable outcome.

Conclusion: IPO can manifest as a complication of SLE and more commonly, as the initial presentation. SLE-IPO always occurs concomitantly with ureterohydronephrosis and biliary dilatation, and these three complications combined indicate a severe situation of SLE. SLE-IPO patients without systemic smooth muscular involvement could achieve better prognosis with early diagnosis and aggressive treatment.

Venous and Arterial Thrombosis in SLE: Differences in Natural History. Katharine Hickman[1], Laurence S. Magder[2] and Michelle Petri[3]. [1]University College London, London, United Kingdom, [2]University of Maryland, Baltimore, MD, [3]Johns Hopkins University School of Medicine, Baltimore, MD.

Background/Purpose: Thrombosis is increased in SLE due to disease activity and co-morbid factors including antiphospholipid antibodies. We separately investigated the natural history of venous vs. arterial thrombosis.

Methods: 2250 patients were enrolled in a prospective cohort; 334 had a thrombotic event before cohort entry or diagnosis of SLE. For ALL thrombosis, age over 60 yrs, male gender, African-American ethnicity, SLEDAI greater than 3, and prednisone greater than 0 were risk factors.

Results: In general, rates of venous thrombosis were fairly constant, while rates of arterial thrombosis increased with age. The figure below shows that initially the venous thrombosis rate is higher (including before diagnosis) and later the arterial thrombosis rate is higher.

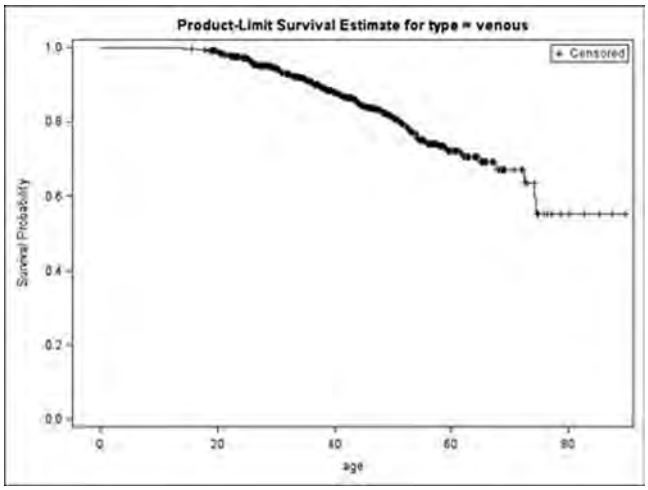

Figure SEQ Figure * ARABIC 1: Probability of remaining thrombosis free, by age

Table 1: Incidence rates (per 1000 patient-years) of thromboses

Characteristic of Person-Month	All Thromboses Rate Ratios (95% CI)	P-values	Arterial Thromboses Rate Ratios (95% CI)	P-values	Venous Thromboses Rate Ratios (95% CI)	P-values
Age	1.0 (Ref Group)	0.47	1.0 (Ref. Group)	0.22	1.0	0.66

1–9	3.3 (2.2, 4.8)	<0.0001	3.5 (2.2, 5.7)	<0.0001	3.2 (1.9, 5.6)	<0.0001
10–19	6.7 (4.5, 10.0)		7.0 (4.2, 11.6)		7.2 (4.1, 12.7)	
20+						

Conclusion: Prevention of venous thrombosis remains important throughout the course of SLE. Prevention of arterial thrombosis becomes more important later in the disease course. Disease activity is a risk factor for arterial thrombosis while prednisone is a risk factor for both venous and arterial thrombosis.

Grip Strength Identifies Increased Physical Disability in Women with Systemic Lupus Erythematosus. James S. Andrews[1], Mary Margaretten[2], Jennifer Barton[2], Jinoos Yazdany[2], Ed Yelin[2] and Patricia P. Katz[3]. [1]University of California San Francisco, San Francisco, CA, [2]University of California, San Francisco, San Francisco, CA, [3]University of California, San Francisco, CA.

Background/Purpose: Muscle weakness is common and contributes to physical disability in women with systemic lupus erythematosus (SLE). Recently, the Foundation for the National Institutes of Health Sarcopenia Project reported grip strength cutpoints that identified weakness associated

with impaired mobility among women aged ≥ 65 years. However, the ability of grip strength to identify SLE patients at increased risk of physical disability is unknown. This study aims to test whether grip strength is associated with increased physical disability in women with SLE.

Methods: Subjects were women in a longitudinal cohort with physician-documented SLE. All measures were collected during an in-person research visit among a subset of the cohort. Grip strength was measured with a handheld dynamometer. Grip strength was classified as "weak" (<16kg), "intermediate" (16–20kg), and "normal" (>20kg). Self-reported physical functioning was assessed using the SF-36 Physical Functioning subscale (range 0–100, mean 50, SD 10) and Valued Life Activities (VLA) Disability (range 0–3) surveys. Higher SF-36 and lower VLA scores indicate higher functioning. Regression analyses controlling for age, SLE duration, prednisone use, SLE disease activity measured with the Systemic Lupus Activity Questionnaire (SLAQ), physical activity level measured by the International Physical Activity Questionnaire (IPAQ), and depressive symptoms measured by the Center for Epidemiological Studies Depression Scale (CES-D) modeled the effects of grip strength on SF-36 and VLA scores.

Results: Of the 146 women, mean age was 48 (±12) years; duration of SLE was 16 (±9) years; SF-36 score was 40.9 (±11.4); VLA disability score was 0.80 (±0.55). Fifteen women (10%) had "weak" grip strength, 31 (21%) "intermediate, 78 (53%) "normal"; and 22 (15%) were missing grip strength data. In both unadjusted and adjusted models, having "weak" compared to "normal" grip strength was associated with significantly worse SF-36 and VLA scores (see Table 1). In sensitivity analyses examining the effects of missing grip strength data and of excluding women aged ≥ 65 years (n=11), the overall trends were unchanged.

Conclusion: Grip weakness was common in our cohort of women with SLE, with a prevalence comparable to that of geriatric populations. Grip weakness successfully identified women with increased physical disability even when adjusting for potential confounders such as disease activity and depression. These findings underscore the high burden of muscle weakness among women with SLE, and they may suggest a clinical role for grip strength testing in identifying women with SLE at greatest risk of physical disability. Further studies will need to examine the ability of grip strength to predict incident disability in SLE.

Table 1. Association between Grip Strength and Disability Scores[#]

	SF-36 Physical Functioning		Valued Life Activities	
	Unadjusted	Adjusted	Unadjusted	Adjusted
Weak (<16kg)	−11.8 (−17.6, −6.1)***	−4.4 (−8.7, −0.1)*	0.68 (0.40, 0.96)***	0.31 (0.11, 0.51)**
Intermediate (16–20kg)	−7.5 (−11.8, −3.2)**	−3.2 (−6.3, 0.01)	0.29 (0.08, 0.50)**	0.08 (−0.06, 0.23)

Osteonecrosis in Systemic Lupus Erythematosus: Prevalence, Patterns and Outcomes. Nimrit Dhillon, Dominique Ibanez, Dafna D. Gladman and Murray B. Urowitz. University of Toronto, Toronto Western Hospital, Toronto, ON.

Background/Purpose: Osteonecrosis is a serious comorbidity of systemic lupus erythematosus (SLE). The reported frequency of symptomatic osteonecrosis in SLE is variable, ranging from 4% to 15%.

The aim of this study is to provide an update of the prevalence, patterns and outcomes of symptomatic osteonecrosis in SLE.

Methods: SLE patients with osteonecrosis were identified from the Lupus Clinic Database containing patients with 4 ACR criteria of SLE or 3 criteria and a biopsy diagnostic of lupus. Osteonecrosis was defined as those patients with clinical symptoms and confirmed osteonecrosis by imaging (x-ray, bone scan, CT, MRI). Demographic and clinical data of affected patients were collected prospectively, stored in an Oracle database and analyzed using descriptive statistics.

Results: Of the 1729 patients with SLE registered in the database as of 1970, 235 patients (13.6%) developed symptomatic osteonecrosis. 86.0% were female, with a mean age of 34.8 ± 12.8 years at first osteonecrosis diagnosis. This involved a total of 542 joints, 383 joints of which were identified at the time of first osteonecrosis occurrence. The mean time from diagnosis of SLE to diagnosis of first osteonecrosis was 8.2 ± 8.1 years, and the time from first osteonecrosis diagnosis to second osteonecrosis diagnosis was 3.4 ± 4.8 years.

111 out of 235 (47%) patients had multiple site involvement at first osteonecrosis occurrence, affecting from 2 to 6 sites. At the time of first diagnosis affected sites included the hip (245), knee (86), shoulder (28), ankle (15), wrist (3), other joints (3) and elbow (2). Those that progressed to surgical intervention included: hip 131/245 (53.5%), knee 18/86 (19.8%), wrist 1/3 (33.3%), shoulder 1/28 (3.6%), ankle 0/15 (0%), elbow 0/2 (0%), and other joints 1/3 (33%). The mean time from osteonecrosis diagnosis to surgery of the hip was 3.8 ± 5.5 years, while the mean time from osteonecrosis diagnosis to surgery of the knee was 5.5 ± 6.2 years.

Conclusion: To our knowledge, this is the largest cohort of SLE patients with symptomatic osteonecrosis. Osteonecrosis continues to be a significant comorbidity of SLE as 13.6% of patients developed symptomatic osteonecrosis. In patients developing osteonecrosis, the presentation occurred after 8.2 ± 8.1 years of SLE disease duration. 47.2% of patients had multiple site involvement at first ON diagnosis. Large weight-bearing joints, including the hip and knee, were most frequently involved. The majority of hips required surgical intervention. Better strategies to prevent this serious complication are needed.

Decreased Lung Diffusion Capacity in Asymptomatic Patients with Systemic Lupus Erythematosus Does Not Predict Future Lung Disease. Ofir Elalouf, Elizabeth Fireman, David Levartovsky, Ilana Kaufman, Ori Rogovski, Ori Elkayam, Dan Caspi and Daphna Paran. Tel-Aviv Medical Center, Sackler Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Israel.

Background/Purpose: In a previous study, performed 9±3.6 years ago 74 asymptomatic patients with systemic lupus erythematosus (SLE) and or antiphospholipid syndrome (APS) who fulfilled the ACR criteria for diagnosis, underwent lung function testing. A significantly low diffusion capacity (DLCO) ranging from 45% to 70% was recorded in 28 of the 74 (37.8%) patients who were all free of respiratory symptoms. This study aims to assess the clinical importance and predictive value of a low diffusion capacity in asymptomatic patients with SLE or APS.

Methods: Asymptomatic patients with SLE and /or APS who were found to have a low DLCO in the previous study were contacted. Of the 28 patients, 15 were recruited and reevaluated in the current study [SLE with APS (n=7), SLE without APS (n=7); primary APS (n=1)]. A detailed history, physical examination, nail bed capillaroscopy, current laboratory tests and lung function tests including DLCO were obtained.

Results: During a surveillance period of 9±3.6 years none of the patients developed lung disease. Diffusion capacity corrected for alveolar volume (DLCO/VA) improved in the study group during this period from 61.3% ± 6.3 to 77% ± 12.7% (p=0.006). Lung function tests including total lung capacity (TLC) and forced expiratory volume in 1s (FEV1) remained within normal limits. Capillaroscopy studies did not reveal changes compatible with scleroderma in any of the patients.

Conclusion: Low diffusion capacity findings on lung function testing does not have a positive predictive value for the development of future lung disease in patients with SLE who are free of respiratory symptoms. Our results suggest that a finding of low diffusion capacity in asymptomatic patients with SLE does not necessarily require further evaluation and imaging and may improve spontaneously over time. Further studies in a larger group of patients are needed to validate these findings.

How Important Is Physical Activity for Patients with Systemic Lupus Erythematodes? -Results of Lula-Study. Isabelle Kloubert[1], Gamal Chehab[1], Jutta Richter[2], Rebecca Fischer-Betz[3], Ralph Brinks[2] and Matthias Schneider[1]. [1]Heinrich-Heine-University Duesseldorf, Duesseldorf, Germany, [2]Heinrich-Heine-University, Düsseldorf, Germany, [3]University of Düsseldorf, Düsseldorf, Germany.

Background/Purpose: Physical activity (PA) plays a decisive role in primary and secondary prevention in various domains of medicine. Our examination aimed to determine association PA and on outcomes in systemic lupus erythematodes (SLE).

Methods: The LuLa-Study is a prospective long-term study since 2001, which systematically collects patients' reported outcomes among members of the German SLE Self-Help Organization. In 2006 and 2009 we analysed data of 750 patients (94.4% female, age 52.3±12.9 years (mean±SD), duration of disease 15.9 years in 2009) with regard to their PA applying the "Freiburger Questionnaire on physical activity". We calculated the Metabolic Equivalent of Task (MET) for every patient. In the univariate analysis we compared 422 patients with low/intermediate PA (<30 MET, n=259) to those with high/very high activity (>30 MET, n=163) in both years. Furthermore, we examined the association of PA to disease activity, HRQoL (SF-12) and clinical symptoms in a multivariate regression analysis with age, sex, BMI and number of comorbidities.

Results: The medium MET of the group with low/intermediate PA was 13.4±7.6 respectively, 73.9±31.5 with high/very high PA. A high PA in 2006 and 2009 was associated with less cephalgia ($p<0.006$) and muscle weakness ($p<0.009$) and with lower disease activity in 2009 (determined with SLE Activity Questionnaire (SLAQ) and VAS; $p<0.001$). No statistically significant relation between PA and myalgia or arthralgia could be found. Patients with high MET in 2006 and 2009 showed a better HRQoL (Physical Component Summary ($p<0.001$) and Mental Component Summary ($p<0.014$) determined with SF 12) in 2009. Both groups of activity improved their emotional HRQoL between 2006 and 2009, whereas the physical HRQoL stagnated in both groups. A higher PA in 2006 and 2009 was connected to a lower damage (determined by System Lupus International Collaborating Clinics/ACR Damage Index for SLE (SLICC-) Score; $p<0.012$) as well as to an improved fatigue (Vanderbilt Fatigue Score (VFS); $p<0.001$) and a different cognition of pain (FSS-Score; $p<0.001$) in 2009. The multivariate analysis included all 750 patients (medium MET in 2006 28.5±26.1, in 2009 34.5±37.7) and affirmed the influence of higher MET to the above outlined scores. It could be shown, that a higher PA of 10 MET is related to a decreasing SLAQ (−0.43 points) three years later ($p<0.001$). This effect remained after adjusting for the covariates. The same activity of 10 MET in 2009 is only associated with a decreasing SLAQ (−0.30 points) ($p<0.001$). A similar observation could be depicted for emotional and physical HRQoL.

Conclusion: PA of SLE patients does have an impact on clinical manifestations and is related to a higher HRQoL. As increased PA has an impact on HRQoL and SLAQ three years later, a recommendation of more PA seems reasonable.

702

Protein Losing Enteropathy in Systemic Lupus Erythematosus. Doo-Ho Lim, Seung-Hyn Bae, Soo Min Ahn, Seokchan Hong, Yong-Gil Kim, Chang-Keun Lee and Bin Yoo. University of Ulsan College of Medicine, Asan Medical Center, Seoul, South Korea.

Background/Purpose: Protein losing enteropathy (PLE), characterized by severe hypoalbuminemia and edema, is rare manifestation of systemic lupus erythematosus (SLE). The study was proposed to identify the distinct features of lupus PLE and to evaluate the factors related with treatment response or outcome of lupus PLE.

Methods: From Mar. 1998 to Mar. 2014, the clinical data of 14 patients with lupus related PLE (lupus PLE) and 7 patients with idiopathic PLE in tertiary center were reviewed. PLE was defined as demonstration of protein leakage from gastrointestinal tract by either technetium 99m-labelled human albumin scan or fecal α1-antitrypsin clearance with no evidence of protein loss from other sources and impaired protein synthesis. Positive steroid response (PSR) was defined as return of serum albumin to ≥ 3.0 g/dl within 4 weeks after initial steroid monotherapy and remission as maintenance of serum albumin ≥ 3.0 g/dl for at least 3 months. High total cholesterol means the serum total cholesterol level of ≥ 240 mg/dl.

Results: The mean age of lupus PLE was 37.0 ± 19.8 years (range: 16 – 72) and 11 patients (78.6%) had PLE as initial manifestation of SLE. The mean follow-up duration was 55.8 ± 16.0 months (range: 6 – 172). There were significant increases in ESR and total cholesterol level in lupus PLE compared with idiopathic PLE. Among 14 patients with lupus PLE patients, 8 patients experienced PSR. Total cholesterol level was significantly higher in PSR group (Table 1). PSR was associated with initial high total cholesterol (OR = 7.0, 95% CI = 1.14 – 42.97) and with achievement of remission in 6 months (OR = 3.0, 95% CI = 0.97 – 9.30). Among 14 patients with lupus PLE, 10 patients who achieved remission in 6 months showed higher total cholesterol level (283.3 ± 79.3 mg/dL) compared to 4 patients who did not (165.3 ± 63.9 mg/dL).

Conclusion: In lupus PLE, high total cholesterol level could be a predictive factor to initial steroid response, expecting good response to steroid therapy alone. Furthermore, we suggest that initial high level of total cholesterol could predict a favorable outcome in patient with lupus PLE.

Table 1 Characteristics of lupus related PLE patients according to steroid response

Characteristic	Positive steroid response (n=8)	Negative steroid response (n=6)
Age, years	37.0 ± 19.8	48.3 ± 7.7
Sex, male (%)	4 (50)	2 (33.3)

Autoimmune Hepatitis in Systemic Lupus Erythematosus. Doo-Ho Lim, Seung-Hyeon Bae, Soo Min Ahn, Seokchan Hong, Yong-Gil Kim, Chang-Keun Lee and Bin Yoo. University of Ulsan College of Medicine, Asan Medical Center, Seoul, South Korea.

Background/Purpose: Autoimmune Hepatitis (AIH) is a chronic progressive liver disease of unknown cause, characterized by circulating autoantibodies and hyperglobulinemia. Patients with AIH often have other autoimmune diseases such as autoimmune thyroiditis and ulcerative colitis. However, AIH accompanied by SLE (AIH-SLE overlap) is relatively rare condition. The aims of our study were to identify the distinct features of AIH-SLE overlap compared with primary AIH (PAIH) and to evaluate the factors related with outcome of AIH-SLE overlap.

Methods: From May. 1995 to Feb. 2014, the clinical data of 164 patients with PAIH and 23 patients with AIH-SLE overlap in a tertiary referral center were reviewed retrospectively. AIH was diagnosed if pretreatment or posttreatment score was above 9 or 11, according to AIH diagnostic scoring system of American Association for the Study of Liver Disease in 2002. Liver biopsy was performed in all AIH patients. SLE patients fulfilled at least 4 of the 1997 revised American College of Rheumatology criteria. Progression was defined as occurrence of liver cirrhosis (LC), hepatocellular carcinoma (HCC), liver transplantation (LT) or death from hepatic failure.

Results: The mean follow-up duration of AIH-SLE overlap and PAIH were 7.62 ± 4.13 years (range: 1.5 – 16) and 6.23 ± 4.21 (0.5 –17.5), respectively (Table 1). The age at AIH diagnosis was younger and initial serum IgG level was higher in AIH-SLE overlap ($P < 0.005$). There were no significant differences of histological findings and treatment strategy. Although proportion of overall progression was not different, severe progression such as HCC, LT or death only happened in PAIH patients. Among 23 patients of AIH-SLE overlap, 8 patients with progression showed higher serum IgG level (4077.38 ± 1641.02 mg/dl) compared to 15 patients without progression (2560.71 ± 932.24) ($p=0.017$). Furthermore, progression in AIH-SLE overlap was associated with serum IgG level of above 2 folds upper limit of normal (OR = 11.00, 95% CI = 1.420 – 85.201, P = 0.026).

Conclusion: The clinical course of AIH might be expected less aggressively in AIH-SLE overlap than PAIH. In addition, we could suggest that initial high level of serum IgG is a poor prognostic factor in patients with AIH-SLE overlap.

Table 1. Characteristics of AIH-SLE overlap and PAIH

Characteristic	AIH-SLE overlap (n = 23)	PAIH (n = 164)
Age at AIH diagnosis, years[a]	37.35 ± 12.55	49.98 ± 12.365
Sex, female (%)	23 (100)	149 (90.9)
Follow up, year	7.62 ± 4.13 (1.5 – 16)	6.23 ± 4.21 (0.5 – 17.5)
Other autoimmune disease (%)	4 (17.4)	21 (12.8)
Arthritis (%)[a]	9 (39.1)	27 (16.6)
Leukopenia (%)	3 (13.1)	25 (15.2)
Thrombocytopenia (%)	11 (47.8)	44 (26.8)
Protein, g/dl	8.40 ± 1.10	8.02 ± 4.07
Albumin, g/dl	3.42 ± 0.70	3.53 ± 0.2
AST, IU/l	402.43 ± 444.87	432.40 ± 552.15
ALT, IU/l	372.70 ± 514.39	355.34 ± 468.92
Alkaline phosphatase, IU/l	235.39 ± 176.12	165.20 ± 116.71
GGT, IU/l	168.24 ± 190.10	162.44 ± 250.23
Total bilirubin, mg/dl	5.99 ± 10.60	5.57 ± 6.83
Serum IgG, mg/dl[a]	3112.23 ± 1411.84	2419.23 ± 899.64
Autoantibody	23/23 (100)	141/162 (87)
anti nuclear antibody (%)	8/21 (38.1)	42/161 (26.1)
anti smooth muscle antibody (%)	1/17 (4.3)	0/136 (0)
anti LKM1 (%)	0/22 (0)	6/160 (3.8)
anti mitochondrial antibody (%)		
Biopsy	16 (69.6)	93 (56.7)
interface hepatitis (%)	5 (21.7)	35 (21.3)
plasma cell infiltration (%)	2 (8.7)	3 (1.8)
rosette (%)	6 (26.1)	23 (14)
biliary change (%)		
Progression at AIH diagnosis (%)	4/23 (17.4)	37/164 (22.5)
Progression after AIH diagnosis (%)	4/19 (21.1)	45/127 (35.4)
liver cirrhosis	4 (21.1)	38 (29.9)
hepatocellular carcinoma	0 (0)	1 (0.8)
liver transplatation	0 (0)	3 (2.4)
death from hepatic failure	0 (0)	3 (2.4)

Utility and Associated Risk of Pulmonary Embolism CT Scans in the Michigan Lupus Cohort. Ruba Kado[1], Emily Siegwald[2], Emily Lewis[2], Mitch Goodsitt[2], Emmanuel Christodoulou[2], Ella Kazerooni[2] and W. Joseph McCune[2]. [1]University of Michigan, Ann Arbor, MI, [2]University of Michigan, Ann Arbor, MI.

Background/Purpose: Ionizing radiation from CT scanning can increase cancer risk. Lupus patients are frequently evaluated for chest pain and may have multiple pulmonary embolism CT (PE-CT) scans in addition to other exposures to diagnostic or therapeutic radiation.

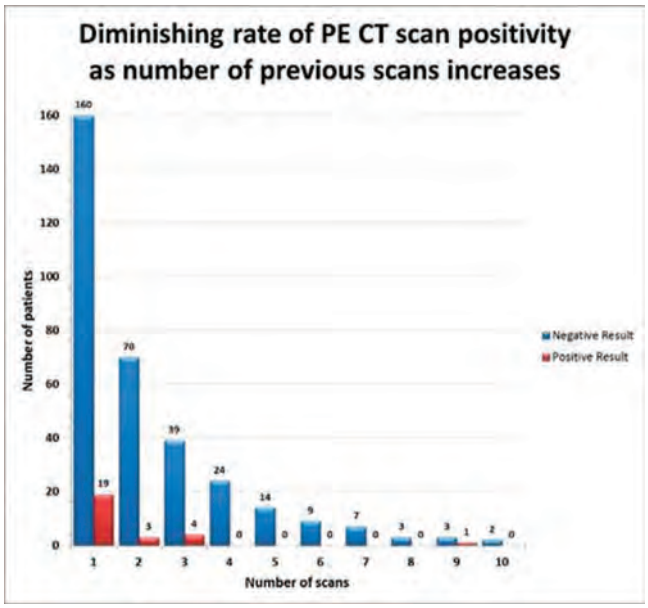
The objective of this study is twofold i) Determine the incidence of PE in University of Michigan Lupus Cohort patients who have undergone PE -CT scans ii) Estimate associated breast and lung cancer incidence.

Methods: We reviewed records of patients in the Michigan Lupus Cohort (N=856), and for each patient determined the number and outcome of PE-CT scans. All patients gave informed consent for review of their records. Based on estimated x-ray exposure from a state of the art GE Discovery CT750 HD CT scanner for an arterial chest scan, we estimated radiation dosage to the breast and lung in an average sized adult woman, utilizing CT-Expo software package.{1] We used the dose information and the patient's age at the time of the CT scan and tabulated risks according to the BEIR VII report to estimate the increased lifetime incidence risks of breast and lung cancer. Risks from multiple CT scans were summed.

Results: 183/856 (21%) patients underwent a total of 358 PE CT scans. The overall rate of positivity was 7.5%. The likelihood of a positive scan decreased in proportion to the number of scans that had been previously performed. (Figure 1) For patients undergoing their first through third CT scans the rate of positivity for PE was 9.2 %, whereas patients undergoing their fourth through tenth CT scans had 1.6% positivity.

We estimated radiation doses of to the breast and lung in female patients from a PE CT arterial scan, as 20mGy and 22mGy respectively. Separating patients based on age and number of CT scans, the estimated lifetime increase incidence risk of breast and lung cancer was calculated. In this simplified model the range of added risk for breast and lung cancer respectively per 100,000 female patients was 0–100 in 72% and 72%; 100– 500 in 25% and 28% and 500– 1000 in 4% and 1%.

Image/graph:



Conclusion: Patients with multiple previous PE CT scans had lower likelihood of a positive result on subsequent scans and higher risks of malignancy. Our conservative estimates of radiation exposure, that do not account for higher radiation doses from older CT scanners, indicate sufficient risk to warrant more precise characterization of radiation exposure in this population; and encourage development of guidelines for PE screening for patients with systemic lupus erythematosus and recurrent chest pain. The magnitude of risk should not discourage performance of PE CT when clinically indicated.

Lupus Chest Pain in the Emergency Department: a Common Diagnostic Dilemma. Masoom Modi[1], Mariko L. Ishimori[1], Daniel J. Wallace[2] and Michael Weisman[1]. [1]Cedars-Sinai Medical Center, Los Angeles, CA, [2]Cedars-Sinai/David Geffen School of Medicine at UCLA, Los Angeles, CA.

Background/Purpose: Chest pain (CP) is a common symptom reported by SLE patients often leading to presentation to Emergency Departments (ED). The origin of CP can be attributed to many causes, which may or may not be cardiac in nature. It is important to understand the prevalence of CP in SLE, with ED visits being a window of opportunity for early detection of SLE heart disease.

Methods: Billing records of patients who presented to Cedars-Sinai Medical Center ED with ICD-9 codes for SLE between 3/2009–10/2013 were reviewed; this data was then examined for secondary ICD-9 codes for CP (786.50–786.59). Two study groups were formed, based on discharge from ED vs. hospital admission. Visits were evaluated for basic cardiac work up with EKG and cardiac enzymes, and number of visits by individual patient recorded. Hospital admissions were evaluated for CP etiology and discharge

diagnoses. Continuous variables were analyzed by paired t test, and categorical data by chi squared test.

Results: Of 2675 ED visits with ICD-9 codes for SLE; 397 had secondary codes for CP (15%). Of the 397 SLE and CP visits, 173 visits were discharged directly from the ED and 224 visits became hospital admissions.

The ED discharged group was significantly younger ($p<0.0005$) compared with the hospital admitted group.

ED discharge group: The 173 ED visits were accounted for by 127 unique patients. 77% of these visits received a basic cardiac work up. While most patients had just 1 visit, a small number (7%) were frequent users of the ED, with an estimated one fourth of all visits.

Hospital Admitted Group: The 224 admissions were accounted for by 161 unique patients. 92% of admitted patients received a basic cardiac work up.

CP in the hospitalized group: The most commonly listed discharge diagnoses based upon primary physician's work up and opinion, and the listed diagnoses for CP in the discharge summary are shown in Table 1. Rule out of Acute Coronary Syndrome (28.6%) was the most common diagnosis. Over 50% of CP at discharge was attributed to non-cardiac causes.

Conclusion: Of all SLE coded patients presenting to the CSMC ED over a 4.5 year period, 15% had complaints of CP, which is higher than the national average for CP in non-SLE patients (10%). Frequent ED users (3 or more visits) made up only 7% of the total sample, but accounted for 24% of all the ED visits. Over90% of admitted patients had a basic cardiac work up performed. However, only a small percentage had a discharge diagnosis that was related to cardiovascular disease (7.2%). There is a high percentage of a negative cardiac work up with a majority of non-cardiac diagnoses in SLE patients, strengthening the need for more research into improved biomarkers or more specific imaging techniques to assess the etiology of CP. This study was a first step in revealing the high prevalence of CP in SLE patients presenting to the ED, while examining the limited diagnostic capabilities of a traditional cardiac work up.

Table 1: Chest Pain in the Hospitalized Group

Discharge Diagnosis	Percentage of Admissions
Cardiovascular Disease (CAD, MI, Unstable Angina, Microvascular Disease)	7.2%
Pericarditis (SLE related)	3.1%
Other Cardiac NOS (CHF, Arrhytmia, PVD)	4%
Rule out of Acute Coronary Syndrome	28.6%
Musculoskeletal/ Costochondritis	24.6%
Pulmonary (Pulmonary Embolism, Pneumonia, COPD)	13.8%
Gastro-Intestinal	8.9%
Multi-Factorial	9.8%

Humoral Immunodeficiency in Patients Presenting with Clinical Features of Systemic Lupus Erythematosus. W. Winn Chatham[1], Duncan Harmon[1] and Harry W. Schroeder Jr.[2]. [1]University of Alabama at Birmingham, Birmingham, AL, [2]University of Alabama-Birmingham, Birmingham, AL.

Background/Purpose: Humoral immunodeficiency syndromes including common variable immune deficiency (CVID) are not uncommonly associated with autoimmunity. The spectrum of autoimmune disorders encountered in CVID patients may include features seen in systemic lupus erythematosus (SLE). Studies were undertaken at an academic center managing both disorders to determine the relative prevalence, clinical features, and outcomes of immunodeficiency associated SLE.

Methods: A retrospective review of records of patients seen between 2011 and 2014 with suspected humoral immunodeficiency and SLE was undertaken. Records for review were identified using an electronic medical record search of diagnosis codes for SLE and hypogammaglobulinemia. The clinical and immunologic profile was determined for patients with confirmed or suspected SLE who also had undergone evaluation for humoral immunodeficiency.hods.

Results: We identified 36 patients meeting ACR criteria for SLE with inadequate response to pneumococcal vaccine challenge (failure to generate protective antibody titer to $\geq$ 5/14 pneumococcal vaccine antigens) and/or low serum IgG levels ($<$ 700 mg/dl) not attributable to antecedent immunosuppressive therapy. This comprised 5.5% of our SLE patients meeting ACR SLE criteria in active follow-up. An additional 30 patients with SLE clinical features but not meeting SLE ACR criteria were identified with low serum IgG and/or inadequate vaccine responses. Among the 36 identified patients meeting ACR SLE criteria, serum immunoglobulin levels ranged from 459–744 mg/dl; 33 (92%) had serum IgG levels $<$700 mg/dl, while 19 (53%) had inadequate response to pneumococcal vaccine challenge, including the three patients with serum IgG $>$ 700 mg/dl. Frequent upper/lower respiratory infections requiring antibiotic treatment ($\geq$3 episodes/year) were reported in 24/36 (67%) patients. SLE features developed 2–26 years (mean = 8.9 years) prior to the recognition of low serum IgG in 25 (69%) patients, whereas initial SLE features were noted concurrently with or 3–4 years following first confirmed low IgG levels in 11 (31%). Arthritis (75%), photosensitivity (81%), malar rash (61%) and mucosal ulcers (56%) were the most prevalent SLE features. Only 9 (25%) of patients had low complement C3 or C4 levels, 6 (17%) had cytopenias, and 2 (6%) had elevated levels of anti-dsDNA. The majority of patients were managed with antimalarials (86%), with 8/36 (22%) also using methotrexate; 18/36(50%) were on treatment with IVIG. Disease activity was low (SLEDAI score $\leq$2) in 32/36 (89%) at the last noted follow-up assessment.

Conclusion: SLE may be a presenting feature of patients with humoral immunodeficiency. Serum immunoglobulin levels and assessment of the response to pneumococcal vaccination for patients with low or low normal serum IgG levels should be included as part of the evaluation for suspected SLE, particularly in the context of frequent respiratory infections. Favorable outcomes are seen in the context of standard of care treatment for SLE combined with immunoglobulin replacement therapy.

Characteristics of Lupus Patients with Interstitial Lung Disease and Relationship with Jo-1 Antibody. Samera Vaseer[1], Judith A. James[2], Aikaterini Thanou[2] and Joan T. Merrill[2]. [1]University Of Oklahoma, Oklahoma City, OK, [2]Oklahoma Medical Research Foundation, Oklahoma City, OK.

Background/Purpose: Pulmonary involvement is frequent in systemic lupus erythematosus (SLE) and can affect the pleura, pulmonary vasculature, and parenchyma. The prevalence of ILD is lower in SLE than in the other CTDs (3–13%). While ILD in SLE is usually mild, it can be progressive or severe in some patients. We aimed to determine clinical and serological characteristics of SLE patients with symptomatic ILD in an outpatient longitudinal lupus cohort.

Methods: The Oklahoma Lupus Cohort consists of a longitudinal cohort of patients who meet 1997 ACR criteria for SLE. Patients are enrolled after informed consent and their clinical and serological data are collected at routine clinic visits. Patients with pulmonary fibrosis or interstitial lung disease were identified using the database, and matched with 5–6 age and gender matched SLE controls without ILD. Data was collected using retrospective chart review. All patients included (n=110) fulfilled 1997 ACR criteria for SLE.

Results: Fifteen SLE patients with a concurrent diagnosis of pulmonary fibrosis or ILD were identified among 517 in SLE cohort giving a prevalence of 2.9%. Fourteen of 15 patients had imaging reports available for review and all patients had radiographic evidence of parenchymal lung involvement. Most commonly reported abnormalities were ground glass opacities and interstitial thickening or fibrosis mostly involving basilar regions followed by traction bronchiectasis, reticular pattern and fibrotic NSIP. Subpleural honeycombing and UIP were least common.

American Indians were 27% of those with ILD and 13% of controls. African Americans were evenly divided (37% cases, 37% controls). 53% of ILD patients had a diagnosis of anti-phospholipid syndrome vs. 32% of controls. Cases had a high rate of serositis history (78% vs. 38% controls, P value 0.006), anti-dsDNA (53% vs 23% p=0.02) and lymphopenia (47% cases vs. 17% controls, P value 0.016). There was a trend to increased frequency of anti-La (43%), anti-Sm (43%), RNP (53%) and lupus anticoagulant (33%) in ILD vs non-ILD (18%, 24%, 37% and 13% respectively, p= 0.07, 0.2, 0.2 and 0.06).

There were only 2 patients positive for anti-Jo1 among 517 SLE patients (0.4%); one by laser immunobead assay and immunodiffusion (patient A), the other by immunobead assay only (patient B). Both were among the cases with significant ILD. Both were African American females; had cytoplasmic ANA

pattern seen on IFA and were positive for anti ds-DNA. They had marked impairment of lung function with FVC 51% (patient A) and 22% (patient B) respectively. Only patient A had clinically significant myositis.

Conclusion: Clinically significant ILD is seen in a small proportion of SLE patients but can cause significant morbidity. Patients with ILD are more likely to have American Indian heritage, earlier history of serositis and positive anti-ds DNA. They may have a higher prevalence of anti-La (SS-B), anti-Sm, RNP and lupus anticoagulant. Testing for overlap syndromes with antibodies associated with ILD may provide useful prognostic information for these patients.

Determining Risk Factors That Increase Hospitalizations in Patients with Systemic Lupus Erythematosis. Hareth M. Madhoun[1], Wael N. Jarjour[1], Peter J. Embi[2], Erinn M. Hade[1] and W Neal Roberts Jr[3]. [1]The Ohio State University Wexner Medical Center, Columbus, OH, [2]The Ohio State University, Columbus, OH, [3]University of Louisville, Louisville, KY.

Background/Purpose: Systemic lupus erythematosis (SLE) is a complex heterogeneous disease which can be associated with significant morbidity and mortality. Hospitalization and readmissions have garnered significant attention in recent years through Medicare reimbursement adjustments. The aim of this study was to determine what factors may increase the risk of hospitalization in patients with SLE. The goal of this project is to develop a lupus specific computerized decision support prompt to improve care and reduce hospitalizations.

Methods: Between 2006–2011, patients with an ICD-9 code of SLE were selected. Additional information that could be relevant to risk profiling were extracted, including: laboratory results, medications, appointments (scheduled and/or kept), and hospitalizations. Patients were divided into two groups: hospitalized and non-hospitalized. Hospitalized patients selected for chart review and inclusion in the cohort, included any with an ICD-9 diagnosis of lupus as the primary reason for admission to the hospital. The non-hospitalized patients included any with an ICD-9 code for lupus who were seen by rheumatology. Patients were selected randomly from among all who met inclusion criteria. The risks associated with hypothesized risk factors, including proportion of missed appointments and creatinine levels, were estimated through weighted Cox regression models to account for patient selection into the study.

Results: 29 patients were selected who met the above lupus hospitalization criteria and 37 patients were randomly selected as non-hospitalized lupus controls. Patients were categorized into three groups based on the percentage of missed appointments (0% missed, >0%-33% missed, 33%-100% missed). Of the 60 patients with appointment data, 12 had no missed appointments, 27 (0–33%), 21 (33–100%). There was a trend toward an elevated risk of hospitalization for those with missed appointments and an elevated creatinine at their last appointment. In a multivariable model accounting for age and last creatinine measurement, patients who missed up to 33% of appointments, were estimated to have 2.92 (95% CI: 0.54–15.76) times the risk of patients who did not miss any appointments. Patients who missed between 33% and 100% of their appointments, the risk was 3.30 (95% CI: 0.52–20.96) times. The estimated risk of hospitalization associated with creatinine measure over 1.25 ml/dl at their last appointment was 4.72 (95% CI: 1.22–18.27) times the risk of those with with lower creatinine.

Conclusion: Patients with SLE appear to have an elevated risk of hospitalization with an increase in missed appointments and higher creatinine. Data about proportion of missed appointments or elevated creatinine might be used to trigger electronic health record-based decision support alerts about such risk that could lead to clinical interventions to help avoid hospitalizations. Further study with larger cohort samples is needed to confirm these findings and potentially identify other risk factors. Ongoing work will incorporate elements from the Systemic Lupus International Correlation Clinics damage index to enhance the predictive value of this model with the goal of helping to reduce hospitalization and readmission.

Impact of Sleep Disorders in Quality of Life, Pain and Disease Activity Using Actigraphy and Pittsburgh Sleep Quality Index (PSQI)in Female with Systemic Lupus Ertyhematosus (SLE). Lilian Reis[1], Marco Tulio de Mello[2] and Virginia M. Trevisani[3]. [1]Federal University of Sao Paulo - UNIFESP, SAO PAULO, Brazil, [2]Universidade Federal de São Paulo (UNIFESP), São Paulo, Brazil, [3]Federal University of São Paulo, São Paulo Brazil, Brazil.

Background/Purpose: Despite the fact that sleep disorders are poorly studied, they′re a frequent complain by patients with SLE (62 to 80% related) and others found their influence over morning fatigue. *Aim of study:* To assess the impact of sleep disorders in quality of life, pain, fatigue and disease activity in female with SLE.

Methods: *Patients and methods:* The actigraphy and sleep diary was used to measure sleep habits during 15 days in 34 female with SLE and who achieve Pittsburgh Sleep Quality Index (PSQI) equal or above 5. Quality of life was assessed through Short form health survey questionnaire (SF-36). Disease activity was measured with SLEDAI. Patients were divided into two groups, according categorical variables of PSQI scoring: less than 10 and more than 10 points. Mann-Whitney U test was used to compare SF-36 domains and the relationship between disease activity and sleep latency were analyzed with Pearson′s correlation coefficient. Significance level adopted was 5%.

Results: Thirty-four (34) female with SLE was analyzed (n=34; mean=43±10 years), disease time 9,5 ± 6,7 years. It was found some disabilities on SF-36 domain. Results of PSQI >10 had less points for Body pain (BP) (p-value=0,016) and role emotional (RE) (p-value=0,056). There wasn′t significant difference in physical functioning (PF) (p-value=0,730), role physical (RP) (p=*0,131*), general health (GH) (*p = 0,769*), vitality (*p = 0,219*), social functioning (SF) (*p = 0,187*) and mental health (MH) (*p = 0,334*). Furthermore the patients with PSQI >10 had longer sleep latency time when it was compared with the patients with PSQI<10 (p = 0,050). There was correlation between disease activity and sleep latency (r = 0,356; *p = 0,046*).

Conclusion: Our results suggest that the patients with PSQI >10 and disease activity are important factors that can affect the quality of life in patients with SLE.

Table 1. Comparison between SF-36 domains and PSQI categorical groups:

	PSQI

Splenectomy in Systemic LUPUS Erythematosus and AUTOIMMUNE Hematological Diseases. a Comparative Analysis. Luis J. Jara[1], Nahim Barron[2], Jesús Arenas-Osuna[3], Arturo Vélazquez-García[3], Arturo González-Zúñiga[3], Miguel A Saavedra[3] and Pilar Cruz-Domínguez[1]. [1]Hospital de Especialidades Centro Médico La Raza, IMSS, Mexico City, Mexico, [2]Hospital de Especialidades Centro Médico La Raza, México, Mexico, [3]Hospital de Especialidades Centro Médico La Raza, Mexico, Mexico.

Background/Purpose: Acute presentation of severe autoinmune thrombocytopenia, and hemolytic anemia in systemic lupus erythematosus (SLE) is associated with high mortality. Splenectomy is the second line of treatment.

The aim of this study is to investigate the efficacy and safety of splenectomy in refractory thrombocytopenia and hemolytic anemia associated or not with SLE.

Methods: From January 2004 to April 2014, 34 patients underwent splenectomy due to severe autoimmune thrombocytopenia and/or hemolytic anemia. The mean age of patients were 34.6 years old (range 18–62 y.o.) and twenty eight patients were female (82.35%). The patients were divided into two groups: Group 1: 18 patients with thrombocytopenia associated with SLE (9), SLE plus antiphospholipid syndrome, APS, (6), and primary APS (3). Group 2: 16 patients without SLE: Fisher-Evans Syndrome (2), and hemolytic anemia (14). All patients had refractory hematological manifestations, which were defined according to Mayo Clinic Criteria as: 1. If patients did not maintain platelets≥ 50,000 per ml for 2 weeks on medical therapy; 2. Medically dependent. 3. Medically intolerant. Patients with hemolytic anemia were submitted to surgery when they developed 2 hemolytic crisis (fever, jaudice, pallor, abdominal pain, and hemoglobin ≤ 6 grams per ml) despite to conventional treatment in a 6 months period. The response to splenectomy were considered for thrombocytopenia as follows: 1. Complete response: ≥150,000 platelets per ml, 2. Partial response: 50,000 to 149,000 per ml or 3. No response: < 50,000 per ml. The complete response for hemolityc anemia as hemoglobin ≥ 9 gr per ml. The inmediate response were evaluated after 7 days. The mean of follow up were 28.5 months (range3–96 months). Statistical Analysis: descriptive stadistics and Chi square Test.

Results: Open splenectomy was performed in 15/34 patients (44.11%) and laparoscopy in 19/34 patients, 3 converted to open surgery. The complete response were observed in 15/34, (44.11%).Group 1, 4/18 (22.2%) and Group 2, 11/16, (68.8%) (p=.006). After 30 days of surgery a complete response were observed in 11/18, (61.1%) for Group 1 and 13/16, (81.2%) Group 2 (p=NS). The complications in the inmediate post-operative period were observed in 6/34, 5 of Group 2 vs 1 in Group 1 (p=0.05). Infections in 3/34, one patient had bleeding and 2 had mesenteric and portal vein thrombosis respectively. In Group 1, the mean of period between hematologic manifestations and surgery was 17.8 months and in Group 2, 16.5 months. After follow up, in Group 1, the relapse were observed in 7/18 patients, and in Group 2, 3/16. In Group 1, steroids were reduced in 13/18 patients, and 14/16 patients of the Group 2.

Conclusion: This study suggest that patients with SLE, SLE plus APS and primary APS have a similar response to splenectomy compared with organ-specific autoinmune diseases despite a partial response in the inmediate period. Patients with organ-specific autoinmune diseases had a significant increase of complications. The splenectomy is safety and effective in severe and refractory hematologic manifestations.The surgery approach has not influence in the prognosis of splenectomy.

Is the Disease-Specific Lupusqol Sensitive to Changes of Disease Activity in SLE Patients after Treatment of a Flare? Kathleen McElhone[1], Jane Burnell[2], Chris Sutton[2], Janice Abbott[2], Peter Lanyon[3], Anisur Rahman[4], Chee-Seng Yee[5], Mohammed Akil[6], Yasmeen Ahmad[7], Ian Bruce[8], Caroline Gordon[9] and Lee-Suan Teh[1]. [1]Royal Blackburn Hospital, Blackburn, United Kingdom, [2]University of Central Lancashire, Preston, United Kingdom, [3]Nottingham University Hospitals NHS Trust, Nottingham, United Kingdom, [4]University College London, London, United Kingdom, [5]Doncaster and Bassetlaw Hospitals NHS Foundation Trust, Doncaster, United Kingdom, [6]Sheffield Center Rheumatic Dis, Sheffield South Yorkshire, United Kingdom, [7]Peter Maddison Research Centre, Bangor, United Kingdom, [8]Arthritis Research UK Epidemiology Unit, Institution of Inflammation and Repair, University of Manchester, NIHR Manchester Musculoskeletal Biomedical Research Unit, Central Manchester University Hospitals, Manchester Academic Health Sciences Centre, Manchester, United Kingdom, [9]Rheumatology Research Group, School of Immunity and Infection, College of Medical and Dental Sciences, University of Birmingham, Birmingham, United Kingdom.

Background/Purpose: With improving survival in SLE patients, patient-reported health-related quality of life (HRQoL) has become an important outcome. The LupusQoL is a disease-specific patient-derived HRQoL measure with good psychometric properties. The aim of the UK multi-centre LupusQoL Sensitivity Study is to assess whether the LupusQoL is sensitive to change when disease activity improves or deteriorates.

Methods: Patients with SLE (≥ 4 1997 ACR criteria), experiencing a flare (new A or B by BILAG-2004 Index) & requiring an increase in treatment (either prednisolone ≥ 20mg daily, introduction of methotrexate, parenteral steroids, cyclophosphamide &/or biologics) were recruited from 9 UK centres. Assessments were undertaken at baseline & monthly for 9 months after initiation of therapy & included BILAG-2004 disease activity index & the LupusQoL with 8 domains (physical health, pain, planning, intimate relationships, burden to others, emotional health, body image, fatigue) and scores ranging from 0 (worst) to 100 (best HRQoL). Changes in disease activity are defined (see Table – first column) as *deterioration*: major & minor and *improvement*: major & minor. Changes in LupusQoL domain scores when disease activity improved, deteriorated or was unchanged between consecutive time-points are reported as mean changes, with 95% confidence intervals (CI) constructed using robust standard errors to account for repeated patient assessments.

Results: Mean (SD) age was 40.9 (12.8) & duration since diagnosis was 9.3 (8.1) years for the 101 patients recruited; 94% females, 62.6% white Caucasians, 15.2% south Asians, 8.1% black Caribbean, 4% black Africans, 5% mixed, 1% Chinese. At baseline mean (SD) BILAG2004 score was 16.4 (8.1); all mean LupusQoL domain scores were < 52. LupusQoL physical health, pain & fatigue domain scores increased when BILAG improved (overall, major & minor). Physical health and pain domain scores decreased when there was a major BILAG deterioration but changes with a minor BILAG deterioration were small and non-significant. The effects of improvements & deterioration in BILAG on the LupusQoL domain scores were smaller or not present (Table).

Mean changes in LupusQoL Domain Scores (95% Confidence Intervals) between monthly visits

BILAG change category (Total n_{pat}=1100; n_{obs}=5724)	Physical health	Pain	Planning	Intimate relationships	Burden to others	Emotional health	Body Image	Fatigue
Major & Minor Deterioration (n_{pat}=73; n_{obs}=160)	−0.8 (−3.0 to 1.4)	−2.4 (−5.9 to 1.1)	−1.2 (−3.8 to 1.4)	2.6 (−1.3 to 6.5)	2.3 (−0.6 to 5.2)	−1.1 (−3.5 to 1.3)	0.5 (−2.2 to 3.2)	−1.0 (−3.5 to 1.5)
Major deterioration (any system to A from B/C/D &/or any 2Bs from C/D) (n_{pat}=32; n_{obs}=43)	−4.9 (−9.4 to −0.4)	−6.9 (−12.9 to −0.8)	−3.0 (−8.2 to 2.1)	4.3 (−6.6 to 15.2)	1.4 (−4.6 to 7.5)	−2.8 (−7.7 to 2.2)	−4.1 (−8.7 to 0.5)	−2.4 (−7.6 to 2.7)
Minor deterioration (one B from C/D & no new As) (n_{pat}=63; n_{obs}=117)	0.7 (−1.6 to 2.9)	−0.8 (−4.6 to 3.0)	−0.5 (−3.6 to 2.6)	2.0 (−1.5 to 5.5)	2.7 (−0.6 to 5.9)	−0.5 (−3.3 to 2.3)	2.2 (−1.0 to 5.4)	−0.5 (−3.3 to 2.4)
Major & Minor Improvement (n_{pat}=97; n_{obs}=199)	4.0 (1.9 to 6.1)	7.7 (4.8 to 10.5)	2.6 (0.1 to 5.1)	2.4 (−1.2 to 6.0)	2.4 (−0.1 to 4.8)	3.1 (0.8 to 5.4)	3.1 (0.1 to 6.1)	4.1 (1.7 to 6.5)
Major improvement (all As to B/C/D &/or all Bs to C/D) (n_{pat}=93; n_{obs}=162)	3.8 (1.3 to 6.3)	7.4 (4.2 to 10.5)	1.8 (−0.9 to 4.6)	2.6 (−1.6 to 6.7)	1.8 (−0.9 to 4.5)	2.7 (0.0 to 5.3)	3.4 (0.2 to 6.6)	3.3 (0.6 to 5.9)
Minor improvement (all As to B/C/D, some Bs to C/D but 1 persistent B) (n_{pat}≥4=; n_{obs}=37)	5.0 (0.6 to 9.3)	8.8 (2.2 to 15.5)	5.9 (−1.9 to 13.7)	1.8 (−4.4 to 7.9)	4.9 (−2.1 to 11.9)	5.0 (−0.3 to 10.4)	2.1 (−4.5 to 8.6)	7.8 (2.1 to 13.4)
Persistent active disease (all As or ≥ 2Bs unchanged) (n_{pat}=57;n_{obs}=127)	−0.9 (−2.7 to 0.9)	−0.9 (−3.6 to 1.7)	0.0 (−1.9 to 1.8)	−2.5 (−6.3 to 1.3)	−1.2 (−4.0 to 1.6)	0.3 (−1.7 to 2.3)	0.6 (−2.0 to 3.2)	2.0 (−0.7 to 4.7)
Persistent inactive disease (all systems remaining C/D) (n_{pat}=65;n_{obs}=238)	1.6 (0.6 to 2.7)	2.0 (0.5 to 3.5)	2.5 (0.9 to 4.0)	1.8 (−0.8 to 4.5)	4.1 (2.2 to 6.0)	2.3 (1.1 to 3.5)	0.2 (−1.2 to 1.5)	1.7 (0.2 to 3.2)

Conclusion: Improvement and deterioration of LupusQoL domain scores for physical health, pain & fatigue domain scores was seen in patients with significant changes in disease activity over 1 month. Sensitivity to change of other LupusQoL domains in relation to changes of disease activity may need to be evaluated over a longer interval as the more emotive type of response to the disease & its consequences may be latent and therefore not evident at monthly intervals.

Mapping the Disease-Specific Lupusqol to the SF-6D. Rachel Meacock[1], Mark Harrison[2], Kathleen McElhone[3], Janice Abbott[4], Sahena Haque[5], Ian N. Bruce[6] and Lee- Suan Teh[3]. [1]The University of Manchester, Manchester, United Kingdom, [2]University of British Columbia, Vancouver, BC, [3]Royal Blackburn Hospital, Blackburn, United Kingdom, [4]University of Central Lancashire, Preston, United Kingdom, [5]University Hospital of South Manchester, Manchester, United Kingdom, [6]NIHR Manchester Musculoskeletal

Biomedical Research Unit, Manchester Academy of Health Sciences, Manchester, United Kingdom.

Background/Purpose: The LupusQoL is a measure of health-related quality of life (HRQoL) developed specifically to assess the impact of systemic lupus erythematosus (SLE) and its treatment. Whilst producing a profile of scores, it is not preference-based, and therefore does not provide utility values. Such utility estimates are necessary to calculate quality-adjusted life years in economic evaluations, which are increasingly needed to guide decisions on how best to allocate health care resources.

The SF-6D (derived from the SF-36/SF-12) is a generic preference-based HRQoL measure which does provide utility scores. Despite evidence to support the validity of the SF-6D in SLE, and growing need for utility data, many trials fail to include a preference-based measure. One solution is empirical mapping; estimating a statistical relationship between a non-preference based and a preference-based measure using a dataset in which both measures have been administered to the same patients.

We aim to derive and test a mapping algorithm to predict SF-6D utility scores from the LupusQoL.

Methods: LupusQoL and SF-6D data were collected from 320 people with SLE at rheumatology outpatient clinics at 7 UK centres. Ordinary least squares regression was used to estimate models of increasing complexity to predict individuals' SF-6D scores from their LupusQoL responses. Model performance was judged on predictive ability through the size and pattern of prediction errors generated, using mean absolute error (MAE) and root mean squared error (RMSE) statistics. Performance of the selected model was externally validated on an independent data set of 113 females with SLE who had completed both the LupusQoL and SF-36. All patients met 4 or more of the ACR criteria for SLE.

Results: Mean age and disease duration of the estimation sample was 44.8 (SD 13.6) and 10.5 (SD 8.7) years respectively. The sample cover the full range of SF-6D scores, mean 0.615 (range 0.296–1.00). Figure 1 shows mean LupusQoL domain scores. Four LupusQoL domains (physical health, pain, emotional health, fatigue) were selected in the final model. The validation dataset were slightly older (mean age 48.6 (SD 9.3) years) with longer disease duration (mean 12.6 (SD 9.7) years), but had comparable range of SF-6D (0.327 – 1.00) and mean LupusQoL scores (Figure 1). Model fit was good in both the estimation data (*R2* 0.7219, MAE 0.0557, RMSE 0.0706) and when applied to the validation sample (*R2* 0.7431, MAE 0.528, RMSE 0.0663). The model predicts mean SF-6D utility in the validation sample extremely well (observed mean 0.624; predicted 0.617).

Conclusion: We provide a method by which utility values can be estimated from patient responses to the non-preference based LupusQoL, generalizable beyond the sample upon which it was estimated. Prediction errors, upon which mapping functions are primarily judged, were lower than those of published studies to date.

Lupuspro Is Responsive to Changes in Disease Activity over Time. David Giangreco[1], Hervé Devilliers[2], Narender Annapureddy[1], Joel A. Block[1] and Meenakshi Jolly[1]. [1]Rush University Medical Center, Chicago, IL, [2]Department of internal medicine and systemic diseases, Dijon, France.

Background/Purpose: Patient reported outcome (PRO) tools are important to understand, educate, manage, and follow patients with systemic lupus erythematosus (SLE). Disease targeted PRO for SLE (LupusPRO) has good reliability and has been validated in several languages and cultural contexts. LupusPRO could be better integrated into routine clinical care and clinical trials in SLE if it was also found to be responsive to physician assessed changes in disease activity. We sought to test the responsiveness of LupusPRO domains to changes in physician disease activity assessments in the routine clinical care setting.

Methods: Longitudinal data on LupusPRO and disease activity assessments were collected in the Rush Lupus Data Repository during routine clinical care visits. We tested only the responsiveness of the health related quality of life domains (HRQOL) as we expect these to change over short periods of time in response to disease activity. Disease activity assessments used as anchors for testing responsiveness included the SLEDAI physician global assessment (PGA), Total SELENA-SLEDAI, and the SELENA-Flare Index (SFI). Cut-offs used to determine change in disease activity were PGA (change of 0.3), SELENA-SLEDAI (change of 4), and SFI (remitting, stable and flaring). Non-parametric analysis of variance was used to compare changes in LupusPRO HRQOL domains against disease activity anchors.

Results: There were 658 visit data available for 185 patients. Consecutive visits were 2–5 months apart with a median number of visits per patient of 7. PGA was available for 651 visits; Total SLEDAI was available for 269 visits; SFI was available for 614 visits. Mean (SD) age and SELENA-SLEDAI were 43.5 (13.2) years and 6.4 (7.3), respectively. PGA changed significantly for 281 visit data (increased in 132, decreased in 142), while 377 visit data had unchanged PGA. LupusPRO HRQOL domains that changed significantly in the appropriate direction included Lupus Symptoms ($p<0.001$), Procreation ($p=0.03$), Pain-Vitality ($p=0.002$), Emotional Health ($p=0.06$), and Body Image ($p=0.03$). SELENA-SLEDAI changed significantly among 73 visits (32 increased, 41 decreased), and remained stable among 196 visits. LupusPRO HRQOL domains of Lupus symptoms ($p=0.0004$) and Pain-Vitality ($p=0.02$) responded significantly and in the appropriate direction. Significant changes in SFI were observed in 151 visit data (79 remitting, 72 flaring), while 463 visit data were unchanged. LupusPRO HRQOL domains that responded significantly in the appropriate direction in response to changes in SFI were Lupus symptoms ($p<0.001$), Procreation (p 0.005), Physical Health ($p=0.0006$) and Pain-Vitality ($p<0.0001$). Mixed model analysis supported similar results.

Conclusion: Most HRQOL domains of LupusPRO are responsive to physician-assessed changes in disease activity in the routine patient care setting. LupusPRO is an appropriate tool to be used not only in clinical trials but also in the clinical care setting.

The Validity of Patient and Physician Global Disease Activity Assessments of Systemic Lupus Erythematosus: Results from the Lupus Activity Scoring Tool (LAST) As Compared to the Selena Sledai (SS) Modification Multicentre Study. Majed Khraishi[1], Rana Aslanov[2], Sanjay Dixit[3], Ramin Yazdani[4], Vandana Ahluwalia[5] and Sarah Khraishi[6]. [1]Nexus Clinical Research, St John's, NF, [2]Memorial University of Newfoundland, St.John's, NF, [3]McMaster University, Hamilton, ON, [4]St. Clare' Mercy Hospital, St. John's, NF, [5]William Osler Health Center, Brampton, ON, [6]NL Research Technologies (NLRT), St. John's, NF.

Background/Purpose: In our centre, new tools for the assessment of SLE activity: the Lupus Activity Scoring Tool (LAST) and Clinical Lupus Activity Scoring Tool (C-LAST) were developed and validated. We aimed to validate the LAST and C-LAST in multiple clinical settings using their correlation to the SELENA SLEDAI modification, and to investigate the correlation of the specific components of the LAST (e.g. patient's and physician's global assessments of disease activity, steroid use) to the SS.

Methods: This multicenter study was initiated in five Canadian clinics: 3 in Newfoundland and 2 in Ontario. The LAST includes patient (PGA)and physician global assessment of disease activity (PHGA), C3, C4 and Anti-ds Anti-DNA titer abnormalities, and a formula incorporating the current immunomodulating medication. The C-LAST does not include laboratory test results. Patients who met the SLE ACR 1997 criteria update were recruited and evaluated in the study centres using LAST/C-LAST. Some of the patients

were prospectively followed and evaluated by the same tools at each visit. The SS was also calculated for each visit.

Results: Fifty-eight patients (84.5% females) with 98 assessments from five study centers were included in this analysis. The median age was 49.0 (Q1-Q3=33.8–60.3) years with the mean (SD) disease duration 12.1 (6.5) years. Scores from the LAST/C-LAST were obtained at each visit in addition to the SLEDAI scores. The mean (SD) SLEDAI score was 8.2 (5.2). The mean (SD) LAST (with C3, C4 and Anti-ds Anti-DNA) score was 30.5 (17.3) and C-LAST – 32.2 (20.1). The SS scores were consistent and strongly correlated with the LAST and C-LAST scores ($r=0.430$, $p<0.001$ & $r=0.215$, $p=0.034$, respectively) at the baseline and follow-up visits: SS scores 0–4 corresponded to the LAST scores of 0–30 while SS scores of 8 or higher corresponded to 50 and higher, respectively. Both SS and LAST scores were significantly correlated with current treatment with Prednisone ($r=0.305$, $p=0.002$ & $r=0.430$, $p<0.001$, respectively); LAST score was also correlated with Mycophenolate mofetil ($r=0.205$, $p=0.043$) and Azathioprine ($r=0.296$, $p=0.003$) treatments. Patient's (PGA) and Physician's (PHGA) Global Assessments of SLE activity were strongly correlated with each other ($r=0.759$, $p<0.001$) and with the LAST score ($r=0.781$, $p<0.001$ & $r=0.826$, $p<0.001$, respectively); PHGA was also significantly correlated with SELENA SLEDAI score ($r=0.324$, $p=0.001$). The LAST and C-LAST scores concurred in 90% of the assessments with $r=0.898$ and $p<0.001$.

We utilized an electronic application of the LAST which was easy to use and no errors were found with its results as compared to the manually obtained scores with the Pearson's correlation coefficient $r=0.995$ & $p<0.001$.

Conclusion: The Lupus Activity Scoring Tool (LAST) and C-LAST are new disease activity indices that correlate well with the SELENA SLEDAI modification. The use of simple clinical variables as a measure of SLE activity seems to be valid under different clinical settings with different assessors. The inclusion of patient's global assessment and the current use of steroids and immunomodulators can be utilized effectively in assessing disease activity.

715

The REAL Life with Lupus Study: Developing a Patient Reported Outcome Measure for Use in Clinical Trials and Clinical Care. R. Paola Daly[1], Sarah Gilman[1], Joan T. Merrill[2], Leslie M. Hanrahan[1], Alisha Ladenburg[1] and Anca Askanase[3]. [1]Lupus Foundation of America, Washington, DC, [2]Department of Clinical Pharmacology, Oklahoma Medical Research Foundation, Oklahoma City, OK, [3]Columbia University Medical Center, New York, NY.

Background/Purpose: The goal of this study is to better understand how people with systemic lupus erythematosus (SLE) in the United States experience the disease. **Results** will be used to develop a patient reported outcome instrument that will form half of the LFA-REAL™ system. The LFA-REAL™ will be a comprehensive system, comprised of complimentary clinician reported outcome (ClinRO) and patient reported outcome measures (PRO). This will be the first system that will allow, from both a physician and patient perspective, both global and organ-specific disease assessment, without complex forms and scoring algorithms. The LFA-REAL™ is undergoing qualification reviews by the United States Food and Drug Administration (FDA) in order to become accepted by the FDA for use in SLE clinical trials. This abstract describes the aims, methods and preliminary findings of the qualitative research used in development of this PRO.

Methods: This exploratory study was designed in two phases. During Phase I, a literature review was conducted, identifying common themes in the experiences of people with lupus. In-depth interviews were then completed with 11 participants, including three men and eight women from a diverse range of demographic and experiential backgrounds, including health history and lupus severity. All study participants were 18 years of age or older and confirmed formal lupus diagnosis by a rheumatologist. The interviews covered the following topics: diagnosis and current treatment, symptoms, experience receiving clinical care, and ideal tool development. Analysis of in-depth interviews was conducted using grounded theory analysis; subsequently a conceptual framework was created to capture emerging codes and themes. This framework was iteratively refined, through a stepwise analytical review. During phase 2, the resulting conceptual framework will be used to create a draft PRO instrument. The conceptual framework and draft PRO will be evaluated through patient and physician focus group discussions, iteratively refined, and finally, tested in tandem with the LFA-REAL™ ClinRO, through a pilot study and large scale validation trial.

Results: Our initial data confirm that, in addition to physical indicators of wellbeing, such as physical functioning, pain, fatigue, and acute and chronic symptoms, mental and emotional indicators of wellbeing are also important to people with lupus. Disease-related factors that cause anxiety or interfere with activities of daily living may be perceived as equally or more limiting than symptoms that indicate severe disease to an MD. Additionally, study subjects indicated that the ideal PRO should be able to track and rate symptoms with visual aids, assess symptoms over time and should also encourage open communication with their healthcare providers.

Conclusion: Findings show that patients view factors that cause anxiety and interfere with daily living as equally or more limiting than symptoms of severe disease. A two part system that addresses both physicians' and patients' views is likely to contribute to reconciling the discordance between physician and patient assessments of disease, improving short and long term outcomes in lupus.

Simple Disease Assessment for People with Lupus Erythematosus. Meenakshi Jolly[1], Winston Sequeira[2], Sergio Toloza[3], Ana M. Bertoli[4], Luis M. Vilá[5], Ivana Blazevic[6], Ioana Moldovan[7], Karina D Torralba[8], Berna Goker[9], Josiane Bourré-Tessier[10], Sandra V. Navarra[11], Daniel Wallace[12], Michael H. Weisman[13], Ann E. Clarke[14], Chi Chiu Mok[15] and Joel A. Block[1]. [1]Rush University Medical Center, Chicago, IL, [2]Rush University, Chicago, IL, [3]Hospital San Juan Bautista, San Fernando del Valle de Catamarca, Argentina, [4]Instituto Reumatológico Strusberg, Cordoba, Cordoba, Argentina, [5]University of Puerto Rico Medical Sciences Campus, San Juan, PR, [6]University of Buenos Aires, Buenos Aries, Argentina, [7]Beaver Medical Group, Redlands, CA, [8]University of Southern California, LA, CA, [9]Gazi University School of Medicine, Ankara, Turkey, [10]Division of Rheumatology, Centre Hospitalier de l'Université de Montréal, Montreal, QC, [11]University of Santo Tomas Hospital, Manila, Philippines, [12]UCLA, LA, CA, [13]Cedars-Sinai Medical Center, Los Angeles, CA, [14]University of Calgary, Calgary, AB, [15]Tuen Mun Hospital, Hong Kong, Hong Kong.

Background/Purpose: Community rheumatologists treating patients with Systemic Lupus Erythematosus (SLE) typically lack user-friendly tools to effectively track SLE disease activity. Current disease activity tools in SLE are resource and effort intensive, require special training and practice, take time, are difficult to implement in busy clinical practices and are of use almost exclusively to SLE researchers. Nonetheless, patient reported outcomes are recognized as important for patient care, and physician reimbursement (quality initiatives) and resource allocation are becoming tied to these outcomes. Here we report a novel user-friendly tool intended for daily clinical use In SLE.

Methods: Using our dataset of approximately 1,150 SLE patients from multiple countries and ethnicities that was accrued during the development of the LupusPRO, a disease targeted health outcome measure, we created multiple models with self reported SLE health survey items (LupusPRO), clinical variables (medications) and laboratory values that would correlate best with physician disease activity assessments (Physician Global Assessment and SLEDAI). Using stepwise regression methods, we parsed our model to keep it simple, included few and easily accessible laboratory values so it can be performed in most locations, and expected minimal real-time physician involvement. "SIMPLE" index equation was derived from the regression model with the best fit (**Sim**ple disease assessment for **P**eople with **LE**). We then prospectively tested the correlation between SIMPLE Index and Total SLEDAI in an independent dataset (n= 150) of SLE patients.

Results: SIMPLE index has two parts (i) patient self-report 16 items and (ii) two laboratory values obtained within 10 days before/after the visit. Requisite physician input pertains to (1) interpretation of one blood and one urine lab result in the context of SLE diagnosis, and (2) addition of weighted scores using a mobile application on a smart phone/computer by health personnel. The SIMPLE equation is as follows:

SI= 2- (0.03) LSX+ 0.02(LIT)+0.28(DHS)+0.95(CSU)+0.04(CSD)+ 5.6(UL)+2.4(BL), where Simple Index: SI, LupusPRO Lupus Symptom domain: 3 items (LSX), Lupus Impact Tracker: 10 items (LIT), Change in Health Status: 1 Item (DHS), Self Report of Current use of corticosteroid: I item (CSU), Self Report of current daily corticosteroid dose (Prednisone

equivalent in mg): 1 item (CSD), Urine Laboratory-Proteinuria (SLEDAI definition) (UL) and Blood Laboratory-Low complement C3/C4 (BL).

The SIMPLE index explained 55% variance of total SLEDAI score. In the second dataset, correlation of SIMPLE index with Total SLEDAI was strong (0.74, p=0.0001).

Conclusion: SIMPLE Index appears to correlate well with disease activity. It is easy, requires minimal physician training and involvement, and has the potential for quick integration into practice with minimal personnel resources. It also allows active patient engagement in care. Longitudinal studies are ongoing to confirm its utility and acceptability.

Comparison of Responsiveness of Lupus Impact Tracker with Lupus Quality of Life to Selena Responder Index. Hervé Devilliers[1], Narender Annapureddy[2], Winston Sequeira[3], Joel A Block[4] and Meenakshi Jolly[2]. [1]Department of internal medicine and systemic diseases, Dijon, France, [2]Rush University Medical Center, Chicago, IL, [3]rush university, chicago, IL, [4]Rush University, Chicago, IL.

Background/Purpose: Lupus Impact Tracker (LIT) is a 10-item patient reported outcome tool to measure the impact of Systemic Lupus Erythematosus (SLE) or its treatment on patients' daily lives. The transformed scores range from 0–100, where higher scores denote greater impact. The tool is responsive to self-reported changes in SLE health status over time. Herein, we compare the responsiveness of the LIT and LupusQoL (34 items) to changes in disease activity as judged by SLE responder index (SRI).

Methods: Adult SLE patients were prospectively recruited from 20 North American Rheumatology clinics for the LIT study- an observational, non-interventional prospective multi center study conducted across the US and Canada. Data (Demographics, LIT, LupusQoL, BILAG, SELENA-SLEDAI) were obtained three months apart. Modified SRI was defined as (1) a decrease in SELENA-SLEDAI (4 points), (2) No new BILAG A and not more than 1 new B and (3) No increase in Physician Global Assessment (PGA). Latter definition was used as our PGA variable was categorical (0/1/2/3). Standardized response mean (SRM) and effect size (ES) for LIT and LupusQoL domains were calculated among SRI responders and non-responders by taking the average difference divided by the standard deviation of the differences between the paired measurements at baseline and 3 month visit LIT scores. Kruskall Walis test was used to compare the SRM among SRI responders (R) and non responders (NR).

Results: 325 patients participated (90% Female); 53% Whites, 33% Black and 17% Hispanic. Mean (SD) age and SELENA-SLEDAI at baseline were 42.3 (16.2) yrs and 4.3 (3.8), respectively. Mean (SD) LIT score at baseline was 39.4 (22.9). SRI data was available for 295 (40 R and 255 NR) at the 3 month timepoint. LIT SRM (ES) was −0.69 (−0.36) and −0.20 (−0.12) among SRI responders and non-responders respectively, (p=0.02).

For LupusQoL, SRM (ES) for Physical health and Pain domains were 0.42 (0.23) and 0.65 (0.44) respectively.

Conclusion: 10 item LIT was modestly responsive to changes in disease activity as assessed by SRI in patients with SLE in this study Two domains (11 items) of LupusQoL showed responsiveness to SRI. Inclusion of the these tools in clinical care and clinical trials may provide further insight into its responsiveness.

	Responders (n=40)					Non-responders (n=255)

Safety of Gardasil® Vaccine in Systemic Lupus Erythematosu, Trial Update. J. Patricia Dhar[1], Lynnette Essenmacher[1], Renee Dhar[2], Ardella Magee[1], Harpreet Sagar[1], Malini Venkatram[1] and Robert Sokol[1]. [1]Wayne State University, Detroit, MI, [2]Central Michigan University College of Medicine, Mount Pleasant, MI.

Background/Purpose: Cervical neoplasia is increased in women with SLE presumably due to cervical infection with oncogenic Human Papillomavirus (HPV) types which persist in an immunosuppressed host. Vaccinating women with SLE against HPV is thus an important part of health prevention in this population. Gardasil® immunizes against the HPV types that cause the majority of cervical cancer (types 16 and 18) and genital warts (types 6 and 11), and has been shown to be protective against these HPV-related diseases.

Methods: For this ongoing trial**,** 36 women ages 19–50 years with a history of mild to moderate SLE and minimally active or inactive SLE disease received Gardasil® at the standard dosing schedule (0, 2 months, 6 months). This study was approved by the Human Investigation Committee at Wayne State University and the U.S. Food and Drug Administration. Patients were excluded if they had active disease (SELENA-SLEDAI >2), a history of severe disease, deep venous thrombosis, were on >400 mg/day of hydroxychloroquine, were on >15 mg/day of prednisone, or had active infections. To date, all 36 patients have completed the vaccine series shots. Patients were monitored for adverse events (AE), SLE flare, and generation of thrombogenic antibodies and thrombosis.

Results: The women in the study were predominantly African-American (81%), mean age 38.4 years with mean age at diagnosis of SLE at 29.4 years. All patients met American College of Rheumatology (ACR) criteria for SLE; 24.3% had a history of smoking, 92% had 4 or more sexual partners, 38.9% had a history of sexually transmitted diseases, and only 30.6% used condoms on a regular basis. History of abnormal pap smears occurred in 44.4% ranging from ASCUS (atypical glandular cells of undetermined significance) to CIN 3 (cervical intraepithelial neoplasia grade 3). Most of our patients had multiple comorbidities in addition to SLE. Vaccine site reactions (VSRs) occurred in 55%, all being mild, with the most common reaction being pain. This compares favorably to data from the current prescribing label showing frequency of VSRs in normal women to be 83.9% for Gardasil® vs. 75.4% for controls. For the non-vaccine site adverse events (nvAE), 90% of our cohort experienced at least one nvAE; there were 467 nvAEs reported from 36 patients and 90% of these nvAEs were mild. There were 9 serious adverse events, none were related to vaccine or SLE and all resolved. The most common nvAEs reported were musculoskeletal (n=99) followed by nervous system (n=93, mostly headaches), gastrointestinal (n=46), general disorders (n=46) and dermatologic (n=45). None of the nvAEs were related to vaccine or SLE. There was no flare of SLE, thrombosis, or generation of thrombogenic antibodies in any patient.

Conclusion: Preliminary data from our study shows that Gardasil® vaccine is safe to use in women with SLE. Vaccine site reactions are not increased in SLE patients. Other than vaccine site reactions, there were no related short term adverse events. Gardasil® vaccine administration did not result in any lupus flare or thrombosis. Women with SLE should be immunized with Gardasil® vaccine as part of their health prevention program, particularly since this population is at increased risk for HPV-related cervical dysplasia.

Target Modulation of a Type I Interferon (IFN) Gene Signature with Sifalimumab or Anifrolumab in Systemic Lupus Erythematosus (SLE) Patients in Two Open Label Phase 2 Japanese Trials. Chris Morehouse[1], Linda Chang[2], Liangwei Wang[1], Philip Brohawn[1], Shinya Ueda[3], Gabor Illei[4], Warren Greth[1], Stephen Yoo[1], Lorin Roskos[4], Yihong Yao[5], Gabriel Robbie[5] and Brandon W. Higgs[1]. [1]MedImmune, LLC, Gaithersburg, MD, [2]MedImmune, Hayward, CA, [3]Astrazeneca, Osaka, Japan, [4]Medimmune, Gaithersburg, MD, [5]MedImmune, Gaithersburg, MD.

Background/Purpose: The pharmacokinetic (PK) and pharmacodynamic (PD) effects of two investigational monoclonal antibodies inhibiting type I IFN signaling - sifalimumab or anifrolumab, specific for IFN-α or IFN-α receptor subunit 1 (IFNAR1), respectively were assessed in the blood of adult SLE Japanese patients.

Methods: Two phase 2 randomized, open label, dose-escalation studies were conducted in adult Japanese patients with SLE - AZD2800C (sifalimumab; N=30) and AZD3461C (anifrolumab; N=17). Patients enrolled in both studies satisfied ACR classification criteria. AZD2800C included dose cohorts of 1, 3, and 10 mg/kg (mpk) administered intravenously (IV) every 4 weeks; 100 mg subcutaneously every 2 weeks; and 600 and 1200 mg IV every 4 weeks. AZD3461C included dose cohorts of 100, 300, and 1000 mg administered IV every 4 weeks. In both studies, blood specimens were collected for PK and PD assessment at multiple time points between predose and 169 days (anifrolumab) or 365 days (sifalimumab) after initial administration. Sifalimumab and anifrolumab concentrations were measured using a validated electrochemiluminescence assay and PK parameters were determined by noncompartmental analysis. Transcript profiling was conducted with qRT-PCR on a 21 IFN gene signature (IFNGS).

Results: Sifalimumab exhibited linear pharmacokinetics with a half-life of about 20 days while, anifrolumab exhibited nonlinear pharmacokinetics. Trough concentrations of both sifalimumab and anifrolumab reached steady state by Day 84. In AZD2800C and AZD3461C, 97% and 88% of patients had elevated IFNGSs at baseline, respectively. In AZD2800C, maximum median suppression of the IFNGS was 63% with 1 mpk, 48% with 3 mpk, 67% with 10 mpk, 37% with 100 mg SC, 76% with 300 mg, and 61% with 1200 mg and was observed within 1 to 3 days of dosing with sifalimumab. In AZD3461C, maximum median suppression of the IFNGS by anifrolumab was 6% in the 100 mg (day 85), 85% (day 169) in the 300 mg, and 97% (day 85) in the 1000 mg cohort, with sustained suppression (>70% and >95%) in the 300 and 1000 mg cohorts after days 141 and 29, respectively. The level of suppression correlated well with increased anifrolumab concentrations. There were no major safety issues in the small sifalimumab and anifrolumab Japanese open-label trials (AZD2800C and AZD3461C, respectively) at the dose regimens studied but there is inadequate data to fully characterize the safety profile adequately and overall safety needs to be confirmed in larger double-blind controlled studies.

Conclusion: Both sifalimumab and anifrolumab showed expected mechanism of action in SLE, with anifrolumab having increased and more sustained target suppression of the IFNGS in Japanese SLE patients compared to sifalimumab.

Measures of Disease Status in Systemic Sclerosis: Systematic Review. Tien Tay[1], Nava Ferdowsi[1], Wendy Stevens[1], Marie Hudson[2], Murray Baron[2], Candice Rabusa[1], David Prior[1], Susanna Proudman[3] and Mandana Nikpour[1]. [1]The University of Melbourne at St Vincent's Hospital, Melbourne, Australia, [2]Lady David Institute for Medical Research and Jewish General Hospital, Montreal, QC, [3]Royal Adelaide Hospital, Rheumatology Unit and University of Adelaide, Discipline of Medicine, Adelaide, Australia.

Background/Purpose: To identify the measures of disease status in systemic sclerosis (SSc) using a systematic review.

Methods: A systematic review of Medline (1966–2014), EMBASE (1974–2014), and Cochrane Library (inception-2014) was undertaken to identify indices of disease status in systemic sclerosis. We focussed on objective measures and excluded non-English articles, animal-only studies and those relating to morphea, localized scleroderma or juvenile systemic sclerosis.

Results: Of the 5687 articles identified through the search, we identified 45 articles for review. We found a further 22 articles through a search of the bibliography of relevant articles. We identified 10 'composite' (multi-organ) indices: two disease activity indices, six disease severity scales, and two combined response indices (Tables 1 and 2). There was no disease damage index for SSc. Furthermore, we found no objective organ-specific index for the gastrointestinal system.

Conclusion: We identified a number of composite and organ-specific indices in SSc, incorporating subjective and/or objective measures, developed to quantify disease activity, severity and response in clinical trials. Most of the existing indices require further evaluation according to the OMERACT filter. None of the indices measures organ damage per se, highlighting this as an area for future research.

Muscle Disease in Systemic Sclerosis Is Associated with an Increased Risk for Cardiac Involvement. Jison Hong[1], Antonia Valenzuela[1], David Fiorentino[2] and Lorinda Chung[1]. [1]Stanford University School of Medicine, Palo Alto, CA, [2]Stanford University, Redwood City, CA.

Background/Purpose: Patients with systemic sclerosis (SSc) and muscle involvement (myopathy/myositis) have more severe disease and worse outcomes. We sought to determine the prevalence of muscle disease in our cohort of SSc patients and to compare these patients to those without muscle disease.

Methods: We conducted a retrospective medical record review of patients with SSc according to 2013 ACR classification criteria, evaluated at Stanford from 2006–2013. We collected demographics, clinical features if ever present, Manual Muscle Test 8 (MMT-8), laboratory data (available autoantibody results and muscle enzymes: CPK, aldolase, LDH, AST and ALT). Muscle involvement was defined by the presence of any of the following criteria: elevation in muscle enzyme(s), physician reported history of myopathy/myositis, and if performed, electromyelogram, MRI, and/or muscle biopsy results consistent with myopathy/myositis. Comparisons between SSc patients with and without muscle disease

were made with Student's t-test for continuous variables and chi-square or Fisher's exact test for categorical variables.

Results: The study included 273 patients (mean age 57.3 years, 88.7% female, 54.6% Caucasian, 37.4% diffuse, and 62.6% limited). Muscle disease was present in 80 patients (29.3%). The most common findings of muscle disease at presentation were elevated muscle enzymes (42.5%) and proximal muscle weakness (42.5%). The first manifestation of muscle disease occurred at a mean time of 7.1±11.1 years after the first non-Raynaud symptom of SSc. As expected, patients with muscle disease were more likely to have diffuse disease, arthralgias, myalgias, muscle weakness, dysphonia, mechanic hands, greater maximum modified Rodnan skin score, lower MMT-8 scores, and positive PM-1 antibody ($p<0.03$). They had less vascular manifestations such as Raynaud's phenomenon (73.8% vs 87.1%; $p=0.008$) and telangiectasias (7.5% vs 21.8%; $p=0.005$) and were less likely to be centromere positive (21.3% vs 36.3%, $p=0.02$). Cardiac disease was more common in patients with muscle disease (13.8% vs 5.7%, $p=0.03$).

Conclusion: 30% of our SSc cohort had muscle disease, which was associated with a higher likelihood of cardiac disease. Obtaining baseline and routine monitoring of muscle enzymes and performing strength exams at every visit may help to identify patients with SSc with muscle involvement who are also at risk for cardiac disease. The current development of a multi-center SSc cohort of patients with muscle disease led by SCTC and EUSTAR will help elucidate the pathophysiology and better define the subtypes of muscle disease in SSc.

Table 1. Baseline characteristics of 80 patients with muscle disease

	Patients n (%)
Disease duration from first Raynaud's symptom to muscle disease diagnosis (years ± SD)*	8.26 ± 10.9
Disease duration from first non-Raynaud's symptom to muscle disease diagnosis (years ± SD)*	7.1 ± 11.1
Symptom at presentation of muscle disease:	34 (42.5)
High muscle enzymes	12 (15)
Myalgias	34 (42.5)
Proximal muscle weakness	
Symptom at any time of muscle disease:	13 (16.25)
Myalgias	21 (26.25)
Subjective muscle weakness	13 (16.25)
Muscle weakness on physical exam	3 (3.75)
Dysphonia	24 (30)
Dysphagia related to muscle weakness

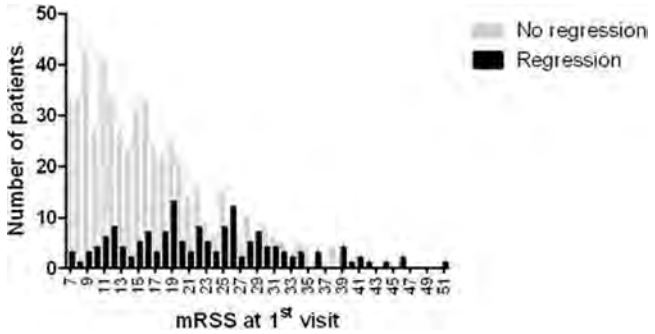
Prediction of Improvement in Skin Fibrosis in Diffuse Cutaneous Systemic Sclerosis. Rucsandra Dobrota[1], Britta Maurer[2], Nicole Graf[3], Carina Mihai[1], Otylia Kowal-Bielecka[4], Yannick Allanore[5] and Oliver Distler on behalf of the EUSTAR investigators and co-authors[2]. [1]Department of Internal Medicine and Rheumatology, Dr. I.Cantacuzino Hospital, Carol Davila University of Medicine and Pharmacy, Bucharest, Romania, [2]Division of Rheumatology, University Hospital Zurich, Zurich, Switzerland, [3]graf biostatistics, Winterthur, Switzerland, [4]Department of Rheumatology and Internal Medicine, Medical University of Bialystok, Bialystok, Poland, [5]Department of Rheumatology, University Paris Descartes and Cochin Hospital, Paris, France.

Background/Purpose: Improvement of skin fibrosis over time is part of the "natural history" of patients with diffuse cutaneous systemic sclerosis (dcSSc). However, in the individual patient, the pattern of change in skin fibrosis varies widely. The extent of skin fibrosis measured by the modified Rodnan skin score (mRSS) is the major outcome measure in clinical trials (CT) in dcSSc. Understanding the factors behind the improvement of skin fibrosis in dcSSc is important to avoid unnecessary use of therapy and medical resources. Moreover, it could improve cohort selection in CT using skin fibrosis as a major outcome.

Methods: A longitudinal analysis including 704 patients with dcSSc from the EUSTAR registry was performed. The inclusion criteria were diagnosis of dcSSc, fulfillment of ACR criteria, mRSS≥7 at baseline and available data for mRSS at 12±2 months follow-up. First entry into the database was defined as baseline. Skin improvement was defined as a decrease in mRSS of >5 points AND ≥25 % within 1 year. Variables with $p<0.2$ in univariate analysis were selected for multivariate analysis through a nominal group technique. To compensate for missing data, a multiple imputation followed by a pooled logistic regression was run. Based on a likelihood ratio test, the full model was compared to a reduced model. The model with the best fit was evaluated in the available data set.

Results: A total of 155/704 patients showed skin improvement. On univariate analysis, cardiac involvement, immunosuppression and ESR<25 mm/h were associated with skin improvement. High baseline mRSS was the strongest parameter ($p<0.001$; Figure 1), with the best sensitivity and specificity for prediction of skin regression at a cut-off of 17.5 points (area under the curve 0.708). In addition, a high skin fibrosis progression rate at baseline was also strongly associated with regression of skin fibrosis at 12-months follow-up. A multivariate pooled logistic regression with 13 variables was run. The likelihood ratio test was in favor of a reduced model: baseline mRSS (Estimate 0.087, $p<0.001$) and ESR >25mm/h (Estimate −0.526, p 0.030). When tested on the available data set, this latter model showed good performance in predicting regression of mRSS (area under the curve 0.726, 95%CI 0.64–0.80). **Figure 1**. Baseline mRSS in patients with and without skin regression: there is a clear trend towards the predominance of regression (black bars) over no regression (grey bars) in patients with high mRSS.



Conclusion: These results show that, opposite to current practice, patients with already advanced skin fibrosis are more likely to regress under standard of care in the next 12 months than patients with milder skin fibrosis. Thus, focus for treatment intervention and recruitment in CT aiming at skin fibrosis should shift from these patients with high baseline mRSS to at risk patients characterized by low to moderate skin fibrosis and high ESR at baseline.

Early Mortality in Australian, Canadian and Spanish Scleroderma Patients: Rationale for Establishing a Multi-National Inception Cohort of Patients with Systemic Sclerosis. YanJie Hao[1], Marie Hudson[2], Patricia Carreira[3], Wendy Stevens[1], Candice Rabusa[4], Solene Tatibouet[5], Loreto Carmona[6], Beatriz E Joven[7], Susanna Proudman[8], Murray Baron[5] and Mandana Nikpour[9]. [1]St. Vincent's Hospital Melbourne, Melbourne, Australia, [2]McGill University, Montreal, QC, [3]Hospital Universitario 12 de Octubre, Madrid, Spain, [4]The University of Melbourne at St Vincent's Hospital, Melbourne, Australia, [5]Lady David Research Institute, Montreal, QC, [6]Instituto de Salud Musculoesqueletica, Madrid, Spain, [7]Hospital Universitario, Madrid, Spain, [8]University of Adelaide, Adelaide, Australia, [9]The University of Melbourne at St. Vincent's Hospital, Melbourne, Australia.

Background/Purpose: Studies of 'prevalent' cohorts wherein most patients have longstanding disease at recruitment may underestimate mortality in systemic sclerosis (SSc) due to survivor bias. The aim of this study was to quantify mortality in Australian, Canadian and Spanish patients with SSc and to compare patients with prevalent and incident disease.

Methods: We quantified mortality as Standardized Mortality Ratio (SMR) and Years of Life Lost (YLL) in each of the cohorts based on Australian Bureau of Statistics, Statistics Canada and Spain National Statistics Institute data for the general population, and percentage survival in the first decade of disease in the whole combined 'prevalent' cohort and a subset of patients recruited within 4 years of onset of disease (the combined 'incident' cohort). We determined a single primary cause of death (SSc or non-SSc related) and all other SSc organ involvement that contributed to death.

Results: In the combined prevalent cohort of 3218 patients (1411 Australian, 1465 Canadian and 342 Spanish), 53% of the primary causes of 440 deaths (157 Australian, 213 Canadian and 70 Spanish) recorded were SSc related; the most common cause of SSc-related death was heart-lung disease (Table 1). Malignancy, atherosclerotic vascular disease and sepsis were the most common non-SSc related causes. SSc organ involvement contributed to 31% of these non-SSc related deaths. In multivariable regression, the predictors of mortality were male sex, older age at disease onset, diffuse subtype and presence of PAH, ILD, myocardial involvement, or renal crisis. The SMR and YLL were higher (Table 2) in Australian and Canadian incident cohorts compared with the respective prevalent cohorts. Survival was lower (Figure 1) in the combined incident cohort than the prevalent cohort.

Conclusion: Mortality in Canadian, Spanish and Australian SSc patients is substantial. Our results suggest that prevalent cohorts underestimate mortality in SSc by failing to capture early deaths, particularly in diffuse disease. These findings provide a compelling rationale for establishing a large multi-national inception cohort of patients with SSc to more accurately quantify early mortality in this disease.

Moderate Decline in Forced Vital Capacity is Associated with a Poor Outcome in Systemic Sclerosis Patients. Anna-Maria Hoffmann-Vold[1], Oyvind Midtvedt[2], Torhild Garen[1], May Brit Lund[3], T. Mogens Aalokken[4], Jan Tore Gran[2] and Oyvind Molberg[5]. [1]Department of Rheumatology, Oslo University Hospital Rikshospitalet, Oslo, Norway, [2]Oslo University Hospital, Oslo, Norway, [3]Department of Respiratory Medicine, Oslo University Hospital Rikshopitalet, Oslo, Norway, [4]Department of Radiology, Oslo University Hospital Rikshospitalet, Oslo, Norway, [5]Department of Rheumatology, Oslo University Hospital, Rikshospitalet, Oslo, Norway.

Background/Purpose: Interstitial lung disease (ILD) is a common manifestation in systemic sclerosis (SSc) and the leading cause of morbidity and mortality. Serial pulmonary function tests are useful for monitoring SSc-ILD, and total decline in forced vital capacity (FVC) above 10% predicts mortality. Moderate FVC decline (5–10%) was recently shown to predict poor outcome in idiopathic pulmonary fibrosis, but it is not known if moderate FVC decline has any impact on the outcome of SSc-ILD.

Methods: The study cohort included 305 SSc patients enrolled in the prospective SSc cohort (Norwegian Systemic Connective Tissue Disease and Vasculitis Registry [NOSVAR]) at the Department of Rheumatology, Oslo University Hospital (OUH). Serial pulmonary function test (PFT), lung fibrosis measured on high resolution computed tomography (HRCT) and clinical data were registered at baseline and then prospectively at annual follow-up visits. Patients were segregated in three groups according to annual FVC decline rates; (A) stable or minimal decline (<5%), (B) moderate decline (5–10%) and (C) major decline (>10%). Mortality and disease progression (fibrosis progression, DLCO and total FVC decline) quantified from baseline data were defined as poor outcome. Descriptive statistics and t-tests were applied; Kaplan-Meyer and Cox proportional hazard models were used to analyse survival.

Results: 305 SSc patients were followed for mean 3.8 years (range 1–15) from the baseline FVC. Altogether, 241 patients (79%) had stable FVC, 43 (14 %) had moderate FVC decline and 21 (7%) had major decline (Table 1). Sixty-seven deaths occurred during the observation period. Moderate decline in FVC was significantly associated with mortality (HR 2.5 (95% CI 1.4, 4.6, p-value 0.003). The 1-year survival rates for the three FVC groups were 100%, 100%, 86%, 5-year survival rates were 97%, 85% and 76% and 10-year survival rates were 85%, 66% and 54%, respectively. Compared to the stable FVC group, the moderate FVC decline group were older at disease onset, had more lung fibrosis at baseline and at follow up, higher total decline in DLCO and lower FVC% at follow up (table 1).

Conclusion: In this prospective SSc cohort, annual moderate FVC decline was associated with high total DLCO decline, high lung fibrosis scores and increased mortality. These results highlight the importance of regular PFT measurements in daily clinical practice.

Reduced Diffusing Capacity of Carbon Monoxide Is Independently Associated with Worse Subclinical Left Ventricular Function on Speckle-Tracking Echocardiography in Systemic Sclerosis. Monique Hinchcliff, Vistasp Daruwalla, Lauren Beussink-Nelson, Sofia Podlusky, Mary A. Carns, John Varga, Michael Cuttica and Sanjiv J. Shah. Northwestern University Feinberg School of Medicine, Chicago, IL.

Background/Purpose: Reduced diffusing capacity of carbon monoxide (DLCO) is a predictor of worse outcomes in patients with systemic sclerosis (SSc). Traditionally, the association between low DLCO and mortality in SSc has been attributed to either interstitial lung disease (ILD) or pulmonary vascular disease due to pulmonary arterial hypertension (PAH). However, patients with primary cardiac involvement in SSc may have reduced DLCO due to pulmonary venous hypertension and/or generalized vascular disease in SSc. We sought to determine the association between DLCO and cardiac mechanics (speckle-tracking strain parameters) in patients with SSc.

Methods: We studied 195 patients with SSc who were enrolled in the Northwestern Scleroderma Program. All patients underwent comprehensive echocardiography using a standardized protocol for image acquisition and interpretation. Indices of cardiac mechanics (LV, RV, and left atrial [LA] strain parameters) were measured using speckle-tracking analysis. We used multivariable-adjusted linear regression analyses to determine the association between DLCO and indices of cardiac mechanics.

Results: The mean±SD age was 51±13 years, 84% were female, 59% had limited cutaneous SSc, 31% had diffuse cutaneous SSc, and 10% had other forms of SSc (e.g., overlap syndromes). Prevalence of SSc complications were as follows: PAH in 10%, significant ILD in 18.5%, and LV systolic dysfunction (EF<50%) in 3.6%. DLCO was not associated with global LVEF, but it was associated with LV, RV, and LA strain parameters, and early LV diastolic (e') tissue velocities, on univariate analysis ($P^2$0.001) (Figure). Reduced DLCO remained associated with reduced absolute global longitudinal systolic strain (GLS, a marker of longitudinal LV systolic function) after adjusting for age, sex, SSc subtype, SSc disease duration, PAH, ILD, e' velocity (a marker of LV diastolic dysfunction), and tricuspid annular plane systolic excursion (a marker of RV function): μ-coefficient = −0.9 (95% CI −1.5 to −0.2) %-units, P=0.009. The association between DLCO and GLS persisted in the subset of patients with normal LVEF (>50%), no PAH, and FVC > 60% of predicted (multivariable-adjusted P=0.014).

Conclusion: In patients with SSc, reduced DLCO is associated with subclinical abnormalities in LV mechanics even in patients without evidence of ILD, PAH, or global LV systolic dysfunction. DLCO may be a marker of SSc cardiac disease.

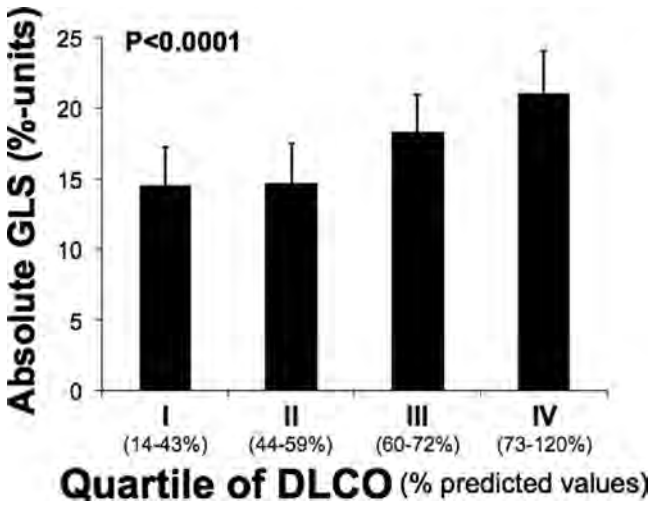

Figure. Diffusing Capacity of Carbon Monoxide (DLCO) Quartiles vs. Absolute Global Longitudinal Strain (GLS). Lower DLCO is associated with worse left ventricular longitudinal systolic function as indicated by lower values of GLS.

Risk of Ischemic Stroke in Patients with Systemic Sclerosis: A Systematic Review and Meta-Analysis. Patompong Ungprasert[1], Praveen Ratanasrimetha[2], Charat Thongprayoon[3], Wisit Cheungpasitporn[3] and Promporn Suksaranjit[4]. [1]Bassett medical center, Cooperstown, NY, [2]Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand, [3]Mayo clinic, Rochester, MN, [4]University of Utah School of Medicine, Salt Lake City, UT.

Background/Purpose: Several chronic inflammatory disorders, such as rheumatoid arthritis and systemic lupus erythematosus, have been shown to increase risk of ischemic stroke secondary to accelerated atherosclerosis. However, the data on systemic sclerosis (SSc), another chronic inflammatory disease, remain unclear due to conflicting epidemiological studies. Thus, to further investigate this possible association, we conducted a systematic review and meta-analysis of observational studies that compared the risk of ischemic stroke in patients with SSc versus participants without it.

Methods: Two investigators (P.U. and P.C.) independently searched published studies indexed in MEDLINE, EMBASE and the Cochrane database from inception to March 2014 using the terms "systemic sclerosis" and "scleroderma" combined with the terms for cerebrovascular disease. A manual search of references of retrieved articles was also performed. The inclusion criteria were as follows: (1) observational studies published as original studies to evaluate the association between SSc and ischemic stroke and (2) odds ratios (OR's), relative risk (RR's) or hazard ratio (HR's) or standardized incidence ratio (SIR's) with 95% confidence intervals (CI's) were provided. Study eligibility was independently determined by the two investigators noted above. Differing decisions were resolved by consensus with the senior investigator. The quality of each study was, again, independently assessed by the two investigators using Newcastle-Ottawa scale.

RevMan 5.2 software was used for the data analysis. Point estimates and standard errors were extracted from individual studies and were combined by the generic inverse variance method of DerSimonian and Laird. Given the high likelihood of between study variance, we used a random-effect model rather than a fixed-effect model. Statistical heterogeneity was assessed using the Cochran's Q test.

Results: Out of 370 potentially relevant articles, three studies (all were retrospective cohort studies) with 3,861 cases of SSc were identified and included in our data analysis. The pooled risk ratio of ischemic in patients with SSc was 1.58 (95% CI, 1.12 to 2.25). The statistical heterogeneity of this meta-analysis was moderate with an I^2 of 70%.

Conclusion: Our study demonstrated a statistically significant increased ischemic stroke risk among patients with SSc.

International Classification of Functioning, Disability, and Health (ICF) Core Sets for Connective Tissue Disease Interstitial Lung Disease (CTD-ILD) and Idiopathic Pulmonary Fibrosis (IPF) – a Necessary Map to Health Care Provision in the Era of ICD-11. Reuben Escorpizo[1], Kevin J. Keen[2], Kim Fligelstone[3], Matthew R. Lammi[4], Daphne LeSage[5], Anne-Marie Russell[6], Surinder Birring[7], Catherine Sarver[8], Janos Varga[9], Oliver Distler[10] and Lesley Ann Saketkoo[11]. [1]ICF Research Branch in cooperation with the WHO Collaborating Centre for the Family of International Classifications in Germany (DIMDI), Nottwil, Switzerland, [2]Health Research Institute, Prince George, BC, [3]Royal Free Hospital, Scleroderma Unit and Scleroderma Society, London, United Kingdom, [4]Louisiana State University Health Sciences Center, Pulmonary and Critical Medicine, New Orleans, LA, [5]Center for CCH at State of Louisiana, New Orleans, LA, [6]Royal Brompton Hospital,, London, United Kingdom, [7]King's College Hospital NHS Foundation Trust, London, United Kingdom, [8]Johns Hopkins, Baltimore, MD, [9]National Koranyi Institute for TB and Pulmonology, Budapest, Hungary, [10]University Hospital Zurich, Zurich, Switzerland, [11]Louisiana State University Health Sciences Center, New Orleans, LA.

Background/Purpose: A recent consensus project (Saketkoo et al, Thorax 2014) recommended a minimum core set of outcome measures for use in future clinical trials of CTD-ILD and IPF. The World Health Organization (WHO) introduced the **International Classification of Functioning, Disability, and Health (ICF)** as a scientific method of disability data collection and a universal framework of >1200 categories to describe disability associated with health conditions in terms of the bio-psycho-social model with consideration of environmental and personal factors. For accurate representation of disease, ease of healthcare provision and fair allocation of resources, it is essential that ICF Core Sets be established for rare and complex diseases.

Methods: Per updated ICF linkage rules, each instrument from the published CTD-ILD and IPF core sets were deconstructed to meaningful concepts and independently linked by 2 health professionals experienced in ICF linkage (RE, LAS). Inter-linker agreement on independent linkages was analyzed (KK). Discordant linkages were resolved between linkers. A 3rd linker (OD) arbitrated if irreconcilable linkages occurred.

Results: Eighty-two ICF categories were identified under the 4 ICF domains for 6 patient questionnaires and 3 traditional objective measures. The proportion of agreement ranged from 0.79 (95% CI: 0.62, 0.91) to 0.93 (0.76, 0.99) (Table 1) on the 5 different survey instruments (Table 2) with the overall proportion of inter-linker agreement 0.86 (0.82, 0.89). Any discordant linkages were reconciled between the initial 2 linkers. A previously linked version of the SF-36 had already existed; All-Cause Mortality and Patient Global of Disease Activity were indefinable in ICF terms. 20 new Personal Factors were generated to capture important disease-specific qualities not elsewhere described in ICF, e.g. 'pf_embarrassed by cough' or 'pf_panic/afraid when can't get breath'.

Table 1. Instruments from published CTD-ILD and IPF minimum core sets for clinical trials; with Instrument Comparison and Inter-Reviewer Agreement.

Minimum Core Set Instruments For CTD-ILD and IPF	Number of Items Linked	Number of Categories Identified	Agreement (%)	Agreement 95% Confidence Interval
Medical Research Council (MRC) Dyspnea Scale	27	34	79	(62, 91)
Dyspnea 12 (D-12)	25	27	93	(76, 99)
University of California San Diego-Shortness of Breath Questionnaire (UCSD-SBQ) (for IPF only)	68	83	82	(76, 90)
Leicester Cough Questionnaire	44	56	79	(66, 88)
St Georges Respiratory Questionnaire	126	138	91	(85, 95)
Medical Outcomes Study Short Form 36 (SF-36)		26*	Based on previously linked version	
Visual Analogue Scale-Patient Global Disease Activity		Not defined by ICF (too broad)		
Forced Vital Capacity on Spirometry	2	2*	100	Not done
Diffusion Capacity of the Lung for Carbon Monoxide (DLCO)	1	1*	100	Not done
Overall Extend of ILD on High Resolution CT (HRCT)	1	1*	100	Not done
All Cause Mortality		Not defined by ICF (too broad)		
Overall Agreement on Questionnaires	290	338 (+30*)	86	(82, 89)

Table 2. Distribution of ICF Categories and Instrument Occurrence according to ICF domains with example linkages.

ICF Domain	Description	Instruments Linked	No. of ICF Categories Linked	Examples from CTD-ILD and IPF Core Sets
Body Structure	Relates to involvement of anatomical structures	HRCT	1	s4301, Structure of lungs
Body Function	include physical, mental and emotional functions	D-12, DLCO, FVC, LCQ, MRC-DS, SF-36, SGRQ, UCSD-SOBQ	17	b1300, Energy level b134, Sleep functions b4402, Depth of respiration b455, Exercise tolerance b28011, Pain in chest
Activities and Participation	Execution of task or action; involvement in a life situation	D-12, LCQ, MRC-DS, SF-36, SGRQ, UCSD-SOBQ	56	d330, Speaking d430, Lifting, carrying objects, d4600, Moving around house d510, Washing oneself d8451, Maintaining a job
Environmental Factors	Positive (e.g. family, medications, assistive devices, oxygen, lifts) or Negative (e.g. stairs, lack of income, cold climate, distance from services) influences on performance.	LCQ, SGRQ	8	e260, Air quality e460, Societal attitudes e2100, Land forms, such as mountains, hills, valleys and plains.
Total			82	

Conclusion: This is the first effort to map CTD-ILD and IPF outcome measures to the ICF. A composite of these ICF linkages will be available to clinicians and researchers with validation studies to follow. ICF Core Sets are intended to be stream-lined disease-specific languages that support global, regional and personal health-related parity across cultures, age and socioeconomic status. ICF Core Sets enable fair assessment that may be utilized in policy making and service provision and funding. Familiarity with ICF Core Sets in CTD-ILD and IPF will enable clinicians to experience a smoother transition to ICD-11 which is under development and will meld diagnostic coding with the ICF.

Prediction and Impact of Attacks of Raynaud's Phenomenon, As Judged By Patient perception. Michael Hughes[1], Amir Snapir[2], Jack Wilkinson[3], Daniel Snapir[2], Fredrick M. Wigley[4] and Ariane Herrick[1]. [1]The University of Manchester, Manchester, United Kingdom, [2]Orion Corporation Orion Pharma, Turku, Finland, [3]Salford Royal NHS Foundation Trust, Salford, United Kingdom, [4]Johns Hopkins University School of Medicine, Baltimore, MD.

Background/Purpose: Our aim was to evaluate (a) whether subjects with Raynaud's phenomenon (RP) can predict RP attacks because if so, then this could have implications for new treatment approaches and (b) the impact of RP attacks on quality of life (QOL).

Methods: Subjects with RP were approached through international patient associations to participate in an online survey. The survey comprised 19 questions including demographic information and details of the RP. Subjects were asked to report their ability to predict (all on an ordinal scale) the occurrence of RP attacks (<20%, 21%–50%, 51%–70% and >70% of times), severity of attacks (very poorly, poorly, fairly well, well, and very well), and their ability to prevent/control RP attacks (very poor, poorly, fairly well, well and very well). Other questions related to medications, how well subjects felt they could control their RP, and the impact of RP on QOL.

Results: A total of 443 responses from subjects with self-reported RP (mean age 41 years, 91% female), from 15 countries were evaluable. 187 subjects (43%) had primary RP (PRP, as judged by self-report), 149 (34%) secondary RP (SRP) and 100 (23%) were not aware of the cause of their RP. 252 (58%) of subjects reported that they could predict at least 51% of RP attacks (66% of subjects with SRP vs. 56% PRP, p=0.03). 248 (57%) subjects reported that they could predict attack severity either 'fairly well' or better (64% of subjects with SRP vs. 58% PRP, p=0.16), with 43% predicting severity only poorly (30%) or very poorly (13%).

64% of all subjects reported either a 'poor' or 'very poor' ability to prevent or control RP attacks. 182 subjects (41%) reported current or previous use of medications for RP: 82% reported at least one currently used medication being tolerated, but only 16% at least one current medication being 'effective'.

Most subjects (78%) reported making at least one life adjustment due to RP, more so in subjects with SRP compared with PRP (87% vs.71%, [P=0.001]). Patients reported the impact of their RP on QOL on a 0–10 scale, where 10 was the best imaginable: the mean QOL for all patients was 6.0 (SD 2.1 [range = 1–10]). PRP subjects' current QOL was higher than SRP subjects (mean QOL 6.5 and 5.2 respectively, difference in means (95% CI): 1.21 (0.76 to 1.66) [P < 0.001]). When asked to imagine their QOL without RP, SRP subjects imagined a greater absolute improvement from their current QOL (2.3 vs. 3.3, difference in means −0.9 (−1.4 to −0.4) [P=0.0002]).

Conclusion: 1. Subjects ability to predict both the occurrence and severity of RP attacks is limited (almost half of patients could predict neither attacks nor their severity), and this must be taken into account when designing clinical trials of future novel, 'PRN' (as required) treatments.

2. Only 16% of subjects currently on medication for RP reported that at least one current medication was 'effective', and most subjects reported a poor ability to prevent/control RP attacks, confirming an unmet need to develop new treatments.

3. RP significantly impacts on QOL, especially in subjects with SRP but also in PRP.

A Dilated Esophagus Is an Independent Risk Factor for Interstitial Lung Disease in SSc. Carrie Richardson[1], Rishi Agrawal[2], Jungwha Lee[2], Orit Almagor[3], John Varga[2], Rowland W. Chang[2] and Monique E. Hinchcliff[4]. [1]McGaw Medical Center of Northwestern University, Chicago, IL, [2]Northwestern University Feinberg School of Medicine, Chicago, IL, [3]Northwestern University, Chicago, IL, [4]Northwestern University, Feinberg School of Medicine, Chicago, IL.

Background/Purpose: High-resolution computed tomography of the chest (HRCT) performed for assessment of interstitial lung disease (ILD) in patients with systemic sclerosis (SSc) frequently reveals a patulous esophagus, but the significance is unclear. Assuming that the risk of aspiration is directly related to the magnitude of esophageal dilatation, we hypothesized that a greater HRCT esophageal diameter is associated with worse pulmonary outcomes, as measured by severity of ILD on HRCT and pulmonary function tests (PFT).

Methods: A cross-sectional study of Northwestern Scleroderma Registry patients with HRCT was conducted. Subjects met the ACR 1980 SSc or three out of five CREST (**C**alcinosis cutis, **R**aynaud phenomenon, **E**sophageal dysmotility, **S**clerodactyly, **T**elangiectasias) criteria. The esophageal diameter was measured at three levels: above the aortic arch, between the aortic arch and the right inferior pulmonary vein, and between the right inferior pulmonary vein and the diaphragmatic hiatus. Widest esophageal diameter (WED) was used as the predictor variable. A modified Likert scale (0= none, 1= <5%, 2= 6–25%, 3 for 26–50%, 4=51–75%, 5= >75%) was used to score fibrosis and ground glass opacities. Total ILD (outcome variable) was calculated as the sum of fibrosis and ground glass scores. Secondary outcomes were PFT including total lung capacity (TLC), forced vital capacity (FVC) and diffusing capacity for carbon monoxide adjusted for hemoglobin % predicted (DLCO). Standardized regression coefficients (β) between WED and the outcome variables were calculated adjusting for age, sex, ethnicity, disease subtype (limited or diffuse cutaneous SSc), disease duration (years since first non-Raynaud symptom), proton pump inhibitor use, C-reactive protein and modified Rodnan skin score.

Results: Three hundred eleven subjects had HRCT. Eight subjects without available HRCT images and one subject who had undergone esophagectomy were excluded. Twenty-eight patients who had mixed connective tissue disease, SSc sine scleroderma, or overlap syndromes were excluded, leaving 275 subjects for analysis. Adjusted standardized regressions demonstrated positive associations between WED and total ILD score (β=0.33, p<0.0001), fibrosis (β=0.32, p<0.0001), and ground glass opacities (β=0.28, p<0.0001) (Table). There were negative associations between WED and TLC % predicted (β=−0.24,p=0.0002), FVC % predicted (β=−0.23, p=0.0004), and adjusted DLCO % predicted (β=−0.23; p=0.005).

Conclusion: Increasing esophageal diameter on HRCT in patients with SSc is associated with more severe radiographic ILD, lower lung volumes, and lower DLCO % predicted. Longitudinal studies should be done to elucidate the temporal relationship between esophageal disease and ILD in persons with SSc. Future trials of aggressive management of esophageal disease to prevent ILD may be warranted in persons with SSc.

Table Association between widest esophageal diameter and HRCT findings and pulmonary function test parameters

	Widest esophageal diameter (WED)			
Variables	**Unadjusted β coefficient (SE)**	**p value**	***Adjusted β coefficient (SE)**	**p-value**
Total ILD score	0.36 (0.07)	<0.0001	0.33 (0.08)	<0.0001
Total fibrosis score	0.32 (0.04)	<0.0001	0.32 (0.04)	<0.0001
Total ground glass score	0.32 (0.04)	<0.0001	0.28 (0.04)	<0.0001
TLC, % predicted	−0.34 (0.12)	<0.0001	−0.24 (0.13)	0.0002
FVC, % predicted	−0.31 (0.12)	<0.0001	−0.23 (0.13)	0.0004
Adjusted DLCO, % predicted	−0.29 (0.14)	<0.0001	−0.23 (0.17)	0.0005

ILD=interstitial lung disease, TLC=total lung capacity, FVC=forced vital capacity, DLCO=diffusion capacity for carbon monoxide.
*Adjusted for age, sex, disease subtype, ethnicity, proton pump inhibitor use, disease duration, C-reactive protein, and modified Rodnan skin score.

Prediction of Cardiac and Vascular Events in Systemic Sclerosis: Input from Endothelin-1 Type a Receptor Antibodies. Jerome Avouac[1], Gabriela Riemekasten[2], Christophe Meune[3], Barbara Ruiz[4] and Yannick Allanore[1]. [1]Paris Descartes University, Rheumatology A Department and INSERM U1016, Cochin Hospital, Paris, France, [2]Charité University Hospital and German Rheumatism Research Centre, a Leibniz Institute, Berlin, Germany, [3]Paris 13 University, University Hospital of Paris-Seine-Saint-Denis, Cardiology Department, Bobigny, France, [4]Paris Descartes University, INSERM U1016, Institut Cochin, Sorbonne Paris Cité, Paris, France.

Background/Purpose: Cardiac and peripheral microvascular alterations are key features of systemic sclerosis (SSc). We have previously reported that angiogenic markers can predict the cardiovascular outcomes in SSc (1). In parallel, a cross-sectional study reported an association between severe cardiovascular complications and functional antibodies against angiotensin II type 1 receptor (AT_1R) and Endothelin-1 type A receptor (ET_AR) (2). Therefore, our aim was to investigate the respective merit of all these markers in a prospective cohort.

Methods: serum levels of anti-AT_1R and anti-ET_AR autoantibodies, placenta growth factor (PlGF) and soluble vascular adhesion molecule (sVCAM) were measured with sandwich ELISA in a prospective cohort of 75 SSc patients. Circulating endothelial progenitor cells (EPCs) were quantified in peripheral blood by flow cytometry after cell sorting. The occurrence of at least one cardiac/vascular event was assessed during a planed 3-year follow-up by a composite index defined by the occurrence of at least one of the following event: a) one or more new ischemic digital ulcer (DU), b) pre-capillary pulmonary hypertension (PH) confirmed by right heart catheterization, c) left ventricular (LV) dysfunction, defined by a LV ejection fraction (EF)<50%, d) scleroderma renal crisis (SRC) (1).

Results: The mean age of SSc patients (64 women) was 55±12 year old and the mean disease duration was 9±8 years at baseline. Twenty-eight patients developed at least one cardiac/vascular event (DU in 18, PH in 5, LV dysfunction in 4 and SRC in a single patient). By univariate analysis, high baseline serum levels of anti-ET_AR were predictive of the occurrence of cardiac/vascular events (p=0.002), together with low EPC counts (p=0.003) and increased levels of PlGF (p=0.0005) and sVCAM (p=0.009). No predictive value of anti-AT_1R antibodies was identified. Multivariate analysis confirmed high serum levels of anti-ET_AR antibodies (hazard ratio, HR: 3.71, 95%CI 1.44–9.52, p=0.03) and PlGF (HR: 5.22, 95%CI 1.96–15.87) as independent predictors of further development of cardiac/vascular events. The combination of high serum levels of anti-ET_AR antibodies and PlGF was highly predictive of cardiac and vascular events occurrence during follow-up (HR 7.27 95%CI 2.49–23.51, P=0.0002).

Conclusion: This study identifies for the first time anti-ET_AR antibodies as an independent predictor of cardiac and vascular events in SSc. This

functional antibody, together with other angiogenic markers and in particular PlGF, may serve as biomarkers to improve cardiovascular risk stratification and therefore allow earlier therapeutic intervention.

Performance of the Old ACR and the New ACR-EULAR Systemic Sclerosis Classification Criteria in Patients with Limited Cutaneous Disease: Effect on the Ascertainment of Severe Pulmonary Arterial Hypertension. Beatriz E. Joven[1], M Jesus Garcia de Yebenes[2], Pilar Escribano[3], Estibaliz Loza[4], M Jose Ruiz-Cano[3], Carmen Jimenez Lopez-Guarch[3], Loreto Carmona[5] and Patricia E. Carreira[1]. [1]Rheumatology Department. Hospital Universitario 12 de Octubre, Madrid, Spain, [2]Instituto de Salud Musculoesqueletica, Madrid, Spain, [3]Multidisciplinary Pulmonary Hypertension Unit. Hospital Universitario 12 de Octubre, Madrid, Spain, [4]Institu, Madrid, Spain, [5]Instituto de Salud Musculoesquelética, Madrid, Spain.

Background/Purpose: To analyze the performance of the old ACR1980 and the new ACR-EULAR2013 classification criteria for systemic sclerosis (SSc) in patients with limited disease in clinical practice, and to compare the characteristics of patients with severe pulmonary arterial hypertension (PAH) who fulfilled or did not fulfill the 1980 criteria.

Methods: All patients with clinical diagnosis of limited cutaneous SSc followed in a single center from Jan1990 to May2014 were included. Descriptive analysis and comparisons between groups, according to their performance in new and old criteria, were carried out by parametric or non parametric tests based on the distribution of the variables.

Results: From 321 patients, 202 (63%) fulfilled the 1980 and 297 (93%) fulfilled the 2013 criteria. Compared to those fulfilling 2013 criteria only, patients fulfilling 1980 criteria also were younger at diagnosis (48 vs 52 y), presented higher mRSS (8.5 vs 2.7) and had significantly more aScl70, esophagic involvement, lung fibrosis, ischaemic lesions, calcinosis and telangiectasia. In contrast, patients not fulfilling 1980 criteria had more ACA (61 vs 44%) and severe PAH (17 vs 9%) (Table 1).

Within the group of patients with severe PAH (n=38), all fulfilled the 2013 but only 18 (47%) fulfilled the 1980 criteria. Clinical characteristics between those who fulfilled and did not fulfill 1980 criteria were similar, except for higher frequency of calcinosis (85 vs 22%) and ischaemic lesions (83% vs 0%) in the former group. In hemodynamics, patients not fulfilling 1980 criteria had higher pulmonary vascular resistance (16 vs 7) and lower cardiac index (2.2 vs 3.2). Mortality was high in both groups (72 vs 65%)(Table 2).

Conclusion: The new SSc ACR-EULAR2013 criteria perform better than the old ACR1980 criteria in clinical practice. Patients with mild symptoms, not fulfilling 1980 criteria, are at higher risk of developing severe PAH, with increased mortality. Our study points out: 1) the need to apply the new criteria to all patients with SSc suspicion; and 2) since SSc-PAH has better prognosis if treated early, all SSc patients, even with very mild disease, should be screened to diagnose PAH as early as possible.

Table 1 Characteristics of the limited cutaneous SSc patients according to the fulfillment of the ACR1980 criteria

Variable	Total (n = 321)	Not fulfilling ACR1980 (n = 119)	Fulfilling ACR1980 (n = 202)	p value*
Quantitative variables, mean (SD)

Predictors of Inpatient Mortality in Patients with Systemic Sclerosis: A Case Control Study. Shiv Tej Sehra[1], Chris T. Derk[1], Andrew Kelly[2] and Joshua Baker[3]. [1]University of Pennsylvania, Philadelphia, PA, [2]Pennsylvania Hospital, Philadelphia, PA, [3]University of Pennsylvania and Philadelphia VAMC, Philadelphia, PA.

Background/Purpose: There are few published studies on predictors of inpatient mortality in patients with systemic sclerosis (SSc). Knowledge of these predictors is important for early identification of patients at high-risk of inpatient death and recognition of potential modifiable factors. Currently available data are mostly from large databases which lack a granular view. The aim of this study was to define factors associated with inpatient mortality in SSc.

Methods: All admissions coded for SSc (ICD-9 710.1) at the Hospital of University of Pennsylvania, between Jan 1, 2001 and Dec 31, 2011 were reviewed. The diagnosis of SSc was confirmed, and deaths were identified by chart review. For each death, an age (±5 years), sex and gender matched control with SSc (who did not die during their hospitalization) was identified. We hypothesized group differences in SSc characteristics, non–SSc comorbidities and admission labs (as summarized in Table 1). Group differences were analyzed using Student's t-test (and non parametric equivalents) as well as Chi^{2}tests for dichotomous variables. Exposures associated with death in univariate analyses were used to form a final parsimonious multivariable logistic regression model.

Results: A total of 593 admissions and 30 deaths were identified. Data was not available on 1 death. A significant difference in non–SSc lung disease ($p = 0.031$), aspiration events ($p < 0.001$), WBC count ($p = 0.048$), Blood Urea Nitrogen (BUN) ($p < 0.001$) and hemoglobin (Hb) ($p = 0.025$) was noted between subjects that died compared to matched controls. Odds of death were higher in patients with a higher BUN (OR = 1.06, CI = 1.02–1.11), non–SSc lung disease (OR = 3.87, CI = 1.26–11.88) and

aspiration events (OR = 30, CI = 3.58–250.80), and lower in patients with a higher Hb (OR = 0.73, CI = 0.54–0.97). High BUN, a history of aspiration events and low Hb were found to be independently associated with mortality.

Conclusion: A high BUN on admission, low Hb, non–SSc Lung disease, and aspiration events are associated with higher in–hospital mortality in patients with SSc. The odds of dying in the hospital were 30 times in patients who aspirated. Therefore, stringent measures should be taken to prevent aspiration in these patients. Also, further study is needed to identify factors that predispose to acute aspiration events.

Impact of Geographic Variation on the Risk of Digital Ulcers Development in Systemic Sclerosis: A Brazilian Multicenter Registry. Eduardo José do Rosário e Souza[1], Carolina de Souza Muller[2], Andrea Tavares Dantas[3], Henrique A. Mariz[3], Alex Magno Coelho Horimoto[4], Renato Alvarenga Rezende[1], Isabela Guimarães[2], Izaias Pereira da Costa[4], Glauce Rejane Leonardi Bertazzi[5], Luiza Paiola[5], Eutília Andrade Medeiros Freire[6], Roberta Ismael[6], Ana Paula Toledo Del-Rio[7], Juliana Sekiyama[7], Carolina Barros Kahwage[8] and Cristiane Kayser[8]. [1]Hospital Santa Casa, Minas Gerais, Belo Horizonte, Brazil, [2]Universidade Federal do Paraná, Curitiba, Brazil, [3]Hospital das Clínicas - Universidade Federal de Pernambuco, Recife, Brazil, [4]Universidade Federal do Mato Grosso do Sul, Campo Grande, Brazil, [5]Faculdade de Medicina de São José do Rio Preto, São José do Rio Preto, Brazil, [6]Universidade Federal da Paraíba, João Pessoa, Brazil, [7]Universidade Estadual de Campinas, Campinas, Brazil, [8]Universidade Federal de São Paulo, São Paulo, Brazil.

Background/Purpose: Digital ulcers (DU) and Raynaud's phenomenon (RP) are a frequent complication in patients with Systemic Sclerosis (SSc). The present study aimed to evaluate the frequency and severity of RP and DU in patients with SSc in four distinct geographic regions of Brazil in order to evaluate the influence of geographic variation on the risk of DU development.

Methods: One hundred and forty-one patients with SSc according to the ACR/EULAR classification criteria of 2013, from centers located in four regions of Brazil (Northeast, Midwest, Southeast and South), were evaluated from January to March 2012. Demographic, clinical, and nailfold capillaroscopy data were collected. The daily mean temperature and the mean temperature in the week before evaluation were also recorded. In order to evaluate a possible association between DUs and climate, the group of patients from the South region (Subtropical climate zone, with lower temperatures), was compared to those from the other regions (Tropical climate zone). Comparisons between groups were made using t-test or chi-square test. Simple and multiple logistic regression models were applied to determine the association between DUs and clinical and demographic variables.

Results: A total of 43 active DUs were observed in 23 (16%) of the 141 patients included. Eighty-six percent were women, with a mean age of 47.8 years, a mean duration of RP of 10.1 years and a mean duration of disease of 5.8 years. Forty-three percent had limited cutaneous SSc, 61.7% had digital pitting scars and 12.1% had a previous history of gangrene or amputation. Twenty-six (18.4%) patients were from the Subtropical climate zone and 115 (81.6%) from the Tropical climate zone, with no difference on age, gender, RP and disease duration between groups. By simple logistic regression model, the presence of DU was associated with a higher modified Rodnan skin score (P=0.023), presence of necrosis or amputation (P=0.008), presence of flexion contracture of the fingers (P=0.002), active smoking (P=0.038), higher avascular score on nailfold capillaroscopy (P=0.019), higher severity of RP in the last week (P=0.007), a higher sHAQ score (P=0.001), and with the Subtropical climate zone patient group (P=0.011). The presence of DU was not significantly associated with the mean daily temperature or the temperature in the week before the evaluation. Using multiple logistic regression model including the significant associations observed in univariate analysis, presence of DU was significantly associated with patients living in the Subtropical climate zone (odds ratio [OR]=3.5, 95% confidence interval [95%CI]=1.10–11.28, P=0.034), with a previous history of necrosis or amputation (OR=4.7, 95%CI=1.20–19.10, P=0.026) and with a higher sHAQ (OR=4.7, 95%CI=1.81–12.5, P=0.002).

Conclusion: This was the first study to evaluate the influence of temperature and geographic variation on DU prevalence in SSc patients. In this multicenter study in a continental country with different climates, patients with SSc living in a colder region (Subtropical climate zone) have a 3.5 times higher risk of developing DU than those patients living in a warmer region (Tropical zone).

Lower Socioeconomic Status, Male Gender and Diffuse Scleroderma Are Associated with Worse Survival in the Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma Cohort. Jessica K. Gordon[1], Wei Zhang[1], Lorinda Chung[2], Yan Ma[1], Virginia D. Steen[3] and PHAROS Investigators. [1]Hospital for Special Surgery, New York, NY, [2]Stanford University School of Medicine, Palo Alto, CA, [3]Georgetown University Medical Center, Washington, DC.

Background/Purpose: Lower socioeconomic status (SES) and male gender have been associated with worse survival in idiopathic pulmonary arterial hypertension (PAH). Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma (PHAROS) is a multicenter, prospective registry of systemic sclerosis (SSc) patients with pulmonary hypertension (PH) or at high risk for the development of PH. In this study we examined whether survival in patients with SSc-PH varied with gender, SES, or race.

Methods: 276 patients with SSc and newly diagnosed PH were enrolled in the PHAROS registry between 2006 and 2014. We used level of education and employment status as surrogates for SES, although more than half of our

patients were retired or medically disabled at the time of PH diagnosis. For employment status we analyzed working versus all other. For level of education, we analyzed 12th grade or less versus some college or more. Statistical analysis was performed using chi-square, univariate and multivariate Cox proportional hazard models.

Results: Baseline characteristics of the patients are described in Table 1. The following variables were examined as prognostic factors for survival: age, scleroderma subtype, disease duration, World Health Organization (WHO) PH Group classification, baseline mean pulmonary artery pressure (mPAP), gender, level of education, and employment status. The univariate and multivariate Cox Proportional Hazard Models are reported in Table 2. Male gender, diffuse subtype, and unemployment were associated with an increased risk of death. WHO group was not a significant predictor. Race was not found to be a significant prognostic factor. Lower level of education was a significant prognostic factor when evaluating the entire group; however, if the analysis is limited to WHO Group 1 PH subtype only, then lower level of education is associated with an increased risk of death with HR 2.1 (95% CI 1.2, 3.6), $p<0.01$ when corrected for age, SSc subtype and mPAP.

Conclusion: Male gender, lower SES, and diffuse SSc are associated with a higher risk of death in the PHAROS cohort. Lower level of education was a risk factor for death only in WHO Group 1 (PAH). Worse survival in males is seen also in idiopathic PAH despite the fact that PAH is more prevalent in females, and the explanation for this is a topic for additional study. Addressing health disparities associated with lower SES may improve the outcomes of patients with SSc-PH.

Table 1 Patient Characteristics

Age-mean ± S.D.	58.4 ± 11.0
Gender-(n=275)	
Male-n (%)	52 (18.9)

735

Sarcopenia in Systemic Sclerosis: Prevalence and Association with Functional Parameters and Quality of Life. Elise Siegert[1], Kristina Norman[2], Emilie Preis[2], Alexander Makowka[2], Gerd Burmester[2] and Gabriela Riemekasten[1]. [1]Charité – University Hospital, Berlin, Germany, [2]Charité – University Medicine Berlin, Berlin, Germany.

Background/Purpose: Systemic Sclerosis (SSc) is an autoimmune disease that characterized by endothelial dysfunction, inflammation and fibrosis. It is associated with high mortality and physical impairment. We assessed the prevalence of sarcopenia in SSc patients and correlated sarcopenia with muscle strength and quality of life, also taking other clinical parameters into account.

Methods: Patients meeting the ACR/EULAR 2013 criteria for SSc were included in this study. Body composition was assessed using bioelectrical impedance analysis. Fat free mass (FFM) was estimated using the equation of Kyle and was normalized to patients' height using the square of body size (FFM/m^2 = FFMI). Sarcopenia was defined as a FFMI value below 17.4 kg/m^2 for men and < 15 kg/m^2 for women. Maximal grip strength was measured using the Jamar Dynamometer, maximal knee extension strength using the Digimax and expiratory peak flow using a peak flow meter. Quality of life was assessed using the SF-36®, while C-reactive protein (CRP), hemoglobin (Hb) and other clinical parameters were quantified by routine laboratory testing or by history taking.

Results: 111 patients were included in this study (101 women and 10 men; age 59.7 ± 13.8 years, BMI 24.5 ± 5 kg/m^2). 53 (47.7%) patients were diagnosed with sarcopenia. Patients with sarcopenia differed significantly from patients without sacropenia with respect to maximal grip strength, knee extension strength, peak flow and CRP. They did not differ in age and select clinical parameters such as gastrointestinal involvement, total number of organs involved, number of comorbidities and number of medical therapies. Absolute FFM correlated significantly with maximal grip, knee extension strength and peak flow ($r = .64$, $r = .366$ and $r = .48$, respectively, $p < 0.0001$). With respect to quality of life there was no significant difference between patients with and those without sarcopenia.

	sarcopenia	no sarcopenia	p-value
sex (m/f)	3/50	7/52	n.s.
age (years)	59.5 ± 15.7	59.9 ± 11.8	n.s.
BMI (kg/m^2)	21.4 ± 2.2	27.3 ± 5.4	.00000000002
anti-Centromer	10	22	.03
anti-Scl-70	21	15	n.s.
mod. Rodnan Skin Score	6.6 ± 7.3	9.8 ± 9.7	.05
hand grip (kg)	13.5 ± 6.6	19.0 ± 8.4	.0003
knee extension (kg)	19.3 ± 14.9	26.4 ± 22.9	.05
peak flow (l/min)	321.0 ± 85.0	360.9 ± 113.2	.05
CRP (mg/l)	6.9 ± 11.7	2.5 ± 2.9	.01
Hb (g/dl)	12.2 ± 1.6	13.2 ± 1.5	.003

Conclusion: There was a high prevalence of sarcopenia among SSc patients in our study. Sarcopenia was associated with an impairment of muscle strength, low hemoglobin and high inflammatory activity.

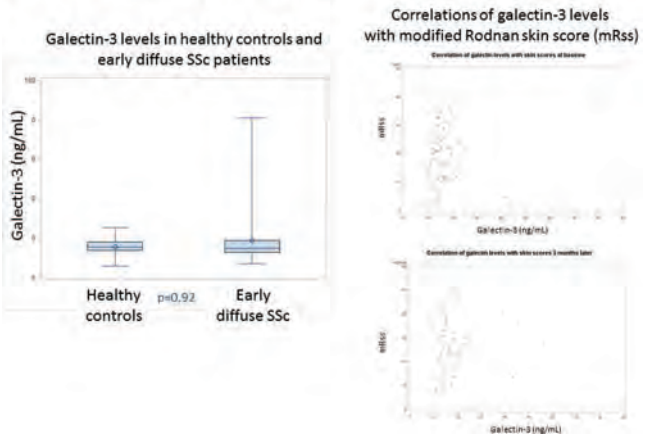
Serum Galectin-3 Levels in Early Diffuse Systemic Sclerosis and the Relationship to Skin Score and Skin Score Change. Siamak Moghadam-Kia, Thomas A. Medsger Jr. and Robyn T. Domsic. University of Pittsburgh, Pittsburgh, PA.

Background/Purpose: Galectin-3 is a β-galactoside-binding animal lectin which is associated with inflammation, angiogenesis and fibrosis. Galectin-3 is upregulated in hepatic fibrosis, idiopathic pulmonary fibrosis and in the myocardium of heart failure patients. In heart failure it is a useful biomarker to predict mortality. In systemic sclerosis (SSc), one report (Koca

2013) suggests higher levels compared to healthy controls (HC). In a second study (Taniguchi 2012) suggested down-regulation in diffuse SSc and on subset analysis, the 6 early diffuse SSc patients had the greatest reduction in galectin-3 levels. They also reported a modest correlation between galectin-3 ($r=0.45$) and skin score. The objective of this study was to assess galectin-3 levels in very early diffuse SSc patients and the relationship to skin score and skin score change.

Methods: We identified patients with very early diffuse SSc who were seen for the first time in a dedicated Scleroderma Center between 1990 and 2010 and met the following criteria: (1) seen within 9 months of the first SSc symptom, (2) skin thickening proximal to the elbows and knees (or skin thickening with tendon friction rubs) and (3) had clinical follow-up with repeat skin scores at either 3 months, 6 month or both. HC were also identified. All SSc and HC first visit serum samples underwent ELISA testing (BGMedicine, Waltham, MA). Differences in galectin-3 levels between SSc and HC were assessed by nonparametric tests. Correlations with skin score at first visit, skin thickness progression rate (STPR) and absolute change in skin score at 3 and 6 months were assessed.

Figure 1: Summary of Galectin-3 levels in early diffuse SSc



Results: We identified 114 SSc patients who met all inclusion criteria. Of these, 94 had available samples taken at the same time as the initial skin assessment. The 37 HC were collected on the same day. All SSc patients and HC were Caucasian and 70% female. Mean age was 51 in SSc and 47 in the HC. Of the SSc patients, 50 had f/u at both 3 and 6 months, 20 at 3 months only and 22 at 6 months only. There was no significant difference in serum galectin-3 level between SSc patients and HC ($p= 0.92$), as shown in Figure 1. Baseline serum galectin-3 levels were not correlated with the skin scores taken at the same time ($p=0.29$) or STPR ($p=0.71$). Skin scores at 3 or 6 months follow-up also showed no correlation ($p=0.43$ and 0.76, respectively). There was a weak correlation with baseline galectin-3 levels and absolute skin score change at 3 months ($r=0.26$, $p=0.02$), but not at 6 month follow-up ($p=0.78$).

Conclusion: Contrary to smaller pilot studies suggesting galectin-3 is significantly different in SSc compared to HC, and may modestly correlate with skin score, our study did not confirm this. We used very early patients not on medications, and it may be that the previously reported differences in galectin-3 occur later in disease and represent fibrotic burden, or may be affected by medications.

Reliability of Nailfold Capillary Density Measurement As a Possible Outcome Measure for Systemic Sclerosis-Related Microangiopathy. Graham Dinsdale[1], Tonia Moore[2], Joanne Manning[2], Andrea Murray[1], Michael Berks[3], Philip Tresadern[3], Chris Taylor[3], Neil O'Leary[4], Chris Roberts[4], John Allen[5], Marina Anderson[6], Maurizio Cutolo[7], Roger Hesselstrand[8], Kevin Howell[9], Paula Pyrkotsch[6], Francesca Ravera[7], Vanessa Smith[10], Alberto Sulli[7], Marie Wildt[8] and Ariane Herrick[1]. [1]Centre for Musculoskeletal Research, University of Manchester, Manchester Academic Health Science Centre, Manchester, United Kingdom, [2]Salford Royal Hospital NHS Foundation Trust, Salford, United Kingdom, [3]Centre for Imaging Sciences, University of Manchester, Institute of Population Health, Manchester, United Kingdom, [4]Centre for Biostatistics, Institute of Population Health, University of Manchester, Manchester, United Kingdom, [5]Regional Medical Physics Department, Freeman Hospital, Newcastle upon Tyne, United Kingdom, [6]Institute of Ageing and Chronic Disease, University of Liverpool, Liverpool, United Kingdom, [7]Research Laboratory and Academic Division of Clinical Rheumatology, Department of Internal Medicine, University of Genova, Genoa, Italy, [8]Lund University, Lund, Sweden, [9]Institute of Immunity and Transplantation, University College London, Royal Free Campus, London, United Kingdom, [10]Department of Rheumatology, Ghent University Hospital, Ghent, Belgium.

Background/Purpose: Nailfold videocapillaroscopy allows non-invasive assessment of the microcirculation. Image annotation software allows tracking of changes over time; a potential outcome measure for systemic sclerosis (SSc) related microangiopathy. Our objective was to assess the reliability of capillary density measurement, known to be reduced in SSc[1].

Methods: 124 patients (102 SSc, 22 primary Raynaud's phenomenon [PRP]), and 50 healthy controls (HC), underwent high-magnification (300x) videocapillaroscopy mosaic imaging of all 10 digits (1740 images).

Image subsets, sampled across disease categories, were randomly allocated to each of 10 capillaroscopy experts. These 'raters' used custom software to assess images. Each image used in this analysis was assigned to at least 2 raters. To assess intra-rater reliability, each rater performed repeat evaluations on an image subgroup. At least 6 images were assessed from each subject.

Raters marked distal vessel locations in an image. Vessel density was calculated as the total number of distal vessels divided by the Euclidean distance between the vessels at the horizontal extremities.

We examined: (1) the probability of raters marking sufficient (2 or more) distal vessels in an image (logistic mixed-effects model). Conditional on an image evaluation having sufficient distal vessels marked (2) distal vessel density (linear mixed-effects model).

Intra and inter-rater reliability was estimated with intra-class correlation coefficients from fitted model variance components.

Results: 3463 images were evaluated. Each rater assessed a median (range) of 112 (87, 1406) unique images from 14 (9, 174) subjects. Same-rater repeat evaluations were performed on (median) 17% of images, and 904 images from 116 patients were evaluated by at least 2 raters.

Raters marked sufficient distal vessels in 79% of evaluations. Compared to HC, SSc and PRP images had odds ratios [95% CI] of sufficient distal vessels marked of 0.23 [0.14, 1.41] and 3.80 [0.37, 5.23] respectively. The mean vessel density in HC was 9.84 vessels/mm. Compared to HC, vessel density was lower in SSc (6.62) but not significantly different in PRP (9.58); respective differences [95% CI] were -3.22 [-3.88, -2.63] and -0.26 [-1.12, 0.63] vessels/mm.

Estimates of intra-rater reliability [95% CI] were 0.91 [0.89, 0.92] for vessel mark-up and 0.89 [0.87, 0.91] for vessel density. Corresponding estimates of inter-rater reliability were 0.51 [0.39, 0.76] and 0.56 [0.47, 0.64] respectively.

Conclusion: Mark-up rate differences between-groups are most likely due to differences in capillary architecture (capillary loss/damage in SSc patients). Density was unmeasurable in a sizable minority (21%) of image evaluations with potential implications for the representativeness of this measure. The high intra-(compared to inter-) rater reliability suggests that density could serve as outcome measure in prospective studies if the same rater examines images. Research on the impact of training on inter-rater reliability, and into more objective (automated) analysis methods is required to further develop this promising outcome measure.

Troponin T as a Diagnostic and Prognostic Biomarker of Primary Cardiac Involvement in Systemic Sclerosis. Silvia Laura Bosello, Giacomo De Luca, Federico Parisi, Giorgia Berardi, Manuela Rucco, Giovanni Canestrari and Gianfranco Ferraccioli. Division of Rheumatology, Institute of Rheumatology and Affine Sciences, Catholic University of the Sacred Heart, Rome, Italy.

Background/Purpose: Heart involvement is common in Systemic Sclerosis (SSc), even if often clinically silent, and represents one of the leading

cause of death in these patients. The aim of our study was to define the role of cardiac troponin T (cTnT) and NT-proBNP to identify a cardiac involvement.

Methods: cTnT and NT-proBNP levels were evaluated in 200 consecutive SSc patients (mean age: 58.7 ± 13.9 years; mean disease duration: 11.1 ± 9.0 years; diffuse disease: 42.0%; anti-Scl70 positivity: 45.5%) from 2008 and 2013. Data regarding disease subtype and organ involvement were available for the entire cohort and all patients underwent: electrocardiogram (EKG), echocardiography and pulmonary function test (PFTs). All SSc-related deaths were registered during a mean follow-up of 40.8±18.7 months.

Results: cTnT levels were above the normal limit in 79 (39.5%) SSc patients (mean levels in positive patients: 0.06 ± 0.08 ng/ml). NT-proBNP levels were above the cut-off limit of 125 ng/ml, recommended by the manufacturer, in 79 patients (39.5%) and 51 of these patients presented also increased levels of cTnT. The increased cTnT levels were associated with diffuse skin involvement and skeletal myositis ($p<0.0001$; $p=0.006$ respectively) and directly correlated with skin score ($R=0.27$; $p<0.0001$). Patients with high cTnT levels presented a lower left ventricular ejection fraction (LV-EF) (59.5±9.3%) and higher pulmonary arterial systolic pressure on echocardiography (37.7±16.8 mmHg) compared to patients with normal cTnT values (63.1±4.9%, $p=0.04$; 28.3±6.8 mmHg, $p<0.0001$). These patients, furthermore, presented more frequently a right bundle branch block on EKG with respect to patients without increasing of cTnT (19.7% vs.7.0%; $p=0.008$). In our cohort 28 patients (14%) presented a LV-EF <55% and the sensitivity of increased cTnT levels (>0.014 ng/ml) in the detection of depressed myocardial contractility was 67.8% and its specificity was 66.8%. It is also noteworthy that its negative predictive value in the assessment of depressed LV-EF was 92%. During the follow-up, 18 SSc-related death occurred; 10 of these were directly related to cardiac involvement (sudden cardiac death or heart failure) and all occurred in patients with increased cTnT levels. Cumulative survival estimated by Kaplan-Mayer curve was worse in patients with increased baseline levels of cTnT ($X^2=21.2$, $p<0.0001$). Died patients presented higher levels of cTnT (0.11±0.03 ng/ml) and of NT-proBNP (7193±5691.3 pg/ml) and lower LV-EF (52.5±11.9%) with respect to survivors (cTnT: 0.02±0.05 ng/ml; NT-proBNP: 585.8±2517.3 pg/ml; LV-EF: 61.9±6.6%; $p=0.001$ for all comparisons).

Conclusion: The cTnT levels were increased in up to 40% of the SSc patients, revealing that myocardial involvement is more relevant in scleroderma disease than appreciated previously. cTnT may provide an opportunity to screen non-invasively SSc patients for subclinical heart involvement. The more impaired systolic function and more frequent EKG abnormalities in SSc patients with increased TnT levels, suggest that cTnT may be a novel biomarker of cardiac damage. Our data on survival suggest it as a possible prognostic biomarker of SSc-related death.

Lack of Association Between Esophageal Symptoms and Abnormal Findings in High-Resolution Manometry in a Mexican Mestizo Cohort with Systemic Sclerosis (SSc).

Ana Arana-Guajardo[1], Miguel Villarreal-Alarcón[2], Gustavo Torres-Barrera[3], David Vega-Morales[4], Hector Maldonado-Garza[3] and Mario Garza-Elizondo[2]. [1]Servicio de Reumatología, Departamento de Medicina Interna del Hospital Universitario "Dr. José Eleuterio González", Universidad Autónoma de Nuevo León, Monterrey, Mexico, [2]Servicio de Reumatología, Departamento de Medicina Interna del Hospital Universitario "Dr. José Eleuterio González", Universidad Autónoma de Nuevo León, Monterrey, Mexico, [3]Servicio de Gastroenterología, Departamento de Medicina Interna del Hospital Universitario "Dr. José Eleuterio González", Universidad Autónoma de Nuevo León, Monterrey, Mexico, [4]Hospital Universitario UANL, Monterrey, Mexico.

Background/Purpose: Esophageal involvement is present in 50–70% of SSc patients and it is the most common visceral organ complication. The impact of the esophageal involvement is related with high morbidity and included the association with intersticial lung disease, weight loss and malnutrition, Barretxs esophagus and adenocarcinoma degeneration. Our objectives were characterize motor esophageal impairment in patients with SSc with or without esophageal symptoms using high-resolution manometry (HRM).

Methods: Observational, descriptive, cross-sectional study. We included SSc patients according to American College of Rheumatology classification criteria of the 1980 and patients with Scleroderma variants with esophageal symptoms; with an age ≥ 18 years old, from a clinic of a tertiary hospital. The demographic data, skin manifestations, esophageal symptoms and drugs used were recorded. The Carlsson-Dent questionnaire (CDQ) was used to evaluate gastroesophageal reflux disease and dysphagia was graded on a five-point scale according to Mellow and Pinkas. The modified Rodnan skin score (mRSS) was used in the skin evaluation. A standard HRM was performed and the results were classified according to Chicago Classification. In the analysis we categorized the grade of dysphagia, the mRSS and HRM results. We used 2x2 contingency tables and chi-square or Fisher's exact test according of their distribution to establish an association between each variable and HRM result. A p value < 0.05 was classified as statistically significant.

Results: We included 19 SSc patients, 1 with morphea and 1 with Scleroderma sine scleroderma. Clinical and demographic variables are shown in Table 1. Most of the patients were on normal BMI, had been classified in limited disease, and had used proton-pump inhibitors. The most common symptoms were dysphagia and heartburn. We found an abnormal HRM in 16 (76.2%) patients; the most common abnormality in HRM was absence of peristalsis in 5 (23.8%) patients. Variables analyzed with HRM are shown in Table 2. We did not find association between any variable (Table 1 and 2) and the presence of abnormal HRM.

Conclusion: We found a lack of association between esophageal symptoms and abnormal findings in HRM. There was not association between CDQ and HRM. Although this study is limited by the number of patients analyzed, we think that due to the large impact of the esophageal involvement in SSc patients, we need to do a systematic esophageal study of this patients with the objective to decrease their morbidity.

Right Ventricular Diastolic Impairment Is Common in Systemic Sclerosis and Is a Marker of Several Organ-Target Damage of the Disease.

Christophe Meune[1], Dinesh Khanna[2], Jamil Aboulhosn[3], Jerome Avouac[4], Andre Kahan[5], Daniel E. Furst[6] and Yannick Allanore[4]. [1]Paris 13 University, University Hospital of Paris-Seine-Saint-Denis, Cardiology Department, Bobigny, France, [2]University of Michigan Health System, Ann Arbor, MI, [3]Department of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA, [4]Paris Descartes University, Rheumatology A Department and INSERM U1016, Cochin Hospital, Paris, France, [5]Paris Descartes University, Rheumatology A department, Cochin Hospital, Paris, France, [6]University of California, Los Angeles, Department of Medicine, Los Angeles, CA.

Background/Purpose: Heart failure and cardiac dysfunctions both of intrinsic or secondary origin and targeting LV (left ventricule) and/or RV (right ventricule) are critical complications promoting mortality in systemic sclerosis (SSc). While several studies reported possible right ventricule (RV) alterations in SSc patients having pulmonary hypertension, only few and small series investigated RV function in unselected SSc patients. Therefore, the aim of the present study is to investigate LV and RV systolic and diastolic function in a large SSc cohort of unselected patients compared to a control group using comprehensive echocardiographic parameters.

Methods: We examined LV and RV systolic and diastolic functions, using echocardiography and Tissue Doppler echocardiography (TDE) indexes, in a cohort of 212 consecutive SSc patients seen during a 9 month-period at two institutions (Paris, France and Los Angeles, USA) and 50 healthy controls.

Results: Patients' characteristics from the two institutions were very similar allowing combined analyses. When compared to controls, SSc patients had consistently impaired RV indices that include reduced RV contractility ($p<0.001$), larger right atrial area ($p=0.027$) and overall RV diastolic dysfunction ($p<0.001$) (Table 1). Patients also exhibited alterations in LV contractility and diastolic function ($p<0.001$ each) (Table 1). Looking at associated parameters, in multivariate analysis, RV contractility as expressed by the TDE S_T parameter was associated with TDE LV contractility S_M ($p=0.030$), DLCO ($p=0.013$) whereas RV diastolic impairment was associated with systolic pulmonary artery pressure ($p=0.015$). In a subset of 27 patients with proven pre-capillary PAH, comparison between SSc-PAH versus SSc free of PAH patients, revealed reduced LV diastolic function (measured by transmitral E/A ratio ($p=0.045$) and E_A <10cm/s ($p=0.029$)), reduced overall RV contractility (21.5 versus 4.5%; $P=0.03$) and reduced RV diastolic function (transtricuspid E/A ratio; $p=0.014$ and 68% versus 29% with impaired function; $p=0.001$).

Conclusion: Whereas most previous studies focused on the LV, we report in the present controlled study that not only systolic but also diastolic RV dysfunction is common in SSc and that several cardiopulmonary factors seem to influence RV function in this multifaceted disease. Given that RV dysfunction and fibrosis are poor prognosticator, possibly associated with lethal ventricular arrhythmias, sudden death, exercise limitation, and impaired RV cardiac output, we assume that RV function should be closely investigated in SSc patients and that the impact on RV diastolic function of future therapies targeting PAH and/or primary myocardial involvement is to be assessed.

Table 1:

	SSc patients (n=212)	Controls (n=50)	p
Age, years	55.3 ± 13.2	53.1 ± 11.0	0.201

Abnormal Right Ventricular Longitudinal Strain Detected in Systemic Sclerosis Patients Prior to Abnormalities in Conventional Measures of Right Ventricular Size and Function.

Monica Mukherjee[1], Shang-En Chung[2], Laura K. Hummers[1], Fredrick M. Wigley[1], Theodore P. Abraham[1] and Ami A. Shah[1]. [1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]Johns Hopkins University, Baltimore, MD.

Background/Purpose: Cardiac involvement in systemic sclerosis (SSc) adversely affects long-term prognosis, remaining undetectable despite frequent echocardiographic monitoring. Speckle tracking derived strain of the RV free wall was utilized to detect whether early changes in regional and global contractility are detectable in SSc patients in comparison to standard 2D measures of RV chamber size and function.

Methods: 138 SSc patients who had technically adequate, clinically indicated 2D echocardiograms were studied, and compared with a cohort of 40 age-matched non-scleroderma controls (C). Conventional 2D and off-line strain analyses were performed. Standard assessment of RV chamber size and function by 2D included linear dimensions of RV base and length, tricuspid annular plane systolic excursion (TAPSE), and RV fractional area change (FAC). RV longitudinal systolic speckle-derived strain (RVLSS) was assessed in the basal, mid and apical free wall. Conventional echo parameters, global RVLSS, and RVLSS in each RV segment were compared between SSc and C by the Student's t test. We also modeled RVLSS as a function of RV segment and disease group (SSc vs C) using GEE analysis to account for the clustering of RV strain values across the 3 RV segments.

Results: Most conventional echo measures of RV size and function were not different between SSc patients and C, including TAPSE (SSc 2.2 ± 0.47 vs C 2.3 ± 0.4 cm; $p=0.119$), linear dimensions of the RV base (SSc 3.6 ± 0.6 vs C 3.4 ± 0.4 cm, $p=0.066$) and RV length (SSc 7.7 ± 0.9 vs C 7.7 ± 0.7 cm, $p=0.832$). While within the normal range, FAC in SSc patients was slightly decreased (48.9 ± 10.9% vs 52.7 ± 8.0, $p=0.045$). In contrast to these conventional parameters, measures of RVLSS were significantly different between SSc and C. Global RVLSS was diminished in SSc compared to C (b 1.5, $p=0.045$). Regional differences in RVLSS were also noted: decreased in the apex (SSc −8.5 vs C −17.2%, $p<0.0001$) and mid (SSc −12.4 vs C −17.8%, $p<0.0001$) segments and increased in the base (SSc −32.2 vs C −22.5%, $p<0.0001$) in SSc vs C. Among C, regional differences in RVLSS were detected in the basal segment relative to the apex (base-apex b −5.4; $p<0.0001$) but not in the mid-apex comparison. In contrast, SSc had significant regional differences throughout (base-apex b −23.6, mid-apex b −3.9, both $p<0.0001$), especially when comparing the basal to apical segments. The base-apex difference was significantly greater in SSc compared to C ($p<0.0001$ for interaction). While SSc had a higher mean PASP than C (SSc 31.4 vs C 22.7 mmHg, $p=0.0001$), the differences observed in regional strain between SSc and C were unchanged when restricting our analyses to those with a PASP<35 mmHg.

Conclusion: Speckle-derived strain reveals a heterogenous pattern of regional longitudinal systolic contraction in scleroderma, that is not detected by conventional echocardiographic measures. These data suggest that significant RV myocardial disease is occult in SSc patients, and may potentially progress with time.

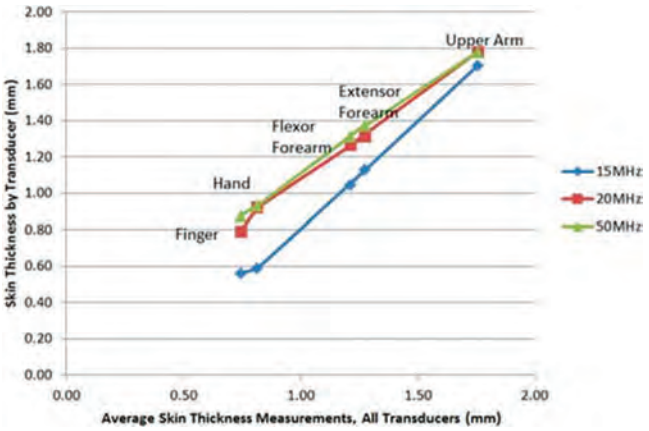
Precision of Ultrasound Skin Thickness Measurements: Influence of Examiner and Ultrasound Transducer. Ingeborg A. Sacksen, P. Scott Pollock and Mark H. Wener. University of Washington, Seattle, WA.

Background/Purpose: Ultrasound has been used to measure scleroderma skin thickness, but it has not been established that routine clinical ultrasound equipment is adequate. We compared skin thickness measured with a common office instrument vs measurements using high frequency research ultrasound equipment, and determined the differences in measurement values and precision.

Methods: Repeated measurement of skin thickness of 1 normal volunteer at 5 reproducible sites on the dorsum of the proximal phalanx of a finger, the dorsum of a hand, the extensor surface and flexor surface of a forearm, and a lateral upper arm. A 15 MHz clinical ultrasound transducer and instrument (Sonosite, Bothell, WA), and 20 MHz and 50 MHz research transducers of a research ultrasound instrument (Sonosite, Bothell, WA) were used. After initial training, 3 examiners independently imaged all 5 sites with each transducer on 3 days over a period of one month. On each image, measurements of dermal thickness were made at 3 representative sites, and averaged to provide the thickness measure of that image.

Results: The overall average coefficient of variation (CV) was 8.6% for the 50 MHz transducer, 5.7% for the 20 MHz transducer, and 14.2% for the 15 MHz transducer. Measurements were more precise at the thicker skin of the arm (CV=5.6%) than at thinner sites. Thickness measured with 15 MHz was smaller than those of the 20 and 50 MHz transducers at all sites, but was generally reproducible at each site. Skin thickness at the finger vs hand differed significantly using the 20 and 50 MHz transducers, but the 15 MHz transducer results at those 2 sites were not statistically distinguishable. Measurements by one examiner were consistently smaller than those of the other 2 observers, whose values matched closely. All showed the expected increase in thickness by site (figure).



Conclusion: The 15 MHz clinical ultrasound instrument is not as precise as higher frequency ultrasound equipment, especially in thin skin such as at the dorsum of the normal finger and hand. However, even at modestly thicker sites, such as the normal arm and forearm, the precision is acceptable. These data suggest that routinely-available mid-range clinical ultrasound equipment can be used to develop ultrasound-based skin thickness measurements, with the potential to improve the ability to monitor changes in skin thickness.

Outcome of Patients with Systemic Sclerosis Admitted to the Intensive Care Unit. Tarik Hissem[1], Alice Berezne[2], David Grimaldi[3], Alain Cariou[1], Julien Charpentier[1], Jean-Daniel Chiche[1], Yannick Allanore[4], Jean-Paul Mira[1], Frédéric Pène[5] and Luc Mouthon[6]. [1]Intensive care unit - Cochin University Hospital, Paris, France, [2]Paris Descartes University, Internal Medicine department, Cochin Hospital, Paris, France, [3]Intensive Care Unit - Cochin University Hospital, Paris, France, [4]Paris Descartes University, Rheumatology A Department and INSERM U1016, Cochin Hospital, Paris, France, [5]Intensive care unit - Cochin university hospital, Paris, France, [6]National Referral Center for Rare Systemic Autoimmune Diseases, Hôpital Cochin, AP–HP, Université Paris Descartes, Paris, Paris, France.

Background/Purpose: Studies on the outcome of patients with systemic sclerosis (SSc) in intensive care unit (ICU) are scarce in the literature.

Objective: To assess the characteristics and outcomes of patients with SSc admitted to ICU.

Methods: We performed a single-center retrospective study over a 4-year period (November 2006-December 2010). All patients with SSc admitted to the ICU were enrolled. The underlying disease's features, reasons for ICU admission and organ failure supports were collected. We studied their short-term (ICU and hospital mortality) and long-term (6-month and 1-year mortality) outcomes, and we sought to identify prognostic factors. Variables were expressed as median (IQR) or number (percentage) as appropriate.

Results: Thirty five patients (age 51 [40–63] years, 77% female, SAPSII 35 [23–51]) were enrolled in the study. Twenty two (63%) and 13 (37%) patients displayed diffuse cutaneous and limited cutaneous SSc, respectively. The time from diagnosis to ICU admission was 80 [27–110] months. Twenty six (74%) patients had pulmonary fibrosis with the following baseline characteristics: diffusion capacity of lung for CO 33% [20–45], forced vital capacity 52% [39–66]. Ten patients had pulmonary hypertension with a systolic pulmonary artery pressure of 55 mmHg [45–63]. Only two (6%) had chronic renal insufficiency requiring long-term hemodialysis.

The main reasons for ICU admission were acute respiratory failure (69%) and acute renal failure (17%). During hospitalisation in ICU, 10 (28%) required endotracheal intubation and mechanical ventilation, 10 (28%) required hemodialysis and 9 (26%) required vasopressors. The overall ICU and hospital mortality rates were 26% and 34% respectively. Six-month and 1-year mortality rates were 40% and 46% respectively. None of the disease characteristics impacted the hospital outcome. Survivors and decedents were mostly different in terms of organ failures, most especially respiratory failure. Invasive mechanical ventilation was associated with a 100-percent hospital mortality rate and was the only independent prognostic factor.

Conclusion: This study reports on the most important cohort of patients with SSc in the ICU. Respiratory failure related to advanced-stage pulmonary fibrosis represents the main reason for ICU admission. In this setting, mechanical ventilation is constantly associated with hospital mortality. These results urge to reappraise the indications for ICU and mechanical ventilation in this high-risk subgroup of patients.

Integrin Inhibitor Modulates Pulmonary Fibrosis in the Reactive Oxygen Species Murine Model of Systemic Sclerosis. Gianluca Bagnato[1], Alessandra Bitto[1], Natasha Irrera[1], Gabriele Pizzino[1], Neal Roberts[2], Domenica Altavilla[1], Francesco Squadrito[1], Antonino Saitta[1] and Gianfilippo Bagnato[3]. [1]University of Messina, Messina, Italy, [2]University of Louisville, Louisville, KY, [3]Universita Messina, Villafranca Tirrena, Italy.

Background/Purpose: Systemic sclerosis (SSc) is an acquired connective tissue disorder in which inflammation, immune dysregulation and vascular damage lead to fibroblast activation that results in fibrosis of the skin and internal organs. Development of therapies is hampered by lack of understanding of the underlying mechanism of disease. It has been recently shown that alterations in cell–matrix interactions are sufficient to initiate and sustain inflammatory and pro-fibrotic programmes [1]. Both SSc fibroblasts [2] and pulmonary T cells of patients affected by SSc with interstitial lung disease highly express $\alpha V\beta 3$ and $\alpha V\beta 5$ integrins and they are required for

lymphocytic infiltration and collagen accumulation [3]. The aim of the study is therefore to evaluate the effect of the αVβ3 and αVβ5 inhibitor (cilengitide) on the development of pulmonary fibrosis in the HOCl-induced murine model of systemic sclerosis.

Methods: Chronic oxidant stress SSc was induced in BALB/c mice by daily s.c. injections of HOCl for 6 weeks. 25 Mice were randomized in three arms: HOCl alone (n=10), HOCl + Cilengitide (n=10) or vehicle alone (n=5). Treatment with cilengitide 20 (mg/kg/i.p./day) was started four weeks after the administration of HOCl and maintained throughout the remaining experimental period (2 weeks). Lung fibrosis was evaluated by histological methods. The severity of fibrosis was assessed using ordinal or nominal scales and the results compared nonparametrically. Lung concentrations of focal adhesion kinase (FAK) were evaluated by western blot analysis.

Results: The administration of HOCl induced lung fibrosis as demonstrated by routine histological analysis. Cilengitide significantly reduced the histopathological change of HOCl-induced pulmonary fibrosis (Figure 1A-D). Additionally, pulmonary FAK expression was increased in mice treated with HOCl and significantly modulated by cilengitide administration (Figure 1E).

Conclusion: The inhibition of integrin signaling could prove useful as future therapeutic targets for treatment of SSc. Further confirmatory results in a second animal model are needed to better assess the specific effect of cilengitide on the development of fibrosis and myofibroblasts differentiation.

Background/Purpose: Systemic sclerosis (SSc) related interstitial lung disease (ILD) has phenotypic similarities to idiopathic interstitial pneumonia (IIP). The objective of this study was to assess whether genetic susceptibility loci which were recently identified in a large idiopathic interstitial pneumonia (IIP) genome-wide association study (GWAS) were also risk loci for SSc overall, for SSc-autoantibody subgroups or for severity of SSc-ILD.

Methods: A total of 2571 North-American Caucasian SSc patients and 4500 unaffected control subjects were investigated in two independent cohorts. The discovery cohort consisted of 1486 SSc cases and 3477 unaffected controls while the confirmation cohort consisted of 1085 additional SSc cases and 1023 unaffected controls. All patients were enrolled in the National Scleroderma Family Registry and DNA Repository and fulfilled the 1980 American College of Rheumatology classification criteria for SSc or had at least three of the five CREST features. Forced vital capacity % predicted (%FVC) as continuous outcome was used as a validated outcome measure for severity of ILD. Single nucleotide polymorphisms (SNPs) rs2736100 (*TERT*), rs2076295 (*DSP*), rs4727443 (*AZGP1*), rs7934606 (*MUC2*), rs2034650 (*IVD*), rs1981997 (*MAPT*), rs12610495 (*DPP9*), rs6793295 (*LRRC34*), rs2609255 (*FAM13A*), rs11191865 (*OBFC1*), rs1278769 (*ATP11A*) and rs1379326 (*CSMD1*), which were identified/confirmed to be associated with IIP in a recently published GWAS (Fingerlin et al. Nat Genetics 2013) were genotyped and analyzed for its association with SSc and severity of SSc-ILD.

Results: In the discovery cohort, we observed nominally significant associations with SSc overall for *LRRC34* rs6793295 (MAF=0.29, OR=1.14, CI 95% 1.03 to 1.25, p value=0.009) and *OBFC1* rs11191865 (MAF=0.52, OR=1.09, CI 95% 1.00 to 1.19, p value=0.043). There were no significant associations in the anti-topoisomerase I (ATA) or anti-centromere (ACA) positive patient subgroups. However, *DSP* rs2076295 (β=−2.29, CI 95% −3.85 to −0.74, p value=0.004) and *MAPT* rs1981997 (β=2.26, CI 95% 0.35 to 4.17, p value=0.02) were associated with forced vital capacity % predicted (% FVC) even after adjusting for ATA status. All SNPs observed to reach nominal significance levels in the discovery cohort were genotyped in the replication cohort. However, none of the above observed associations were confirmed in the replication cohort.

Conclusion: Herein, we add new evidence that SSc and SSc related ILD are genetically distinct from IIP, although they share phenotypic similarities. This finding might have important implications for follow-up mechanistic studies and identification of therapeutic targets. Genetic background of SSc seems to be mainly related to innate and adaptive immunity while IIP genetic susceptibility relates to epithelial cell injury and dysfunction, mucin production, and telomere length. Interstitial lung involvement in SSc-ILD and IIP might be the common end-product of two different pathological backgrounds.

Elevated Pentraxin 3 in Patients with Systemic Sclerosis: Associations with Vascular Manifestations and Defective Vasculogenesis. Yuichiro Shirai[1], Yuka Okazaki[1], Yumiko Inoue[1], Yuichi Tamura[1], Hidekata Yasuoka[2], Tsutomu Takeuchi[1] and Masataka Kuwana[1]. [1]Keio University School of Medicine, Tokyo, Japan, [2]Keio Univ School of Medicine, Tokyo, Japan.

Background/Purpose: Pentraxin 3 (PTX3) is a multi-functional pattern recognition protein involved in inflammation, extracellular matrix deposition, and suppression of neovascularization mediated by fibroblast growth factor-2 (FGF2). Several lines of recent evidence suggest that PTX3 is constitutively

overexpressed in fibroblasts and endothelial cells derived from systemic sclerosis (SSc) patients. The aim of this study is to examine roles of PTX3 in pathogenic processes of SSc.

Methods: We enrolled 171 patients with SSc and 19 age- and sex-matched healthy controls. Circulating levels of PTX3 and FGF2 were measured by enzyme immunoassay and their correlations with SSc-related organ involvement were evaluated. Univariate and multivariate analysis was conducted to investigate if PTX3 and FGF2 were correlated with the presence or future development of vascular manifestations, including digital ulcer (DU) and pulmonary arterial hypertension (PAH). Circulating $CD34^+CD133^+$ $CD309^+$ endothelial progenitor cells (EPCs) were enumerated by flow cytometry. Effects of recombinant PTX3 on EPC differentiation were evaluated in pro-angiogenic cultures of mouse bone marrow mononuclear cells, followed by colony formation assay.

Results: PTX3 and FGF2 were significantly increased in SSc patients than in healthy controls ($P < 0.001$ and $P = 0.001$, respectively). When PTX3 and FGF2 levels were compared between two groups stratified by the presence or absence of individual organ involvement, PTX3 was increased in SSc patients with DU or PAH than in those without ($P < 0.001$ and $P = 0.006$, respectively), while FGF2 was reduced in patients with PAH ($P < 0.001$). Multivariate analysis revealed that elevated PTX3 was an independent parameter associated with the presence of DU (odds ratio (OR) = 1.50, $P < 0.001$) and PAH (OR = 1.23, $P = 0.002$), and was useful in predicting future occurrence of DU (hazard ratio = 1.12, $P = 0.04$). In contrast, reduced FGF2 was independently associated with the presence of PAH (OR = 0.91, $P = 0.02$). EPC counts were significantly reduced in patients with DU or PAH than in those without ($P = 0.003$ and 0.003, respectively), and were correlated negatively with circulating PTX3 concentration ($r = -0.53$, $P < 0.001$) and a PTX3/FGF2 ratio ($r = -0.35$, $P = 0.003$). Finally, exogenous PTX3 significantly inhibited differentiation of EPCs from mouse bone marrow stem cells *in vitro*.

Conclusion: PTX3 was elevated in circulation of SSc patients and was a useful biomarker that predicts the presence of DU and PAH as well as future development of DU. In addition, continuous exposure to a high PTX3 concentration may contribute to SSc vasculopathy through inhibition of vasculogenesis by exerting its suppressive effects on FGF2.

Background/Purpose: Systemic sclerosis (SSc), also known as scleroderma, is an inflammatory autoimmune disease characterized by fibrosis of the skin and internal organs, vascular damage and altered immune responses with autoantibody production (especially anticentromere (ACA) and antitopoisomerase I (ATA)). As a complex disease, SSc, is caused by a combination of genetic and environmental factors. In recent years, the number of new susceptibility loci associated with SSc has remarkably grown due to genome-wide association studies (GWAS). Nevertheless, the current knowledge of the influence of SSc risk loci in the clinical sub-phenoytpes is limited and one of the main reasons is the low sample size in sub-phenotypes that triggers a lower statistical power. In this regard, ATA^+ SSc patients have been recently associated with *CCR6* gene variants and the main limitations of the study was the low sample size due to the low frequency of ATA among SSc patients (around 20%). Thus, in order to confirm the *CCR6* association with ATA^+ SSc, we performed an independent replication study in populations of European ancestry and a meta-analysis with the previous data published.

Methods: We selected for replication SNP rs3093024, in high linkage disequilibrium with the SNPs previously associated with ATA^+ SSc, rs3093023 ($r^2=1$) and rs10946216 ($r^2=0.96$). We designed a replication study with two phases: In phase I, we analyzed 454 ATA^+ SSc cases and 4,867 controls from available GWAS genotyped platform by Radstake *et al.* and in phase II, 446 ATA^+ SSc cases and 2,998 controls from five additional European cohorts were genotyped using TaqMan SNP® genotyping assay. Approval of local ethical committees and informed written consent was obtained for all participants. The meta-analysis of our study with the previous one included 1,548 ATA^+ SSc cases and 14,777 controls and reached statistical power of the analysis to 99% (OR 1.16, MAF 0.43, at the 5% significant level).

Results: Results obtained in meta-analysis showed significant association between SNP rs3093024 and ATA^+ SSc patients ($P = 1.0 \times 10^{-4}$, OR=1.16) (Table 1). Thus we confirm the association previously observed between *CCR6* and ATA^+ SSc patients harnessing the largest cohort of patients. The relevance of *CCR6* gene lies in its function as specific marker for Th17 cells. These cells are characterized by the production of interleukin-17 (IL- 17) which has been found to be increased in patients with SSc. Besides serum levels of IL-17 and ATA presence have been both correlated with disease severity. Interestingly, *CCR6* expression levels and IL-17 levels showed correlation with a *CCR6* functional variant which was in high linkage disequilibrium with SNP rs3093024 in rheumatoid arthritis patients.

Conclusion: Taken all together, our findings suggest that the presence of the risk variant of rs3093024 in *CCR6* gene may acts as a marker of severity in SSc patients.

Increased Expression of Chemerin in Endothelial Cells Due to Fli1 Deficiency May Contribute to the Development of Digital Ulcers in Systemic Sclerosis. Kaname Akamata, Yoshihide Asano, Takashi Taniguchi, Hayakazu Sumida, Naohiko Aozasa, Shinji Noda, Tetsuo Toyama, Takehiro Takahashi, Yohei Ichimura, Ayumi Yoshizaki and Shinichi Sato. University of Tokyo Graduate School of Medicine, Tokyo, Japan.

Background/Purpose: Systemic sclerosis (SSc) is a multisystem autoimmune disorder characterized by vascular injuries and fibrosis development. In SSc lesional skin, transcription factor Friend leukemia virus integration 1 (Fli1) is constitutively down-regulated in various cell types, especially by an epigenetic mechanism in dermal fibroblasts, and Fli1 deficiency is deeply related to the pathogenesis of SSc. In particular, endothelial Fli1 deficiency reproduces the histological and functional abnormalities characteristic of SSc vasculopathy *in vivo*. Recently, adipocytokines have drawn much attention in the research field of various autoimmune diseases. Chemerin is a member of adipocytokines with a chemoattractant effect and a pro-angiogenic property, and has been shown to have pivotal roles in the pathogenesis of various autoimmune diseases. To elucidate the role of chemerin in the developmental process of SSc, we investigated the expression levels of chemerin in SSc lesional skin and the mechanism underlying its altered expression, and the clinical correlation of serum chemerin levels in SSc patients.

Methods: Expression of chemerin and its receptor, ChemR23, was evaluated by immunostaining and/or quantitative reverse transcription-real time PCR in human and/or murine skin. The mechanisms regulating chemerin expression in dermal fibroblasts and endothelial cells were examined by gene silencing technique and chromatin immunoprecipitation. Serum chemerin levels were determined by enzyme-linked immunosorbent assay in 64 SSc and 19 healthy subjects.

Results: In SSc lesional skin, chemerin was up-regulated in small blood vessels, down-regulated in activated fibroblasts surrounded with thickened collagen bundles, but not altered in inflammatory cells, while ChemR23 expression was comparable in various cell types. Chemerin expression was also markedly decreased in dermal fibroblasts of bleomycin-treated SSc model mice. Importantly, the decreased expression of chemerin was significantly reversed by blocking autocrine transforming growth factor (TGF)-β signaling with TGF-β1 antisense oligonucleotide in cultured SSc dermal fibroblast. As for endothelial cells, gene silencing of Fli1, which directly bound to the chemerin promoter, induced chemerin expression in human dermal microvascular endothelial cells and *Fli1*$^{+/-}$ mice exhibited elevated chemerin expression in dermal blood vessels. Regarding the correlation of serum chemerin levels with clinical features in SSc patients, serum chemerin levels inversely correlated with estimated glomerular filtration rate in SSc patients with renal dysfunction while, in SSc patients with normal renal function, patients with digital ulcers had higher serum chemerin levels than those without.

Conclusion: Chemerin is down-regulated in SSc dermal fibroblasts by autocrine TGF-β, while up-regulated in SSc dermal blood vessels through endothelial Fli1 deficiency. In SSc, dysregulated chemerin/ChemR23 axis by endothelial Fli1 deficiency may contribute to the development of SSc vasculopathy through altering angiogenic/angiostatic signaling pathways.

Progranulin Overproduction Due to Fli1 Deficiency Contributes to the Resistance of Dermal Fibroblasts to Tumor Necrosis Factor a in Systemic Sclerosis. Yohei Ichimura, Yoshihide Asano, Kaname Akamata, Shinji Noda, Takashi Taniguchi, Takehiro Takahashi, Tetsuo Toyama, Yayoi Tada, Makoto Sugaya, Shinichi Sato and Takafumi Kadono. University of Tokyo Graduate School of Medicine, Tokyo, Japan.

Background/Purpose: Systemic sclerosis (SSc) is a multisystem fibrotic connective tissue disease characterized by a dysregulated activation of fibroblasts following inflammation, autoimmune attacks, and vascular injuries. Although the pathogenesis of SSc remains currently elusive, chronic activation of wound healing-related gene programs is a hall mark of this disease. Progranulin (PGRN) is a wound healing-associated growth factor with an antagonistic property against tumor necrosis factor (TNF) receptors, regulating fibroblast activation, angiogenesis, and inflammation, i.e. three major pathological components of SSc. Therefore, we hypothesized that PGRN is involved in the mechanism underlying dermal fibrosis of SSc.

Methods: PGRN expression levels were determined by immunohistochemistry and quantitative reverse transcription-PCR in the skin of human subjects and murine SSc models. The role of PGRN in dermal fibroblast activation was examined with gene silencing technique. Serum PGRN levels were determined by ELISA in 60 SSc and 16 healthy subjects.

Results: In immunostaining with human skin samples, the expression levels of PGRN were increased in SSc dermal fibroblasts compared with normal dermal fibroblasts, while comparable in inflammatory cells, endothelial cells, and epidermal keratinocytes between SSc and control subjects. This finding was also confirmed *in vitro* with cultured SSc dermal fibroblasts, showing a significant increase of PGRN mRNA expression compared with normal dermal fibroblasts. Furthermore, bleomycin-treated mice exhibited the up-regulated expression of PGRN in dermal fibroblasts, suggesting the potential contribution of this molecule to the pathological dermal fibrosis, including SSc. Importantly, transcription factor Fli1, whose deficiency due to epigenetic mechanism contributes to the constitutive activation of SSc dermal fibroblasts, bound to the promoter of the *PGRN* gene and gene silencing of Fli1 resulted in a robust increase in mRNA levels of the *PGRN* gene in human dermal fibroblasts. Consistently, the up-regulated expression of PGRN was observed in dermal fibroblasts of *Fli1*$^{+/-}$ mice *in vivo*. Given that PGRN serves as an antagonist of TNF-a, a pro-inflammatory cytokine with a potent anti-fibrotic effect on dermal fibroblasts, we hypothesized that PGRN renders SSc dermal fibroblasts resistant to the anti-fibrotic effect of TNF-a. Supporting our idea, TNF-a suppressed the expression of type I collagen in SSc dermal fibroblasts treated with PGRN siRNA, while not in those treated with non-silencing scrambled RNA. To further assess the role of PGRN in SSc, we measured serum PGRN levels and examined their clinical correlation. Serum PGRN levels were elevated in early diffuse cutaneous SSc patients, especially in those with inflammatory skin symptoms, and positively correlated with C-reactive protein.

Conclusion: PGRN overproduction due to Fli1 deficiency may contribute to the constitutive activation of SSc dermal fibroblasts by antagonizing the anti-fibrotic effect of TNF-a. PGRN may also be involved in the inflammatory process associated with progressive skin sclerosis in early diffuse cutaneous SSc.

Molecular Characterization of Systemic Sclerosis Esophageal Pathology Identifies Inflammatory and Proliferative Signatures with Few Fibrotic Markers. Jaclyn Taroni[1], Viktor Martyanov[2], Chiang-Ching Huang[3], J. Matthew Mahoney[4], Ikuo Hirano[5], Tammara A. Wood[2], Brandon Shetuni[5], Guang-Yu Yang[5], Darren Brenner[5], Barbara Jung[6], Swati Bhattacharyya[7], Orit Almagor[8], Jungwha Lee[5], Arlene Sirajuddin[5], Rowland W. Chang[5], John Varga[5], Michael Whitfield[2] and Monique Hinchcliff[5]. [1]Giesel School of Medicine at Dartmouth, Hanover, NH, [2]Geisel School of Medicine at Dartmouth, Hanover, NH, [3]University of Wisconsin, Milwaukee, Milwaukee, WI, [4]University of Vermont, Burlington, VT, [5]Northwestern University Feinberg School of Medicine, Chicago, IL, [6]University of Illinois at Chicago, Chicago, IL, [7]Northwestern University, Feinberg School of Medicine, Chicago, IL, [8]Northwestern University, Chicago, IL.

Background/Purpose: Esophageal involvement in patients with systemic sclerosis (SSc) is common, but tissue-specific pathological mechanisms are poorly understood. Esophageal muscle atrophy without concomitant fibrosis is found in the majority of SSc patient autopsy specimens. We hypothesized that detailed characterization of SSc esophageal histopathology and molecular signatures at the level of gene expression would provide insights into SSc esophageal disease pathogenesis.

Methods: Esophageal biopsies were prospectively obtained during esophagogastroduodenoscopy (EGD) in 16 clinically well-characterized SSc patients and 7 subjects without SSc. Upper and lower esophageal biopsies were evaluated for histopathology and gene expression by DNA microarray. Biopsies were scored for basal cell hyperplasia, lymphocyte infiltration, and degree of collagen deposition. The presence of a hiatal hernia and/or esophagitis on gross examination of the esophageal lumen at the time of EGD was considered evidence for esophagitis. Transcripts with the most similar expression between an individual's upper and lower biopsies, but most different expression between individuals, termed 'intrinsic genes,' were identified and hierarchically clustered to define molecular subsets (FDR $<$1.1%). Consensus clustering and SigClust formally confirmed the number of significant clusters within the cohort. Significance Analysis of Microarrays (SAM) identified differentially expressed transcripts between subsets, and g:Profiler identified functional terms enriched in subsets.

Results: Upper and lower esophageal biopsies showed nearly identical patterns of gene expression within an individual. Three groups of patients with SSc were identified molecularly: an inflammatory group (upregulated genes related to immune processes), a proliferative group (upregulated genes indicative of proliferating cells), and a non-inflammatory group (downregulated immune genes). The inflammatory signature was independent of esophagitis as assessed by basal cell hyperplasia grade, infiltrating lymphocyte counts, and presence of gross esophagitis/hiatal hernia indicating im-

mune cell activation may underlie the inflammatory esophageal gene expression signature. Inflammatory patients tended to have more collagen deposition than patients in the combined non-inflammatory/proliferative, but the results were not statistically significant ($p = 0.38$). Molecular classification of esophageal biopsies was independent of SSc subtype ($p=0.62$), serum autoantibodies ($p=0.23$) and esophagitis ($p=1.00$).

Conclusion: Similar to skin, Inflammatory and Proliferative Intrinsic Subsets are present SSc patients' esophagi suggesting that molecular subsets are a global feature of SSc end target organ pathology. SSc esophageal molecular subsets are distinct from subtypes identified clinically. Inflammation rather than fibrosis was the most dominant gene expression signature in SSc esophageal biopsies. The inflammatory signature is observed in biopsies that lack large inflammatory infiltrates suggesting that immune activation is a major driver of SSc esophageal pathogenesis.

Dissecting the Heterogeneity of Skin Gene Expression Patterns in Systemic Sclerosis. Shervin Assassi[1], William Swindell[2], Minghua Wu[1], Filemon K. Tan[1], Dinesh Khanna[2], Daniel E. Furst[3], Donald Tashkin[3], Richard Jahan-Tigh[1], Maureen D Mayes[1], Johann Gudjonsson[2] and Jeffrey T. Chang[1]. [1]University of Texas Health Science Center at Houston, Houston, TX, [2]University of Michigan, Ann Arbor, MI, [3]University of California at Los Angeles, Los Angeles, CA.

Background/Purpose: To examine the heterogeneity of global transcriptome patterns in systemic sclerosis (SSc) skin from a large cohort of patients and controls.

Methods: Skin biopsies from 61 patients (70.5 % diffuse cutaneous involvement) enrolled in the GENISOS cohort or at the baseline visit of an imatinib study, as well as 36 unaffected controls of similar demographic background, were examined by Illumina HT-12 gene expression arrays. Follow-up q-PCR and immunohistochemistry experiments were also performed. Using a novel analytic approach based on expression profiles, we investigated how heterogeneity within SSc samples relates to specific disease-relevant cell types (e.g. fibroblasts or macrophages).

Results: We identified 2754 differentially expressed transcripts in SSc patients compared to controls. Clustering analysis revealed two prominent transcriptomes in SSc patients: Keratin and fibro-inflammatory signatures. Higher keratin transcript scores were associated with shorter disease duration and interstitial lung disease while higher fibro-inflammatory scores were associated with diffuse cutaneous involvement, higher skin score at biopsy site and higher modified Rodnan Skin Score. There were no significant associations with disease-related autoantibodies or concomitant treatment with immunosuppressive agents. A subgroup of patients with significantly longer disease duration had a normal-like transcript pattern.

Further analysis and immunohistochemistry staining indicated that the above-mentioned keratin signature was not a general marker of keratinocyte activation, but was in fact associated with an activation pattern in hair and adnexal structures.

As shown in Figure 1, analysis of cell type-specific signature scores revealed remarkable heterogeneity across patients (each row represents a patient sample). Significantly high scores were observed in the majority of patients for fibroblasts (72% of patients), microvascular (61%), and macrophages (54%). The majority of samples with significant fibroblast scores (35 of 44 = 80%) also had significantly increased macrophage and/or dendritic cell scores. Only a minority of samples showed significantly high CD4+ T-cell, CD8+ T-cell and plasma cell scores (18%, 21%, and 26%).

Conclusion: In this large gene expression data set, a prominent keratin signature was present in addition to a fibro-inflammatory signature, supporting the notion that molecular dysregulations in SSc skin are not confined to the dermal layer but are in fact present in several skin compartments. Furthermore, the novel cell-specific transcript analysis showed significant heterogeneity of inflammatory profiles from SSc skin, which might be useful for stratifying patients for targeted treatment and/or predicting their response to immunosuppression.

Potential Roles of Toll-like Receptor 4 in the Murine Models of Systemic Sclerosis. Takehiro Takahashi, Yoshihide Asano, Yohei Ichimura, Tetsuo Toyama, Takashi Taniguchi, Shinji Noda, Kaname Akamata and Shinichi Sato. University of Tokyo Graduate School of Medicine, Tokyo, Japan.

Background/Purpose: Bleomycin **(**BLM)-induced fibrosis model and tight skin mice (TSK/+) model are well-established experimental murine models of human systemic sclerosis (SSc). Growing evidence has demonstrated the pivotal role of Toll-like receptors (TLRs) in several autoimmune inflammatory diseases including SSc. The aim of this study is to determine the role of TLR4 in the fibrotic process in these models.

Methods: We generated a BLM-induced SSc murine model with mice deficient for TLR4. The mechanism by which TLR4 contributes to this fibrotic model was investigated with histologic examination, hydroxyproline assay, ELISA, real-time PCR, and flow cytometry. In addition, to examine the role of TLR4 in less inflammatory fibrotic model, we also investigated fibrosis in TSK/+ mice lacking TLR4.

Results: Dermal and lung fibrosis was attenuated in BLM-treated $TLR4^{-/-}$ mice compared with their wild type counterparts. Consistently, inflammatory cell infiltration, expression of various inflammatory cytokines, pathological angiogenesis, hypergammaglobulinemia and elevated titer of anti-DNA topoisomerase I antibody induced by BLM treatment were suppressed with TLR4 deletion. Furthermore, the increased expression of interleukin (IL)-6 in fibroblasts, endothelial cells, and immune cells in response to BLM *in vivo* and to LPS *in vitro*was remarkably abrogated in the absence of TLR4. Moreover, TLR4 deletion was associated with alleviated skew in Th2/Th17 response against BLM treatment. In parallel with these observations, TLR4 abrogation attenuated skin fibrosis in TSK/+ mice as well.

Conclusion: These results indicate the pivotal contribution of TLR4 to the pathogenesis in a BLM-induced SSc murine model and TSK/+ model, two major models which mimic early and late phase of SSc respectively. Our results indicate the critical role of TLR4 signaling in the pathogenesis of fibrosis, suggesting that the biomolecular TLR4 targeting might be a potential therapeutic approach to SSc.

Background/Purpose: A recent large-scale fine mapping study -Immunochip- in systemic sclerosis (SSc) identified 3 novel genome-wide significant hits as well as a wide number of *loci* putatively associated with SSc (*P*-values between $5x10^{-3}$ and $5x10^{-8}$), which might result in real association signals that could be masked owing to a limited power. In this line, one of the *locus* that showed suggestive association signals was *IL12RB1*, which encodes the beta 1 subunit of the interleukin-12 (IL-12) receptor. Interestingly, several IL-12 pathway-related genes are confirmed genetic risk factors for SSc, such as *IL12RB2*, *STAT4* and *IL12A*. Therefore, our aim was to evaluate the genetic contribution of the *IL12RB1*region in SSc through a follow-up strategy.

Methods: Forty-six single-nucleotide polymorphisms (SNPs) within the *IL12RB1* region were screened in a discovery cohort comprising 1,871 SSc cases and 3,636 controls from the previously published Immunochip dense fine-mapping study. Four *IL12RB1* SNPs were selected for genotyping in a large Caucasian replication cohort. A meta-analysis of the data from the original Immunochip discovery cohort and the replication cohort was performed for a combined total of 5,052 SSc patients and 8,712 healthy controls. We also performed *in sillico* functional analyses for SNPs characterization.

Results: In the first phase of our study, 11 out of the 46 SNPs showed nominal association signals (*P*-values between $5x10^{-3}$ and $5x10^{-5}$). After conditional logistic regression analyses, we selected four SNPs (rs8109496, rs2305743, rs436857 and rs11668601) as the genetic variants which better explained the observed signals in the *IL12RB1* region. One SNP, rs2305743, reached the genome-wide significance level in the independent replication cohort ($P_{MH} = 3.936 \times 10^{-8}$, OR= 0.79). Interestingly, the combined analysis (discovery plus replication cohorts) showed that the four selected SNPs were associated with SSc at the genome-wide significance level. Finally, our *in silico* functional analyses showed that the minor allele of rs436857 promoter SNP was in an *IL12RB1* cis-expression Quantitative Trait *Loci* (eQTL) that decreased *IL12RB1* expression (*P*-value = 2.4×10^{-81}, Z-score = −19.10). Additionally, rs436857 showed evidence to affect the binding of several transcription factors. These results pinpoint rs436857 as the most likely causal variant for driving the reported association, narrowing down the signal to the promoter region of the gene.

Conclusion: The present study reports for the first time robust evidence for the implication of *IL12RB1* in SSc genetic background and highlights the importance of the follow-up studies. The results reinforce the relevance of IL-12 pathway in SSc pathophysiology, shedding light on our understanding of the immune system processes implicated in SSc development, and suggest that blocking this pathway could be a possible new therapeutic target.

The Global miRNA Whole Blood Profile in Systemic Sclerosis and Its Correlation with Serum Cytokine Levels. Gloria Salazar[1], Maureen Mayes[2], John Hagan[3], Minghua Wu[1], John D. Reveille[1] and Shervin Assassi[1]. [1]University of Texas Health Science Center at Houston, Houston, TX, [2]University of TX Health Science Center -Houston, Houston, TX, [3]University of Texas at Houston, Houston, TX.

The Global miRNA Whole Blood Profile in Systemic Sclerosis and its Correlation with Serum Cytokine Levels

Background/Purpose: Several studies have implicated miRNAs in the pathogenesis of systemic sclerosis (SSc). [1–3] Recent advances in quantitative polymerase chain reaction (qPCR) allow simultaneous measurement of hundreds of miRNAs. The objective of this study was to use this technology to identify the unbiased, global miRNA profiling of SSc whole blood and evaluate its correlation with plasma cytokine levels.

Methods: We investigated the miRNA profile in SSc whole blood compared to unaffected controls using multiplex qPCR platform. We obtained blood samples from 10 patients with early SSc (≤5 yrs, on no immunosuppression) and 10 age-, gender- and ethnicity matched controls. Eight patients had diffuse disease and two had limited disease. The mean disease duration was 2.2 years. Levels of 752 miRNAs were determined. Unsupervised hierarchical clustering analysis was performed. Patient and control samples miRNA levels were compared and differences with a $p<0.01$, false discovery rate (FDR) <10% and fold change >2 were considered statistically significant.

A quantitative, multiplexed immunoassay designed to measure 45 cytokines, chemokines and acute-phase reactants was used to determine the serum cytokine levels (myriad human inflammationMAP) in order to correlate expression of miRNA with their predicted targets.

Results: The comparison of patient to control whole blood samples revealed 16 miRNA that were differentially expressed (Table 1). All miRNAs, except for miR-10b-5p, were downregulated in SSc compared to controls. Notably four differentially expressed miRNA in whole blood originate from the same cluster located in 14q32.3. The unsupervised hierarchical clustering analysis of whole blood miRNA profile separated the two groups but three patients clustered along with controls.

In the cytokine analysis, MCP1 (CCL2), IL-10, MMP-9, TNFR2, VCAM1 and ICAM1 were differentially expressed in SSc patients. MiR-370 levels highly correlated with MCP-1 protein levels ($r_s = -0.6$, $p=0.004$) which is a predicted target of this miRNA.

Conclusion: To our knowledge, this is the first global, unbiased examination of miRNA in SSc whole blood and the first correlation of miRNA with SSc plasma cytokine levels. The miRNA profile showed 16 miRNAs that are dysregulated in SSc whole blood. MiR-370 levels were differentially expressed in SSc blood and highly correlated with MCP-1 protein levels. We have previously reported also an upregulation of this miRNA in SSc skin. Furthermore, miR-370 targeted TGFbR-II in two independent studies underscoring its potential role in SSc pathogenesis.

Table 1. SSc whole blood dysregulated miRNA

miRNA	Location	Fold Change	*p*
miR-1238-3p	19p13.2	0.18	<0.001
miR-506-3p	Xq27.3	0.33	<0.001

miR-134	14q32	0.42	0.001

Increased Degradation of BMPR2 in a TGFβ Dependent Transgenic Mouse Model of Scleroderma with Susceptibility to Pulmonary Arterial Hypertension. Adrian J Gilbane[1], Emma C. Derrett-Smith[2], Andrew Pearce[3], Christopher P Denton[2] and Alan M. Holmes[4]. [1]UCL Medical School, London, United Kingdom, [2]UCL Medical School Royal Free Campus, London, United Kingdom, [3]Novartis, London, United Kingdom, [4]UCL, London, United Kingdom.

Background/Purpose: Scleroderma patients are susceptible to development of pulmonary arterial hypertension (PAH) that has similarities to some forms of heritable PAH. The basis for this susceptibility is unclear and SSc-PAH has a worse clinical outcome. We have previously shown that a TGFβ dependent mouse model of scleroderma (TβRIIΔk-fib) develops PAH in response to pulmonary endothelial cell injury. Using this model as a platform and clinical material form SSc lungs we explored expression and proteasomal degradation of BMPRII that is implicated in development of heritable PAH.

Methods: We investigated BMP signalling in the lung in the TβRIIΔk-fib model of PAH-SSc in which TGFβ signalling is upregulated. The TβRIIΔk-fib mouse develops a structural pulmonary vasculopathy with smooth muscle hypertrophy and raised right ventricular pressures. Experiments were performed on whole lung isolates and explant cultured fibroblasts (n=6) from the TβRIIΔk-fib mouse and compared with wildtype controls. TGFβ/BMP signalling pathways were investigated by Western blot and immunohistochemistry and qPCR. MG132, an inhibitor of proteasomal degradation, was used to explore the role of proteasomal degradation on BMPRII protein levels in vitro.

Results: The TβRIIΔk-fib model has increased levels of pSmad2/3, indicative of enhanced TGFβ signalling. The TβRIIΔk-fib model exhibits a significant reduction in BMPRII protein expression in whole lung isolates (1.43, 0.38) ($p<0.05$), and explant cultured fibroblasts (0.299, 0.09) ($p<0.05$). A reduction of BMPRII was also observed in whole lung (0.095, 0.03) and explant cultured lung fibroblasts from SSc patients compared to healthy controls ($p<0.05$) but there was an increase in BMPRII gene expression. Interestingly, both TβRIIΔk-fib and SSc fibroblasts exhibited refractory responses to BMP4 ($p<0.05$). MG132 was able to restore BMPRII protein levels and restore BMP4 ligand response of SSc fibroblasts.

Conclusion: Here we demonstrate the TβRIIΔk-fib transgenic murine model of PAH-SSc exhibits reduced expression of BMPRII as a reciprocal response to increased TGFβ signalling. Collectively our data suggests loss of BMPRII expression by non-genetic means may contribute to the development of PAH in SSc. Further, our results suggest that use of a proteasomal degradation inhibitor might reduce the risk of developing PAH by restoring BMPRII expression.

Nucleosome, a Basic Repeating Unit of Chromatin, in Patients with Systemic Sclerosis: Possible Association with Immunological Abnormalities Via Abnormal Activation of T and B Cells. Ayumi Yoshizaki, Yoshihide Asano, Takashi Taniguchi, Ryosuke Saigusa, Kouki Nakamura, Takashi Yamashita, Takehiro Takahashi, Tetsuo Toyama, Yohei Ichimura, Zenshiro Tamaki, Miki Miyazaki and Shinichi Sato. University of Tokyo Graduate School of Medicine, Tokyo, Japan.

Background/Purpose: Nucleosome is the basic repeating units of chromatin. Each nucleosome is composed of an inner core of histones H3 and H4 and an outer portion of histones H2A and H2B. Protruding tails of the histones can establish contact with other nucleosomes. In addition, these tails can be modified by methyl-, acetyl-, or ubiquitin-groups. DNA surrounds the protein core about 1.5 times on the flat outside and is connected with histones at 14 sites. Nucleosomes are released from cells during apoptosis and necrosis. Although elevated serum nucleosome levels have been described in various autoimmune disorders, only one previous study has shown that systemic sclerosis (SSc) exhibits elevated serum nucleosome levels in less than 15 patients. In addition, correlations of serum nucleosome levels with immunological parameters and organ involvement were not investigated. Although nucleosome contains DNA and histone, which are major autoantigens of various autoimmune diseases, the relationship of nucleosome and disease progression are still unknown. Therefore, we investigated the role of nucleosome in SSc and correlation of serum nucleosome levels with immunological parameters, extent of skin and lung fibrosis, vascular damage, and presence of other organ involvements in SSc.

Methods: Serum nucleosome levels were examined in SSc (n=91) and controls (n=20) by enzyme-linked immunosorbent assay. We also examined serum nucleosome levels in bleomycin-induced SSc model mice and phosphate-buffered saline-treated control mice.

Results: Nucleosome levels in limited cutaneous SSc and diffuse cutaneous SSc patients were significantly higher than in normal controls ($p<0.0001$, respectively). Similarly, in bleomycin-induced SSc model mice, serum nucleosome levels were higher than in control mice ($p<0.0001$). SSc patients with elevated nucleosome levels had significantly higher modified Rodnan total skin thickness score, high frequency of diffuse cutaneous SSc, and more frequent involvement of pitting scar/ulcer, pulmonary fibrosis, esophagus, heart, kidneys, joints, and muscle than those with normal levels ($p<0.05$, respectively). Nucleosome levels also significantly correlated inversely with %VC ($r=-0.22$, $p<0.01$) and %DLco ($r=-0.68$, $p<0.001$) and positively with modified Rodnan total skin thickness score ($r=0.58$, $p<0.001$). SSc patients with elevated nucleosome levels had significantly higher frequency of elevated levels of serum IgG and more frequent presence of anti-topoisomerase I and centromere antibodies compared with those with normal levels ($p<0.05$, respectively). Moreover, in this study, we demonstrated that nucleosome could activate T and B cells which were obtained from SSc patients.

Conclusion: These results suggest that elevation of nucleosome levels is associated with the disease severity. In addition, this study is the first to reveal the association of nucleosome levels with various immunological abnormalities in SSc.

Distinctive Patterns of Telomere Shortening and Apoptosis in Limited and Diffuse cutaneous Systemic Sclerosis. Jasper Broen[1], Liane McGlynn[2], Dagmara McGuinness[2], Rina Wichers[3], Jacqueline Thomson[2], Rajan Madhok[4], Robert Lafyatis[5], Carol A. Feghali-Bostwick[6], Paul Shiels[2] and T.R.D.J. Radstake[1]. [1]University Medical Center Utrecht, Utrecht, Netherlands, [2]University of Glasgow, Glasgow, United Kingdom, [3]UMC Utrecht, Utrecht, Netherlands, [4]Glasgow Royal Infirmary, Glasgow, United Kingdom, [5]Boston University, Boston, MA, [6]Medical University of South Carolina, Charleston, SC.

Background/Purpose: Aberrant telomere shortening and DNA damage-responses have been previously described in SSc, here we aim to validate these observations and incorporate them in a functional and clinical relevant framework.

Methods: We measured telomere length in peripheral blood leukocytes, monocytes, B cells, myeloid dendritic cells, T cells and plasmacytoid dendritic cells from a total of 103 healthy controls, 121 lcSSc patients and 83 dcSSc patients. In addition, telomere measurements were performed in 21 monozygotic twin pairs with SSc. We finally analyzed apoptosis and telomere gene expression arrays to investigate underlying pathways and used them to stratify patients.

Results: We found that suffering from dcSSc is an independent risk factor for shorter telomeres in full blood cells, which is on the cellular level reflected by significantly shorter telomeres in T cells and pDCs compared to healthy controls and lcSSc (all $p<0.001$). Based on the analyses of 21 monozygotic twin pairs with SSc we conclude that this seems to be an inborn error in

dcSSc, whereas in lcSSc telomere shortening seems to be caused by disease itself. We establish by gene expression arrays that this seems to be mainly caused by aberrant expression of apoptotic genes, of which expression of *BIRC5* and *P53* have a specificity of 91% to predict dcSSc from a mixed-pool of 72 healthy controls, lcSSc patients, patients with Raynaud's phenomenom, ANA+ patients and early SSc patients identified by nail-capillaroscopy, making these genes clinically relevant.

Conclusion: Telomere shortening and apoptotic pathways are differentially regulated in lcSSc and dcSSc and provide novel avenues for patient stratification.

Assessment of mRNA Gene Expression Based on Forearm Skin Score in Systemic Sclerosis Patients. Lisa Rice[1], Giuseppina Stifano[1], Jessica Ziemek[2] and Robert Lafyatis[2]. [1]Boston University Medical Center, Boston, MA, [2]Boston University School of Medicine, Boston, MA.

Background/Purpose: The extent of skin disease in patients with systemic sclerosis is typically measured through physical examination of patients at 17 sites and involvement is quantified on a scale from uninvolved to severe involvement (0 to 3). The total of all 17 sites scores is defined as the Modified Rodnan Skin Score (MRSS). We have shown previously that gene expression of skin biopsies taken from the mid-forearm correlates well with overall skin disease as assessed by the MRSS. However, it remained unclear whether the success of such an approach represented a particularly accurate, molecular, quantification of local skin disease or a manifestation of altered gene expression known to occur in all the skin of systemic sclerosis patients, both lesional and non-lesional.

Methods: Skin biopsies (n=42) from the forearms of patients with diffuse cutaneous SSc (dcSSc) and healthy donors (n=5) were assessed for expression of genes we have previously identified as elevated in SSc skin. The results were assessed for difference (one-way ANOVA) in gene expression ($p \leq 0.05$) with forearm skin score (0 to 3) and correlation with forearm skin score (Pearson's).

Results: Expression of all genes examined form patients showing a local skin score of 1 or greater were different from healthy control. Several inflammatory, TGFβ, and WNT regulated genes (CCL2, IL13RA1, COMP, THBS-1, ADAM12, and WIF1) showed a significant correlation with the local forearm score (1 or greater). Other inflammatory and macrophage related genes (IFI44, CD163, SIGLEC1, CD14) showed no significant correlation between the level of gene expression and the local skin score.

Conclusion: The different relationships between local gene expression, and local versus systemic assessment of the skin score (MRSS) suggest a hierarchy of molecular events. Gene expression correlating most highly with the local skin score may represent molecular events closest to clinical manifestations. Altered gene expression that does not correlate with the skin score may represent more molecular events earlier in the pathogenic cascade, or alternatively epiphenomena without direct roles in pathogenesis. These results have particular implications for biomarker selection in clinical trials of drugs delivered by local topical application.

The Anti-Fibrotic Effect of Endostatin-Derived Peptide Is Mediated By Urokinase. Tetsuya Nishimoto[1], Takahisa Takihara[2], Yunyun Su[1], Roger Chambers[1], Logan Mlakar[1] and Carol Feghali-Bostwick[1]. [1]Medical University of South Carolina, Charleston, SC, [2]Tokai University School of Medicine, Kanagawa, Japan.

Background/Purpose: Fibroproliferative disorders such as systemic sclerosis (SSc) have no effective therapies and result in significant morbidity and mortality as a result of organ fibrosis. We recently demonstrated that the C-terminal domain of endostatin known as E4, corresponding to amino acid sequence 133–180, is a promising therapeutic agent for fibrotic disorders. E4 prevented and reversed both dermal and pulmonary fibrosis. Our goal was to delineate the mechanism by which E4 abrogates fibrosis. Preliminary gene expression data from primary human fibroblasts suggested that E4 treatment resulted in increased expression of urokinase (uPA).

Methods: Bleomycin (60 μg/mice) or Bleomycin in combination with E4 (10 ug/ml) was administered intratracheally to 6 to 8-week-old C57BL/6J male mice to induce lung fibrosis. Bronchoalveolar lavage (BAL) fluid was collected on days 3, 5, 7, and 14 post treatment, and the levels and activity of uPA and plasminogen activator inhibitor-1 (PAI-1), an inhibitor of uPA, were measured. Primary human fibroblasts were treated with TGF-b (10 ng/ml) to induce a fibrotic phenotype or TGF-b in combination with E4 (10 ug/ml). The mRNA and protein levels of uPA, PAI-1, matrix metalloproteinase-1 (MMP-1), and MMP-3 were determined using real-time PCR and immunoblotting, respectively. Secreted uPA activity was also measured in fibroblast supernatants. Since MMP-1 and MMP-3 are downstream effectors of uPA, we assessed MMP-1 and -3 activity using collagen and casein zymography, respectively. The mRNA levels of uPA and PAI-1 in human whole lung tissue and lung fibroblasts from 9 healthy control (HC) and 32 SSc patients were examined using real-time PCR.

Results: *In vivo*, bleomycin reduced uPA levels and activity and increased PAI-1 activity. E4 peptide partially blocked these effects. The reduction of PAI-1 caused by E4 administration preceded the increase in uPA activity, suggesting that a release from inhibition may explain in part the increase in uPA activity. *In vitro*, TGF-b reduced uPA levels and increased PAI-1 levels in primary fibroblasts. E4 peptide cancelled these effects and increased the uPA/PAI-1 ratio. Moreover, the expression and activity of MMP-1 and MMP-3 were increased by E4 treatment. The mRNA levels of uPA both in whole lung tissue and lung fibroblasts were comparable between HC and SSc patients, however, those of PAI-1 were increased in SSc patients, resulting in a decrease of the uPA/PAI-1 ratio.

Conclusion: Our results demonstrated that E4 increases uPA activity by both increasing uPA levels and activity and reducing PAI-1-mediated inhibition. The ability of E4 to reverse fibrosis can be explained by its ability to induce MMP-1 and MMP-3 levels and activity, thus promoting extracellular matrix degradation. In SSc patients, the uPA/PAI-1 balance shifted toward PAI-1. Taken together, our findings suggest that the anti-fibrotic effects of E4 peptide are mediated, at least in part, by the uPA fibrinolytic system, and that E4 peptide exerts its therapeutic effects in organ fibrosis via regulation of the urokinase pathway.

Use of Multiplex Cytokine Analysis of Dermal Blister Fluid to Assess Local Inflammatory and Immune Activity in Systemic Sclerosis. Kristina E.N. Clark[1], Henry Lopez[2], Xu Shiwen[1], Bahja Ahmed Abdi[1], George Martin[3], Korsa Khan[4], David J. Abraham[1], Christopher P. Denton[5] and Richard J. Stratton[1]. [1]UCL Medical School, London, United Kingdom, [2]Murigenics, Vallejo, CA, [3]Aero Dap, Vallejo, CA, [4]UCL medical School, London, United Kingdom, [5]UCL Medical School Royal Free Campus, London, United Kingdom.

Background/Purpose: Clinical diversity in systemic sclerosis (SSc) suggests complex multifaceted pathogenesis involving interplay of growth factors or cytokines within the lesional microenvironment. We analysed dermal suction blister fluid to investigate protein expression in skin of SSc patients and healthy controls. We compared the levels of key candidate proteins that may be relevant to pathogenesis.

Methods: Blister fluid (BF) samples from the forearm skin of patients (n=25; DcSSc =19, LcSSc=6) or healthy controls (HC)(n=10) were collected using a dermal suction blister method with paired serum samples, and profiled by Luminex array. Permutation analysis was used for statistical testing.

Results: BF: Profiling showed increased inflammatory cytokines (mean IL-6 in SSc- 77.2 pg/ml, HC-17.8 pg/ml, p=0.009, mean IL-17 in SSc-0.61 pg/ml, HC- 0 pg/ml, p=0.03), and vascular growth factors (PDGF-aa 16.4 pg/ml in SSc, HC-0.97 pg/ml, p=0.049). Additionally MCP-3 (CCL7), IL-15 and IFN-g were all significantly increased in SSc ($p<0.05$). Plasma: 19/26 SSc patients, and 8/10 HCs were available. Proteins that were significantly raised ($p<0.05$) in plasma compared to HC, that were also raised in BF were MCP-3 (p=0.025), IL-15 (p=0.02) and IL-6 (p=0.04). Also raised in plasma were IL-1Rα, IL-1a, IL-12p40, GM-CSF, IL-2, IL-4, IL-9, Flt-3L and VEGF (all $p<0.05$). Of interest Th2 cytokines IL-4, 5, and 13, were only detectable in SSc plasma.

Proinflammatory cytokines (IL-6 (p=0.23), IL-17 (p=0.56)), and growth factors (VEGF(,p=0.47), PDGF(p=0.22)) showed no correlation between serum samples and BF. The healthy controls showed greater correlation

between BF and serum, often reaching significance (IL-10,MCP-3,IL1ra, FGF-2).

Heatmaps of BF (Figure 1). Unbiased BF analysis by CIMminer (NIH) revealed clustering of SSc patients into 3 groups; Group 1, high IL-6, IL-10, TNFα, and IL-1α high (innate) consisted of mainly early DcSSc with high skin score. Group 2 comprised late stage DcSSc with increased levels of IFNγ, IL-2, IL-4, IL-5, MCP-3, IL12p40, IL12p70 (adaptive). Group3 quiescent with low levels of cytokines and chemokines, and LcSSc or DcSSc patients with low skin score. Plasma analysis did not cluster into distinct clinical groups. ANOVA showed significant difference between skin scores ($p=0.003$), with Scheffe post hoc analysis showing significant higher skin scores in Group 1 ($p=0.005$).

Conclusion: Our results confirm the value of dermal blister analysis in SSc, and identify key factors expressed locally. Whilst plasma analysis revealed some overlap with the blister fluid analysis, it did not reflect all of the changes present in the dermal microenvironment. This method profiles the local inflammatory process occurring within the skin and complements clinical and gene expression based classification, as well as suggesting markers of disease activity or treatment effect.

Specific Autoantibody Profiles and Disease Subgroups Correlate with Circulating Micro-RNA in Systemic Sclerosis. Dirk Wuttge[1], Anting L. Carlsen[2], Gabriel Teku[1], Samantha Steen[2], Marie Wildt[1], Mauno Vihinen[1], Roger Hesselstrand[1] and Niels H. H. Heegaard[3]. [1]Lund University, Lund, Sweden, [2]Statens Serum Institut, Copenhagen, Denmark, [3]Odense University Hospital, Odense C, Denmark.

Background/Purpose: Systemic sclerosis (SSc) is a serious autoimmune disease with clinical phenotypes of different prognosis, progression rate, and different extent of involvement of internal organs. Specific circulating autoantibody profiles contribute to forecasting the prognosis of SSc cases. Circulating micro-RNA (miRNA) profiles also are characteristic in SSc but clinical phenotypes, autoantibody profiles, and circulating miRNA profiles have not yet been correlated. The aim of the study, therefore, was to evaluate the expression profiles of cell-free plasma miRNAs in SSc and study their correlation with disease subgroups (limited cutaneous SSc (lcSSc) and diffuse cutaneous SSc (dcSSc)) and with clinical and paraclinical parameters including circulating autoantibody profiles.

Methods: Total RNA was purified from plasma and the abundance of 45 mature miRNAs were measured using quantitative polymerase chain reaction assays after reverse transcription. A total of 95 SSc patients (n=94 fulfilling the ACR criteria for SSc, n=1 with limited SSc) were included (lcSSc, n=63; dcSSc, n=32). The patients represented the following autoantibody subgroups: anti-centromere group (ACA, n=35); anti-DNA topoisomerase I group (ATA, n=20), anti-RNA polymerase III group (ARA, n=20); and anti-U1-RNP group (RNP, n=20). MiRNA expression data, clinical data, autoantibody data, and other paraclinical data were analyzed for correlations. Regression analysis was performed to optimize models for prediction of SSc disease subgroups and autoantibody classes.

Results: A total of 36 miRNAs were measurable in all samples. Six of these miRNAs were statistically significantly differently expressed between the lcSSc and dcSSc groups in univariate tests and three (miRNAs -223, -181b, and 342-3p) remained significant after correction for multiple comparisons. Ten miRNAs exhibited statistically significant different levels in one or more autoantibody groups and three of these miRNAs were also found to differ between the dcSSc and lcSSc groups. Five miRNAs (miRNAs -409-3p, -184, -92a, -29a, and -101) retained significance after correction for multiple comparisons. Analysis of patterns of miRNA levels and clinical and paraclinal parameters showed correlations between C-reactive protein and glomerular filtration rates and the specific regulation of distinct miRNAs.

Conclusion: The profile of circulating miRNAs from plasma samples of SSc patients differ between patients classified as lcSSc and dcSSc and between the four autoantibody groups. Especially the ACA group is distinctive in terms of its specific circulating miRNA profile. This is the first time autoantibody profiles, disease phenotypes, and plasma miRNA profiles have been shown to correlate in an autoimmune disease. The data supports the role of miRNAs in SSc by showing that specific miRNAs are associated with autoantibody profiles of known diagnostic and prognostic value.

IQGAP1 Enhances Contractility of Scleroderma Lung Fibroblasts and Promotes Bleomycin-Induced Pulmonary Fibrosis. Tanjina Akter[1], Ilia Atanelishvili[1], Yuichiro Shirai[2], Sybil Prince Nelson[2], Alvaro Garcia-Martos[3], Thomas A. Morinelli[2], Richard M. Silver[1] and Galina S. Bogatkevich[1]. [1]Medical University of South Carolina, Charleston, USA, Charleston, SC, [2]Medical University of South Carolina, Charleston, USA, chareston, SC, [3]Hospital la Zarzuela, Madrid, Spain, Madrid, Spain.

Background/Purpose: Scleroderma associated interstitial lung disease (SSc-ILD) is an irreversible and progressive complication and a leading cause of death among SSc patients. Constitutive overexpression of connective tissue growth factor (CTGF) has been observed in both *in vivo* and *in vitro* studies of SSc patients. Proteomic analysis of CTGF-activated lung fibroblasts demonstrated that CTGF induces IQ motif containing GTPase activating protein (IQGAP1). IQGAP1 is a multifunctional scaffold protein that integrates diverse signal transduction pathways and regulates fibroblast migration. Our recent findings demonstrate the profibrotic role of IQGAP1 in the bleomycin-induced murine model of SSc-ILD. Here we report our latest data focusing on the molecular mechanism and pathophysiologic action of IQGAP1 in this mouse model of ILD.

Methods: Lung injury was induced in female C57BL/6 mice by a single intratracheal instillation of bleomycin (0.05U/mouse). IQGAP1-siRNA and CTGF-siRNA were delivered by intranasal instillation every other day. Mice were sacrificed 3 weeks after bleomycin instillation and lungs were harvested. Lungs were perfused with neutral buffered formaldehyde, embedded in paraffin, stained with hematoxylin and eosin (H&E), and scored for fibrosis. Lung tissue was harvested, lyophilized and run on western blot. IQGAP1 knockout mice were challenged with bleomycin and histology was performed. Assessment of collagen was accomplished by Masson's trichrome staining and by Sircol Collagen Assay. The role of IQGAP1 in F-actin filament formation was examined by immunofluorescence staining and by actin polymerization assay. The rate of actin polymerization was measured in terms of fluorescence intensity by Fluorometric Imaging Plate Reader.

Results: A profound antifibrotic effect was observed in the bleomycin lung fibrosis model when IQGAP1-siRNA treatment was combined with CTGF-siRNA treatment. Partial reduction of fibrosis was detected with treatment by either of these two siRNA's alone. Western blot results showed that IQGAP1-siRNA decreased the expression of IQGAP1 by 70% and had no effect on CTGF expression. However, CTGF-siRNA reduced the expression of CTGF by 80% and IQGAP1 by 40%. A similar trend of reduction in fibrosis was observed in IQGAP1 knockout mice. Decreased collagen expression was detected by Masson's trichrome stain and by Sircol Collagen Assay. Immunofluorescence staining of IQGAP1 and F-actin on human SSc lung fibroblasts demonstrated that IQGAP1 co-localizes with globular actin but not with filamentous stress fiber actin, indicating a crucial role of IQGAP1 in actin rearrangement. The actin polymerization assay demonstrated that the rate of actin polymerization is IQGAP1 dependent.

Conclusion: IQGAP1 forms a signal transduction complex with CTGF in lung fibroblasts, regulates the expression of α-SMA, and promotes pulmonary fibrosis. Inhibition of IQGAP1 has a marked antifibrotic effect in a bleomycin model of pulmonary fibrosis and should be considered as a potential new therapeutic target for the treatment of SSc-ILD.

Caveolin-1 and Peroxisome Proliferator-Activated Receptor Gamma Co-Regulate the Differentiation of Monocytes to Adipocytes and Myofibroblasts in Vivo and in Vitro. Rebecca Lee[1], Charles Reese[1], Michael Bonner[1], Beth Perry[1], Richard M. Silver[2], Richard P. Visconti[1], Stanley Hoffman[1] and Elena Tourkina[1]. [1]Medical University of South Carolina, Charleston, SC, [2]Medical University of South Carolina, Charleston, USA, Charleston, SC.

Background/Purpose: Skin fibrosis in scleroderma is associated with the loss of subcutaneous adipose tissue (lipodystrophy). The mechanisms underlying lipodystrophy and its relationship to fibrosis are not known. Monocytes are precursors of several cell types including myofibroblasts and adipocytes. We recently showed that this myofibroblast differentiation is inhibited by the master regulatory protein caveolin-1. Similarly, caveolin-1-deficient mice are lean with small adipocytes. The nuclear receptor PPARγ also regulates adipose differentiation and lipid homeostasis. Here we examine the coordinate roles of caveolin-1 and PPARγ in adipogenesis and fibrosis.

Methods: Mini-osmotic pumps are implanted into 10 week-old CD1 male mice. The pump delivers 100 U/kg bleomycin or saline and is removed on day 10. Mice are injected i.p. daily with 100 μl caveolin-1 scaffolding domain peptide (CSD, final concentration 0.1 mM) or phosphate-buffered saline (PBS) vehicle over the entire course of the experiment and sacrificed on day 28. Cutaneous fibrosis and lipodystrophy are analyzed histologically and immunohistologically. Monocytes are obtained from scleroderma patients and healthy controls. Monocyte differentiation to adipocytes and myofibroblasts is evaluated using Oil red O stain and ASMA stain. PPARγ and caveolin-1 expression are determined by Western blot and immunohistochemistry.

Results: We previously observed a loss of subcutaneous adipose tissue concomitant with dermal fibrosis in bleomycin treated mice, both of which were blocked by CSD. We now show that levels of caveolin-1 and PPARγ are reduced in adipocytes of SSc patients and bleomycin-treated mice. CSD significantly enhances the expression of PPARγ and FABP4 in adipocytes in bleomycin-treated mice. Low levels of PPARγ are observed in monocytes from SSc patients and are increased by CSD treatment. PPARγ ligand triglitazone (TRLZ) and CSD inhibit, and TGFβ promotes human monocytes differentiation to myofibroblasts. Conversely, these treatments have the opposite effects on monocyte differentiation into adipocytes. These treatments affected PPARγ signaling through their effects on PPARγ levels and localization.

Conclusion: The present studies demonstrate the importance of both caveolin-1 and PPARγ in the regulation of adipogenesis in fibrotic skin. These studies further validate CSD as a novel therapy for both fibrotic disease and lipodystrophy.

ERG and FLI1 in Systemic Sclerosis-Associated Pulmonary Complications. Rong Han and Maria Trojanowska. Boston University, Boston, MA.

Background/Purpose: Pulmonary arterial hypertension (PAH) and pulmonary fibrosis (PF) are the two major lung complications associated with the autoimmune disease systemic sclerosis (SSc), and constitute the leading causes of mortality and morbidity in patients with SSc. Endothelial dysfunction and inflammation have both been described in these two diseases. We hypothesize that disturbed transcriptional control of endothelial cell function can induce inflammation in the lung, which in turn drives the initiation and progression of PAH and PF in SSc. Deficiency of the ETS family transcription factor FLI1 has been implicated in scleroderma vasculopathy, while its closest homolog, ERG, has been demonstrated to suppress inflammatory gene expression in endothelial cells. The purpose of this study is to determine whether ERG and FLI1 deficiency plays a pathogenic role in SSc-associated lung manifestations.

Methods: Paraffin sections of lung samples from patients with SSc were subjected to immunohistochemical staining for ERG and FLI1. ERG and FLI1 were inhibited in human pulmonary arterial endothelial cells (HPAEC) with siRNA, and gene expression changes were analyzed by microarray and then validated with quantitative RT-PCR. *Erg* and *Fli1* double heterozygote mice were generated and lung samples from these mice were analyzed.

Results: ERG protein level was significantly reduced in the endothelium of lung samples from patients with SSc, while FLI1 was similarly reduced but to a lesser extent, suggesting that the loss of ERG and FLI1 is associated with the vascular changes occurring in the lung of patients with SSc. In HPAECs treated with *ERG* and *FLI1* siRNA, a number of inflammatory genes, including *CXCL10*, *IL8*, *IRF1*, *GBP1*, *IFIT2*, *VCAM1*, were upregulated, whereas genes regulating endothelial homeostasis and cell-cell adhesion, such as *APLN*, *FABP4*, *PECAM1* and *VECADHERIN*, were downregulated. Simultaneous knockdown of both *ERG* and *FLI1* had a synergistic effect on the expression of these genes, suggesting that ERG and FLI1 co-regulate at least a subset of their target genes. Consistent with the upregulation of inflammatory genes seen in vitro with *ERG* and *FLI1* knockdown, *Erg* and *Fli1* double heterozygote mice show increased lymphocyte infiltration in the lung.

Conclusion: Loss of ERG and FLI1 might contribute to the pathogenesis of SSc-associated lung complications through the induction of inflammation in the tissue.

Gene-Gene Interaction of *IRF5* and *BLK* Polymorphisms in US and Spanish Cohorts of Systemic Sclerosis (SSc). Pravitt Gourh[1], Yoonhee Kim[2], Sandeep K. Agarwal[3], Filemon K. Tan[4], Shervin Assassi[4], Javier Martin[5], Frank C. Arnett[4] and Maureen D. Mayes[4]. [1]National Institutes of Health, Bethesda, MD, [2]NIH, Bethesda, MD, [3]Baylor College of Medicine, Houston, TX, [4]University of Texas Health Science Center at Houston, Houston, TX, [5]Instituto de Parasitología y Biomedicina López-Neyra, IPBLN-CSIC, Armilla (Granada), Spain.

Background/Purpose: Systemic sclerosis (SSc) is a complex autoimmune disease and several genetic loci increasing SSc susceptibility have been identified with small to modest effect sizes. These loci even when taken together are not able to fully explain the heritability of SSc. We believe that genetic epistasis along with rare variants and gene-environment interaction may explain the missing heritability. In this study, we test two seemingly distinct loci, rs2004640 on *IRF5* and rs2736340 on *BLK* both of which have previously been associated with SSc, for genetic epistasis.

Methods: In this study, we combined genetic data from rs2004640 variant on *IRF5* and rs2736340 variant on *BLK* from 1024 patients with SSc and 694 unrelated healthy controls from University of Texas and a Spanish case–control series of 395 SSc patients and 443 healthy controls. Odds ratios (OR) and biologic interactions as departures from additivity or multiplicity were analyzed by logistic regression. To quantify the amount of interaction in terms of departure from additivity of effects, the relative excess risk due to interaction (RERI), proportion attributable to interaction (AP), and the synergy index (S) were calculated. Interaction between the two SNPs was evaluated using the cross-product of the risk factors in a logistic-regression model as interaction criteria (multiplicative interaction). We adjusted for gender and cohort in the analyses. Recoding of *IRF5*, *BLK* genotypes from protective effects to risk effects were done to produce the meaningful measures for departures of additivity. Statistical analyses were performed using SAS 9.3. Gene expression array of PBMCs from PAXgene tubes were analyzed with BRB-ArrayTools.

Results: Both *IRF5*:rs2004640 and *BLK:* rs2736340 variants show independent association with SSc. The OR of single effects was 1.40 for *IRF5*:rs2004640 and 1.44 for *BLK:* rs2736340 (Table 1).

We observed a significant multiplicative interaction between *IRF5* GT/TT & *BLK* CT/TT genotypes as compared to *IRF5* GG & *BLK* CC genotypes ($p=0.02$). The OR of joint effects for *IRF5* GT/TT & *BLK* CT/TT genotypes was higher than the wildtype genotype ($P=0.0003$, OR=2.26; 95%CI 1.7–3.1). RERI<0, AP<0, and S<1 mean negative interaction and less than additivity. P value of S is significant, but 95% CI includes 1.

PBMC RNA gene expression arrays predicted more T & B cell pathways in SSc as compared to controls for *IRF5* GT/TT & *BLK* CT/TT genotypes and PPAR-γ and WNT signaling pathways in SSc as compared to controls for *IRF5* GG & *BLK* CC genotypes.

Conclusion: In an effort to explore genetic epistasis we demonstrate genetic interaction using multiple methodologies between two well-replicated and distinct loci on *IRF5* and *BLK*. We also observed differences in the gene expression pathways based on the *IRF5* and *BLK* genotypes. Additional studies are needed to test them in other autoimmune diseases and discern their role at a molecular level.

Endothelial Fli1 Deficiency Delays Wound Healing Due to Impaired Anastomosis of Newly Formed Vessels – a Possible Mechanism of Refractory Skin Ulcers in Systemic Sclerosis. Yoshihide Asano[1] and Maria Trojanowska[2]. [1]University of Tokyo Graduate School of Medicine, Tokyo, Japan, [2]Boston University, Boston, MA.

Background/Purpose: Systemic sclerosis (SSc) is a multisystem inflammatory and vascular disease resulting in fibrosis of the skin and certain internal organs. Although the pathogenesis of SSc still remains unknown, we have recently demonstrated that Fli1 deficiency at least partially due to epigenetic suppression contributes to the development of fibrosis and vasculopathy characteristically seen in this disease. A critical complication associated with SSc vasculopathy is refractory and recurrent skin ulcers which largely affect morbidity of SSc patients. To elucidate a potential mechanism rendering skin ulcers refractory to the treatments in SSc, we employed endothelial cell-specific Fli1 knockout (Fli1 ECKO) mice and carried out a wound healing experiment.

Methods: Fli1 ECKO mice were generated by crossing $Fli1^{flox/flox}$ mice with Tie2-Cre transgenic mice under a C57B/6 background. An 8 mm full-thickness skin wound was generated on the back of wild type (WT) and Fli1 ECKO mice with a punch biopsy. Vascular structure was visualized by FITC-dextran injection. The expression levels of target molecules were determined by immunohistochemistry *in vivo* and immunoblotting and quantitative reverse transcription-PCR *in vitro* using murine dermal microvascular endothelial cells (MDMECs). Promoter occupancy was evaluated by chromatin immunoprecipitation in MDMECs

Results: Wound healing was markedly delayed in Fli1 ECKO mice compared with WT mice. When vascular structure around scars was visualized with FITC-dextran injection, newly formed blood vessels were oriented toward the central area of scars in WT mice, while Fli1 ECKO mice lacked blood vessels around the central area of scars, suggesting that angiogenesis is impaired in Fli1 ECKO mice. At day 7 after wounding, many newly formed blood vessels filled with erythrocytes were present in granulation tissue in WT mice, while there were many dilated vessels with a few or no erythrocytes and a small number of vessels filled with erythrocytes in Fli1 ECKO mice. Since day 7 is a time point when newly formed blood vessels connect with pre-existing ones, it suggested that anastomosis may be impaired in Fli1 ECKO mice. In line with this idea, mRNA levels of the *Notch1* and *Dll4* genes, which code key molecules regulating anastomosis, were markedly decreased in ECs derived from Fli1 ECKO mice compared with those from WT mice. Furthermore, Fli1 occupied the promoter region of these genes in MDMECs.

Conclusion: Fli1 deficiency decelerates wound healing by inhibiting anastomosis of newly formed vessels with pre-existing ones and a similar process may contribute to the delayed wound healing associated with SSc.

The Impact of Plasmacytoid Dendiritc Cells (pDCs) on Fibrosis in bleomycin–induced Murine Model of Systemic Sclerosis (SSc). Suzanne Kafaja[1], Isela Valera[1], Anagha Divekar[2], Daniel E. Furst[3] and Ram Singh[1]. [1]University of California, Los Angeles, Los Angeles, CA, [2]Biolegend, San Diego, CA, [3]University of California, Los Angeles, Department of Medicine, Los Angeles, CA.

Background/Purpose: Pathogenesis of systemic sclerosis (SSc) remains unclear. Alterations in adaptive and innate immune responses, with increased T-cells that produce type 2 cytokines and impaired responsiveness to Toll-like receptors, have been reported in patients with SSc. Dendritic cells (DC) that participate in both innate and adaptive immunity are increasingly being investigated in the pathogenesis and immune intervention in various autoimmune diseases and other immune-mediated conditions. Little is known about the alterations and role of DC in SSc. Our goal in this study is to investigate alterations of DC subsets and their roles in the pathogenesis of SSc.

Methods: In order to investigate the time kinetics of DC alterations in the affected and lymphoid organs and to manipulate DCs in vivo, we used the bleomycin-induced mouse model where the exact timing of pathogenic insult is known. Although, the bleomycin or any of the currently available animal models do not reproduce all aspects of human SSc, bleomycin-induced dermal and pulmonary fibrosis mimics human SSc in many ways. C57BL/6 mice were injected with bleomycin or PBS for 2 weeks, and cells isolated from lung tissue or lavage, skin, lymph nodes, spleen and bone marrow were analyzed for various immune cell types including DC subsets namely myeloid DC (mDC) and plasmacytoid DC (PDC). To directly determine the role of pDC, these cells were depleted using an anti-PDCA1 antibody (Miltenyi Biotec) or an IgG isotype control antibody. Animals were euthanized 2 weeks after treatment. Disease was assessed by clinical and histological scoring.

Results: Both DC subsets were increased in the lungs of bleomycin-injected mice, with a more profound increase in pDCs that were significantly elevated in the lungs ($p<0.008$), skin ($p<0.04$), and their associated draining lymph nodes in bleomycin-injected mice compared to PBS controls. Neither DC susbets differed in the spleen of bleomycin-injected mice when compared to controls. Treatment with anti-PDCA1 antibody significantly reduced pDC numbers in the spleen and lung by two-fold as compared to animals injected with an isotype control antibody. pDC-depleted mice had a significant improvement in combined clinical disease severity score ($p<0.001$) and histopathology ($p<0.009$), along with a reduction in cellular infiltrates comprising of B-cells, T-cells, NK and NK-T cell as compared to control mice. qPCR array analysis of lung tissue for molecules potentially involved in DC function and recruitment thus far shows alterations in chemokines *Ccl2* and *Ccl19*, and in macrophage migration inhibiting factor namely *Cd74*, which have been implicated in fibrosis development.

Conclusion: A more profound accumulation of pDCs, as compared to the other major DC subset, in the affected organs and their draining lymph nodes, but less so in the lymphoid organs, of bleomycin-injected mice suggests a possible role of pDC in SSc process. Indeed, antibody depletion of pDC reduces skin and lung fibrosis in the bleomycin model. A significant reduction in several immune cell types in pDC-depleted mice suggests a major pathogenic role of pDC in inflammatory/fibrosis process.

Background/Purpose: Systemic Sclerosis (SSc) is an autoimmune disorder characterized by tissue fibrosis and vasculopathy. A proteomic analysis of the secretome of SSc dermal fibroblasts (SSc-FBs) identified increased protein levels of Pigment Epithelium Derived Factor (PEDF), which is the major endogenous inhibitor of intraocular angiogenesis. Here we aimed to validate the findings in vitro and in vivo and determine whether PEDF could be involved in SSc vasculopathy.

Methods: PEDF expression was investigated in the skin and FBs of 4 early diffuse SSc patients and 4 healthy controls (HC) by immunohistochemistry (IHC), qRT-PCR and flowcytometry. Functional effects of PEDF on angio/vasculogenesis were examined by Matrigel assays and CD31 IHC on organotypic co-culture assays of endothelial cells and either HC-FBs or SSc-FBs. Vascular tubule number, length and junctions were analyzed by Angiosys software. Caveolin expression was silenced by lentiviral induced shRNA expression. PEDF expression was also investigated by IHC on skin biopsies from wild-type (WT) and TβRIIΔk mice, which have fibroblast-specific constitutive activation of transforming growth factor-beta (TGF-β) signaling.

Results: In SSc skin 52% of FBs showed a strong expression of PEDF vs. 13% in HC skin ($p<0.0006$). Double IHC studies indicated that FBs positive for PEDF showed a decreased expression of cav-1. SSc-FBs *in vitro* showed on average a 5-fold PEDF expression compared to HC-FBs ($p<0.05$). Increased PEDF expression was inducible by either TGF-β stimulation or silencing of cav-1 expression *in vitro*. Concordantly, TβRIIΔk-fib mice showed an increased PEDF expression and decreased CAV-1 expression *in vivo*. Recombinant human PEDF inhibited vasculogenesis in vitro by suppressing >50% of tubule length, number and junctions ($P<0.01$). Consistently, organotypic co-culture assays indicated that SSc- FBs inhibited tubulogenesis in vitro. shCAV-1 FBS displayed a similar phenotype to SSc fibroblasts, which was abrogated by immunodepletion of PEDF from shCAV supernatants.

Conclusion: PEDF expression is increased in SSc biopsies and SSc-FBs and in TβRIIΔk-fib mice. PEDF expression is associated with decreased cav-1 expression *in vivo* and it is induced by silencing cav-1 *in vitro*. Functionally, PEDF can suppress vasculogenesis both in Matrigel and organotypic co-culture assays. This suggest that the decreased expression of cav-1 observed in SSc-FBs may contribute to the SSc vasculopathy through PEDF as well as other factors. Further studies unraveling the mechanisms of the antiangiogenic effect of PEDF may shed light in understanding the molecular events linking the profibrotic phenotype and SSc vasculopathy.

769

Anti-Fibrotic Effects of an Investigational Drug: Bis-Oxetanyl Sulfoxide. Logan Mlakar[1], Takahisa Takihara[2], Melissa Sprachman[3], Peter Wipf[4] and Carol Feghali-Bostwick[1]. [1]Medical University of South Carolina, Charleston, SC, [2]Tokai University School of Medicine, Kanagawa, Japan, [3]Massachusetts General Hospital, Boston, MA, [4]University of Pittsburgh, Pittsburgh, PA.

Background/Purpose: The hallmark of pulmonary fibrosis is thickening and scarring of the tissue caused by increased deposition of extracellular matrix (ECM) proteins like collagen and fibronectin. Pulmonary fibrosis is a feature of several diseases including systemic sclerosis (SSc). MMS-350, a highly soluble small organic bis-oxetanyl sulfoxide, was recently shown to protect against radiation induced fibrosis. The low toxicity, high solubility and oral bioavailability of MMS-350 make it a promising therapeutic agent. Our goal was to determine the efficacy of this novel drug, MMS-350 and its analogs, in both *in vitro* and *in vivo* models of pulmonary fibrosis.

Methods: Primary human lung fibroblasts from normal donors were treated with TGFβ and MMS-350 for 72 h. Levels of ECM and pro-fibrotic proteins were assessed using immunoblotting. To study the effects of MMS-350 *in vivo*, 8-week old C57BL/6J mice were given bleomycin intratracheally to induce pulmonary fibrosis and PBS or MMS-350 orally on a daily basis for either 5 or 14 days. RNA was isolated from lung tissues and collagen 1A2 mRNA levels were measured by qRT-PCR. Paraffin embedded lung tissues were examined histologically following H&E staining and imaging. Collagen content was measured using the hydroxyproline assay.

Results: Fibroblasts treated with TGFβ and MMS-350 versus TGFβ alone showed a significant reduction in ECM (collagen and fibronectin), secreted (CTGF and IGFBP-3), and intracellular (α-SMA) pro-fibrotic markers. MMS-350 decreased these markers when added at the same time and when added up to 6 hours after TGFβ. One analog that differed from MMS-350 by the replacement of an oxetanyl methylene side chain with a phenyl ring, KRL507-031, showed a decrease in ECM and pro-fibrotic factors at concentrations 10-fold lower than the parent compound. Both the survival and mouse weight improved in the MMS-350 treated mice. Collagen 1A2 mRNA levels were significantly reduced in MMS-350 treated mice. H&E staining of lung tissue from mice treated with bleomycin and MMS-350 exhibited a reduction of scarring, and a significant reduction of collagen content in comparison to bleomycin.

Conclusion: These studies demonstrate that MMS-350 is an anti-fibrotic agent and are consistent with recent data demonstrating the ability of MMS-350 to reduce fibrosis in thoracic irradiated C57BL/6NTac mice. MMS-350 significantly reduced pro-fibrotic factors and ECM proteins both *in vitro* and *in vivo*. A lipophilic analog of MMS-350, KRL507-031, exhibited similar anti-fibrotic effect albeit at lower concentrations. The fact that MMS-350 was effective at reducing pulmonary fibrosis induced by different triggers and that it is orally available make it an attractive lead candidate for the development of a therapy for organ fibrosis.

Detection of Proteins in Lung Tissues of Patients with Systemic Sclerosis Using Tissue Microarrays. Frank Schneider[1] and Carol A. Feghali-Bostwick[2]. [1]University of Pittsburgh, Pittsburghh, PA, [2]Medical University of South Carolina, Charleston, SC.

Background/Purpose: Research on systemic sclerosis (SSc)-associated interstitial lung disease (ILD) has been hindered by the paucity of lung tissues, as SSc patients with lung involvement are not routinely biopsied. To gain further insights into the pathogenesis of lung fibrosis in SSc, we used lung tissue microarrays (TMAs) for the detection of 4 proteins of interest in SSc-associated ILD and idiopathic pulmonary fibrosis (IPF).

Methods: Lung tissues were obtained from the explanted lungs of patients undergoing lung transplantation. Normal lung tissues were obtained from controls. H&E sections were used for the selection of suitable regions. These regions were used for obtaining 1 mm cores. A TMA was constructed containing 117 cores from patients with SSc-associated ILD, IPF, and normal controls. Sections from the TMA block were used for detection of TTF-1, thrombomodulin, laminin, and Smad4 using immunohistochemistry (IHC). Distribution and levels of expression were qualitatively assessed using light microscopy.

Results: TTF-1, thrombomodulin, laminin, and Smad4 were detected in all cores on the TMA slide. The distribution of the proteins differed in normal lungs compared to fibrotic lungs since the two subepithelial layers in normal lungs are closely apposed in the absence of fibrosis. We observed subtle differences in distribution and levels of protein expression between SSc and IPF. TTF-1 expression appeared reduced in areas of fibrosis and inflammation

in both diseases. Thrombomodulin staining of airway basal cells was weaker and patchier in SSc than IPF. Laminin expression was reduced in areas of fibrosis in both SSc and IPF, but IPF lungs showed stronger laminin staining around vessels compared to SSc lungs. Nuclear Smad4 expression was more prominent and more widespread in perivascular smooth muscle cells of SSc than IPF lungs.

Conclusion: Lung TMAs are useful to simultaneously compare localization and expression levels of proteins in lung tissues from multiple patients and controls. Our initial IHC findings suggest that differences exist in the distribution and levels of TTF-1, thrombomodulin, laminin, and Smad4, and such differences can be identified using TMAs.

Development of a Bifluorescent Lineage Tracker Reporter Mouse Strain to Analyze the Phenotypic Conversion of Endothelial Cells into Myofibroblasts *in Vivo*. Application to Study the Synergistic Effects of Endothelin-1 on TGF-β1-Induced Endothelial-to-Mesenchymal Transition. Peter J. Wermuth and Sergio A. Jimenez. Jefferson Institute of Molecular Medicine, Division of Connective Tissue Diseases and Scleroderma Center, Thomas Jefferson University, Philadelphia, PA.

Background/Purpose: Endothelial-to-mesenchymal transition (EndoMT) may be a crucial pathway in generating activated myofibroblasts, cells that play a pivotal role in the development of tissue and organ fibrosis in diseases such as Systemic Sclerosis (SSc). It has been previously demonstrated that endothelin 1 (ET-1) synergistically enhances TGF-β-induced EndoMT *in vitro* in murine lung endothelial cells (ECs). The purpose of this study was to develop a mouse model expressing a green distinct fluorescent label in ECs (green fluorescent protein; GFP) and a red fluorescent label in fibroblasts (mCherry protein) to allow monitoring of EndoMT *in vivo*.

Methods: Homozygous Tie2GFP transgenic mice expressing GFP under control of the EC specific *Tie2* promoter (Tie2GFP mice) were crossed with homozygous mice expressing a doxycycline inducible red fluorescent mCherry protein in mesenchymal cells and fibroblasts under control of the *Col1a1* promoter (Col1mCherry mice) to generate heterozygous bifluorescent Tie2GFP-Col1mCherry mice. At 4 weeks of age, osmotic pumps containing either saline, 2.5 μg TGF-β, or 2.5 μg TGF-β+5.0 μg ET-1 were implanted subcutaneously in the right intrascapular region of the mice (2 mice per treatment group). The pumps deliver their contents at a rate of 0.5 μl/h over a 2 week period. Mice received IP injections of 1 mg/kg doxycycline every other day starting at 2 weeks post-implantation of the pump and were sacrificed one week later. Both lungs and two skin samples, one at the pump dispersal site and one opposite to the pump site, were isolated. A portion of each tissue was fixed in formalin and processed for histopathologic analysis (hematoxyllin/eosin and Masson's trichrome stains) whereas another portion was frozen and sectioned for evaluation of fluorescence. Another sample portion of each tissue was hydrolyzed for measurement of hydroxyproline content.

Results: Histopathology studies in samples from TGF-β-treated mice showed mononuclear cell infiltration and peribronchial fibrosis and diffuse interstitial fibrosis in lungs. Dermal fibrosis was present in both samples of skin. ET-1 synergistically enhanced the severity of fibrosis in all three tissues. Hydroxyproline levels in skin taken from the site of the osmotic pump demonstrated a 61% increase in response to TGF-β alone and a 113% increase ($\sim$2.2 fold) in response to TGF-β+ET-1 whereas skin from the opposite side of the back displayed a 29% increase in response to TGF-β alone and a 102% increase ($\sim$2 fold) in response to TGF-β+ET-1. In the lung, TGF-β increased hydroxyproline levels by 38% and TGF-β+ET-1 increased hydroxyproline levels by 75%.

Conclusion: Tie2GFP-Col1mCherry mice represent a valuable resource for monitoring EndoMT *in vivo*. ET-1 plays an important *in vivo* role in regulating EndoMT by causing a synergistic potentiation of TGF-β1-induced EndoMT. Since ET-1 plays a crucial role in the pathogenesis of SSc-associated pulmonary arterial hypertension and may play a profibrotic role in skin and lung fibrosis, the results described here identify a novel mechanism supporting the concept that ET-1 plays a key pathogenetic role *in vivo* in SSc-associated tissue fibrosis.

RNA-Seq and Mir-Seq Analysis of SSc Skin Across Intrinsic Gene Expression Subsets Shows Differential Expression of Non-Coding RNAs Regulating SSc Gene Expression. Zhenghui Li[1], Eleni Marmarelis[1], Kun Qu[2], Lionel Brooks[1], Patricia Pioli[1], Howard Chang[2], Robert Lafyatis[3] and Michael Whitfield[1]. [1]Geisel School of Medicine at Dartmouth, Hanover, NH, [2]Stanford University School of Medicine, Stanford, CA, [3]Boston University, Boston, MA.

Background/Purpose: Systemic sclerosis (SSc) is an autoimmune disease with a heterogenous and complex phenotype. Previously, our lab has identified four gene expression subsets (fibroproliferative, inflammatory, limited and normal-like) among SSc patients by their gene expression in skin using DNA microarrays. We have extended these findings by using RNA-Seq in a subset of SSc skin biopsies to detect mRNA levels, splice variants, novel non-coding RNAs, and coding region SNPs in a lower background signal over microarray.

Methods: We performed RNA-Seq on eight SSc patients and four healthy controls and skin biopsies. The eight SSc patients included five individuals that mapped to the inflammatory subset and three from the fibroproliferative subset. We sequenced the small and large RNA fraction extracted from each biopsy by Illumina Solexa sequencing. We obtained 90–100 million 50 bp paired-end reads for the mRNA fraction and 25 – 50 million 36 bp reads for the miRNA fraction.

Results: Our analyses reveal significant ($p<0.05$) gene expression differences between healthy controls and SSc patients, as well as between intrinsic subsets. Specifically, we found >1000 genes are significantly expressed in the inflammatory and the fiboproliferative subsets of patients. Many of the significant genes are involved in cellular proliferation or immune responses, consistent with results found by DNA microarray hybridization. We did not observe any significant differential splicing between the healthy controls and the SSc patients. We identified 228 novel long non-coding RNAs (lncRNAs) that are significantly differentially expressed in the inflammatory subset and fibroproliferative subsets. The lncRNAs differentially expressed in the inflammatory subset map to Gene Ontology terms including *inflammatory response*, *immune response*, *response to wounding*, and *defense response* and those in the fibroproliferative group map to *cell cycle*, *M phase*, and *RNA metabolism*. We also identified 54 miRs differentially expressed in the inflammatory subset of SSc patients. These include the well-characterized miR21 that has previously been reported to be differentially expressed in SSc as well as many novel miRs. We have previously shown CCL2 to be highly expressed in the inflammatory subset of SSc and inhibiting its function prevents development of disease in the sclGVHD mouse model. We now identify a novel miR with decreased expression that is predicted to target the 3'UTR of CCL2. We show that transfection of the CCL2-targeting miR, but not a negative control miR, into RAW264.7 macrophage cells expressing a heterologous Luciferase-CCL2 (3'UTR) reduced luciferase activity by 74%.

Conclusion: To summarize, we conducted the first comprehensive RNA-Seq study in SSc skin and identified differentially expressed non-coding RNAs genome-wide. Our findings show that a complex network of regulatory factors controls the disease specific gene expression subsets in SSc skin.

Functional Autoantibodies from Patients with Systemic Sclerosis Reactive to Angiotensin II Type 1 and Endothelin-1 Type a Receptor Induce Inflammatory Lymphocyte Infiltration into Lungs of Mice. Angela Kill[1], Clement Braesch[1], Anja Kühl[2], Jeannine Guenther[1], Mike O. Becker[2], Gerd Burmester[3], Thomas Walther[4] and Gabriela Riemekasten[5]. [1]Charité University Hospital, German Rheumatology Research Center, a Leibniz Institute, Berlin, Germany, [2]Charité University Hospital, Berlin, Germany, [3]Charité University Medicine, Berlin, Germany, [4]University College Cork, Cork, Ireland, [5]Charité University Hospital and German Rheumatism Research Centre, a Leibniz Institute, Berlin, Germany.

Background/Purpose: Functional autoantibodies reactive to the angiotensin II type 1 receptor (AT_1R) and endothelin 1 type A receptor (ET_AR) were found in elevated levels in systemic sclerosis (SSc) patients, with clinical connections to lung involvement. Functional effects on T-lymphocyte migration were studied previously *in vitro* and first *in vivo* experiments on C57BL/6 mice demonstrated agonistic effects on lung architecture. Here, functional effects of anti-AT_1R and

anti-ET_AR autoantibodies on inflammatory cell infiltration into lungs of mice deficient for the AT receptor and on their respective WT mice (129 × C57BL/6), were studied for the first time.

Methods: Female mice deficient for AT_{1a}, AT_{1b}, and AT_2 receptor (ATR −/−, 129 × C57BL/6, n=5 per group) and WT controls (129 × C57BL/6, n=4 per group) were treated with SSc-IgG with elevated levels of anti-AT_1R and anti-ET_AR autoantibodies. In control experiments same groups were treated with healthy donor IgG (NC-IgG). IgG samples were transferred into ATR −/− and into WT groups five times over three months. Lungs were examined using histological staining and an index-system was developed to assess CD3+T-lymphocyte infiltration around vessels. Samples were analysed in a blinded fashion using imageJ software.

Results: Mice of the ATR −/− and WT group treated with SSc-IgG showed a dramatically decreased survival in both groups, with worst survival rate in the ATR −/− group. Groups with the control treatment NC-IgG showed a better survival compared to SSc-IgG, with a slightly lower survival rate in ATR −/− group, than in the WT group. Histological analyses of lungs revealed a statistically higher T-lymphocyte infiltration in both groups with SSc-IgG than with NC-IgG. Furthermore, ATR −/− group with SSc-IgG showed a statistically higher infiltration rate than WT group with SSc-IgG.

Conclusion: These preliminary experiments demonstrate a dramatic survival reduction by treatment with SSc-IgG containing anti-AT_1R and anti-ET_AR autoantibodies (SSc-IgG) in both groups, ATR −/− and WT. Moreover, a major inflammation in ATR −/− and in WT mice was induced by SSc-IgG, reflected by T-lymphocyte infiltration into lung tissue. Increased inflammation in ATR −/− vs. WT group by SSc-IgG, suggests a possible ET_AR-mediated inflammation in ATR −/− mice. Anti-AT_1R and anti-ET_AR autoantibodies react presumably in a cross-reactive way and mice deficient for angiotensin-receptors could therefore enable detailed studies of ET_AR-mediated effects, providing thereby a deeper understanding of involved mechanisms. Moreover, the data demonstrate the recruitment and activation of immune cells by autoantibodies and could as a result offer deeper insight into autoantibody-mediated T-lymphocyte recruitment and reveal potential therapeutic targets for treatment of SSc.

Endothelin-1 Synergistically Increases TGF-β-Induced Hif1α Expression Under Normoxic Conditions during Endothelial-to-Mesenchymal Transition in Murine Endothelial Cells. A Novel Mechanism for the Fibrogenic Effects of Endothelin. Peter J. Wermuth and Sergio A. Jimenez. Jefferson Institute of Molecular Medicine, Division of Connective Tissue Diseases and Scleroderma Center, Thomas Jefferson University, Philadelphia, PA.

Background/Purpose: Tissue hypoxia is a consequence of vascular damage and Hif-1α accumulation is a major mechanism of hypoxia response pathways. HIF-1α induces the transcriptional upregulation of expression of numerous genes encoding proteins involved in vascular repair including soluble growth factors (TGF-β and VEGF), and extracellular matrix components (type I collagen and fibronectin), rendering HIF-1α as a positive regulator of wound healing and a potential mediator of organ repair and tissue fibrosis, suggesting that HIF1-α may play an important role in the pathogenesis of fibrotic diseases such as Systemic Sclerosis (SSc). Recent studies have shown that TGF-β causes a potent increase in HIF-1α protein levels. Since endothelin 1 (ET-1) synergistically enhances TGF-β mediated endothelial-to-mesenchymal transition (EndoMT), we examined the transcriptional regulation of Hif-1α and of several of its downstream targets in response to TGF-β alone or TGF-β in combination with ET-1 in cultured murine lung microvascular endothelial cells (MVEC).

Methods: Murine pulmonary MVEC were isolated from C57Bl/6J mice employing trypsin/collagenase tissue digestion followed by sequential immunomagnetic selection with anti-CD31 and anti-CD102 antibodies. The purified EC were treated in monolayer cultures with ET-1 (100 ng/mL) in the presence and absence of TGF-β1 (10 ng/mL) and the induction of Hif-1α as well as several Hif-1α targets including lysyl oxidase (Lox), Lox-like 1 protein (Loxl1), Loxl2, Loxl3, and LoxL4 was assessed employing semi-quantitative RT-PCR.

Results: Exposure of murine pulmonary MVEC to ET-1 induced a three-fold increase in Hif-1α levels compared to non-treated controls. TGF-β1, however, induced a nearly 500-fold increase in expression whereas samples treated with TGF-β1 plus ET-1 increased Hif-1α transcript levels nearly 2500-fold compared to the saline control. This profound synergistic increase was abrogated by the dual ET-1 receptor antagonist, Bosentan, demonstrating that the observed effect was indeed mediated by ET-1. Similarly, TGF-β alone induced significant increases in the expression of Hif-1α target genes Lox, LoxL1, LoxL2, LoxL3 and LoxL4. ET-1 alone did not alter the expression of these genes whereas ET-1 in combination with TGF-β synergistically increased their levels. Bosentan abrogated the increased expression levels of these genes observed for TGF-β plus ET-1, indicating that the synergistic increases were mediated by ET-1.

Conclusion: TGF-β potently increased Hif-1α and Hif-1α target gene expression in murine pulmonary MVEC under normoxic conditions. ET-1 synergistically enhanced these effects. Since vascular damage plays a crucial role in SSc-associated pulmonary arterial hypertension pathogenesis and participates in the development of skin and lung fibrosis, the results described here identify ET-1 as a potentially key regulator of TGF-β-mediated activation of Hif-1α in response to vascular damage causing a synergistic enhancement of HIF-1α-mediated profibrotic effects suggesting that this process may play a key pathogenetic role in SSc-associated tissue fibrosis and fibroproliferative vasculopathy.

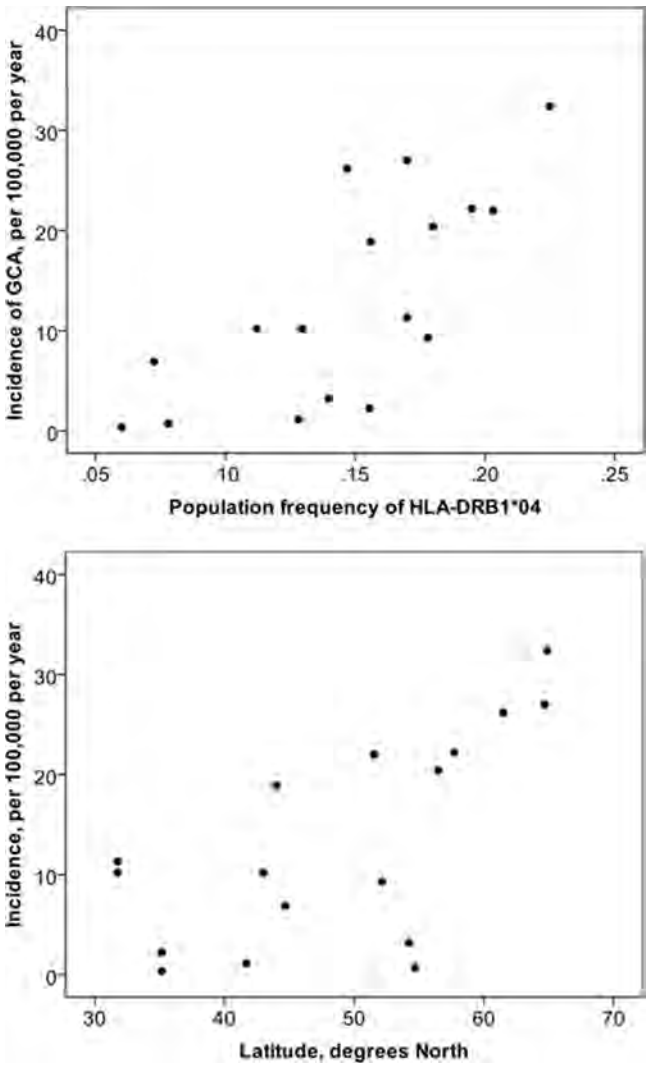
***HLA-DRB1* Alleles in Susceptibility to Giant Cell Arteritis: Literature Review and Meta-Analysis.** Sarah Mackie[1], John Taylor[1], Lubna Shafi[1], Stephen Martin[1], Bhaskar Dasgupta[2], Andrew Gough[3], Michael Green[4], Lesley Hordon[5], Stephen Jarrett[6], Colin T. Pease[7], Jennifer Barrett[1], Richard Watts[8] and Ann W. Morgan[1]. [1]University of Leeds, Leeds, United Kingdom, [2]Southend University Hospital, Essex, United Kingdom, [3]Harrogate and District Foundation Trust, Harrogate, United Kingdom, [4]York Teaching Hospital NHS Foundation Trust, York, United Kingdom, [5]Mid Yorkshire Hospitals NHS Trust, Dewsbury, United Kingdom, [6]Mid Yorkshire Hospitals NHS Trust, Wakefield, United Kingdom, [7]Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom, [8]Norwich Medical School University of East Anglia, Norwich, United Kingdom.

Background/Purpose: Giant cell arteritis (GCA) has been reported by many studies (but not all) to be associated with carriage of *HLA-DRB1**04, with variable results relating to other alleles, but formal meta-analysis has never been performed. Our objective was to study the influence of *HLA-DRB1* alleles on GCA susceptibility and incidence, combining new UK data with a meta-analysis of the literature.

Methods: GCA patients from the UK GCA Consortium were genotyped using single strand oligonucleotide polymerization, allele-specific polymerase chain reaction and direct sequencing. Control data was provided by the UK RA Genetics (UKRAG) Consortium. Meta-analysis was used to combine our results with previously-published data. Finally we determined the relationship of *HLA-DRB1**04 population carrier frequency to the incidence of GCA reported in different countries.

Results: In the new UK data (225 cases, 1378 controls), *HLA-DRB1**04 carriage was associated with GCA susceptibility (OR=2.69, $p=1.5\times10^{-11}$), but *HLA-DRB1**01 was protective (adjusted OR=0.55, p=0.0046). In meta-analysis combined with 14 published studies (an additional 691 cases, and 4038 controls), protective effects were seen from HLA-DR2, comprising *HLA-DRB1**15 and *HLA-DRB1**16 (OR=0.65, $p=8.2\text{x}10^{-6}$), and possibly from *HLA-DRB1**01 (OR=0.73, p=0.037). The incidence of GCA (n=17 countries) was associated with *HLA-DRB1**04 allele frequency in the population (p=0.008; adjusted $R^2=0.51$ on univariable analysis, adjusted $R^2=0.62$ after also including latitude).



Conclusion: This meta-analysis confirms *HLA-DRB1**04 as a GCA susceptibility allele but fails to show a susceptibility effect of *HLA-DRB1**01, despite sharing amino acids in common in the third hypervariable region. Variations in population frequency of *HLA-DRB1**04 might help explain worldwide variations in GCA incidence; latitude appears to make an independent contribution to GCA risk.

Background/Purpose: IL-33, through binding to its receptor ST2 (suppression of tumorigenicity 2), encoded by the interleukin 1 receptor-like 1 (*IL1RL1*) gene, activates mast cells and Th2 lymphocytes. Additionally, IL-33 acts as an activator of endothelial cells promoting angiogenesis and vascular permeability. Different studies have supported a pathogenic role of IL-33 axis in autoimmunity. Interestingly, an increased expression of this cytokine and its receptor has been detected in the inflamed arteries of GCA patients, mainly in endothelial cells of newly formed vessels, thus suggesting a possible role of IL-33 in the angiogenesis-dependent inflammation in GCA. The aim of the present study was to investigate for the first time the potential influence of the *IL33* and *IL1RL1 loci* on GCA predisposition.

Methods: A total of 1,363 biopsy-proven GCA patients and 3,908 healthy controls from four European case/control sets (Spanish cohort: 894 cases and 2,047 controls, German cohort: 103 cases and 444 controls, Italian cohort: 255 cases and 1,141 controls, and Norwegian cohort: 111 cases and 276 controls) were combined in a meta-analysis. Six genetic variants: rs3939286, rs7025417 and rs7044343, within the *IL33* gene, and rs2058660, rs2310173 and rs13015714, within the *IL1RL1* gene, previously associated with autoimmunity, were genotyped using predesigned TaqMan® assays.

Results: A consistent association between the rs7025417 polymorphism and GCA was evident in the overall meta-analysis, under both allele (P_{MH}=0.041, OR=0.88, CI 95% 0.78–0.99) and recessive (P_{MH}=3.40E-03, OR=0.53, CI 95% 0.35–0.80) models. No statistically significant differences between allele or genotype frequencies for the other *IL33* and *IL1RL1* genetic variants were detected in this pooled analysis.

Conclusion: Our results clearly evidenced the implication of the *IL33 locus* in the genetic network underlying GCA. This study, together with previous findings, supports an important role of this cytokine in the inflammatory process occurring in GCA.

Background/Purpose: A recent study has showed that the number of Th17 lymphocytes is significantly increased in patients with GCA, resulting in an imbalance between Th17 and regulatory T cells. In addition, an increased expression of IL-17A, a Th17 cytokine leading to pro-inflammatory responses, has been detected in temporal artery samples from GCA patients. Considering the proposed crucial role of Th17 cells in this vasculitis, we aimed to assess whether polymorphisms at the *IL17A* gene are involved in the genetic predisposition to GCA and its main clinical subgroups.

Methods: We carried out a large meta-analysis including a total of 1,266 biopsy-proven GCA patients and 3,779 healthy controls from four European populations (Spanish cohort: 931 cases and 1,845 controls, German cohort: 74 cases and 480 controls, Italian cohort: 178 cases and 1,175 controls, and Norwegian cohort: 83 cases and 279 controls). Five *IL17A* polymorphisms (rs4711998, rs8193036, rs3819024, rs2275913 and rs7747909), which tag over 86% of the variability of this *locus*, were genotyped using TaqMan® assays. Allelic combination and dependency tests were also performed.

Results: In the pooled analysis, two of the five analyzed polymorphisms showed evidence of association with GCA (rs2275913: P_{MH}=1.85E-03, OR= 1.17 [1.06–1.29]; rs7747909: P_{MH}=8.49-03, OR= 1.15 [1.04–1.27]). A clear trend of association was also found for the rs4711998 variant (P_{MH}=0.059, OR= 1.11 [1.00–1.23]). An independent effect of rs2275913 and rs4711998 was evident by conditional regression analysis. In addition, the haplotype harboring the risk alleles better explained the observed association than the polymorphisms independently (likelihood P-value$<10^{-05}$).

Conclusion: Our study provides clear evidence of the role of *IL17A* as a novel genetic risk *locus* for GCA, thus contributing to the advance in the knowledge of the genetic network underlying this vasculitis susceptibility.

PTPN22 rs2476601 and Susceptibility to Biopsy Proven Giant Cell Arteritis (GCA) in an Australian Sample. Susan Lester[1], Alex Hewitt[2], Linda Bradbury[3], Elisabeth De Smit[4], Andrew Harrison[5], Graeme Jones[6], Geoffrey O. Littlejohn[7], Tony R. Merriman[8], Bain Shenstone[9], Malcolm D. Smith[10], Maureen Rischmueller[11], Matthew A. Brown[12] and Catherine L. Hill[13]. [1]Queen Elizabeth Hospital, Woodville South, Australia, [2]University of Western Australia, Perth, Australia, [3]The University of Queensland, Brisbane, Australia, [4]University of Melbourne, Melbourne, Australia, [5]University of Otago, Wellington, New Zealand, [6]University of Tasmania, HOBART, Australia, [7]Monash Medical Center, Melbourne, Australia, [8]University of Otago, Dunedin, New Zealand, [9]Concord Hospital, Sydney, Australia, [10]Repatriation General Hospital, Adelaide SA, Australia, [11]The Queen Elizabeth Hospital, SA, Australia, [12]University of Queensland Diamantina Institute, Brisbane, Australia, [13]University of Adelaide, Adelaide, Australia.

Background/Purpose: The aetiology and genetic background of GCA remains unclear, although genetic susceptibility is known to play a role. Recently, an association with the minor, loss of function, allele of PTPN22 rs2476601 (R620W), was reported in a Spanish cohort of biopsy-proven GCA (odds ratio = 1.62, 95%CI 1.29–2.04, p = 0.0001)[1]. Therefore, dysregulation of TCR signalling may be implicated in the pathogenesis of GCA. The aim of this study was to determine the association between the PTPN22 rs2476601 minor (A) allele and biopsy-proven GCA in an Australian cohort.

Methods: rs2476601 genotyping was performed by a Taqman assay (C-16021387, Applied Biosystems) in 209 GCA cases. Genotype data from 1407 healthy ethnically-matched unrelated postmenopausal women included in the Anglo-Australian Osteoporosis Genetics Consortium study of bone density variation were used as healthy controls. All GCA cases were temporal artery biopsy proven, and were recruited in Australia by the Arthritis Genomics Recruitment Initiative in Australasia (AGRIA). The mean age of GCA patients at diagnosis was 73 yrs (SE 8 yrs), with 68% female.

Results: The frequency of the A allele was 0.093 in GCA cases and 0.103 in the controls. Overall, there was no evidence of an association between GCA and controls, (OR=0.89, 95% CI 0.63, 1.27, p = 0.52). A random effects meta-analysis of replication datasets from Germany[1], Norway[1], UK[1], and Australia, included 769 GCA patients and 14,214 controls, did not reach statistical significance (OR 1.21, 95% CI 0.73, 2.00, p = 0.32). Similarly, a random effects meta-analysis which included the original Spanish dataset (1,392 GCA cases and 15,943 controls), also did not reach statistical significance (OR 1.31, 95% CI 0.90, 1.90, p = 0.11), Figure 1.

Conclusion: There was no statistically significant association between PTPN22 rs2476601 in this Australian GCA cohort. Nor does a meta-analysis of combined, available data reach statistical significance. However, an association with small effect size cannot yet be definitively excluded, and further studies may be required.

Toll-like Receptor 2 Agonism Induces Inflammation, Angiogenesis and Cell Migration in Giant Cell Arteritis. Lorraine O'Neill[1], Aoife Maher[1], Jennifer McCormick[2], Conor Murphy[3], Geraldine M. McCarthy[4], Douglas J. Veale[1], Ursula Fearon[2] and Eamonn S. Molloy[1]. [1]St. Vincent's University

Hospital, Dublin 4, Ireland, [2]Translational Rheumatology Research Group, Dublin, Ireland, [3]Royal Victoria Eye and Ear Hospital, Dublin, Ireland, [4]Mater Misericordiae University Hospital, Dublin 7, Ireland.

Background/Purpose: Activation of dendritic cells (DCs) is one of the earliest inciting events in Giant Cell Arteritis (GCA). TLR 2 is expressed on DCs in normal temporal arteries and is also found ubiquitously throughout the macro vasculature. [1] Stimulating temporal arteries implanted into SCID mice with TLR 2 activates dendritic cells. [2] Therefore TLR 2 is likely to play a major role in the pathogenesis of GCA while the exact mechanisms involved are yet to be fully elucidated.

This study examines the functional effects of TLR 2 on induction of pro-inflammatory cytokines, angiogenesis and cell migration in GCA.

Methods: 15 patients with biopsy proven GCA and meeting 1990 ACR classification criteria for GCA were prospectively recruited. To directly examine the effects of TLR 2 on pro-inflammatory cytokines, growth factors and gelatinase expression in GCA, *ex-vivo* temporal artery (TA) whole tissue explant models were established. PBMCs and TA explants were cultured in the presence of Pam3CSK4 (a TLR 2 agonist) (1μg/ml) for 24 hours. Supernatants were harvested and assayed for IL-6, IL-8 Ang2, and VEGF by ELISA and MMP-2 and MMP-9 by gelatin zymography. Endothelial cell tube formation was assessed following culture with TLR 2-induced TA explant conditioned media. To examine the effect of TLR 2 on migration/ invasion in GCA, TA explants were embedded in Matrigel, stimulated with Pam3CSK4 and myofibroblast outgrowths observed. Myofibroblasts were also isolated from TA explants, cultured and wound repair assays performed. To examine the effects of TLR 2 on cytoskeletal architecture, cultured myofibroblasts were treated with Pam3CSK4 and stained for F-actin.

Results: In PBMC cultures, Pam3CSK4 induced a 7.7 and 3.6 fold increase in expression of IL6 and IL8 respectively, from a basal IL-6 level of 34.58 $\pm$ 6.77 pg/ml to 266.1 $\pm$ 117.6 pg /ml and basal IL-8 level of 1769 $\pm$ 731.7 pg/ml to 6388 $\pm$ 1632 pg/ml.

In temporal artery explant cultures stimulation with Pam3CSK4 increased expression of IL- 6 from 26,800 $\pm$ 9209 pg/ml to 47494 $\pm$ 10,946pg/ml ($p=0.01$). Expression of IL-8 was also increased from basal levels of 20,593 $\pm$ 8224 pg/ml to 40,793 $\pm$ 16, 670 pg/ml ($p=0.058$).

Stimulation with Pam3CSK4 significantly increased Ang 2 expression from basal levels of 727.9 $\pm$ 254.5 pg/ml to 1415 $\pm$ 459.6 pg/ml ($p=0.011$). There was a trend towards increased expression of VEGF, from basal levels of 107.5 $\pm$ 33.38 pg/ml to 200 $\pm$ 69.95pg/ml but this was not statistically significant. ($p=0.19$) Differential effects for MMP2/9 expression were observed on zymography. Pam3CSK4 induced endothelial cell tube formation. Pam3CSK4 also promoted myofibroblast outgrowths from the TA explants and cytoskeletal disassembly in the cultured myofibroblasts.

Conclusion: In an *ex vivo* temporal artery culture model, Pam3CSK4, a TLR 2 agonist, enhances production of pro inflammatory mediators, promotes angiogenesis, myofibroblast migration and cytoskeletal rearrangement. TLR2 signalling may therefore play a role in driving vascular inflammation and remodelling in GCA, and may represent a potential therapeutic target in GCA.

Novel Roles for Zyxin in the Pathogenesis of Giant Cell Arteritis. Rie Karasawa[1], Paul A. Monach[2], Mayumi Tamaki[1], Takahiro Okazaki[3], Masamichi Oh-Ishi[4], Yoshio Kodera[4], Toshiko Sato[1], Shoichi Ozaki[3], Kaiyu Jiang[5], Kazuo Yudoh[1], James N. Jarvis[5] and Peter A. Merkel[6]. [1]Institute of Medical Science, St. Marianna University School of Medicine, Kawasaki, Japan, [2]Vasculitis Center, Boston University School of Medicine, Boston, MA, [3]St. Marianna University School of Medicine, Kawasaki, Japan, [4]School of Science, Kitasato University, Sagamihara, Japan, [5]The University at Buffalo, Buffalo, NY, [6]Vasculitis Center, Division of Rheumatology, University of Pennsylvania, Philadelphia, PA.

Background/Purpose: The mechanisms of the blood vessel injury in giant cell arteritis (GCA), a systemic vasculitis characterized by inflammation of large- and medium-sized vessels, remain to be fully solved. Anti-endothelial cell antibodies (AECA) are antibodies that are detected frequently in vasculitis, including GCA. However, AECA target molecules have been poorly incompletely identified, which hampers our understanding the roles of AECA in disease pathogenesis.

Methods: We identified target antigens for AECA in patients with GCA using agarose 2-dimensional electrophoresis (agarose 2DE) and WB followed by mass spectrometry and accessed to pathophysiological roles in GCA. To detect antigens recognized by GCA sera predominantly in extracted proteins from endothelial cells (EC-specific proteins), the results of agarose 2DE-WB using human aortic endothelial cells (HAEC) were compared with that using human aortic adventitial fibroblasts. Furthermore, to detect antigens on HAEC recognized predominantly in sera with patients with GCA (GCA-specific proteins), the results of 2DE-WB using sera from GCA were compared with that using sera from healthy donors.

Results: A total of 31 proteins identified from 23 protein spots recovered from 2DE gel were determined successfully. Three proteins, Ezrin, Zyxin and FK506-binding protein 4, were EC-specific proteins as well as GCA-specific proteins. Gene Ontology analysis showed the EC-specific protein group was mainly classified into the metabolism and the defense and immunity group. In the GCA-specific protein group, the proteins were classified into broad functional categories except for metabolism group. By IPA analysis, more than half of the identified proteins were closely related ubiquitin. Regarding relationships between the identified proteins and cytokines, chemokines, and adhesion molecules, TNF-α was also involved in this signaling network. Using both proteomics and immunocytochemical analyses, we report here for the first time the identification of a specific target antigen for AECA in GCA, zyxin, a focal adhesion protein. Anti-zyxin antibodies were detected in 37% of patients with GCA and in 15% of patients with Takayasu's arteritis but not in healthy controls. Interestingly, the titer of anti-zyxin antibodies tended to be higher in all untreated patients with GCA than in treated patients. Half of GCA patients with polymyalgia rheumatica had antibodies to zyxin. Using immunocytochemistry analysis, we observed that zyxin translocated from cytoplasm or membrane to the nucleus in ECs stimulated with TNF-α and IL-1β, respectively. Using zyxin siRNA knockdown, zyxin mainly regulates IL-8 production from ECs stimulated with TNF-α and IL-1β, respectively. Furthermore, the increased IL-8 production via zyxin from ECs was inhibited by treatment with glucocorticoids and treatment with anti-zyxin antibodies.

Conclusion: Zyxin is a target antigen for AECA in GCA. Because zyxin is involved in regulating inflammatory responses in ECs via its translocation to the nucleus, the presence of anti-zyxin antibodies in GCA strongly implicates these antibodies in the pathogenesis of GCA or in disease progression.

Rho Kinase (ROCK) Activity in Aortitis: Comparison of Giant Cell Arteritis (GCA), Takayasu Arteritis (TA) and Isolated Aortitis (IA). Lindsay Lally[1], Navneet Narula[2] and Robert F. Spiera[1]. [1]Hospital for Special Surgery, New York, NY, [2]Weill Cornell Medical College, New York, NY.

Background/Purpose: Aberrant ROCK activity is implicated in the pathogenesis of many autoimmune and vascular disease states as ROCKs promote Th17 differentiation and vascular remodeling. Increased ROCK activity has been demonstrated in temporal artery biopsies from GCA patients and ROCK is proposed to play a role in aortic aneurysm formation; however the role of ROCK in aortitis is unknown. The aim of this study was to assess ROCK activity in aortic specimens from patients with GCA, TA and IA.

Methods: All aortic aneurysm specimens with histopathologic evidence of aortitis diagnosed during a 1 year period at a single institution identified and corresponding medical record reviewed. Patient history and ACR criteria were used to confirm diagnosis of GCA, TA, or IA. Those with IgG4 disease were excluded. Paraffin-embedded specimens were stained for Phospho-Ezrin/Radixin/Moesin (pERM), a surrogate of ROCK activity, using immunohistochemical stain. Sections also stained for the un-phosphorylated ERM protein. Inflammatory cells characterized using CD3/CD20 stain for T/B cells. Aortic specimens without aortitis were also stained for ERM/pERM as controls. Stained slides reviewed by a pathologist blinded to clinical status. pERM intensity in the vasculature and inflammatory infiltrate was assessed.

Results: Of 12 eligible aortitis cases, 4 were in those with prior history of GCA, 3 had TA and 5 had IA. Expected demographic differences noted between groups.

In all compartments, pERM staining was notably more intense than ERM suggesting activation of ROCK. All patients with aortitis had >50% of the inflammatory infiltrate staining positive for pERM, though TA patients had

greater proportion of pERM negative inflammatory cells (CD 163+ histiocytes) than those with GCA or IA. All patients, including 10 with non-inflammatory aortic aneurysms, had intense pERM staining of stromal cells in the adventitia and vasa vasorum, which was not affected by use of medications or co-morbidities known to influence ROCK (Table 1).

Conclusion: The markedly more intense pERM staining compared to ERM in the vasculature and lymphocytic infiltrate from those with GCA, TA, and IA suggest the ROCK pathway is active in these disease states, though no major differences in stain intensity between groups was noted. The pERM intensity in vessels of non-aortitis aneurysm controls supports the idea that ROCK may promote aneurysm development. ROCK activation likely reflects a response to vascular damage and repair regardless of etiologic mechanism, though staining in the infiltrating lymphocytes suggests ROCK is also involved in the inflammatory response in aortitis. These findings may ultimately have therapeutic implications, if confirmed in larger cohorts, especially in GCA as inhibition of ROCK may mitigate the initial inflammatory milieu as well as aneurysm formation, the most significant late disease manifestation.

Temporal Artery Microbiome in Giant Cell Arteritis. Alison Clifford*[1], Pauline Funchain*[2], Lisa Lystad[3], Charissa Peterson[4], Jessica Altemus[4], Gary S. Hoffman[1] and Charis Eng[2]. [1]Center for Vasculitis Care and Research, Cleveland Clinic Foundation, Cleveland, OH, [2]Taussig Cancer Institute, Cleveland Clinic Foundation, Cleveland, OH, [3]Cole Eye Institute, Cleveland Clinic Foundation, Cleveland, OH, [4]Genomic Medicine Institute, Lerner Research Institute, Cleveland, OH.

Background/Purpose: Whether infectious agents play a part in giant cell arteritis (GCA) remains controversial. We have performed the first microbiome study of snap-frozen temporal arteries, collected and processed under sterile conditions, from GCA patients and controls using metagenomic sequencing.

Methods: Patients undergoing temporal artery biopsy for possible GCA were prospectively enrolled. Biopsies were collected under strictly sterile conditions and split, with one part sent for routine histopathological review and one part snap-frozen for microbiome studies. Patients were classified according to clinical presentation as either biopsy-positive GCA (TA+), biopsy-negative clinically classical GCA (TA-) or controls. Long-read 16S ribosomal RNA (rRNA) sequencing was used to describe the entire microbiome of temporal arteries. Total DNA was isolated, and V1-V4 regions of the gene encoding bacteria-specific 16S rRNA were amplified and Sanger sequenced. Taxonomic classification of bacterial sequences was performed using an in-house analysis pipeline and relative abundances of species were calculated. Microbiomes were plotted by principal-coordinate analysis (PCoA) using a de novo operational taxonomic unit (OTU) picking protocol (using the MacQIIME 1.7 toolkit). Functional composition of microbiomes was analyzed using the PICRUSt bioinformatics package.

Results: Eleven patients were enrolled, including 3 TA+ GCA patients, 2 TA- GCA patients and 6 controls. All patients were receiving empiric prednisone therapy at time of biopsy and 1 control patient was also receiving doxycycline. Using PCoA, the microbiomes of control temporal arteries clustered tightly together in the center of the plot, showing high degrees of taxonomic relatedness, while GCA microbiomes (both TA+ and TA – patients) plotted in the periphery, clearly separated from controls. One control outlier was noted. Stratification of the samples by prednisone dosage did not account for the separation of GCA and controls on PCoA. Taxonomic classification revealed a wide variety of bacteria in each temporal artery (mean 10.8 species/control vs 10.6 species/GCA), with no overarching species common to all. Significant upregulation of 4 functional pathways (nucleotide metabolism, steroid hormone biosynthesis, biosynthesis of siderophore group nonribosomal peptides, and electron transport) was identified in the GCA microbiomes (both TA+ and TA-) as compared to controls.

Conclusion: Temporal arteries are not sterile. They are inhabited in both the control and diseased state by a community of bacteria. GCA temporal artery microbiomes (from both TA+ and TA- patients) differ from controls with respect to both the taxonomy and function of bacterial species present. Whether these shifts in the GCA microbiome represent the cause or effect of vascular inflammation remains to be elucidated.

Increased Migration and Proliferation Potential Characterize Vascular Smooth Muscle Cells from Patients with Giant Cell Arteritis. Alexis Regent[1], Kim-Heang Ly[2], Matthieu Groh[1], Chabha Khifer[3], Sebastien Lofek[3], Guilhem Clary[4], Philippe Chafey[4], Cédric Broussard[4], Christian Federici[4], Claire Le Jeunne[1], Elisabeth Vidal[5], Antoine Brezin[6], Veronique witko-Sarsat[4], Loïc Guillevin[1] and Luc Mouthon[1]. [1]National Referral Center for Rare Systemic Autoimmune Diseases, Hôpital Cochin, AP–HP, Université Paris Descartes, Paris, Paris, France, [2]Laboratoire d'immunologie, EA3842, Faculté de médecine, Limoges, Limoges, France, [3]Institut Cochin, INSERM U1016, CNRS UMR 8104, Université Paris Descartes, Paris, France, Paris, France, [4]Institut Cochin, INSERM U1016, CNRS UMR 8104, Université Paris Descartes, Paris, France, [5]Laboratoire d'immunologie, EA3842, Faculté de médecine, Limoges, France, [6]Service d'ophtalmologie, hôpital Cochin, AP-HP, Paris, France.

Background/Purpose: The pathophysiology of GCA is poorly understood. Questions remain regarding the mechanisms underlying vascular remodeling.

Methods: Vascular smooth muscle cells (VSMC) were cultured from temporal artery biopsies (TAB) of consecutive patients suspected of GCA. We selected four patients with biopsy proven GCA (TAB^+-GCA), four patients with biopsy-negative GCA (TAB^--GCA), and four patients with another diagnosis than GCA (GCA-control). Normal human aorta VSMC were used as control. Proteomes of VSMC from patients in TAB^+-GCA, TAB^--GCA or GCA-control groups were compared using two-dimension DIGE (2D-DIGE) at pH range of 3–11. Transcriptomic analysis of VSMC from patients within the three GCA groups was performed using affimetrix chips. Proliferation of VSMC was performed with BrDU proliferation assay ELISA kit in unstimulated condition and with paxillin siRNA.

Results: We could identify 16, 28 and 2 protein spots that were differentially expressed between VSMC from TAB^+-GCA and GCA-control patients, between TAB^+-GCA and TAB^--GCA patients and between TAB^--GCA and GCA-control patients respectively (fold change$\geq$1.5 and $p\leq0.05$). Principal component analysis differentiated VSMC proteomes from TAB^+-GCA, TAB^--GCA and GCA-control. Ingenuity analysis comparing TAB^+-GCA and aorta revealed that identified proteins interact with paxillin.

Genes differentially expressed between VSMC from patients with TAB^+-GCA, TAB^--GCA and GCA-control were involved in cellular movement, organismal injury, tissue development, and cancer.

Unstimulated proliferation and in the presence of paxillin siRNA are currently being investigated in order to evaluate its potential involvement in the dysregulated proliferative phenotype observed in VSMC from GCA patients

Conclusion: VSMC from patients with GCA expressed proteins that confer increased proliferation and migration potential. Inhibition of the increased proliferation of VSMC during GCA through paxillin targeting might represent a promising therapeutic approach in patients with GCA.

Novel Inhibitory Effects of Mast Cells in Aortitis Involves Aortic Expression of Suppressor of Cytokine Signaling-1. Jason Springer, Vineesh Raveendran, Donald Smith, Mehrdad Maz and Kottarappat Dileepan. University of Kansas Medical Center, Kansas City, KS.

Background/Purpose: Early in the pathogenesis of Giant Cell Arteritis (GCA) dendritic cells interact with T cells of both Th1 and Th17 origin. IL-6; released by Th17 T-cells, macrophages and endothelial cells; plays an important role in the pathogenesis of GCA. Mast cells (MCs) are important constituents of the immune system. They possess both pro-inflammatory and anti-inflammatory functions. There is an increased presence of mast cells in the temporal arteries of GCA patients. Furthermore, MCs have been shown to have an immunomodulatory effect in an MPO-associated vasculitis mouse model. The mechanism by which MCs modulate vascular inflammation in large vessel vasculitis, such as GCA, is not known. Suppressor of Cytokine Signaling-1 (SOCS-1), a JAK-STAT inhibitor, plays a role in inhibiting cytokine signaling. The objective of this study was to test the hypothesis that MCs regulate LPS induced aortic IL-6 production through SOCS-1 proteins.

Methods: Two month old male C57Bl/6J mice were randomized into 4 treatment groups. The treatment groups were administered intraperitoneal injections with: saline (control), Compound 48/80 (C48/80, MC degranulating agent, 1mg/kg), LPS (1mg/kg) or C48/80+LPS. Mice were sacrificed at either 24 hours (single injection) or 10 days (serial injections), and blood and aortas were collected for various analyses as presented in '**Results**'. Data were analyzed for statistical significance and $p < 0.05$ was considered significant.

Results: In the single injection groups, LPS significantly enhanced serum IL-6 (350±146 pg/ml vs 21.3±5.5 pg/ml) and aortic IL-6 gene expression (18.0±5.4 fold vs 1.03±0.025 fold) compared to normal saline-injected mice. When MCs were degranulated by C48/80, LPS-induced aortic expression of IL-6 and serum IL-6 were significantly reduced when compared to LPS alone (IL-6: 101±13 pg/ml vs 350±146 pg/ml; IL-6 mRNA: 4.3±0.5 vs 18.0±5.4 fold change). Aortic expression of SOCS-1 mRNA was found to be 2- and 3-fold higher, respectively, in the LPS and C48/80 + LPS groups compared to controls. In mice receiving serial injections, there were significantly higher levels of IL-18 and tissue inhibitor of metalloproteinase-1 ($p<0.0001$) in the LPS and LPS+C48/80 groups compared to controls. Thrombopoetin was significantly higher in the LPS group compared to the C48/80 and control groups but no difference was seen between C48/80 + LPS compared to C48/80 group alone. No significant differences between groups were seen for IL-1 alpha, IL-1 beta, monocyte chemotactic protein (MCP) 1, MCP-3 or VEGF-A.

Conclusion: These results demonstrate that MC degranulation inhibits LPS- induced aortic expression of IL-6 and systemic production of IL-6. The inhibitory effect of MCs was associated with an increased expression of SOCS-1 in the aorta. This suggests that SOCS-1 plays a role in mast cell-mediated regulation of IL-6 as well as other cytokines associated with the pathogenesis of GCA homeostasis. Identifying the MC factor or factors involved in the inhibition of LPS-induced inflammation in the aorta may provide novel therapeutic strategies for GCA.

Incidence, Prevalence and Survival of Biopsy-Proven Giant Cell Arteritis in Northern Italy. Mariagrazia Catanoso[1], Pierluigi Macchioni[1], Luigi Boiardi[1], Francesco Muratore[1], Giovanna Restuccia[1], Alberto Cavazza[1], Ferdinando Luberto[2] and Carlo Salvarani[1]. [1]Arcispedale S Maria Nuova, Reggio Emilia, Italy, [2]Azienda Usl Reggio Emilia, Reggio Emilia, Italy.

Background/Purpose: To investigate the incidence, prevalence and mortality of biopsy proven giant cell arteritis (GCA) over a 27-year period in a defined area of northern Italy.

Methods: All patients with incident GCA diagnosed from January 1, 1986 to December 31, 2012 living in the Reggio Emilia area were identified through computerized hospital discharge diagnosis and a structured review of all histopahology reports. Patients were followed up from the time of diagnosis until either their death or December 31, 2012.

Results: Two hundred and eighty-five patients (75 men and 210 women) had biopsy proven GCA according to the histopathological examination. Mean+SD age at diagnosis was 74.4+7.3 years. The mean annual incidence rate (IR) of GCA was $58.16/10^6$ (95% CI: 51.4–64.9). The mean IR was $31.1/10^6$ (95% CI: 26.9–35.4) among women and $11.6/10^6$ (95% CI: 8.9–14.2) for men ($p < 0.05$). The estimated incidence for people over 50 y was 78.11 (95% CI: 67.4–88.7) for women and 33.4 (95% CI: 25.7–41) for men. The lowest IR occurred in male patients in the 50–59 years age group ($5.13/10^6$; 95% CI: 1.4–13.1), the highest IR was observed in female patients 80–84 years age group ($215.4/10^6$; 95% CI: 184.7–297.2). IR difference between sex was significant only in the 60–69 age group (IR male/female 14.6/67.1, 95% CI 7.0–26.9 vs 49.8–88.4). The average annual IR increased from $5.63/10^6$ during 1986–1988 to $45.23/10^6$ during 1998–2000 period and was stable thereafter with IR of $30–23/10^6$. Point prevalence on December 31st 2012 was $304.5/10^6$ (95% CI: 258.0–355.7) (women 453.1, 95% CI: 376–541.4, men 148.8, 95% CI: 105.3–204.2).

At histological examination 13.6% (39 pts) had only small vessels perivascular involvement (adventitial vasa vasorum and peri-adventitial capillaries). Prevalence of small vessels involvement was significant higher among male patients (male 30% vs 7%female, $p< 0.001$). One hundred and twenty-nine patients (45.2%) died during the follow-up period (median survival after diagnosis 152 months [range 4–320 months]). Survival did not differ nor between gender or between different histopathological pattern

Conclusion: This population-based study is the first to report the incidence of biopsy proven GCA in Italy. Our average annual IR is similar to that reported in the period 1984–1988 in Finland (1).

The Incidence and Mortality Rates of Giant Cell Arteritis in Southern Norway Are Lower Than Previous Reported. Andreas P. Diamantopoulos, Glenn Haugeberg, Lisa Amundsen, Elisabeth Wigaard, Dag Magnar Soldal and Geirmund Myklebust. Hospital of Southern Norway Trust, Kristiansand, Norway.

Background/Purpose: Giant cell arteritis (GCA) is the most common form of vasculitis. The highest incidence rates of GCA have been reported from Southern Norway (29–32/ 100000 >50 years and mortality rates has been reported not to be different from the background population. However, data are from the end of 80's to the early 90's and no recent reports exist.

The aim of this study was to examine the incidence and standardized mortality ratios (SMR) of GCA in Southern Norway in the period of the last 13 years.

Methods: GCA patients were identified by using the hospital records during the years 2000–2013. The ICD-10 coding system (M31.5- 6) was used to identify the patients and the diagnoses were carefully verified. In addition, a retrospective study of the archives of the Department of Pathology was conducted, in order to identify patients with biopsy that were not registered by the ICD-10 system. SMR was calculated by using the death rates of the Norwegian population per 100 000.

Results: Mean age (95% CI) among the 212 identified GCA patients was 73.2 (72.0–74.4) years. Among them, 60 were males [mean age 73.4 years (71.0–75.7)] and 152 females [mean age 73.2 years (71.8–74.5)]. One-hundred fifty-five patients (73.1%) had a positive biopsy of the temporal artery, 42 patients (19.9%) a negative and in 15 patients (7.0%) biopsy was not performed. All the patients with a negative or not performed biopsy satisfied the ACR classification criteria for GCA.

The incidence rate for GCA was 17.2 per 100 000 >50 years (males 10.4 and females 23.4). The incidence rate of the biopsy-proven GCA was 12.6 per 100 000 >50 years. The yearly distribution of the incidence rates of GCA in Southern Norway is displayed in figure 1.

Among the 212 GCA patients, there were 52 deaths during the period 2000–2014. The overall SMR was 0.5 (95%CI 0.3– 0.6) [0.5 for males (95%CI 0.3– 0.7), and 0.4 for females (95%CI 0.3– 0.6)]. For biopsy-proven GCA the SMR rates were 0.7 (95%CI 0.4–1.0) for males and 0.4 (95%CI 0.2– 0.5) for females.

Conclusion: The incidence rate of GCA in Southern Norway during the years 2000–2013 is 45 % lower than this reported in previous studies. However, a rising tendency of the incidence rates has been noticed at the last 5 years (fig 1). Interestingly, the mortality of GCA patients appears to be lower compared to the background population. Better quality of health care in this group of patients could be a reason.

Cardiovascular Risk Factors and Incident Giant Cell Arteritis. Gunnar Tomasson[1], Jóhannes Björnsson[2], Vilmundur Gudnason[3], Yuqing Zhang[4] and Peter A. Merkel[5]. [1]University of Iceland, Reykiavik, Iceland, [2]Akureyri Hospital, Akureyri, Iceland, [3]The Icelandic Heart Association, Kopavogur, Iceland, [4]Boston University School of Medicine, Boston, MA, [5]Vasculitis Center, University of Pennsylvania, Philadelphia, PA.

Background/Purpose: To assess the effect of cardiovascular risk factors on incidence GCA within a longitudinal cohort study in which detailed information on cardiovascular risk factors has been collected.

Methods: The data source is the Reykjavik Study (RS), a population-based, prospective cohort study with a primary focus on cardiovascular disease. All persons born in 1907–1935 that were living in Reykjavik, Iceland or adjacent communities on December 1, 1967 were invited to participate. Subjects came for a study visit in 1967–1996 and information on cardiovascular risk factors, including smoking habits, blood pressure, diabetes, body mass index, and serum cholesterol was obtained. All temporal artery biopsies (TABs) obtained from 1961–2009 on members of the cohort were identified through all three pathology laboratories in Iceland. All TABs were re-examined in a standardized fashion by a single pathologist with expertise in vascular pathology. Incidence of GCA was calculated for exposed (GCA) and unexposed (no GCA) subjects and incidence rate ratios (IRR) were calculated with 95% confidence intervals adjusted for age and sex.

Results: Data were obtained from 19,241 subjects that were followed for a median 23.1 (IQR: 17.6–29.4) years after the age of 50. During the follow-up of 444,396 person-years, 194 subjects had GCA, corresponding to an incidence rate of 45.0 (95% CI: 38.8–51.2) per 100,000 person-years after the age of 50. Woman had increased incidence of GCA compared to men, IRR= 2.03 (95% CI: 1.49 – 2.76). BMI was inversely associated with GCA; subjects with a BMI >25 had an IRR= 0.68 (95% CI: 0.50–0.90). Smoking was inversely associated with GCA among men IRR= 0.51 (95% CI: 0.30–0.86), but not women IRR=1.12 (95% CI: 0.79–1.57). Hypertension was associated with incident GCA among men IRR= 1.91 (95% CI: 1.12–3.25), but not among women IRR= 0.86 (95% CI: 0.60–1.24). Serum cholesterol was not associated with incident GCA.

Conclusion: This study confirms a high incidence of GCA in Iceland. Lower BMI is associated with the occurrence of GCA. Among men, hypertension is positively associated with GCA and smoking is inversely associated with incident GCA.

Fast-Track Diagnostic Procedure for Giant Cell Arteritis. Alojzija Hočevar[1], Ziga Rotar[2] and Matija Tomsic[3]. [1]University Medical Centre Ljubljana, 1000 Ljubljana, Slovenia, [2]University Medical Centre Ljubljana, Ljubljana, Slovenia, [3]BioRx.si, University Medical Centre Ljubjana, Ljubljana, Slovenia.

Background/Purpose: Giant cell arteritis (GCA) represents the most common primary vasculitis among adults aged 50 years or above. Recently, the national annual incidence rate in this population was determined at 10.5 per 10^5. GCA may lead to ischemic complications, which among others include permanent visual loss in up to 20% of patients and ischemic stroke in 2–4%. Early diagnosis and initiation of treatment is thus of paramount importance. At our secondary/tertiary level department of rheumatology we examine majority of patients with referral diagnosis of GCA within 24 hours from referral, and those referred during the week-end in up to 72 hours. Also, rheumatologists have been performing temporal artery biopsies (TAB) ourselves for decades with an excellent safety record. Snap frozen TAB specimens are processed and analyzed at the attached university institute of pathology. **Results** are obtained within three hours from TAB. Since September 2011 Color Doppler ultrasonography of temporal arteries (CDS-TA) is routinely performed in every potential case of GCA to aid diagnosis and guide TAB. Our aim was to analyze the performance of this approach to GCA patient work-up.

Methods: We retrieved and analyzed electronic and paper patient charts of patients diagnosed with GCA form September 1, 2011 to May 31, 2014. Appropriate descriptive statistical methods were used describe our cohort.

Results: During the 32 month observation period, 66 new GCA cases were identified. Their characteristics are presented in Table 1. Median (interquartile range (IQR), range) symptom duration prior to presentation was 30 (14–77, range 2–365) days. Patients were referred to our outpatient clinic by their general practitioners (33/66), infectious disease specialists (13/66), specialists of internal medicine (12/66) ophthalmologists (6/66), and neurologists (2/66). Except for two polymyalgia rheumatica patients, all other patients were glucocorticoid naïve at the time of diagnostic procedures. CDS-TA was performed in 65/66, and TAB in 54/66 cases. Median time to CDS-TA (IQR; range) was 0 (0–1; 0–6) days, and 1 (0–1.75; 0–15) day for TAB. CDS-TA, and TAB were performed on the day of referral to our department in 48/66 (73%), and 20/66 (30%) of patients, respectively. Notably, 24/66 (36.4%) patients reported visual manifestations. Unilateral permanent visual loss developed in 4/66 patients (6.1%)—in one patient despite prompt initiation of glucocorticoid treatment, and in the remaining three cases 13 days, 14 days, and 2 months before diagnosis. One patient had an ischemic stroke 8 days prior to diagnosis.

Conclusion: This fast-track pathway enables us to obtain a definitive diagnosis even before the initiation of treatment, and might contribute to a relatively low incidence of irreversible sight loss in our cohort compared to reported data, as well as avoidance of overtreatment with glucocorticoids.

Association Between Histological Features and Clinical Features of Patients with Biopsy Positive Giant Cell Arteritis. Kimberley Ting[1], Susan Lester[2] and Catherine L. Hill[3]. [1]The Queen Elizabeth Hospital,

Adelaide, Australia, [2]Queen Elizabeth Hospital, Woodville South, Australia, [3]University of Adelaide, Adelaide, Australia.

Background/Purpose: Temporal artery biopsy is the gold standard for diagnosing giant cell arteritis (GCA). The pathology of GCA characteristically involves transmural infiltrates, giant cell formation and intimal hyperplasia. However the significance of histopathology characteristics, in terms of clinical features and complications of GCA, remains unknown. The aim of this study was to investigate the association between histological biopsy features and clinical features, such as blindness, in patients with biopsy positive GCA.

Methods: Positive temporal artery biopsies registered on the South Australian Giant Cell Arteritis Registry were identified between 1991 and 2013 (n=186). Clinical and serological data was recorded using both patient questionnaire and case note review. Patients without clinical data were excluded from the analysis (n=42). Statistical analysis was performed using chi-squared and Wilcoxon's tests.

Results: 144 biopsy positive GCA cases were analysed. The mean age at biopsy was 77 years. 71% were female, and in total 30% experienced blindness. Although not individually significant, transmural inflammation ($p = 0.11$), luminal thrombus ($p = 0.17$) and giant cells ($p = 0.20$) were more frequent in GCA patients with blindness, whereas fragmentation of the internal elastic lamina ($p = 0.04$), and intimal thickening ($p = 0.02$) were more frequent in GCA patients without blindness (Table 1). The presence of giant cells was associated with transmural inflammation ($p = 0.06$), jaw claudication ($p = 0.02$), and higher inflammatory markers. In contrast, characteristics of patients with intimal thickening included a lower frequency of giant cells (0.01) and jaw claudication ($p = 0.01$), and lower inflammatory markers.

Table 1: Association Between Histopathology and Blindness

Histological Feature	*GCA with Blindness n (%)*	*GCA with Blindness n (%)*	*p value*
Giant cells	29/35 (85%)	61/82 (74%)	0.20
Macrophages	9/24 (37.5%)	25/68 (36.7%)	0.95
Lymphocytes	22/24 (91.7%)	64/68 (94.1%)	0.68
Plasma Cells	5/24 (20.8)	8/68 (11.8%)	0.27
Neutrophils	2/24 (8.3%)	6/68 (8.8%)	0.94
Histiocytes	11/24 (45.8%)	31/68 (45.6%)	0.98
Transmural Inflammation	16/24 (66%)	32/67 (47.8%)	0.11
Fragmentation of internal elastic lamina	15/36 (41.7%)	53/85 (62.4%)	0.04
Intimal thickening	13/36 (36.1%)	51/85 (60%)	0.02
Luminal Thrombus	6/36 (16.7%)	7/85 (8.2%)	0.17

Conclusion: Giant cells are strongly associated with jaw claudication and systemic markers of inflammation. We did not find any histological features that were individually significantly associated with an increased risk of blindness in GCA patients. However patients with intimal thickening by histology are less likely to have giant cells, have less acute systemic inflammation, and have a lower risk of blindness. This group may reflect a different disease subgroup or late stages of inflammation, highlighting the challenges in the pathological diagnosis and biopsy reporting of active GCA.

Correlations Between Histopathological Findings and Clinical Manifestations in a Large Monocentric Cohort of Patients with Biopsy-Proven Giant Cell Arteritis. Luigi Boiardi, Francesco Muratore, Giovanna Restuccia, Alberto Cavazza, Pierluigi Macchioni, Giuseppe Germanò, Nicolò Pipitone and Carlo Salvarani. Arcispedale S Maria Nuova, Reggio Emilia, Italy.

Background/Purpose: Giant cell arteritis (GCA) is a vasculitis that involves large and medium sized arteries in patients older than 50 years. Temporal artery biopsy (TAB) is the gold standard for the diagnosis of GCA. Cranial symptoms are the most common manifestations of the disease, while permanent visual loss is the most feared ischaemic complication of GCA and is reported in 10–20% of patients. Previous study have tried to correlate histological features of TAB with cranial and visual symptoms, but the results reported are not conclusive. The aim of our stuy was to correlate histological findings of TAB with clinical manifestations in a large monocentric cohort of consecutive patients with biopsy-proven GCA.

Methods: A pathologist with expertise in vasculitis and blinded to clinical data and final diagnosis reviewed all TABs performed for suspected GCA at our hospital between January 1986 and December 2012. Positive TABs showing only small vessel vasculitis and/or vasa vasorum vasculitis without transmural inflammation were excluded from the comparison analysis. Histopathologic features evaluated were: the severity of inflammation and intimal hyperplasia, both graded on a semiquantitative scale (mild=1, moderate=2 severe=3), the presence of intraluminal acute thrombosis, calcifications, giant cells, fibrinoid necrosis and laminar necrosis, consisting in a band of coagulative necrosis sometimes bordered by palisading histiocytes and following the internal elastic lamina.

Results: 271 patients had a final diagnosis of biopsy-proven GCA and were included in the study. More severe inflammation on semiquantitative scale was more frequently seen in patients with any cranial symptoms (88.4% grade 3; 87.5 % grade 2 and 74.7% grade 1, p=0.026), headache (80.4% grade 3; 80% grade 2 and 65.3% grade 1, p=0.038), abnormalities of TA at physical examination (82.6% grade 3; 63.5 % grade 2 and 56.9% grade 1, p=0.001) and halo at TA colour duplex sonography (CDS) (75.5% grade 3; 78.4 % grade 2 and 48.5% grade 1, p=0.011). The presence of laminar necrosis was more frequent in patients with visual symptoms (43.1% vs 24.8%, p=0.005), and in those with abnormalities of TA at physical examination (82.3% vs 65.3%, p=0.012). The presence of calcifications was more frequent in patients with visual symptoms (45.5% vs 25%, p=0.003), and in patients without systemic symptoms (71.3% vs 52.7%, p=0.009). More severe intimal hyperplasia on semiquantitative scale was less frequently seen in patients with polymyalgia rheumatica (PMR) (32.2% grade 3; 53.8 % grade 2 and 56.3% grade 1, p=0.008). The presence of giant cells was more frequent in patients with jaw claudication (49.2% vs 30.8%, p=0.006). Fibrinoid necrosis was present only in 2 cases (0,7%), in both sparing the temporal artery and limited to a small branch

Conclusion: The data of this large monocentric cohort of biopsy-proven GCA patients evidenced that visual symptoms correlate with the presence of laminar necrosis and calcifications. Cranial symptoms and halo at TA CDS correlate with the severity of mural inflammation. PMR inversely correlates with intimal hyperplasia. Fibrinoid necrosis was not a features of GCA.

Comparison of Clinical Manifestations in Different Histological Subsets of Biopsy-Proven Giant Cell Arteritis. Luigi Boiardi[1], Francesco Muratore[1], Alberto Cavazza[1], Giovanna Restuccia[1], Pierluigi Macchioni[1], Giuseppe Germanò[1], Nicolò Pipitone[1], Gianluigi Bajocchi[2] and Carlo Salvarani[1]. [1]Arcispedale S Maria Nuova, Reggio Emilia, Italy, [2]Arcispedale S Maria Nuova, Reggio Emilia, Japan.

Background/Purpose: Temporal artery biopsy (TAB) showing transmural inflammation is considered the gold standard for the diagnosis of giant cell arteritis (GCA). In some cases of GCA, inflammation is confined to the periadventitial small vessels, the vasa vasorum and/or the adventitia. These patients seem to closely resemble classic GCA, but the final significance of this more limited inflammation need more confirmation. The aim of our study was to describe and correlate the different histological subsets of GCA with demographic and clinical manifestations in a large monocentric cohort of biopsy positive GCA patients

Methods: All TABs performed for suspected GCA between 1986 and 2012 were reviewed by a single pathologist. Based on the localization of the inflammation, positive TABs were classified into 4 categories: small vessel vasculitis (SVV), with inflammation limited to small periadventitial vessels devoid of muscular coat; vasa vasorum vasculitis (VVV), with inflammation surrounding the adventitial vasa vasorum; inflammation limited to adventitia (ILA), with inflammation spreading from vasa vasorum to the adventitia without extension to the media; transmural inflammation (TMI), with external elastic lamina disruption and extension of the inflammation to the medi

Results: 317 TABs were positive for inflammation and were classified as: 253 (79.8%) TMI, 18 (5.7%) ILA, 19 (6.%) VVV and 27 (8.5%) SVV. Compared to patients with TMI, those with SVV and VVV had a significantly lower frequency of headache (55.6% vs 77.9%, p=0.010 for SVV and 57.9% vs 77.9%, p=0.048 for VVV), jaw claudication (7.4% vs 44.7%, p<0.0001 for SVV and 15.8% vs 44.7%, p=0.015 for VVV), abnormalities of TA at physical examination (33.3% vs 71.3%, p<0.0001 for SVV and 47.1% vs 71.3%, p=0.036 for VVV), halo at TA color duplex sonography (CDS) (27.3% vs 72.4%, p<0.0001 for SVV and 16.7% vs 72.4%, p<0.0001 for VVV), systemic symptoms (only for VVV, 42.1% vs 66.8%, p=0.029), a

lower levels of ESR (70.4±30.9 vs 86.5±30.1, p=0.011 for SVV and 64.9±34.7 vs 86.5±30.1, p=0.010 for VVV, mean ± DS mm/hour) and CPR (7.4±8.4 vs 8.9±6.1, p=0.027 for SVV and 3.5±3.7 vs 8.9±6.1, p<0.0001 for VVV, mean ± DS mg/dl) an higher frequency of male gender (63% vs 22.1%, p<0.0001 for SVV and 42.1% vs 22.1%, p=0.048 for VVV) and peripheral arthritis (only for SVV, 22.2% vs 6%, p=0.002) but a similar frequency of polymyalgia rheumatica, large vessel involvement and visual symptoms (including blindness). Patients with ILA were more similar to those with TMI, showing only a lower frequency of headache (55.6% vs 77.9%, p=0.031), abnormalities of TA at physical examination (40% vs 71.3%, p=0.011) and halo at TA CDS (14.3% vs 72.4%, p=0.003).

Conclusion: The histological spectrum of inflammatory lesions that can be found in TAB is broad and constitutes a continuum, ranging from SVV at one extreme, through VVV and the more spread ILA in the middle, to TMI at the other extreme of the spectrum. Despite the differences in cranial symptoms, halo sign at CDS and levels of acute-phase reactants, it is crucial that clinicians be aware that all different histologic TAB patterns are equally associated with a risk of visual loss, thus requiring prompt glucocorticoid treatment.

Is Temporal Artery Biopsy the Gold Standard for the Diagnosis of Giant Cell Arteritis? Marina Scolnik[1], Aldo Fabian Ojeda[2], Valeria Scaglioni[3] and Enrique R. Soriano[4]. [1]Rheumatology Unit, Internal Medical Services, Hospital Italiano de Buenos Aires, Instituto Universitario Hospital Italiano de Buenos Aires, and Fundacion PM Catoggio, Buenos Aires, Argentina, [2]Departamento de Reumatología, Hospital de Clínicas, FCM-UNA, Asuncion, Paraguay, [3]Rheumatology Unit, Internal Medical Service, Hospital Italiano de Buenos Aires, Instituto Universitario Hospital Italiano de Buenos Aires, and Fundacion PM Catoggio, Buenos Aires, Argentina, [4]Rheumatology Unit, Internal Medicine Service, Hospital Italiano de Buenos Aires, Instituto Universitario Hospital Italiano de Buenos Aires, and Fundacion PM Catoggio, Buenos Aires, Argentina.

Background/Purpose: The only test that confirms diagnosis of Giant Cell Arteritis (GCA) is a temporal artery biopsy showing vasculitis with mononuclear cell inflammatory infiltrates, often with giant cells. Due to the focal and segmental nature of the infiltrates, areas of inflammation may be missed by the biopsy. Some imaging modalities may aid in the diagnosis such as color duplex ultrasonography of the temporal arteries. When the clinical suspicion is strong and temporal biopsy is negative or can't be performed, patients are treated as GCA. Our objective was to analyze all patients with GCA seen at our hospital in order to address value of temporal biopsy result in relation to the clinical course.

Methods: We retrospectively reviewed electronic medical records of patients registered in our hospital between 2000–2013 with the problem: vasculitis, Giant Cell Arteritis or Temporal Arteritis. Patients fulfilling ACR 1990 criteria for GCA were included. Clinical and treatment information was collected. Temporal biopsies were reviewed. Ultrasound of temporal arteries was performed by an experienced vascular sonographer if requested by the treating rheumatologist and the finding of the halo sign was considered compatible with GCA diagnosis.

Results: 101 patients were included with GCA diagnosis, 79 females (78.2%), with a mean age at diagnosis of 74.9 years (SD 8.1). Temporal biopsy was positive in 52 patients, negative in 21 and was not performed in 28. Clinical characteristics are shown in table 1 grouped by biopsy result. Multivariate analysis showed that abnormal temporal pulse on examination had an OR of 19.7 (CI 2.9–131.9) for predicting a positive biopsy. Having symptoms of polymyalgia rheumatica (PMR) and age were also associated with a positive biopsy (OR 4.5, CI 1.03–19.4, and OR 1.11, CI 1.01– 1.24 respectively). No differences were found in clinical presentation, treatment, relapses or recurrences between groups. Ultrasound was performed in 42 patients (41.6%). Results according to temporal biopsy are shown in table 2. Ultrasound had an overall sensitivity of 29%, and a sensitivity of 25% and a specificity of 84% versus temporal biopsy; it helped in diagnosing 2 patients with negative biopsy and 6 patients without biopsy.

Conclusion: Abnormal temporal pulse, PMR symptoms and age were associated with a positive biopsy. Clinical presentation, course, treatment and relapses/recurrences didn't differ between patients with positive or negative or unperformed biopsy. In our experience, clinical judgement continues to be relevant in the diagnosis of GCA, aided partially by biopsy, less so by ultrasound.

Preliminary Analysis of Histological Findings in GCA Biopsy Positive Patients. Surjeet Singh[1], Andrew Hutchings[2], Wulf Forrester-Barker[3], Bhaskar Dasgupta[4], Andreas P. Diamantopoulos[5], Peter Lanyon[6], Malgorzata Magliano[7], Brendan McDonald[8], Konrad Wolfe[4] and Raashid Luqmani[9]. [1]Nuffield Department of Orthopaedics, Rheumatology and Musculoskeletal Sciences, University of Oxford, Oxford, United Kingdom, [2]London School of Hygiene and Tropical Medicine, London, United Kingdom, [3]Nuffield Department of Orthopaedics, Rheumatology and Musculoskeletal Sciences, Oxford, United Kingdom, [4]Southend University Hospital, Essex, United Kingdom, [5]Hospital of Southern Norway Trust, Kristiansand, Norway, [6]Nottingham University Hospitals NHS Trust, Nottingham, United Kingdom, [7]Stoke Mandeville Hospital, Aylesbury, United Kingdom, [8]John Radcliffe Hospital, Oxford, United Kingdom, [9]University of Oxford, Oxford, United Kingdom.

Background/Purpose: A positive temporal artery biopsy (TAB) with giant cells, active inflammation and intimal hyperplasia is the gold standard test for diagnosing temporal arteritis. However, a negative TAB does not rule out the disease. In this preliminary analysis we have looked at the histological features of the TAB's assessed in a prospective multicentre study of patients with suspected temporal arteritis (TABUL).

Methods: Temporal artery biopsies were performed in all patients with suspected temporal arteritis from June 2010 to December 2013. All biopsies were taken from the symptomatic side and examined by the local pathologist, recording results on a standardised case report form in addition to a routine pathology report. We describe the key histological features in the intima and internal elastic lamina, the presence of inflammatory infiltrates (including giant cells), thrombus, occlusion and recanalisation. Age, sex, median time to biopsy from starting steroids, biopsy length and clinical diagnosis at baseline assessment were recorded.

Results: In this preliminary analysis, data was available from 350 patients (254 female: 86 male, mean age = 71.1±9.5 (SD), [range 47–96]), of whom 348 received steroids. The mean time to biopsy following initiation of steroids was 5±3 (SD) days with 6 GCA biopsy positive cases greater than 10 days. The mean length of the temporal artery biopsy was 11.9±7.4 (SD) mm. Only 332 biopsies consisted of an artery (94.9%), from which 89 cases were positive for GCA (26.8%). Of the 89 cases, 69 had internal hyperplasia and 11 had both internal hyperplasia and arteriosclerosis in the intima. Fragmentation in the internal elastic lamina was reported in 53 cases, 24 cases reported both fragmentation and reduplication. In 98.9% of GCA biopsy positive cases, inflammatory infiltrate were present, with transmural (41.6%) and adventitia

(18.0%) recorded as the predominant sites of inflammation. Giant cells were seen in 67 (75.3%) of GCA biopsy positive cases. Completely occluded vessels were found in 20 cases, usually due to internal hyperplasia (in 16), although 4 cases had additional thrombus. Furthermore, 7 cases had evidence of recanalisation in at least one section of the biopsy. We analysed the clinician's initial assessment at baseline (prior to biopsy): 88, 189 and 73 out of 350 cases were defined as possible, probable or definite GCA: of these, 7 (8.0%), 45 (23.8%) and 37 (50.7%) respectively had a biopsy consistent with GCA.

Conclusion: Histological features in biopsy positive patients with GCA are not confined to one particular form of inflammation. The most common finding was transmural inflammation. We report a relatively low number of positive biopsies (89/350) which may reflect the low index of suspicion of GCA in this group, technical difficulties in obtaining an adequate sample, or skip lesions missed due to inadequate length of tissue, or the effects of glucocorticoid therapy in changing the biopsy result. Our findings highlight the need for a better diagnostic strategy for patients with suspected temporal arteritis.

Colour Doppler Ultrasonography Findings in Giant Cell Arteritis (GCA) and Their Relationship with Clinical Manifestations. Cristina Ponte[1], Ruth Geraldes[2], Anthea Craven[1], Andrew Judge[1], Peter C. Grayson[3], Ravi Suppiah[4], Joanna Robson[1], Richard A. Watts[5], Peter A. Merkel[6] and Raashid Luqmani[1]. [1]University of Oxford, Oxford, United Kingdom, [2]Lisbon Academic Medical Centre, Lisbon, Portugal, [3]National Institutes of Health, Bethesda, MD, [4]Auckland District Health Board, Auckland, New Zealand, [5]Rheumatology Department Ipswich Hospital and University of East Anglia, Ipswich, United Kingdom, [6]Vasculitis Center, University of Pennsylvania, Philadelphia, PA.

Background/Purpose: Colour Doppler ultrasonography (CDU) of the temporal (TA), axillary (AA) and common carotid arteries (CA) has excellent sensitivity and specificity for the diagnosis of GCA, typically showing halos (dark areas around the arterial walls) and stenoses or occlusions. The CDU pattern of patients with extra cranial and cranial GCA has been reported to substantially differ; visual impairment and age are inversely correlated to extra cranial GCA. In addition, involvement of the vertebral arteries (VA) is associated with vertebrobasilar stroke. The aim of this analysis was to evaluate the type and frequency of CDU abnormalities in the TA, AA, CA and VA and their relationship with clinical features amongst patients with a submitted diagnosis of GCA in the DCVAS study (a multinational observational study to develop diagnostic criteria and update classification criteria for primary vasculitis, using data from patients with vasculitis and comparators).

Methods: This analysis included data from all patients recruited into DCVAS through April 2014 who had complete 6 month follow-up data, a submitted diagnosis of GCA, and whose tests included a CDU of TA, AA, CA or VA. The presence of halo was considered diagnostic of GCA. Patients were defined as having cranial GCA if they underwent CDU of at least TA and AA but only had abnormities in TA; patients with extra-cranial GCA had involvement of the proximal arm arteries. CDU findings of each artery and cranial/extra cranial pattern were compared to clinical features using Chi-square or Mann-Whitney tests.

Results: GCA was diagnosed in 431 patients; 336 underwent TA biopsy (78%) and 133 (31%) underwent CDU of the following arterial territories: 107 TA, 72 CA, 42 AA and 21 VA. In 8 cases all 4 areas were evaluated; in 27 cases 3 areas; in 31 cases 2 areas; and in 67 cases 1 area. Halo occurred in 75% (TA), 16% (CA), 34% (AA), 41% (VA) of cases; stenosis was seen in 31% (TA), 11% (CA), 16% (AA) and 41% (VA); occlusion was present in 11% (TA), 0% (CA), 3% (AA) and 6% (VA); CDU was normal in 16% (TA), 73% (CA), 58% (AA) and 39% (VA). Table 1 shows that older people were more prone to having a positive TA CDU; headache was less frequent in extra-cranial GCA; PMR occurred in a higher number of patients with CA involvement; and an association between vascular examination and CDU was only found in AA ($p<0.05$). Moreover, no type of CDU involvement correlated to eye symptoms.

Conclusion: Despite the high sensitivity of CDU and its ability to evaluate several vessels, clinicians usually use TA biopsy for the diagnosis of GCA. Extra-cranial involvement is frequent in GCA and inversely correlated to history of headache. The presence of abnormal CDU findings in several arterial territories supports the use of more extensive imaging in GCA. No significant correlation between cranial GCA and eye symptoms was found, but the low number of patients with extra cranial CDU was a limitation in the analysis.

High Interobserver Agreement on Ultrasonographic Findings in Patients with Large Vessel Vasculitis. Andreas P. Diamantopoulos[1], Julia Geiger[2], Frode Lohne[3], Geirmund Myklebust[1] and Wolfgang A. Schmidt[4]. [1]Hospital of Southern Norway Trust, Kristiansand, Norway, [2]University Children's Hospital, Zurich, Switzerland, [3]Unilabs Røntgen Kristiansand, Kristiansand, Norway, [4]Immanuel Krankenhaus, Berlin, Germany.

Background/Purpose: Ultrasound has a high sensitivity and specificity regarding the diagnosis of giant cell arteritis (GCA). Ultrasound can also depict extracranial large vessel vasculitis (LVV) in both GCA and Takayasu arteritis (TA) patients. Until now, no studies have examined the inter-observer agreement of the ultrasonographic findings in LVV patients.

Hence, the aim of this study was to examine the inter-observer agreement of the ultrasound examination of temporal arteries and large vessels in LVV patients.

Methods: This study is a part of the MUSES project (Magnetic resonance angiography vs Ultrasonography in Systemic large vEssel vasculitiS), a prospective cross-sectional study. Patients who were diagnosed with LVV by ultrasound, MRA or CTA were identified and included in the study at the Department of Rheumatology, Hospital of Southern Norway Trust in Kristiansand from January 2014 to June 2014. One ultrasonographer experienced in the use of vascular ultrasound (APD) examined and recruited the LVV patients. The common temporal (TC), temporal parietal branch (TP), temporal frontal branch (TF), carotid (AC), subclavian (AS), vertebral (AV), axillary (AA) arteries, abdominal aorta (AAR) and ascending thoracic aorta (TAR) were scanned in all patients. Films of ultrasound evaluation of every artery both in longitudinal and transverse view (TAR-only longitudinal view) were recorded, and these data were surveyed by an expert on vascular ultrasound (WAS) who was blinded to clinical and laboratory data. To calculate the inter-observer agreement the Cohen's kappa test has been used.

Results: Nineteen patients were included in this study [(9 males, 10 females, median age 65 (32–78)]. Eighteen patients were diagnosed with GCA and one with TA. Six patients had new onset LVV and 13 had long lasting [(mean disease duration 3.3 years, 95% CI 1.95–4.67)]. Median CRP was 5 mg/l (1–133) and ESR 25 mm/hr (4–112).

The inter-observer agreement for the various arteries was: TC 0.94 (95% CI 0.82–1.00), TP 0.94 (95% CI 0.83–1.00), TF 0.87 (95% CI 0.70–1.00), AC 0.67 (95% CI 0.45–0.89), AS 0.94 (95% CI 0.84–1.00), AV 0.84 (95% CI 0.54–1.00), AA 1.00, TAR 1.00. None of the patients had affection of the abdominal aorta on ultrasound examination.

Conclusion: Ultrasonographic findings of aorta, temporal and supraaortic arteries in patients with LVV appears to be highly reproducible and can be recorded in films for further evaluation. Nonetheless, experience in the use of vascular ultrasound is required to achieve these promising results.

Early Halo Sign Features on Ultrasound Examination of Treated Patients with Giant Cell Arteritis. Ana Sofia Serafim[1], Surjeet Singh[1], Jennifer Piper[2], Andrew Hutchings[3], Mike Bradburn[4], Cristina Ponte[5], Bhaskar Dasgupta[6], Wolfgang A. Schmidt[7], Andreas P. Diamantopoulos[8], Eugene McNally[9] and Raashid Luqmani[2]. [1]Nuffield Department of Orthopaedics, Rheumatology and Musculoskeletal Sciences, University of Oxford, Oxford, United Kingdom, [2]University of Oxford, Oxford, United Kingdom, [3]London School of Hygiene and Tropical Medicine, London, United Kingdom, [4]Sheffield University, Sheffield, United Kingdom, [5]Lisbon Academic Medical Centre, Lisbon, Portugal, [6]Southend University Hospital, Essex, United Kingdom, [7]Immanuel Krankenhaus, Berlin, Germany, [8]Hospital of Southern Norway Trust, Kristiansand, Norway, [9]Oxford University, Oxford, United Kingdom.

Background/Purpose: The TABUL study (Temporal Artery Biopsy Vs Ultrasound in diagnosis of Giant Cell Arteritis) is assessing the relative performance of ultrasound and temporal artery biopsy for diagnosing GCA. All patients with newly suspected GCA underwent a single ultrasound scan of both temporal and axillary arteries within 7 days of commencing glucocorticoid therapy. We aimed to examine the ultrasound response to treatment as a potential biomarker in GCA, by measuring differences in the size of the halo around the arteries with different steroid duration within a 7 day period; furthermore we correlated the halo size with ischaemic symptoms of GCA.

Methods: All 415 cases with suspected GCA had an ultrasound examination of the temporal and axillary arteries and a biopsy of the temporal artery within 7 days of inclusion. The 301 patients with clinically defined definite or probable GCA at baseline were included in this analysis. Using the IBM SPSS Statistics package v20, we performed a cross-sectional analysis with linear and logistic regression models to determine the relationship of the halo size with days of steroid treatment and with ischaemic symptoms of GCA (jaw and tongue claudication, amaurosis fugax and reduced, lost or double vision).

Results: We included 214 women and 87 men (mean age 72.6 and 71.2 years old respectively) from 20 different recruitment centres. Fifty percent were scanned on the second day of steroid treatment or before. Forty three per cent (131 patients) had one or more temporal segments with a halo, 48.5% (146 patients) had bilateral temporal artery halos and 12.6% (38 patients) had axillary involvement. The linear regression model showed a consistently smaller halo size over the 7 days of steroid treatment ($p<0.005$) for the temporal arteries. The likelihood of finding a halo diminished with time, which was confirmed in a logistic regression until day 4 of steroid treatment ($p<0.005$), whereas this trend was not possible to predict after that time. At least one ischaemic symptom was present in 42% of the patients: jaw claudication in 48.2% (146 patients), reduced or lost vision in 36.6% (111 patients), double vision in 8.6% (26 patients), tongue claudication in 6.6% (20 patients) and amaurosis fugax in 4% (12 patients). The presence of jaw claudication was more frequent in patients with a halo ($p<0.05$). The symptomatic side of temporal arteries correlated significantly with the ipsilateral ultrasound findings ($p<0.05$ for right and left side findings on physical examination).

Conclusion: In newly diagnosed GCA, ultrasound halo size decreases with steroid treatment and correlates with the presence of ischaemic symptoms, supporting its early use as a diagnostic and potentially prognostic marker. We are exploring the potential value of change in halo size in individual patients over time to determine its value in monitoring response to treatment.

PET/CT for the Diagnosis of Giant Cell Arteritis: A Prospective Study. Alison Clifford[1], Elana Murphy[1], Steven Burrell[1], Matthew Bligh[1], Godfrey Heathcote[1], Mathieu Castonguay[1], Kara Thompson[2] and John G. Hanly[1]. [1]Dalhousie University and Capital Health, Halifax, NS, [2]Department of Medicine, Queen Elizabeth II Health Sciences Centre and Dalhousie University, Halifax, NS.

Background/Purpose: Temporal artery (TA) biopsies are negative in up to 50% of patients with giant cell arteritis (GCA). In such cases, increased uptake in large arteries on PET/CT may support the clinical diagnosis. The objective of this study was to compare vascular (18F)-FDG uptake in patients with clinically diagnosed GCA to controls, and to compare uptake in GCA TA biopsy positive (TA+) patients to those with negative TA biopsies (TA-). Secondary outcomes evaluated the correlation of vascular uptake on PET/CT with clinical and laboratory variables and medications, including use of corticosteroids.

Methods: Patients with a clinical diagnosis of GCA and meeting ACR 1990 classification criteria were prospectively enrolled. Controls were identified from an oncology database, matched for age and sex. All GCA cases were treated per standard of care with high dose corticosteroids and underwent both TA biopsy and PET/CT. Using a 4 point scale, vascular FDG uptake was scored in 8 vascular territories and overall (total) by two nuclear medicine specialists, blinded to the clinical diagnosis. TA biopsies were interpreted by 2 anatomical pathologists with differences resolved by consensus. Statistical analysis used non-parametric Wilcoxon exact tests, Spearman correlations and analysis of variance.

Results: Twenty-eight patients with GCA (61% female, mean age $\pm$ SD: 70 $\pm$ 8.9 yrs) and 28 controls (61% female, 64 $\pm$ 8.2 yrs) were enrolled. TA biopsy was positive in 64% of GCA patients. Mean total PET/CT uptake scores were significantly higher in those with GCA (10.34 $\pm$ 2.72) compared to controls (7.73 $\pm$ 2.56, $p=0.001$.) Six of 8 vascular territories evaluated showed significantly greater uptake in GCA patients. TA+ and TA- GCA patients had similar total PET/CT uptake (10.86 $\pm$ 2.63 vs. 9.4 $\pm$ 2.76, $p=0.2$) and in each specific vascular territory. The optimal cut-off for distinguishing GCA cases from controls by total PET/CT uptake score was 9. This resulted in area under the curve of 0.75, with a sensitivity of 71.4% and specificity of 64.3%. The presence of systemic symptoms ($p=0.015$), lower hemoglobin levels ($p=0.009$) and higher platelet counts ($p=0.008$) were associated with higher PET/CT scores but ESR and CRP levels were not. The only association with corticosteroids was between higher daily dose adjusted for body weight with higher total PET/CT scores ($p=0.033$).

Conclusion: Large vessel disease was identified in the majority (71.4%) of GCA patients by PET/CT despite initiation of corticosteroids, with similar uptake noted in TA+ and TA- patients. The sensitivity of PET/CT was superior to that of TA biopsy for identification of patients with a clinical diagnosis of GCA. Systemic symptoms, in particular, were associated with greater total uptake scores.

Disclosure: A. Clifford, None; **E. Murphy**, None; **S. Burrell**, None; **M. Bligh**, None; **G. Heathcote**, None; **M. Castonguay**, None; **K. Thompson**, None; **J. G. Hanly**, None.

Frequency and Predictive Variables of Relapses in Patients with Biopsy-Proven Giant Cell Arteritis. Luigi Boiardi[1], Giovanna Restuccia[1], Francesco Muratore[1], Alberto Cavazza[1], Luca Cimino[1], Raffaella Aldigeri[2], Pierluigi Macchioni[1], Maria Grazia Catanoso[1], Nicolò Pipitone[1] and Carlo Salvarani[1]. [1]Arcispedale S Maria Nuova, Reggio Emilia, Italy, [2]Università di parma, Parma, Italy.

Background/Purpose: Giant cell arteritis (GCA) is a vasculitis that involves large and medium sized arteries in patients older than 50 years. Relapses and recurrences of the disease have been reported in 40.8–48% of patients, leading to longer duration of glucocorticoids (GCs) therapy and to increased risk of GCs side effects. The aim of our study was to determine the frequency and the predictors of disease relapses in a large monocentric cohort of consecutive patients with biopsy-proven GCA.

Methods: All patients with a diagnosis of biopsy-proven GCA made at our centre between 1986 and 2007 were identified. Only patients with a follow-up period longer than 6 months were included in the study. A pathologist with expertise in vasculitis reviewed all temporal artery biopsies (TABs). Demographic, clinical and laboratory data at presentation and at each follow-up visit were retrospectively collected. Relapse was defined as recurrences of symptoms with rise in inflammatory markers during tapering of GCs or after GCs discontinuation.

Results: 181 patients had a diagnosis of biopsy-proven GCA in the study period. 22 patients had a follow-up shorter then 6 months, and were excluded from further analyses. Median (Q1,Q3) follow-up period for the 159 patients included was 80 (49,125) months. 57/159 (35.8%) patients relapsed during the follow-up period, with a median of 1 (range: 1–7) relapses. Most common clinical manifestation at first relapse was polymyalgia rheumatica (44%), followed by headache (37%). Only 1 patient developed visual loss secondary to disease relapse. Mean (DS) prednisone dose at the time of first relapse was

6.3 (10.1) mg/day. At univariate analysis predictors of relapses were the levels of hemoglobin (Hb) (HR 0.793, p=0.037), fever (HR 1.938, p=0.029), presence of giant cells (HR 2.560, P=0.031), acute thrombosis (HR 2.805, p= 0.003), and a more severe inflammation on a semiquantitative scale (HR 3.973, p=0.011 for moderate inflammation; HR 3.051, p=0.039 for severe inflammation) at TAB. Furthermore total duration of corticosteroid therapy [mean (SD) 64 (46) vs 31 (32) months, p<0.0001] and cumulative dose of prednisone [mean (SD) 16.7 (12.3) vs 9.7 (9.2) grms, p<0.0001) were significantly higher in patients whit disease relapses than in those without. Multivariate analysis confirmed as independent predictors of relapses the levels of Hb, [HR (CI 95%) 0.738 (0.575–0.947), p=0.017], the presence of moderate and severe inflammation at TAB [HR (CI 95%) 4.648 (1.328–16.363), p=0.016; and 3.653 (1.085–12.302), p=0.037 respectively for moderate and severe inflammation] and the presence of acute thrombosis at TAB [HR (CI 95%) 2.29 (0.974–5.383), p=0.05].

Conclusion: The results of the present study confirm that relapses are frequent in patients with biopsy-proven GCA. The levels of hemoglobin at diagnosis, the severity of inflammation and the presence of acute thrombosis at TAB are independent predictors of disease relapses.

Peripheral Arterial Disease in Patients with Giant Cell Arteritis: A Systematic Review and Meta-Analysis. Patompong Ungprasert[1], Praveen Ratanasrimetha[2], Charat Thongprayoon[3], Wisit Cheungpasitporn[3] and Promporn Suksaranjit[4]. [1]Bassett medical center, Cooperstown, NY, [2]Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand, [3]Mayo clinic, Rochester, MN, [4]University of Utah School of Medicine, Salt Lake City, UT.

Peripheral Arterial Disease in Patients with Giant Cell Arteritis: A Systematic Review and Meta-analysis

Background/Purpose: Several chronic inflammatory disorders, such as rheumatoid arthritis and systemic lupus erythematosus, have been shown to increase cardiovascular disease risk secondary to accelerated atherosclerosis. Similarly, there are data to suggest that patients with giant cell arteritis (GCA), another common chronic inflammatory condition, have an increased risk of coronary artery disease. However, the data on peripheral arterial disease (PAD) remain unclear due to conflicting epidemiological studies. Thus, to further investigate this association, we conducted a systematic review and meta-analysis of observational studies that compared the risk of PAD in patients with GCA versus participants without it.

Methods: Two investigators (P.U. and P.C.) independently searched published studies indexed in MEDLINE, EMBASE and the Cochrane database from inception to March 2014 using the terms “giant cell arteritis” and “temporal arteritis” combined with the terms “peripheral artery disease”, “peripheral vascular disease” and “arterial occlusive disease” A manual search of references of retrieved articles was also performed. The inclusion criteria were as follows: (1) observational studies published as original studies to evaluate the association between GCA and clinically relevant PAD and (2) odds ratios (OR’s), relative risk (RR’s) or hazard ratio (HR’s) or standardized incidence ratio (SIR’s) with 95% confidence intervals (CI’s) were provided. Study eligibility was independently determined by the two investigators noted above. The quality of each study was, again, independently assessed by the two investigators using Newcastle-Ottawa scale.

RevMan 5.2 software was used for the data analysis. Point estimates and standard errors were extracted from individual studies and were combined by the generic inverse variance method of DerSimonian and Laird. Given the high likelihood of between study variance, we used a random-effect model rather than a fixed-effect model. Statistical heterogeneity was assessed using the Cochran’s Q test.

Results: Out of 460 potentially relevant articles, four studies (three retrospective cohort studies and one case-control study) were identified and included in our data analysis. The pooled risk ratio of PAD in patients with GCA was 1.77 (95% CI, 1.01 to 3.12). The statistical heterogeneity of this meta-analysis was high with an I^2 of 89%.

Conclusion: Our study demonstrated a statistically significant increased PAD risk among patients with GCA.

Hospitalization Rates and Utilization Among Patients with Giant Cell Arteritis: A Population-Based Study from 1987 to 2012. C. John Michet III[1], Sara J. Achenbach[2], Cynthia S. Crowson[2] and Eric L. Matteson[2]. [1]Mayo Clinic College of Medicine, Rochester, MN, [2]Mayo Clinic, Rochester, MN.

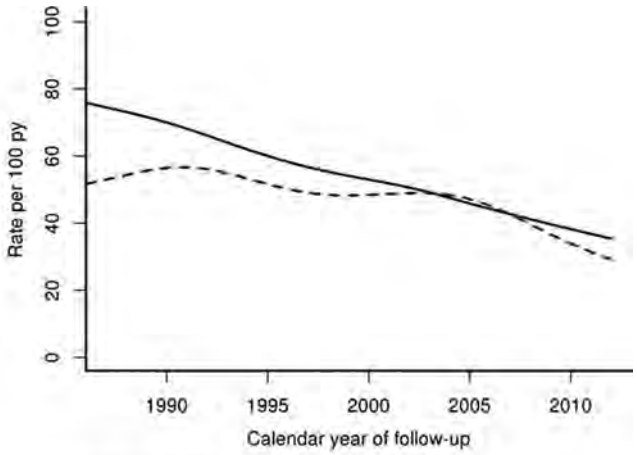
Background/Purpose: Patients with giant cell arteritis (GCA) may experience serious vascular and visual complications. It is unknown, however, to what extent the difficulties of the disease may lead to hospitalization. The goal of this study is to discern whether patients with GCA are at greater risk for all-cause hospitalizations when compared to the general population.

Methods: This retrospective, population-based cohort study utilized patients with large vessel or visual involvement who were diagnosed with GCA (as defined by the 1990 ACR criteria) between 1/1/1950 and 12/31/2009, and a reference cohort of patients without GCA matched on age, sex, and calendar year. Each patient’s medical record was examined for hospitalizations from 1987 through 2012. For this analysis, follow-up began with the latter of index date or 1/1/1987 and ended at the earlier of death, last follow-up, or 12/31/2012. Discharge diagnoses were grouped together using the Clinical Classifications Software (CCS) for ICD-9-CM from Healthcare Cost and Utilization Project (HCUP). Data were analyzed using person-year methods and rate ratios comparing GCA to non-GCA.

Results: The GCA cohort consists of 199 patients with a mean age of 76.2 (79.9% female) and follow-up of 8.2 years. The non-GCA cohort is comprised of 194 patients with a mean age of 75.7 (78.9% female) and follow-up of 8.6 years. The patients with GCA had 816 hospitalizations and the non-GCA patients had 737 hospitalizations. GCA patients proved to be at a marginally greater risk for all causes of hospitalization (Rate Ratio [RR] 1.13, 95% Confidence Interval [CI] 1.02, 1.25); however, the rate of hospitalization for patients with GCA decreased substantially from 1987 to 2012 (Figure 1).

Two specific discharge categories are of interest. First, transient cerebral ischemia (TCI) is a greater risk of hospitalization for patients with GCA who had 16 hospitalizations compared to patients without GCA who only had 5 hospitalizations (RR 3.06, CI 1.27, 9.47),. Second, patients with GCA (21 hospitalizations) are at greater risk of hospitalization for syncope than patients without GCA (5 hospitalizations) (RR 3.98, CI 1.72, 12.14).

Conclusion: In this first ever analysis of all-cause hospitalizations in a population-based cohort, patients with GCA appear to be at a marginally greater risk for hospitalization than patients without GCA, although the rate of hospitalization for GCA patients decreased from 1987 to 2012. Patients with GCA are at increased risk of hospitalization for both transient cerebral ischemia and syncope.



Solid line – patients with GCA
Dashed line – patients without GCA

Venothromboembolism in Large Vessel Vasculitis. Sankalp V. Bhavsar[1], Nader A. Khalidi[2], Simon Carette[3], David Cuthbertson[4], Peter C. Grayson[5], Gary S. Hoffman[6], Curry L. Koening[7], Carol A. Langford[8], Carol McAlear[9], Larry Moreland[10], Paul A. Monach[11], Christian Pagnoux[3], Philip Seo[12], Kenneth J. Warrington[13], Steven R. Ytterberg[13] and Peter A. Merkel[9]. [1]Division of Rheumatology, McMaster University, Hamilton, ON, [2]St. Joseph's Hospital, McMaster University, Hamilton, ON, [3]University of Toronto, Toronto, ON, [4]University of South Florida, Tampa, FL, [5]National Institutes of Health, Bethesda, MD, [6]Cleveland Clinic Foundation, Cleveland, OH, [7]University of Utah, Salt Lake City, UT, [8]Center for Vasculitis Care and Research, Cleveland Clinic, Cleveland, OH, [9]Vasculitis Center, University of Pennsylvania, Philadelphia, PA, [10]Vasculitis Center, of University of Pittsburgh Medical Center, Pittsburgh, PA, [11]Vasculitis Center, Boston University School of Medicine, Boston, MA, [12]Johns Hopkins Vasculitis Center, Johns Hopkins University, Baltimore, MD, [13]Mayo Clinic, Rochester, MN.

Background/Purpose: Venous thromboembolic disease (VTE) is a recognized characteristic of various systemic vasculitides, particularly small-vessel vasculitis. However, there are no reports describing the frequency of VTE in Takayasu's arteritis (TAK) and no large studies examining VTE in patients with giant cell arteritis (GCA) using a standard case definition. The aim of this study was to determine the prevalence and incidence of VTEs in patients with large-vessel vasculitis (LVV), describe these VTEs, and assess the timing of VTEs in relation to the diagnosis of LVV.

Methods: The data source was the Vasculitis Clinical Research Consortium Longitudinal Studies of TAK and GCA, which enrolled patients with new onset or established disease. At baseline visits any history of VTE is recorded to determine the baseline prevalence of VTE. Also collected are data on traditional VTE risk factors such as history of malignancy, hematological disease, and other autoimmune diseases, and use of oral contraceptives or hormone replacement therapy. In follow-up visits, the occurrence of any new/interval VTEs is recorded. The timing of new VTEs in relation to the diagnosis of LVV or to flares of LVV was also evaluated.

Results: 159 patients with TAK and 256 patients with GCA were included for analysis. In patients with TAK, 5 patients (3.1%) had a history of VTE recorded at the baseline visit. No patients had identifiable traditional risk factors for VTE. 4 of the 5 events occurred within 4 years of diagnosis. New VTEs occurred in 4 patients with TAK over a mean observation period of 2.6 years after the baseline visit (incidence 1.0 per 100 person-years vs. a rate of 0.06 per 100 person-years in age matched controls). No patients experienced a flare of vasculitis when a new VTE was recorded. One patient with TAK with a new VTE had a history of inflammatory bowel disease. The overall prevalence of VTE in patients with TAK was 5.7%. In the GCA group, a history of VTE was recorded at the baseline visit in 12 patients (4.7%). One patient had a history of estrogen use; no other patients with VTE had a history of identifiable traditional risk factors for VTE. Over a mean observation period of 3.2 years after the baseline visit, no patients with GCA experienced a new VTE (incidence 0.0/100 person-years). All 21 VTEs in the patients with LVV occurred in females ($p < 0.05$). 19% of VTEs occurred within one year of diagnosis of LVV.

Conclusion: This is the first large study to describe VTEs in patients with TAK and GCA using a standardized case definition. Patients with TAK but not GCA appear to have an increased risk of developing VTEs after diagnosis, especially among female patients. VTEs in LVV appear likely to occur more frequently around the time of the diagnosis of LVV. In LVV the pathogenesis of VTE, the role of prophylactic antiplatelet/anticoagulation therapy, and determining if VTEs should be considered a criterion for disease relapse are all areas for future study suggested by these results.

Inpatient Complications in Patients with Giant Cell Arteritis: Increased Risk of Thromboembolism, Delirium and Adrenal Insufficiency. Sebastian Unizony, Mariano Menendez, Naina Rastalsky and John H. Stone. Massachusetts General Hospital, Boston, MA.

Background/Purpose: The morbidity and mortality of hospitalized giant cell arteritis (GCA) patients has been largely unexplored. The aim of this study was to analyze inpatient complications experienced by patients with GCA.

Methods: We used the Nationwide Inpatient Sample (NIS) database to study a large group of patients admitted with medical and surgical problems that commonly affect the elderly (pneumonia, myocardial infarction, ischemic stroke and femoral neck fracture). Patients were divided in 2 cohorts based on whether or not they carried the diagnosis of GCA. Outcomes evaluated included inpatient mortality, the occurrence of adrenal insufficiency (AI), deep vein thrombosis (DVT), pulmonary embolism (PE), and delirium. GCA and non-GCA groups were compared using chi-square tests. Multivariate logistic regression analysis was performed to control for potential confounders such as age, sex, characteristics of the admitting hospital (teaching versus non-teaching; urban versus rural), and the presence of co-morbid conditions such as diabetes, hypertension, chronic kidney disease, coronary artery disease, and congestive heart failure. In order to maintain the family-wise error rate below a significance level of 0.05, adjustment for multiple comparisons was applied using Bonferroni's method.

Results: From 2008 to 2011, 8,203,447 patients older than 50 years of age were discharged from acute care facilities across the US after admission with pneumonia (3,232,939), myocardial infarction (2,180,990), ischemic stroke (1,623,564), or hip fracture (1,165,954). Among these individuals, a group of 9,311 (0.11%) carried the diagnosis of GCA. Compared to the non-GCA cohort, GCA patients were significantly older (mean age 80 versus 74 years, $p < 0.001$) and predominantly female (76% versus 53%, $p < 0.001$). Most hospitalizations in both GCA and non-GCA subjects occurred in urban locations (~80%).

During hospitalization, 4.1% of the patients with GCA died in comparison to 4.8% of the individuals without GCA ($p = 0.006$). After accounting for potential confounding factors, multivariable logistic regression analysis showed that the OR for in-hospital mortality among GCA subjects was 0.73 (95% CI 0.66 – 0.81; $p < 0.001$). In contrast, when compared with the non-GCA population, those with GCA suffered from DVT (1.5% versus 0.7%), PE (0.9% versus 0.6%), delirium (3.1% versus 1.5%), and AI (1.3% versus 0.3%) significantly more often ($p < 0.001$). Multivariate analyses revealed that GCA persisted as an independent risk factor for each of these complications. The OR for DVT was 2.08 (95% CI 1.76 – 2.45, $p < 0.001$); for PE, 1.58 (95% CI 1.27 – 1.96, $p < 0.001$); for delirium, 1.60 (95% CI 1.42 – 1.80, $p < 0.001$); and for AI, 4.95 (95% CI 4.13 – 5.93, $p < 0.001$).

Conclusion: GCA patients admitted for pneumonia, myocardial infarction, ischemic stroke and femoral neck fracture had a slight but significant reduction in inpatient mortality compared to the general population. However, GCA was an independent risk factor for AI, DVT, PE and delirium in the hospitalized population. Increased awareness among providers caring for inpatients with GCA may help prevent, diagnose and treat these important complications.

Corticosteroid-Related Adverse Events in Patients with Giant Cell Arteritis: A Claims-Based Analysis. Gordon H. Sun[1], Khaled Sarsour[2], Eunice Chang[1], Michael S. Broder[1], Neil Collinson[3], Katie Tuckwell[3], Pavel Napalkov[2] and Micki Klearman[2]. [1]Partnership for Health Analytic Research, LLC, Beverly Hills, CA, [2]Genentech, Inc., a Member of the Roche Group, South San Francisco, CA, [3]Roche Products Ltd., Welwyn Garden City, United Kingdom.

Background/Purpose: Giant cell arteritis (GCA) is an inflammatory vasculitis preferentially affecting large and medium-sized arteries with an incidence of 1 to 30/100,000. High-dose oral corticosteroids (CS) are the mainstay of GCA therapy. We examined the risk of oral CS-related adverse events in a US commercially insured population.

Methods: This was a retrospective cohort study using MarketScan® during 2003–2012. We identified GCA patients who had at least 2 medical claims with a GCA diagnosis (International Classification of Diseases, 9th Revision, Clinical Modification code 446.5), had at least 1 oral CS prescription fill within 6 months before or after the first GCA diagnosis, and were at least 50 years old. Patients were followed for at least 1 year until disenrollment or study end. We measured oral CS use in 3 ways: cumulative number of days, cumulative prednisone-equivalent exposure, and contemporaneous use (time from the date of interest to last oral CS use). We prospectively reviewed published literature to identify adverse events of interest known to

be associated with oral CS use. Adverse events included cataracts, glaucoma, pneumonia, opportunistic infections, peptic ulcer disease, and bone-related conditions. We conducted Cox regression analyses to model oral CS use across time and the resultant risk of developing adverse events.

Results: The cohort contained 2,497 GCA patients with mean age 71 years, 71% women, and mean Charlson comorbidity index 1.5. Median initial oral CS dose in the cohort was 40 mg/day. Patients required a median 190 days to reduce this dose to ≤7.5 mg/day and received a median cumulative oral CS dose of 3,380 mg until this level was reached. They required a median 210 days to reach ≤5.0 mg/day and received a median 3,600 mg until this level was reached.

Patients with any adverse event were prescribed more days of oral CS (median 195 vs. 102.5 days) and received a higher cumulative prednisone-equivalent dose (median 3,400 vs. 2,145 mg) than those without an adverse event.

After adjusting for patient characteristics, each additional 1 gram increase in cumulative prednisone-equivalent exposure increased the hazard ratio of developing a first adverse event by 3% ($p<.001$). Similar patterns of increase were observed for individual adverse events, as well as for adverse event risk regardless of the method used to measure oral CS use (**Table**). Each additional cumulative month of oral CS increased the hazard ratio for first adverse event by 1% ($p=.003$). For current oral CS users, the hazard ratio for first adverse event was 1.47 ($p<.001$) compared to non-users.

Table

Risk of Developing Oral Corticosteroid-Related Adverse Events Based on Model of Oral Corticosteroid Use

Oral Corticosteroid Use Model	Hazard Ratio of First Adverse Event	Hazard Ratio of Osteoporosis	Hazard Ratio of Fracture	Hazard Ratio of Cataract	Hazard Ratio of Glaucoma	Hazard Ratio of Pneumonia	Hazard Ratio of Diabetes Mellitus
Each Additional Gram of Prednisone-Equivalent Exposure	1.03*	1.05*	1.04*	1.03*	1.05*	1.03*	1.05*
Each Additional Month of Oral Corticosteroid Use	1.01*	1.02*	1.01*	1.01	1.02*	1.01*	1.00
Current Oral Corticosteroid Use vs. No Use in 1 Year of Follow-Up	1.47*	2.28*	2.05*	1.39*	1.57	1.63*	1.51*

* p-value <.05

Conclusion: In a large cohort of GCA patients, high-dose oral CS use was near-universal. Patients were maintained on oral CS for a median 7 months before tapering to a daily dose of ≤5.0 mg. By multiple measures, high-dose oral CS use was associated with a significantly increased risk of adverse events.

Vasculitis and Inflammatory Bowel Diseases: A Study of 32 Patients with Both Conditions and Systematic Review of the Literature. Alice Sy[1], Natasha Dehghan[2], Nader A. Khalidi[3], Lillian Barra[4], Simon Carette[5], David Cuthbertson[6], Gary S. Hoffman[7], Curry L Koening[8], Carol A. Langford[9], Carol McAlear[10], Paul A. Monach[11], Larry W. Moreland[12], Philip Seo[13], Ulrich Specks[14], Steven R. Ytterberg[14], Gert Van Assche[15], Peter A. Merkel[16] and Christian Pagnoux[5]. [1]Medicine Division, London, ON, [2]Rheumatology Division, Vancouver, BC, [3]McMaster University, Hamilton, ON, [4]St. Joseph's Health Care, London, ON, [5]University of Toronto, Toronto, ON, [6]University of South Florida, Tampa, FL, [7]Cleveland Clinic Foundation, Cleveland, OH, [8]George E. Wahlen Department of Veterans Affairs Medical Center Salt Lake City and University of Utah, University of Utah School of Medicine, Salt Lake City, UT, [9]Center for Vasculitis Care and Research, Cleveland Clinic, Cleveland, OH, [10]University of Pennsylvania, Philadelphia, PA, [11]Boston University, Boston, MA, [12]University of Pittsburgh, Pittsburgh, PA, [13]Johns Hopkins Vasculitis Center, Rheumatology Division, Johns Hopkins University, Baltimore, MD, [14]Mayo Clinic, Rochester, MN, [15]Mount Sinai Hospital, Toronto, ON, [16]Vasculitis Center, University of Pennsylvania, Philadelphia, PA.

Background/Purpose: Small case series suggested that vasculitis and inflammatory bowel disease (IBD; Crohn's disease [CD] or ulcerative colitis [UC]) can co-occur more commonly than the prevalences of the individual diseases suggest. This study aimed to describe this association through the analysis of a large cohort of carefully studied patients and a systematic literature review.

Methods: Clinical data was available from patients with both IBD and vasculitis with follow-up >6 months enrolled in the Vasculitis Clinical Research Consortium (VCRC) Longitudinal Studies, followed in Canadian Vasculitis research network (CanVasc) centers, and/or in the University of Toronto's IBD clinic. Individuals in which ANCA-associated vasculitis (AAV) and IBD were diagnosed within the same 12-month period were excluded because diagnostic misclassification as IBD is common at initial presentation of ileocolitis due to vasculitis. A systematic review of the literature (through 02/2014) for patients with IBD and vasculitis was conducted through a PubMed search. The main characteristics of patients with Takayasu arteritis (TAK) were compared to those patients in the VCRC with TAK but no IBD.

Results: 32 patients (17 VCRC, 15 CanVasc) with vasculitis and IBD satisfying our study criteria were identified. The main group included 13 patients with large vessel vasculitis (LVV): 12 TAK and 1 giant cell arteritis; 8 patients had CD and 5 had UC. Eight patients had AAV (6 granulomatosis with polyangiitis, GPA), 2 eosinophilic granulomatosis with polyangiitis, EGPA, 5 isolated cutaneous vasculitis, and 6 other vasculitides (Kawasaki, IgA nephropathy, polyarteritis nodosa, or central nervous system vasculitis). Patients with LVV and AAV were mostly female (18/21) with a median age of 20 (8 to 52) and 27 (17 to 58) years at diagnosis of IBD and vasculitis, respectively. The diagnosis of IBD preceded that of vasculitis in 12/13 LVV and 8/8 AAV patients, 3/5 with cutaneous vasculitis and 3/6 with other vasculitides.

305 other patients with IBD and vasculitis were identified in the literature, distributed among 4 similar subsets: LVV (n=143, 116 female, 69 CD, 74 UC, 132 TAK, 87 with IBD preceding vasculitis), cutaneous vasculitis (n=66, 33 with IBD preceding vasculitis), AAV (n=19, 13 GPA, 3 MPA, 3 EGPA), and other vasculitides (n=77, including IgA vasculitis, retinal vasculitis, CNS vasculitis, polyarteritis nodosa, Kawasaki disease, vasculitic neuropathy).

As shown in the Table, no differences other than in ethnicity (likely due to center or publication biases) and age at TAK diagnosis were observed between patients with TAK with or without IBD. Mortality was low.

Characteristic	Patients with TAK but no IBD (VCRC) N = 152	Patients with TAK and IBD from this series N = 12	Patients with TAK and IBD from this series and literature N = 144
Female/Male, No.	143/9	11/1	110/24*
Median age at diagnosis of TAK, years (range)	31 (4 to 63)	19 (8 to 52)	23 (8 to 69)
Ethnicity, No. (%)			
Caucasian	127 (84%)	8 (67%)	18 (24.7%)
Asian	14 (9%)	3 (25%)	48 (65.8%)
Clinical manifestations, No (%)			n = 75*
Claudication of extremities	96 (63%)	8 (67%)	26 (35%)
Decreased brachial pulse	92 (61%)	9 (75%)	47 (63%)
Blood pressure difference between arms	70 (46%)	7 (58%)	45 (62%)
Bruit over subclavian artery or aorta	77 (51%)	5 (42%)	40 (55%)
Renal hypertension	20 (13%)	4 (33%)	15 (21%)
Median number of ACR criteria met	4 (1 to 6)	4.5 (2 to 6)	4 (2 to 6)
Median duration of follow-up, years	6.25 (0.25 to 31)	4.7 (0.75 to 28)	0.6 (0.1 to 28)
Outcomes, No (%)			n = 75*
Remission of vasculitis at last follow-up	108/122 (89%)*	5/8 (63%)	59 (79%)
Stroke	9 (7%)	0	4 (5%)
Myocardial infarction	4 (3%)	0	1 (1%)
Deaths	0	0	6 (8%)

* Complete information was not available for all patients, especially those from the literature.

Conclusion: These findings highlight the risk in patients with IBD (both CD and UC) to develop vasculitis, especially TAK. Further investigation of patients with both vasculitis and IBD may provide intriguing insights into common underlying mechanisms.

Background/Purpose: Takayasu arteritis (TAK) is a systemic vasculitis affecting large arteries and large branches of the aorta. Ulcerative colitis (UC) is a prevalent autoimmune colitis. Since TAK and UC share HLA-B*52:01 and IL12B as genetic determinants, and concurrent cases of these two diseases have been reported, we hypothesized that UC is a common complication of TAK. Here, we performed an observational study to evaluate concurrence ratio of TAK and UC followed by genetic analysis of shared susceptibility genes between the two diseases.

Methods: A total of 470 consecutive patients with TAK from 14 Japanese institutions were registered. Concurrence ratio of TAK and UC were searched in each institution. We characterized patients with TAK and UC by analyzing clinical manifestations and genetic components. Genetic overlapping of TAK and UC was evaluated with use of UC susceptibility SNPs by comparing risk directions and effect sizes between susceptibility to the two diseases.

Results: We found that 29 patients out of 470 patients with TAK suffered from UC (6.2% (95%CI:4.2%-8.7%)). This ratio was much higher than expected based on prevalence of UC (0.11%). Patients with TAK and UC developed TAK at an earlier stage of life ($p=0.0051$) and showed significant enrichment of HLA-B*52:01 in comparison to patients without UC ($p=1.9\times10^{-5}$, OR:11.60, 95%CI:2.82–102.65). The patients with the two diseases did not display higher frequency of aortic regurgitation (AR) or severer AR than patients without UC. While the TAK patients with UC displayed high risk allele frequency of rs6871626 in the IL12B region in comparison with patients without UC, the difference did not reach the significant level (88.0% vs 75.7%, $p=0.22$, OR:2.35 (0.68–12.53)). The 103 susceptibility SNPs to UC displayed common risk directions with TAK susceptibility ($p=0.00074$), while the 133 susceptibility SNPs to human height as a non-immunological reference did not show common risk directions with TAK susceptibility ($p=0.13$).

Conclusion: UC is a major complication of TAK. These two diseases share a significant proportion of their genetic background and HLA-B*52:01 may play a central role on the concurrence.

Association of a Single Nucleotide Polymorphism (SNP) in *IL-12B* Region with Clinical Features and Peripheral T Cell Profiles of Patients with Takayasu Arteritis. Toshiki Nakajima[1], Hajime Yoshifuji[1], Chikashi Terao[2], Koji Kitagori[1], Ran Nakashima[1], Yoshitaka Imura[1], Naoichiro Yukawa[1], Koichiro Ohmura[1], Takao Fujii[1] and Tsuneyo Mimori[1]. [1]Kyoto University Graduate School of Medicine, Kyoto, Japan, [2]Kyoto University, Kyoto, Japan.

Background/Purpose: We preliminarily found a SNP (A vs. C, rs6871626) in *IL-12B* region as a susceptibility gene to Takayasu arteritis (TAK) by genome-wide association study. *IL-12B*encodes IL-12/IL-23 p40 that regulates differentiation and activation of Th1 and Th17. In the present study, we investigated the association of this SNP with clinical characteristics and pathophysiology of TAK.

Methods: We investigated 1) the association of the SNP with clinical features of 84 TAK patients who have visited Kyoto University Hospital and 2) the association of the SNP with expression levels of surface markers and intracellular cytokines in peripheral T cells sampled from 21 TAK patients and 15 healthy controls (HC). We obtained peripheral blood mononuclear cells from the TAK patients and HC, stained them with fluorescent antibodies, and analyzed them with flow cytometry.

Results: 1) In 84 patients with TAK, 68 were the risk group (R-Group; AA+AC) and 16 were the non-risk group (NR-Group; CC). The complication rate of aortic regurgitation (AR) was 51% in R-Group, significantly higher than 13% in NR-Group ($p<0.01$). The ultrasound-evaluated severity of AR was higher in R-Group ($p<0.01$). eGFR tended to be lower in R-Group than in NR-Group (70.5 vs. 80.3 mL/min/1.73m^2, $p=0.2$). The complication rate of abdominal arterial lesions was 58% in R-Group, significantly higher than 27% in NR-Group ($p<0.05$). 2) In 21 patients with TAK analyzing T cells, 14 and 7 were R-Group and NR-Group, respectively. In $CD4^+$ T cells, $CXCR3^+$ (Th1) cells were 6.9% in patients (7.5% in R-Group and 5.7% in NR-Group), tended to be higher than 5.7% in HC ($p=0.16$), while $CCR6^+$ (Th17) cells were 16.0% in patients (16.5% in R-Group and 15.4% in NR-Group), significantly higher than 8.3% in HC ($p<0.01$). In $CD4^+$ T cells, IFN-γ^+ cells in R-Group was significantly higher than in NR-Group (23% vs.7%, $p=0.02$), while IL-17^+cells were not significantly different between R-Group and NR Group (0.7% vs. 1.4%, $p=0.37$).

Conclusion: In TAK patients with the risk allele of *IL-12B*, the complications of aortic valve and abdominal arteries were more frequent than in patients with the non-risk allele. TAK patients showed a tendency to have higher percentage of Th1 and Th17 cells than HC, and R-group had higher percentage of Th1 cells than NR-Group. The results suggested a possibility that this SNP may be involved in the pathophysiology of TAK through increased expression of cytokines.

Serum Cytokine Profiles in Takayasu's Arteritis: A Search for a Biomarker. Fatma Alibaz-Oner[1], P.Sibel Yentür[2], Guher Saruhan-Direskeneli[3] and Haner Direskeneli[1]. [1]Marmara University, School of Medicine, Istanbul, Turkey, [2]Istanbul University, Istanbul Medical Faculty, Istanbul, Turkey, [3]Istanbul University, Istanbul Faculty of Medicine, Istanbul, Turkey.

Background/Purpose: Assessment of disease activity is one of the main difficulties in patients with Takayasu Arteritis (TAK) during follow-up. In this study, we aimed to investigate serum interleukin (IL)-6, IL-8, IL-10, IL-18, IL-23 and granulocyte-macrophage colony-stimulating factor (GM-CSF), as possible biomarkers of disease activity in patients with TAK.

Methods: The study included 51 patients (age: 40.6±12.2 years, F/M: 45/6) with TAK and 42 age and sex matched healthy controls (age: 38.1±7.4 years, F/M: 38/4). All patients with TAK fulfilled the criteria of American College of Rheumatology (ACR) and were evaluated by physician's global assessment (PGA: active/inactive) and ITAS2010 (Indian Takayasu Clinical Activity Score) in terms of clinical activity at baseline and follow-up visits. Commercial enzyme linked immunosorbent assay (ELISA) kits were used for the measurements of serum IL-6, IL-8, IL-10, IL-18, IL-23 and GM-CSF.

Results: At baseline, 21 (41.2%) patients were active assessed with PGA and 8 (15.7%) with ITAS2010. Serum IL-6, IL-8 and IL-18 levels were significantly higher in patients with TAK (TAK vs HC, respectively; 194.7±485 (0–2555) vs 64.3±156.8 (0–748), 49.4±189 (0–1349) vs 8.4±23.8 (0–97), 535.1±252 vs 268.8±216.2) whereas GM-CSF, IL-10 and IL-23 levels were similar to healthy controls. Comparing baseline and follow-up visits, IL-8 levels significantly decreased in follow-up together with a decrease of clinical activity by PGA, whereas IL-23 levels significantly increased. IL-18 levels were associated with disease activity assessed with ITAS2010, but not with PGA. IL-18 was also the only cytokine correlating with CRP. No association of IL-6 levels were observed with disease activity.

Conclusion: We found significantly increased IL-6, IL-8 and IL-18 levels in patients with TAK compared to healthy controls, suggesting their role in disease pathogenesis. However, no consistent association of any

cytokine is observed with disease activity to use as a biomarker. In addition to anti-IL-6 treatment currently investigated, blockage of other pro-inflammatory cytokines IL-8 and IL-18 might be new therapeutic approaches in refractory TAK.

Biomarkers of Disease Activity in Vasculitis. Alicia Rodriguez-Pla[1], Roscoe L. Warner[2], David Cuthbertson[3], Simon Carette[4], Gary S. Hoffman[5], Nader A. Khalidi[6], Curry L Koening[7], Carol A. Langford[8], Kathleen Maksimowicz-McKinnon[9], Larry W. Moreland[10], Christian Pagnoux[4], Philip Seo[11], Ulrich Specks[12], Kenneth J. Warrington[12], Steven R. Ytterberg[12], Peter A. Merkel[13], Kent J. Johnson[2], Paul A. Monach[14] and For the Vasculitis Research Consortium[15]. [1]Boston University, Boston, MA, [2]University of Michigan, Ann Arbor, MI, [3]University of South Florida, Tampa, FL, [4]University of Toronto, Toronto, ON, [5]Cleveland Clinic Foundation, Cleveland, OH, [6]McMaster University, Hamilton, ON, [7]George E. Wahlen Department of Veterans Affairs Medical Center Salt Lake City and University of Utah, University of Utah School of Medicine, Salt Lake City, UT, [8]Center for Vasculitis Care and Research, Cleveland Clinic, Cleveland, OH, [9]Henry Ford Hospital, Detroit, MI, [10]University of Pittsburgh, Pittsburgh, PA, [11]Johns Hopkins Vasculitis Center, Johns Hopkins University, Baltimore, MD, [12]Mayo Clinic, Rochester, MN, [13]Vasculitis Center, University of Pennsylvania, Philadelphia, PA, [14]Vasculitis Center, Boston University School of Medicine, Boston, MA, [15]U Pennsylvania, Philadelphia, PA.

Background/Purpose: To identify circulating proteins that distinguish between active vasculitis and remission in giant cell arteritis (GCA), Takayasu's arteritis (TAK), polyarteritis nodosa (PAN) and eosinophilic granulomatosis with polyangiitis (EGPA, Churg-Strauss), using a panel of markers known to be elevated in ANCA-associated vasculitis.

Methods: 22 serum proteins (MMP-3, NGAL, ACE, sIL-6R, osteopontin, PAI-1, PDGF-AB, RANTES, sICAM-1, TIMP-1, BCA-1, G-CSF, GM-CSF, IFNγ, IL-15, IL-18, IL-18BPa, sIL-2Ra, IL-6, IL-8, IP-10, and sTNFRII) linked to possible pathways relevant to vasculitis were measured using a microarray platform. Disease activity during the past 28 days was classified by physician global assessment (PGA), where remission is indicated by PGA=0 and active disease by PGA 1–10. Spearman's correlation was used to study the association between serum proteins and ESR. To compare marker values between active disease and remission, mixed models were used to account for repeated measures with unequal spacing between visits. Prednisone and immunosuppressive treatments were included as independent variables. Fold-change (FC) in marker values between active and mean remission values was used as the measure of effect.

Results: 479 samples from 174 patients (66 GCA, 35 TAK, 31 PAN, 42 EGPA, with 1 active visit and 1–3 remission visit samples per patient) were tested. 440 samples (92%) were obtained while the patient was on treatment. Disease activity ranged from PGA 1 to 9. In GCA, sIL-6R (FC 1.1, p=0.024), BCA-1 (FC 2.08, p=0.008), GM-CSF (FC 32.5, p=0.04; 7 patients with FC >2), IL-18BPa (FC 1.16, p=0.026), sIL-2Ra (FC 2.03, p=0.018), IL-6 (FC 2.54, p=0.032), and TIMP-1 (FC 1.18, p=0.034) were significantly higher in active than remission samples; in TAK, only IL-18BPa was higher in active than in remission samples (FC 1.16, p=0.029); and in PAN, only MMP-3 was significantly different, being higher in remission samples (FC 0.71, p=0.045). ESR was significantly elevated in active GCA (FC 1.43, p=0.001) and PAN (FC 1.45, p=0.013), and no differences were observed in TAK or EGPA. The correlation of ESR with the majority of the protein markers was weak; the highest correlation was observed in GCA with IL-6 (r=0.34, p<0.0001). FC and p-values were similar when use of prednisone and other immunesuppressive drugs were included in the models. The majority of the samples were obtained while the patients were on prednisone (81.2% of the active and 79.1% of the remission samples). Trajectories of selected markers are shown in Figure 1.

Conclusion: This study identifies several potential biomarkers of disease activity in GCA, although effect sizes were modest in this partially-treated cohort. Promising markers included several cytokines (IL-6, GM-CSF, BCA-1), soluble cytokine receptors (sIL-6R, IL-18BPa), and the metalloproteinase inhibitor TIMP-1. Larger studies are needed to test the utility of these biomarkers for disease monitoring.

Risk Factors for Severe Ischemic Complications in Takayasu Arteritis: A French Multicenter Retrospective Cohort of 182 Patients. Cloé Comarmond[1], Tristan Mirault[2], Jean-Emmanuel Kahn[3], Philippe Cluzel[4], Fabien Koskas[5], Laurent Chiche[6], Julien Gaudric[7], Emmanuel Messas[8], Patrice Cacoub[9] and David Saadoun[10]. [1]Internal Medicine and Clinical Imunology, Hôpital Pitié Salpétrière, Paris, France, [2]HEGP vascular department, paris, France, [3]Internal Medicine, Foch Hospital, Suresnes, France, [4]Vascular and Interventional Imaging Department, Paris, France, [5]Assistance Publique-Hôpitaux de Paris, Hopital Pitié-Salpétrière, Paris, France, [6]Vascular Surgery, Paris, France, [7]Department of Vascular surgery GHPS, Paris, France, [8]Vascular Department, Paris, France, [9]Groupe Hospitalier Pitié Salpétrière, Service de Médecine Interne, DHU i2B, Paris, France, [10]DHU 2iB Internal Medicine Referal Center for Autoimmune diseases Pitie Hospital, Paris, France.

Background/Purpose: Takayasu arteritis (TA) is a chronic inflammatory disease that primarily affects large vessels, such as the aorta and its main branches. To report clinical features, morphologic findings, treatment and long-term outcome of a large cohort of patients with TA, and to determine risk factors for the occurrence of severe ischemic complications (SIC) during follow-up.

Methods: We performed a retrospective multicenter study of characteristics and outcomes of 182 patients with TA fulfilling the American College of Rheumatology criteria. Characteristics at presentation, SIC, relapses and deaths were recorded.

Results: The median age [interquartile range] at onset of symptoms was 31 [24; 45] years and with a predominance of females (85%). The median delay of diagnosis was 10 [0; 47] months. The most common clinical findings were vascular bruits (52%), unequal or absent pulses (47%), and upper extremity blood pressure discrepancy >10 mm Hg (44%). Major complications at diagnosis were hypertension (36%), aneuvrysm (24%), and aortic regurgitation (18%). Forty six percent of patients had extensive disease at diagnosis according to Numano type V. Twenty percent of patients had another inflammatory or auto-immune disease associated to TA, mostly ankylosing spondylitis, crohn disease and sarcoidosis. Stenotic lesions were 3.1-fold more common than were aneuvrysms (78% versus 25%, respectively). Revascularization procedure was required for 49% of patients. The median delay between diagnosis and first surgery or endovascular intervention was 5 [0; 17.5] months. Glucocorticoids were prescribed in 151 (83%) patients. The median delay in initiation of corticosteroids was 1 [0; 5] months. Fifty eight percent of patients required additional immunosuppressive agent. The median delay in initiation of the first immunosuppressor was 11 [2; 29.5] months. Twenty six percent of patients required three or more antihypertensive drugs. SIC occurred in 38 (21%) patients after TA diagnosis. SIC-free

survival at 10 years was 82% in patients without refractory hypertension versus 34% in patients with refractory hypertension (i.e. requiring ≥ 3 antihypertensive drugs) (P = 0.003). SIC-free survival at 5 years was 89% in patients with immunosuppressive agent versus 78% without immunosuppressive agent (P = 0.175). In multivariable analysis, predictive variables for the occurrence of SIC after TA diagnosis were refractory hypertension (OR 12.03 [95%CI 2.78–52.07], P = 0.001), relapse (OR 7.11 [95%CI 1.82–27.78], P = 0.005) and SIC at time of TA diagnosis (OR 4.65 [95%CI 1.10–19.67], P = 0.036). Forty four percent relapsed after a median follow-up of 69 [31; 145] months. The median relapse-free survival was 16 [7; 62] months. The mortality rate was 12%. Five of 7 (71%) deaths were related to cardiovascular complication.

Conclusion: In this cohort of TA patients, risk factors for late-developing SIC were refractory hypertension, relapse and SIC at time of TA diagnosis. Immunosuppressive agents may reduce late-developing SIC. Despite prolonged and intensive therapy, TA remains a major cause of cardiovascular morbi-mortality.

Damage Assessment in Takyasu Arteritis Using Takayasu Arteritis Damage Score (TADS). Debashish Danda[1], Ruchika Goel[2], Raheesh Ravindran[2] and George Joseph[2]. [1]Christian Medical College, Vellore Tamilnadu, India, [2]Christian Medical College & Hospital, Vellore, India, Vellore, India.

Background/Purpose: Takayasu arteritis (TA) is a prototype large vessel vasculitis. Assessment of disease activity and damage has been challenging in TA due to lack of composite indices and biomarkers. TADS is damage index devised by the Indian Rheumatology Association Vasculitis Group. It consists of 42 items with 8 from cardiovascular system, classified under 7 headings. Only features persistently present for at least the preceding 6 months are scored. Both TADS[1] and DEI.TAK[2] (Disease Extent Index.TA) are derived from Birmingham vasculitis activity score (BVAS). We aimed to assess damage in TA using TADS, a novel composite clinical index.

Methods: TADS and DEI.TAK were calculated prospectively at baseline visit for incident patients with TA (ACR 1990 classification criteria) from our rheumatology and cardiology clinics between May 2012 and May 2014. TADS of this prospective cohort was compared with that calculated retrospectively for TA patients presenting to us prior to May 2012. SPSS version 16 was used; data was depicted as median (Inter Quartile Range) and Pearson's correlation coefficient between TADS and selected parameters were done.

Results: A total of 102 consecutive TA patients (80 females, 22 males) with age of 27.5 (20.7– 36) years, disease duration of 27 (9.8– 65.8) months and diagnostic delay of 12 (6–36) months were recruited. Type 5 was the commonest angiographic type (n=60) with DEI.TAK of 9 (7–13) at presentation. Coronaries and pulmonary artery were involved in 18 and 9 patients respectively. Median TADS score at presentation was 6.0 (4–10) with a third of our patients (n=34) having very high damage score (TADS >8). Absent arterial pulse (59%), persistent claudication (59%), hypertension (56%), persistent dyspnea (41%) and cardiac damage (23.5%) contributed to most of the damage as reflected in TADS. Period of delay in diagnosis and age at presentation did not correlate with the damage score (r= - 0.073 and −0.87 respectively).

A marginally lower TADS [6.0 (4–10)] at presentation in the prospective cohort of 102 patients was noted as compared to that [8(4–11)] of the earlier retrospective cohort of 48 patients whose TADS was calculated from hospital records. No other parameter was different between these two cohorts. A follow up of these 48 patients for 36 (24–57) months showed an insignificant rise in TADS to 9(6–12) at the last recorded visit from 8(4–11) at baseline, in spite of treatment with steroids and 2nd line cytotoxic agents in all.

Conclusion: This is the first study using TADS for damage assessment in a large cohort of TA. Over these years, TA continues to be associated with high damage score right from its initial presentation. Ongoing damage can probably be prevented by aggressive immunosuppression from early disease.

Background/Purpose: The aim of this registry is to determine: (1) the real-life use of various biological targeted treatments in Takayasu arteritis (TA) in France; (2) to compare the efficacy of different biologics among them; (3) to evaluate the tolerance.

Methods: French practionners from the departments of internal medicine, of vascular medicine and rheumatology were contacted to declare the patients with TA under biologics. Complete response was defined as the NIH<2 with prednisone<10 mg/day, the partial response as NIH and prednisone decrease at least at 50%.

Results: Forty eight patients with TA (age 42 years [20–55], 38 women) were included with 74 treatment lines including various biologics. The biologics were mostly used in second-line (n=21; 29%) and third-line regimen (n=27; 37%) for steroid dependence, non-response or relapses. At the initiation of the biologics, the vascular symptoms were present in 39 (67%) cases, constitutional signs in 25 (46%), with radiological activity in 37 (64%) of cases. NIH was ≥2 in 62 (93%) cases.

Among the biologics, most of the patients were treated by infliximab (59%), and etanercept (8%), adalimumab (8%), tocilizumab (19%), anakinra (3%) and rituximab (3%). The biologics duration was 1.8±1.1 year, with the mean follow-up of 3±1.5 years. A complete/partial response to biologics was shown in 15 (39%) and 17 (44%) of patients at 3 months, and 23 (62%) and 4 (11%) at 6 months, whereas a non-response was noted in 7 (18%) and 10 (27%), respectively. During the follow-up, NIH, C-reactive protein levels and prednisone amount significantly decreased (p<0.001). Only 58% of patients were still under steroids at 3 years versus 82% before biologics.

The comparison of patients treated with TNFa antagonists (n=55) to patients with tocilizumab (n=14) showed that the number of partial/complete responses was similar at 3 and 6 months, as were the NIH scale and the associated immunosuppressive agents.

Six infusion related reactions were noted (infliximab in 5 cases and tocilizumab in one), one EBV reactivation (infliximab) and 5 severe infections (3 with infliximab, one with etanercept and tocilizumab, respectively). One patient under tocilizumab experienced severe neutropenia (<500/mm3), but without any infection or antibiotics needs in relation with tocilizumab.

Two neoplasms occurred during the biologics treatment, one lung cancer (infliximab) and one breast cancer (tocilizumab).

Conclusion: This is the first nationwide registry of TA treated by biologics which show an overall response rate to biologics, with similar response rates between TNFa antagonists and tocilizumab.

Prognosis of Clinically Inactive Takayasu's Arteritis. Seung-Hyeon Bae, Seokchan Hong, Soo Min Ahn, Doo-Ho Lim, Yong-Gil Kim, Chang-Keun Lee and Bin Yoo. University of Ulsan College of Medicine, Asan Medical Center, Seoul, South Korea.

Background/Purpose: Takayasu's arteritis (TA) is a chronic inflammatory vasculitis, and immunosuppressants including glucocorticoids are generally required for treatment. Although, some portions of patients with TA have no evidence of active disease at the time of diagnosis, but the prognosis has not been reported. Therefore, aim of our study is to investigate the outcome and to identify the predictors of activation of clinically inactive TA.

Methods: We reviewed data of patients who was diagnosed with TA according to the 1990 ACR classification criteria between January 1990 and December 2012 at the Asan Medical Center. Patients were classified as an inactive disease at the time of diagnosis, based on the NIH definition of active disease in TA. During follow-up, activation of TA was defined based on acquisition of criteria for active disease. The pattern of vascular involvement was classified according to the International Conference on TA in Tokyo, 1994.

Results: Total 199 TA patients were identified, and 59 (29.6%) patients were classified as inactive disease at the time of diagnosis. The mean age of 59 patients was 42.9 ± 12.9 years and 50 (84.7%) patients were female. The median follow-up duration was 58 months (IQR, 37.0–107.0). During follow-up, 13 (22.0%) patients experienced disease activation of TA with median 37.0 months (IQR, 23.5–46.5) after the diagnosis of TA (***activation group***). On the other hand, remaining 46 (78.0%) patients did not experience the activation (***stable group***). There were no significant differences in baseline clinical characteristics and laboratory findings between activation group and stable group. The presence of renovascular hypertension, however, was more commonly observed in activation group than in stable group (4/13, 38.5% vs. 4/46, 8.7%, p=0.019). Further, type V, which is the most extensive type in involved pattern, was found more frequently in activation group (12/13, 92.3%) than in stable group (18/46, 39.1%. p=0.008). In a multivariate analysis, involvement of type V (OR=10.969, 1.144–105.182, p=0.038) was significantly associated with increased risk for disease activation in clinically inactive TA. In addition, the cumulative probability of activation was significantly higher in TA patients with type V than those without type V by Kaplan–Meier analysis (p=0.002) (**Figure 1**).

Conclusion: In the present study, substantial portions of patients with clinically inactive TA at diagnosis experienced an activation of disease during long-term follow-up. We suggested that the type V angiographic pattern can be used as an important predictor for disease activation.

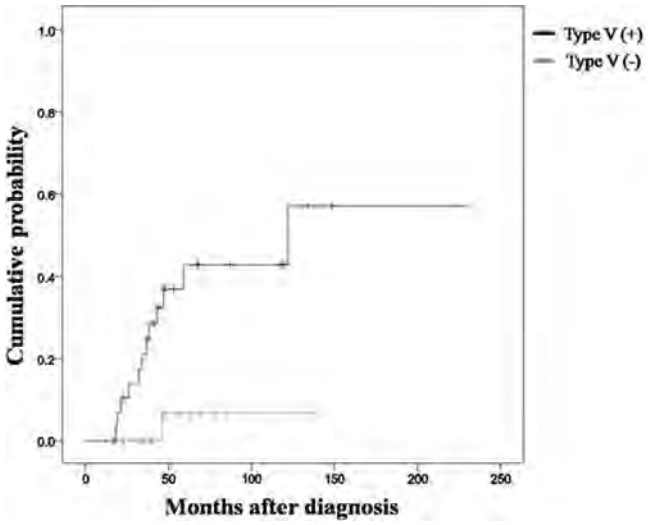

Figure 1. Cumulative probability of activation in patients with clinically inactiva TA

Long-Term Outcomes of Takayasu's Arteritis Patients with Renal Artery Involvement. Corisande Baldwin[1], Aladdin Mohammad[2] and David Jayne[3]. [1]University of British Columbia, Vancouver, BC, [2]Lund University, Lund, Lund, Sweden, [3]Addenbrookes Hospital University of Cambridge, Cambridge, United Kingdom.

Background/Purpose: Takayasu's Arteritis (TAK) is a chronic inflammatory large vessel vasculitis characterized by granulomatous inflammation of the aorta and its branches. TAK incidence is 2.6/million annually in Minnesota. Prevalence is higher in Asian and Indian populations. TAK predominantly affects younger woman under 40 years of age. Renal artery involvement (RAI) in TAK is a poor prognostic factor. However, long-term outcomes of TAK patients with RAI have not been reported.

Methods: We performed a retrospective chart review of 37 patients from Addenbrooke's Hospital, UK, and 13 patients from Skane University Hospital, Sweden. Diagnosis of TAK was based on the presence of constitutional symptoms, elevated inflammatory markers, and vascular abnormalities on angiography. RAI was identified based on conventional, CT or MR angiography. Data was collected on patient demographics and presenting symptoms, signs, co-morbidities, blood pressure and medications. Laboratory values including creatinine, erythrocyte sedimentation rate, and c-reactive protein were collected. Disease activity was assessed using the Indian Takayasu Activity Index 2010 (ITAS2010). Irreversible organ damage was assessed using the vasculitis damage index (VDI). Worsening or improved renal function was defined as a drop or increase in eGFR > 20%.

Results: Sixteen of 50 (32%) TAK patients were identified to have RAI. Presenting demographics and disease parameters are summarized in Table 1. Two patients had structural renal disease (PUJ obstruction and prior renal surgery undefined) and are among the 7 patients with renal asymmetry; one was among the nine patients with pre-existing hypertension. The three with eGFR <60 ml/min had moderate renal dysfunction (eGFRs of 45, 57, and 59 ml/min).

Table 1 Presenting Demographics & Disease Parameters

Demographic/Disease Parameter	
Mean Age	32 years (9–68)
Female (%)	15 (94)
White (%)	13 (81)
Comorbidities	
Structural Renal Disease (%)	2 (13)
Inflammatory Bowel Disease (%)	2 (13)
Hypertension (%)	8 (50)
Other (%)	5 (31)
Nil (%)	3 (19)
≥ 3 ACR Criteria Met (%)	14 (88)
Age < 40 (%)	12 (75)
Limb Claudication (%)	7 (44)
Reduced pulses (%)	9 (56)

Assymmetrical blood pressure (%)	10 (63)
Vascular Bruit, (%)	5 (31)
Abnormal Angiography (%)	16 (100)
Unilateral (%)/Bilateral (%) RAI	7 (44)/9 (56)
Median ITAS2010 (range)	13 (5–18)
Prior Therapy	
Systemic (%)	11 (69)
Vascular (%)	2 (13)

Follow-up data is presented in Table 2. Median follow-up duration was 8.8 years (10 months - 30 years). Among the 13 with hypertension including two who developed hypertension over the follow-up period; 11 were on anti-hypertensive drugs. Among the six patients with renal asymmetry; five were known and one developed this over the follow-up period. Among those with eGFR $<$ 60 ml/min at presentation, one improved, one declined (patient with PUJ obstruction), and one remained stable.

eGFR $\geq$ 60 ml/min (%)	13 (81)	14 (88)
eGFR $<$ 60 ml/min (%)	3 (19)	2 (12)
Change in eGFR		
Stable (%)	–	7 (44)
Improved (%)	–	4 (25)
Reduced (%)	–	3 (19)

* Follow-up ITAS2010 score only available for 10 patients
** Follow-up renal angiography available for 14 patients
*** Not calculated at presentation

Conclusion: The prevalence of RAI in this population (32%) is comparable to that in the literature. Hypertension was common. Most patients had normal eGFRs, despite severe disease. Disease progression was minimal. Our results suggest renal prognosis is better than previously thought.

Background/Purpose: Giant cell arteritis (GCA) is a primary vasculitis that involves the aorta and its major branches. It usually affects people aged more than 50 years. GCA may be refractory to standard therapy with corticosteroids that, in turn, may be associated with substantial adverse events. Tocilizumab (TCZ) has demonstrated efficacy in single cases or in small series of patients with GCA. Our aim was to assess the efficacy and side-effects of TCZ in a multicenter study of patients with refractory GCA.

Methods: Multicenter open-label study of patients with refractory GCA. TCZ was used because of inadequate response to corticosteroids and in most cases to other therapies. All the patients meet the 1990 ACR criteria for GCA. TCZ therapy was used at standard dose of 8 mg/kg/monthly.

Results: 22 patients (17 women/ 5 men; mean age$\pm$SD was 69$\pm$8 years) were assessed. Sixteen (73%) of them had a positive temporal artery biopsy. The main clinical features at the time of TCZ onset were: polymyalgia rheumatica (n=15), asthenia (n=7), headache (n=5), constitutional syndrome (n=4), jaw claudication (n=2), visual manifestations (n=2), claudication of the lower limbs (n=1), chest pain (n=1), arthritis (n=1), dyspnea (n=1) and scapular pain (n=1). Fifteen patients also had aortitis. Besides corticosteroids and before TCZ therapy, 19 patients had received several traditional immunosuppressive agents: methotrexate (n=19), azathioprine (n=1) and leflunomide (n=1). In addition, 2 patients had also been treated with other biologic agents before starting on TCZ. One patient received etanercept that was switched to TCZ due to inefficacy. Another patient received infliximab that was switched to rituximab, then to abatacept and finally to TCZ because of inefficacy. Most patients experienced clinical and laboratory improvement within the first 3 months after the onset of TCZ **(TABLE).** After a median [IQR $25^{th}-75^{th}$] follow-up of 6 [3–16] months, the erythrocyte sedimentation rate decreased from a median value of 44 [20–81] to 12 [3–20] mm/1^{st} hour. Similarly, C-reactive protein levels also decreased from a median initial value of 1.9 [1.2–5.4] to 0.2 [0.1–0.9] mg/dL. A corticosteroid sparing effect was also achieved (from a median [IQR] prednisone dose of 18.75 [10–45] mg/day at TCZ onset to 5 [0–7.5] mg/day at last visit). In 3 patients TCZ was discontinued due to severe neutropenia (351 neutrophils/mm^3); recurrent pneumonia; and cytomegalovirus infection, respectively. Also, one patient died after the second infusion of TCZ as the result of a stroke in the setting of an infectious endocarditis.

Conclusion: In our series, TCZ seems to be effective in the treatment of GCA refractory to corticosteroids and other immunosuppressive agents.

Netosis Induced Histone Citrullination Facilitates Onset and Propagation of Rheumatoid Arthritis. Dong Hyun Sohn[1], Kazuhiro Onuma[1], Chris Rhodes[1], Xioayan Zhao[1], Tal Gazitt[2], Rani Shiao[1], Justyna Fert Bober[3], Danye Cheng[1], Lauren J. Lahey[1], Heidi Wong[4], Jennifer van Eyk[3], William H. Robinson[1] and Jeremy Sokolove[1]. [1]VA Palo Alto Healthcare System and Stanford University, Palo Alto, CA, [2]University of Washington, Seattle, WA, [3]Johns Hopkins University and Cedars Sinai Medical Center, Los Angeles, CA, [4]Stanford University School of Medicine, Stanford, CA.

Background/Purpose: Anti-citrullinated protein antibodies (ACPAs) are characteristic of rheumatoid arthritis however, their presence years before onset of clinical RA is perplexing. Although multiple putative citrullinated

antigens have been identified, including citrullinated products of NETosis, no studies have demonstrated the capacity of these antigens to initiate inflammatory arthritis. We sought to identify citrullinated products of NETosis targeted by the RA immune response and with the capacity to drive inflammatory arthritis.

Methods: We performed proteomic analysis of human NETs to identify all citrullinated proteins including those targeted as part of the RA immune response. Using a combination of ELISA and IHC we compared RA and OA serum, synovial fluid and synovial tissue for levels of histone 2B (H2B), anti-H2B antibodies, as well as H2B-containing immune complexes. Using macrophage activation assays we assessed the effect of histone citrullination on immunostimulatory capacity and evaluated the stimulatory capacity of native and citrullinated H2B-containing immune complexes. Finally, we immunized mice with citrullinated H2B (cH2B) with and without the induction of low grade collagen induced arthritis to assess the potential for anti-cH2B antibodies to mediate arthritis *in vivo*.

Results: Proteomic interrogation of NET-derived proteins, RA serum, synovium, and synovial fluid identified robust targeting of NET-derived citrullinated histones by the ACPA immune response. Over 90% of RA patients have anti-cH2B antibodies and over half have measurable levels of synovial fluid H2B immune complexes. We observe that histone citrullination increases innate immunostimulatory capacity and that immune complexes containing citrullinated histones both activate macrophage cytokine production and propagate NETosis. Finally, we demonstrate that autoimmunity to cH2B is arthritogenic, both by primary immunization as well as immune serum transfer, but only in the setting of underlying low grade articular inflammation.

Conclusion: We identify cH2B as an antigenic target of the ACPA immune response and our findings suggest that intra-articular histone citrullination can link innate immunity via NETosis and adaptive immunity via generation of citrullinated histone immune complexes. The generation of citrullinated histone antigens during low grade articular inflammation provides a potential mechanism for the conversion from asymptomatic ACPA seropositivity to clinical RA.

***TRNT1* Missense Mutations Define a New Periodic Fever Syndrome.** Angeliki Giannelou[1], Qing Zhou[2], Monique Stoffels[3], Amanda Ombrello[4], Deborah Stone[2], Jehad H. Edwan[5], Martin Pelletier[6], Wanxia Tsai[7], Katherine Calvo[8], Sergio Rosenzweig[9], Karyl Barron[10], Massimo Gadina[11], Ivona Aksentijevich[2] and Daniel L. Kastner[2]. [1]National Institute for Arthritis and Musculoskeletal and Skin Diseases, bethesda, MD, [2]National Human Genome Research Institute, Bethesda, MD, [3]National Human Genome Research Institute, bethesda, MD, [4]National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, [5]NIAMS NIH, Bethesda, MD, [6]Immunoregulation Section, Autoimmunity Branch, Bethesda, MD, [7]NIAMS/NIH, Bethesda, MD, [8]National Institutes of Health Clinical Center, Bethesda, MD, [9]National Institute of Allergy and Infectious Diseases, Bethesda, MD, [10]NIH, Bethesda, MD, [11]NIAMS/NIH, Bethesda, MD.

Background/Purpose: Two thirds of the 1700 patients seen at our NIH clinic for autoinflammatory diseases do not have a genetic diagnosis. Whole exome sequencing permits analysis of most of the protein coding regions of the human genome.

Methods: With the use of whole exome sequencing and candidate gene screening, we identified five children from four unrelated families, who had unexplained autoinflammatory disease and shared mutations in one common gene. One family from Saudi Arabia was consanguineous with two affected daughters. The second family of mixed Czech and British background had one affected boy. The third and fourth families were of mixed European ancestry from the United States and each family had one affected daughter. We performed additional experiments in patients samples including flow cytometry, immunophenotyping, cytokine profiling, mitochondria related function and ribosomal assembly assays. Protein function was studied with morpholino knockdowns in zebrafish embryos.

Results: All patients carried missense recessive mutations in one common gene, the *TRNT1* (tRNA Nucleotidyl Transferase, CCA-Adding, 1), on chromosome 3. The two affected Saudi Arabian sisters were homozygous for a p.H215R missense mutation, while the other three children were compound heterozygous for a missense mutation, p. I223T or p. R99W, and one shared mutation p.D163V. The p.H215R mutation was not found in any public database neither in 1061 Arab control DNA samples. From the three Caucasian mutations, the p.R99W was novel whereas the p. I223T and p.D163V were found at a very low allele frequency (<0.001) at the NHLBI exomedatabase. All mutations affect highly conserved amino acid residues and are predicted to be damaging to the protein function. All children had recurrent episodes of high fevers with negative sepsis work up that occurred in association with microcytic anemia, and a spectrum of multisystem features. Neurologic involvement ranged from mild developmental delay to nystagmus, hypotonia, optic nerve atrophy, and sensorineural hearing loss. Other variables manifestations include dysmorphic fea-

tures, musculoskeletal and gastrointestinal symptoms, B cell immunodeficiency and hypogammaglobulinemia. Studies performed so far, point towards a maturation defect of the B cell lineage in the bone marrow, as a possible cause of the observed immunodeficiency. Preliminary data from cytokine analysis in two patients have shown elevated levels of the proinflammatory cytokines interleukin 6 and type 1interferon, suggesting possible therapeutic targets. Knockdown of the zebrafish *TRNT1* homologue caused hydrocephaly, defects in tail development, anemia and a reduction in the number of hair cells present in the lateral line, that has function resembling human inner ear.

Conclusion: The CCA-adding TRNT1 enzyme catalyzes the addition of the CCA terminus to the 3 prime end of all tRNAs precursors, a step that is essential for tRNA aminoacylation and protein synthesis. The discovery that missense mutations in this essential and ubiquitiously expressed gene cause a newly defined periodic fever syndrome, will allow further understanding of mechanisms underlying inflammation.

Mortality in a Large Cohort of Patients with Early Rheumatoid Arthritis That Were Treated-to-Target for 10 Years. I.M. Markusse[1], L. Dirven[1], J.H. van Groenendael[2], K.H. Han[3], H.K Ronday[4], P.J.S.M. Kerstens[5], W.F. Lems[6], T.W.J. Huizinga[1] and C.F. Allaart[1]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]Fransiscus Hospital, Roosendaal, Netherlands, [3]MCRZ hospital, Rotterdam, Netherlands, [4]Haga Hospital, The Hague, Netherlands, [5]Jan van Breemen Research Institute | Reade, Amsterdam, Netherlands, [6]VU Medical Center, Amsterdam, Netherlands.

Background/Purpose: Recent studies showed diverging results about mortality trends in patients with rheumatoid arthritis (RA). Our aim was to determine survival after 10 years of treat-to-target therapy in patients with early RA, to compare these survival rates with the general population and to define risk factors for mortality during the 10 years duration of the BeSt study.

Methods: The BeSt study enrolled 508 Dutch patients with recent-onset active RA (1987 criteria) who were randomized to: sequential monotherapy, step-up therapy, initial combination including either prednisone or infliximab. During 10 years, all patients were treated-to-target, aiming at a disease activity score (DAS) ≤2.4. Kaplan-Meier curves and the log-rank test were used to compare survival rates in the four treatment strategies. Standardized mortality ratios (SMR) were calculated to compare the BeSt population to the general Dutch population, matched by age, gender and calendar year. Cox regression was used to calculate hazard ratios (HR) to determine baseline risk factors for increased mortality in the BeSt population.

Results: During 10 years, 72 of 508 patients died at a mean age of 75 years. No difference in survival was observed between the treatment strategies (p=0.805) (figure), with 16/126, 15/121, 21/133 and 20/128 deaths in arm 1 to 4, respectively. Based on the general Dutch population, 62 deaths were expected and 72 deaths occurred, resulting in an overall SMR of 1.16 (95% confidence interval, CI 0.92 – 1.46). Comparing the general population to each of the treatment strategies resulted in a SMR (95% CI) of 1.00 (0.61 – 1.64), 1.02 (0.61 – 1.69), 1.30 (0.85 – 1.99) and 1.32 (0.85 – 2.04) in arm 1 to 4, respectively.

In the BeSt population, baseline age (HR 1.13, 95% CI 1.10–1.16), male gender (HR 1.78, 95% CI 1.06–2.99), smoking at baseline (HR 5.19, 95% CI 3.08–8.75) and health assessment questionnaire at baseline (HR 1.89, 95% CI 1.29–2.76) were associated with an increased risk of mortality. Randomization arm was not associated with an increased risk of mortality (arm 1 as reference category; arm 2 HR 0.99, 95% CI 0.49 – 2.00; arm 3 HR 1.27, 95% CI 0.66 – 2.44; arm 4 HR 1.25, 95% CI 0.65 – 2.41).

Conclusion: After 10 years of continued tight controlled treatment in patients with rheumatoid arthritis in the BeSt study, the survival rate was comparable to the general Dutch population, without differences between the treatment strategies. Higher age, male gender, smoking and worse functional ability were associated with an increased risk of mortality within our study population. These results suggest that treatment targeted at DAS ≤2.4 prevents increased mortality previously associated with RA, and that the medication used in these strategies does not increase mortality.

Incident Rheumatoid Arthritis and Risk of Mortality Among Women Followed Prospectively from 1976 to 2010 in the Nurses' Health Study. Jeffrey A. Sparks, Shun-Chiao Chang, Katherine P. Liao, Bing Lu, Daniel H. Solomon, Karen H. Costenbader and Elizabeth W. Karlson. Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Background/Purpose: RA has been associated with increased mortality compared to general population estimates. Previous studies were limited due to the inability to directly compare RA patients to controls, short follow-up, and lack of detailed data on clinical, lifestyle, and serologic factors. We evaluated mortality among women followed prospectively prior to RA diagnosis, directly comparing to women without RA.

Methods: We conducted a study of RA and mortality among 121,700 women followed from 1976 to 2010 in the Nurses' Health Study (NHS). Incident RA was validated by medical record review according to the 1987 ACR RA criteria and classified by serostatus. Women who reported RA or other connective tissue diseases before the start of NHS were excluded. Women were followed from cohort entry to death or end of follow-up and were censored for loss to follow-up. Deaths were validated by the National Death Index; death certificate and medical record review determined cause of death. Cox regression models estimated hazard ratios (HRs) and 95% confidence intervals (CIs) for all-cause, cardiovascular disease (CVD), cancer, and respiratory mortality for women with RA compared to women without RA. We obtained HRs for mortality by RA duration and serologic RA phenotype. Models were adjusted for age, demographics and other mortality factors, including physical activity, smoking, obesity, comorbidities, and family history of cancer, CVD, and diabetes.

Results: We validated 960 incident RA cases and identified 25,699 deaths in 34 years of NHS follow-up. Of the 261 deaths among women with RA, 75 (29%) were from cancer, 58 (22%) were from CVD, and 43 (16%) were from respiratory causes. Compared to women without RA, women with RA had increased all-cause mortality that remained significant after adjusting for age and other mortality factors (HR 2.07, 95% CI 1.83–2.35, **Table**). Mortality was significantly increased for seropositive (HR 2.33, 95% CI 2.00–2.71) and seronegative RA (HR 1.60, 95% CI 1.30–1.98) compared to non-RA women. Each five years of RA duration conferred a 32% (95% CI 27–36%) increased mortality compared to non-RA. Women with RA had significantly increased risk for mortality from CVD (HR 1.87, 95% CI 1.44–2.43), cancer (HR 1.35, 95% CI 1.07–1.69) and respiratory (HR 4.50, 95% CI 3.28–6.17) causes compared to women without RA. Respiratory mortality for women with seropositive RA was six-fold higher than non-RA women (HR 6.23, 95% CI 4.38–8.85).

Conclusion: In 34 years of prospective follow-up, women diagnosed with RA had a two-fold increased risk of death from any cause compared to women without RA. Respiratory mortality was six-fold higher in seropositive RA and women with RA were significantly more likely to die from CVD and cancer than women without RA. Respiratory mortality appears to be an important but understudied cause of death in RA. These findings provide evidence of high RA mortality burden that is unexplained by traditional mortality predictors.

Table. Hazard ratios for all-cause and cause-specific mortality in RA serologic phenotypes among women in the Nurses' Health Study, 1976–2010 (n = 119,264)

Secukinumab, a Monoclonal Antibody to Interleukin-17A, Significantly Improves Signs and Symptoms of Active Ankylosing Spondylitis: Results of a 52-Week Phase 3 Randomized Placebo-Controlled Trial with Intravenous Loading and Subcutaneous Maintenance Dosing. Dominique L. Baeten[1], Juergen Braun[2], Xenofon Baraliakos[2], Joachim Sieper[3], Maxime Dougados[4], Paul Emery[5], Atul A. Deodhar[6], Brian Porter[7], Ruvie Martin[7], Shephard Mpofu[8] and Hanno Richards[8]. [1]Department of Clinical Immunology and Rheumatology and Department of Experimental Immunology, Academic Medical Centre/University of Amsterdam, Amsterdam, Netherlands, [2]Rheumazentrum Ruhrgebiet, Herne, Germany, [3]Charité University Medicine Berlin, Berlin, Germany, [4]Université Paris René Descartes and Hôpital Cochin, Paris, France, [5]University of Leeds, Leeds, United Kingdom, [6]Oregon Health and Sciences University, Portland, OR, [7]Novartis Pharma AG, East Hanover, NJ, [8]Novartis Pharma AG, Basel, Switzerland.

Background/Purpose: A phase 2, proof-of-concept study indicated that secukinumab, an anti–IL-17A monoclonal antibody, suppressed signs and symptoms of active ankylosing spondylitis (AS) by Week (Wk) 6. We present Wk 16 and Wk 52 efficacy and safety data from MEASURE 1 (NCT01358175), a phase 3 study assessing secukinumab vs. placebo (PBO) in patients (pts) with AS.

Methods: Pts with active AS fulfilling modified New York Criteria and BASDAI ≥ 4, despite current or previous therapy with NSAIDs, DMARDs and/or anti-TNF agents, were randomized to receive: i.v. secukinumab 10 mg/kg (Wk 0, 2, 4) followed by s.c. secukinumab 75 mg every 4 wks (10 IV → 75 SC), s.c. secukinumab 150 mg every 4 wks (10 IV → 150 SC), or PBO on same i.v. and s.c. schedules. Endpoints included ASAS20 at Wk 16 (primary), ASAS40, hsCRP, ASAS 5/6, BASDAI, SF-36 PCS, ASQoL and ASAS partial remission. Statistical analyses followed a pre-defined hierarchical hypothesis testing strategy to adjust for multiplicity. PBO pts were re-randomized to secukinumab 75 mg or 150 mg s.c. based on ASAS20 response at Wk 16, with non-responders switched at Wk 16 and responders at Wk 24.

Results: Baseline characteristics of the 371 randomized pts were similar between study arms: mean age 40.1–43.1 years, mean disease duration 6.5–8.3 years, mean BASDAI 6.05–6.51, ~27% inadequate response to anti-TNF agents (TNF-IR). The study met its primary efficacy endpoint with a significantly higher ASAS20 response at Wk 16 in the 10 IV → 75 SC (59.7%) and 10 IV → 150 SC (60.8%) groups vs. PBO (28.7%; $P < 0.01$ for each dose); ASAS20 response rates in TNF-naïve pts were 60.0%, 66.3% and 32.6%, and in the TNF-IR pts were 58.8%, 45.5% and 18.2%, in the 10 IV → 75 SC, 10 IV → 150 SC and PBO groups, respectively ($P< 0.01$ vs. PBO). Significant improvements with both doses of secukinumab vs. PBO were observed for all pre-specified secondary endpoints at Wk 16 (Table), with responses sustained through Wk 52. Onset of action of secukinumab was rapid, with significant improvements in ASAS20, ASAS40, hsCRP, ASAS5/6 and BASDAI seen at Wk 1. Through to Wk 16, drug exposure levels were similar in the secukinumab groups due to the i.v. loading doses. Secukinumab was generally well tolerated. At Wk 16, 66.9% of pts in the 10 IV → 75 SC group and 69.6% in the 10 IV → 150 SC group experienced an AE, vs. 55.7% on PBO; SAE rates were 1.6%, 2.4% and 4.1%, respectively. Through Wk 52 visit of the last pt (average exposure [range]: 451.7 [8–757] days), AE/SAE rates were 76.5%/10.1% and 85.1%/9.4% for pts receiving secukinumab 75 or 150 mg s.c., respectively, at any point in the study.

Table. Summary of 16-week efficacy results

Week 16 Data	Secukinumab 10 mg/kg i.v. → 75 mg s.c. (N = 124)	Secukinumab 10 mg/kg i.v. → 150 mg s.c. (N = 125)	Placebo (N = 122)
ASAS20 response	59.7%*	60.8%*	28.7%
ASAS40 response	33.1%*	41.6%*	13.1%
hsCRP, post-baseline to baseline ratio (LSM±SE)	0.45 ± 1.092*	0.40 ± 1.090*	0.97 ± 1.095
ASAS5/6	45.2%*	48.8%*	13.1%
BASDAI, mean change from baseline score (LSM±SE)	−2.34 ± 0.175*	−2.32 ± 0.172*	−0.59 ± 0.180
SF-36 PCS, mean change from baseline score (LSM±SE)	5.64 ± 0.595*	5.57 ± 0.586*	0.96 ± 0.612
ASQoL, mean change from baseline score (LSM±SE)	−3.61 ± 0.424*	−3.58 ± 0.420*	−1.04 ± 0.437
ASAS partial remission	16.1%*	15.2%*	3.3%

*$P<0.01$ vs. placebo

Table. Summary of 16-week efficacy results

Prespecified hierarchical statistical testing strategy used to account for multiplicity. Missing data for categorical variables were imputed as nonresponse

ASAS, Assessment of SpondyloArthritis International Society Criteria; ASQoL, Ankylosing Spondylitis Quality of Life; BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; hsCRP, high-sensitivity C-reactive protein; LSM, least square mean; SE, standard error; NS, not significant; SF-36 PCS, short form 36 physical component summary

Conclusion: The selective IL-17A inhibitor secukinumab provided rapid and significant improvement of signs and symptoms in pts with active AS, regardless of prior anti-TNF exposure. Improvements were observed from Wk 1 and sustained through 52 wks. Secukinumab was well tolerated through 52 wks with no unexpected safety findings.

Herpes Zoster Infection Risk in Auto-Immune and Inflammatory Diseases: Implications for Vaccination. Huifeng Yun[1], Shuo Yang[2], Lang Chen[2], Fenglong Xie[2], K. L. Winthrop[3], John Baddley[2], Kenneth G. Saag[4], Jasvinder Singh[2] and Jeffrey R. Curtis[2]. [1]University of Alabama at Birmingham School of Public Health, Birmingham, AL, [2]University of Alabama at Birmingham, Birmingham, AL, [3]Oregon Health and Science University, Portland, OR, [4]The University of Alabama at Birmingham, Birmingham, AL.

Background/Purpose: Herpes zoster (HZ) vaccine is recommended for healthy people age >= 60 years in US. It is unclear whether the absolute risk for younger patients (pts) with autoimmune or inflammatory (AI) diseases is high enough to warrant vaccination. We evaluated the overall and age-stratified absolute incidence of HZ infection associated with different AI

diseases compared to healthy older adults who are recommended for vaccination by the CDC.

Methods: Using 2007–2010 Multi-Payer Claims Database, we assembled 7 AI disease cohorts, requiring pts to have ≥ 13 months continuous medical and pharmacy coverage. Pts with at least one prescription and two diagnoses of rheumatoid arthritis (RA), psoriasis arthritis (PsA), psoriasis (PsO), ankylosing spondylitis (AS), inflammatory bowel disease (IBD), lupus (SLE), gout were included and compared with diabetic pts and healthy pts without diabetes or any autoimmune disease. We identified HZ using diagnosis codes and antiviral agent +- 30 days. Age-adjusted incidence rates (AAIR) and age-specific rates for HZ per 1,000 person-years were calculated for each disease and compared to healthy older people age 60–69 using Poisson regression. Based upon external data, we used a non-inferiority margin of an HZ IR ratio (IRR) of 0.62 to establish non-inferiority of HZ rates of younger pts with AIs versus healthy older people. Rates were classified as significantly higher (bold) if the lower limit of the IRR 95% CI >1, comparable (i.e. non-inferior, bold, underlined) if the lower limit of the IRR 95% CI > 0.62 but ≤ 1, or inconclusive.

Results: The study population consisted of 50,646 pts with RA, 2629 with PsA, 4299 with PsO, 1,019 with AS, 7,916 with IBD, 8,395 with SLE, 5893 with gout, 214,631 with diabetes and 330,727 in the healthy cohort. The AAIRs among the 7 disease cohorts ranged from a high of 14.6 per 1,000 person years (SLE) to a low of 5.0 (gout). AAIR was 5.9/1000 for diabetes and 3.9/1000 for healthy cohort. The age-specific rate of HZ for RA, IBD and SLE pts in the 20s, 30s, and 40s, was non-inferior or significantly greater than the corresponding rate in healthy people individuals age >=60 (Table, bold). Compared with the healthy cohort, the adjusted HR for RA (1.4, 95% CI: 1.2–1.5), Gout (1.4, 1.2–1.5), IBD (1.8, 1.5–2.1) and SLE (2.1, 1.8–2.4) were increased significantly.

Conclusion: RA, IBD and SLE are associated with an increased risk of HZ infection compared to healthy people. Based on absolute risk compared to healthy people age >= 60, RA, IBD and SLE patients age >30 may benefit from vaccination for HZ.

Table: Incidence rate of herpes zoster per 1000 person years by 10 year age group and auto-immune disease or comparator cohort

		Cohorts

Pregnancy Outcome in Women Treated with Adalimumab for the Treatment of Rheumatoid Arthritis. Christina D Chambers[1], Diana L Johnson[2], Yunjun Luo[2], Ronghui Xu[1] and Kenneth L Jones[2]. [1]University of California San Diego Department of Family and Preventive Medicine, La Jolla, CA, [2]University of California San Diego Department of Pediatrics, La Jolla, CA.

Background/Purpose: Adalimumab is a fully human monoclonal antibody to tumor necrosis factor alpha and is approved for several indications including rheumatoid arthritis (RA).

Methods: The OTIS Collaborative Research Group conducted a prospective cohort study in the U.S. and Canada between 2004 and 2013 comparing pregnancy outcomes in women with RA treated with adalimumab for some period of the first trimester to women with RA not treated with any adalimumab in pregnancy. No women in either group were also treated with methotrexate, but women may have been treated with another DMARD or steroid. An additional comparison group included women without any autoimmune disease. All three groups were recruited prior to 19 completed weeks' gestation and followed by extensive telephone interviews throughout pregnancy and after birth. Medical records were reviewed, and a subset of live born infants received dysmorphological examination by a study physician (blinded to the mother's status). Outcomes were compared using logistic regression techniques and survival methods as appropriate with adjustment for confounders using propensity scoring if two or more confounders were identified.

Results: Seventy-four women exposed to adalimumab, 80 disease-matched comparison women, and 218 non-diseased women enrolled in the study. All women in the adalimumab-exposed group had at least one dose of the medication in the first trimester; approximately 43% of those women used the medication in all three trimesters. The overall lost-to-follow up rate was 5.9%. Disease severity, as measured by the HAQ at the time of enrollment and at 32 weeks' gestation, was similar between the two disease-matched groups. The rate of major defects in the exposed, disease-matched, and non-diseased comparison groups was 5.6%, 7.8% and 5.5% respectively. In adjusted analysis, there was no significant difference in the overall rate of major malformations among live births in the adalimumab exposed vs. disease-matched group (adjusted Relative Risk (RR) 1.14, 95% Confidence Interval (CI) 0.26, 4.93). A total of 234 infants (70% of live born infants) received the study-related physical examination. The proportion of children with 3 or more minor malformations in the three groups did not differ, and there was no specific pattern of minor malformations identified. Using Cox Proportional Hazards modeling, the adjusted hazard ratio (HR) for spontaneous abortion was 1.96 (95% CI 0.47, 8.26) comparing the adalimumab vs. disease-matched groups; the rate was elevated in comparison to the non-diseased group (adjusted HR 3.79, 95% CI 1.01, 14.23), although the number of events was small. The rate of preterm delivery did not differ significantly among groups, nor did the proportion of infants who were small for gestational age.

Conclusion: Pregnant women with RA who are treated with adalimumab during the first trimester compared to women with the same underlying condition do not appear to be at increased risk of any of the adverse pregnancy outcomes evaluated. Although the sample size is small, these results provide reassuring data to women with RA who require treatment with adalimumab.

Meloxicam and Risk of Myocardial Infarction: A Population-Based Cohort Study. Deepan Dalal[1], Maureen Dubreuil[2], Yuqing Zhang[2], Christine Peloquin[2], Tuhina Neogi[2], Hyon Choi[2] and David T. Felson[2]. [1]Boston Medical Center, Boston, MA, [2]Boston University School of Medicine, Boston, MA.

Background/Purpose: Certain non-steroidal anti-inflammatory drugs (NSAIDs) have been associated with an increased risk of myocardial infarction (MI). MI risk for different NSAIDs varies largely because of different levels of cyclo-oxygenase (COX) 2 inhibition. Given this differential MI risk, it is clinically important to understand which NSAID options are safer vs. which ones confer an increased risk. For example, naproxen has shown no increased risk of MI, whereas diclofenac has shown an increased risk. However, Meloxicam, which is considered to inhibit COX-2 selectively over COX-1, is used widely across the world, but the risk of MI with Meloxicam has not been quantified.

Methods: The Health Improvement Network (THIN) is a national population-based cohort of over 10 million patients from 580 general practices in the UK. We conducted a nested case-control study of patients between 35 and 89 years of age who had at least 1 year of enrollment between 2000 and 2013 in the cohort and at least 1 prescription for an NSAID. Individuals with a history of MI were excluded. Cases of MI were identified by Read codes and the date of MI was considered the index date. Each case

was matched with up to 4 unique controls on age, sex and practice ID. NSAID exposure was categorized as remote (greater than 60 days prior), recent (between 1 and 60 days) or current to the index date. Current NSAID users were further classified as Naproxen, Diclofenac, Meloxicam or other NSAID users. Multivariate logistic regression analysis with 6 categorical variables for NSAID exposure categories was conducted to determine the risk of MI among various current NSAID users compared with that of remote users, adjusting for potential confounders including traditional cardiac risk factors, comorbidities and cardiovascular drug use.

Results: We identified 9817 MI cases and 12860 matched controls from the cohort. The cases had a higher prevalence of traditional cardiac risk factors, more frequent use of cardiovascular medications, and a higher prevalence of chronic kidney disease and inflammatory arthritis (Table 1). The adjusted odds ratio (aOR) for MI with current Meloxicam use was 1.40 (95% CI, 1.15–1.71) as compared with remote NSAID use. While, the aOR with current Naproxen use was 1.01 (95% CI, 0.84–1.22) and with current Diclofenac use was 1.35 (95% CI, 1.21–1.5).

Conclusion: In this large population-based cohort, Meloxicam significantly increased the risk of MI at a level similar to that of Diclofenac. As previously shown, Naproxen was not associated with an increased risk of MI. Drugs like Diclofenac and Meloxicam are widely used across the world should be used cautiously because of the increased risk of MI they pose.

Table 1: Baseline characteristics

		MI Cases	Controls
Subjects (n)		9817	12860
Age (years)		62.8 ± 12.4	63.1 ± 12.2

Risk of Active Tuberculosis in Patients with Arthritis Receiving TNF-α Inhibitors: A Look Beyond the Baseline Tuberculosis Screening Protocol. Alina Soare, Carina Mihai, Ana Maria Gherghe, Rucsandra Dobrota, Raida Oneata, Simona Pintilie, Mihaela Milicescu, Ioan Ancuta, Andrei Martin, Mariana Sasu, Claudia Ciofu, Liviu Macovei, Victor Stoica and Mihai Bojinca. Carol Davila University of Medicine and Pharmacy & Cantacuzino Hospital, Bucharest, Romania.

Background/Purpose: Tuberculosis (TB) is a major concern in patients receiving TNF inhibitors (TNFi), especially in countries with a high TB burden. Careful TB screening is mandatory before TNFi initiation, and patients with latent TB receive prophylactic treatment. This study aimed to assess the incidence of active TB and the efficacy of TB prevention measures in a cohort of patients with rheumatoid arthritis (RA), psoriatic arthritis (PsA) and ankylosing spondylitis (AS)receiving TNFi, in an academic Rheumatology center.

Methods: Data of all patients who received treatment with TNFi in our clinic between Jan 1st 2001 and June 1st 2014 have been retrospectively analyzed. Demographics, baseline TB screening, TB prophylaxis, duration of TNFi treatment and reported active TB data were extracted from clinical records. The cohort was divided into 3 groups according to the mandatory TB screening method at baseline: tuberculin skin test (TST) with a positive threshold of either >10mm (01.2001–12.2005) = group TST1, or >5mm (01.2006–08.2010) = group TST2, and QuantiFERON®-TB Gold test (09.2010–06.2014) = group QTF. All patients tested positive for latent TB received prophylaxis with isoniazide for 9 months. Cases of TB reactivation were defined as TB occurring at <12 months since TNFi initiation. The incidence of active TB was analyzed for each group and compared to TB incidence data in Romanian general population, retrieved from the World Health Organization (WHO) reports. The impact of the screening method on the incidence of active TB was assessed using Cox proportional hazard regression.

Results: A total of 550 patients were included (304 RA, 43 PsA and 203 AS). According to the initial TB screening method, 77 patients belonged to the TST1, 251 to the TST2 and 222 to the QTF group. The number of active TB cases/ time of exposure to TNFi in person-years (PY) in the 3 groups was 9/477.3, 9/1081.5 and 3/445.5 respectively, accounting for an incidence of 1885.7, 832.2 and 673.4 cases per 100,000 PY. These numbers are significantly higher than the incidence of TB in Romania, which decreased from 147 to 94 per 100,000 PY from 2001 to 2013.

Cases classified as latent TB reactivation/total TB cases in the TST1, TST2 and QTF groups were only 2/9, 2/9 and 1/3 respectively, while the remaining TB cases were more likely new TB infection. Using Cox regression adjusted for age, sex and disease, we found no influence of the TB screening method on the risk of latent TB reactivation. However, the TST1 group had a significantly higher TB risk, with the QTF group as reference, when all cases of active TB were analyzed: hazard ratio [95% confidence interval] were 9.33[1.64–53.10], p=0.012 for TST1 and 1.68 [0.43–6.59], p=0,445 for TST2, suggesting that the period of TNFi initiation in TST1, when the TB incidence in general population was higher than in the later years, determined a higher risk for active TB.

Conclusion: In a country with high TB burden, where all patients initiated on TNFi are screened for latent TB at baseline, new TB infection exceeds latent TB reactivation. TB incidence in these patients is much higher than in the general population and baseline screening does not solve the problem of later infection, suggesting the necessity of yearly TB re-screening.

Impact of Oral Glucocorticoid Therapy on Mortality in Patients with Rheumatoid Arthritis and Diabetic Mellitus. Mohammad Movahedi and William G Dixon. Arthritis Research UK Centre for Epidemiology, The University of Manchester, Manchester, United Kingdom.

Background/Purpose: Glucocorticoid (GC) therapy is known to increase the risk of new-onset type 2 diabetes mellitus (DM). Furthermore, GC therapy increases blood glucose in diabetic patients, thereby potentially leading to worse outcomes. This study aimed to examine the impact of GC use on all-cause and cardiovascular (CV) mortality in patients with RA and DM, and to compare to the impact of GC use on mortality in patients with RA but no DM.

Methods: Adult patients with RA were identified from the Clinical Practice Research Datalink, a UK primary care research database. Type 2 DM was defined using READ codes, anti-diabetic treatment or abnormal blood results. GC exposure was identified from oral GC prescriptions. Mortality data, including cause of death, were obtained through linkage to the Office for National Statistics. All-cause and CV mortality rates with 95% confidence Interval (CI) were calculated for ever/ never GC use and categories of cumulative dose. Data were analysed using multivariable time-dependent Cox models to assess the association between GC and death, adjusting for potential confounders.

Results: We studied 3,397 patients with RA and DM and 17,883 patients with RA but no DM with a median follow-up of 3.6 and 5.3 years, respectively, during which 699 (266 from CVD cause) and 2,887 (1,016 from CVD cause) patients died. All-cause mortality rate was 4.6 (95% CI 4.3–5.0) and 2.7 (95% CI: 2.6–2.8) per 100 person-years (pyrs) in DM and non-DM cohorts, respectively.

In patients with RA and DM, the adjusted relative risk (aRR) and absolute risk difference (ARD) of all-cause mortality were 2.0 (95% CI: 1.6–2.4) and 4.2 per 100pyrs (95% CI: 3.5–5.0) in ever GC use compared with never GC use, respectively. There was a dose response relation between both all-cause and CV mortality, and cumulative GC dose category. Patients in the highest category of cumulative GC dose (≥7,299 mg) had an aRR of 3.4 (95%CI: 2.5–4.6) and compared to non GC users for all-cause mortality.

In patients with RA but no DM, the aRR and ARD of all-cause mortality was 2.3 (95% CI: 2.0–2.5) and 2.9 per 100pyrs (95% CI: 2.7–3.2) in ever GC use compared to never GC use, respectively. Risk of all-cause mortality was increased with increasing cumulative dose category. Similar results were observed for risk of CV mortality in association with cumulative GC dose.

Whilst the aRR for all-cause mortality was lower in patients with RA and DM compared to patients without DM (2.0 vs 2.3), the ARD was higher (4.2 vs 2.9 per 100 pyrs). The table below shows the association between GC use patterns and all-cause and CV mortality.

All cause mortality

	RA and DM		RA but no DM	
Oral GC pattern	**aRR**	**ARD Per 100 pyrs**	**aRR**	**ARD Per 100 pyrs**
Never use	Ref	-	Ref	-
Ever use	2.0 (1.6–2.4)	4.2 (3.5–5.0)	2.3 (2.0–2.5)	2.9 (2.7–3.2)
Cumulative dose category				
Non GC use	Ref	-	Ref	-
Low (>0–959.9 mg)	1.7 (1.3–2.2)	0.6 (−0.4–1.7)	1.8 (1.6–2.1)	0.3 (0.1–0.6)
Med (960–3054.9 mg)	1.8 (1.3–2.3)	1.6 (0.4–2.9)	2.2 (1.9–2.6)	1.7 (1.3–2.2)
High (3055–7298.9 mg)	2.3 (1.7–3.0)	3.8 (2.4–5.3)	3.3 (2.8–3.8)	4.5 (3.9–5.1)
Very high (≥7299 mg)	3.4 (2.5–4.6)	5.4 (3.8–7.1)		

CV mortality

	RA and DM		RA but no DM	
Oral GC pattern	**aRR**	**ARD Per 100 pyrs**	**aRR**	**ARD Per 100 pyrs**
Never use	Ref	-	Ref	-
Ever use	2.0 (1.4–2.7)	1.4 (0.9–1.9)	1.8 (1.5–2.2)	0.9 (0.8–1.1)
Cumulative dose category				
Non GC use	Ref	-	Ref	-
Low (>0–959.9 mg)	1.7 (1.2–2.7)	0.3 (–0.3–1.1)	1.4 (1.2–1.9)	−0.02 (−0.2–0.2)
Med (960–3054.9 mg)	1.8 (1.2–2.8)	0.7 (−0.1–1.5)	1.5 (1.2–2.0)	0.4 (0.2–0.7)
High (3055–7298.9 mg)	2.3 (1.5–3.6)	1.7 (0.8–2.6)	2.8 (2.2–3.7)	1.6 (1.2–1.9)
Very high (≥7299 mg)	2.4 (1.5–4.0)	1.0 (0.1–1.9)		

Conclusion: Oral GC therapy is associated with higher all-cause and CV mortality in RA patients with DM, although residual confounding may explain some of the association. Whilst the aRR is slightly lower that that seen in patients with RA but no DM, the higher background mortality rate in patients with DM means this lower aRR is associated with more excess deaths.

Serious Infections on TNF Inhibitors: Have the Risks Changed over Calendar Time, and How High Are They? Elizabeth V. Arkema[1], Johan Askling[1] and the ARTIS Study group[2]. [1]Karolinska Institutet, Stockholm, Sweden, [2]Karolinska Institutet och Svensk Reumatologisk förening, Solna, Sweden.

Background/Purpose: The rheumatoid arthritis (RA) population starting tumor necrosis factor inhibitors (TNFi) today is much different in terms of accumulated and concurrent disease activity and comorbidity, than patients starting treatment 10 years ago. Still, few studies have investigated time-trends in infection risks and their determinants, on a clinically relevant scale. Our aim was to calculate the absolute risk of serious infection (SI) within 1 year of TNFi-initiation in patients with RA in Sweden and to examine whether the risk changes over calendar time and patient characteristics.

Methods: Patients with RA who initiated a TNFi from 2004 to 2011 were identified from the Anti-Rheumatic Therapies in Sweden (ARTIS) register. Patient demographics, concomitant medications and clinical measures were collected from the patient's first visit (baseline). ICD-10 codes for SI hospitalizations were identified in the inpatient register (2004–2012) and linked to the study population using each patient's unique personal identification number. We calculated the absolute risk of SI hospitalization within 1 year of treatment start using modified Poisson regression models stratified by risk factors previously identified by the German biologics register, RABBIT: concomitant corticosteroid use, total number of risk factors (age≥60, previous serious infection 1 year before TNFi-initiation, COPD or chronic kidney disease). We additionally stratified risks by calendar year of initiation (2004–4007 vs. 2008–2011) and investigated other comorbidities (cardiovascular disease, diabetes, number of hospitalizations, days hospitalized, outpatient visits) and disease activity measurements (DAS-28 and its components, HAQ, disease duration).

Results: We included 8562 biological-initiators with RA. A total of 344 (4.0%) individuals had at least one SI hospitalization within a year of biological initiation (2004–2007 4.4%; 2008–2011 3.7%). Serious infection risk decreased over time in age and sex-adjusted models (p value for calendar year 0.02) but when adjusted for comorbidities, year of TNFi-initiation was no longer significantly associated with a decreased risk of SI (p=0.15). Individuals who were older, male, with longer disease duration, a history of infection and higher disease severity were at an increased risk of SI. Our results from 2004–2007 were very similar to those reported by RABBIT. When examining risks from 2008–2011, the majority of the increased risk was observed in individuals with 3 or 4 risk factors (**Figure**).

Conclusion: Risks of SI within 1 year of TNFi initiation were similar to those reported by the German Biologics Register 2004–2007. Although the population starting TNFi has changed over time, the one-year risks of SI has only dropped modestly, but the relative importance of SI risk factors has changed, such that infection risk calculators need be updated using contemporary data.

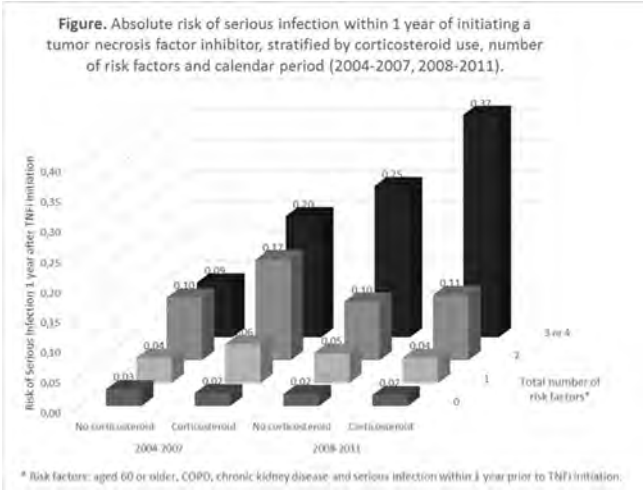

Figure. Absolute risk of serious infection within 1 year of initiating a tumor necrosis factor inhibitor, stratified by corticosteroid use, number of risk factors and calendar period (2004-2007, 2008-2011).

Comparison of Classification Criteria for Gout Using Monosodium Urate Crystal Identification By a Certified Examiner As the Gold-Standard in a Large Multi-National Study. William Taylor[1], Nicola Dalbeth[2], Jaap Fransen[3], Tuhina Neogi[4], H. Ralph Schumacher Jr. [5] and Tim Jansen[6]. [1]University of Otago Wellington, Wellington, New Zealand, [2]University of Auckland, Auckland, New Zealand, [3]Radboud University, Nijmegen, Netherlands, [4]Boston University School of Medicine, Boston, MA, [5]University of Pennsylvania VA Medical Center, Philadelphia, PA, [6]Radboud University Medical Center, Nijmegen, Netherlands.

Background/Purpose: Most gout is managed in primary care where the diagnosis seldom relies upon identification of MSU crystals. Several classification criteria for gout have been developed but there is little information on the relative performance of these criteria, especially in comparison to competent identification of MSU crystals in synovial fluid. This study,

undertaken as part of an ACR-EULAR project to update gout classification criteria compares the performance of existing criteria.

Methods: Investigators from 25 sites in 16 countries contributed data on consecutive patients with at least 1 recent swollen joint or subcutaneous nodule that conceivably might be gout. All patients underwent arthrocentesis or tissue aspiration and examination of synovial fluid or tissue with polarizing microscopy by an examiner who had undergone a 2-step certification procedure. Case-control status was defined by the presence or absence of MSU crystals. Data were collected that enabled classification into each of 5 published classification criteria for gout. Both full and survey versions of 1977 American Rheumatism Association (ARA) criteria were used for this analysis. The original NEW YORK and ROME criteria and a modification to contain only clinical items were included. Specificity, sensitivity and AUC were calculated and the differences in test performance were assessed with logistic regression. The reference category was MEX for each regression model.

Results: Data from 983 patients (509 cases, 474 controls) were collected, of whom 702 were male. The mean (SD) age was 58.5 (17.2) and duration of disease since first ever symptoms was 7.8 (24.6) years. Controls had a clinical diagnosis of gout (MSU crystals not observed by microscopy, n=50), CPPD (109), osteoarthritis (67), rheumatoid arthritis (69), septic arthritis (10), SLE (5), spondyloarthritis (71), undifferentiated arthritis (60), other (31). Not all patients could be classified by every criteria because of missing data, particularly radiographs.

The performance of the criteria is shown in the Table. Analysis of subjects without tophi generally led to minor differences in criteria performance. Excluding controls with a clinical diagnosis of gout led to slightly better specificity (54% MEX to 84% NEW YORK).

Overall, sensitivity was very high. The high sensitivity of the ARA (full) and NEW YORK criteria is due to the fact that presence of MSU crystals is sufficient for classification; therefore all cases meet these criteria by study design. The sensitivity of ARA, ROME and NEW YORK criteria are greatly reduced by excluding MSU crystal data. MEX has worse specificity than all other criteria sets and NETH has worse specificity than NEW YORK or ROME.

Conclusion: Although sensitivity of existing criteria is satisfactory, the specificity of every set is less than 80%, which is not ideal. There is a need for better performing criteria.

	Sensitivity	Specificity	AUC (95% CI)	Not classified
ROME[1]	97.6%	+74.5%	0.87 (0.84, 0.89)	8.2%
ROME (clinical 2 of 3)[1]	†77.6%	†74.5%	0.77 (0.73, 0.80)	8.2%
NEW YORK[2]	†100.0%	†78.4%	0.88 (0.85, 0.91)	0.2%
NEW YORK (clinical 2 of 4)[2]	†78.9%	†78.4%	0.78 (0.75, 0.81)	0.5%
ARA (full)[3]	†100%	†64.8%	0.82 (0.79, 0.86)	20.6%
ARA (survey)[3]	†85.7%	†68.1%	0.77 (0.74, 0.80)	19.3%
NETH[4]	93.7%	†60.7%	0.76 (0.73, 0.80)	9.0%
MEX[5]	95.3%	49.5%	0.72 (0.68, 0.76)	9.1%

Gout and the Risk of Alzheimer's Disease: A Population-Based Cohort Study. Na Lu[1], Yuqing Zhang[1], Alberto Ascherio[2], Miguel Hernan[2], Tuhina Neogi[1], Maureen Dubreuil[3] and Hyon Choi[4]. [1]Boston University School of Medicine, Boston, MA, [2]Harvard School of Public Health, Boston, MA, [3]Boston University Medical Center, Boston, MA, [4]Harvard Medical School, Boston, MA.

Background/Purpose: While gout is associated with cardiovascular (CV)-metabolic comorbidities and their sequelae, uric acid's anti-oxidant effects may have neuroprotective benefits. Several studies have found an inverse association between a history of gout and the future risk of Parkinson's disease, but no such evidence is available for the risk of Alzheimer's disease (AD). To that effect, a Rotterdam study has found an inverse association between prior serum uric acid levels and the risk of AD. Thus, we evaluated the potential impact of incident gout on the risk of developing AD in a general population context.

Methods: We conducted a matched cohort study using data from The Health Improvement Network (THIN), an electronic medical records database representative of the UK general population. Study population included individuals aged ≥ 40 who had at least 1 year of active enrollment with the general practice during 1 January 1995 to 31 May 2010. For each case of incident gout patient, up to 5 non-gout individuals were selected and matched on age, sex, date of study entry and year of enrollment. Gout diagnoses, outcomes, and dementia risk factors were identified from electronic medical records. We compared incidence rates (IRs) of AD between the gout and comparison cohorts, excluding individuals with prevalent gout or dementia at baseline. Cox proportional hazards models were used to estimate the hazard ratio (HR), adjusting for body mass index (BMI), smoking, alcohol use, prior comorbid conditions, and use of CV medicines.

Results: Among 55,471 individuals with gout (28% female, mean age 63 years), we identified 179 new cases of AD over a 4-year median follow up. The IR of AD was 0.7 per 1000 person-years (PY) vs. 1.3 per 1000 PY in the comparison cohort, and the multivariate HR of AD among those with gout was 0.69 (95% CI, 0.58 to 0.81). The inverse association was similarly present among men and those < vs ≥ 75 years, but was stronger among those with CV disease (i.e., ischemic heart disease or stroke) than those without (HRs, 0.37 [95% CI, 0.24 to 0.58] vs. 0.76 [95% CI, 0.61 to 0.93]) (p for interaction, 0.02).

Conclusion: These findings provide the first general population-based evidence that gout is associated with a protective effect against developing AD and support the purported potential neuro-protective role of uric acid. These associations may be more evident among those with CV disease.

Table 1 Incidence Rates and Relative Risks (RR) for Alzheimer's disease by Gout Status (Total and Subgroups)

	Gout Status	N	Cases	Follow-up Time (person-years)	Mean Follow-up (years)	Incidence Rate (cases per 1000 person-years)	Crude RR (95% CI)*	+ GPs visits, BMI, smoking and alcohol Adjusted RR (95% CI)	+ Comorbidity and CVD drug classes Adjusted RR** (95% CI)

Extent of Urate Deposition in Asymptomatic Hyperuricemia and Symptomatic Gout: A Dual Energy Computed Tomography Study. Nicola Dalbeth[1], Meaghan House[1], Opetaia Aati[1], Paul Tan[1], Christopher Franklin[1], Anne Horne[1], Gregory Gamble[1], Lisa K. Stamp[2], Anthony Doyle[1] and Fiona M. McQueen[1]. [1]University of Auckland, Auckland, New Zealand, [2]University of Otago, Christchurch, New Zealand.

Background/Purpose: Recent studies have reported that ultrasound features of urate crystal deposition are present in some asymptomatic individuals with hyperuricemia, suggesting that subclinical urate deposition occurs prior to presentation with symptomatic disease. Dual energy computed tomography (DECT) allows both specific detection and volume measurement of urate crystals. The aim of this study was to compare the frequency and volume of DECT urate deposits in people with asymptomatic hyperuricemia and symptomatic gout.

Methods: DECT scans of both feet were prospectively obtained from asymptomatic individuals with serum uric acid ≥9mg/dL recruited from community laboratories (n=25), and those with crystal proven gout without clinically apparent tophi (n=33). The gout group was separated into two groups: early gout (pre-defined as onset of symptoms in the preceding 3 years, n=14), and late gout (disease duration >3 years, n=19). Asymptomatic individuals with serum uric acid <6mg/dL (negative controls, n=10) and individuals with crystal proven tophaceous gout (positive controls, n=20) were studied to optimize the DECT settings. Two readers, blinded to all clinical features including gout status and serum uric acid, independently scored the scans for the presence and sites of urate deposition, and measured the urate volume in both feet using automated volume measurement software. For the purposes of analysis, DECT urate deposits were considered to be present if scored by both readers.

Results: DECT urate deposits were observed in 6/25 (24%) participants with asymptomatic hyperuricemia, 11/14 (79%) participants with early gout and 16/19 (84%) participants with late gout ($p<0.001$, Figure 1A). In those with urate deposits, the volume of urate deposition was significantly lower in those with asymptomatic hyperuricemia, compared with the early and the late gout groups (Kruskall-Wallis $p=0.02$, Figure 1B). Similar urate volumes were observed in the early and late gout groups (Figure 1B). DECT urate deposition was observed in both joints and tendons in the asymptomatic hyperuricemia group, but significantly less frequently than in both the early and late gout groups ($p\leq0.001$ for both joint and tendon sites).

Conclusion: Although DECT can detect urate deposition in the feet of some asymptomatic individuals with hyperuricemia, these deposits are far more frequently observed in those with symptomatic gout. Urate deposit volumes are also greater in those with symptomatic disease. These data suggest that a threshold of urate crystal volume may be required before symptomatic gout occurs.

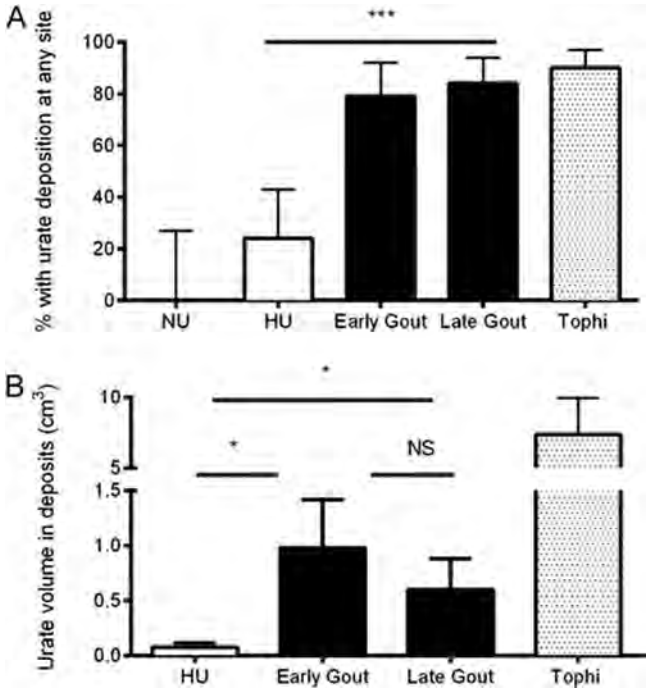

Figure: A. Frequency with urate deposition at any site, ***Chi-Square test $p<0.001$. B. Urate volume in those with deposits detected, *Dunn's multiple comparison test $p<0.05$. NU: asymptomatic normouricemia, HU: asymptomatic hyperuricemia.

Asymptomatic Deposit of Monosodium Urate Crystals Associates to a More Severe Coronary Calcification in Hyperuricemic Patients with Acute Coronary Syndrome. Mariano Andrés[1], María Amparo Quintanilla[1], Francisca Sivera[1], Paloma Vela[2] and Juan Miguel Ruiz-Nodar[3]. [1]Hospital General Universitario de Elda, Alicante, Spain, [2]Universidad Miguel Hernández, Alicante, Spain, [3]Hospital General Universitario de Alicante, Alicante, Spain.

Background/Purpose: Increased cardiovascular (CV) risk in gout relates to crystal-driven inflammation. Monosodium urate (MSU) crystals are found in ~25% of patients with asymptomatic hyperuricemia (AH) by ultrasound (US) [1,2]. Whether AH patients with crystal deposits depict an increased CV risk has not been assessed so far. We aimed to assess the association between the deposit of MSU crystals in AH and the severity and extension of the coronary atherosclerotic disease (CAD).

Methods: Cross-sectional study, approved by the local ethics committee. Consecutive patients with AH (serum uric acid [SUA] >7.0 mg/dL) admitted due to an acute coronary event were selected. Those with current urate lowering treatment (ULT) were excluded. US of both knees and 1st MTP joints was performed to detect signs of MSU crystals deposition: doble contour sign, snow storm sign, tophus or joint effusion. When present, US-guided arthrocentesis was performed to confirm MSU crystals by polarised light microscopy. US and microscopy findings were later reviewed by a blinded rheumatologist. CAD was assessed through the severity of coronary artery calcification (absent, mild, moderate or severe) and the total of significant coronary lesions (>50% of the diameter) at coronariography by a blinded cardiologist. Traditional CV risk factors were also collected. Association between coronariographic features and crystal identification was analysed by logistic regression for binary variables and lineal regression for continous variables.

Results: Fifty-one patients were enrolled, median (p25–75) age 73 years (59–81), 76.5% males. Median SUA at admission was 7.6 mg/dL (7.08–8.6). Moderate-to-severe calcification was present in 21 (41.2%) patients, and the median number of significant coronary lessions was 3.0 (2–5). US found lesions in 49 (96.0%) patients: joint effusion in 94.1%, tophi in 9.8%, doble contour sign in 9.8% and snow storm sign in 3.9%. Arthrocentesis was performed in 48 patients. MSU crystals were identified in 11 patients (21.6% of total). No significant differences between groups were found in traditional CV risk factors or SUA levels. The presence of moderate to severe coronary calcification significantly differed between groups and strongly associate to the detection of MSU crystals [Table]. The number of significant lesions did not associate to MSU crystals identification, though a trend tomards more lesions in MSU+ patients was noted.

Conclusion: Our study found a more severe coronary calcification in those AH patients with deposits of MSU crystals. These patients might benefit from ULT aiming to reduce their CV risk, but this should be addressed in future studies.

Profound Hypouricemia Induced in Human Subjects By Novel Bifunctional Inhibitors of Xanthine Oxidase and URAT1. Raymond P. Warrell Jr.[1], Anna Klukovits[2], Keith Barnes[3], Chitkala Satyanarayana[4], Chris Cheeseman[5] and John Piwinski[1]. [1]Relburn-Metabolomics, Inc., Westfield, NJ, [2]SOLVO Biotechnology, Budapest, Hungary, [3]AMRI, Albany, NY, [4]AMRI, Singapore, Singapore, [5]University of Alberta, Alberta, AB.

Background/Purpose: A prototype anticancer drug (RLBN1001) induced marked hypouricemia in studies of > 350 human subjects. Preliminary exploration suggested dual effects on uric acid (UA) production and excretion, whereas studies by others showed the agent was a catalytic (Type 2) inhibitor of topoisomerase-II. Given the unusual clinical potency, we sought to: identify the hypouricemic mechanism(s); clarify structure-activity relationships (SARs) to both the uric acid and genotoxic targets; and develop novel analogs that would enhance the hypouricemic effect and eliminate genotoxicity, thereby discovering potentially useful treatments for gout.

Methods: We verified clinical proof-of-concept by examining biochemical effects in 50 human subjects treated with RLBN1001. We explored SARs in recursive chemical syntheses using four principal bioassays: renal UA transporters URAT1 (SLC22A12) and splice variants of GLUT9a/b (SLC2A9); xanthine oxidase (XO); and *in vitro* mouse micronucleus (MMN) (to detect genotoxicity).

Results: Over a 15-fold dosing range with RLBN1001, nadir levels of clinical hypouricemia (≤ 1.0 mg/dL) were not dose-related, indicating the minimal effective dose was below the lowest administered dose in this study (100 mg/m^2/d × 5d). At both low and high doses, hypouricemia was associated with increased urinary excretion of both UA and total oxypurines, suggesting bifunctional equilibrium effects on both production and excretion. We found that the RLBN1001 prototype was a potent inhibitor of URAT1 but not GLUT9a, a modest inhibitor of XO, and a potent clastogen in the MMN assay. We iteratively synthesized a series of novel analogs and identified new compounds that are potent inhibitors of both XO (i.e., 4-fold more potent than allopurinol) and URAT1 (equipotent to lesinurad), but devoid of genotoxicity. One compound showed moderate inhibition of GLUT9b (data not shown), but other compounds showed minimal effects on this target. Data for reference and selected new compounds are shown in the table.

Conclusion: Having established compelling clinical POC with the RLBN1001 prototype, we have synthesized a library of unique compounds with strongly enhanced activities that both reduce UA production and enhance UA excretion. A lead compound is expected to enter initial clinical trials as a novel, potential first-line treatment for hyperuricemic patients with gout.

Compound	URAT1 Inhibition IC50 mM Mean ± SEM	XO Inhibition IC50 mM Mean ± SEM	MMN
Allopurinol	>300	2.8 ± 0.33	ND
Benzbromarone	0.2	ND	ND
Lesinurad	3.54	>300	ND
RLBN1001	5.4 ± 1.0	274	+
RLBN2022	1.2	>300	+
RLBN2027	6.3	243	+
RLBN2023	2.6 ± 0.6	1.1	Negative
RLBN2024	9.4 ± 0.6	0.7	Negative

Bisphosphonates and Risk of Acute Pseudogout: A Case-Control Study in the Clinical Practice Research Datalink (CPRD). Edward Roddy, Sara Muller, Zoe Paskins, Samantha Hider, Milisa Blagojevic-Bucknall and Christian Mallen. Keele University, Keele, United Kingdom.

Background/Purpose: Acute pseudogout is the most dramatic clinical manifestation of calcium pyrophosphate crystal deposition (CPPD). CPPD is most commonly sporadic and age-related but can rarely occur secondary to metabolic diseases or a familial trait. Published case reports also suggest that acute pseudogout can occur as a consequence of bisphosphonate therapy. This matched case-control study aimed to examine whether acute pseudogout is associated with bisphosphonate prescription with the preceding 60 days.

Methods: The study was nested within the UK Clinical Practice Research Datalink (CPRD) which houses clinical data from over 600 general practices. Cases aged ≥18 years with a first-ever diagnosis of pseudogout between 01/03/1987 and 31/12/2012 were individually matched for age, gender and practice to four controls without pseudogout. The exposure of interest was prescription of an oral bisphosphonate in the 60 days prior to the diagnosis of pseudogout. It was estimated that 2147 eligible cases of pseudogout would be identified conferring 98% power to detect an odds ratio (OR) of 2.0. Unadjusted conditional logistic regression was used to assess the association between oral bisphosphonate prescriptions and pseudogout and then adjusted for hyperparathyroidism, osteoarthritis, rheumatoid arthritis, and prescription of diuretics and corticosteroids. Analyses were then repeated for individual bisphosphonates. In order to address the possibility of misdiagnosis of crystal arthritis, a sensitivity analysis was undertaken excluding cases or controls who had a prior diagnosis of gout. ORs were presented as incident rate ratios (IRR) with 95% confidence intervals (CI).

Results: 2011 cases of incident pseudogout were identified and successfully matched to 8013 controls (mean age 72 years; male 52%). Those with incident pseudogout were more likely than controls to have received a bisphosphonate prescription in the preceding 60 days (6.1% vs 3.8%; IRR 1.69; 95%CI 1.35, 2.11). On multivariate analysis, this association attenuated slightly (IRR 1.33; 95%CI 1.05, 1.69). A similar significant association was seen for prescription of alendronic acid (multivariate IRR 1.35; 95%CI 1.02, 1.79) but not etidronate disodium, risedronate sodium, ibandronic acid or sodium clodronate although the absolute number of prescriptions for these drugs was small. After excluding known cases of gout, multivariate associations with both any bisphosphonate (IRR 1.43; 95%CI 1.11, 1.84) and alendronic acid (IRR 1.53; 95%CI 1.14, 2.06) remained.

Conclusion: Bisphosphonate prescription appears to be a risk factor for pseudogout, independent of co-morbid conditions and medications. Prescribers should be aware of this uncommon cause of acute pseudogout.

ACR Concurrent Abstract Session
Miscellaneous Rheumatic and Inflammatory Diseases
Sunday, November 16, 2014, 2:30 PM–4:00 PM

832

NOD2-Associated Autoinflammatory Disease: The Largest Cohort Study. Qingping Yao, Min Shen, Christine McDonald, Felicitas Lacbawan and Bo Shen. Cleveland Clinic, Cleveland, OH.

Background/Purpose: *NOD2*-associated autoinflammatory disease (NAID) is an emerging systemic inflammatory disease. The aim is to report our extended study of the phenotypic and genotypic features of the disease.

Methods: A total of 143 adult patients with autoinflammatory phenotypes at presentation were suspected of having NAID over the past 4 years. All patients were genotyped for the *NOD2* mutations. They were then clinically followed and prospectively studied. All patients were divided into two groups predicated on the presence or absence of the *NOD2*mutations. NAID was diagnosed according to our previously reported criteria. The data of the 2 groups were compared and analyzed.

Results: Of 143 patients, we identified 46.9% of patients carrying *NOD2* mutations. The genotype frequencies were significantly higher than historical healthy controls, with IVS8+158 being 35.7%, R702W 11.2% and rare mutations 14.0% (Table 1). The frequency of IVS8+158 was significantly higher than non-Jewish white Crohn's patients. Fifty seven of the 67 *NOD2* positive patients were diagnosed with NAID. The remaining included 5 cases of Crohn's disease, 2 ulcerative colitis, 2 Blau syndrome, and 1 autoimmune disease. The frequency of NAID was estimated to be 3%-7% of our outpatients.

All 57 NAID patients were white with 68.4% of women. The mean age at onset was (33.2 ± 14.0) years, and the mean disease duration at diagnosis was (10.6 ± 8.3) years. NAID was sporadic in 93% of cases. The phenotypic features of this disease included periodic fever (63.2%), dermatitis (91.2%) and inflammatory arthritis/arthralgia (87.7%)(Table 2). Compared with *NOD2* negative patients, the skin disease was overrepresented by dermatitis manifested as erythematous patches or plaques on trunk(Figure 1). Oligo-polyarthritis were common mainly involving the lower extremities. Distal lower extremity swelling was more common(Figure 1). There were gastrointestinal symptoms in 73.7% but without inflammatory bowel disease and sicca-like symptoms in 56.1%. Pericarditis and pleuritis were occasionally

seen. Acute phase reactants were elevated in 40.4%, and autoantibodies are largely absent, with only 8.8% of patients having low titters of ANA. Associated *NOD2* gene mutations were IVS8+158 (80.7%) and/or R702W (26.3%), and rare mutations (24.1%)(Table 2).

Of the 76 *NOD2* mutation negative subjects, 28 patients turned out to have autoimmune diseases and 4 cases of autoinflammatory disease. The remaining were still non-diagnostic. The medications used to treat the disease entailed nonsteroidal anti-inflammatory agents (34.5%), glucorcorticoids (36.4%), sulfasalazine (32.1%) and biologics (7.1%). Prednisone and sulfasalazine were found effective and 2 cases were treated with infliximab and tocilizumab.

Conclusion: The largest cohort study has demonstrated that the *NOD2* genotype frequencies are significantly higher in our study patients and associated with NAID. NAID represents a genetically complex autoinflammatory disorder, and is distinct from Crohn's disease. This disease is more prevalent than initially thought, with an estimated frequency of about 5% in our rheumatology outpatients. This report will further increase awareness of this entity in the medical community.

Canakinumab Use in Patients with Cryopyrin-Associated Periodic Syndrome: Interim Safety and Efficacy Results from Beta-Confident Registry. Hal M. Hoffman[1], Jasmin B. Kuemmerle-Deschner[2], Philip N. Hawkins[3], T. van der Poll[4], Ulrich A. Walker[5], Ken Abrams[6] and Hugh H. Tilson[7]. [1]University of California at San Diego, La Jolla, CA, [2]University Hospital Tuebingen, Tuebingen, Germany, [3]University College London Medical School, London, United Kingdom, [4]University of Amsterdam, Amsterdam, Netherlands, [5]Department of Rheumatology, University Hospital Basel, Basel, Switzerland, Basel, Switzerland, [6]Novartis Pharmaceutical Corporation, East Hanover, NJ, [7]University of North Carolina, Chapel Hill, NC.

Background/Purpose: The three phenotypes in the order of severity: familial cold auto-inflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and chronic infantile neurologic cutaneous and articular syndrome/neonatal onset multisystem inflammatory disease (CINCA/NOMID), constitute the cryopyrin-associated periodic syndrome (CAPS). [1] Here we present the interim safety data of canakinumab (CAN) use in CAPS patients (pts) in clinical practice from the on-going observational β–Confident Registry, that involves 40 sites in 13 countries. To monitor and explore the overall safety of CAN with a focus on serious adverse events (SAEs) including serious infections, vertigo, malignancies and hypersensitivity reactions. The secondary objective is to measure efficacy using physician global assessments (PGA).

Methods: β–Confident Registry protocol does not mandate any visits or procedures, but records all observed and reported adverse events (AEs) and serious AE (SAEs) or AEs potentially related to treatment with CAN. Cumulative safety data are reported as incidence rate (number of events) per 100 patient-years (IR/100 pyr) from the date of first pt enrollment (19 November 2009) until the current data cut-off date (15 April 2014). Additional safety data will be updated, as available, at the time of the presentation.

Results: 272 pts (FCAS, n=38; MWS, n=164; NOMID, n=32; others, n=37) were enrolled with a mean±SD duration of 164±61.3 weeks in the registry. Of these, 17 (6.3%) pts discontinued CAN: 5 each due to AE, poor efficacy and patient preference; 2 for unknown reasons. The incidence rate of overall AEs was 100.0 per person-years (pyr). Pts with FCAS, the least severe phenotype, had the lowest AE incidence rate (49.1/100 pyr) as compared with pts with MWS (107.3/100 pyr) and NOMID (130.4/100 pyr), the more severe phenotypes. The most common types of AEs were infections and infestations with an incidence rate of 35.6/100 pyr. A total of 79 SAEs were reported by 47 pts resulting in an incidence rate of 13.2 SAEs/100 pyr. The most common type of SAE was infection (3.5/100 pyr). One death in a 76 yr MWS old pt with metastatic rectal adenocarcinoma was reported. Of 14 (5.1%) pts that received pneumococcal vaccination (PPV), 10 reported a local post-PPV injection site reaction; of which 4 were considered as serious. Based on PGA assessment, nearly half the pts had no disease activity while most others had mild/moderate disease activity, at the current data cut-off. There was no evidence of loss of effect with time.

Conclusion: The safety profile observed with the use of CAN in CAPS registry is consistent with that observed in the clinical trial program. Response rates were as expected based on clinical trial experience with no evidence of loss of efficacy.

Interleukin-18 (IL-18) As a Biomarker for Diagnosis and Evaluation of Disease Activity in Patients with Adult Onset Still's Disease and Systemic Onset Juvenile Idiopathic Arthritis. Holger Kudela[1], Susanne Drynda[2], Anke Lux[3], Gerd Horneff[4] and Joern Kekow[2]. [1]Univ of Magdeburg, Clinic for Rheumatology, Vogelsang-Gommern, Germany, [2]Univ of Magdeburg, Clinic of Rheumatology, Vogelsang-Gommern, Germany, [3]Univ of Magdeburg, Institute for Biometry and Medical Informatics, Magdeburg, Germany, [4]Asklepios Clinic Sankt Augustin, Sankt Augustin, Germany.

Background/Purpose: Establishing the diagnosis of adult onset Still's disease (AOSD) as well as of systemic onset juvenile idiopathic arthritis (sJIA) is very challenging. Mostly it is still a diagnosis of exclusion. Along with IL-1β, IL-6 and TNFα, IL-18 is one of the cytokines which seem to play a pivotal role in the pathogenesis of both diseases. It has been described as a potential biomarker to support the diagnosis of AOSD and sJIA. Regarding the importance of IL-18 as a marker for disease activity published data are so far conflicting. The aim of the study was to clarify the role of IL-18 as a diagnostic marker and its importance as a measure for disease activity in AOSD and sJIA.

Methods: Thirty adult patients diagnosed with AOSD and twenty children diagnosed with sJIA were included in the study. Twenty adults and three children were analyzed repeatedly. At each visit patients underwent clinical evaluation and laboratory analysis. IL-18 serum levels were determined using an IL-18 ELISA (MBL, Japan) according to the manufacturer's instructions. As comparison groups served 65 adults and 23 children with other rheumatic diseases. To evaluate the disease activity Rau's criteria and CRP values were used. Active disease was defined as a Rau's score ≥2 and/or CRP≥ 2 ULN.

Results: In 83 samples from 30 AOSD patients IL-18 levels were determined. At the time of blood sample collection clinical parameters were obtained as well. In active disease (n=27) patients showed a mean activity score of 3.9±1.4 and a mean CRP value of 106.5±86.1 mg/l. Patients in remission (n=43) showed a mean activity score of 0.14±0.35, and mean CRP value of 5.6±1.5 mg/l. IL-18 levels were significantly increased in patients with active AOSD compared to patients in remission and to the comparison group with a median of 16327 pg/ml, 470 pg/ml, and 368 pg/ml, respectively ($p<0{,}001$). In active disease (n=16) the sJIA cohort showed a mean activity score of 3.4±1.0 and mean CRP value of 133.9±81.8 mg/l. Analogous to AOSD in active sJIA the median IL-18 serum level with 21512 pg/ml was significantly higher than in the comparison group (n=25) with a median IL-18 serum level of 2580 pg/ml ($p<0.001$) and a mean CRP value of 67.6±77.7 mg/l.

For evaluation of IL-18 serum levels as marker for AOSD or sJIA a receiver operating characteristic curve analysis was used. At a cutoff point of 5000 pg/ml IL-18 specificity for AOSD was 96.9 %, and sensitivity 63.3 % (AUC=0.870, $p<0.001$). For diagnosis of sJIA in children a cutoff value of 10000 pg/ml was chosen with a specificity of 100 % and a sensitivity of 60 % (AUC=0.774, $p = 0.003$).

In 11 AOSD patients with active disease at the first visit (Rau's score 4.2±1.5) the reduction of disease activity (Rau's score 0.4±0.7) went along with a significant reduction in IL-18 serum levels from medians of 12500 pg/ml to 402 pg/ml (Wilcoxon sign rank test $p<0{,}001$).

Conclusion: We could confirm earlier publications that highly elevated IL-18 serum levels are common in active AOSD and sJIA, with up to 1000fold higher concentrations compared to other rheumatic diseases. A clear association of IL-18 serum levels with disease activity in AOSD was found. The results give further evidence for the use of IL-18 as diagnostic biomarker in AOSD and sJIA.

Relapsing Polychondritis Can be Characterized By 3 Different Clinical Phenotypes: Analysis of a Series of 142 Patients. Jeremie Dion[1], Nathalie Costedoat-Chalumeau[1], Damien Sène[2], Judith Cohen-Bittan[3], Gaëlle Leroux[3], Charlotte Dion[4], Camille Francès[5] and Jean-Charles Piette[3]. [1]National Referral Center for Rare Systemic Autoimmune Diseases, Hôpital Cochin,

AP–HP, Université Paris Descartes, Paris, Paris, France, [2]Hopital Lariboisière, service de Médecine Interne, Paris, France, [3]CHU Pitié-Salpêtrière, Paris, France, [4]Ecole des hautes études en sciences sociales, Paris, France, [5]Hôpital Tenon, Paris Cedex 20, France.

Background/Purpose: We previously described clinical characteristics and evolution of 142 patients with relapsing polychondritis (RP) followed in a single center and seen at least once since 2000 (1). A cluster analysis was performed with the aim to identify different subtypes of RP.

Methods: A cluster analysis using a k-mean clustering method preceded by a multiple correspondence analysis was performed on 142 patients with RP according to Michet's criteria.

Results: We identified 3 clusters corresponding to 3 distinct clinical phenotypes (Table 1). Cluster 1 (n=12, 8%) corresponded to the more severe phenotype, with a mortality rate of 58% and intensive care unit (ICU) admission rate of 50%. This cluster mainly included men (83%), older at diagnosis, with myelodysplasia (83%), cutaneous (92%) and cardiac (58%) involvement, but with rare tracheobronchial involvement. They were more frequently treated with biologics (58%) than with immunosuppressive agents (33%).

Cluster 2 (n=37, 26%) was characterised by patients with predominant tracheobronchial (76%) involvement and abnormal functional respiratory test results (57%). None had myelodysplasia, and cardiac involvement was less frequent (24%). The prognosis was intermediate: mortality was 14%, but these patients with high infection rate (35%) were frequently admitted to ICU (27%). They frequently received immunosuppressive agents (84%).

Cluster 3 (n=93, 65%), the largest and less severe, was mainly composed of women (68%) with infrequent tracheobronchial (3%) and hematological involvement (2% had myelodysplasia and 5% another hematological disease). Few patients died (4%) or were admitted to ICU (2%). All patients with long-lasting remission (n=15) were in this group.

Conclusion: Using cluster analysis, we were able to distinguish three distinct subgroups of RP. Cluster 1 and 2 had the worst prognosis: older men with myelodysplasia were more likely to have a fatal issue and patients with a respiratory tract involvement were more likely to be admitted to intensive care and had an intermediate survival. By contrast, the last group, mainly composed of patients without hematological or respiratory involvement, had a good prognosis. These results need to be confirm in further studies.

1. Dion J, Costedoat-Chalumeau N, Sène D, Piette JC. Description of 142 cases of relapsing polychondritis followed in a single center since 2000 (abstract). ArthritisRheum 2013;10(supplement):S868.

Categorical Change in 6MWD in Patients with Connective Tissue Disease Associated Pulmonary Arterial Hypertension Receiving Ambrisentan over 3-Years. Aryeh Fischer[1], Virginia D. Steen[2], Steven Nathan[3], Hunter Gillies[4], James Tislow[4] and Chris Blair[4]. [1]National Jewish Health, Denver, CO, [2]Georgetown University Medical Center, Washington, DC, [3]Inova Medical Group, Falls Church, VA, [4]Gilead Sciences, Inc., Foster City, CA.

Background/Purpose: The 6MWD is a valuable tool for evaluating response to therapy in patients with pulmonary arterial hypertension and may be considered a surrogate measure for survival in PAH. However, due to musculoskeletal and other non-PAH related factors, there has been a less robust effect on 6MWD in patients with CTD-PAH. We analyzed the ARIES database to determine the percentage of CTD-PAH patients who have achieved categorical changes in 6MWD while receiving ambrisentan.

Methods: Data from the combined ARIES 1 & 2 placebo controlled studies (ARIES-C) as well as the extension study (ARIES-E) were used. Based upon the previously determined MID of 26m in the overall PAH population participating in the ARIES clinical trials (Minnai, ATS 2014), we chose to evaluate the number of patients achieving changes from their baseline 6MWD in 30m intervals. Analysis was broken down by 6MWD at the end of each year through year 3 and observed cases are reported. Patients who discontinued participation prior to completing year three continued to have survival status evaluated and overall survival status is reported. Adverse events over three years are also reported.

Results: There were 124 CTD-PAH patients who participated in the ARIES clinical trials. At the end of year 3, 6MWD data was available for 55 patients and was unavailable for 69 patients (died = 29, missing 6MWD, alive = 29, and missing 6MWD with survival status unknown = 11). Of patients with an evaluable 6MWD at each yearly interval, the majority [57/91 (63%) at year 1, 43/75 (57%) at year 2, and 32/55 (58%) at year 3] demonstrated improvement from baseline and this was maintained throughout the three years. Additionally, of the patients demonstrating improvement in 6MWD, most were categorized as demonstrating an improvement of at least +60m over baseline which is well above the MID. At the completion of 3 years, survival status is unknown for 11 of the 124 CTD-PAH patients participating. Of the 113 patients where survival status is known, 84 (74.3%) were alive at three years. Adverse events occurring over 3 years were consistent with observed AEs in both PAH and CTD, and were consistent with the known profile of ambrisentan.

Table 1.

	Year 1	Year 2	Year 3
CTD-PAH patients with evaluable 6MWD	n = 91	n = 75	n = 55
≥60m improvement	25 (27.5%)	23 (30.7%)	14 (25.5%)
≥30–60m improvement	17 (18.7%)	12 (16%)	6 (10.9%)
0–30m improvement	15 (16.5%)	8 (10.7%)	12 (21.8%)
0–30m worsening	18 (19.8)	11 (14.7%)	5 (9.1%)
>30m–60m worsening	5 (5.5%)	9 (12%)	8 (14.5%)
>60m worsening	11 (12.1%)	12 (16%)	10 (18.2%)
Overall improved	57 (62.6%)	43 (57.3%)	32 (58.2%)
Overall worsening	34 (37.4%)	32 (42.7%)	23 (41.8%)

Conclusion: Although CTD-PAH patients often do not have a robust improvement in 6MWD, among patients with CTD-PAH who received ambrisentan and had evaluable 6MWD, the majority demonstrated increases in 6MWD over 3 years with 58.2% maintaining improvement by the end of year 3.

Progressive Multifocal Leukoencephalopathy Associated with Biologic Therapy in Rheumatic Diseases: Strengthening Association with Rituximab. Eamonn Molloy[1] and Leonard H. Calabrese[2]. [1]St Vincent University Hospital, Dublin, Ireland, [2]Cleveland Clinic Foundation, Cleveland, OH.

Background/Purpose: Progressive Multifocal Leukoencephalopathy (PML) is a rare and often fatal opportunistic infection recently associated with several biologic therapies. However, ascribing risk to individual therapies has been problematic. A previous study of the aggregate experience of PML reported in association with autoimmune rheumatic diseases (ARD) in the FDA Adverse Event Reporting System (AERS) database, through March 31, 2010 identified 15 cases associated with biologic therapies for rheumatic diseases.

Methods: A Freedom of Information Act request was submitted for all cases of PML and/or JC virus infection within the FDA AERS database, updated through August 27, 2012. MedWatch forms with identified ARD were selected for further analysis. Exclusions included: [1] cases where the ARD was not the primary indication for biologic therapy [2] where another condition was the key underlying factor for PML (e.g. HIV positivity) [3] where PML was classified as unconfirmed. A case was considered as confirmed PML once there was a clear description of compatible clinical and neuroimaging findings AND positive identification of the JC virus by PCR in cerebrospinal fluid AND/OR compatible findings on brain biopsy or autopsy. Relevant data collected included drug treatment and disease association cofactors of PML.

Results: 30 confirmed cases of PML associated with biologic therapy in the setting of ARD were identified (11 SLE, 11 RA, 5 dermato/polymyositis, 3 other). Median age was 53 yrs (range 28–76yrs), 25 were female. Rituximab (RTX) and anti-TNF therapies were the most recently administered biologic therapy in 26 and 4 cases respectively. There were no cases in which abatacept, tocilizumab, belimumab or anakinra was the most recently administered biologic therapy.

PML developed after a median of 2 courses of RTX (range 1–5). The median interval between the first and last infusion of RTX and the development of PML was 15 months (range 1–66) and 5 months (range 0–66), respectively. 4 patients were receiving concomitant cyclophosphamide (CYC), 5 additional patients had previously received CYC. 18/26 were receiving one or more additional immunosuppressive therapies at the time of diagnosis of PML. 7/26 had received an anti-TNF therapy prior to treatment with rituxmab. Two RTX-treated patients had received chemotherapy for malignancy (1 oropharyngeal cancer, 1 MALT lymphoma), 1 had a prior history of breast cancer, 5 additional patients had documented significant lymphopenia.

4 patients developed PML during treatment with anti-TNF therapy, 1 receiving concomitant CYC and 1 treated with CYC prior.

Conclusion: PML is a rare event overall in ARD patients treated with biologic immunosuppressive therapies. The small numbers of cases involved and existence of confounders in many cases precludes definitive attribution of causality. However, the relative paucity of confirmed cases in patients recently treated with anti-TNF therapy, despite their widespread use, suggests that a causal relationship is less likely. In contrast, albeit rare, there is a discordant signal regarding the association between rituximab and PML, requiring continued pharmacovigilance.

ACR Concurrent Abstract Session
Rheumatoid Arthritis - Clinical Aspects: Cardiovascular Disease Risk

Sunday, November 16, 2014, 2:30 PM–4:00 PM

838

The Impact of Rheumatoid Arthritis Disease Activity on Cardiovascular Disease Risk: What Is the Role of the Flare? Elena Myasoedova[1], Arun K. Chandran[1], Birkan İlhan[2], Brittny T. Major[1], C. John Michet[1], Eric L. Matteson[1] and Cynthia S. Crowson[1]. [1]Mayo Clinic, Rochester, MN, [2]Marmara University School of Medicine, Istanbul, Turkey.

Background/Purpose: Patients with rheumatoid arthritis (RA) are at increased risk of cardiovascular disease (CVD). Longitudinal studies assessing the effect of changes of RA activity on CVD risk are lacking. We aimed to examine the impact of RA flare, remission, and cumulative burden of RA severity on CVD in RA.

Methods: In a population-based cohort of patients with RA (age≥30 years; 1987 ACR criteria met in 1988–2007) with no history of CVD we performed a retrospective medical records review of each clinical visit to estimate flare/remission status. RA flare was defined as any worsening of RA activity leading to initiation/change/increase of therapy (OMERACT 9). Remission was defined as the absence of disease activity (i.e. tender joint count [TJC]=0 + swollen joint count [SJC]=0 + ESR<10 mm/hr) (OMERACT 7). The previously validated RA medical Records-Based Index of Severity (RARBIS) and Claims-based Index of RA Severity (CIRAS) were used to estimate RA severity. Data on joint surgeries, erosions, extra-articular manifestations, RA flares, morning stiffness, rheumatoid factor (RF), acute phase reactants, antirheumatic drugs were gathered to calculate RARBIS. Claims data were used to calculate the CIRAS based on the number of rheumatology visits, rehabilitation visits; tests for inflammatory markers, RF, platelet counts, chemistry panels. The comparison cohort included age- and sex-matched non-RA subjects without CVD from the same underlying population. Data on CVD risk factors and incident CVD (i.e. myocardial infarction, cardiovascular death, angina, heart failure, stroke, intermittent claudication) were collected. All subjects were followed until death, migration or 07/01/2012. The association of RA activity/severity measures with CVD was examined using Cox models with time-dependent covariates, adjusting for age, sex, calendar year of RA, CVD risk factors and antirheumatic drug use.

Results: The study included 525 RA patients and 524 non-RA subjects (mean age 54.5 yrs; 71% female in both groups). During the mean follow-up of 10.3 years in RA cohort and 8.8 years in the non-RA cohort, 129 RA patients and 77 non-RA subjects developed CVD. There was a significant increase in CVD risk in RA per each acute flare vs remission (hazard ratio [HR] 1.07 per 6-week flare; 95% confidence interval [CI] 1.01–1.15). The CVD risk for RA patients during remission was not significantly different from the non-RA subjects adjusting for age, sex and calendar year (HR 0.90; 95%CI 0.51–1.59). Increased cumulative moving average of daily RARBIS (HR 1.16, 95%CI 1.03–1.30) and CIRAS (HR 1.38, 95%CI 1.12–1.70) was associated with CVD. RA patients who spent more time in medium and high CIRAS tertiles tended to have higher CVD risk vs those in the lower tertile (HR 1.08, 95%CI 0.98–1.20 and HR 1.18, 95%CI 1.06–1.31, respectively, per 1yr increase).

Conclusion: There was a meaningful 7%-increase in CVD risk with the exposure to each acute flare, but not remission, in RA vs general population highlighting the pivotal role of RA flares in shaping CVD risk in RA. Higher long-term burden of RA severity was associated with significantly increased CVD risk in RA suggesting accrued detrimental impact of RA severity over time.

839

Cardiovascular Risk with Nsaids in Rheumatoid Arthritis: An Analysis Using Routinely Collected Data. Fowzia Ibrahim[1], Antigoni Grigoriou[2], Khaldoun Chaabo[2], David L. Scott[2], Sophia Steer[2] and James Galloway[2]. [1]King's College London, Department of Rheumatology, London, United Kingdom, [2]King's College Hospital, Department of Rheumatology, London, London, United Kingdom.

Background/Purpose: Atherosclerotic disease increases the morbidity and mortality in Rheumatoid Arthritis (RA). NSAIDs are associated with Cardiovascular (CV) risk in the general population. Data from RA cohorts are limited, but some evidence suggests that the association with CV risk may be less marked when NSAIDs are used in RA. We aimed to assess the extent of prescribing NSAIDs amongst a contemporary RA cohort and to evaluate the relationship between NSAIDs use and hospitalized cardiac events.

Methods: We collected data using the electronic medical record (EMR) at King's College Hospital, United Kingdom, for routine clinical care which contains detailed information on disease as well as drug exposure.

Patients with a consultant diagnosis of RA were classified into regular NSAID users and non-users. Low dose aspirin was not considered an NSAID. Cox-II inhibitors were combined with NSAIDs for this analysis.

Disease activity was analyzed using the mean DAS over the duration of follow up. Patients entered follow up from either March 2008 (when the EMR current coding system was established) or date of diagnosis. Follow up was

censored at date of CV event or October 2013 whichever occurs first. CV events (hospitalization with myocardial infarction, angina, heart failure, TIA or stroke) were identified using the hospital electronic coding system and subsequently validated by a physician (AG).

Cox proportional hazard modeling was used to compare rates. The potential influence of confounding due to age, disease severity or existing IHD was explored using multivariate regression.

Results: The clinical characteristics of the population are presented in table 1. In total, 1089 patients with RA were under follow up during the time period available for analysis. The characteristics are typical of a UK cohort with RA, with a mean age 55 years, a female predominance (78%) and mean DAS28 score of 4.0 and a moderate level of disability as measured by HAQ (median 1.625). 28% of the cohort were treated for hypertension. The median follow up time in whole cohort was 3.7 years.

In our practice NSAIDs use is not associated with a significantly increased rate of CV events. Inclusion of PRN users did not influence estimates.

Exclusion of naproxen raised adj HR to 1.2 (0.54, 2.45). Naproxen use accounted for 24% of NSAIDs prescriptions.

Conclusion: These data are reassuring about the use of NSAIDs in RA in our practice, as these drugs remain an important adjunct to therapy. This approach to analysis using the EMR opens doors to future research, highlighting the power of routine captured data. Important limitations include unmeasured confounding, challenges of potential misclassification as well as left and right censorship. Awareness of these issues can help drive innovative solutions to make the data more robust for future analyses.

Table 1

Characteristic	All patients n=1089	No NSAIDs n=866	NSAIDs n=223	p value

Vascular Calcifications on Hand and Wrist Radiographs Are Associated with Cardiovascular Risk Factors, Antigen-Specific Anti-Citrullinated Protein Antibodies, and Mortality in Rheumatoid Arthritis.

E. Blair Solow[1], Fang Yu[2], Geoffrey M. Thiele[3], Jeremy Sokolove[4], William H. Robinson[5], Zachary M. Pruhs[3], Kaleb Michaud[3], Alan R. Erickson[3], Harlan Sayles[3], Gail S. Kerr[6], Angelo L. Gaffo[7], Liron Caplan[8], Lisa A. Davis[8], Grant W. Cannon[9], Andreas M. Reimold[10], Joshua Baker[11], Pascale Schwab[12], Daniel Anderson[3] and Ted R. Mikuls[3]. [1]UT Southwestern Medical Center, Dallas, TX, [2]University of Nebraska Medical Center, Omaha, NE, [3]Omaha VA Medical Center and University of Nebraska Medical Center, Omaha, NE, [4]VA Palo Alto Healthcare System and Stanford University, Palo Alto, CA, [5]VA Palo Alto Health Care System and Stanford University, Palo Alto, CA, [6]Washington DC VAMC, Georgetown and Howard University, Washington, DC, [7]Birmingham VA Medical Center and University of Alabama at Birmingham, Birmingham, AL, [8]Denver VAMC and Univ of Colorado School of Medicine, Aurora, CO, [9]Salt Lake City VA and University of Utah, Salt Lake City, UT, [10]Dallas VA and University of Texas Southwestern, Dallas, TX, [11]University of Pennsylvania and Philadelphia VAMC, Philadelphia, PA, [12]Oregon Health & Science University, Portland, OR.

Background/Purpose: Rheumatoid arthritis (RA) is associated with increased mortality due to cardiovascular disease (CVD). Select antigen-specific anti-citrullinated protein antibodies (ACPA) are associated with atherosclerotic burden in RA. Furthermore, citrullinated proteins have been localized in atherosclerotic plaque. Vascular calcifications (VC) may be found incidentally on hand and wrist radiographs in RA. This study examined the relationship of VC with CVD risk factors, ACPA subtypes, and all-cause mortality in RA.

Methods: Hand and wrist radiographs from 906 RA patients were scored for the presence of VC as either "positive" or "negative". Patient characteristics associated with VC were assessed using univariate and multivariable logistic regression. ACPAs were measured using an enzyme-linked immunosorbent assay for second generation anti-cyclic citrullinated peptide (CCP2) antibodies, then 19 distinct ACPA subtypes were measured by a bead-based immunoassay and sorted based on q-values calculated by Significance Analysis of Microarrays (SAM). ACPA associations with VC were further examined using multivariable quantile regression. VC and all-cause mortality were examined using Cox proportional hazards regression.

Results: Ninety-nine (11%) patients demonstrated VC on hand and wrist radiographs (Table 1). In multivariable analyses, factors associated with VC included diabetes (OR 2.85; 95% CI 1.43, 5.66, p=0.003), history of CVD (OR 2.48; 95% CI 1.01, 6.09, p=0.047), prednisone use (OR 1.90; 95% CI 1.25, 2.91, p=0.003), current vs. never smoking (OR 0.06; 95% CI 0.01, 0.23, p=0.001) and former vs. never smoking (OR 0.36; 95% CI 0.27, 0.48, p=0.001). In the ACPA subtype analyses using SAM, antibodies to citrullinated forms of Apolipoprotein E (anti-Cit-ApoE), fibrinogen, and vimentin, but not anti-CCP antibody, were differentially expressed in patients with VC (Table 2). The association of anti-Cit-ApoE with VC remained significant following all multivariate adjustments, as well as adjustment for known CVD. After adjusting for significant covariates and stratifying by age and gender, VC were associated with increased all-cause mortality (HR = 1.41; 95% CI 1.12, 1.78, p=0.004).

Conclusion: In this cohort, ~1 in 10 RA patients had VC on hand and wrist radiographs. VC were associated with traditional CVD risk factors and prednisone use and yielded an independent association with all-cause mortality. ACPA targeting Cit-ApoE were increased among patients with VC. Mechanisms underpinning the association of select ACPA with CVD in RA warrant further investigation.

Table 1 Hazard ratios for association of vascular calcification all-cause mortality (top). Demographics of rheumatoid arthritis subjects with and without radiographic vascular calcifications with unadjusted comparisons (bottom).

Lipid Control and Cardiovascular Risk for Patients with Rheumatoid Arthritis Compared with Matched Non-Rheumatoid Arthritis Patients.

J. An[1], E. Alemao[2], K. Reynolds[3], H. Kawabata[2], D. H. Solomon[4], K. P. Liao[4] and T. C. Cheetham[3]. [1]Western University of Health Sciences, Pomona, CA, [2]Bristol-Myers Squibb, Princeton, NJ, [3]Kaiser Permanente Southern California, Pasadena, CA, [4]Brigham and Women's Hospital, Boston, MA.

Background/Purpose: Lipid levels are known to be lower in patients with RA compared with the general population; however, differences in cardiovascular (CV) risk associated with lipid control between patients with RA and non-RA patients remain uncertain. The purpose of this study is to evaluate the association between low-density lipoprotein cholesterol (LDL) control and CV outcomes among RA and matched non-RA populations.

Methods: Between 01/01/2007 and 12/31/2011, adult patients with RA were identified within Kaiser Permanente Southern California. Two age- and sex-matched cohorts were identified as non-RA: 1) 1:4 matched general population, and 2) 1:1 matched osteoarthritis (OA) population. Individuals were followed from their index date until the first CV outcome (myocardial infarction, angina, stroke, transient ischemic attack, intermittent claudication, heart failure or CV disease death), end of enrollment or death from other causes. Univariate and multivariate Cox proportional hazard analyses were conducted for patients treated for dyslipidemia who had ≥1 LDL measurement during the follow-up period. LDL measures closest to the end of follow-up were used to define LDL control (mg/dL) stratified by CV risk.

Results: Cohort 1 consisted of 1522 patients with RA and 6511 matched patients from the general population; Cohort 2 had 1746 patients with RA and 2554 matched patients with OA. Median follow-up was 3.1 years for Cohort 1, and 4.0 years for Cohort 2. Mean (SD) age was 63.5 (10.2) years for both cohorts; there were 71.4% females in Cohort 1 and 75.8% in Cohort 2. In addition to dyslipidemia, 74.2% of patients with RA had hypertension, 40.9% had diabetes, 46.7% were obese, 10.5% were smokers, 41.3% had high CV risk, and 51.3% had medium CV risk. Traditional CV risk factors were higher in RA compared with general (Cohort 1) or OA populations (Cohort 2). Mean (SD) LDL levels (mg/dL) were 96.8 (32.7) for RA, 100.1 (35.1) for the general population, and 99.1 (34.3) for the OA population. The rate of LDL control was 78.7% for both the RA and general populations, and 80.0% for the OA population. Adjusting for age, sex, hypertension, antihypertensive medication use, smoking status, and diabetes, controlled LDL was associated with a 33% reduced CV risk compared with uncontrolled LDL in patients with RA (hazard ratio [HR] [95% CI] = 0.67 [0.46, 0.96] for Cohort 2). Controlled LDL was also associated with a reduced CV risk compared with uncontrolled LDL in the general population (HR = 0.72 [0.55, 0.95]). Similar HR results were found in the OA population; however, the association was not statistically significant (HR = 0.76 [0.53, 1.07]) (Table).

Table. Association between LDL Control and Cardiovascular Events for Patients with Treated Dyslipidemia

Cohort	Cohort 1 RA population N=1522		Cohort 2 RA population N=1746	
RA patients	HR (95% CI)	p-value	HR (95% CI)	p-value
LDL control (vs no control)*	0.72 (0.49, 1.07)	0.104	0.70 (0.49, 1.00)	0.053
LDL control (vs no control)μ	0.68 (0.46, 1.02)	0.060	0.67 (0.46, 0.96)	0.028
	General population N=6511		**Osteoarthritis population N=2554**	
Non-RA patients	**HR (95% CI)**	**p-value**	**HR (95% CI)**	**p-value**
LDL control (vs no control)*	**0.83 (0.63, 1.09)**	**0.179**	**0.93 (0.65, 1.31)**	**0.659**
LDL control (vs no control)μ	0.72 (0.55, 0.95)	0.021	0.76 (0.53, 1.07)	0.118

* Results from univariate analyses μ Results from multivariate analyses adjusting for age, sex, hypertension, antihypertensive medication use, smoking, diabetes

Conclusion: LDL control was associated with a reduced CV risk in the RA and matched general populations. These results suggest an important role for LDL control in preventing CV events among patients with RA as well as non-RA patients.

Is Rheumatoid Arthritis a Coronary Heart Disease Risk Equivalent, Similar to Diabetes?

Jie Zhang[1], Shuo Yang[2], Lang Chen[2], Fenglong Xie[2], Huifeng Yun[3], Paul M. Muntner[2], Emily Levitan[2], Monica Safford[2], Kenneth G. Saag[4], Jasvinder Singh[2] and Jeffrey R. Curtis[2]. [1]Univ. of Alabama at Birmingham, Birmingham, AL, [2]University of Alabama at Birmingham, Birmingham, AL, [3]University of Alabama at Birmingham School of Public Health, Birmingham, AL, [4]The University of Alabama at Birmingham, Birmingham, AL.

Background/Purpose: Recently cholesterol treatment guidelines recommend that diabetes (DM) should be considered a CVD risk equivalent to a history of coronary heart disease (CHD). Despite the well-recognized increased CVD risk in rheumatoid arthritis (RA) patients, the guidelines do not recommend that RA should be considered a CHD risk equivalent. We compared the incidence of hospitalized acute myocardial infarction (MI) among patients with DM alone, RA alone, both conditions and neither of them.

Methods: Using a mix of private and public health plans claims data from 2006 to 2010 with medical and pharmacy coverage; we identified 4 mutually exclusive cohorts: patients with 1) RA and DM; 2) RA only; 3) DM only; 4) Neither RA nor DM. Patients with prevalent CHD during a baseline period of ≥ 1 year were excluded. Acute MI was defined as ≥ 1 inpatient hospital claim with a discharge ICD-9 code in any position for 410.x (excluding 410.x2) and at least one overnight stay, unless the patient died. We compared the age- and gender-specific incidence rates (IRs) of acute MI across the four cohorts and calculated differences in IRs between select cohorts.

Results: We identified 1,070,212 eligible participants in our study. MI IRs were highest among adults with both RA and DM, followed by those with DM alone, with RA alone, and lowest in those without either condition. Findings were consistent for both sexes and across all age strata (Table). Among women 41 years of age or older, the absolute difference in IRs between the two cohorts peaked at 4.3 cases per 1,000 Person-Years (PYs) among those 71 or older. Among men, the peak difference (4.61 cases per 1,000 PYs) was observed among those 51–60 years of age. We found large increases in MI IR among RA patients if they were also diagnosed with DM, especially among women with the greatest difference (9.3 cases per 1,000 PYs) observed among women 51–60 years of age.

Conclusion: In this analysis, the incidence of MI was consistently lower in patients with RA alone than in those with DM alone, which does not support RA as a CHD risk equivalent. Our findings have important clinical implications in the treatment of hyperlipidemia for RA patients.

Table: Comparison of Age- and Gender-Specific MI Risk between Patients with RA, Diabetes (DM) and Both to Healthy Patients

	Both DM and RA		DM Only		RA Only		Neither DM Nor RA		Risk Difference

Exercise Is Associated with Protective Cardiovascular Risk Profile Including Increased HDL Particle Number in Patients with Rheumatoid Arthritis. Kevin Byram, Annette Oeser, MacRae F. Linton, Sergio Fazio, C. Michael Stein and Michelle Ormseth. Vanderbilt University, Nashville, TN.

Background/Purpose: Patients with rheumatoid arthritis (RA) have increased cardiovascular risk. In the general population, exercise improves several cardiovascular risk factors, including HDL cholesterol concentrations. Although exercise is known to improve quality of life measures in patients with RA, less is known about its effects on cardiovascular risk factors, particularly lipoprotein particle concentrations, which provide information not always concordant to that of lipoprotein cholesterol concentrations. Therefore, we examined the hypothesis that increased exercise is associated with beneficial effects on cardiovascular risk factors, including HDL particle concentration.

Methods: Patient-reported exercise outside of daily activities was quantified as metabolic equivalents measured in minutes per week (METmin/week), according to the 2011 Compendium of Physical Activities, in 165 patients with RA. Hypertension was defined as current use of antihypertensive agents or systolic blood pressure ≥140 mmHg and/or a diastolic pressure ≥90 mmHg. Insulin resistance was measured by the homeostasis model assessment of insulin resistance (HOMA). Standard lipid profiles were measured by our diagnostic clinical laboratory, whereas HDL and LDL particle concentrations were determined by nuclear magnetic resonance spectroscopy (LipoScience). The relationship between METmin/week and cardiovascular risk factors was assessed with Spearman correlation and with linear and logistic regression with adjustment for age, race and sex.

Results: The mean ± standard deviation [range] of exercise was 311 ± 786 METmin/week [0 – 7200 METmin/week]. Exercise was inversely associated with heart rate (P=0.02), waist-hip ratio (P=0.02), and systolic blood pressure (0.03), but not with the degree of insulin resistance (HOMA) or BMI. We found no significant association between exercise and LDL or HDL cholesterol concentrations. Exercise was positively associated with the concentration of both total and small HDL particles (P=0.003 and P=0.001, respectively), but not with LDL particle concentrations (Table). Those who exercised had 2.6 μmol/L greater HDL particle concentration (P=0.002) and 2.8 μmol/L greater small HDL particle concentration (P=0.001), after adjustment for age, race and sex.

Conclusion: The amount of self-reported exercise in patients with RA was independently associated with beneficial changes in several cardiovascular risk factors including heart rate, waist-hip ratio, systolic blood pressure and HDL particle concentration.

Table: Relationship between METmin/week and cardiovascular risk factors in patients with RA

	Spearman rho	P	Adjusted P value
Heart rate, bpm	−0.197	0.011	0.022
Systolic BP, mm Hg	−0.110	0.161	0.027

Frequency of Significant Infection in Patients with RA Following Initiation of Rituximab with up to 5 Years of Follow-up in a US Observational Study. Kenneth G. Saag[1], Kevin L. Winthrop[2], D. E. Furst[3], Kimberly Alexander[4], Angelika Jahreis[5], Carol Chung[6] and Kurt Oelke[7]. [1]The University of Alabama at Birmingham, Birmingham, AL, [2]Oregon Health & Science University, Portland, OR, [3]University of California at Los Angeles, Los Angeles, CA, [4]Genentech, Inc., South San Francisco, CA, [5]Genentech, South San Francisco, CA, [6]Genentech, Inc, South San Francisco, CA, [7]Rheumatic Disease Center, Glendale, WI.

Background/Purpose: Rituximab (RTX) is an approved treatment for rheumatoid arthritis (RA) in patients (pts) with an inadequate response to anti–TNF therapy (aTNF-IR). Long-term infection risk data of RTX use in real-world settings are limited. The objective of this study was to describe the frequency of significant infections in pts with RA initiating RTX in the US.

Methods: SUNSTONE was a prospective observational cohort study designed to evaluate the safety of RTX in TNF-IR RA pts in a real-world setting. Pts were evaluated and treated according to their physicians' standard practices and followed at visits every 6 months. Pts were followed for 5 years (regardless of RTX discontinuation or start of another biologic DMARD), until death, withdrawal of consent or loss to follow-up. Significant infections were defined as infections that meet FDA serious AE criteria or require IV antibiotics. For calculation of incidence rates (IRs), pts were censored at the time of first event, switch to another biologic DMARD, death, withdrawal of consent or loss to follow-up. IRs by year after RTX initiation and by RTX course are described. Course was defined as 2 × 1000-mg infusions separated by ≤21 days. Pts not treated according to this regimen were excluded from the course analysis. Among pts who switched to another biologic DMARD during follow-up, the IRs of significant infection before and after switch were also calculated. IR calculations after switch were censored at the time of first event, death, withdrawal of consent or loss to follow-up. IRs per 100 pt-yrs (PY) are reported.

Results: Overall, 938 pts (3778 PY) received RTX (82% F; median age, 58 y; median disease duration, 9 y; 72% RF+). Mean duration of follow-up was 4 y and mean number of RTX courses was 4; however, not all pts were treated following the labeled dose regimen. Four pts with insufficient information to calculate IRs were excluded. Significant infections were reported in 160 pts (17%), with an IR of 6.4 (95% CI, 5.5 to 7.4). IRs in 1-y increments following RTX initiation were 7.1 (95%CI: 5.5–9.2), 6.5 (95%CI: 4.8–8.7), 8.0 (95%CI: 5.9–10.9), 9.2 (95%CI: 6.6–12.7) and 7.0 (95%CI: 4.7–10.3) in years 0–1, 1–2, 2–3, 3–4, and 4–5, respectively. See table for IR and 95%CI by course; exposure is less than 100PY from Course 7 onward resulting in wide 95%CIs around IR estimates. Among 338 pts who switched to another biologic DMARD, IRs before and after switch were 4.6 (95% CI, 3.1 to 6.7) and 4.5 (95% CI, 3.3 to 6.2), respectively.

Conclusion: Data from SUNSTONE with up to 5 years of follow-up showed that risk of significant infection among pts with refractory RA that were treated with RTX after an inadequate response to an aTNF agent did not increase over time and with multiple courses. In addition, switch from RTX to another biologic DMARD was not associated with an increased risk of significant infection.

	Course 1 N = 859; PY = 676	Course 2 N = 558; PY = 459	Course 3 N = 378; PY = 282	Course 4 N = 281; PY = 186	Course 5 N = 212; PY = 143	Course 6 N = 158; PY = 100	Course 7 N = 115; PY = 73	Course 8 N = 83; PY = 46	Course 9 N = 57; PY = 28

The Risk of Cancer with Tumor Necrosis Factor Inhibitors in Patients Concomitantly Exposed to Non-Biological Immunosuppressants Differs According to the Indication. Layla Saliba[1], Guillaume Moulis[2], Malak Aboutaam[3], Grégory Pugnet[2], Vanessa Rousseau[1], Leila Chebane[1], Nadine Petitpain[4], Bernadette Baldin[5], Jean-Louis Montastruc[1] and Haleh Bagheri[1]. [1]Toulouse University Hospital, Clinical Pharmacology Department, University of Toulouse, Toulouse, France, [2]Toulouse University Hospital, Department of Internal Medicine, University of Toulouse, INSERM UMR 1027, Toulouse, France, [3]Reims University Hospital, Pharmacovigilance Regional Center, Reims, France, [4]Nancy University Hospital, Pharmacovigilance Regional Center, Nancy, France, [5]Nice University Hospital, Pharmacovigilance Regional Center, Nice, France.

Background/Purpose: The risk of cancer with TNF-a inhibitor (TNFi) in patients concomitantly exposed to non-biological immunosuppressants (NBIS) is highly debated in RA, AS and psoriasis/PsA. In contrast, it has been suggested that the excess risk of some lymphomas in IBD was due to NBIS exposure and not to add-on TNFi. The primary objective of this study was to detect a signal of an increased risk of cancer in patients treated with TNFi and NBIS compared with NBIS alone for these diseases. The secondary objective was to compare this risk between the different TNFi.

Methods: We conducted a disproportionality analysis (case/non-case study) in the French National PharmacoVigilance Database. Study population was all the reports of serious adverse drug reactions from 2000 to 2010 in patients treated with NBIS for labeled indications of TNFi. Cases were all the reports of cancer that occurred after a minimal exposure of three months to NBIS. Non-cases were all the other reports. We searched for exposure to TNFi in cases and non-cases, leading to Reporting Odds Ratio (ROR) calculations. The analyses were stratified on the condition and the type of cancer (blood and solid cancer, non-melanoma skin cancers – NMSCs, melanoma), and were adjusted on the age, the gender, the history of cancer, the type of NBIS and the year of reporting. Sensitivity analyses were carried out to detect event- or drug-related competition biases.

Results: Out of the 1,918 reports meeting the study population definition, 217 were cases (135 solid and 82 blood cancers). RA was the leading indication among the study population (n=1200), followed by IBD (n=422), psoriasis or PsA (n=126), and AS (n=92). Exposure to TNFi was found in 156 (72.7%) cases (infliximab, 48.9%, adalimumab, 28.8% and etanercept, 37.2%) and in 698 (43.0%) non-cases (infliximab, 63.5%, adalimumab, 18.8% and etanercept, 18.8%). A safety signal was found as regards the risk of cancer with exposure to both TNFi and NBIS compared with NBIS alone in RA (ROR: 5.43, 95%CI[3.52–8.38]). The signal was significant for every type of cancer, but was the most important for NMSCs (ROR: 20.17, 95%CI[2.49–163.36]). In contrast, no signal was found in AS, psoriasis/PsA and IBD, whatever the type of cancer. As regards the secondary objective, there was no difference between TNFis. Sensitivity analyses confirmed these results.

Conclusion: This study adds strong argument for an increased risk of cancer, and particularly NMSCs, in RA patients exposed to TNFi in addition to NBIS compared with NBIS alone. The signal seems similar with infliximab, adalimumab and etanercept. In contrast, it suggests that there is no signal in AS, psoriasis/PsA and IBD.

Rheumatoid Arthritis, Anti-Tumor Necrosis Factor Therapy, and Risk of Squamous Cell and Basal Cell Skin Cancer- a Nationwide Population Based Prospective Cohort Study from Sweden. Pauline Raaschou[1], Julia F Simard[2], Charlotte Asker-Hagelberg[3], Johan Askling[4] and the ARTIS Study group[5]. [1]Karolinska Institutet, Stockholm, Sweden, [2]Stanford School of Medicine, Stanford, CA, [3]Swedish Medical Products Agency, SE-751 03 Uppsala, Sweden, [4]Clinical Epidemiology Unit, Department of Medicine, Karolinska Institutet, Stockholm, Sweden, [5]Karolinska Institutet och Svensk Reumatologisk förening, Solna, Sweden.

Background/Purpose: There is a concern that tumor necrosis factor inhibitors (TNFi) may interplay with tumor biology and increase the risk of cancer, in particular cancer types already associated with states of immune perturbation, such as skin cancers. We therefore investigated the risk of first squamous cell (SCC) and basal cell (BCC) cancers in TNFi-treated rheumatoid arthritis (RA) compared to biologics-naïve RA, and also in biologics-naïve RA compared to the general population, taking several potential confounders into account.

Methods: Through register-linkages, we assembled a cohort of biologics-naïve patients with RA (n=54,450), one cohort of patients with RA starting TNFi-treatment as first biologic 1998–2011 (n=10,974), and a general population comparator cohort (matched 5:1 to the biologics-naïve RA-patients). Individuals with a history of organ transplantation and/or invasive malignancy were excluded. The primary outcome was defined as first in situ or invasive SCC (1998–2011), and first BCC (2004–2011) during follow-up. Hazard ratios (HR) were estimated adjusting for several potential confounders including invasive malignancy during follow-up, use of immuno-suppressive medications and history of non-melanoma skin cancer. We performed a series of sensitivity analyses using different definitions of the study population, risk window, and outcome.

Results: Comparing biologics-naïve RA to the general population, the HR of first in situ or invasive SCC in RA was 2.01 (95% CI 1.80–2.33). Based on 168 vs. 803 first invasive or in situ SCC, the adjusted HR was 1.20 (95% CI 0.96–1.51) comparing TNFi-treated to biologics-naïve RA. The HR of SCC was driven mainly by in situ lesions. Similarly, comparing biologics-naïve RA to the general population, the HR of first BCC was 1.22 (95% CI 1.23–1.34). Based on 169 vs. 1,439 first BCC, the adjusted HR was 1.01 (95% CI 0.85–1.21) comparing TNFi-treated to biologics-naïve RA.

Conclusion: RA (in the absence of TNFi-treatment) was associated with a doubled risk of SCC. TNFi-treatment was associated with a further 20% increase in the risk of in situ, but not invasive SCC. For BCC, RA (in the absence of TNFi treatment) was a much weaker risk factor, and TNFi treatment did not increased the risk of BCC. Whilst we cannot exclude surveillance bias as an explanation for our findings regarding SCC, the risks observed call for vigilance of skin lesions in RA, irrespective of treatment.

Table 1. Occurrence and hazard ratios (HR) with 95% confidence intervals (CI), of squamous cell cancer (SCC) in 10,974 TNFi-treated, compared to 41,031biologics-naïve Swedish rheumatoid arthritis (RA)-patients. Occurrence and hazard ratios (HR) with 95% confidence intervals (CI), of basal cell cancer (BCC) in 7,397 TNFi-treated, compared to 38,679 biologics-naïve Swedish RA-patients.

Squamous cell cancer	TNFi (n events/ person-years)	Biologics-naïve RA (n events/ person-years)	HR[1]	HR[2]
First during follow-up	168/66,010	803/221,081	1.24 (1.04–1.47)	1.20 (0.96–1.51)
Invasive	61/66,673	334/223,571	1.12 (0.84–1.50)	0.98 (0.71–1.35)
In situ	126/66,224	580/222,080	1.25 (1.03–1.53)	1.26 (1.02–1.57)
Basal cell cancer				
First during follow-up	169/29,432	1,439/184,441	1.14 (0.97–1.36)	1.01 (0.85–1.21)

HR[1] Stratified for sex, county and civil status. Adjusted for age
HR[2] Stratified for sex, county, civil status, and education level. Adjusted for age, country of birth, co-morbidities during follow-up (chronic obstructive pulmonary disease, psoriatic disease, any benign skin disease, non-melanoma skin cancer, malignant melanoma, all-site cancer, and joint surgery)solid organ transplantation, ever use of cyclosporine, cyclophosphamide or azathioprine.

Safety of TNF Inhibitor Therapy in Patients Who Have Had a Prior Malignancy. Seung-Hyeon Bae, Doo-Ho Lim, Soo Min Ahn, Seokchan Hong, Yong-Gil Kim, Chang-Keun Lee and Bin Yoo. University of Ulsan College of Medicine, Asan Medical Center, Seoul, South Korea.

Background/Purpose: A few is known about the effects of biologic therapy in patients with a history of a solid cancer. According to the 2012 updated American College of Rheumatology Recommendations, it is possible to start or resume any biologic agent in patients who have been treated for solid tumor (level of evidence C). But, there is no evidence in patients with history of a solid cancer within the past 5 years because of the lack of studies examining the risk of recurrent cancer in this subgroup. The purpose of this study was to explore the influence of TNF inhibitor (TNFi) therapy in patients with prior cancer treatment within the past 5 years.

Methods: The medical records of all patients (n=859) that received TNFi therapy at a single rheumatology clinic between June 2005 and May 2014 were retrospectively reviewed. Among them, data from patients who had a history of solid cancer treatment before TNFi therapy were collected and patient outcomes were evaluated especially for those who have been treated cancer within the last 5 years.

Results: Of 859 patients who underwent TNFi therapy, 22 patients (1 on infliximab, 11 on etanercept, 7 on adlimumab and 3 on golimumab) had a history of malignancy before initiating TNFi therapy for ankylosing spondylitis (AS) and rheumatoid arthritis (RA) (Table 1). The median AS, RA disease duration was 8 (3.75–12.25) years and median time to TNFi therapy after prior cancer treatment was 62.5 (21.25–140.25) months. Most common site of prior cancer is stomach (36.4%) and followed by thyroid, colorectum, liver, kidney, and breast. There was no recurrence of previous cancer during 40 (7.0–50.75) months of TNFi therapy. Especially, 10 patients started TNFi therapy before 5 years prior cancer treatment (Table 2). All of our 10 cases were limited in an early stage without distant metastasis. When they have been followed for 36 months, recurrence of cancer was not found.

Conclusion: Our results suggest that starting TNFi therapy in patients with history of solid cancer in locally limited stage is safe even less than 5 years after prior cancer treatment.

Table 1 Clinical characteristics of patients with prior cancer history when starting TNFi

Characteristics	Patients (n=22)
Age, mean(range), years	63 (41–81)

[1]Copenhagen University Hospital Gentofte, Hellerup, Denmark, [2]The Danish Cancer Society, Copenhagen, Denmark, [3]Copenhagen University Hospital Glostrup. On behalf of all departments of Rheumatology in Denmark., Glostrup, Denmark.

Background/Purpose: Recent studies have found that a high proportion of female rheumatoid arthritis (RA) patients are chronic carriers of high-risk HPV-strains and that these patients are at increased risk of high-grade cervical dysplasia (CD) and cervical cancer. There are uncertainties regarding the safe use of biological DMARDs (bDMARDs) in arthritis patients with premalignant conditions. The aim of the present study was to investigate the occurrence of premalignant lesions of the uterine cervix progressing to a more malignant stage or developing another HPV associated cancer in female RA, ankylosing spondylitis (AS) and psoriatic arthritis (PsA) patients treated with bDMARDs or conventional synthetic DMARDs (csDMARDs).

Methods: In this observational study, we used the nationwide Danish DANBIO Registry covering > 90% of rheumatologic patients treated with bDMARDs in routine care and also patients treated with csDMARDs have been registered since 2006. Patient data from RA, AS and PsA patients registered from 2000–2011 was linked with data from The Danish Cancer Registry. We specifically included patients with a history of mild, moderate and severe cervical dysplasias (CD) or carcinoma in situ (CIS) of the cervix, including both CD/CIS diagnosed before or after DANBIO entry. Patients were followed up for a cancer diagnosis or progression of the premalignant grading of the lesion from the date of diagnosis of CD/CIS of the cervix or first registration in DANBIO, whichever came latest. End of follow-up was date of diagnosis with cervical cancer or other HPV-associated cancer (vulvar, vaginal, anal or oropharyngeal cancer), other cancer diagnosis, death or end of 2011, whichever came first.

Results: We identified 905 arthritis patients with a history of CD or CIS. Of these, 806 were diagnosed with CD/CIS prior to DANBIO entry, while the remaining 99 were diagnosed during their time registered in DANBIO. Overall, 356 had ever been exposed to bDMARDs and 673 to csDMARDs of which 124 patients switched from csDMARD to bDMARD therapy and therefore contributed with person-years of observation in both csDMARD and bDMARD groups. The table shows the number of arthritis patients registered in DANBIO with a history of CD/CIS and characteristics of the RA patients. Only 1 of the 356 bDMARD exposed patients experienced malignant progression from CD to CIS of the cervix. None were diagnosed with cervical cancer or any other HPV-related cancer after DMARD treatment initiation during 2740 person years of observation.

Conclusion: Our findings suggest that DMARD – and bDMARD treatment in particular – has limited harmful effects on precancerous lesions of the uterine cervix in female arthritis patients, but more patients and longer follow-up are required to confirm these findings.

Table: Number of arthritis patients in DANBIO with a diagnosis of cervical dysplasia (CD) or carcinoma in situ of the cervix (CIS) and occurrence of malignant progression. Characteristics of RA patients at first registration according to ever biological DMARD (bDMARD) or conventional synthetic DMARD (csDMARD) exposure, respectively.[#]

Tofacitinib, an Oral Janus Kinase Inhibitor, in the Treatment of Rheumatoid Arthritis: Safety and Efficacy in Open-Label, Long-Term Extension up to 6 Years. J. Wollenhaupt[1], J. Silverfield[2], E.B. Lee[3], S.P. Wood[4], K. Terry[4], H. Nakamura[5], K. Kwok[6], A. Anisfeld[6], C. Nduaka[4], R. Riese[4] and L. Wang[4]. [1]Schoen-Klinik Hamburg-Eilbek Teaching Hospital of the University of Hamburg, Hamburg, Germany, [2]Healthpoint Medical Group, Tampa, FL, [3]Seoul National University, Seoul, South Korea, [4]Pfizer Inc, Groton, CT, [5]Pfizer Inc, Tokyo, Japan, [6]Pfizer Inc, New York, NY.

Background/Purpose: Tofacitinib is an oral Janus kinase inhibitor for the treatment of rheumatoid arthritis (RA). Here we report tofacitinib safety, tolerability, and durability of response through 72 months (mo) in long-term extension (LTE) studies.

Methods: Data were pooled from two open-label studies (NCT00413699 [ongoing; database unlocked as of April 2014 data cut-off] and NCT00661661) of patients (pts) with RA who participated in randomized Phase (P)1, P2, or P3 tofacitinib studies. Treatment was initiated with tofacitinib 5 or 10 mg BID as monotherapy or with background DMARDs; data from both doses ± background DMARDs were pooled. Baseline (BL) was that of P1, P2, or P3 studies for pts enrolling within 14 days of participation; for all other pts, BL was the start of the LTE study. Primary endpoints were adverse events (AEs) and laboratory safety data. Confirmed (2 sequential abnormalities) data are reported for decreased hemoglobin (HgB), absolute neutrophil counts, absolute lymphocyte counts, and increases >50% from BL in creatinine. Secondary endpoints included ACR responses, DAS28-4(ESR), and HAQ-DI. Safety data were included over 84 mo and efficacy data up to Mo 72 (limited pt numbers [n≤29] post-Mo 72 for efficacy).

Results: Overall, 4,858 pts were treated for a mean (maximum) duration of 918 (2,535) days. Total tofacitinib exposure was 12,359 pt-years (pt-y). In total, 1747 pts (36.0%) discontinued (AEs: 866 [17.8%]; insufficient clinical response: 133 [2.7%]). The most commonly reported classes of AEs were infections and infestations (63.4%), musculoskeletal/connective tissue disorders (33.9%), and GI disorders (29.9%). The most frequently reported individual AEs were nasopharyngitis (16.3%), upper respiratory tract infection (14.5%), and urinary tract infection (10.3%). Serious AEs (SAEs) were reported in 19.0% of pts with an incidence rate (IR) of 8.1 per 100 pt-y (95% CI 7.6, 8.7). Serious infection events (SIEs) were reported in 7.2% of pts with an IR of 2.9 per 100 pt-y (95% CI 2.6, 3.2). All malignancies excluding NMSC were reported in 2.4% of pts with an IR 1.0 per 100 pt-y (95% CI 0.8, 1.2). IRs for SAEs, SIEs and malignancies through Mo 84 did not increase compared with previously reported data through Mo 72. [1] Decreased Hgb (>2 g/dL change from BL, or Hgb <8 g/dL) was observed in 5.7% of pts. Increased aminotransferases (>3 × ULN) were observed in 4.7% (ALT) and 2.6% (AST) of pts. Moderate to severe neutropenia (absolute neutrophil count [ANC] 0.5–1.5 × 10^3/mm^3) was reported in 1.2% of pts; there were no cases of ANC <0.5 × 10^3/mm^3. Absolute lymphocyte counts <0.5 × 10^3/mm^3were reported in 1.1% of pts. Increases >50% from BL in creatinine were noted in 3.4% of pts. ACR20, ACR50, and ACR70 response rates for tofacitinib were sustained between Mo 1 (72.7%, 48.7%, and 29.0%, respectively) and Mo 72 (80.8%, 62.8%, and 37.2%, respectively). Mean DAS28-4(ESR) was 6.29 at BL, 3.74 at Mo 1, and 3.32 at Mo 72. Mean HAQ-DI score was 1.42 at BL, 0.81 at Mo 1, and 0.77 at Mo 72.

Conclusion: A consistent safety profile and sustained efficacy through 72 mo was observed in patients with RA receiving tofacitinib at either 5 or 10 mg BID in LTE studies.

Targeting Synovial Mast Cells in Spondyloarthritis: A Proof-of-Concept Study with the Tyrosine Kinase Inhibitor Nilotinib. Jacqueline E. Paramarta[1], Maureen C. Turina[1], Tanja F. Heijda[1], Iris C. Blijdorp[2], Troy Noordenbos[1], Nataliya Yeremenko[1] and Dominique L. Baeten[2]. [1]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands, [2]Department of Clinical Immunology and Rheumatology and Department of Experimental Immunology, Academic Medical Centre/University of Amsterdam, Amsterdam, Netherlands.

Background/Purpose: Immunopathological studies on synovitis recently identified the mast cell as potential novel therapeutic target in spondyloarthritis (SpA).[1] Mast cells can be targeted by inhibiting the signalling of c-Kit, which is one of the targets of the tyrosine kinase inhibitor nilotinib. The aim of this study was to evaluate the immunomodulating and clinical effects of nilotinib in the treatment of SpA.

Methods: 28 patients with active peripheral and/or axial SpA were included in a randomized, double-blind, placebo-controlled clinical trial. Patients were treated 1:1 with nilotinib or placebo for 12 weeks, followed by an open label extension for another 12 weeks. Paired synovial tissue biopsies, serum sampling and assessment of clinical symptoms were performed serially.

Results: In peripheral SpA (n=13) synovial inflammation was markedly reduced after 12 weeks of nilotinib treatment as evidenced by histopathology (decrease in number of infiltrating CD68+ and CD163+ macrophages and mast cells). Compared to placebo the mRNA expression of c-Kit as mast cell marker (p=0.037) and of pro-inflammatory cytokines such as IL-6 (p=0.024) were reduced. The improvement of synovial inflammation was paralleled by a decrease in serum biomarkers of inflammation such as C-reactive protein (CRP) from 9.2 (IQR 1.7–33.1) to 5.2 (IQR 1.7–25.1) mg/L (p=0.024) and calprotectin from 359.9 (IQR 183.3–484.9) to 287.9 (IQR 116.7–457.1) ng/mL (p=0.055). Also clinical parameters such as patient's global assessment of disease activity (week 0: 52 (IQR 43–65) vs week 12: 21 (IQR 0–51) mm; p=0.031) and Ankylosing Spondylitis Disease Activity Score (ASDAS) (week 0: 2.2 (IQR 1.2–3.0) vs week 12: 1.1 (IQR 0.7–2.4); p=0.031) showed improvement upon 12 weeks of nilotinib but not placebo treatment, and this improvement was further augmented at week 24. In sharp contrast to peripheral SpA, neither serum biomarkers of inflammation nor clinical parameters improved upon nilotinib treatment in axial SpA. During the trial one serious adverse event occurred, which was considered unrelated to the study drug. There were no unexpected safety signals in comparison with published large scale data on nilotinib in chronic myeloid leukemia (CML).

Conclusion: This proof-of-concept study supports the concept that mast cells can contribute to synovial inflammation in SpA and that tyrosine kinase inhibition targeting these cells has a biological and clinical immunomodulatory effect in peripheral but not axial SpA. These results support further clinical evaluation of nilotinib in larger clinical trials in pure peripheral SpA, as well as evaluation of other drugs targeting mast cells in SpA.

A Tailored Approach to Reduce Dose of Anti-TNF Drugs Is Equally Effective, but Substantially Less Costly Than Standard Dosing in Patients with Ankylosing Spondylitis over One Year: A Propensity Score-Matched Cohort Study.

Jakub Zavada[1], Michal Uher[2], Katarina Sisol[3], Sarka Forejtova[3], Katerina Jarosova[3], Herman F. Mann[4], Jiri Vencovsky[5] and Karel Pavelka[6]. [1]Charles University, Prague, Czech Republic, [2]Institute of Biostatistics and Analyses, Masaryk University, Brno, Czech Republic, [3]Institute of Rheumatology, Prague, Czech Republic, [4]Institute of Rheumatology and Department of Rheumatology, 1st Faculty of Medicine, Charles University, Prague, Prague, Czech Republic, [5]Institute of Rheumatology and Clinic of Rheumatology, 1st Faculty of Medicine, Charles University in Prague, Prague, Czech Republic, [6]Institute of Rheumatology, Praha, Czech Republic.

Background/Purpose: To compare effectiveness, safety and costs of standard versus individually tailored reduced doses of anti-TNF drugs in patients with Ankylosing Spondylitis (AS) after achieving low disease activity.

Methods: This was a single center prospective observational study performed within the national biologics registry. The anti-TNF dose tapering strategy was chosen by treating physicians, without pre-specified protocol. We used propensity score (PS) methodology to identify 2 cohorts of patients matched for relevant baseline characteristics (table 1) who were treated with either reduced (n=53) or standard (n=83) doses of TNF inhibitors. One year outcomes and costs of anti-TNF drugs were compared between both PS-matched cohorts.

Results: In the reduced dosing group the median dose of TNF inhibitor corresponded to 0.67, and 0.5 of the standard dose initially, and at 12 months resp., and 21% of patients required return to standard dosing regimen. The mean change per year in BASDAI, CRP, HAQ and BASFI, as well as QALY area under the curve were no different between both groups (table 2). The hazard ratio (95% confidence interval) of reduced versus standard dosing group for relapse and any adverse event was 1.46 (0.66; 3.19), and 0.56 (0.22; 1.44) resp. (Figure 1) Mean difference (95% confidence interval) in cost of anti-TNF drugs was −4214 (−4707; −3701) € per year of treatment in favor of reduced dosing strategy.

Conclusion: In AS patients after reaching low disease activity, a tailored approach to reduce doses of anti-TNF drugs produced similar clinical outcomes at 1 year, but was substantially less costly.

Safety and Efficacy of Certolizumab Pegol over 96 Weeks in Patients with Axial Spondyloarthritis, Including Ankylosing Spondylitis and Non-Radiographic Axial Spondyloarthritis.

Joachim Sieper[1], Martin Rudwaleit[2], Désirée M. van der Heijde[3], Walter P. Maksymowych[4], Maxime Dougados[5], Philip Mease[6], Jürgen Braun[7], Atul A. Deodhar[8], Bengt Hoepken[9], Tommi Nurminen[9] and Robert B. M. Landewé[10]. [1]Charité Universitätsmedizin Berlin, Berlin, Germany, [2]Endokrinologikum, Berlin, Germany, [3]Leiden University Medical Center, Leiden, Netherlands, [4]University of Alberta, Edmonton, AB, [5]Université Paris René Descartes and Hôpital Cochin, Paris, France, [6]Swedish Medical Center and University of Washington, Seattle, WA, [7]Ruhr-University Bochum, Herne, Germany, [8]Oregon Health and Sciences University, Portland, OR, [9]UCB Pharma, Monheim, Germany, [10]Amsterdam Rheumatology Center, Amsterdam, Netherlands.

Background/Purpose: Previous reports of RAPID-axSpA (NCT01087762) demonstrated efficacy and safety of certolizumab pegol (CZP) in patients (pts) with axial spondyloarthritis (axSpA) including pts with ankylosing spondylitis (AS) and pts with non-radiographic (nr-)axSpA to Week (Wk) 48. [1] Here, we report the clinical efficacy and safety of CZP in axSpA from a 96-wk interim data cut of RAPID-axSpA.

Methods: The RAPID-axSpA trial[1] is double-blind and placebo (PBO)-controlled to Wk24, dose-blind to Wk48 and open-label (OL) to Wk204. Pts fulfilled ASAS criteria and had active axSpA. Pts originally randomized to CZP (200mg Q2W or 400mg Q4W, following 400mg loading dose [LD] at Wks 0, 2, 4) continued on their assigned dose in the OL phase; PBO pts entering dose-blind phase were re-randomized to CZP LD followed by CZP 200mg Q2W or CZP 400mg Q4W after Wk24 or, for non-responders, after Wk16. We present efficacy data for all pts originally randomized to CZP (combined dose regimens). Outcome variables assessed included ASAS20/40 and BASDAI50 responses and ASAS PR, ASDAS, ASDAS ID, ASDAS MI, BASDAI, BASFI and BASMI-linear. Data are shown as observed case and with imputation (NRI for categorical measures; LOCF for continuous measures). Safety set consists of all pts treated with ≥1 dose of CZP to Wk96.

Results: 325 pts were randomized, of whom 218 received CZP from Wk0. Of CZP-randomized pts, 203 (93%) completed to Wk24, 191 (88%) to Wk48 and 174 (80%) to Wk96. The proportion of pts achieving ASAS20/40 and PR responses was maintained from Wk24 through to Wk96 (Figure). Improvements in all ASAS and ASDAS response measures, BASDAI, BASFI and BASMI-linear were maintained to Wk96 (Figure). Similar improvements were seen with both dosing regimens (data not shown) and in both AS and nr-axSpA pts. Rapid clinical improvements were also observed in pts originally randomized to PBO who switched to CZP at Wk16 or Wk24 (data not shown). In the safety set (N=315) total exposure to CZP was 486 pt-yrs. Adverse events (AEs) occurred in 279 pts (88.6%; event rate per 100 pt-yrs [ER/100PY]=360.3). The ER/100PY for serious AEs was 10.9, and for serious infections was 2.7, including 1 confirmed case of active tuberculosis. No deaths or malignancies were reported in the overall 96-wk period.

Conclusion: In RAPID-axSpA, improvements in both CZP dosing regimens observed over 24 wks in clinical efficacy and patient-reported outcomes were sustained throughout the dose-blind and OL study periods to Wk96. Similar sustained improvements were observed in both AS and nr-axSpA subpopulations. The safety profile was in line with that previously reported from the RAPID-axSpA trial, with no new safety signals observed with increased exposure.

Cancer Incidence in TNF Inhibitor Treated Patients with Axial Spondyloarthritis and Psoriatic Arthritis - a Study from the ARTIS and Danbio Registers.

Johan Askling[1], Lene Dreyer[2], Merete Lund Hetland[3], Lennart Jacobsson[4], Lars-Erik Kristensen[5], Bente Glintborg[6],. ARTIS and DANBIO study groups[7] and Karin Hellgren[1]. [1]Karolinska Institutet, Stockholm, Sweden, [2]Gentofte University Hospital, Hellreup, Denmark, [3]Glostrup University Hospital, Glostrup, Denmark, [4]Sahlgrenska Academy, Gothenburg, Sweden, [5]Lund University, Lund, Sweden, [6]Gentofte University Hospital, Gentofte, Denmark, [7]Karolinska Institutet, stockholm, Sweden.

Background/Purpose: Most studies of the safety profile of TNF inhibitors (TNFi) - in particular in relation to cancer risks - have been performed in patients with rheumatoid arthritis. Today, however, TNFi are widely used in patients with axial spondyloarthritis (AxSpA) and psoriatic arthritis (PsA), i.e., in populations with different age/sex distributions and with potentially different underlying risks for cancer. The aim of this study was to assess risks of overall and site-specific cancers in patients with AxSpA and PsA treated (vs. not) with TNFi, and to compare these risks to the risk in the general population. To do this we used pooled data from two Scandinavian national biologics registers and other population-based data-sources.

Methods: By linking data from the Swedish (ARTIS) and Danish (DANBIO) biologics registers, we assembled a cohort of 8,156 (ARTIS=4,901 and DANBIO=3,255; total person-years=29,011) patients with AxSpA (57%) and PsA (43%) that started a TNFi 2001–2010. From the Swedish National Patient Register we identified a national TNFi-naïve AxSpA/PsA comparator cohort (n=24,058, person-years=112,714), and a Swedish age- and sex matched general population comparator cohort (n=103,380, person-years=535,345). The first invasive cancer for each subject was identified through linkage with the nationwide Swedish and Danish Cancer Registers (2001–2010). Subjects with previous cancers were excluded in all three cohorts. Age- and sex-standardized incidence rates and relative risks (RR) were calculated for cancer overall, and for six specific cancer sites (lung-, colorectal-, female breast-, prostate cancer, malignant melanoma, and lymphoma).

Results: In total we identified 129 cancers among the TNFi treated patients, 744 in the TNFi –naïve cohort, and 3,259 in the general population comparator cohort. TNFi-naïve patients were not at increased cancer risk vs. the general population (RR=1.06), but displayed a lower risk for colorectal cancer (RR=0.70). Based on 129 incident cancers, TNFi treated patients did not have a higher risk of cancer (vs. TNFi-naïve patients), RR=0.80 (95% CI 0.66–0.98). Point estimates below 1 were noted for lung-, colorectal- and prostate cancer though only the latter reached statistical significance (Table).

Conclusion: Based on these nationwide clinical data from Sweden and Denmark, TNFi treatment in patients with AxSpA and PsA was not associated with any significantly increased risks of cancer overall, nor for the six most common cancer types. The tendency towards decreased risks for lung, and prostate cancer following TNFi treatment may reflect selection related to pre-treatment screening. Furthermore, we observed a decreased risk of colorectal cancer in AxSpA/PsA.

Table Age- and sex-adjusted relative risks (RR) of overall and site-specific cancers in patients with axial spondyloarthritis (AxSpA) and psoriatic arthritis (PsA) from ARTIS and DANBIO treated with TNFi (n=8,156, persons-years=29,011) versus a Swedish AxSpA/PsA comparator cohort (n=24,058, person-years=112,714) and a Swedish general population comparator cohort (n=103,340, person-years=535,345) from 2001 to 2010.

Golimumab Versus Pamidronate for the Treatment of Axial Spondyloarthropathy (SpA): A 48-Week Randomized Controlled Trial. Chi Chiu Mok, Angela Li, Kar Li Chan and Ling Yin Ho. Tuen Mun Hospital, Hong Kong, Hong Kong.

Background/Purpose: To compare the efficacy of golimumab(GLM) and pamidronate(PAM) in the treatment of SpA.

Methods: Inclusion criteria: (1) patients ≥18 years of age; (2) fulfills the 2009 ASAS classification criteria for axial SpA; (3) Active spondylitis defined by a BASDAI score of ≥4 (with spinal pain score ≥4), despite treatment with NSAIDs for ≥3 months. Exclusion criteria: (1) Hepatitis B/C carriers; (2) Biological treatment in the past year; (3) Major surgery within 8 weeks; (4) Active infection; (5) Pregnancy/lactation; (6) Contraindications to anti-TNF or bisphosphonates. Patients were randomized to receive GLM (50mg subcutaneously monthly) or PAM (60mg intravenously monthly) in a 2:1 ratio on top of existing therapies. Latent tuberculosis was screened and treated in the GLM arm. Assessment for clinical efficacy (BASDAI, BASFI, BASMI, ESR, CRP, ASDAS, VAS pain, global assessment, SF36) was performed at week 0,2,4,8,12,16,20,24,32,40 and 48. MRI of the spine and SIJ was performed at week 0, 24 and 48 and graded by the Spondyloarthritis Research Consortium of Canada (SPARCC) scoring system (SIJ score 0–72; spinal score 0–108). The primary efficacy end-point was the proportion of patients who achieved the ASAS20 response at week 48. Intra-group paired data over time were compared by the paired Students' t-test whereas inter-group differences were compared by ANCOVA with adjustment for baseline values.

Results: 30 patients were recruited (83% men; age 33.4±10.9 years; disease duration 4.4±3.4 years) – 20 assigned to GLM and 10 assigned to PAM. Baseline demographic and clinical characteristics were not significant different between the two arms, except for a non-significantly higher mean ASDAS (CRP) (4.07±0.77 vs 3.70±0.65) and SIJ SPARCC (15.8±17.7 vs 7.8±5.93) score in GLM-treated patients. At week 48, a higher proportion of patients achieved ASAS20 (50% vs 20%; p=0.23) and ASAS40 (35% vs 0%; p=0.04) responses in the GLM compared to the PAM group. The ASDAS, BASDAI, BASFI, CRP and ESR levels significantly improved with GLM treatment but not with PAM. Interestingly, patient reported outcomes such as pain score and SF36 improved significantly in both treatment groups. In patients treated with GLM, the SPARCC SIJ (15.8±17.7 to 3.80±5.19; p<0.01) and spine (11.4±10.8 to 3.56±5.65; p<0.01) scores at week 48 decreased significantly compared to baseline. However, there was only a modest but non-significant reduction in the corresponding MRI scores observed in PAM-treated patients. There was no serious adverse events (SAEs) reported and the frequency of any adverse events (AEs) was not significantly different between the two arms. Minor upper respiratory infection (URI) was the commonest AE (30%), followed by dyspepsia (10%) and deranged liver function (10%) in GLM-treated patients. In patients treated with PAM, the commonest AE was post-infusion fever / myalgia / headache (30%), followed by dyspepsia (10%), phlebitis (10%) and minor URI symptoms (10%).

Conclusion: In patients with axial SpA, GLM was more effective than PAM in reducing clinical disease activity and MRI spinal / SIJ inflammation. PAM led to improvement in subjective pain and quality of life but did not have significant effects on MRI inflammation, CRP or ESR.

Active and Structural Lesions on MRI of the Sacroiliac Joints Predict Major Clinical Responses in Patients with Non-Radiographic Axial Spondyloarthritis Treated with Etanercept. W. P. Maksymowych[1], S. Wichuk[1], H. Jones[2], A. Szumski[2], L. Marshall[2], J. Bukowski[2] and R. G. Lambert[1]. [1]University of Alberta, Edmonton, AB, [2]Pfizer Inc., Collegeville, PA.

Background/Purpose: Previous studies evaluating predictors of major clinical response in patients with non-radiographic axial SpA (nr-axSpA) receiving treatment with anti-TNF agents have been limited by the heterogeneity of patients recruited according to classification criteria and/or disease duration. We aimed to assess the predictive capacity of active and structural lesions on MRI of the sacroiliac joints (SIJ) in a cohort of patients selected according to objective measures of inflammation and limited duration of disease.

Methods: Patients had axial SpA per the Assessment of SpondyloArthritis (ASAS) classification criteria, but did not meet modified NY radiographic criteria. Patients had symptoms for >3 months and <5 years, Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) ≥4, and failed ≥2 NSAIDs. Patients were randomly assigned to etanercept 50 mg/week or placebo, then after 12 weeks, all patients received open-label etanercept 50 mg/week. Clinical and health outcomes were assessed throughout the study, and MRI of the SIJ and spine was performed by two central readers at baseline, weeks 12 and 48 to assess bone marrow edema (BME) using the Spondyloarthritis Research Consortium of Canada (SPARCC) score. Additionally, a post-hoc analysis was conducted to score structural lesions using the SPARCC SIJ structural method (SSS), which assesses fat metaplasia, erosion, backfill, and ankylosis on T1-weighted spin echo (T1WSE) MRI. Two independent readers scored baseline and 48 week T1WSE MRI scans from 187 cases blinded to patients and short tau inversion recovery (STIR) MRI scans. Mean scores of the readers were used. Baseline high sensitivity CRP (hsCRP) levels, SPARCC MRI inflammation and SSS erosion scores were analyzed using logistic models of week 48 ASAS40 and ASDAS major improvement (ASDAS MI change ≥2.0), adjusted for treatment.

Results: Mean (SD) age was 32 (7.8) years, 60.5% were male, and mean (SD) duration of disease symptoms was 2.5 (1.8) years. A total of 73% of patients were human leukocyte antigen B27 (HLA-B27) positive and 81% met the ASAS MRI imaging criteria at baseline. Baseline CRP, SPARCC SIJ inflammation, and SSS erosion scores, but not fat metaplasia, backfill, or ankylosis were significant predictors of both ASAS40 and ASDAS MI responses at week 48 in both last observation carried forward and observational data analyses (see table). The higher the baseline value the greater the likelihood of response.

Table: Logistic Models of week 48 ASAS40 or ASDAS MI for each of the baseline SSS components, adjusted for treatment

Week 48 Outcome	Baseline Predictor	Adjusted Odds Ratio (95% CI)	P-value
ASAS40, LOCF	CRP	1.05 (1.02,1.09)	0.0042
ASAS40, LOCF	SSS Erosion Score	1.09 (1.00,1.19)	0.0432
ASAS40, LOCF	SPARCC SIJ	1.06 (1.02,1.09)	0.0006
ASAS40, OC	CRP	1.05 (1.01,1.09	0.0110
ASAS40, OC	SSS Erosion Score	1.09 (1.00,1.19)	0.0412
ASAS40, OC	SPARCC SIJ	1.05 (1.01,1.08)	0.0057
ASDAS MI, LOCF	CRP	1.17 (1.11,1.24)	<0.0001
ASDAS MI, LOCF	SSS Erosion Score	1.11 (1.03,1.21)	0.0099
ASDAS MI, LOCF	SPARCC SIJ	1.07 (1.04,1.10)	<0.0001
ASDAS MI, OC	CRP	1.15 (1.09,1.22)	<0.0001
ASDAS MI, OC	SSS Erosion Score	1.12 (1.03,1.21)	0.0088
ASDAS MI, OC	SPARCC SIJ	1.07 (1.04,1.11)	<0.0001

LOCF=last observation carried forward, OC=observed case, CI=confidence interval

Conclusion: The presence of objective manifestations of active disease as indicated by CRP and inflammatory or erosive lesions on MRI prior to the start of anti-TNF therapy has predictive capacity for major treatment responses.

A Pathogenic Role for the Gut Microbiota in Murine Antiphospholipid Syndrome and Lupus. Silvio M. Vieira, Andrew Yu, Michael Hiltesperger, Odelya E. Pagovich, Eleni Tiniakou, William Ruff, John Sterpka and Martin Kriegel. Yale School of Medicine, New Haven, CT.

Background/Purpose: The etiology of lupus-associated antiphospholipid syndrome (APS) is unknown but microbial triggers have been implicated in transient antiphospholipid antibody production in both mice and humans. We hypothesize that a constant trigger of autoreactivity lies within the gut microbiome and tested if persistent reactivity to β_2-glycoprotein I (β_2GPI) and mortality in the spontaneous (NZWxBXSB)F_1 model of lupus-associated APS are sustained by specific members of the gut microbiota.

Methods: (NZWxBXSB)F_1 hybrid male mice were treated orally with combined or single antibiotics (vancomycin, metronidazole, neomycin and ampicillin) targeting different microbial community structures starting at 6 weeks of age. Female TLR7 transgenic C57BL/6 mice were similarly treated with broad-spectrum antibiotics. Sera, urine and fecal pellets were collected longitudinally and analysed for anti-β_2GPI titers, proteinuria from lupus nephritis and eubacterial 16S rDNA load by real-time PCR. H&E slides were prepared from tissues for histologic analysis. Splenocyte proliferation was assessed by [^{3}H]-thymidine incorporation.

Results: Not only broad-spectrum antibiotics but also vancomycin or ampicillin alone lowered anti-β_2GPI antibodies at 4 months of age (n=5 each; p=0.014) and protected mice from deaths due to coronary microthrombi, pulmonary emboli or strokes (n=5 each; p=0.005). Proliferation of splenocytes to the autoantigen (using recombinant β_2GPI) was diminished compared to anti-CD3-induced proliferation (n=8 each; p=0.0012). Proteinuria due to lupus nephritis was also suppressed in microbiota-depleted mice (n=8 each; p=0.026). Furthermore, mortality from systemic lupus-like disease was significantly reduced in lupus-prone TLR7 transgenic C57BL/6 mice treated with antibiotics (n=9–10 each; p=0.0154).

Conclusion: Vancomycin-sensitive gut commensals are necessary for anti-β_2GPI-antibody-induced thrombembolic deaths. Broad-spectrum antibiotics selectively reduced T cell proliferation to β_2GPI but not anti-CD3, suggesting antigen-specific effects of the gut microbiota. These results support that gram-positive members of the gut microbiota are fundamentally involved in the pathogenesis of APS. The gut microbiota modulate also lupus pathogenesis in two spontaneous models, suggesting that not only APS but also SLE is dependent on the gut microbial community composition we are currently defining to identify novel biomarkers and treatment targets.

Amelioration of Systemic Lupus Erythematosus (SLE) in NZM 2328 Mice By Selectively Blocking Engagement of Two BAFF Receptors. Chaim O. Jacob, Ning Yu and William Stohl. University of Southern California Keck School of Medicine, Los Angeles, CA.

Background/Purpose: BAFF, a potent B cell survival factor, is an established therapeutic target in SLE, with the anti-BAFF antibody, belimumab, being FDA-approved for the treatment of SLE. Nevertheless, large percentages of SLE patients failed to respond to belimumab in the seminal phase-III trials, pointing to an ongoing large unmet therapeutic need. Inhibition of one or more of the individual BAFF receptors (BCMA, TACI, BR3) may, in principle, be more efficacious than global inhibition of BAFF. Indeed, whereas the contribution of BAFF to SLE has been the subject of substantial investigation, the contributions of the individual BAFF receptors to SLE have undergone only limited investigation to date. In the SLE-prone NZM 2328 (NZM) mouse model, NZM mice singly-deficient in any BAFF receptor develop clinical SLE with a time course indistinguishable from that of NZM wild-type (WT) mice, demonstrating sufficient functional redundancy among the BAFF receptors to render any single BAFF receptor dispensable to the development of SLE in these mice. To determine whether elimination of combinations of BAFF receptors could be clinically beneficial, we examined the effect of eliminating discrete pairs of BAFF receptors on the development of disease in NZM mice.

Methods: NZM mice singly-deficient in BCMA, TACI, and BR3 were intercrossed to yield NZM mice deficient two BAFF receptors (NZM.*Br3*$^{-/-}$.*Bcma*$^{-/-}$, NZM.*Br3*$^{-/-}$.*Taci*$^{-/-}$, and NZM.*Bcma*$^{-/-}$.*Taci*$^{-/-}$). These mice were evaluated for BAFF receptor expression and lymphocyte phenotype by flow cytometry, for renal immunopathology by immunofluorescence and histopathology, and for clinical disease by assessment of proteinuria (≥3+ by dipstick) and death.

Results: The only BAFF receptor expressed by NZM.*Br3*$^{-/-}$.*Bcma*$^{-/-}$ mice is TACI; the only BAFF receptor expressed by NZM.*Br3*$^{-/-}$.*Taci*$^{-/-}$ mice is BCMA; and the only BAFF receptor expressed by NZM.*Bcma*$^{-/-}$.*Taci*$^{-/-}$ mice is BR3. All B cell subsets are reduced in NZM.*Br3*$^{-/-}$.*Bcma*$^{-/-}$ and NZM.*Br3*$^{-/-}$.*Taci*$^{-/-}$ mice but are increased in NZM.*Bcma*$^{-/-}$.*Taci*$^{-/-}$ mice. All T cell subsets, other than naive CD4$^+$ cells, are reduced in NZM.*Br3*$^{-/-}$.*Taci*$^{-/-}$ mice but are increased in NZM.*Bcma*$^{-/-}$.*Taci*$^{-/-}$ mice. CD4$^+$ memory cells are reduced in NZM.*Br3*$^{-/-}$.*Bcma*$^{-/-}$ mice. Renal immunopathology and clinical disease are significantly delayed and attenuated in NZM.*Br3*$^{-/-}$.*Bcma*$^{-/-}$ and NZM.*Br3*$^{-/-}$.*Taci*$^{-/-}$ mice but are significantly accelerated in NZM.*Bcma*$^{-/-}$.*Taci*$^{-/-}$ mice (Figure 1).

Conclusion: Elimination of both BR3 and TACI (while retaining BCMA) or both BR3 and BCMA (while retaining TACI) markedly inhibits development of SLE in NZM mice. By extension, selective pharmacologic targeting of BR3 + TACI (while preserving BCMA engagement) or BR3 + BCMA (while preserving TACI engagement) may represent a successful therapeutic approach in human SLE.

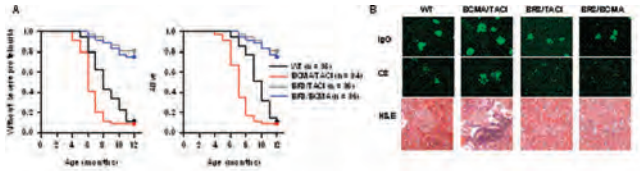

Figure 1. Clinical disease and renal immunopathology among NZM mice deficient in two BAFF receptors. Panel A: WT (n = 35, black lines), BCMA/TACI (n = 34, red lines), BR3/TACI (n = 36, gray lines), and BR3/BCMA (n = 36,blue lines) mice were monitored for 12 months for development of severe proteinuria (left) and survival (right). Data are plotted as the fraction of mice over time that did not develop severe proteinuria (left) or remained alive (right). Panel B: Kidney sections from 6- to 7-month-old NZM WT, BCMA/TACI, BR3/TACI, and BR3/BCMA mice were stained for IgG immunofluorescence (top row) or C3 immunofluorescence (middle row) or with hematoxylin and eosin (H&E) for histologic evaluation. Original magnification 200X.

ABT-199, a Potent and Selective BCL-2 Inhibitor, Prevents Lupus Nephritis in the Spontaneous NZB/W F1 Mouse Model By Depleting Selective Lymphocyte Populations While Sparing Platelets. Li Chun Wang[1], Stuart Perper[1], Annette Schwartz[1], Christian Goess[1], Liz O'connor[1], Dawna Hartman[1], Candace Graff[1], Andrew Souers[2], Joel Leverson[2], Steven Elmore[2] and Lisa Olson[1]. [1]AbbVie Inc, AbbVie Bioresearch Center, Worcester, MA, [2]AbbVie Inc, North Chicago, IL.

Background/Purpose: Proteins in the BCL-2 family are key regulators of apoptosis, or programmed cell death. Navitoclax, a selective inhibitor of both BCL-2 and BCL-X(L) demonstrated efficacy in the IFN-α induced lupus model in NZB/W F1 mice suggesting that dysregulation of this pathway is operative in lupus disease. However, thrombocytopenia caused by BCL-X(L) inhibition limits the chronic use of this therapeutic agent. We have conducted studies to evaluate a highly potent and orally available BCL-2-selective inhibitor, ABT-199, for efficacy and mechanism of action in the spontaneous NZB/W F1 mouse model.

Methods: 26 week old NZB/W F1 mice were treated daily for 24 weeks with vehicle or ABT-199. Proteinuria and survival data are presented as Kaplan-Meyer survival curves. Changes in lymphocytes and platelets in peripheral blood were assessed by Celldyn 3700 blood analyzer. Renal pathology was evaluated by a board certified pathologist. IgG deposition and changes in leukocyte subsets in the kidney were evaluated by immunohistochemistry. Circulating anti-dsDNA antibody levels were determined using a semi-quantitative ELISA assay. In a separate study NZB/W F1 mice were treated daily with vehicle or ABT-199 at 30mg/kg for 16 weeks, leukocyte subsets in spleen, kidney and bone marrow were analyzed by flow cytometry.

Results: ABT-199 treatment dose-dependently reduced the incidence of severe proteinuria compared to vehicle control and conferred 100% survival at the higher doses in the spontaneous NZB/W F1 lupus model. Treatment with ABT-199 also resulted in attenuated glomerulonephritis, tubular dilatation and IgG deposition in the kidney. ABT-199 treatment resulted in reductions in numbers of B220+, CD3+, F4/80+ and CD138+ cells in the kidneys compared with vehicle-treated mice. Consistent with its BCL-2 selectivity profile, ABT-199 mediated efficacy in NZB/WF1 mice correlated with a dose-dependent reduction of lymphocytes in peripheral blood (45% reduction for ABT-199 11mg/kg vs. vehicle; 70% reduction for ABT-199 100 mg/kg vs. vehicle) with no effect on platelet numbers. ABT-199 also demonstrated a significant reduction in the numbers of splenic T cells (CD4+, CD8+), B cells (transitional 2, germinal center, and mature). Interestingly, other B cell subsets (transitional 1, marginal zone, and B1) were largely unaltered. ABT-199 did not impair early B cell development or the number of CD138+ long-lived plasma cells in the bone marrow. These data were consistent with the unaltered anti-dsDNA titers in these animals.

Conclusion: Treatment of spontaneous lupus in NZB/W F1 mice with the BCL-2 selective inhibitor ABT-199 resulted in preservation of renal function and complete protection against severe proteinuria and mortality. ABT-199 treatment resulted in lymphopenia and a reduction of cell infiltration into the kidney while sparing circulating platelets. Splenic marginal zone B cells, the first line of defense against blood-borne pathogens, were resistant to ABT-199. Taken together, these data underscore the essential role of BCL-2 in the pathogenesis of lupus and support a role for BCL-2 selective inhibition in the treatment of autoimmunity.

TGF-β3-Producing CD4$^+$CD25$^-$LAG3$^+$ Regulatory T Cells Control B Cell Responses. Tomohisa Okamura[1], Kaoru Morita[1], Mariko Inoue[1], Toshihiko Komai[1], Yukiko Iwasaki[1], Shuji Sumitomo[1], Shinichiro Nakachi[1], Hirofumi Shoda[2], Keishi Fujio[2] and Kazuhiko Yamamoto[1]. [1]Graduate School of Medicine, the University of Tokyo, Tokyo, Japan, [2]The University of Tokyo, Tokyo, Japan.

Background/Purpose: Systemic lupus erythematosus (SLE) is an autoimmune disease characterized by autoantibody production and associated with a wide range of clinical manifestations. Recent case-control association study suggests that polymorphisms in the early growth response gene-2 (*EGR2*), a zinc-finger transcription factor, influence SLE susceptibility in humans. In line with the observation, T-cell-specific Egr-2-deficient mice show lupus-like autoimmune disease. We previously described CD4$^+$CD25$^-$Foxp3$^-$ regulatory T cells (Treg) that characteristically express both lymphocyte activation gene 3 (LAG3, CD223) and Egr2 (hereinafter referred to as 'LAG3$^+$ Treg'). Therefore, we have examined whether LAG3$^+$ Treg suppress the development of follicular helper T cell (T_{FH}) and germinal center B cell (GCB), antibody production, and disease progression in lupus-prone MRL-*Fas*$^{lpr/lpr}$ (MRL/*lpr*) mice.

Methods: B cells from C57BL/6 (B6) mice and helper T (Th) cells from OT-II mice were injected i.v. into Rag1KO mice in combination with or without LAG3$^+$ Treg from B6, Egr2 conditional knockout (CKO) (*Egr2*$^{fl/fl}$ CD4-*Cre*$^+$), or Fas-mutated B6/*lpr* mice. Mice were subsequently immunized with NP-OVA/alum 24 hr after the cell transfer. Mice were re-immunized with NP-OVA/alum 14 days after the first immunization. Serum anti-NP antibody levels were analyzed by ELISA, and splenocytes were analyzed by FACS 7 days after the re-immunization. To examine the therapeutic effects of LAG3$^+$ Treg in lupus-prone mice, 8-week-old MRL/*lpr* mice were randomly assigned to specific treatment groups. Ten-week-old MRL/*lpr* mice in the treatment group were injected i.v. with LAG3$^+$ Treg, CD4$^+$CD25$^+$Treg, or naïve T cells obtained from MRL/+ mice. Mice were sacrificed at 18 weeks of age to examine pathological alterations. Anti-ds DNA antibodies were measured by ELISA.

Results: Transfer of LAG3$^+$ Treg from wild type (WT) mice, but not Egr2 CKO or B6/*lpr* mice, significantly suppressed NP-specific antibody responses and the development of GCB and T_{FH} in Rag1KO mice transferred with B cells and OT-II Th cells. Interestingly, LAG3$^+$ Treg produce high amounts of transforming growth factor-β3 (TGF-β3) in an Egr2- and Fas-dependent manner. Treatment with a TGF-β3 or FasL blocking antibody cancelled the suppressive activity of WT LAG3$^+$ Treg. Adoptive transfer of LAG3$^+$ Treg from control MRL/+ mice significantly suppressed the progression of nephritis and autoantibody production in MRL/*lpr* mice. In contrast, CD4$^+$CD25$^+$ Treg and naïve T cells from MRL/+ mice exhibited no significant therapeutic effect upon transfer to MRL/*lpr* mice. TGF-β3-blockade also abrogated the therapeutic effects of MRL/+ LAG3$^+$ Treg in MRL/*lpr* mice.

Conclusion: These results clarified the molecular basis underlying TGF-β3-producing LAG3$^+$ Treg-mediated B cell regulation, which indicated that LAG3$^+$ Treg may be a suitable target for immune manipulation in autoantibody-mediated autoimmune diseases, including SLE.

Inhibition of G Protein $\beta\gamma$ Signaling Inhibits Nephritis in Lupus Prone Mice. Teresa Owen, Javier Rangel-Moreno, Jesi To, Bruce Goldman, Alan Smrcka and Jennifer H. Anolik. University of Rochester, Rochester, NY.

Background/Purpose: G protein-coupled receptors (GPCRs), including chemokine receptors on leukocytes, signal through G protein G$\beta\gamma$ subunits. An important target of G$\beta\gamma$ is phosphoinositide 3 kinase γ (PI3Kγ), a major isoform of PI3K whose receptor-dependent activation relies primarily on the G$\beta\gamma$ subunit. We hypothesized that G$\beta\gamma$ inhibition may be an effective treatment for lupus as it will prevent PI3Kγ activation which is upstream of T and B cell survival and the migration and activation of innate immune cells. Here, we evaluated the effects of gallein, a small molecule novel G$\beta\gamma$ inhibitory compound (Lehmann 2008, Mol Pharmacol 73: 410), in lupus prone mice.

Methods: 18 week old NZB/NZW mice were treated daily with 20 mg/kg or 35 mg/kg gallein (intraperitoneal injection) or vehicle (n=8 per group) for 15 weeks. For therapeutic intervention, mice with established disease (26 weeks old) were treated for 4 weeks with gallein at 35 mg/kg. Lymphocytes were enumerated by flow cytometry, auto-reactive antibody secreting cells (ASC) were quantitated by ELISpot, kidney inflammation was evaluated by histology (H&E, immunofluorescence), and renal function was assessed by monitoring changes in proteinuria. To determine the effect of gallein on cell migration, BM neutrophils or Jurkat T cells were stimulated in the presence of fMLP (250nM) or CXCL2 (30 or 100 ng/ml).

Results: In a prevention model, gallein therapy significantly abrogated the progression of proteinuria (35 mg/kg: p=0.0001, 20mg/kg p=0.0116). There was a significant dose dependent reduction in the number of effector T cells (20 mg/kg: p=0.0495, 35 mg/kg: p=0.0001) and central memory T cells (35 mg/kg: p=0.0029) in spleens of lupus prone mice. Mice treated with a high dose of gallein (35 mg/kg) had a significant reduction in the number of T follicular helper cells (p=0.0092) and germinal center B cells (p=0.0411). Although auto-reactive IgG ASC and dsDNA specific ASC were not reduced in the spleen, mice treated with gallein (35 mg/kg) had a reduction in IgG$^+$ and dsDNA$^+$ ASC in the BM (p=0.0029 and 0.0571). Strikingly, both doses of gallein caused a marked reduction in the number of dsDNA$^+$ ASC in the kidneys (20 mg/kg: p=0.0103, 35 mg/kg: p=0.0308). Treated mice also had a significant reduction in glomerular, interstitial inflammation (p=0.01 and 0.03 respectively), perivascular inflammation (35 mg/kg: p<0.0001), and IgG deposition. Treatment of mice with established disease also resulted in a significant reduction in the numbers of IgG$^+$ (p=0.0173) and dsDNA$^+$ASCs (p=0.0031) in the kidneys and reduced proteinuria (p=0.0236). Gallein inhibited the migration of WT murine neutrophils and cultured Jurkat T cells in response to fMLP and CXCL12, respectively. Similarly, in vivo administration of gallein in NZB/NZW mice resulted in a less efficient migratory response of BM isolated neutrophils in response to CXCL2.

Conclusion: These results suggest that G$\beta\gamma$ inhibition with gallein may modulate the generation of PCs in GC reactions as well as alter the kidney inflammatory milieu and PC survival niche in lupus, possibly by influencing the influx and function of inflammatory cells.

Ultraviolet B Generates Type 1 Interferon and Induces Autoantibody-Mediated Disease in a Mouse Model of Cutaneous Lupus. Clayton Sontheimer and Keith B. Elkon. University of Washington, Seattle, WA.

Background/Purpose: Photosensitivity is a common symptom in patients with systemic lupus erythematosus (SLE) and lupus skin lesions often contain plasmacytoid dendritic cells (pDC). The mechanisms linking ultraviolet (UV) light to inflammation and cutaneous flares is not well understood. While *in vitro* experiments have suggested that UV-induced apoptosis exposes lupus-specific nuclear antigens and immune complex mediated inflammation, this has not been shown *in vivo*. Here, we asked whether, and under what conditions, UVB-induced inflammation could induce Type I interferon (IFN-I) and the roles of pDCs and also autoantibodies in cutaneous lupus.

Methods: Shaved C57BL/6 (B6), IFNAR KO, BDCA2 DTR, and huFcgR2a transgenic mice were irradiated with narrowband UVB at 100 mJ/cm^2/day for 5 consecutive days. To induce interface dermatitis, shaved and depilated mice were subject to 15 strokes of tape stripping using medical tape (3M). Serial punch biopsies (6 mm) were obtained at 3, 24, and 72 hrs following UVB exposure or tape stripping. PDCs were detected in enzyme

digested skin samples by flow cytometry (CD45+, Ly6C+, PDCA1+, CD11c+, Siglec H+). Skin samples were examined for mRNA expression by QPCR of pro-inflammatory cytokines and Interferon Stimulated Genes (ISG). mRNA fold change was calculated by comparison with non-irradiated control mice. In experiments with huFcgR2a Tg mice, mice were irradiated as above but injected i.p. at the time of the final UVB exposure with purified immunoglobulin pooled from human lupus patients and the skin was examined by immunofluorescence for the presence of human IgG.

Results: Whereas tape stripping induced a robust ISG response associated with the presence of pDC in the skin, repeated UVB exposure induced a more modest IFN-I skin response with bimodal peaks at 3 and 72 hrs when compared to control mice ($p<0.05$, $n=20$). UVB-irradiated IFNAR KO mice had increased levels of pro-inflammatory cytokines TNFα and IL-6 at ($p<0.01$ at 3 and 24 hr time points, $n=12–13$) and had increased levels of inflammation by visual scoring suggesting a protective role for IFN-I. Interestingly, pDCs did not appear to be the source of IFN following UVB as pDC-depleted BDCA2 DTR mice maintained moderate expression of ISGs. Immunoglobulin from human lupus patients, but not IVIG, localized to the skin at the dermal/epidermal junction following UVB of FcgR2A transgenic and wild-type mice, but FcgR2a signaling was required for cellular uptake and enhanced Type 1 IFN signaling ($p<0.05$, $n=5–9$).

Conclusion: In the normal host, repeated doses of UVB induce a protective, pDC-independent Type1 IFN response in the skin that attenuates pro-inflammatory signals and limits tissue damage. In contrast, in situations associated with the presence of autoantibodies as occurs in lupus, the antibodies bind to UVB-exposed antigen, deposit in the skin and require Fcgr2a-mediated uptake to produce enhanced expression of IFN-I. This novel FcgR2a mouse model of cutaneous lupus establishes the role of UVB in exposing otherwise sequestered nuclear antigens and in facilitating immune-complex mediated skin disease in lupus.

Risk Factors for Changes in Subclinical Atherosclerosis As Measured By Carotid Intima Media Thickness (IMT) and Plaque over 5 Years in Women with Systemic Lupus Erythematosus (SLE). Apinya Lertratanakul[1], Peggy W. Wu[1], Alan Dyer[1], William Pearce[1], Emma Barinas-Mitchell[2], Trina Thompson[2] and Rosalind Ramsey-Goldman[3]. [1]Northwestern University, Chicago, IL, [2]University of Pittsburgh, Pittsburgh, PA, [3]Northwestern University and Feinberg School of Medicine, Chicago, IL.

Background/Purpose: Women with SLE have increased rates of subclinical atherosclerosis. We have investigated which risk factors may be related to the increase in subclinical atherosclerosis, as measured by carotid plaque and IMT in women with SLE (cases) and without SLE (controls), over 5 years.

Methods: Baseline data including demographics and cardiovascular risk factors (CVRF) were collected from 151 cases and 126 controls in the Study of Lupus Vascular and Bone Long-term Endpoints (SOLVABLE). SLE factors measured included the modified American College of Rheumatology/Systemic Lupus International Collaborative Clinics Damage Index (excluding CV outcomes), Systemic Lupus Erythematosus Disease Activity Index 2000, disease duration, complement C3 and C4 levels, and self-reported use of corticosteroids, hydroxychloroquine, and immunosuppressants. Plaque and IMT were measured by B-mode ultrasound at baseline and at a follow-up visit. Plaque progression was defined as any increase in plaque number at follow-up. Logistic and linear regression were used to identify predictors of progression in plaque and increase in IMT, respectively; multivariate models included adjustment for the a priori CV risk factors age, hypertension, and total cholesterol/HDL ratio.

Results: The mean $\pm$ SD follow-up time was 5.36 ± 0.60 years in cases and 5.63 ± 0.66 years in controls. Mean IMT change per year was 0.0037 ± 0.024 in cases and -0.0001 ± 0.029 in controls ($p=0.25$); 71% of cases and 63% of controls had an increase in IMT at follow-up. Of cases, 28% had more plaque at follow-up, compared with 11.9% of controls with a relative risk for plaque progression of 2.34 (95%CI 1.36–4.01) (Table 1). Only in cases, higher fasting glucose ($\beta=0.005$ for glucose higher by one SD, 95%CI 0.0001–0.009) was significantly associated with increase in IMT in adjusted models. In adjusted models, the presence of SLE, higher cumulative and baseline corticosteroid dose were significantly associated with plaque progression in cases (Table 2). No CVRF were associated with either increase in IMT or plaque progression in controls, in the adjusted models.

Conclusion: SLE itself infers a greater risk for subclinical atherosclerosis progression over 5 years in women, as measured by an increase in carotid plaque. Higher baseline and cumulative corticosteroid dose were associated with an increased risk for plaque progression, suggesting that earlier and more aggressive treatment of SLE may be beneficial. No CVRF were associated with plaque progression in controls. Only higher baseline fasting glucose level independently predicted increase in IMT in cases.

Table 1 Plaque Progression at 5-year Follow-up

		Normal, No Change (N(%))	Normal and Progressed (N(%))	Abnormal and Regressed (N(%))	Abnormal, No Change (N(%))	Abnormal with Progression (N(%))	Relative Risk (95% CI)
5-year	Cases (N = 151)	75 (49.7)	20 (13.2)	22 (14.6)*	12 (8.0)	22 (14.6)	2.34 (1.36–4.01)
	Controls (N = 126)	70 (55.6)	6 (4.8)	29 (23.0)**	12 (9.5)	9 (7.1)	

*N = 18 regressed to normal, N = 4 regressed but were still abnormal
**N = 20 regressed to normal, N = 9 regressed but were still abnormal
Relative Risk was calculated as the proportion of cases who progressed compared with the proportion of controls who progressed.

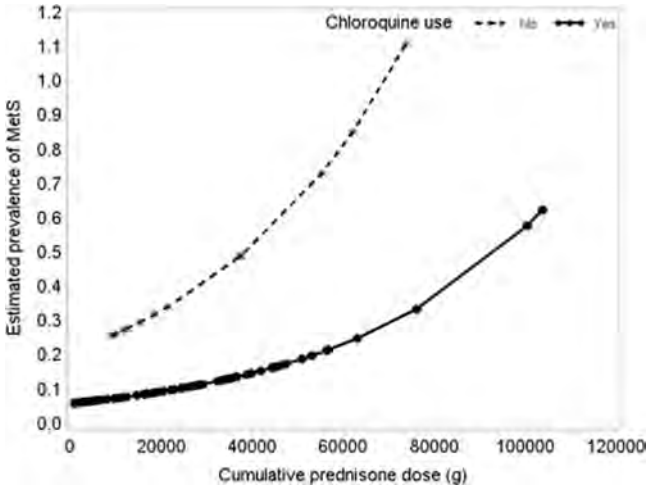
Metabolic Syndrome in Young Premenopausal Female Lupus Patients Is Mainly Influenced By Therapies. Luciana Muniz[1], Rosa M.R. Pereira[1], Thiago Silva[1], Eloisa Bonfá[2] and Eduardo Ferreira Borba[1]. [1]University of São Paulo, São Paulo, Brazil, [2]Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil.

Background/Purpose: A high prevalence of metabolic syndrome (MetS) has been observed in Systemic Lupus Erythematosus (SLE) patients, but there are scarce data about the main factors for MetS in young patients. The aim of the present study was to evaluate MetS frequency in premenopausal SLE patients and to identify factors that could contribute to this condition.

Methods: One hundred and three female SLE patients (fulfilled the revised American College of Rheumatology criteria) with age less than 40 years old were selected. Demographical, clinical, laboratorial and therapeutics data about SLE and MetS were assessed. Thirty-five healthy female age-matched were selected as controls. MetS was defined according to the 2009 Joint Interim Statement. Data analysis (SAS 9.3): t Student's test or Mann-Whitney's test (continuous data) and chi-square test or Fisher's exact test

(categorical variable) was performed as appropriate. Multivariate analysis used the Poisson regression.

Results: A higher frequency of MetS (22.3 *vs.* 5.7%, p=0.03) was observed in SLE group even as higher mean homeostasis model assessment index (HOMA-IR) (1.8 ± 0.9 *vs.* 1.3 ± 1.0, p=0.0008) and mean systematic coronary risk evaluation (SCORE) risk (1.4 ± 0.8 *vs.* 1.1 ± 0.4, p=0.01). Regarding MetS criteria, hypertension (42.7 *vs* 2.9%, p<0.0001) and waist circumference (83.5 *vs* 37.1%, p<0.0001) were most frequently observed in SLE group. The comparison of SLE patients with and without MetS showed no differences in mean disease duration and damage index score but higher SLE Disease Activity Index (SLEDAI) scores (median [range] 2 [0–31] *vs.* 2 [0–14], p=0.006) and more frequently previous (73.9 *vs.* 51.2%, p=0.05) and current renal (34.8 *vs.* 10.0%, p=0.008) disease in MetS-SLE group. MetS-SLE patients had higher current prednisone dose (20 [0–60] *vs.* 5 [0–60] mg/dl, p=0.018), cumulative dose (41.48 ± 27.81 *vs.* 24.7 ± 18.66 g, p=0.023) but no differences in the duration of its use or methylprednisolone pulse use. A higher frequency of chloroquine use was identified in SLE patients without MetS (90.0 vs. 65.2%, p=0.008). In multivariate analysis, only current chloroquine use (prevalence ratio [PR]=0.29; 95% confidence interval [CI] 0.13–0.64) and cumulative prednisone dose (PR=1.02; 95% CI 1.01–1.04) were associated with MetS in SLE. Patients that were not using chloroquine had a 3.48-fold higher risk of MetS and the prevalence of MetS increased by 2% for each increase of one gram of cumulative prednisone dose. The chloroquine use reduced the estimated prevalence of MetS even in patients on steroids and this benefit appears to be greater the higher the cumulative dose of prednisone (figure below):



Conclusion: The prevalence of MetS is high in premenopausal SLE patients and is mainly influenced by lupus therapy with prednisone or chloroquine rather than disease itself. Chloroquine use appears to decrease MetS prevalence even in patients on steroids.

Association of Coronary Artery Calcification with Brown and White Pericardial Adipose Tissue in SLE. Kelly J. Shields. Lupus Center of Excellence/Allegheny Health Network, Pittsburgh, PA.

Background/Purpose: Women with systemic lupus erythematosus (SLE) have an increased risk of cardiovascular disease (CVD). We have shown that clinically CVD-free women with SLE have an increased volume of descending aortic perivascular adipose tissue, which is also associated with aortic calcification independent of overall adiposity. The relative volumes of brown (BAT) versus white adipose tissue (WAT) may also influence the development of exacerbated CVD. Typically, increased BAT has been associated with a leaner and healthier phenotype.while increased WAT has been associated with an obese-like state. We hypothesized that greater pericardial adipose tissue (PAT) and WAT volumes will be associated with coronary artery calcification (CAC) in clinically CVD-free women with SLE.

Methods: Women participating in the "Heart Effects on Atherosclerosis and Risk of Thrombosis in SLE" (HEARTS) study were clinically CVD-free and diagnosed with SLE for at least 2 years. CAC was measured using electron beam computed tomography (EBCT) and quantified by Agaston scoring. The PAT (epicardial + paracardial adipose tissue) was quantified using commercially available software and attenuation values for overall adipose volume (–190 to –30 HU), WAT (−190 to −75HU), and BAT (−75 to −30 HU). Logistic regression modeling for any CAC was used to evaluate associations. Models were adjusted for CVD risk factors (age, waist-to-hip ratio, menopausal status and hypertension) and circulating inflammatory markers (C3, C4 and CRP).

Results: The study included 156 SLE women and 46% (72/156) had any CAC. SLE women with CAC had higher circulating levels of C3 (p=0.0002), C4 (p=0.001), and CRP (p=0.0001). The WAT to BAT ratio ($r_{Spearman}$=0.35, p=0.006) was significantly correlated with the extent of CAC. In unadjusted logistic regression models PAT (Odds Ratio/OR[95% CI], p-value: 1.02[1.01–1.03], <0.0001), WAT (1.03[1.01–1.04],<0.0001), and BAT (1.05[1.03–1.08],<0.0001) were significantly associated with any CAC. The three volumetric adipose measures maintained significance after adjusting for CVD risk factors (PAT (p=0.006), WAT (p=0.02), and BAT (p=0.002)) and circulating inflammatory markers (PAT (p=0.002), WAT (p=0.007), and BAT (p=0.0005).

Conclusion: Approximately half of the clinically CVD-free SLE women in this study had CAC. Traditional CVD risk factors do not explain the exacerbated CVD risk in the SLE population. We found that PAT and the relative WAT and BAT volumes were independently associated with any CAC even after adjustment for CVD risk factors and circulating inflammatory markers. Small visceral adipose depots surrounding the heart and vasculature may provide localized inflammation promoting CVD.

Cardiovascular Events Prior to or Early after Diagnosis of SLE. Murray B. Urowitz[1], Dafna D. Gladman[1], Nicole Anderson[1], Dominique Ibanez[1] and Systemic Lupus International Collaborating Clinics (SLICC)[2]. [1]University of Toronto, Toronto Western Hospital, Toronto, ON, [2]University of Toronto, Toronto Western Hospital (Coordinating Center), Toronto, ON.

Background/Purpose: A large multicenter multinational inception cohort was established to study risk factors for atherosclerosis (AS) in SLE. Previous studies have shown a history of cardiovascular events prior to diagnosis of systemic lupus erythematosus (SLE) and rheumatoid arthritis. This study describes the frequency of myocardial infarction (MI) prior to the diagnosis of SLE and within the first 2 years of follow-up.

Methods: An inception cohort of SLE patients from 31 centers in 12 countries has been assembled and followed at yearly intervals according to a standardized protocol between 2000 and 2014. Patients enter the cohort within 15 months of SLE diagnosis (≥4 ACR criteria). MIs were reported and attributed on a specialized vascular event form. MIs were confirmed by one or more of the following: abnormal EKG, typical or atypical symptoms with EKG abnormalities and elevated enzymes (≥2 times ULN), or abnormal stress test, echocardiogram, nuclear scan or angiogram. Descriptive statistics were used.

Results: 31 of 1848 patients that entered the cohort had an MI. Of those, 23 patients had an MI occur prior to SLE diagnosis or within the first 2 years of disease. Of the 23 patients studied 60.3% were female, 82.6% were Caucasian, 4.3% Black, 8.7% Hispanic and 4.3% other. The mean age at SLE diagnosis was 52.5 ± 15.0 years. Of the 23 MIs that occurred, 16 MIs occurred at a mean of 6.1 ± 7.0 years prior to diagnosis and 7 occurred within the first 2 years of follow-up.

Table 1. Cohort Characteristics and CAD risk Factors at Baseline

	Early MI Patients	Non-early MI Patients	p
N	23	1825	
Sex (female)	14 (60.9%)	1626 (89.1%)	<0.0001
Age at SLE Diagnosis (years)	52.5 ± 15.0	34.5 ± 13.2	<0.0001
SLEDAI-2K	3.65 ± 3.54	5.35 ± 5.39	0.03
Anti-dsDNA	7/22 (31.8%)	650/1661 (39.1%)	0.48
Low C3 and C4	8/22 (36.4%)	617/1666 (37.0%)	0.95
HsCRP	3/12 (25%)	141/742 (19.0%)	0.60
ESR	8/14 (57.1%)	519/927 (55.9%)	0.93
On Steroid	19 (82.6%)	1260 (69.1%)	0.16
On Antimalarials	14 (60.9%)	1234 (67.8%)	0.48
On Immunosuppressives	10 (43.5%)	725 (39.8%)	0.72
Family History of MI	4/9 (44.4%)	127/228 (55.7%)	0.51
Hypercholesterolemia	6 (28.6%)	549 (35.7%)	0.50
Hypertension (≥ 140/90)	7 (30.4%)	213 (11.9%)	0.007
BP Diastolic	74.2 ± 12.2	75.2 ± 11.0	0.67

BP Systolic	125.8 ± 18.5	119.6 ± 16.8	0.08
Diabetes	1 (4.6%)	68 (3.8%)	0.85
Metabolic Syndrome	5/19 (26.3%)	238/1647 (14.5%)	0.15
ACL	1.47 ± 6.06	4.23 ± 13.41	0.09

Risk factors associated with early MI in univariate analysis are male sex, older age at diagnosis, lower SLEDAI-2K and hypertension. In multivariate analysis only age (OR=1.07 95% CI (1.04, 1.10)) and male sex (OR=3.2, 95% CI (0.13, 0.78)) remained significant risk factors.

Conclusion: MI prior to or early in diagnosis of SLE may indicate earlier low grade disease activity not diagnosed or a concomitant alternative predisposition to AS and SLE.

Heart Rate Variability: An Inflammatory Biomarker in Systemic Lupus Erythematosus. Aikaterini Thanou[1], Stavros Stavrakis[2], John Dyer[2], Stan Kamp[1], Melissa E. Munroe[1], David Albert[3], Judith A. James[1] and Joan T. Merrill[1]. [1]Oklahoma Medical Research Foundation, Oklahoma City, OK, [2]University of Oklahoma Health Sciences Center, Oklahoma City, OK, [3]AliveCor, Inc., San Francisco, CA.

Background/Purpose: Heart rate variability (HRV) is a marker of vagus nerve activity and can be easily obtained with minimal technical expertise in the outpatient setting, using software calculating the distance between consecutive R waves on the electrocardiogram tracing. Decreased HRV is strongly associated with cardiovascular morbidity and mortality, and measures of HRV have been inversely correlated with inflammatory biomarkers in the general population. The current study evaluates the relationship of HRV with clinical disease activity and cytokine pathways in patients with systemic lupus erythematosus (SLE).

Methods: 58 patients with SLE from the Oklahoma Lupus Cohort were evaluated at two visits with the stipulation that there must be at least mild/moderate disease activity, in the clinician's opinion, at the first visit. Standard of care was rendered to each patient per usual clinic practice. Clinical assessments included the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI), the British Isles Lupus Assessment Group (BILAG 2004) index and the Physician Global Assessment (PGA). A 5-minute ECG was obtained at each visit for HRV analysis using the AliveCor iPhone ECG device. Serum cytokine levels, including interleukin 6 (IL-6) and B Lymphocyte Stimulator (BLyS) were measured with an enzyme-linked immunoassay (ELISA). Linear regression analysis and multivariate linear mixed effect models were used.

Results: At baseline, mean SLEDAI was 7.6±0.3, mean cumulative BILAG 2004 index was 10.0±0.6 and mean PGA was 1.4±0.1. Baseline HRV measures were negatively associated with baseline disease activity using the BILAG 2004 index ($p=0.01$), but less consistently with the SLEDAI score ($p=0.60$) and the PGA ($p=0.16$). HRV measures were also negatively associated with baseline IL-6 levels ($p=0.02$). At the follow up visit (median 1 month from the baseline visit), there was a significant decrease in SLEDAI (average decrease −2.3±0.5), BILAG 2004 index (average decrease −3.7±1.0) and PGA (average decrease −0.4±0.1) compared to baseline. Change in HRV measures was negatively associated with change in the BILAG 2004 index ($p=0.03$) and the PGA ($p=0.02$) and less well with change in SLEDAI ($p=0.12$), indicating that an increase in HRV is associated with a favorable change (decrease) in disease activity at follow up. In addition, there was a significant association between the change in HRV measures and improvement in IL-6 ($p=0.04$) and BLyS ($p=0.03$). None of the disease activity indices were correlated with change in IL-6 levels ($p>0.05$ for each); however, the change in BLyS levels was positively associated with change in SLEDAI ($p=0.03$) and BILAG 2004 index ($p=0.02$).

Conclusion: These pilot findings suggest that HRV measures could provide a sensitive marker for lupus disease activity and improvement, and support a role for HRV as an easily measured, non-invasive, in- office procedure. Its relevance to specific clinical or immunologic phenotypes or potential utility as a treat to target endpoint remain to be further explored.

Specific SLE Disease Manifestations in the Six Months Prior to Conception Predict Similar Manifestations during Pregnancy. Sara K. Tedeschi, Hongshu Guan, Alexander Fine, Bonnie L. Bermas and Karen H. Costenbader. Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Background/Purpose: Active SLE, in particular lupus nephritis, during the six months prior to conception is associated with disease flare during pregnancy. Previous studies, however, have not evaluated how other disease manifestations prior to conception are related to disease activity during pregnancy. We sought to investigate the relationship between SLE organ-specific disease activity in the six months prior to conception and organ-specific disease activity during pregnancy.

Methods: We identified SLE patients with >2 visits to our Lupus Center and ≥1 pregnancy lasting >12 weeks from 1990–2013, who had clinical and lab data available for the six months prior to conception and during pregnancy. All women had confirmed SLE by rheumatologist review for 1997 ACR Criteria for Classification. We collected data on: age, pregnancy outcomes, SLE medication use, history of nephritis, serositis (pleuritis, pericarditis), inflammatory arthritis, skin disease (malar rash, discoid lesions, photosensitivity), antiphospholipid antibody syndrome, hematologic disorder (leukopenia, hemolytic anemia, thrombocytopenia), anti-dsDNA elevation, and low complement, both in the six months preceding and during pregnancy. We analyzed the data using Fisher's exact tests.

Results: Among 1,127 women with SLE, 149 pregnancies occurred in 115 women. Mean age at SLE diagnosis was 23.8 (SD 6.8) years and at conception was 31.1 (SD 5.2) years; average SLE duration prior to pregnancy was 7.8 (SD 5.8) years; 8.7% were diagnosed with SLE during pregnancy. 68.7% were White, 14.8% Hispanic, 9.6% Black, and 7.0% Asian. During pregnancy the most common SLE manifestations were hematologic (15.4%), nephritis (10%), skin (9.4%), arthritis (6.7%), and serositis (4.7%). Activity of each of these SLE manifestations in the six months prior to conception was significantly associated with occurrence of the same manifestation during pregnancy. In contrast, patients without these clinical findings in the six months prior to pregnancy were unlikely to have activity in these organ systems during pregnancy. (Table 1)

Conclusion: Among women with SLE who had any organ system disease activity six months prior to conception, a large proportion had persistent symptoms of the same type during pregnancy. Those patients with quiescent organ-system manifestations six months prior to pregnancy were unlikely to become symptomatic during pregnancy. To our knowledge, this is the first study to reveal that organ-specific SLE manifestations, in addition to nephritis, in the six months prior to conception portend similar disease manifestations during pregnancy.

Table 1. Organ-specific SLE disease activity six months prior to conception and during pregnancy, N=149 pregnancies

	Active 6 months prior		Inactive 6 months prior		
	Active during pregnancy	Inactive during pregnancy	Active during pregnancy	Inactive during pregnancy	p value
Arthritis	n=13		n=136		
	4 (31%)	9 (69%)	6 (4%)	130 (96%)	0.006
Serositis	n=5		n=144		
	2 (40%)	3 (60%)	6 (4%)	138 (96%)	0.024
Skin	n=15		n=134		
	7 (47%)	8 (53%)	7 (5%)	127 (95%)	<0.001
Hematologic	n=17		n=132		
	12 (71%)	5 (29%)	14 (11%)	118 (89%)	<0.001
Nephritis	n=8		n=131

Protein Phosphatase 5 (PP5) Regulates Methylation Sensitive Gene Expression in CD4+ T Cells. Dipak R. Patel, Gabriela Gorelik and Bruce C. Richardson. University of Michigan, Ann Arbor, MI.

Background/Purpose: CD4+CD28- T cells are enriched in chronic inflammatory diseases like rheumatoid arthritis (RA) and lupus. They are cytotoxic and resistant to apoptosis. Compared to CD28+ cells, CD28- CD4 T cells over-express killer immunoglobulin-like receptors (KIRs) and other pro-

inflammatory molecules. These genes are regulated by DNA methylation, so they are over-expressed by CD4 T cells that are demethylated in vitro. This is a result of decreased signaling through the ERK and JNK pathways and, consequently, decreased activity of the DNA methyltransferase enzymes (DNMTs) responsible for DNA methylation. Protein phosphatase 5 (PP5) is a stress induced regulator of gene expression in multiple signaling pathways, including those involved in aging. It is expressed in CD4+CD28-, but not CD4+CD28+ T cells, and it inhibits both ERK and JNK signaling. We hypothesized that PP5 is over-expressed in CD4+ T cells in patients with RA and lupus, and that over-expressing PP5 in CD4 T cells from healthy donors will induce expression of methylation sensitive genes unique to CD4+CD28- T cells.

Methods: CD4+ T cells were isolated from healthy controls and patients, and PP5 mRNA was measured by RT-PCR. To study the effects of PP5 on gene expression, PBMCs from healthy donors were stimulated with phytohemagglutinin and cultured for 3 days with IL-2. CD4+ T cells were then isolated by negative selection, transfected (Amaxa Nucleofector) with constructs encoding GFP and PP5 or GFP alone, and cultured 24–72 hours. Expression of DNMT1 and methylation sensitive genes was assessed by RT-PCR in sorted CD4+GFP+ T cells. DNMT1 expression was measured 24 hours after transfection, and the other genes were analyzed 72 hours after transfection. Cell surface protein expression was measured by flow cytometry 72 hours after transfection.

Results: Compared to CD4+ T cells from healthy donors, PP5 mRNA is over-expressed in patients with lupus (1.97 fold change $\pm$0.18 SEM, $p=0.03$) and RA (1.6 ± 0.2, $p=0.06$). When transfected into CD4+ T cells from healthy donors, PP5 increased mRNA levels of KIR (2DL4 gene, 2.4 ± 0.7, $n=3$, $p=0.04$), perforin (1.38 ± 0.07 fold, $p=0.03$, $n=3$), CD11a (1.2 ± 0.1 fold, $p=0.047$, $n=5$), and CD70 (10.5 ± 4.1 fold, $p=0.03$, $n=7$). PP5 also increased the percentage of cells expressing surface KIRs ($33\pm7\%$ with control vs. $62\pm7\%$ with PP5, $n=7$, $p<0.01$), CD70 ($18.3\pm7\%$ with control vs. $34\pm10.8\%$ with PP5, $n=3$, $p=0.06$), and CD40L ($15\pm6.1\%$ with control vs. $27.3\pm9\%$ with PP5, $n=3$, $p<0.05$). Finally, PP5 caused a corresponding $20\pm8\%$ decrease ($n=5$, $p=0.02$) in DNMT1 mRNA expression.

Conclusion: CD4+CD28- T cells, which are enriched in lupus and RA, over-express pro-inflammatory methylation sensitive genes. These data demonstrate, for the first time, that PP5 contributes to the regulation of these genes (KIR, perforin, CD70, CD40L, and CD11a) in CD4+ T cells. PP5 is hypothesized to accomplish this by demethylating regulatory elements in the promoters for these genes, and this is currently being tested. PP5 expression is induced by oxidative and replicative stress, so it could provide a mechanistic link between those physiologic stressors and autoimmune disease flares.

***UBE2L3* genotype Influences Plasma Cell Proliferation in Systemic Lupus Erythematosus By Regulation of NF-κB By the Linear Ubiquitination Assembly Complex.** Myles J. Lewis[1], Simon Vyse[1], Adrian M. Shields[2], Sebastian Boeltz[2], Patrick Gordon[2], Timothy D. Spector[2], Paul J. Lehner[3], Henning Walczak[4] and Timothy J. Vyse[2]. [1]Queen Mary University of London, London, United Kingdom, [2]King's College London, London, United Kingdom, [3]University of Cambridge, Cambridge, United Kingdom, [4]University College London, London, United Kingdom.

Background/Purpose: Genome-wide association studies have identified a strong association between a single risk haplotype of the *UBE2L3*gene and Systemic Lupus Erythematosus (SLE), as well as multiple autoimmune diseases (rheumatoid arthritis, juvenile idiopathic arthritis, inflammatory bowel disease, psoriasis). UBE2L3 is an E2 ubiquitin-conjugating enzyme specific for RING/HECT hybrid or HECT E3 ligases. Linear ubiquitination is a newly described form of ubiquitination, whose only known function is controlling activation of NF-kB, mediated by the linear ubiquitination chain assembly complex (LUBAC).

Methods: *UBE2L3* genotype data from GWAS in SLE was imputed up to 1000 Genomes level. UBE2L3 function was studied *in vitro* using standard molecular biology techniques in HEK293 cells, or *ex vivo* using B cells and/or monocytes from healthy individuals or SLE patients (NF-kB translocation by Imagestream, multicolour flow cytometry of B cell subsets) stratified by *UBE2L3*genotype.

Results: Data from SLE GWAS, imputed to 1000 Genomes level identified rs140490 as the most strongly associated *UBE2L3* SNP, located at -270bp of the promoter region ($P=8.6\times10^{-14}$; OR 1.30, 95%CI: 1.21–1.39). Microarray /western blot studies found that the rs140490 risk allele increased UBE2L3 expression in B cells and monocytes from PBMC. Overexpression of UBE2L3 in combination with LUBAC in HEK293-NF-kB reporter cell line led to a marked upregulation in NF-kB activity, which was abolished by dominant-negative mutant UBE2L3[C86S]. RNAi blockade of UBE2L3 antagonised TNF signalling by inhibiting IκBα processing. *Ex vivo* human B cells and monocytes were isolated from genotyped healthy twins stimulated with CD40L or TNF respectively and NF-kB translocation quantified by Imagestream analysis. rs140490 genotype was correlated with both basal NF-kB activation in healthy human individuals, as well as the sensitivity of NF-kB to CD40 stimulation in B cells and TNF stimulation in monocytes. UBE2L3 expression was 3–4-fold elevated in peripheral blood plasmablasts and plasma cells ($P<0.0001$), with increased UBE2L3 expression in plasma cells from SLE patients compared to controls ($P=0.01$). UBE2L3 expression was significantly elevated in Ki-67^+ B cells consistent with a functional role in B cell proliferation. Consistent with the functional effect of *UBE2L3* on CD40 driven NF-kB activation in human B cells, rs140490 genotype correlated with increasing plasmablast and plasma cell differentiation in SLE patients ($P<0.001$).

Conclusion: Our study is the first to show that the *UBE2L3* risk haplotype exerts a critical rate-limiting effect on TNF and CD40 activation of NF-kB in primary human cells, and that this effect is mediated through LUBAC. By tracking NF-kB nuclear translocation in B cells and monocytes from genotyped individuals, we have shown that the *UBE2L3* risk variant amplifies both basal NF-kB activation and sensitivity of NF-kB to stimulation in *ex vivo* cells, leading to increased plasma cell proliferation in SLE.

IRF1 Influences on Histone H4 Acetylation in Systemic Lupus Erythematosus. Yiu Tak Leung[1], Lihua Shi[2], Kelly Maurer[2], Li Song[2], Zhe Zhang[3], Michelle Petri[4] and Kathleen E. Sullivan[2]. [1]University of Pennsylvania, Philadelphia, PA, [2]The Children's Hospital of Philadelphia, Philadelphia, PA, [3]Bioinformatics, Children's Hospital of Philadelphia, Philadelphia, PA, [4]Johns Hopkins University School of Medicine, Baltimore, MD.

Background/Purpose: Systemic lupus erythematosus (SLE) is the classical systemic autoimmune disease. Epigenetic processes, such as posttranslational histone modifications, can regulate gene expression without altering the underlying genomic sequence; these disease mechanisms that have had little attention in SLE to date. We previously reported that histone H4 acetylation (H4ac) is globally increased across the genome in monocytes of SLE patients as compared to healthy controls using tiling array. Transcription factor motif analysis then found that 63% of genes with increased H4ac had potential interferon regulatory factor (IRF) 1 binding sites, associating this transcription factor in the dysregulated gene expression. In order to investigate how IRF1 interactions influence H4ac in SLE, we identified the specific hyperacetylated H4 lysine residues, looked for histone acetylatransferases (HATs) and histone deacetylases (HDACs) dysregulation that may lead to the pathological hyperacetylation pattern and examined IRF1 associations with HATs and HDACs.

Methods: Flow cytometry for H4 lysine groups: K5, K8, K12 and K16 were ran using isotype controls. H4ac was defined in monocytes from 21 controls and 34 SLE patients. RNA-Seq studies were performed on monocytes from a different set of 8 controls and 8 SLE patients to look for an imbalance in HAT and HDAC expression; these imbalances were validated using real-time quantitative reverse transcription polymerase chain reaction (qRT-PCR). IRF1 influences on H4ac were evaluated in vitro using D54MG cells overexpressed with IRF1. IRF1 interactions with HATs and HDACs were studied using co-immunoprecipitation assays.

Results: Flow cytometry data showed that H4K5, H4K8, H4K12, and H4K16 acetylation were significantly increased in SLE monocytes. RNA-Seq results identified HDAC3 and HDAC11 with significantly decreased expression in SLE monocytes as compared to controls. HDAC3 can deacetylate all H4 lysine acetyl groups, preferentially acetylated H4K5 and H4K12. In contrast, the expression of PCAF, a HAT, was significantly increased in SLE monocytes as compared to controls. PCAF can place H4K5, H4K8, and H4K16 acetylation marks with a preference for H4K8. qRT-PCR data validated the HAT/HDAC expression patterns seen in the RNA-Seq studies. SLE monocytes had decreased gene expression levels of HDAC3 and HDAC11; PCAF had significantly higher gene expression in SLE than controls. IRF1-overexpressed in D54MG cells was associated with significantly increased H4K8 and H4K12 as compared to vector-only D54MG cells. While there was also some increase in acetylation at H4K5, no increase in acetylation was seen at H4K16 in IRF1-overexpressing D54MG cells. Co-immunoprecipitation studies using D54MG cells revealed IRF1 associations with PCAF, P300, CBP, GCN, ATF2, HDAC3 and SIRT1.

Conclusion: We hypothesize that IRF1 responds to alpha-IFN activation in SLE, and activated IRF1 recruits HATs, which then increases H4ac and leads to the chronic pathological gene expression in SLE. These studies have identified pivotal enzymes participating in the global hyper-acetylation in SLE.

Antimalarials Regulate TLR7/8 Mediated Macrophage Activation Via Epigenetic Modification at the TNFα Promoter. Androo J. Markham[1], Mark Halushka[2], Cristiana Guiducci[3], Robert M. Clancy[1] and Jill P. Buyon[1]. [1]New York University School of Medicine, New York, NY, [2]John Hopkins Pathology, Baltimore, MD, [3]Dynavax Technologies, Berkeley, CA.

Background/Purpose: Maternal anti-SSA autoantibodies contribute to the pathogenesis of congenital heart block by the formation of immune complexes (IC) comprised of Ro and ssRNA (hY3) which, via FcgR uptake, result in macrophage TLR signaling, a finding also applicable to other cell types and the pathogenesis of lupus in general. Accordingly, antagonists of innate cell drivers such as TLR7/8 and NF-κB would constitute a multi-target approach to the inhibition of proinflammatory and profibrotic mediators and subsequent organ injury. This study examined the role of TLR7/8 ligation and the modulatory effects of antimalarials on the epigenetic signature (methylation state) of histone 3 at lysine 4 (H3K4), a regulatory site in the promoter region of genes such as TNFα whose transcription is augmented by NF-kB binding.

Methods: The approach included both in vitro and in vivo studies. The former employed TLR7/8 stimulated human macrophage cells including THP1 and peripheral blood macrophages and the latter immunohistochemistry of autopsy tissue from the heart of a fetus dying with CHB and an age matched control.

Results: As expected, H3K4me2 (reflecting increased promoter activity) was expressed in both the CHB and control hearts. In the former, highly positive mononuclear infiltrates were identified in the AV nodal region. Based on these novel findings, in vitro experiments were initiated to examine the role of TLR7/8 ligation (hY3, surrogate for IC) on the epigenetic modification at histone 3 using broadly based and specific readouts, the latter for expression of TNFα, a cytokine linked to inflammation and fibrosis. Compared with no treatment, hY3 transfection of THP1 cells (N = 4) and isolated macrophages (N=2) increased the expression of H3K4me2 (but not H3K4me1, H3K4me3) by immunofluorescence, confirmed by immunoblot (IB, pixel values 0.39 ± 0.09 vs. 1.6 ± 0.23, no treatment and hY3, respectively, p=0.024). Since H3K4 dimethylation leads to increased promoter activity, parallel experiments evaluated the secretion of TNFα, which was significantly increased compared with control (1540 ± 234 vs 148 ± 49 pg/ml, respectively, p=0.02). The addition of hydroxychloroquine (HCQ, 5–100 uM) resulted in dose dependent inhibition of TNFα release (63% reduction with 5uM, approaching levels in patients, p =0.04 vs hY3, N=3). In parallel, HCQ treatment reduced hY3-stimulated H3K4me2 expression as assessed by immunofluorescence of THP-1 cells (confirmed by immunoblot). Similar results were obtained with both chloroquine and IRS661 (TLR7/8 inhibitor). ChIP was employed to assess the NF-κB binding site at the TNF promoter. Using hY3-treated THP-1 and H3K4me2-immunprecipitated chromatin, qPCR showed an enrichment of TNFα promoter binding by H3K4me2 (0.64 fold of the total input chromatin) which was attenuated by HCQ (0.31 fold of the total input chromatin).

Conclusion: These data support a link between TLR7 activation and dimethylation of lysine 4 of histone 3 (H3K4me2), which has been shown to increase binding of NF-κB at inflammatory gene promoters. Epigenetic modification by antimalarials supports the benefit of HCQ in the treatment of lupus and potential for prevention of organ damage, inclusive of heart block in an anti-Ro offspring.

Interferon-α and Angiogenic Dysregulation in Pregnant Lupus Patients Destined for Preeclampsia. Danieli Andrade[1], Mimi Kim[2], Luz P. Blanco[3], S. Ananth Karumanchi[4], Gloria Koo[1], Patricia M. Redecha[1], Kyriakos A. Kirou[1], Angela M. Alvarez[5], Melissa J. Mulla[5], Mary K. Crow[1], Vikki Abrahams[5], Mariana J. Kaplan[3] and Jane E. Salmon[1]. [1]Hospital for Special Surgery, New York, NY, [2]Albert Einstein College of Medicine, Bronx, NY, [3]National Institutes of Health, Bethesda, MD, [4]Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, [5]Yale School of Medicine, New Haven, CT.

Background/Purpose: Pregnant patients with SLE are at increased risk of placental insufficiency and preeclampsia, disorders associated with angiogenic factor imbalance. IFN-α, a critical element in SLE pathogenesis, is a potent antiangiogenic factor. In a case-control longitudinal study of lupus pregnancies from PROMISSE (Predictors of Pregnancy Outcome: Biomarkers In Antiphospholipid Antibody Syndrome and Systemic Lupus Erythematosus), we investigated whether elevated IFN-α early in pregnancy might be associated with poor pregnancy outcomes.

Methods: Each of 28 SLE patients with poor pregnancy outcome was matched to an SLE patient with an uncomplicated pregnancy and to a pregnant healthy control. Serum samples obtained monthly through pregnancy were assayed for IFN-α activity using a reporter cell assay, and for antiangiogenic factor, sFlt1, and proangiogenic factor, placenta growth factor (PlGF). Human umbilical vein endothelial cells (HUVEC) were cultured in the presence of IFN-α and/or sFlt1, and gene expression assessed by q-RT PCR. The effect of IFN-α and sFlt1 on endothelial-trophoblast interactions was assessed in an *in vitro* model of spiral artery transformation in which the capacity of human first trimester extravillous trophoblasts to stabilize endometrial endothelial cell tube structures is measured.

Results: Compared to SLE patients with uncomplicated pregnancies, those with preeclampsia had increased IFN-α before clinical symptoms. Non-autoimmune patients destined for preeclampsia did not have increased IFN-α. In SLE patients with low IFN-α, marked angiogenic imbalance (higher sFlt1, lower PlGF and higher sFlt1/PLGF ratios) precedes maternal manifestations of preeclampsia, whereas in SLE with high IFN-α, preeclampsia occurs without evidence of systemic angiogenic imbalance. To investigate this result, we treated HUVEC with exogenous sFlt1 and IFN-α. Treatment with sFlt1 induced the expression of *sFlt1* mRNA, and IFN-α dramatically amplified the endothelial response to sFlt1, leading to a local positive feedback loop. Furthermore, in an *in vitro* model of spiral artery transformation, only IFN-α and sFlt1 together disrupted the ability of trophoblast cells to remodel endothelial tube structures.

Conclusion: Our studies identify a new mechanism by which IFN-α induces an antiangiogenic milieu in the vasculature leading to inadequate spiral artery remodeling and poor placentation early in pregnancy and maternal endothelial dysfunction presenting as preeclampsia later in pregnancy. They suggest that elevated IFN-α may contribute to the pathogenesis of preeclampsia in some pregnant women with SLE.

The Second Messenger, Cyclic GMP-AMP Dinucleotide (cGAMP) and the Enzyme, Cyclic GMP-AMP Synthase (cGAS), Are Expressed in Systemic Lupus Erythematosus. Jie An, Joshua Woodward, Reynold Karr, Thomas H. Teal and Keith B. Elkon. University of Washington, Seattle, WA.

Background/Purpose: The type I IFNs (IFN-I), are strongly associated with Systemic Lupus Erythematosus (SLE). It is generally considered that IFN-I is induced by immune complexes (IC) containing (ribo)nucleoprotein antigens. However, this conclusion is based on in vitro studies and doesn't address how IFN-I may be induced prior to the formation of IC. Cytosolic DNA induces IFN-I and other cytokines which are important for antimicrobial defense but can also trigger autoimmunity. Cytoplasmic DNA frequently transduces signals via the adaptor protein, STING, and the transcription factor IRF3, however how cytosolic DNA is sensed in eukaryotic cells remains under intense investigation. Recently it was shown that a newly discovered enzyme called cyclic-di-GMP–AMP (cGAMP) synthase (cGAS) detects cytosolic DNA, synthesizes cGAMP which then acts as a second messenger to trigger a signaling pathway through STING and IRF3, resulting in production of IFN-β in mammalian cells. Our research aim is to determine whether the cGAS pathway could contribute to IFN I production in SLE.

Methods: cGAS and Interferon Stimulated Genes (ISGs) mRNA expression was quantified by quantitative PCR (qPCR). IRF3 phosphorylation was determined by anti-phospho-IRF3 antibody and western blot. cGAMP levels were monitored by Selective Reaction Monitoring (SRM) with High Performance Liquid Chromatography-tandem Mass Spectrometry (HPLC-MS/MS).

Results: When compared to normal controls (n=20), SLE patients (n=51) had a significant increase of the expression of cGAS (P=0.0045) in peripheral blood mononuclear cells (PBMC). cGAS expression positively correlated with

ISGs expression and IFN score in SLE patients consistent with it being an IFN signature gene. We further quantified IRF3 activation by phosphorylation in PBMC and found that IRF3 was activated in a higher proportion of SLE patients compared to controls. To quantify c-GAMP in patient PBMC samples we used a reference cyclic GMP-AMP dinucleotide that is comprised of the unusual 2'-5' and 3'-5' phosphodiester linkage and demonstrated the ability to distinguish the cyclic dinucleotide from other species by HPLC-MS/MS. Of 23 SLE patients tested, we could detect cGAMP in approximately one fourth of SLE patients but not in any of the normal controls and RA patients.

Conclusion: Our findings implicate the activation of cGAS pathway in at least some patients with SLE. While increased cGAS gene expression may be induced in response to IFN-I, DNA binding to cGAS is required for synthesis of cGAMP. Defining the molecular mechanisms responsible for activation of the cGAS enzyme, will contribute to our understanding of IFN-I stimulation in SLE patients. Furthermore, since IFN-β primes other cells such as pDC for heightened expression of IFN-α, targeted approaches to reduce DNA/cGAS interaction may be a useful therapeutic strategy in SLE.

ACR Concurrent Abstract Session

Systemic Sclerosis, Fibrosing Syndromes and Raynaud's - Clinical Aspects and Therapeutics I: Systemic Sclerosis, Advances in Therapy

Sunday, November 16, 2014, 2:30 PM–4:00 PM

874

Safety and Efficacy of Subcutaneous Tocilizumab in Adults with Systemic Sclerosis: Week 24 Data from a Phase 2/3 Trial. Dinesh Khanna[1], Christopher P. Denton[2], Jacob M. van Laar[3], Angelika Jahreis[4], Sabrina Cheng[4], Helen Spotswood[5], Jeffrey Siegel[4] and Daniel E. Furst on behalf of FaSScinate Clinical Trial in Patients With SS[6]. [1]University of Michigan Health System, Ann Arbor, MI, [2]University College London Medical School, London, United Kingdom, [3]University Medical Center Utrecht, Utrecht, Netherlands, [4]Genentech, South San Francisco, CA, [5]Roche Products Ltd., Welwyn Garden City, United Kingdom, [6]University of California, Los Angeles, CA.

Background/Purpose: Systemic sclerosis (SSc) is a progressive, debilitating disease with limited treatment options. IL-6 has been implicated in disease pathogenesis.[1,2] IL-6 receptor inhibition prevented and reversed skin fibrosis in a murine scleroderma model.[3] Tocilizumab (TCZ), an IL-6 receptor inhibitor, is under evaluation in the ongoing 2-y faSScinate study, a randomized, double-blind, placebo-controlled trial. Wk 24 efficacy and safety data of TCZ in SSc pts are presented here.

Methods: Pts (≥18 y) with active SSc (1980 ACR criteria,[4] ≤5-y disease duration, mRSS 15–40 units, and elevated acute-phase reactants) were randomized 1:1 to subcutaneous TCZ 162 mg or placebo (PBO) wkly for 48 wks. The primary end point was mean change in mRSS from baseline (BL) at wk 24, with patient and lung responses as secondary/exploratory measures.

Results: Eighty-seven pts (43 TCZ, 44 PBO) were enrolled. BL characteristics were similar between arms, including mean (SD) mRSS (TCZ, 26.4 [7.2]; PBO, 25.6 [5.9]). The primary end point, change in mRSS, and secondary end point, change in HAQ-DI, from BL to wk 24 are displayed in the Table. At 24 wks, a numerically favorable but not statistically significant effect of TCZ over PBO on mRSS was noted (TCZ, –3.9; PBO, –1.2; adjusted mean difference, –2.7 [95% CI, –5.85, 0.45]). In addition, a numerically greater proportion of TCZ pts achieved clinically meaningful reduction in mRSS of ≥4.7[5] (TCZ, 43.2% [16/37]; PBO, 26.3% [10/38]; $p = 0.15$, Fisher exact test). Exploratory analysis of change in forced vital capacity (FVC; liters) showed more PBO than TCZ patients (81% vs 50%) with progression of FVC decline (≤0%) (Table) and 27% of PBO pts vs 3% of TCZ pts with ≥10% FVC decline ($p = 0.009$, Van Elteren test). Adverse events (AEs)/serious AEs were reported in 88.4%/20.9% of TCZ and 90.9%/25.0% of PBO pts. Fewer noninfectious SAEs were reported in the TCZ arm (5 pts) than the PBO arm (10 pts), whereas infection/infestation SAEs were more common in TCZ than PBO pts (6 pts vs 1 pt). By system organ class, the following SAEs, potentially indicative of SSc complications, were reported more frequently in the PBO than in the TCZ arm: cardiac SAE (TCZ, 0 pts; PBO, 3 pts), gastrointestinal SAE (TCZ, 0 pts; PBO, 2 pts), and renal SAE (TCZ, 0 pts; PBO, 2 pts). Three pts in the TCZ arm and 2 pts in the PBO arm discontinued due to AEs. One death occurred in each arm: 1 pulmonary infection in a TCZ pt on day 109 and 1 heart failure in a PBO pt 131 days after withdrawal.

Conclusion: In this phase 2 study, favorable trends in skin score for TCZ were detected though the primary skin score end point was not met. In addition, encouraging changes in FVC were noted. The ongoing double-blind and open-label phases of this trial will provide additional information.

Treatment-Related Outcomes in Connective Tissue Disease-Associated Pulmonary Arterial Hypertension: A Pooled Analysis of 12 Randomized Controlled Trials. Rennie L. Rhee[1], Nicole B. Gabler[1], Amy Praestgaard[1], Peter A. Merkel[2] and Steven M. Kawut[1]. [1]University of Pennsylvania, Philadelphia, PA, [2]Vasculitis Center, University of Pennsylvania, Philadelphia, PA.

Background/Purpose: Recent studies have shown that therapies for pulmonary arterial hypertension (PAH) improve exercise capacity, but subgroup analyses suggest that these therapies may be less effective in patients with connective tissue disease (CTD-PAH). The aim of this study was to compare the effect of treatment on the change in six minute walk distance (Δ6MWD) and clinical events in CTD-PAH vs idiopathic PAH (IPAH).

Methods: A pooled analysis was performed on patient-level data from 12 Phase III randomized placebo-controlled trials of advanced therapies for PAH that were submitted to the FDA for approval. Outcomes for this analysis included Δ6MWD from baseline to 12 weeks, the occurrence of clinical worsening (defined as first occurrence of death, hospitalization for PAH, addition of other PAH medications, lung transplant, atrial septostomy, or worsening exercise capacity and/or functional class), and all-cause mortality. Missing 6MWD at 12 weeks was multiply imputed. A robust generalized estimating equation within a linear or logistic regression model was utilized using an exchangeable correlation structure and clustering on study trial. Effect modification of treatment assignment (drug vs placebo) by diagnosis (CTD-PAH vs IPAH) was assessed. All regression models were adjusted for age, sex, race, drug class, baseline 6MWD, functional class, and baseline hemodynamics (right atrial pressure, pulmonary vascular resistance, and cardiac index).

Results: The study sample included 2,736 participants: 824 had CTD-PAH and 1,912 had IPAH. Patients with CTD-PAH were significantly older, more often female, and had a lower baseline 6MWD compared to patients with IPAH (**Table 1**). There was a significant interaction between treatment assignment and diagnosis in terms of the Δ6MWD, such that the treatment-related improvement in Δ6MWD was significantly less in CTD-PAH than in IPAH (difference-in-difference −11.3 meters, [95% CI −20.0, −2.6], p for interaction = 0.011). There was also greater treatment-associated reduction in clinical worsening and mortality in IPAH than in CTD-PAH (**Table 2**).

Conclusion: In clinical trials, treatment for PAH was less effective in CTD-PAH compared to IPAH in terms of increasing 6MWD, preventing clinical worsening, and possibly reducing the risk of death. The differential treatment response in CTD-PAH and IPAH supports the need for stratified analysis in future trials and suggests that a different pathophysiological process may exist in the two phenotypes of disease.

Table 1: Characteristics of Study Participants

	CTD-PAH (n = 824)	IPAH (n = 1,912)	p-value
Age, years	54 ± 14	47 ± 16	<0.001

SAR100842, an Antagonist of Lysophaphatidic Acid Receptor 1, As a Potential Treatment for Patients with Systemic Sclerosis: Results from a Phase 2a Study. Dinesh Khanna[1], Christopher P. Denton[2], Alexandre Jagerschmidt[3], Martine Jasson[4], Oliver Distler[5] and Yannick Allanore[6]. [1]University of Michigan Scleroderma Program, Ann Arbor, MI, [2]UCL Medical School Royal Free Campus, London, United Kingdom, [3]Sanofi-Aventis, Chilly-Mazarin, France, [4]Sanofi-Aventis, Paris, France, [5]Zurich University Hospital, Zurich, Switzerland, [6]Department of Rheumatology, University Paris Descartes and Cochin Hospital, Paris, France.

Background/Purpose: Preclinical genetic and pharmacological studies suggest a role for Lysophosphatidic acid (LPA) involvement in three key processes of systemic sclerosis: fibrosis, microangiopathy and immunoinflammation. We have assessed SAR100842, a potent selective orally available antagonist of LPA1 receptor and explored safety, skin biomarkers of disease activity and clinical efficacy in patients with diffuse cutaneous SSc (dcSSc) in a phase 2a clinical trial.

Methods: ACT12339, study NCT01651143 sponsored by SANOFI, was an 8-week double-blind, randomized, placebo-controlled study followed by a 16 week open label extension study with SAR100842. 32 patients with dcSSc <36 months since the onset of the first non-Raynaud's SSc manifestation and an mRSS ≥15 were included. Patients with severe organ involvement that was deemed unsafe were excluded. Background stable immunosuppressant therapy was allowed. The primary endpoint was safety. Secondary end-points included effect on potential biomarkers from skin biopsies and blood samples as well as change in mRSS and S-HAQ at week 8 and 24 in the modified intent to treat (ITT) population defined as any patient with a post investigational product evaluation in each part of the study.

Results: 17 patients were randomized to the placebo group and 15 to the SAR100842 group. 30 patients participated in the extension study.

The most frequent adverse events reported under SAR100842 during the blinded period were headache, diarrhea and nausea.

No statistically significant difference between the 2 groups was observed in skin biopsy and blood biomarkers at week 8. However, a greater reduction of some skin LPA-induced marker mRNA levels (e.g. Wnt2, PAI1 and SFRP4) was observed in the SAR100842 group compared to placebo, consistent with sucessful target engagement. At week 8 an improvement in mRSS (median improvement= - 4.0 versus −1.0 units) and in HAQ-DI were observed in the SAR100842 group compared to placebo, respectively.

The safety profile was good during the extension part. The most frequent adverse events in this part were headache, arthralgia, fatigue and nausea. After 24 weeks of treatment with SAR100842 key skin fibrotic biomarkers (COMP and TSP1) were reduced from baseline. LPA-induced biomarker mRNA levels were improved after 16 weeks of treatment with SAR100842 in the group of patients who initially received placebo. In parallel and of interest, there was a clinically meaningful improvement of clinical parameters as indicated in the table below. 78.5% of patients achieved MCID estimate of mRSS.

	Placebo/SAR100842	SAR100842/SAR100842
mRSS total score (0–51) at baseline	25.23 (7.47)	23.07 (8.32)
Mean change to Week 24 (SD)	−7.31 (4.59)	−7.36 (4.24)
HAQ-DI total score (0–3) at baseline	1.32 (0.79)	1.20 (0.79)
Mean change to Week 24 (SD)	−0.23 (0.30)	−0.15 (0.33)

Conclusion: SAR100842 was well tolerated in patients with dcSSc and resulted in a reduction of skin thickness assessed by mRSS. The clinical efficacy was supported by biological evidence of the LPA target engagement. Altogether these data suggests that SAR100842 may be an effective treatment for dcSSc that need to be confirmed in a larger controlled trial.

Sildenafil Attenuates the Fibrotic Phenotype in Scleroderma Skin Fibroblasts. Tomoaki Higuchi[1], Yasushi Kawaguchi[1], Kae Takagi[1], Akiko Tochimoto[1], Yuko Ota[1], Yasuhiro Katsumata[1], Takahisa Gono[1], Masanori Hanaoka[1], Yuko Okamoto[1], Hidenaga Kawasumi[1] and Hisashi Yamanaka[2]. [1]Tokyo Women's Medical University, Tokyo, Japan, [2]Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan.

Background/Purpose: Systemic sclerosis (SSc) is a connective tissue disease characterized by inflammation, vasculopathy and fibrosis. Tissue fibrosis directly contributes to mortality or quality of life. However, the effective therapy has not been established. Aberrantly activated fibroblasts in the affected area of SSc, which play a main role in the production and remodeling of collagen and other extracellular matrix components, is thought to be a key therapeutic target. Recent researches showed that stimulation of soluble guanylate cyclase (sGC) reverted fibrotic phenotype of SSc and other fibrotic disorders *in vivo* and *in vitro* by increasing levels of intracellular cyclic GMP (cGMP). The purpose of the present study is to assess the anti-fibrotic properties of cGMP in cultured fibroblasts from patients with SSc.

Methods: Skin fibroblasts were obtained from patients with diffuse cutaneous SSc. Intracellular cGMP levels were measured using a commercially available ELISA kit. To increase the intracellular concentration of cGMP, sildenafil, an inhibitor of phosphodiesterase (PDE) 5, was added. Expression of PDE5 and alpha smooth muscle actin (αSMA) were analyzed by immunohistochemistry. Gene expressions related to profibrotic marker were evaluated by quantitative RT-PCR. Western blotting and ELISA were performed to investigate the effects of sildenafil on the downstream pathway of TGF-β.

Results: PDE5 expression on skin fibroblasts was confirmed by immunohistochemistry. Baseline cGMP levels in SSc skin fibroblasts were significantly higher than those in healthy skin fibroblasts. Sildenafil increased cGMP levels in a dose dependent manner in skin fibroblasts, and then our results indicated that sildenafil significantly decreased the expression of profibrotic genes, which were augmented by TGF-β1, including *COL1A1, COL1A2, CTGF and ACTA2* in SSc skin fibroblasts. Conversely, these inhibitory effects of sildenafil were found to be weak in healthy skin fibroblasts. Also, we confirmed using immunohistochemistry that the protein levels of αSMA in SSc skin fibroblasts were down-regulated by sildenafil. Next, we explored the effects of sildenafil on

the signal pathway of TGF-β. Sildenafil significantly reduced phosphorylation of p38 induced by TGF-β1, but did not affect phosphorylation of Smad3. In addition, sildenafil reduced Rho kinase activity.

Conclusion: We demonstrated that sildenafil attenuated the fibrotic phenotype of SSc skin fibroblasts induced by TGF-β1. This effect may be attributed by non-Smad signaling pathways, including MAPK and Rho kinase cascade. Sildenafil has been used for the treatment of SSc -associated pulmonary arterial hypertension and Raynaud phenomenon by its potent vasodilating effect. In addition, our findings would provide the evidence that sildenafil may have the potential to improve fibrotic lesions in SSc.

Luminex and Autoantigen Microarray Analysis of Sera from Patients with Diffuse Cutaneous Systemic Sclerosis Reveals Changes Associated with Imatinib Mesylate Treatment. D. James Haddon[1], Hannah Wand[1], Paul J. Utz[1], Robert F. Spiera[2], Jessica K. Gordon[2] and Lorinda Chung[3]. [1]Stanford University School of Medicine, Stanford, CA, [2]Hospital for Special Surgery, New York, NY, [3]Stanford University School of Medicine, Palo Alto, CA.

Background/Purpose: Tyrosine kinase inhibitors (TKIs), including imatinib mesylate, have been studied for the treatment of diffuse cutaneous Systemic Sclerosis (dcSSc). In a previously reported single center, open-label study of imatinib for dcSSc, a significant improvement in the modified Rodnan skin score (MRSS) was observed. In this study, we analyzed the patient serum samples collected during the trial by Luminex and autoantigen microarray to investigate the mechanism of action of imatinib in dcSSc, and to identify biomarkers that are predictive of response to imatinib.

Methods: Thirty patients who fulfilled ACR criteria for SSc, with dcSSc, were enrolled in the trial, and 24 completed 12 months of treatment with oral imatinib 400 mg daily. Serum samples were collected at −1, 0, 6, 12, and 15 (post-treatment follow-up) months. Twenty-six patient serum samples were available for analysis at screening/baseline, 25 at 6 months, 20 at 12 months, and 15 at the follow-up time point.

Luminex immunoassays were used to measure the levels of 44 cytokines, chemokines and growth factors in each serum sample in duplicate. Autoantigen microarrays were used to measure the levels of 30 autoantigens known to be associated with dcSSc, in parallel. Luminex and microarray results were analyzed by Significance analysis of microarrays (SAM), a statistical technique that uses permutation to adjust for multiple testing. SAM was used to identify Luminex analytes and autoantibodies that were present at significantly different levels: 1) in healthy controls vs. patients with dcSSc at baseline, 2) during treatment with imatinib vs. baseline; and 3) in the baseline samples of responders vs. non-responders. For this analysis, a decrease in MRSS $\geq$ 5, previously defined as the minimal clinically important difference, was considered a response to treatment.

Results: Luminex analysis identified 18 analytes that were present at significantly higher levels in the serum of patients with dcSSc than in healthy control serum, including previously reported factors IL-6, MCP-1, VEGF, IL-17 and MIP-1β (fold-change $>$ 2, q $<$.001). Autoantigen microarray analysis revealed 7 autoantibodies present at significantly higher levels in dcSSc patient sera than in healthy control sera, including Scl-70 and RNA Pol III (fold-change $>$ 1.5, q $<$.001). We observed significant reductions in 5 autoantibodies following 6 months of treatment with imatinib, including Scl-70 and RNA Pol III, compared to baseline (q $<$.001). Imatinib treatment was also associated with reductions in 8 Luminex analytes, including VEGF, IL-17, MCP-1, PDGF-AA, and PDGF-BB (q $<$.001). Levels of VEGF, IL-17, and MIP-1β were significantly higher in responders than non-responders at baseline.

Conclusion: Treatment with imatinib was associated with a reduction in the serum levels of VEGF and IL-17. Increased serum levels of VEGF, IL-17 and MIP-1β in dcSSc patients at baseline were associated with an increased likelihood of clinical improvement in MRSS with imatinib treatment. Investigation of the utility of the baseline levels of IL-17, VEGF and MIP-1β for patient stratification in the context of future randomized controlled trials of TKIs in SSc is warranted.

Efficacy of Autologous Hematopoietic Stem Cell Transplantation in Rapidly Progressive Systemic Sclerosis: Prolonged Remission of Disease Activity in a Long-Term Follow up. Eleonora Zaccara[1], Domenico Sambataro[2], Wanda Maglione[1], Gianluca Sambataro[1], Francesco Onida[3], Claudio Annaloro[3], Giorgia Saporiti[3], Elena Tagliaferri[3], Agostino Cortelezzi[3], Rosaria Giordano[3], Claudio Vitali[4] and Nicoletta Del Papa[2]. [1]Osp. G. Pini, Milano, Italy, [2]Istituto G.Pini, Milan, Italy, [3]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico-University of Milan, Milano, Italy, [4]Istituto San Giuseppe, Lecco, Italy.

Background/Purpose: In the recent years, autologous haematopoietic stem cell transplantation (AHSCT) has been shown to represent an effective therapeutic option for patients (pts) suffering from rapidly progressive SSc, although the number of available clinical trials at present is relatively scant. Aim of the study was to retrospectively evaluate the efficacy of AHSCT in a long term in a number of patients with severe diffuse cutaneous SSc after a long lasting period of observation.

Methods: Since 2003, 18 pts affected by diffuse cutaneous SSc (male 5, female 13; median age 40 years, range 20 – 62), underwent AHSCT using positively selected CD34+ cells. Pts were eligible if they had a rapidly progressive disease, a modified Rodnan Skin Score (mRSS) $>$ 14 and a clinical activity score $>$ 3 (evaluated according to the European Scleroderma Study Group – ESSG), in the absence of major organ involvement. Mobilisation was performed with CTX 4000 mg/m2 given over two days and G-CSF 10 μg/m2/day. Conditioning regimen included CTX 50 mg/kg/day on days −5 to −2 and rabbit ATG 2.5 mg/kg/day on days −3 to −1. The major outcome variables were treatment safety and clinical response, in terms of mRSS and ESSG improvements. The long-term follow-up of organ disfunction was evaluated by echocardiographic LEVF or PAPs, and functional respiratory parameters DLCO and VC.

Results: The median follow-up was of 37 months (range 6–138). Ninety-four % (17/18) of the pts demonstrated a beneficial clinical response with significant reduction of mRSS $>$ 30% and ESSG at Month 6, and a further reduction of mRSS at year 1 of the most part of them was observed.

The mean mRSS was 19.8 (SD + 5.3) at baseline, 9.3 + 4.6 at Month 6, 6.21 + 7.4 at year 1 and 3.0 + 2.2 at year 5; all the reductions were statistically significant ($<$ 0.001). The mean ESSG was 5.3 + 0.85 at baseline, 2.1 + 0.8 at Month 6, 2.0 + 1.6 at year 1 and 1.5 + 0.96 at Year 5; all the reductions were statistically significant (p$<$ 0.0001). Organ involvement was nearly unchanged during follow-up: mean value of DLCO at baseline 65.0% + 19%, at Year 1 67.2% + 17.8% and at Year 5 58.0% + 14.7% (p=ns); mean value of VC at baseline 81% + 23.6%, 82% + 15.7%, 89.2% + 26% (p=ns). No echocardiographic changes were identified during follow-up. Two patients died during follow-up of SSc from pulmonary and cardiac complications due to the disease. One patient died from interstitial pneumonia at day + 65, leading to a TRM of 5.6% (1/18).

Conclusion: This study confirms that AHSCT in selected patients with rapidly progressive SSc results in sustained improvement of skin thickening and stabilisations of organ function up to 10 years after transplantation, so leading to a global clinical improvement, as showed by the persistent reduction in the ESSG clinical activity score. According to other experiences, TRM resulted reasonable, as a possible result of patients selection. These finding are in keeping with the view that AHSCT is effective in improving the active phase of SSc, while letting unchanged and stable the fibrosclerotic one. Further studies are needed to evaluate the importance of CD34 selection, the need of immunosuppressive therapy post-AHSCT and the best timing of HSCT in the treatment of SSc patients.

Background/Purpose: Giant cell arteritis (GCA) is a chronic autoimmune vasculitis with an important genetic component. We aimed to identify relevant risk *loci* for GCA predisposition by performing a large-scale genetic analysis on this disease.

Methods: We genotyped a large cohort of patients with GCA using the Illumina Immunochip. The study cohort was of European ancestry and comprised 1,892 cases of GCA confirmed by temporal artery biopsy or vascular/imaging and 15,306 unrelated controls from 6 different countries (Spain, UK, USA, Italy, Norway and Germany). To test for association, we compared the variation frequencies of cases and controls by logistic regression under a fixed-effects model using the three first principal components (PCs), sex, and country of origin as covariates. We also imputed the HLA region using a previously validated imputation method to perform a more comprehensive analysis of this region.

Results: The strongest association signals were observed in the HLA region, specifically histidine at position 13 of HLA-DRB1 (P=3.46e-38, OR=1.92, 95% CI=1.74–2.12). A multivariate model including 3 amino acids (a histidine in position 13 of DRB1, a leucine in position 69 of DQA1, and a threonine in position 45 of HLA-B) explained most of HLA association with GCA. All 3 amino acids are located in the binding pocket of their corresponding HLA molecule and interact directly with the antigen. Outside the HLA region, the most highly associated SNPs were located within *PTPN22* (rs2476601, P=1.73E-06, OR=1.38, 95% CI=1.21–1.58) and *LRRC32* (rs10160518, P=4.39E-06, OR= 1.20, 95% CI=1.11–1.29). The latter gene is selectively expressed on Tregs.

Conclusion: Our data provide evidence of a strong contribution of HLA Class I and II molecules to susceptibility to GCA. Regarding the non-HLA region, we confirmed a key role for the functional *PTPN22* rs2476601 variant and identified *LRRC32* as a putative risk factor for GCA, suggesting a possible role of Tregs in the pathophysiology of GCA.

DNA Methylation Analysis of the Temporal Artery Microenvironment Reveals a Robust T Cell Signature and Suggests a Role for TNF-α in Giant Cell Arteritis. Patrick S. Coit, Lindsey B. De Lott, Bin Nan, Victor M. Elner and Amr H. Sawalha. University of Michigan, Ann Arbor, MI.

Background/Purpose: Giant cell arteritis (GCA) is a systemic large vessel vasculitis of unknown etiology. A hallmark of GCA is the presence of granulomatous inflammation of the arterial wall. The DNA methylation status of the arterial environment in GCA patients has not been previously elucidated. This study characterizes the DNA methylation profile of formalin-fixed, paraffin-embedded (FFPE) temporal artery tissue biopsies taken from GCA patients and age, sex, and ethnicity matched controls that presented with similar symptoms, but had normal temporal artery biopsies.

Methods: Temporal artery biopsies performed at the University of Michigan from 1988–2012 were reviewed. Twelve patients with non-equivocal histological evidence for GCA and twelve age, sex, and ethnicity matched controls with normal biopsies were included in this study. All patients fulfilled the ACR classification criteria for GCA and were not taking steroids for more than 48 hours prior to biopsy. DNA was extracted from the affected portions of FFPE temporal artery tissue in GCA patients and from histologically-confirmed normal arteries in controls. Genome-wide DNA methylation status was evaluated using the Illumina Infinium HumanMethylation 450 BeadChip Array, which covers 99% of RefSeq genes and over 485,000 methylation sites across the genome. Differentially methylated loci between affected and unaffected arterial tissues were identified, and subsequent bioinformatic analysis performed.

Results: We identified 1558 hypomethylated CpG sites (853 genes) and 2754 hypermethylated CpG sites (1471 genes) in GCA patients compared to controls. Gene ontology enrichment analysis of hypomethylated genes revealed significant representation in T cell activation and differentiation pathways, including both Th1 and Th17 related cytokine gene signatures (Table 1). Other proinflammatory genes such as *TNF*, *LTA*, and *LTB* were significantly hypomethylated in the cellular milieu of GCA arteries. Of the hypomethylated CpG sites in *TNF*, which is a known genetic susceptibility locus for GCA, two are within 1500bp upstream of the transcription start site, while two CpG sites are in the gene body. In addition, other genetic susceptibility loci for GCA such as *IFNG*, *PTPN22*, and *NLRP1* were also hypomethylated in this study. *CCR7* which is expressed on mature DCs, was amongst the most hypomethylated genes in GCA, consistent with a previously described pathogenic role for mature DCs within GCA affected arteries. Gene ontology analysis of hypermethylated genes displayed enrichment for genes related to actin cytoskeletal arrangement and regulation of GTPase-mediated and Ras protein signal transduction.

Table 1. Biological Process Gene Ontology (GO) Terms Most Enriched Among Hypomethylated Genes in GCA Arterial Lesions

GO Term	GO Term ID	Fold Enrichment	P value (Benjamini)	Genes

A Signature of microRNAs Overexpressed in Inflamed Temporal Arteries of Patients with Giant Cell Arteritis. Stefania Croci, Alessandro Zerbini, Luigi Boiardi, Francesco Muratore, Alessandra Bisagni, Giulia Pazzola, Luca Cimino, Antonio Moramarco, Davide Nicoli, Enrico Farnetti, Bruno Casali, Alberto Cavazza, Maria Parmeggiani and Carlo Salvarani. Arcispedale S Maria Nuova, Reggio Emilia, Italy.

Background/Purpose: MicroRNAs (miRNAs) are small, non-coding RNAs that suppress gene expression at post-transcriptional level. MiRNAs can regulate innate and adaptive immunity. Moreover, they have been found deregulated in various autoimmune diseases emerging as biomarkers and novel therapeutic targets. Giant cell arteritis (GCA) is an autoimmune inflammatory vasculitis affecting large and medium-sized arteries. Temporal artery biopsy (TAB) showing resident immune cells is the gold standard for the diagnosis of GCA. Nevertheless, a negative TAB does not rule out GCA and some patients receive a diagnosis of TAB-negative GCA according to clinical and laboratory parameters. The present study aimed to identify miRNAs deregulated in GCA and to determine if miRNA levels might allow to discriminate between patients with GCA and those without.

Methods: 48 patients undergoing TAB for suspected GCA were included in the study and divided into 3 groups: GCA with positive TABs (n=23), GCA with negative TABs (n=7) and non-GCA with negative TABs receiving a different diagnosis (n=18). 1990 ACR classification criteria for GCA were satisfied in all GCA patients with positive TABs, in 6 of the 7 GCA patients with negative TABs and in none of the non-GCA patients. To identify candidate miRNAs deregulated in GCA, expression of 1209 miRNAs was profiled with a miRNA array (Ocean Ridge Biosciences, Palm Beach Gardens, FL) in inflamed TABs from 7 GCA patients *versus* normal TABs from 8 non-GCA patients. MiRNAs showing a >2 fold, statistically significant differential expression with a false discovery rate <10%, were selected for further analyses. Their expression was validated by real-time PCR (QIAGEN, Milan, Italy) in different TAB samples as well as PBMCs and PMN cells isolated from GCA and non-GCA patients. To identify which cell type expressed miR-21 in TABs, in situ hybridization (Exiqon, Vedbaek, Denmark) was performed on FFPE tissue sections.

Results: 10 miRNAs emerged deregulated in inflamed TABs from GCA patients by a high throughput miRNA profiling assay. Subsequent real-time PCRs confirmed that miR-146b-5p, -146a, -155, -150 and -21 were significantly more expressed in TABs from GCA patients positive for a transmural inflammatory infiltrate. Negative TABs from GCA patients had a miRNA profile similar to negative TABs from non-GCA patients suggesting that miRNAs might be downstream inflammation. Expression of miR-146b-5p was particularly promising in a diagnostic perspective because it was possible to set a threshold level which correctly classified TABs as inflamed or normal. Within inflamed TABs, miRNA expression levels did not positively correlate with the load of infiltrating immune cells suggesting that miRNAs might be expressed by tissue cells. Indeed, in inflamed TABs, miR-21 was mainly expressed by spindle shaped cells of the media layer and stellate fibroblast-like cells of the intima layer. Moreover, miRNAs were expressed at comparable levels by circulating PBMCs and PMN cells from GCA and non-GCA patients.

Conclusion: miR-146a, -21, -150 and -155 and above all miR-146b-5p emerged as markers of inflammation in TABs from GCA patients, might be involved in GCA pathogenesis thus further investigated as therapeutics targets.

Accuracy of High Resolution MRI of Scalp Arteries for the Diagnosis of Giant Cell Arteritis: Results of a Prospective Study. Maxime Rhéaume[1], Ryan Rebello[2], Christian Pagnoux[3], Simon Carette[3], Marie Clements-Baker[4], Violette Cohen-Hallaleh[2], David Doucette-Preville[2], B. Stanley Jackson[5], Sam Salama[6], George Ioannidis[7] and Nader A. Khalidi[8]. [1]Division of Rheumatology, St. Joseph's Hospital, McMaster University, Hamilton, ON, [2]Department of Radiology, St. Joseph's Hospital, McMaster University, Hamilton, ON, [3]University of Toronto, Toronto, ON, [4]Queens University, Kingston, ON, [5]Department of Surgery, St. Joseph's Hospital, McMaster University, Hamilton, ON, [6]Department of Pathology, St. Joseph's Hospital, McMaster University, Hamilton, ON, [7]St Joseph's Healthcare Hamilton, Hamilton, ON, [8]St. Joseph's Hospital, McMaster University, Hamilton, ON.

Background/Purpose: Temporal artery biopsy (TAB) remains the gold standard for the diagnosis of giant cell arteritis (GCA). It is invasive and its sensitivity is limited by segmental arterial involvement. We sought to determine the diagnostic accuracy of high-field MRI compared to TAB in patients with suspected GCA.

Methods: All patients referred for TAB at our center were approached for this study. A high-resolution 3T MRI of the scalp arteries was obtained before the TAB was performed. Arterial abnormalities on MRI were assessed according to a previously published grading scheme, evaluating mural thickness and enhancement based on multiplanar postcontrast T1-weighted spin-echo images. Diagnostic accuracy of MRI was evaluated by comparison with TAB results as a primary analysis. Secondary analyses included comparison to clinician diagnosis and ACR criteria.

Results: 191 patients were screened and 171 were included in the study. Exclusions were based on withdrawal of consent (11), contra-indication to MRI (3), non-diagnostic test (3 MRI, 2 TAB) or failure to obtain MRI (1). ACR criteria were met in 137 patients (80.1%). Physician diagnosis was available for 162 subjects, with 78 (48.2%) considered as GCA. The MRI showed abnormal scalp arteries in 60 patients (35.1%) while biopsy was positive in 31 (18.1%). MRI was positive in 29 of those 31 patients with positive TAB (Sensitivity 93.6%). MRI was normal in 109 of those 140 with negative TAB (Specificity 77.9%). Relative to TAB, the negative predictive value of MRI was 98.2%.

Conclusion: High-resolution MRI detects biopsy-positive GCA with high sensitivity. A negative MRI is highly predictive of a negative TAB, such that patients with a negative MRI could safely be spared TAB. The significance of a positive MRI is not as well defined, and this should be the focus of future research.

MRI: Sensitivity, Specificity, Positive predictive value (PPV) and Negative predictive value (NPV)

Index Test	Reference Test	Sensitivity (95% CI)	Specificity (95% CI)	PPV (95% CI)	NPV (95% CI)

Interleukin 6 Does Not Upregulate Pro Inflammatory Cytokine Expression in an *Ex-Vivo* Model of Giant Cell Arteritis. Lorraine O'Neill[1], Jennifer McCormick[2], Wei Gao[2], Conor Murphy[3], Geraldine M. McCarthy[4], Douglas J. Veale[1], Ursula Fearon[2] and Eamonn S. Molloy[1]. [1]St. Vincent's University Hospital, Dublin 4, Ireland, [2]Translational Rheumatology Research Group, Dublin, Ireland, [3]Royal Victoria Eye and Ear Hospital, Dublin, Ireland, [4]Mater Misericordiae University Hospital, Dublin 7, Ireland.

Background/Purpose: Interleukin 6 (IL 6) is postulated to play a role in the pathogenesis of Giant Cell Arteritis. Several studies have demonstrated increased circulating IL 6 levels and upregulation of IL 6 in the temporal arteries of patients with GCA.

Multiple recent uncontrolled reports have noted improvements in clinical and laboratory parameters in patients with GCA treated with tocilizumab, an IL 6 receptor antagonist. However, persistent vascular inflammation has been reported in some cases.

The aim of this study was to examine the ability of IL 6 to induce pro-inflammatory mediators in *ex -vivo* temporal artery explant cultures.

Methods: 28 patients meeting 1990 ACR classification criteria for GCA were prospectively recruited. To directly examine the effects of IL 6 on pro-inflammatory mediators in GCA, *ex-vivo* temporal artery explant models were established.

Temporal artery explants were cultured in the presence or absence of recombinant human IL 6 (20 or 40 ng/ml) for 24 hours.

IL 6 mediates its effects through gp130 and the IL6 receptor. While gp130 is ubiquitous, the IL 6 receptor is limited to certain cells and therefore cells lacking the IL 6 receptor are unresponsive to the direct effects of IL 6. To overcome this, explants were co-cultured with rIL 6 and its soluble receptor (sIL6R).

Explant supernatants were harvested after 24 hours and assayed for IFNg, TNF, SAA, IL1b, IL 17, IL 8 and VEGF by ELISA. Of the cultured biopsies, 4 were snap frozen, protein was extracted and pSTAT3 expression assessed by Western Blot.

Graphpad Prism Ver 6.0d was used for statistical analysis. **Results** are presented as the mean +/− SEM in pg/ml/mg of biopsy weight.

Results: Stimulation with IL 6 did not induce any of the pro -inflammatory mediators assayed. No differences were observed in the explants cultured in the presence or absence of the sIL6R or between those with a positive (n=11) or negative (n=17) temporal artery biopsy. Increasing the concentration of IL 6 to 40 ng/ml did not alter our findings.

Mean values of VEGF did increase following treatment with IL6, even in the absence of sIL6R in keeping with the known ability of IL 6 to promote angiogenesis.

Western Blot analysis revealed increased expression of pSTAT3 in response to the combination of IL6+sIL6R, but not IL 6 alone, suggesting that the addition of the sIL6R is necessary to induce signal transduction.

	Basal:	Stimulated: IL6 (20 ng/ml)	p value: Wilcoxon signed-rank test
INFg	27.13 ± 8.6	36.10 ± 12.8	0.148
TNF	5.93 ± 1.9	7.39 ± 2.6	0.460
IL1b	2.45 ± 0.6	2.52 ± 0.85	0.945
IL 17	11.08 ± 4.9	16.92 ± 8.20	0.843
IL 8	16, 563 ± 5458	19,118 ± 6698	0.277
SAA * ng/ml/mg	10.42 ± 4.31	7.45 ± 2.54	0.625
VEGF	7.74 ± 3.45	107.3 ± 78.44	0.062

Conclusion: IL6 stimulation of temporal artery explants from patients with GCA, at concentrations sufficient to activate STAT3 and up regulate VEGF, did not result in increased expression of key pro-inflammatory mediators. This data argues against a central role for IL6 in driving vascular inflammation in GCA and raises the hypothesis that anti-IL6 based therapeutic strategies may have a lesser impact on vascular inflammation than on the systemic inflammatory syndrome in patients with GCA.

A 2-Week Single-Blind, Randomized, 3-Arm Proof of Concept Study of the Effects of Secukinumab (anti-IL17 mAb), Canakinumab (anti-IL-1 b mAb), or Corticosteroids on Initial Disease Activity Scores in Patients with PMR, Followed By an Open-Label Extension to Assess Safety and Effect Duration. Eric L. Matteson[1], Bhaskar Dasgupta[2], Wolfgang A. Schmidt[3], Carlo Salvarani[4], Nagui Gendi[5], Mauro Galeazzi[6], Sylvie Stitah[7], Yue Li[7], Marie-Anne Valentin[7], Bolan Linghu[8] and Stephen J. Oliver[7]. [1]Mayo Clinic, Rochester, MN, [2]Southend University Hospital, Essex, United Kingdom, [3]Immanuel Krankenhaus, Berlin, Germany, [4]Arcispedale-Santa-Maria-Nuova, Reggio Emilia, Italy, [5]Basildon & Thurroch University Hospitals NHS Trust, Basildon, Essex, United Kingdom, [6]Università di Siena, Siena, Italy, [7]Novartis Pharma AG, Basel, Switzerland, [8]Novartis Pharma AG, Cambridge, MA.

Background/Purpose: To assess the effects of a single dose of secukinumab or canakinumab in patients with new onset, untreated polymyalgia rheumatica (PMR).

Methods: In this single-blinded, double-dummy, randomized, active-controlled, parallel-group study, patients with PMR of >1 week duration were randomized 1:1:1 to receive single dose (3 mg/kg/body weight) of either secukinumab or canakinumab, or daily oral prednisone (PRED) at 20 mg a day. The primary endpoint was efficacy after 2 weeks, assessed by the PMR activity score (PMR-AS components: CRP, morning stiffness, ability to elevate arms; 100 mm VAS assessments for patient pain and physician global). Complete response was defined as >70% reduction in patient global assessment VAS compared with baseline, morning stiffness <30 min, and CRP <1.0 mg/dl. Partial response was defined as >50% reduction in patient global assessment VAS compared with baseline and morning stiffness <60 min. Patients treated with biologics failing to achieve criteria for either complete or partial response by Day 15 initiated treatment with PRED 20 mg/day. All patients receiving PRED underwent a scheduled taper after 2 weeks treatment. Patients were followed up to 154 days for safety and duration of treatment effects. Serum levels of IL-6 and VEGF were measured by ELISA.

Results: 16 patients (11 females) were randomized (secukinumab, n=6, mean baseline PMR-AS 46.6; canakinumab, n=5, mean PMR-AS 54.3; PRED n=5, mean baseline PMR-AS 37.5). The primary endpoint was assessed in 13 patients (secukinumab, 6; canakinumab, 3; PRED, 4). PMR-AS reductions from baseline were seen in all patients at day 15: secukinumab =52%; canakinumab =65%; PRED 92%. By Day 15 no biologic-treated patients achieved complete response and only 1 patient in each biologic group achieved a partial response, whereas 1 patient in the PRED arm had complete response and 3 patients had partial responses. CRP reductions were most rapid in the PRED group and more consistent in patients treated with either PRED or secukinumab. In patients treated with PRED, rapid reductions were observed in mean VAS for physician global assessment and patients' assessment of pain compared to only moderate or minimal effects in the secukinumab and canakinumab groups, respectively. PRED induced a rapid and consistent decrease in IL-6 while no consistent effects were noted in patients treated with biologics. Secukinumab induced rapid and consistent decreases in VEGF levels that were not observed in the other two groups. Patients in secukinumab (n=4) and canakinumab (n=3) groups who required switch to PRED with subsequent taper had a 40% and 35% lower monthly average steroid use, respectively, compared to the PRED group (n=4) that had not been exposed to a biologic. All three study treatments were well-tolerated without SAEs or increased infections noted.

Conclusion: In this study PMR-AS reduced more rapidly by Day 15 in prednisone-treated patients than in patients receiving secukinumab or canakinumab. Patients receiving biologics followed by prednisone had overall lower cumulative steroid doses. The therapeutic effects of secukinumab and canakinumab in PMR remains uncertain and deserves further study.

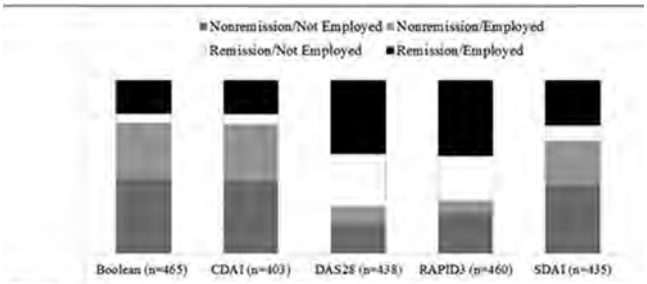
Measuring Rheumatoid Arthritis Remission: Which Index of Disease Activity Best Predicts Work Status? Nancy A. Baker[1], Heather Eng[2], Juan (June) Feng[2], Jason Lyons[2], Yong Gil Hwang[1], Kimberly P. Liang[1] and Larry W. Moreland[1]. [1]University of Pittsburgh, Pittsburgh, PA, [2]University of Pittsburgh, Graduate School of Public Health, Pittsburgh, PA.

Background/Purpose: Disease remission is the goal of treat-to-target initiatives in rheumatoid arthritis (RA). There are multiple indices to measure disease activity and remission status including those recommended by ACR and EULAR in 2011: the Simplified Disease Activity Index (SDAI) and a Boolean based definition (tender joint count, swollen joint count, C-reactive protein, patient global assessment ≤ 1). The choice of these measures was based on their predictive validity for radiographic damage and the Health Assessment Questionnaire (HAQ), outcomes which are focused on impairment and activity levels. Remission scores should be predictive of community participation, such as employment. As work disability is common for people with RA, it is particularly important that indices can accurately predict work status. This study evaluated each of five common indices of disease activity (Boolean, SDAI, Clinical Disease Activity Index [CDAI], Disease Active Score-28 joint count [DAS28], Routine Assessment of Patient Index 3 [RAPID3]) to identify the best predictor of work status.

Methods: In this cross-sectional study we extracted data on 511 working aged (≤65 year old) RA patients from the Rheumatoid Arthritis Comparative Effectiveness Research (RACER) longitudinal registry based at the University of Pittsburgh. This registry, started in 2010 has enrolled 1,045 RA patients with over 7000 usual care clinic visits. Work status and index data are collected at most visits and we selected the most recent visit that contained information on both. Patients self-identified as "employed" were coded as such; all other categories were coded as not employed. We calculated the Boolean, SDAI, CDAI, DAS28, and RAPID3 scores and coded each patient as in remission/not in remission based on published cut-off scores (Figure 1). We completed 5 separate logistic regressions with work status as the outcome and each index as the predictor variable. Covariates were age, gender, remission duration, disease duration and the presence of any comorbidities (yes/no) measured through the Charlson score, which we dichotomized. We report the C-statistic, which is equivalent to the area under a ROC curve and allows us to judge how well each model discriminated between employed and not employed.

Results and Conclusion: In all models except CDAI, remission status was significantly associated with work status. While all models were moderately good at predicting work status (C-statistic range 0.66 to 0.77), the RAPID3 was the most accurate and the DAS28 and CDAI were the least. A score indicating remission on the RAPID3 would correctly identity that someone would or would not be employed 77% of the time. This superior accuracy may be related to the functional questions included in this index, whereas all other indices rely on symptoms and patient assessment of health without a functional component.



Cut-off	measures ≤1	≤2.8	≤ 2.6	≤1	≤3.3
C-statistic	0.72	0.66	0.67	0.77	0.73
[95% CI]	[0.67, 0.76]	[0.60, 0.72]	[0.61, 0.73]	[0.72, 0.82]	[0.68, 0.78]

Outcome variable: Work status (employed not employed). Predictor variable: Remission status (yes/no). Covariates: Age, gender, remission duration (days), Charlson score (yes/no), disease duration (years).
*All models were significant ($p \leq .05$). Age was a significant predictor in all models, remission status was a significant predictor in all models except the CDAI. Remission duration was a significant predictor in only the RAPID3 model.

Figure 1 – The ability of each index of disease activity to predict work status.

The Impact of Inadequate Health Literacy on Disease Activity in Patients with Rheumatoid Arthritis. Maria Celeste Orozco[1], Maria Florencia Marengo[1], Christian A. Waimann[1], Ana Inés Marcos[2], Amelia Granel[2], Sofia Velez[3], Federico Zazzetti[3], Juan C. Barreira[4], Paula Kohan[5], Oscar L. Rillo[6], María Victoria Collado[7], Graciela Gómez[8], Ricardo V. Juárez[9], Veronica Lencina[9], Andrea D'Orazio[10], Gustavo Rodriguez Gil[10], Mariana Salcedo[11] and Gustavo Citera[1]. [1]Instituto de Rehabilitación Psicofísica, Buenos Aires, Argentina, [2]Hospital San Roque de Gonnet, La Plata, La Plata, Argentina, [3]Hospital Britanico, Buenos Aires, Argentina, [4]British Hospital, Buenos Aires, Argentina, [5]Hospital Gral. de agudos Dr. E. Tornú, Buenos Aires, Argentina, [6]Hospital General de Agudos Dr. E. Tornú, Buenos Aires, Argentina, [7]Instituto de Investigaciones Medicas Alfredo Lanari, Buenos Aires, Argentina, [8]Insituto de Investigaciones Medicas de la UBA, Capital Federal, Argentina, [9]Hospital Señor del Milagro, Salta, Argentina, [10]Hospital Municipal de agudos Dr. Leonidas Lucero, Bahía Blanca, Argentina, [11]Consultorio Privado, San Nicolás, Argentina.

Background/Purpose: Health literacy is the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions. It is being increasingly recognized as important determinant to health outcomes. Patients with low health literacy are less able to manage chronic conditions effectively. The aim of our study was to measure the level of health literacy in patients with Rheumatoid Arthritis (RA) and assess its association with clinical outcomes.

Methods: A multicenter cross-sectional study was conducted. Patient were recruited from 7 outpatients clinics including consecutive patients with diagnosis of RA according to American College of Rheumatology (ACR) 1987 criteria and/or ACR/European League Against Rheumatism (EULAR) 2010 criteria. Health literacy was assessed using the Test of Functional Health Literacy in Adults (S-TOFHLA) (0–36, 0 worst health literacy). Patients were categorized as having low or adequate health literacy using the standard cutoff (<23). Patient reported clinical outcomes included the Clinical Disease Activity Index (CDAI) and the Health Assessment Questionnaire (HAQ). We also collected data regarding patient demographics, comorbidities and treatment adherence -. Adherence to treatment was assessed using the Compliance Questionnaire Rheumatology (CQR; 0 – 100, 0 low adherence). The association between health literacy and clinical/functional outcomes were evaluated using univariate and multivariate models adjusting by age, gender, educational level, disease duration and treatment adherence.

Results: Three hundred and thirty-eight patients were included, 84 % were female, mean age was 53 ± 12 years, disease duration 13 ± 10 years, CDAI 13 ± 11 and HAQ 1.00 ± 0.75. Mean S-TOFHLA score was 26 ±12. Three hundred and two patients (76%) had adequate health literacy. These patients had significantly lower age ($r=-0.22$, $p<0.01$), higher level of education($r=0.40$, $p<0.01$), less number of comorbidities($r=-0.13$, $p<0.01$) and shorter disease duration($r=-0.14$, $p<0.01$). After adjusting for multiple confounders, patients with low level of health literacy showed significantly higher disease activity ($b = 3.7$, $p=0.01$). Health literacy was not associated with HAQ ($b=0.14$, $p=0.14$). Using S-TOFHLA as continuous variables did not affect the results.

Conclusion: A quarter of patients with rheumatoid arthritis had inadequate health literacy, showing higher level of disease activity. Physicians

should recognize that literacy levels of their patients could affect clinical outcomes, and provide appropriate interventions to ease this burden.

Annual Medical Care Expenditures Among US Adults with Gout, 2005–2011. Miriam G. Cistcrnas[1], Louise Murphy[2], David J. Pasta[3], Edward H. Yclin[4], and Charles Hclrnick[2]. [1]MGC Data Services, [2]Centers for Disease Control and Prevention, [3]DMA Corporation[4]University of California, San Francisco.

Background/Purpose: Costs associated with gout arc of growing interest due to its increasing prevalence, but quantifying those costs has been hampered by its co-occurrence with other highly prevalent, high-cost conditions. We estimated all-cause medical care expenditures and gout-attributable expenditures among US adults with gout age ≥18 years.

Methods: Using the 2005–2011 Medical Expenditure Panel Survc (MEPS), we identified adults with gout by the presence of ICD-9-CM 274. We estimated annual national total (aggregate) and mean per-person all-cause and gout-attributable expenditures overall and for four expenditure categories: ambulatory care (office-based and hospital outpatient); inpatient care; prescriptions; and other (emergency room visits, home health care, vision aids, dental visits, and medical devices). Gout-attributable expenditures were calculated using multis agc regression models that adjusted for demographics (age, sex, race, Hispanic ethnicity, and education), health insurance coverage (any private, public only, or none), and a count of nine costly comorbid conditions. All estimates are in 2011 US dollars.

Results: National total all-cause medical care cxpcnditurcs among the 2.7 million adults reporting gout were $31.8 billion; mean per-person expenditures among US adults with gout were $11,663, compared to $4,643 for all adults. Across expenditure categories, all-cause mean per-person expenditures were: inpatient ($4,329), ambulatory care ($3,704), prescriptions ($2,497), and other ($1,133). National gout-attributable expenditures totaled $7.7 billion (mean per person=$2.805) and accounted for 24% ($7.7 billion/$31.8 billion) of all medical expenditures among US adults with gout. Mean per-person gout-attributable expenditures for inpatient ($1,488) and ambulatory care ($1,349) accounted for essentially all of the attributable expenditures. Attributable expenditures for prescription and other were less than $100 in magnitude and much less than the estimated error.

Conclusion: Mean per-person all-cause medical expenditures were more than 2.5 times higher among adults with gout compared to the entire adult population. Total annual national medical expenditures attributable to gout were $7.7 billion, accounting for almost one of four dollars spent for medical care of US adults with gout. The increasing prevalence of gout suggests increasing costs in the future. Raising awareness about recent therapies and guidelines to identify and treat gout at earlier stages and increase compliance may help moderate those costs.

Exercise, Manual Therapy, and Use of Booster Sessions in Physical Therapy for Knee OA: A Multi-Center Randomized Clinical Trial. G Kelley Fitzgerald[1], Julie Fritz[2], John Childs[3], Gerard P. Brennan[4], Douglas P. Landsittel[5], Brett Neilson[6], Alexandra Gil[1] and J. Haxby Abbott[7]. [1]University of Pittsburgh, Pittsburgh, PA, [2]University of Utah, Salt Lake City, UT, [3]US Army-Baylor University, Schertz, TX, [4]Intermountain Healthcare, Murray, UT, [5]University of Pittsburgh, Center for Health Care Research Data Center, Pittsburgh, PA, [6]Henry M. Jackson Foundation, Bethesda, MD, [7]University of Otago, Dunedin, New Zealand.

Background/Purpose: There is need to improve the magnitude and duration of treatment effects of exercise therapy (ET) for patients with knee osteoarthritis (KOA). There is conflicting evidence that manual therapy (MT) can enhance treatment effect magnitude of ET for pain and function. The use of booster treatment sessions have also been suggested to improve sustainability of these treatment effects, but evidence is lacking. The aims of the study were to: 1) determine if adding MT to ET programs would result in an additive treatment effect on pain and function, and 2) determine if use of booster treatment sessions would result in greater sustainability of these effects in patients with KOA.

Methods: Multi-center randomized clinical trial, including three clinical sites from different regions of the United States. 300 subjects (mean age = 58 ± 9 years; 199 female) meeting the ACR clinical criteria for KOA were randomly allocated to 1 of 4 groups; 1) ET- no booster, 2) ET + booster, 3) MT+EX-no booster, and 4) MT+Ex + booster. Subjects not receiving booster sessions received 12 treatment sessions in 9 weeks. Subjects receiving booster sessions received 8 treatment sessions in 9 weeks then received 4 additional booster treatment sessions distributed over the remaining year. Primary outcome measure was the WOMAC total score. Secondary outcome measures included the numeric knee pain rating, the Timed Up and Go (TUG) test, the 30 sec. chair rising test, and the 40m walk test. Outcome measures were obtained at baseline, 9 weeks, and 1 year. Data was analyzed using a repeated measures linear mixed model of treatment effect and the treatment group by time interaction was performed, adjusting for treatment site location and bilateral knee involvement. Statistical significance was $\alpha = .05$.

Results: The figure summarizes the WOMAC total scores at each time point. There were no statistical or clinically meaningful differences between treatment groups at either follow-up time point. There was no significant treatment group by time interaction. All treatment groups demonstrated meaningful changes in clinical outcome from baseline to the 9 week follow-up (within group effect sizes range =.69 to 1.2; percent change from baseline range = 37%-54%) which was also maintained over the 1 year follow-up period (within group effect sizes range =.70 to.85; percent change from baseline range = 37%-40%). Similar results were observed for all other outcome measures.

Conclusion: Adding MT to ET did not increase the magnitude of treatment effect and use of booster sessions did not exhibit superior sustainability of treatment effects over time. All four treatment approaches tested in this study yield moderate to large improvements in pain and function that were sustained over a one year period.

Test of the NIH Patient-Reported Outcomes Measurement Information System (PROMIS) 29-Item Profile in a Large Cohort of Rheumatic Disease Patients. Patricia P. Katz[1], Sofia Pedro[2] and Kaleb Michaud[3]. [1]University of California, San Francisco, San Francisco, CA, [2]National Data Bank, Wichita, KS, [3]University of Nebraska Medical Center and National Data Bank, Omaha, NE.

Background/Purpose: Patient-reported outcomes are routinely used in rheumatology research and clinical care. Yet, often outcomes cannot be compared across studies or diseases because a variety of measures are used in these assessments, and many important health domains are not assessed because of lack of measures or concerns about questionnaire burden. Further, many "traditional" patient-reported outcomes measures are available only in English, which is an increasingly limiting factor. The NIH Patient-Reported Outcomes Measurement Information System (PROMIS) consists of a group of patient-reported outcome measures that span a wide array of physical, social, and emotional health outcomes; are applicable across health conditions; and are available free of charge and in multiple languages. A test of the PROMIS measures has not been undertaken in patients with RA, OA, or

fibromyalgia. This analysis presents an initial psychometric evaluation of PROMIS measures in a large cohort of these patients.

Methods: Data were from a subset of respondents to a single administration of a questionnaire that included the PROMIS 29-item profile. The sample included 528 individuals (RA: 323; OA: 109; fibromyalgia: 96). Using short questionnaires, the PROMIS-29 assesses 7 of the PROMIS health domains: Physical Function, Pain Interference, Fatigue, Depression, Anxiety, Sleep Disturbance, and Ability to Participate in Social Roles. Each section was scored and converted to t-scores, with mean = 50 and SD = 10. Analyses examined correlations of PROMIS measures with scales measuring related constructs (SF-36 subscales, Health Assessment Questionnaire [HAQ], and numeric rating scales for pain, fatigue, and sleep problems), for the total sample and within disease groups. Analyses also examined ability of PROMIS measures to discriminate among levels of satisfaction with health.

Results: PROMIS scales exhibited moderate ($r<0.7$) correlations with most of the comparison measures, with some correlations slightly higher, indicating that similar constructs were being measured (Table 1). Results were similar for each disease group. All PROMIS scales discriminated among levels of satisfaction with health, yielding significant overall ANOVA results and significant non-parametric tests of trend (Table 2).

Conclusion: These PROMIS short forms exhibited strong psychometric properties. Use of PROMIS offers important expansions of current measures so that aspects of health, social functioning, and quality of life that are important to patients can be included without increasing questionnaire burden.

Table 1 Correlation of PROMIS Scales with Related Measures

	PROMIS 29-Item Profile scales*						
	PF	**PI**	**FAT**	**DEP**	**ANX**	**SLP**	**SocR**
SF-36 Physical Function	0.83						
SF-36 Role Physical							0.62
SF-36 Role Emotional							0.43
SF-36 Vitality			−0.77				
SF-36 Bodily Pain		−0.73					
SF-36 Mental Health				−0.69	−0.67		
HAQ	−0.74						
NRS-pain		0.62					
NRS-fatigue			0.71				
NRS-sleep						0.71	

* For all PROMIS scales, higher scores reflect "more" of the construct being measured. E.g., Higher Physical Function scores reflect better functioning; higher Pain Interference scores reflect greater pain interference
PF = Physical Functioning; PI = Pain Interference; FAT = Fatigue; DEP = Depression; ANX = Anxiety; SLP = Sleep disturbance; SocR = Ability to Participation in Social Roles.
HAQ = Health Assessment Questionnaire

Table 2 PROMIS 29-Profile Scores* by Levels of Satisfaction with Health

	PROMIS 29-Item Profile scales*						
Satisfaction with health:	**PF**	**PI**	**FAT**	**DEP**	**ANX**	**SLP**	**SocRole**
Very satisfied (n=61)	46.9	52.7	48.0	45.0	44.6	47.5	52.5
Somewhat satisfied (n=173)	41.1	58.1	53.8	47.9	47.9	51.4	45.8
Neither satisfied nor dissatisfied (n=81)	37.9	61.1	57.9	51.3	51.3	55.0	40.9
Somewhat dissatisfied (n=139)	35.8	63.6	60.9	52.7	52.8	56.0	38.3
Very dissatisfied (n=89)	33.0	66.7	67.2	60.3	58.8	61.7	32.2

* Table presents mean scores for individuals in each satisfaction with health rating group. Differences were tested with ANOVA and non-parametric test for trend. All were significant p<.001.

Randomized Clinical Trial of Group Vs. Individual Physical Therapy for Knee Osteoarthritis. Kelli D. Allen[1], Dennis Bongiorni[2], Hayden B. Bosworth[3], Cynthia Coffman[3], Santanu Datta[3], David Edelman[3], Jennifer H. Lindquist[2], Eugene Oddone[3] and Helen Hoenig[3]. [1]Durham VA Medical Center and University of North Carolina at Chapel Hill, Durham, NC, [2]Durham VA Medical Center, Durham, NC, [3]Durham VA Medical Center and Duke University Medical Center, Durham, NC.

Background/Purpose: Physical therapy (PT) is a key component of treatment for knee osteoarthritis (OA). There is a high demand for PT services in many healthcare systems, resulting in a need for evidence-based models for delivering PT in an efficient manner. A group-based approach to PT can extend services to more patients with lower staffing requirements than typical individual PT. The objective of this trial was to compare the effectiveness of a group-based PT program (GPT) with usual individual PT (IPT) for knee OA.

Methods: 320 patients with knee OA at the VA Medical Center in Durham, NC (mean age = 60, SD=10; 88% male; 58% non-white) were randomized to either GPT or IPT. GPT included six 1-hour sessions, every other week, co-led by a physical therapist and PT assistant, with 8 participants per group. IPT, modeled after typical outpatient PT care for knee OA at the Durham VAMC, included two 1-hour visits with a physical therapist, 2–3 weeks apart. Both PT interventions included a home exercise program, as well as individual evaluations of functional limitations and needs for braces or assistive devices. GPT sessions also included exercise sessions supervised by the PT assistant. The primary outcome was the Western Ontario and McMasters Universities Osteoarthritis Index (WOMAC; range 0–96, higher scores indicate worse symptoms), and the secondary outcome was objective physical function (Short Physical Performance Battery; SPPB, range 0–20, higher scores indicate better function); both were assessed at baseline and 12-weeks, and WOMAC was also assessed at 24-weeks. Linear mixed models were used to assess the difference in improvement in outcomes between arms, adjusting for clustering of group sessions within the GPT arm.

Results: The median numbers of sessions attended for GPT and IPT were 5 (out of 6 possible) and 2 (out of 2 possible), respectively. At 12-week follow-up, WOMAC scores were 2.7 points lower in the GPT group vs. IPT [95% confidence interval (CI) = −5.9, 0.5; p=0.10], indicating no meaningful difference in improvement between arms. However, mean total WOMAC scores declined −4.5 points from baseline across both arms combined [95% CI =−6.8,-2.2; p=0.0001], indicating meaningful improvement. Similarly, for the WOMAC pain and function subscales and SPPB scores there was improvement across both arms at 12-weeks ($p<0.0001$, p=0.001, and p=0.02) but no difference in improvement between arms (p=0.19, p=0.12, and p=0.37). At 24-week follow-up, WOMAC scores across both arms were 3.1 points lower compared to baseline [95% CI = −5.4, −0.7; p=0.01], indicating some sustained improvement in both groups, with no difference between groups (p=0.45).

Conclusion: Results of this study confirm that PT improves pain and functional outcomes in patients with knee OA. Outcomes did not differ substantially between GPT and IPT arms, suggesting that either is an effective means of delivering PT services for knee OA. The GPT approach in this study required less overall staff time per patient to deliver, and it could provide services efficiently to larger numbers of patients. Therefore it should be considered as a viable model for health systems to provide this service to patients with knee OA.

Symptom Increase in Fibromyalgia Is Not Consistent with the Central Sensitization or Central Hyperresponsiveness Hypothesis. Frederick Wolfe[1], Brian T. Walitt[2], Johannes Rasker[3], Robert S. Katz[4] and Winfried Häuser[5]. [1]National Data Bank for Rheumatic Diseases, Wichita, KS, [2]Washington Hospital Center, Washington, DC, [3]University Twente, Enschede, Netherlands, [4]Rush Medical College, Chicago, IL, [5]Klinikum Saarbrücken, Saarbrücken, Germany.

Background/Purpose: The current dominant hypothesis explains fibromyalgia (FM) as a centralized pain state in which the CNS originates or amplifies pain, which is then accompanied by fatigue, memory problems, and sleep and mood disturbances[1]. The often noted "pan-positive review of symptoms" is attributed to central hyperresponsiveness not to psychological factors or "somatization."[1] Surprisingly, this explanation of non-pain symptoms has never been validated. As fibromyalgia and widespread pain (WP) have been accepted as evidence of the presence of central sensitization (CS), we used the widespread pain index (WPI), a non-symptom containing component of the polysymptomatic distress scale (PSD), to test whether the rate of increase in non pain symptoms as WP increased was greater in the presence of PSD defined fibromyalgia and WSP then in their absence.

Methods: We studied 3,562 mixed rheumatic disease patients, and diagnosed FM by modified ACR FM criteria. To preclude bias because of the non-pain symptoms included in the PSD, we used WPI alone and as a surrogate for the PSD. We formed an ad hoc fibromyalgia symptom count

(FSC) (0–19) by summing 19 non-pain related symptoms. We used linear splines and regression models to calculate separate slopes for symptom prediction at WPI levels between 0–6 and 7–19. An increase in the slope of the 7–19 WPI scores compared with the 0–6 WPI scores was accepted as evidence of the effect of CS.

Results: 96% of those with a WPI score ≥7 satisfied WP criteria, and FM was correctly classified in 89% (kappa 0.703). The FSC increased monotonically as WPI increased (Figure 1), and the slope for WPI 0–6 was 0.68 compared with 0.25 for 7–12 ($P<0.001$). For each of the 19 symptoms examined, slopes were compared by odds ratios and were significantly lower in the 7–12 group (Table 1).

Conclusion: Our data show no increase in non-pain symptom slopes in subjects with high WPI. Instead, symptom increase is monotonic, and the rate of increase is greater at lower levels of WPI. Alternative hypotheses for increase in symptoms should include factors such non-CS pain and psychological variables.

Polysymptomatic Distress Categories for Clinical and Research Use.

Frederick Wolfe[1], Brian T. Walitt[2], Johannes Rasker[3], Robert S. Katz[4] and Winfried Häuser[5]. [1]National Data Bank for Rheumatic Diseases, Wichita, KS, [2]Washington Hospital Center, Washington, DC, [3]University Twente, Enschede, Netherlands, [4]Rush Medical College, Chicago, IL, [5]Klinikum Saarbrücken, Saarbrücken, Germany.

Background/Purpose: The polysymptomatic distress (PSD) scale is derived from variables used in the 2010 American College of Rheumatology (ACR) fibromyalgia (FM) criteria as modified for survey and clinical research. The scale is useful in measuring the effect of PSD over the full range of human illness, not just in those who are ACR criteria positive. However, no PSD scale categories have been defined to distinguish severity of illness in FM or in those who do not satisfy criteria. We analyzed the scale and multiple covariates to develop useful clinical categories for PSD and to further validate the scale.

Methods: Fibromyalgia was diagnosed according to the research criteria modification of the 2010 ACR fibromyalgia criteria. We used the 2012 German general population survey (N=2445) to establish "normal" values. We then investigated categories in a large sample of patients with pain: 2,732 with rheumatoid arthritis (RA), and developed categories by utilizing germane clinic variables that had been previously studied for severity groupings. By ACR definition, FM cannot be diagnosed unless PSD is at least 12.

Results: The mean PSD of those with FM in the General population was 16.2 and was 19.2 in the RA clinical sample. Based on population categories and regression analysis and inspections of curvilinear relationships in RA, we established PSD severity categories of None (0–3), Mild (4–7), Moderate (8–11), Severe (12–19) and Very severe (20–31). Categories were statistically distinct, and a generally linear relationship between PSD categories and covariate severity was noted (Table and figures). The thin line in the figures represents the distribution of PSD values.

Conclusion: The described PSD categories are clinically relevant and demonstrate FM type symptoms over the full range of clinical illness, not just in FM positive subjects. Although FM criteria can be clinically useful, no clear-cut distinction between FM (+) and FM (−) subjects can be seen in our data.

Table 1. Clinical variables according to PSD severity groups.

PSD Group	PSD (0–3)	PSD (4–7)	PSD (8–11)	PSD FM (+) (12–19) FM (−) excluded	PSD FM (+) (20–31) FM (−) excluded
Pain (0–10)	1.3	2.7	4	5.3	6.8
Global severity (0–10)	1.4	2.8	3.9	5.2	6.3
HAQ (0–3)	0.4	0.8	1.1	1.4	1.7
PCS score (SF-36)	47.4	40.2	34.6	30.8	27.5
GAD Anxiety case (%)	1.3	3.4	6.8	22.3	30.6
PHQ-2 Depression case (%)	0.1	2.3	5.6	26.1	34.8
Regional Pain Scale (0–19)	0.8	2.6	5	8.2	16.3
Symptom severity (0–12)	0.9	2.8	4.3	7.2	8.2
ACR FM criteria (+) (%)	0.0	0.0	0.0	100.0	100.0
PSD (0–31)	1.7	5.4	9.3	15.4	24.5
Widespread pain (%)	0.8	18.0	57.5	87.8	100.0

Small Fiber Neuropathy in Women with Fibromyalgia. a Clinical-Pathological Correlation Using Confocal Corneal Biomicroscopy. Manuel Ramírez-Fernández[1], Laura-Aline Martinez-Martinez[2], Angelica Vargas-Guerrero[2], Manuel Martínez-Lavín[2], Everardo Hernandez Quintela[1] and Jorge Velazco-Caspia[1]. [1]Asociación para Evitar la Ceguera en México, Mexico City, Mexico, [2]Instituto Nacional de Cardiologia, Mexico City, Mexico.

Background/Purpose: A consistent line of investigation proposes that fibromyalgia is a sympathetically maintained neuropathic pain syndrome (Semin Arthritis Rheum 2000;29:197). This view has been recently reinforced by several controlled studies describing decreased small nerve fiber density in skin biopsies of patients with fibromyalgia (Brain 2013;136:1857).

Small fiber neuropathy is a disorder of the peripheral nerves that primarily affects small somatic fibers and sympathetic fibers resulting in sensory changes and autonomic dysfunction. The cornea receives the densest small fiber innervation of the body. Confocal corneal biomicroscopy is a new noninvasive method to assess small nerve fiber pathology.

The main objective of this cross-sectional investigation was to assess the corneal small nerve fiber morphology in patients with fibromyalgia using confocal microscopy. The secondary objective was to correlate corneal nerve microscopic features with fibromyalgia severity parameters contained in several validated questionnaires.

Methods: We studied 17 female patients with fibromyalgia (mean age = 43 ± SD 5) and 17 age-matched healthy female control subjects. A central scan of the total corneal thickness was obtained with a confocal microscope (Confoscan 4, Fortune Technologies, Italy). A single ophthalmologist expert in corneal pathology evaluated stromal nerves morphology and thickness using the Navis v. 3.5.0. Software (NIDEK, Multi-Instrument Diagnostic System, Japan). Nerve thickness was defined as the mean between the widest and the narrowest portion of each analyzed stromal nerve. Nerve smoothness was defined as the difference between the widest and the narrowest portions of each analyzed stromal nerve. Measurements were done without knowledge of the clinical diagnosis. All studied subjects filled out different questionnaires assessing fibromyalgia severity, including a neuropathic symptom questionnaire (LANSS).

Results: Corneal stromal nerves were easily identified as bright linear silvery structures. Patients with fibromyalgia had nerve thickness of 5.9 ± 2.2 micrometers (mean ± SD) significantly different from control's values (7.4 ± 2.4) $p < 0.0001$. The difference between widest and narrowest nerve diameter was also dissimilar in patients (1.8 ± 1.3) vs. controls (2.6 ± 1.5) $p < 0.0001$. Remarkably; when patients and controls were grouped together (n = 34), there was a negative correlation between corneal stromal nerve thickness and LANSS neuropathic symptoms questionnaire score (Spearman's r = - 0.36, $p = 0.03$) as well as with tender points number (r = - 0.38, $p = 0.02$), and other non-pain-related fibromyalgia symptoms.

Conclusion: Confocal biomicroscopy demonstrates that women suffering from fibromyalgia have thinner and smoother corneal nerve fibers when compared to healthy controls. When controls and patients are grouped together, there is a correlated continuum between the degree of corneal nerve pathology and fibromyalgia symptoms. Small fiber neuropathy may play a key role in fibromyalgia's pathogenesis.

The Fibromyalgia Syndrome and Widespread Pain Frequency in Active Duty U.S. Service Members with Posttraumatic Stress Disorder. Bernard Hildebrand Jr. [1], Jay B. Higgs[1], Douglas Williamson[2], Edna Foa[3], Patricia Resick[4], Jim Mintz[2], Antoinette Brundige[2], Kevin Kelly[5], Adam Borah[5], Stacey Young-McCaughan[2], Brett Litz[6], Elizabeth Hembree[3] and Alan Peterson[2]. [1]San Antonio Military Medical Center, JBSA - Fort Sam Houston, TX, [2]The University of Texas Health Science Center at San Antonio, San Antonio, TX, [3]University of Pennsylvania, Philadelphia, PA, [4]Duke University, Durham, NC, [5]Carl R. Darnall Army Medical Center, Fort Hood, TX, [6]VA Boston Healthcare System, Boston, MA.

Background/Purpose: Posttraumatic stress disorder (PTSD) and pain are common amongst US military service members who have deployed to Iraq and Afghanistan. Studies suggest the co-morbidity of PTSD and pain exacerbates somatic symptoms, and the relationship between PTSD and somatic symptom disorders, including the fibromyalgia syndrome (FMS), is a subject of much importance. The STRONG STAR Consortium offers a unique opportunity to study FMS in the context of a series of investigations of PTSD risk factors, features, and treatment methods in active duty personnel during a period of ongoing military conflict. We report the prevalence of FMS and widespread pain (WP) in pre-deployment, active duty US military service members and in post-deployment service members with PTSD.

Methods: Active duty US veterans of the wars in Iraq and Afghanistan enrolled in STRONG STAR Consortium studies were evaluated. A questionnaire screening for WP, symptom severity, symptom duration, and a prior diagnosis of a pain disorder was administered as part of the assessment battery for two treatment studies of PTSD patients and a prospective study assessing the effect of military deployment on PTSD development. The prevalence of WP and FMS were determined using 1990 ACR Criteria and the Wolfe modification to the 2010 ACR criteria, respectively.

Results: Of 4120 active duty military service members assessed pre-deployment, 118 (3%) met study criteria for the classification of FMS and 244 (5.9%) for WP. In a cohort of 181 service members with PTSD, 57 (31%) met criteria for FMS and 48 (27%) had WP. A separate cohort of 171 service members with PTSD identified 67 (37%) patients with FMS and 51 (30%) with WP.

Conclusion: The prevalence of FMS and WP was markedly elevated in active duty military service members seeking treatment for PTSD when compared to a sample of active duty personnel screened just prior to deployment. Further study may help answer questions regarding the intersection of FMS with PTSD and enable development of tailored therapies appropriate for US service members and veterans with PTSD, FMS and related disorders.

Development of Fibromyalgia and Polysymptomatic Distress Definitions in the National Health Interview Survey. Brian Walitt[1], Richard Nahin[2], Robert S. Katz[3], Martin J. Bergman[4] and Frederick Wolfe[5]. [1]MedStar Health, Washington, DC, [2]National Institutes of Health, Bethedsa, MD, [3]Rush Medical College, Chicago, IL, [4]Taylor Hospital, Ridley Park, PA, [5]National Data Bank for Rheumatic Diseases, Wichita, KS.

Background/Purpose: A detailed understanding of fibromyalgia and its symptoms in the US population would be valuable. The National Health Interview Survey (NHIS) is the principal source of civilian population data in the USA. To study fibromyalgia in the NHIS requires the development of a fibromyalgia definition that uses NHIS questions and a subsequent validation of that definition with a standard fibromyalgia definition. However, the 2011 modified American College of Rheumatology (ACR) criteria and the NHIS questionnaire set evaluate pain differently and over different time periods. In particular, NHIS inquires about joints while the ACR criteria about painful regions. To reconcile and adjust for these differences we administered the ACR criteria and questions from the NHIS at the same time to rheumatic disease patients.

Methods: In 2012, NHIS collected data about joint pain, fatigue, subjective cognitive impairment, mood, headaches, and sleep. A questionnaire was developed that incorporated 2012 NHIS questions along with the questions of the 2011 modified ACR research criteria for fibromyalgia. These questionnaires were sequentially administered to 415 patients during office visits in 2 rheumatology clinics.

Results: For the 415 questionnaires, the average missing items per questionnaire was 1.4, with percent missing for items ranging between 0 and 19.2%. 274 questionnaires were completed without missing data. We used multiple imputation by chained equations and 10 iterations to develop a complete imputed set of 415 questionnaires. We tested a series of matching and regression techniques to identify the optimum set of predictors based on measurements of PSD and ACR criteria as determined by the 2010 modified ACR research criteria. The R-Squared for measured and predicted PSD was 0.781. In a logistic model, we tested NHIS predictors against observed ACR criteria positivity. The area under the receiver-operating curve (AUC ROC) was 94.6. 88.0% of cases were properly classified, and the sensitivity/specificity was 74.7%/93.4%.The NHIS definition found to best approximate 2010 ACR criteria included specific multiple painful joint sites, problems with concentration, fatigue and abdominal pain.

Conclusion: It is feasible to use NHIS questions to approximate both fibromyalgia diagnoses and polysymptomatic distress in 2012 NHIS data. This definition can be used for the epidemiologic study of fibromyalgia in NHIS.

Resting State Functional Connectivity Differs Between Chronic Fatigue Syndrome Patients and Healthy Controls. Jason Craggs[1], Charles Gay[1], Andrew O'Shea[1], Ricky Madhavan[1], Donald Price[1], Michael Robinson[1] and Roland Staud[2]. [1]University of Florida, Gainesville, FL, [2]Univ of Florida Med Ctr/JHMHC, Gainesville, FL.

Background/Purpose: Examining neural activity in the absence of task (i.e. resting state) is an active area of research. Functional connectivity, defined as correlations in BOLD signal between two brain regions, is a promising component of fatigue/pain research. Seed to voxel analyses are one approach used to estimate functional connectivity between brain areas. This approach takes the BOLD signal time course of a priori defined seeds and compares their signals to all other voxels in the brain. We determined brain areas of chronic fatigue syndrome (CFS) patients as seeds for connectivity analysis that demonstrated abnormal resting cerebral blood flow during arterial spin labeling (ASL) functional MRI.

Methods: CFS was determined using the CDC Criteria. 15 CFS patients (age = 50.5±13.0)) and 12 HC (age = 49.2±12.2) were MRI scanned with a 3 Tesla Achieva during rest using a pseudo-continuous arterial spin labeling (pCASL) sequence. ASL data were corrected for rigid body motion and smoothed in SPM8. Label and control images were subtracted to create a perfusion time series. The perfusion time series was used to quantify cerebral blood flow (CBF) using the software aslTBX. A mean CBF image was created which was normalized to MNI space and resampled into 2mm isotropic voxels. An independent samples t-test was used to examine voxel-wise differences in CBF between CFS patients and HC. Resulting t-maps were thresholded with a t-statistic > 4.0 and a cluster size > 120 mm^3. 2 distinct clusters passed this threshold and were used to create seed masks for subsequent BOLD functional connectivity analyses. BOLD resting state data were slice-time corrected, realigned and resliced into 3mm isotropic voxels, co-registered to the anatomic volume, warped into MNI standard space and spatially smoothed. Data were spike-corrected to reduce the impact of artifacts using the post-processing Artifact Detection Tool. The final processing steps were then carried out using the functional connectivity toolbox Conn that implements the component-based noise correction method strategy for physiological and other noise source reduction, which included: Temporal (band-pass) filtering, and removal of several nuisance variables, such as CSF and white matter signal, rigid body motion parameters, and outlier data points.

Results: Significantly decreased blood flow was observed in the right parahippocampal gyrus of CFS patients [27.69 (6.22)] compared to HC [40.51 (7.89) (ml/100g/min)]]. Subsequent analyses showed increased connectivity between the parahippocampal seed and the supramarginal gyrus of CFS patients compared to HC.

Conclusion: Our novel method of generating seeds for functional connectivity analyses, using multi-modal neuroimaging data, demonstrated increased connectivity between brain areas involved in memory and language processing of CFS patients.

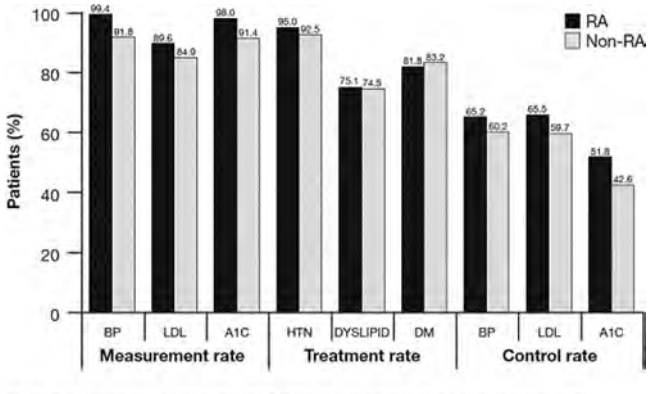
Traditional Cardiovascular Risk-Factor Management in Patients with Rheumatoid Arthritis Compared with Matched Non-Rheumatoid Arthritis Patients in a US Managed Care Setting. J. An[1], K. Reynolds[2], E. Alemao[3], H. Kawabata[3], D. H. Solomon[4], K. P. Liao[4] and T. C. Cheetham[2]. [1]Western University of Health Sciences, Pomona, CA, [2]Kaiser Permanente Southern California, Pasadena, CA, [3]Bristol-Myers Squibb, Princeton, NJ, [4]Brigham and Women's Hospital, Boston, MA.

Background/Purpose: Studies have suggested suboptimal care of traditional cardiovascular risk factors (CRF) in patients (pts) with RA as a reason for elevated CV risk compared with the general population. However, these studies lacked a comparison group, laboratory test results and data on blood pressure (BP) measurements. In this study, we compared CRF management for pts with RA with that of matched non-RA pts within an integrated healthcare delivery system with access to electronic medical records.

Methods: Pts aged ≥18 yrs with ≥2 RA diagnoses plus a DMARD were identified as an RA cohort between 01/01/2007 and 12/31/2011 within Kaiser Permanente Southern California. Pts with RA were followed from their first RA diagnosis or prescription date (index). Each pt with RA was matched by age and sex to 4 pts without any RA diagnoses. Non-RA pts were required to have at least one office visit or hospitalization within 12 months from the index date of the matched pair, and the closest encounter date was specified as an index date. Pts without continuous enrollment 12 months prior and post the index date were excluded from the study cohort. Descriptive statistics were used to compare CRF management between RA and non-RA pts. The same analyses were repeated for 1:1 age- and sex-matched osteoarthritis pts as a non-RA group.

Results: A total of 9440 RA and 31,009 matched non-RA pts were included in the study. Mean [SD] age was 56.8 [14.1] for RA and 56.5 [13.9] years for non-RA pts, and 76% were female in both groups. At baseline, 42.9% of RA pts had hypertension, 30.2% had dyslipidemia, 22.9% were obese, and 11.6% were smokers, whereas 32.4% of non-RA pts had hypertension, 35.8% had dyslipidemia, 23.1% were obese, and 10.5% were smokers. Mean [SD] number of office visits during the first yr of follow-up was higher in RA compared with non-RA pts (13.2 [10.8] vs 8.2 [9.1], $p<0.001$). Rates of BP measurement for treated hypertension and low-density lipoprotein (LDL) cholesterol measurement for treated dyslipidemia were higher in pts with RA compared with non-RA pts (BP: 99.4 vs 91.8%, $p<0.001$; LDL: 89.6 vs 84.9%, $p<0.001$). Treatment rates for hypertension were slightly higher in pts with RA compared with non-RA pts (95.0 vs 92.5%, $p<0.001$) and similar for dyslipidemia (75.1 vs 74.5%, $p=0.393$). RA pts and non-RA pts had similar rates of BP control but higher rates of LDL and A1C control (BP: 65.2 vs 60.2%, $p=0.996$; LDL: 65.5 vs 59.7%, $p=0.005$; A1C: 51.8 vs 42.6%, $p<0.001$). These results were consistent with results for pts with osteoarthritis as a matched non-RA group.

Conclusion: CRF management in pts with RA was slightly better than the management in non-RA pts in a US managed care setting. The finding of this analysis indicates that the higher CV risk in pts with RA is unlikely to be driven by poor control of traditional CV risk factors.



BP=blood pressure; LDL=low-density lipoprotein cholesterol; A1C=hemoglobin A1C; HTN=hypertension; DYSLIPID=dyslipidemia; DM=diabetes

Insurance Status and U.S. Region Associated with Placement of Permanent Vascular Access in Dialysis Patients with End-Stage Renal Disease Secondary to Lupus Nephritis. Laura Plantinga[1], Cristina M. Drenkard[1], Rachel Patzer[1], William McClellan[1], Stephen Pastan[1] and S. Sam Lim[2]. [1]Emory University, Atlanta, GA, [2]Emory University School of Medicine, Division of Rheumatology, Atlanta, GA.

Background/Purpose: Prior data suggest sociodemographic and regional variability in various indicators of quality of end-stage renal disease (ESRD) care, both overall and in the SLE population, but, to our knowledge, no study has addressed the placement of a permanent vascular access prior to the start of hemodialysis in patients with ESRD secondary to lupus nephritis (LN-ESRD). We aimed to describe permanent vascular access placement among hemodialysis patients with LN-ESRD and to examine whether this placement differs by sociodemographic factors and across the 18 U.S. ESRD Networks, which are Centers for Medicare & Medicaid Services-defined regions that implement ESRD quality-of-care initiatives.

Methods: Among 5562 incident U.S. hemodialysis patients with LN-ESRD initiating treatment 7/05–9/11, we estimated the associations between permanent access placement (arteriovenous fistula or graft used or in place on first dialysis, vs. temporary catheter only) and race/ethnicity, insurance at the start of ESRD, and ESRD Network using national surveillance data (United States Renal Data System). Logistic regression models were used to estimate odds ratios (ORs) and confidence intervals (CIs), with adjustment for potential demographic (age, sex, race/ethnicity, insurance) and clinical (BMI, hypertension, cardiovascular disease) confounders.

Results: Fewer than one-quarter (24.4%) of incident hemodialysis patients with LN-ESRD patients had a permanent vascular access placed at start of dialysis, compared to 36.0% of other ESRD patients. Hispanic LN-ESRD patients were less likely than their white counterparts to have a permanent vascular access (20.5% vs. 28.2%), but the association was not statistically significant after adjustment (OR=0.85; 95% CI, 0.69–1.05). Placement did not differ in black vs. white LN-ESRD hemodialysis patients. After adjustment, private, Medicaid, and other insurance were associated with equivalent likelihood of permanent vascular access, but having no insurance was associated with 38% lower likelihood of permanent vascular access among LN-ESRD patients (OR=0.62; 95% CI, 0.49–0.79). There was substantial, statistically significant Network-level variation in likelihood of permanent vascular access, with adjusted probabilities of permanent vascular access used or in place at first dialysis ranging nearly 2-fold, from 0.17 (Network 10, Illinois) to 0.33 (Network 16, Northwest).

Conclusion: The vast majority of LN-ESRD patients on hemodialysis are not initiating treatment with a permanent vascular access. LN-ESRD patients who are Hispanic or uninsured or who live in the Midwest or Southern California at the start of ESRD are less likely to have permanent vascular access. Targeted interventions to increase permanent vascular access among SLE patients with ESRD are warranted to prevent potential morbidity and mortality associated with temporary catheters.

Race and Sex Specific Incidence Rates and Predictors of Total Knee Arthroplasty: Data from the Osteoarthritis Initiative, 7 Years Follow up. Jamie E. Collins, Bhushan Deshpande, Jeffrey N. Katz and Elena Losina. Brigham and Women's Hospital, Boston, MA.

Background/Purpose: Total knee arthroplasty (TKA) is used to reduce pain and improve functional status in persons with symptomatic knee osteoarthritis (OA). Several studies point to differential uptake of TKA in women and racial minorities, but most do not distinguish between the effect of demographic factors on the prevalence of knee OA vs. uptake of TKA among those with knee OA. We sought to estimate sex-, race- and age-stratified incidence rates of TKA among persons with symptomatic radiographic knee OA in the Osteoarthritis Initiative (OAI) over 7 years of follow up and document the independent effect of demographic factors on TKA incidence.

Methods: We used data from the OAI, a U.S. multicenter, longitudinal, observational study of knee OA. We selected knees with radiographic, symptomatic OA at baseline (KL 2+, WOMAC Pain at least 1). We determined the TKA incidence rate as the ratio of number of TKAs in a specific subgroup over time at risk for TKA. Time at risk was defined from time of enrollment to time of TKA or to the last available visit date for those without TKA. We computed incidence rate per person-year and used repeated measures Poisson regression to identify the independent contribution of sex, age and race to the incidence of TKA.

Results: We used data from 2,630 knees (1,915 subjects) with radiographic, symptomatic knee OA at baseline. 1,488 (57%) were KL2, 871 (33%) were KL3, and 271 (10%) were KL4. There were 281 TKAs over 84 months of follow-up, for an overall annual incidence rate of 1.7% (95% CI: 1.5 – 2.0). The annual incidence rate of TKA among Whites was estimated at 2.0% (1.8 – 2.3) compared to 1.1% (0.8 – 1.5) in non-Whites. The annual incidence rate of TKA among those who were younger than 65 years was estimated at 1.5% (1.2 – 1.8) compared to 2.1% (1.8 – 2.6) among older persons. In adjusted analysis, higher incidence of TKA was significantly associated with White race and female sex (Table). After adjusting for income and health insurance status, Whites had 1.7 times the rate of TKA compared to non-Whites. Whites were more likely to earn more than $50k annually compared to non-Whites (62% vs. 38%); in income-stratified analysis the racial disparity in TKA incidence persisted: Whites had 1.5 (1.0 – 2.3) times the rate of TKA vs. non-Whites among subjects earning less than $50k and 2.2 (1.2 – 3.8) times the rate among subjects earning more than $50k.

Conclusion: We used a large longitudinal cohort of persons with diagnosed knee OA to determine the incidence of TKA in specific demographic subgroups. This approach overcomes prior estimates from population-based samples that could not distinguish risk factors for OA from risk factors for TKA. In this cohort, with adjustment for age, sex, radiographic severity, income and insurance status, Whites had 1.7 times the TKA incidence of non-Whites. These data confirm the racial disparity suggested by population-based estimates and underscore the need for interventions to address the disparity.

Table: Independent predictors of incident TKA

	RR	95% CI	p-value
Age 65+ vs. <65	1.2	0.9, 1.5	0.255
Sex Female vs. Male	1.6	1.3, 2.1	<.001
Baseline KL 4 vs. 2	8.9	6.4, 12.4	<.001
Baseline KL 3 vs. 2	3.0	2.2, 4.1	<.001
Race White vs. Non-White	1.7	1.2, 2.4	0.002
Yearly Income <$50K vs. >$50K	0.9	0.7, 1.2	0.420
Health Insurance No vs. Yes	0.8	0.4, 1.8	0.596

Rate of Serum Uric Acid (SUA) Assessment in Gout Patients Treated with Urate-Lowering Therapy: Treating to Target? Robert Morlock[1], David M. Kern[2], Ozgur Tunceli[2], Siting Zhou[2], Laura Horne[3], Sulabha Ramachandran[3] and Hyon Choi[4]. [1]Ardea Biosciences, San Diego, CA, [2]HealthCore, Inc., Wilmington, DE, [3]AstraZeneca, Wilmington, DE, [4]Harvard Medical School, Boston, MA.

Background/Purpose: Gout is the most common form of inflammatory arthritis and is caused by chronic hyperuricemia, leading to urate crystal deposition disease and subsequent intermittent flares and tophi development. ACR guidelines recommend treating to target SUA levels (<6 mg/dL or, in some cases, <5 mg/dL as needed to control signs/symptoms). This study aimed to describe overall rates of SUA testing and differences in patient characteristics, comorbidities, treatments, and flare rates by SUA testing status.

Methods: Gout patients treated with urate-lowering therapy (ULT) were identified between Feb 1, 2011 and Jan 31, 2012 from the HealthCore Integrated Research Environment. Index event was considered to be the earliest of the following: a prescription for ULT; or a gout diagnosis (ICD-9 274.xx) or a claim for colchicine with ULT therapy in the year prior. Patients with <12 months pre- and post-index enrollment or with a diagnosis of cancer, evidence of hematologic cancer, tumor lysis syndrome, Lesch-Nyhan syndrome or juvenile gout, familial Mediterranean fever, or pregnancy in the pre- or postindex periods were excluded. Patient demographics and comorbid conditions were captured during the 12-month pre-index period. SUA laboratory testing, treatment characteristics, and overall gout control (SUA ≤6 mg/dL, no flares, no tophi) were examined during the 12 month post-index period. Target SUA level was ≤6 mg/dL. Flares were defined during the post-index period as either a claim for colchicine, or a healthcare visit recording gout together with ≥1 of the following within 1 week: joint aspiration/injection (corticosteroids), prescription of NSAIDs, corticosteroids, adrenocorticotropic hormone, or IL-1 antagonist.

Results: 50,602 ULT-treated patients met inclusion criteria (average age, 59; 82% male). During follow-up, 90% of patients received allopurinol, 6% febuxostat, and 4% probenecid. SUA testing occurred in 47% of patients during 1-year follow-up. Those with SUA testing were younger (57 vs. 61 years) and had higher rates of colchicine use (23% vs 13%), hyperlipidemia (64% vs. 59%), and chronic kidney disease (15% vs 13%) compared to those without testing. Patients without SUA testing had higher rates of cardiac-related comorbidities: coronary artery disease (21% vs 17% in those with testing), angina (21% vs 16%), and peripheral vascular disease (10% vs 8%). A higher proportion of patients seen by a rheumatologist had testing compared with those not visiting a rheumatologist (75% vs 44%, respectively). Among patients with available SUA results (n=6649), 47% of subjects had SUA levels ≤6 mg/dL, and 30% achieved overall gout control.

Conclusion: Guidelines describe treating to target SUA as appropriate care. This study finds <50% of all gout patients treated with a ULT have SUA assessed at any time during a 12-month period. Patients most likely to have SUA assessments are younger, have more flares, or visit a rheumatologist. In patients with SUA assessment, <50% achieve SUA goal and less than a third achieve overall gout control. These findings suggest that contemporary gout care is suboptimal, leaving considerable room for improvement.

Co-Management for Children with JIA: A Survey of Primary Care Providers Regarding Current Practices and Willingness to Provide Services. Amanda Mroczek, Gary Freed and Meredith Riebschleger. University of Michigan, Ann Arbor, MI.

Background/Purpose: Pediatric Rheumatology (PR) is among the smallest and least geographically accessible of the pediatric subspecialties. This problem may be addressed by utilizing the more extensive primary care provider (PCP) workforce, in combination with new technologies such as telemedicine. The objectives of this study were to 1) determine current PCP provision of medical services for children with JIA and 2) determine the willingness of these PCPs to provide services in the future.

Methods: Surveys were mailed to PCPs who had referred ≥2 patients to the University of Michigan Division of PR 2/2012-2/2014. Survey domains included the current provision of and willingness to provide medical services to children with JIA who are also followed by a pediatric rheumatologist. Services assessed included administration of immunizations, performance of a focused joint exam, monitoring for the adverse effects of rheumatology medications, and making medication adjustments. Statistical analyses included proportions and chi square tests.

Results: After 2 of 3 planned mailings, 154/230 PCPs had responded (response rate=67%). The majority of PCPs reported that they already provide many of the assessed services, especially those that are typically performed for all of their patients, such as administering immunizations. Fewer PCPs reported performing services traditionally done by specialists, such as monitoring for adverse effects of medications or making dose adjustments (Figure 1). With the exception of changing medications without PR input, over 90% of PCPs reported willingness to provide the assessed services in the future (Figure 2).

Conclusion: This study found that the majority of PCPs already provide many of the assessed medical services for children with JIA and that an even larger majority are willing to provide these services in the future. Co-management between PCPs and PRs could benefit children and their families by limiting travel expenses and time missed from work and school, while promoting communication and collaboration between PCPs and PRs. The current practices and willingness of PCPs to provide services to their patients with JIA should be used to guide future co-management activities for PCPs and PRs.

Poor Adherence to Medications for Systemic Lupus Erythematosus Predicts Higher Health Care Utilization in U.S. Medicaid Beneficiaries. Jinoos Yazdany[1], Candace H. Feldman[2], Hongshu Guan[3] and Karen H. Costenbader[3]. [1]University of California, San Francisco, San Francisco, CA, [2]Brigham and Women's Hospital, Boston, MA, [3]Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Background/Purpose: Immunosuppressive and antimalarial drugs improve outcomes in systemic lupus erythematosus (SLE), including reducing disease activity, damage and mortality. Although prior studies have found low adherence to medications in SLE, little information is available on the impact of adherence on health utilization and outcomes. In this study, we examined whether poor adherence is associated with higher acute care utilization in a nationwide study of Medicaid beneficiaries.

Methods: We used 2000–2006 U.S. Medicaid Analytic eXtract (MAX) data containing person-level files on Medicaid eligibility, utilization and payments. We identified patients with at least two years of continuous enrollment, who met an administrative definition of SLE and had received either an immunosuppressive (cyclophosphamide, mycophenolate, mycophenolic acid, azathioprine, leflunomide, methotrexate, or tacrolimus) or antimalarial (hydroxychloroquine) drug through an outpatient pharmacy. Pharmacy claims were used to assess adherence by calculating a medication possession ratio (MPR) in the 1st year ("baseline year"), defined as the proportion of days covered by the total days' supply dispensed after the first claim for each drug. Average MPR for SLE drugs in the baseline year was used to examine outcomes in a subsequent one-year

period ("follow-up year"). Outcomes included all cause hospitalizations, SLE-related hospitalizations and emergency room (ER) visits. We used Poisson regression models to evaluate the impact of low adherence (average MPR<80%) on utilization outcomes in the follow-up year, adjusting for baseline age, sex, race/ethnicity, Charlson comorbidity index, SLE-specific risk index (Ward M, *J Rheum,* 2000) and number of SLE drugs taken.

Results: 15,955 patients with SLE were taking at least one immunosuppressive or anti-malarial drug and continuously enrolled in Medicaid over the two-year period. Mean age was 38.6 years (SD 11.3), 95% were female, and 39% were Black, 34% White, 16% Hispanic, 5% Asian, 5% other, 1% Native. The average MPR during the baseline year was 49% (SD 30%). In the follow-up year, 28% had one or more hospitalizations, 17% SLE-related hospitalizations, and 49% ER visits. Lower adherence was associated with significantly increased risks of subsequent hospitalizations and ER visits, even after adjustment for sociodemographic factors, SLE risk index, comorbid disease, and number of SLE drugs taken (**Table**).

Conclusion: We found that lower adherence (MPR<80%) significantly increased risks of subsequent hospitalizations and ER visits in Medicaid beneficiaries with SLE. These results are consistent with past studies highlighting the importance of promoting medication adherence to improve health outcomes and decrease costs. Further research is warranted to gain a better understanding of how disease activity and severity influence this relationship.

Table Relationship between Adherence and Subsequent Hospitalizations and Emergency Room Encounters in U.S. Medicaid beneficiaries with SLE.

	All-cause hospitalizations IRR (95% CI)	SLE-related hospitalizations IRR (95% CI)	Emergency Room visits IRR (95% CI)
Adherence in year one (MPR*≥80%)	Referent	Referent	Referent
Non-adherence in year one (MPR*<80%)	**1.43 (1.33, 1.54)**	**1.36 (1.25,1.46)**	**1.55 (1.45, 1.65)**

*MPR=Medication Possession Ratio IRR= Incidence rate ratio. Poisson regression models were adjusted for baseline age, sex, race/ethnicity, SLE-specific risk index, Charlson comorbidity index and number of concomitant SLE medications. Each column represents a separate Poisson regression model.

Ultrasound Synovitis Reflects Synovial Inflammation at a Histopathological Level. Nora Ng, Stephen Kelly, Frances Humby, Maria DiCicco, Vidalba Rocher, Rebecca Hands, Michele Bombardieri and Costantino Pitzalis. William Harvey Research Institute, Queen Mary University of London, London, United Kingdom.

Background/Purpose: Ultrasound (US) is widely used by rheumatologists to assess inflammatory burden on patients with inflammatory arthritis. Some studies have shown that US measures of inflammation reflects aspects of histological synovitis in a heterogeneous groups of patients with rheumatoid arthritis (RA). Little work has been done to describe this relationship in an early arthritis population.

Our aim of this study is to investigate, at a single joint level, the correlation of US synovitis with histological synovial inflammation before and after treatment initiation in a homogenous cohort of patients with early RA.

Methods: Data was collected from 54 patients with early RA (fulfills 1987 ACR classification, symptom onset <12 months). Patients were naïve to both disease modifying anti-rheumatic drugs (DMARD) and to steroids. All patients underwent a core data set assessment including clinical, biochemical, imaging and an US guided minimally invasive synovial biopsy of the most inflamed joint. Patients were then initiated on DMARD according to standardised protocol. A repeat assessment and US guided biopsy was performed at 6 months follow up. US images of the joint are scored using a semi quantitative score (0–3). Sections of paraffin embedded synovial tissue received immunohistochemical staining for CD3, CD20, CD68, CD68sland CD138 and these parameters were graded in a semiquantitative fashion (0–4). Spearman's rho was used to correlate scores at each time point.

Results: At baseline, US power doppler (PD) was significantly correlated with histological markers of inflammation - CD3 ($r=0.43$, $p<0.05$), CD20 ($r=0.46$, $p<0.01$), CD68 ($r=0.37$, $p<0.05$), CD68sl ($r=0.46$, $p<0.01$) and CD138 ($r=0.61$, $p<0.001$), and with inflammatory markers erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) ($r=0.4$, $p<0.05$). After 6 months of therapy, most of these correlations were still present, most notably with CD68sl ($p<0.05$). Interestingly, we also found that a fall in US PD in response to treatment at 6 months is associated with a fall in CD68sl ($r=0.50$, $p<0.005$) and a fall in DAS28 ($r=0.40$, $p<0.05$).

Conclusion: US PD has long been recognised as an accurate reflection of disease activity in inflammatory arthritis. Our results have shown that US PD also reflects synovial inflammation at a histopathological level. The association of US PD, CD68sl and DAS28 supports the current opinion that Power Doppler US is a biomarker for treatment response and reflects both clinical and histological markers of disease activity in patients with RA.

First Step in the Development of an Ultrasound Joint Inflammation Score for Rheumatoid Arthritis: A Data Driven Approach. Anna-Birgitte Aga[1], Hilde Berner Hammer[1], Inge C. Olsen[1], Till Uhlig[1], Tore K. Kvien[1], Désirée van der Heijde[2], Elisabeth Lie[1], Espen A. Haavardsholm[1] and the Arctic study Group[1]. [1]Diakonhjemmet Hospital, Oslo, Norway, [2]Leiden University Medical Center, Leiden, Netherlands.

Background/Purpose: The use of ultrasonography (US) in rheumatoid arthritis (RA) is rapidly increasing. Currently, there is no consensus regarding which joints and tendons should be systematically assessed. Validity, including comprehensiveness, and responsiveness must be weighted against feasibility. Our objectives were to develop candidate sets for assessment of US joint inflammation through a data driven approach using data from early RA patients, and then perform initial validation in an established RA cohort.

Methods: Between January 2010 and June 2013 patients (pts) were included in one of two cohorts: Early RA (DMARD-naïve pts with RA of <2 yrs symptom duration fulfilling 2010 ACR/EULAR classification criteria), and established RA (pts starting or switching biologic DMARDs). An extensive US examination was performed by experienced sonographers using a validated grey-scale (GSUS) and power Doppler (PDUS) semi-quantitative scoring system with scores 0–3 for GSUS and PDUS in each of the following 36 joints and 4 tendons: MCP 1–5, PIP 2–3, radiocarpal, distal radioulnar, intercarpal, elbow, knee, talocrural, MTP 1–5, extensor carpi ulnaris and tibialis posterior tendons, bilaterally. An US atlas was used as reference[1]. We performed principal component factor analyses (PCA) in the early RA US data to identify joint groups with high internal correlation, and selected candidate joint/tendon sets based on these analyses. We assessed the loss of information compared to the full score by R^2 from linear regression analysis. Finally, the candidate sets were validated in the established RA cohort.

Results: A total of 439 patients were included, 227 with early and 212 with established RA; 62% vs. 77% anti-CCP pos, mean(SD) age 51(14) vs. 52(13) yrs, DAS28 4.7(1.2) vs. 4.7(1.4), median(25–75 percentile) 28-SJC 6(3–11) vs. 5(2–10), disease duration 0.5(0.2–0.9) vs. 8(3–15) yrs, mean(95% CI) 36-joint GSUS score 23(21–25) vs. 28(25–30) ($p=0.003$), 36-joint PDUS score 11(10–12) vs. 13(11–15) ($p=0.20$). Nearly 17,000 individual joints/tendons were assessed. We identified 9 groups based on PCA in the early RA data, presented in table 1. Comparisons between the candidate sets and the total GSUS and PDUS scores in the early RA cohort as well as validation in the established RA cohort are presented in table 2.

Conclusion: We used a data driven approach to develop candidate sets of joints/tendons to be assessed by GS and PD US, and the resulting reduced scores retained most of the information from the total score of 40 joints/tendons. Unilateral reduced scores explained 78% to 85% of the total score, while bilateral reduced scores explained 89% to 93% of the total score. The candidate scores performed equally well in a validation cohort of established RA. Our results show that a reduced US assessment may efficiently contribute to disease assessment in RA. Further validation in longitudinal RA cohorts and data on responsiveness are needed.

How Long Does Sonographic Joint Activity Continue in Clinically Remittive Joints of Patients with Rheumatoid Arthritis? Miriam Gärtner, Farideh Alasthi, Gabriela Supp, Peter Mandl, Josef Smolen and Daniel Aletaha. Medical University of Vienna, Vienna, Austria.

Background/Purpose: Ultrasound (US) assessment was shown to be a sensitive tool for the evaluation of inflammatory joint activity in patients with rheumatoid arthritis (RA). Synovial effusion and hypertrophy are evaluated by gray scale (GS), while hypervascularisation, can be measured using power Doppler (PD) signals. Both types of signals are highly sensitive, and may persist even in clinical inactivity. It is conceivable that such subclinical US signals may resolve if clinical inactivity of the respective joint is sustained, but this has not yet been shown during long-term follow-up.

It was the objective of this study to evaluate the persistence of subclinical US signals in previously clinically active joints, which have reached a state of continuous clinical inactivity.

Methods: We performed US imaging of 22 joints of the hands of RA patients, including GS and PD, each graded on a four point scale (0=no, 1=mild, 2=moderate, 3=marked). All joints with no activity by clinical assessment at the same time of the US examination were selected, and we identified the last time point of clinical joint activity (swelling, tenderness, or both). The time between the last clinical joint activity and the current sonographic assessment in that joint was determined and persistence of subclinical US activity was estimated for all patients and all joints using time-to-event analysis.

Results: A total of 90 RA patients with 1980 assessed joints were included in this study: 67.1% (1329) of the joints were positive on GS and 20.7% (410) showed PD signals. The mean±SD number of joints showing signs of sonographic activity was: 15±5 for GS, 5±3.8 for PD.

The median (IQR) time between the last visit exhibiting clinical activity in a single joint and the US assessment in the same joint was 3.6 (1.2;6.3) for joints with PD signals, and 3.5 (1.3;5.6) years for joints with GS signals.

If GS signals were ≥2 we found a significantly shorter time to the last visit with clinical activity compared to joints with GS=1 (median[IQR] 2.6[0.6;2.6] vs. 3.9[1.9;6.6]; p<0.001); for PD signals we saw the same trend (median [IQR] of 2.4[0.5;5.3] for PD≥2 vs. 4.3[1.0;6.2] for PD=1; p=0.066). In joints showing both highly positive GS and PD signals (both≥2), the time to the last clinical activity was even shorter, with a median of 1.4 years. (Figure 1)

Conclusion: We conclude that subclinical joint activity is long lasting in RA joints in clinical remission, but resolves over time. The latter is indicated by a shorter period from last clinical activity for strong signals (PD≥2, GS≥2) as compared to weak signals (PD≤1, GS≤1).

Ultrasonographic Tenosynovitis Score Is Responsive to Biologic Treatment in Patients with Rheumatoid Arthritis. Hilde B. Hammer and Tore K. Kvien. Diakonhjemmet Hospital, Oslo, Norway.

Background/Purpose: Ultrasound (US) is sensitive for detecting tenosynovitis in patients with rheumatoid arthritis (RA), where the synovitis can be assessed by grey scale (GS) and the increased vascularization by power Doppler (PD). The extensor carpi radialis (ECU) tendon in the wrist and the tibialis posterior (TP) tendon in the ankle are frequently involved in RA patients, and the tenosynovitis can be scored by use of a semi-quantitative (0–3) scoring system. The objective of the present study was to assess the involvement of ECU and TP tendons in patients with established RA as well as to explore the change in US scores of these tendons during treatment with biologic disease-modifying anti-rheumatic drugs (bDMARDs).

Methods: A total of 181 RA patients (83% women, mean (SD) age 51 (13) years, disease duration 11 (9) years, 77 % positive for anti-CCP) were examined when they started bDMARD (infliximab 10%, etanercept 43%, adalimumab 8%, golimumab 5%, certolizumab pegol 5%, rituximab 19%, abatacept 4% and tocilizumab 6%). All were examined at baseline and after 1, 2 and 3 months with US (GS and PD of ECU and TP tendons bilaterally, all assessments performed by one sonographer (HBH) with Siemens Acuson Antares, Excellence version, using a 5–13 MHz probe with an optimized pre-setting of the machine for all examinations), laboratory and clinical assessments. The changes from baseline were assessed by use of paired samples T-test.

Results: Tenosynovitis was found in a high number of tendons at baseline (table). The mean (SD) sum score of the four tendons was 2.7 (2.7) for GS and 1.6 (2.2) for PD, including 26% of the patients with no GS inflammation and 51% with no PD activity in any tendon. Mean (SD) baseline values for the clinical examinations were: ESR 28.6 (21.7), CRP 14.2 (20.6) and DAS28 4.6 (1.5). Both sum scores GS and PD decreased significantly from baseline to 1 month (p<0.001 and p=0.013, respectively), and both showed highly significant reduction after 3 months (p<0.001) (figure). Also ESR, CRP and DAS28 decreased already after 1 month (p<0.001 for all), as well as after 3 months (p<0.001 for all).

Conclusion: A large number of ECU and TP tendons were inflamed at baseline, and the sum scores of both GS and PD fell significantly already after 1 month. Since tenosynovitis in ECU and TP tendons are common in RA patients and responsive to change during bDMARD treatment, US of these tendons should be considered as candidates for inclusion in future US scores of RA patients.

	ECU tendons		TP tendons	
	Grey scale (percentage involvement)	Power Doppler (percentage involvement)	Grey scale (percentage involvement)	Power Doppler (percentage involvement)
Score 0	57	76	64	76

Ultrasound-Detected Tenosynovitis Independently Associates with Flare in Patients with Rheumatoid Arthritis in Clinical Remission. Rummo, Benevento, Italy, [31]University of Florence, Florence, Italy.

Background/Purpose: Clinical remission is now an achievable goal in patients with rheumatoid arthritis (RA). Much has been done in order to better understand and define the concept of remission; in the field of ultrasonography (US) some studies have focused on joint synovitis and its significance in terms of prognosis. In the literature, data on the prevalence of tenosynovitis in patients in clinical remission are scarce and its clinical and prognostic significance has not been studied yet. The objective of this study is to assess whether the US tenosynovitis is associated with a decreased risk of flare.

Methods: Sonographic Tenosynovitis Assessment in RheumaToid arthritis patiEnts in Remission (STARTER) is a multicentre cohort study promoted by the Italian Society for Rheumatology (SIR) that includes 26 rheumatology centres recruited across Italy between Oct 2013 and Jun 2014. Ultrasonographers were trained and selected by an inter-reader reliability exercise against a reference standard using static images, setting to 0.7 one ad hoc weighted kappa as entry criterion. Only high level US machines and high frequency probes were allowed. Patients with RA and clinical remission (DAS28 or SDAI or CDAI) were eligible. All patients underwent full clinical evaluation and US examination (synovitis (-S) and tenosynovitis (-T). A 0–3 semiquantitaive score of Grey Scale (GS-) and Power Doppler (PD-) was calculated for wrists, metacarpophalangeal, interphalageal joints and extensor and flexor tendon sheets. Flare was assessed using the flare questionnaire score ranging from 0 (no flare) to 10 (definite flare) [1], dichotomized at the median value (=3). The cross-sectional relationship between presence of GS-T/-S, PD-T/-S were evaluated by logistic models, and presented as odds ratios (OR) and 95%CI, both crude and adjusted for pre-specified confounders.

Results: A total of 408 RA patients in clinical remission were included in the analyses: 103(25.4%) men, mean(SD) age 56.4(13.5), median(IQR) disease duration 7.1(3.7–13.5) years, median(IQR) remission duration 12 (8–28) months, RF positive 249/360 (69.2%), mean(SD) DAS28 2.1 (0.8), median(IQR) HAQ 0.125(0–0.375), on DMARDs 300 (73.5%), on biologics 161 (39.5%), on glucocorticoids 170 (43.8%).

GS-T was present in 198/373 (53.1%) patients, PD-T in 88/372 (23.7%), while GS-S was present in 270/368 (73.4%) patients and PD-S in 171/372 (46.5%). The association between US variables and flare is reported in the Table.

Outcome: flare questionnaire >3	Crude OR (95%CI)	Adjusted* OR (95%CI)
Grey Scale Tenosynovitis	1.05 (0.69, 1.58)	1.09 (0.68, 1.75)
Power Doppler Tenosynovitis	**2.11 (1.29, 3.45)**	**2.29 (1.29, 4.07)**
Grey Scale Synovitis	1.09 (0.68, 1.74)	0.88 (0.50, 1.56)
Power Doppler Synovitis	**1.60 (1.05, 2.43)**	1.48 (0.91, 2.40)

age, sex, disease duration, remission duration, musculoskeletal comorbidities, RF, ACPA, DMARDs, biologics, glucocorticoids (oral and injections), NSAIDs.

Using absence of PD-T and PD-S as reference, PD-S alone showed an adjusted OR(95%CI) of 1.45(0.82, 2.58), PD-T alone 3.84(1.33, 11.08) and both PD-S and PD-T 2.55(1.27, 5.10).

Conclusion: Power Dopper tenosynovitis is independently associated with patient reported flare more strongly than synovial indexes. US-tenosynovitis is new promising feature to identify patients in remission at higher risk of flare.

A Diagnostic Protocol for Giant Cell Arteritis (GCA) Using Ultrasound Assessment. Jennifer Piper[1], Ana Sofia Serafim[1], Cristina Ponte[1], Surjeet Singh[2], Bhaskar Dasgupta[3], Wolfgang A. Schmidt[4], Eugene McNally[5], Andreas P. Diamantopoulos[6], Andrew Hutchings[7] and Raashid Luqmani[8]. [1]University of Oxford, Oxford, United Kingdom, [2]Sciences, Oxford, England, [3]Southend University Hospital, Essex, United Kingdom, [4]Immanuel Krankenhaus, Berlin, Germany, [5]Oxford University, Oxford, United Kingdom, [6]Hospital of Southern Norway Trust, Kristiansand, Norway, [7]London School of Hygiene and Tropical Medicine, London, United Kingdom, [8]Oxford NIHR Musculoskeletal Biomedical Research Unit, Oxford, United Kingdom.

Background/Purpose: Ultrasound (US) has not yet superseded temporal artery biopsy as a diagnostic test. This may reflect poor consistency of the scanning technique, due to the lack of a standardised scanning protocol. We have developed a standardised protocol which was implemented in a prospective study of 857 participants: 439 healthy controls and 418 patients with suspected GCA (Temporal Artery Biopsy versus Ultrasound, TABUL). We assessed each patient for evidence of typical ultrasound features of GCA: the presence of a halo surrounding the vessel wall, stenosis or occlusion of the vessel.

Methods: A detailed scanning protocol was developed for all cases and controls. We recorded the presence or absence of ultrasound features of GCA in each segment of each temporal artery (common, parietal, frontal proximal and frontal distal) and both axillary arteries. Sonographers were asked to acquire video and static images for each patient to ensure accuracy of findings. The sonographer measured and documented: halo diameter (based on a normal range of up to 0.3 mm for the temporal artery and up to 1.0 mm in the axillary artery) and length; pulse Doppler measurements prior to and within a stenosis (confirmed if the highest maximum systolic velocity was over twice the lowest maximum systolic velocity) and arterial occlusion. Each study site sonographer was required to be proficient in the protocol by scanning at least 10 healthy controls, passing an online test showing normal and abnormal scans (pass mark >75%) and scanning a patient with ultrasound evidence of active GCA.

Results: The US scanning protocol was started by 33 sites, with only 22 sites completing the training in 6.7 months [range 0.2 – 16.4 months]. A total of 439 controls were scanned across 31 sites (1 sonographer covered 3 sites). The online test was passed by 39 sonographers (multiple sonographers at some sites) with an average of 2 attempts [range 1–4]); 22 sonographers successfully scanned an active GCA patient, validated by the expert panel. The longest delay in completing the training was due to difficulty in recruiting a patient with active GCA (hot case), which was necessary for each site prior to it joining the main study. Common issues encountered were a lack of time away from clinical duties and locating a new suspected GCA case for the hot case assessment.

We have created a bank of 857 sets of consistently recorded US images of temporal and axillary arteries from 418 patients with suspected GCA and 439 healthy controls. Expert review of the first 263 suspected patients has confirmed positive US findings of GCA in 100 patients and no US evidence in 163 cases.

Conclusion: Quality and accuracy are imperative for the clinical use of ultrasound data in the diagnosis of GCA. We have developed an effective training program and scanning protocol which ensures consistency and proficiency. The methodology can be adapted and extended to allow for additional artery assessment, including carotid, vertebral and subclavian arteries, extending the value of a structured approach. We recommend the TABUL study scanning protocol as the standard approach for diagnosis of GCA using ultrasound.

The Selective Sphingosine-1- Phosphate Receptor 1/5 Modulator Siponimod (BAF312) Shows Beneficial Effects in Patients with Active, Treatment Refractory Polymyositis and Dermatomyositis: A Phase IIa Proof-of-Concept, Double-Blind, Randomized Trial. Katalin Danko[1], Jiri Vencovsky[2], Ingrid E. Lundberg[3], Anthony A Amato[4], Chester V. Oddis[5], Maria Molnar[6], Antonette Mallari Moher[7], Laurence Colin[8], Florian Muellershausen[9], David Lee[9] and Peter Gergely[9]. [1]University of Debrecen, Hungary, Debrecen, Hungary, [2]Charles University, Prague, Czech Republic, [3]Rheumatology Unit, Karolinska University Hospital, Solna, Karolinska Institutet, Stockholm, Sweden, [4]Brigham and Women's Hospital and Harvard Medical School, Boston, MA, [5]University of Pittsburgh, Pittsburgh, PA, [6]Institute of Genomic Medicine and Rare Disorders, Semmelweis University, Budapest, Hungary, [7]Novartis Institutes for Biomedical Research (former emplyee), Basel, Switzerland, [8]Novartis Pharma, Basel, Switzerland, [9]Novartis Institutes for Biomedical Research, Basel, Switzerland.

Background/Purpose: Polymyositis and dermatomyositis (PM/DM) comprise a heterogeneous group of chronic inflammatory muscle diseases where infiltration of lymphocytes in the skeletal muscle plays a key pathogenic role. BAF312 (siponimod), an oral sphingosine-1-phosphate (S1P) receptor 1/5 modulator may be efficacious in inflammatory myopathies by inhibiting lymphocyte trafficking from secondary lymphoid organs to the muscle. A randomized, double–blind, placebo-controlled, multi-centric, partial cross-over Phase IIa Proof of Concept study was conducted to evaluate the safety, tolerability and efficacy of BAF312 in patients with PM/DM.

Methods: Eighteen patients with clinically active PM/DM who had responded inadequately to conventional treatment were randomized to receive 10 mg BAF312 or matching placebo (1:1) once daily for 12 weeks. The 10 mg dose was reached by a dose up-titration regimen over 10 days to minimize bradycardia, a common adverse effect of the S1P1 receptor modulator class. Following the placebo-controlled Period 1, all patients received 10 mg BAF312 for an additional 12 weeks in Period 2. No immunosuppressives but oral corticosteroids at a stable dose (max. 20 mg prednisone/day) were allowed as concomitant medication. Key outcomes were safety and efficacy as assessed by the responder rate according to the Definition of Improvement by the IMACS (International Myositis Assessment Study) group. Clinical response was defined as an improvement in the IMACS core set measure of myositis disease global activity by greater than 30% and an improvement in manual muscle testing (MMT8) by 1 –15 %; or an improvement in MMT8 by greater than 15% and in myositis disease global activity by greater than 10%; and in either case, with no more than 2 IMACS measures worsening by 25%.

For safety, in addition to routine assessments, cardiac monitoring for the first 10 days, pulmonary function testing, ocular coherence tomography were performed. Peripheral absolute lymphocyte counts were measured to monitor the pharmacodynamic (PD) effect of BAF312.

Results: Eighteen patients were enrolled into this trial and 16 patients received BAF312 either in Period 1 and/or Period 2. Overall, BAF312 was safe and well tolerated with no significant bradycardia observed. Four serious adverse events occurred in three patients, all in the Placebo group. Fourteen patients were evaluable for the efficacy analysis. The observed responder rates at week 12 were 4/7 (57%) for BAF312 and 1/7 (14%) for placebo using the IMACS definition of improvement. A Bayesian analysis of the IMACS responder status at week 12 yielded a probability of 0.96 that BAF312 is superior to Placebo. The PD effect of BAF312 (i.e. decrease in absolute lymphocyte count) was confirmed in all subjects receiving BAF312, with a mean decrease by >75% after 4 weeks of treatment.

Conclusion: Considering disease heterogeneity and low sample size firm conclusions should not be drawn, but further investigations of BAF312 as a new treatment modality for patients with refractory PM/DM are warranted.

Although disease heterogeneity and low sample size prevent definite conclusions, further investigations of BAF312 as a new treatment modality for patients with refractory PM/DM are warranted.

Bioluminescent Imaging of Histidyl-Transfer RNA Synthetase-Induced Myositis Reveals Early-Phase Involvement of NF-Kb-Mediated Inflammation. Nicholas A. Young[1], Lai-Chu Wu[1], Michael Bruss[1], Wael N. Jarjour[1] and Dana P. Ascherman[2]. [1]The Ohio State University Wexner Medical Center, Columbus, OH, [2]Miami VAMC, Miami, FL.

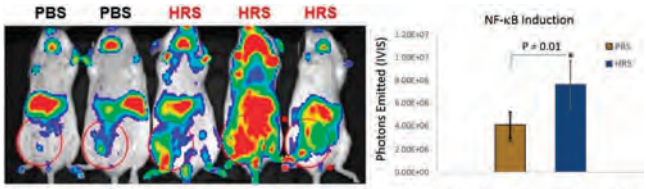
Background/Purpose: The idiopathic inflammatory myopathies represent a group of autoimmune diseases that target muscle as well as

extra-muscular organs, leading to significant morbidity and mortality. Among the most common specific autoantibodies associated with these disorders is Anti-histidyl-tRNA synthetase (HRS; Jo-1), which defines a subgroup of patients with clinical features. In order to further advance targeted therapies, we have modified a previously established model of HRS-induced myositis to highlight the potential role of NF-kB activation in early stages of disease.

Methods: BALB/C-Tg(NFkB-RE-luc)-Xen mice, which contain a firefly luciferase cDNA reporter gene under the regulation of 3 kB responsive binding sites, were injected intra-muscularly with 50 ml of recombinant murine HRS (5 mg/ml) affinity purified following amplification in a bacterial expression system. Inflammation was determined by measuring whole-body bioluminescent signals using the Xenogen *in vivo* imaging system (IVIS 200). The emitted photons from injected muscle were quantitated for each mouse at time zero and at 2 and 4 weeks. At 5 weeks post-HRS injection, mice were sacrificed; sections of injected as well as non-injected muscle tissue were then paraffin embedded and stained by H&E for histological analysis.

Results: NFkB-RE-luc mice inoculated with recombinant HRS developed a robust inflammatory response at the 2 week time point. This statistically significant inflammatory response measured by IVIS photon quantification was most pronounced at the site of injection, but did extend beyond this area in some mice (see figure). NF-kB activation subsided after 4 weeks, with residual bioluminescent signals approaching those induced by injection with PBS alone. Despite this apparent reduction in NF-kB activity, however, histologic analysis of HRS-injected muscle tissue revealed significant endomysial inflammatory infiltrates at these later time points.

Conclusion: This novel application of NF-kB-regulated luciferase mice establishes a system that may facilitate therapeutic drug development for myositis through longitudinal analysis of candidate NF-kB inhibitors in different strains expressing the NF-kB-luciferase transgene. However, because our results suggest that NF-kB-mediated signaling pathways primarily impact early stages of disease in this model system, alternative therapeutic targets must be sought for more temporally advanced disease; thus underscoring the need for phase-specific treatment in idiopathic inflammatory myopathy.



NF-κB activation is induced in histidyl-tRNA synthetase (HRS)-stimulated myositis. Transgenic mice expressing a luciferase reporter gene under the control of NF-κB responsive elements were injected intra-muscularly with PBS (n = 4) or recombinant HRS (n = 5). (left) After 14 days, bioluminescent signals in the injected muscle (red circles) were measured in the *in vivo* imaging system (IVIS). (right) The emitted photons were quantitated using IVIS software (±SD).

Gaslini, Genova, Italy, [20]NIEHS, NIH, Bethesda, MD, [21]Charles University, Prague, Czech Republic.

Background/Purpose: To develop consensus on definitions of improvement (DOIs) for minimal and moderate improvement (and draft preliminary criteria for major improvement) in adult dermatomyositis (DM) and polymyositis (PM) for therapeutic trials.

Methods: Patient profiles from natural history and/trial data were rated by myositis experts. Consensus (≥70%) was reached in 91%; 157 rated with minimal, 72 moderate and 12 major improvement. Conjoint analysis was performed on forced-choice surveys (using 1000Minds software) that were administered to myositis experts. Candidate DOIs based on changes in IMACS core set measures (CSMs) were generated for minimal, moderate and major improvement: A) 23 previously-published DOIs; B) 408 new DOIs (called "Base") using expert survey and variations of published DOIs; C) 56 DOIs derived from logistic regression; D) 6 DOIs derived from a Conjoint Analysis survey that yielded scores with different levels of improvement in different CSMs; E) 8 DOIs drafted by combining changes in each CSM with respective Conjoint Analysis weights; and F) 194 DOIs drafted by applying weights from Conjoint Analysis to the base DOIs. Relative and absolute percentage change DOIs were tested for minimal, moderate and major improvement. The consensus-rated patient profiles were then used to: a) validate DOIs (including definitions A, B, D, E, F) for their sensitivity, specificity, kappa, odds ratio, and area under the curve (AUC); and b) develop logistic regression DOIs (definition C using 2/3rd of data) and then internal validation (using 1/3rd data). High performing DOIs were externally validated using Rituximab in Myositis (RIM) trial data (N=152 DM/PM), followed by a consensus meeting using nominal group technique (NGT). The 17 highest performing candidate DOIs with AUC ≥ 0.90 in profile data and with good validation (AUC > 0.70) in RIM, some from each category A-F, were discussed for their performance characteristics and clinical face validity at a consensus conference.

Results: A final ranking of the top DOIs from the adult working group yielded 92% consensus (among 12 adult PM/DM experts) for a Conjoint Analysis hybrid DOI using relative % change in CSMs with different cutpoints for minimal, moderate and major improvement. NGT discussion with the adult and pediatric working groups yielded consensus (91% agreement) in use of a different Conjoint Analysis hybrid DOI (Table 1) for both adult DM/PM and JDM clinical trials using absolute % change with different cutpoints for minimal, moderate and major improvement.

Conclusion: A Conjoint Analysis-driven hybrid DOI with a continuous score of improvement based on absolute % change in CSMs with different cut points for minimal, moderate and major improvement (prelim) was selected by a data and consensus-driven process as a final DOI to be used for clinical trials in adult DM/PM. Criteria for major improvement is considered preliminary.

Table 1. *Final Myositis Response Criteria Model*

Long Term Outcomes of Patients with Moderate Creatine Kinase (CK) Elevation Seen in a Rheumatology Clinic. Lyudmila Kirillova[1], Abraham Tacang[1], Andrea Berger[2], Thomas M. Harrington[1] and Androniki Bili[1]. [1]Geisinger Health System, Danville, PA, [2]Center for Health Research, Geisinger Health System, Danville, PA.

Background/Purpose: Asymptomatic or mildly symptomatic patients with moderate creatine kinase (CK) elevation are commonly referred to rheumatologists. In patients without a clearly established diagnosis, the significance of the CK elevation and long term outcomes are unclear and there is lack of data to help rheumatologists to counsel these patients. The purpose of this study was to examine the outcomes of patients with moderate CK elevation of unclear etiology and identify possible predictors of CK normalization and symptom resolution.

Methods: Retrospective chart review of asymptomatic or mildly symptomatic patients with moderate (250–1000 U/L) CK elevation who were referred to a rheumatologist for that reason, in a tertiary health system. Patients with known inflammatory myopathy, elevated troponin, cardiovascular disease, epilepsy or rhabdomyolysis were excluded. Patients with an established diagnosis within the first two visits with the rheumatologist were also excluded. Comparisons between groups were tested using two-sample t-tests, Wilcoxon rank sum tests, or Kruskal-Wallis tests, and Pearson's chi-square or Fishers exact tests, as appropriate.

Results: 62 patients were included of which 67.7% were male, 95.2% Caucasian, with median CK 368 U/L at baseline, median highest CK 602 U/L and median follow up of 7 years (interquartile range 5 to 8 years). At the end of the observation period, 2 patients (3.2%) were diagnosed with inflammatory myopathy, 36 patients (58.1%) were thought to have elevated CK due to medications (mostly cholesterol lowering medications), 5 patients (8.1%) were classified as "other" (race, exercise) causes and for 19 (30.6%) patients there was no established cause for the elevated CK. There were no differences between the outcome groups regarding demographics, median CK or symptoms at baseline. In 27 patients (43.5%) CK normalized at follow-up. Patients with normalized CK were older (median age 66 vs. to 56 years, p= 0.03) and had lower CK levels (median CK 306 vs. to 403 U/L, p= 0.009) at baseline compared to patients whose CK remained elevated. Of the 56 patients with symptoms at baseline 28 (50%) became symptom-free at follow up; absence of muscle weakness was associated with resolution of the symptoms in follow-up (92.3% vs. 67.9%, p = 0.026). In the 36 patients with CK elevation due to medications, CK normalized in 19 (52.8%) and symptoms subsided in 20 (55.6%) patients at follow-up. In the 19 patients with CK elevation of unknown etiology, CK normalized in 6 (31.6%) and symptoms subsided also in 6 (31.6%) patients at follow-up.

Conclusion: In patients with asymptomatic or mildly symptomatic moderate CK elevation, the main etiology is lipid lowering medicines but in a substantial proportion the etiology remains unclear. In older patients and patients with lower CK at baseline it is more likely that CK normalizes in follow-up; patients without weakness as the main symptom at baseline were more likely to become asymptomatic at follow-up. These are encouraging findings that can help rheumatologists counsel these patients on their long term prognosis.

A Predictive Model of Disease Outcome in Rituximab-Treated Myositis Patients Using Clinical Features, Autoantibodies, and Serum Biomarkers. Jeannette Olazagasti[1], Cynthia S. Crowson[1], Molly S. Hein[1], Consuelo Lopez de Padilla[1], Rohit Aggarwal[2], Chester V. Oddis[2] and Ann M. Reed[1]. [1]Mayo Clinic, Rochester, MN, [2]University of Pittsburgh, Pittsburgh, PA.

Background/Purpose: Develop predictive models of early (8 week) and late (24 week) disease outcomes using clinical features, autoantibodies, and serum biomarkers in patients with refractory myositis treated with rituximab.

Methods: In the Rituximab in Myositis (RIM) trial, all subjects (76 with adult dermatomyositis, 76 with adult polymyositis and 48 with juvenile dermatomyositis) received rituximab (2 doses on consecutive weeks) with half the patients receiving drug at baseline and half receiving drug 8 weeks later. Using start of treatment as baseline, serum samples (n=177) were analyzed at baseline and after 8 and 24 weeks after rituximab. Potential predictors included the following baseline factors: clinical features, serum muscle enzymes, interferon gene score, autoantibodies (anti-synthetase n=28, TIF1-g n=19, Mi-2 n=25, SRP n=21, NXP2 n=18, non-myositis associated n=24, undefined autoantibody n=9), and cytokines/chemokines measured by multiplexed sandwich immunoassays (Meso Scale Discovery) (type-1 IFN-inducible [IP-10, I-TAC, MCP1], Th1 [IFNγ, TNFα, IL2], Th2 [IL4, IL5, IL10, IL12, IL13], Th17 [IL6, IL17, IL1β] and regulatory cytokines [IL10, TNFa, MIP-1α, MIP-1β]). Our primary definition of response to treatment was based on absolute change from baseline to 8 weeks and 24 weeks in physician global visual analog scale (VAS), muscle VAS, and extramuscular VAS. Multivariable linear regression models were developed using stepwise variable selection methods.

Results: Preliminary models were built with good predictive ability both for change in physician global assessment and muscle disease activity at 24 weeks (R-square=0.41 and 0.40, respectively). The model for change in physician global assessment included the following baseline clinical and lab features: muscle disease activity, physician global assessment, and I-TAC (Table). The model for change in muscle disease activity included baseline physician global assessment, skeletal disease activity, I-TAC and IFNγ. Similarly, a predictive model was built with excellent predictive ability (R-square=0.67) for change in extramuscular disease activity at 24 weeks. This model included the following baseline clinical and lab features: constitutional, skeletal and extramuscular disease activity by VAS, and MIP-1β and Mi-2. We also built models from baseline to 8 weeks but their predictive ability was inferior compared to those for 24 weeks (R-square<0.3).

Conclusion: Changes in disease activity over time following treatment with rituximab in patients with refractory myositis can be predicted. These models could be clinically useful to optimize treatment selection in these patients.

Increased Risk of Myocardial Infarction in Dermatomyositis and Polymyositis: A General Population-Based Cohort Study. Kateryna Vostretsova[1], Erin Carruthers[2], Eric C. Sayre[2], John Esdaile[2] and J Antonio Avina-Zubieta[3]. [1]University of British Columbia, Vancouver, BC, [2]Arthritis Research Centre of Canada, Richmond, BC, [3]University of British Columbia, Department of Experimental Medicine, Vancouver, BC.

Background/Purpose: Patients with polymyositis (PM) and dermatomyositis (DM) may have an increased risk of myocardial infarction (MI), similar to other connective tissue diseases. However, no relevant data are scarce to date. We estimated the future risk and time trends of **newly recorded cases of MI** among **individuals with incident PM/DM (**1996–2010**)** compared to controls using physician-billing data from the province of British Columbia (~4.4 million).

Methods: Our data include all visits to health professionals and all hospital admissions, investigations (1990–2010) and all dispensed medications (1995–2010) for all individuals. We conducted a retrospective matched cohort study. Ten controls matched by birth year, sex and calendar year were randomly selected from the general population for each case. **Outcome**: Newly recorded MI events during follow up from hospitalization (ICD-9CM 410 or ICD-10 code: I21). In addition, we defined death from MI based on the death certificate diagnostic codes, including out of hospital deaths (ICD-10 code: I21). We calculated incidence rate ratios (IRR) overall and stratified by disease duration. We calculated hazard ratios (HR) and 95% confidence intervals (95% CI) adjusting for relevant confounders. Sensitivity analyses were conducted to assess for unmeasured confounders.

Results: Among 431 with PM (59% female, mean age 59.9 years y) and 352 with DM (65% female, mean age 55.7 yeas) the corresponding incidence rate ratio (IRRs)for MI were 8.14 (95% CI; 4.62–13.99) and 3.80 (95% CI; 1.89–7.09) respectively (**see table)**. Overall, the highest IRRs for MI were observed in the first year after PM diagnosis (IRR= 12.65, 95% CI: 5.11–31.65) as well as DM diagnosis (IRR= 6.32, 95% CI; 1.66–21.03). The risk of MI remained statistically significant in the fully adjusted models (hazard ratios= 3.78 (95% CI 2.05–6.95 and 6.54 (95% CI; 2.73–15.67), respectively) **(see table).** Our results remained statistically significant after adjusting for the potential impact of an unmeasured confounder.

Conclusion: The results of this large truly general population-based study indicates an increased risk of MI in people with PM (four fold) and DM (seven-fold) particularly in the first year after diagnosis, suggesting that inflammation plays a key role in the pathogenesis of MI. Our results support the need for increased monitoring for cardiovascular disease and risk modification to prevent this potentially fatal complication in patients with DM and PM.

ACR Concurrent Abstract Session
Osteoporosis and Metabolic Bone Disease - Clinical Aspects and Pathogenesis: Clinical Osteoporosis: Treatment and Safety
Sunday, November 16, 2014, 4:30 PM–6:00 PM

916

Effects of 2 Years of Treatment with Romosozumab Followed By 1 Year of Denosumab or Placebo in Postmenopausal Women with Low Bone Mineral Density. MR McClung[1], A Chines[2], JP Brown[3], A Diez-Perez[4], H Resch[5], J Caminis[6], MA Bolognese[7], S Goemaere[8], HG Bone[9], JR Zanchetta[10], J Maddox[2], O Rosen[2], S Bray[11] and A Grauer[2]. [1]Oregon Osteoporosis Center, Portland, OR, [2]Amgen Inc., Thousand Oaks, CA, [3]Laval University and CHU de Québec Research Centre, Quebec City, QC, [4]Autonomous University of Spain, Barcelona, Spain, [5]St. Vincent Hospital, Vienna, Austria, [6]UCB, Raleigh, NC, [7]Bethesda Health Research Center, Bethesda, MD, [8]Ghent University Hospital, Ghent, Belgium, [9]Michigan Bone and Mineral Clinic, Detroit, MI, [10]Instituto de Investigaciones Metabólicas, Buenos Aires, Argentina, [11]Amgen Ltd., Cambridge, United Kingdom.

Background/Purpose: We previously reported that 1 year of treatment with the sclerostin antibody romosozumab (Romo) was associated with increased bone mineral density (BMD) and bone formation and with decreased bone resorption in postmenopausal women with low BMD (McClung MR et al., *N Engl J Med* 2014;370:412–20). Here, we report the results of 2 years of treatment with Romo, followed by 1 year of denosumab (DMAb) or placebo.

Methods: This phase 2 study enrolled 419 postmenopausal women age 55 to 85 years with a lumbar spine, total hip, or femoral neck T-score ≤–2.0 and ≥–3.5. For the results described here, women received 1 of 5 regimens of Romo (70 mg QM, 140 mg QM, 210 mg QM, 140 mg Q3M, 210 mg Q3M; data for the 210 mg QM group are shown in the figure) or placebo for 2 years. At the end of 2 years, eligible subjects entered a 1-year extension phase and were re-randomized 1:1 within their original treatment group to placebo or DMAb 60 mg Q6M. Only women who entered the extension were included in these analyses.

Results: Romo led to rapid and marked increases in lumbar spine and total hip BMD during year 1 and continued increases through year 2. The largest gains were observed with Romo 210 mg QM, with BMD increases of 15.7% (lumbar spine) and 6.0% (total hip) (Figure). Women receiving Romo 210 mg QM who transitioned to DMAb continued to accrue BMD at a rate similar to that in the second year of Romo; in those who transitioned to placebo, BMD returned toward pretreatment levels.

Romo induced rapid stimulation of bone formation (P1NP) and decreased bone resorption (CTX). Increases in P1NP were transitory, returning toward baseline within 6 to 12 months and remaining below baseline through year 2. CTX remained below baseline through year 2. In subjects receiving Romo 210 mg QM who transitioned to DMAb, P1NP and CTX decreased; for those who transitioned to placebo, P1NP gradually returned to pretreatment levels, while CTX initially increased above baseline and gradually returned toward baseline.

Adverse events were balanced between the placebo and Romo groups during the first 2 years of the study (with the exception of injection site reactions, most reported as mild) and in the placebo and DMAb groups during year 3.

Conclusion: Romo led to rapid and marked increases in lumbar spine and total hip BMD over 2 years, which continued with DMAb and resolved after

transition to placebo. These data suggest that the treatment effects observed with Romo are further augmented by follow-on treatments like DMAb.

Evaluation of Invasive Oral Procedures and Events in Women with Postmenopausal Osteoporosis Treated with Denosumab. Results from the Pivotal Phase 3 Fracture Study Extension Nelson B. Watts[1], John T. Grbic[2], Michael McClung[3], Socrates Papapoulos[4], David Kendler[5], Christence S. Teglbjaerg[6], Lawrence O'Connor[7], Rachel B. Wagman[7], Eric Ng[7], Nadia S. Daizadeh[7] and Pei-Ran Ho[7]. [1]Mercy Health Osteoporosis and Bone Health Services, Cincinnati, OH, [2]Columbia University, New York, NY, [3]Oregon Osteoporosis Center, Portland, OR, [4]Leiden University Medical Center, Leiden, Netherlands, [5]University of British Columbia, Vancouver, BC, [6]Center for Clinical and Basic Research, Ballerup, Denmark, [7]Amgen Inc., Thousand Oaks, CA.

Background/Purpose: Osteonecrosis of the jaw (ONJ) is a rare but serious adverse event of some antiresorptive therapies, including denosumab (DMAb), and invasive oral procedures and events (OPEs) are suggested to be an important risk factor (Ruggiero, *J Oral Maxillofac Surg* 2009). The incidence of positively adjudicated ONJ in the DMAb bone loss clinical program is rare (between ≥ 1 and < 10 per 10,000). In this study, we assessed the occurrence of invasive OPEs through Year 5 of the ongoing, 7-year FREEDOM Extension (EXT) trial.

Methods: In FREEDOM, women were randomized to receive DMAb 60 mg SC or placebo every 6 months for 3 years. Those who missed ≤ 1 dose of investigational product and completed the Year-3 visit were eligible for the open-label FREEDOM EXT; women in the EXT long-term group (N = 2343) received DMAb in FREEDOM and EXT, and women in the EXT cross-over group (N = 2207) received placebo in FREEDOM and DMAb in EXT. Women who reached the EXT Year-3 visit were asked to chronicle their history of invasive OPEs (eg, dental implants, tooth extraction, natural tooth loss, or scaling or root planing [extensive subgingival cleaning]) during the EXT. Every 6 months thereafter, women were asked to document their oral health history since the last visit. Jaw surgery information was collected starting from month 30 of the EXT.

Results: The majority of women (78%) participated in the survey. Over 5 years of the EXT, 42.4% of these women reported an invasive OPE; the incidence of the 5 individual OPEs reported was similar between groups (Table). ONJ incidence was 0.4% (7/1500 subjects) in women reporting invasive OPEs and 0.05% (1/2036 subjects) in women reporting no invasive OPEs. The actual number of invasive OPEs may be underestimated due to limited capture of OPEs in medical charts and due to subjects' recall bias of events that occurred in the first 3 years of the EXT. During the EXT (Years 1–5), the exposure-adjusted incidence of ONJ was 4.2 per 10,000 patient-years. Of the 8 ONJ cases, 6 have resolved, 1 is ongoing and continues to be followed, and the final outcome of 1 is unknown, as consent was withdrawn.

Conclusion: While invasive OPEs were common in this group of DMAb-treated women with postmenopausal osteoporosis, ONJ incidence was low. Invasive OPEs will continue to be queried prospectively in the EXT to characterize the long-term background rate.

Table: Summary of Invasive Oral Procedures and Events

	FREEDOM Extension Years 1–5		
	Long-term (N = 1827)	Cross-over (N = 1709)	All (N = 3536)
Age at EXT baseline in years, mean (SD)	74.4 (4.7)	74.2 (4.8)	74.3 (4.8)
Any invasive oral procedure or event, n (%)	763 (41.8)	737 (43.1)	1500 (42.4)
Scaling or root planing	500 (27.4)	481 (28.1)	981 (27.7)
Tooth extraction	387 (21.2)	354 (20.7)	741 (21.0)
Dental implant	88 (4.8)	79 (4.6)	167 (4.7)
Natural tooth loss	59 (3.2)	57 (3.3)	116 (3.3)
Jaw surgery	11 (0.6)	9 (0.5)	20 (0.6)

N = Number of subjects who received ≥ 1 dose of investigational product in FREEDOM Extension and responded to ≥ 1 ora event questionnaire related to FREEDOM Extension. n = Number of subjects with ≥ 1 invasive oral procedure or event.

Findings from Denosumab (Prolia®) Postmarketing Safety Surveillance for Serious Infections. W. Golden[1], D. B. Crittenden[1], M. Uhart[1], R. B. Wagman[1], C. Stehman-Breen[1], S. Papapoulos[2] and N. B. Watts[3]. [1]Amgen Inc., Thousand Oaks, CA, [2]Leiden University Medical Center, Leiden, Netherlands, [3]Mercy Health Osteoporosis and Bone Health Services, Cincinnati, OH.

Background/Purpose: Prolia has marketing authorization in the EU, US, Canada, Japan, and over 40 countries or administrative districts worldwide for the treatment of postmenopausal women with osteoporosis at high/increased risk for fracture. As part of pharmacovigilance activities, Amgen Global Safety (AGS) continually assesses postmarketing adverse events reported by health care providers, patients, and other sources. Spontaneous adverse event reports, while often with insufficient information, are the cornerstone of safety surveillance programs and help detect rare and serious adverse drug reactions. Here we characterize the Prolia postmarketing experience for serious infections, including opportunistic infections.

Methods: A cumulative analysis of all non-clinical trial postmarketing serious infection reports (defined as those leading to ER visit or hospitalization) for Prolia in the AGS Database was conducted as of May 10, 2014 from solicited and spontaneous sources. Using postmarketing exposure estimates, we calculated overall reporting rates over time as well as cumulative rates for several serious infection subtypes, including opportunistic infections. Each infection subtype includes ≥ 1 related MedDRA Preferred Terms (PTs).

Results: Cumulatively through May 10, 2014, the total estimated postmarketing Prolia exposure was 1,963,794 patient-years (p-ys). There were 1,232 postmarketing reports of serious infection. The top 5 most frequently reported PTs were pneumonia (236), urinary tract infection (166), cellulitis (145), diverticulitis (59), and sepsis (59). Time to onset after the first dose of Prolia (reported for 305 cases) was highly variable, ranging from 1 to 916 days (mean 156, median 82.5). Among the 7 reported cases of endocarditis, only 2 were confirmed by echocardiography; both cases had confounding factors. The reporting rate of overall serious infection has decreased over time since product registration (first reporting period in 2010: 153 cases/100,000 p-ys; current reporting period in 2014: 57 cases/100,000 p-ys). Cumulative reporting rates of serious infection subtypes were low (Table) and below the background rates estimated from insurance claims data. Few cases of opportunistic infections were reported and included herpes zoster (32 cases; 1.6 cases/100,000 p-ys), unspecified fungal infections (10 cases; 0.5 cases/100,000 p-ys), and mycobacterium tuberculosis (5 cases; 0.3 cases/100,000 p-ys).

Conclusion: Recognizing the limitations of postmarketing safety data, these data suggest that reporting rates of serious infections decreased over time, and rates of events reported are lower than estimated background rates. The benefit/risk profile for Prolia remains favorable. Ongoing safety surveillance continues through clinical studies and pharmacovigilance activities.

Table. Cumulative Reporting Rates of Serious Infection Subtypes

Serious Infection Subtypes*	Reports (n)	Reporting Rate (per 100,000 p-ys)
Pneumonia	256	13.0
Urinary tract infection/cystitis	235	12.0
Cellulitis	149	7.6
Sepsis	95	4.8
Diverticulitis	59	3.0
Endocarditis	7	0.4

*Each serious infection subtype includes ≥ 1 related MedDRA Preferred Terms.

Glucocorticoid Exposure and Fracture Risk in a Large Cohort of Commercially-Insured Rheumatoid Arthritis Patients Under Age 65. Akhila Balasubramanian[1], Sally Wade[2], Robert A Adler[3], Celia Fang (Lin)[4], Michael Maricic[5], Cynthia O'Malley[1], Kenneth G. Saag[6] and Jeffrey R. Curtis[6]. [1]Amgen, Inc., Thousand Oaks, CA, [2]Wade Outcomes Research and Consulting, Salt Lake City, UT, [3]Hunter Holmes McGuire VA Medical Center, Richmond, VA, [4]Amgen, Thousand Oaks, CA, [5]Catalina Pointe Rheumatology, Tucson, AZ, [6]The University of Alabama at Birmingham, Birmingham, AL.

Background/Purpose: Systemic glucocorticoid use can increase fracture risk, although dose-specific effects are not well understood, especially in younger adults. Underlying diseases (e.g., rheumatoid arthritis [RA]) can confound these associations. This study evaluated the impact of glucocorticoid exposure on risk of fragility fracture in RA patients.

Methods: The 42,034 study patients identified in the MarketScan® claims database were newly treated for RA (index date) between 1/1/2005 and 12/31/2011, aged 18–64 years at index, had benefits coverage for ≥12 months pre-index, and no pre-index cancer. Patients with pre-index glucocorticoid use were glucocorticoid-free for ≥ 12 months prior to their first glucocorticoid pharmacy claim, and had continuous benefits coverage from first glucocorticoid claim to index date. Glucocorticoid use (any; cumulative, peak, and average daily dose; cumulative days exposed; days of continuous exposure; days since most recent exposure) was assessed for each patient-day and censored at the earliest of post-index fragility fracture, cancer diagnosis, or end of follow-up. Exposures were converted to prednisone equivalents and cumulative measures included pre-index use. Patient demographics at index and pre-index clinical characteristics were assessed. Incidence rates per 1,000 person-years for post-index fragility fracture were stratified by glucocorticoid exposure. Cox's proportional hazards models estimated age- and sex-adjusted fracture risk by exposure level.

Results: Patients averaged 738 (standard deviation [SD] 615) post-index follow-up days. Most patients (82%) had glucocorticoid exposure during the study (43% with cumulative dose < 675 mgs; 73% had peak dose ≥ 15 mg/day). Exposed and unexposed patients were demographically similar (74% female; mean age 49.4 [10.7] and 49.8 [10.2] years); 1% had pre-index fracture. Fragility fracture incidence rates (95% confidence intervals) were 5.1 (4.6, 5.6) and 16.8 (11.4, 24.0) at daily doses of 0 mg/day and ≥ 15 mg/day, respectively, and 4.8 (3.8, 6.0) and 13.7 (10.6, 17.4) at cumulative doses of 0 mg and ≥ 5400 mgs, respectively. Among patients ever-exposed to glucocorticoids, fracture risk was significantly elevated at cumulative dose ≥ 2700 mg and daily dose ≥ 15 mg/day (Table). Following glucocorticoid discontinuation, fracture risk (adjusted for age, sex, and cumulative dose) was 32% lower at 60–181 days since last exposure versus current exposure. Analyses restricted to patients younger than 50 years also showed highest fracture risk at highest exposures.

Conclusion: In this large, relatively young cohort of RA patients, fracture risk increased by 2- to 3-fold at high levels of daily and cumulative glucocorticoid dose, and began to decline within months of glucocorticoid discontinuation.

Table: Risk of Post-Index Fragility Fracture among Rheumatoid Arthritis Patients Ever-Exposed to Systemic Glucocorticosteroids

		Hazard Ratio	95% C.I.	P-Value
Sex	Male (n=31,104)	ref		
		1.71	(1.33, 2.20)	<.0001

Randomized Controlled Trial to Assess the Safety and Efficacy of Odanacatib in the Treatment of Men with Osteoporosis. Eric Orwoll[1], Silvano Adami[2], Neil Binkley[3], Roland Chapurlat[4], Bente Langdahl[5], Steven Doleckyj[6], Hilde Giezek[7], Boyd Scott[8] and Arthur Santora[8]. [1]Oregon Health and Science University, Portland, OR, [2]Rheumatology Department, University of Verona, Verona, Italy, [3]University of Wisconsin, Madison, WI, [4]Hopital Edouard Herriot, Lyon, France, [5]Aarhus University Hospital, Aarhus, Denmark, [6]Merck & Co., Inc., Whitehouse Station, NJ, [7]MSD Belgium, Brussels, Belgium, [8]Merck Sharp & Dohme Corp., Whitehouse Station, NJ.

Background/Purpose: Osteoporosis in men is an important clinical problem, associated with significant morbidity, mortality and societal expense. Men with osteoporosis represent between 20 and 25% of all osteoporotic patients and men are at greater risk of death following a hip fracture. Odanacatib (ODN), a selective inhibitor of cathepsin K, is currently being investigated as a treatment for osteoporosis. In a Phase II study in postmenopausal women, treatment with ODN 50mg once-weekly resulted in increases in bone mineral density (BMD) vs. baseline at the lumbar spine (LS) (11.9%) and total hip (TH) (8.5%) over 5 years. In this 2-yr Phase III study safety and efficacy of ODN in the treatment of men with osteoporosis was investigated.

Methods: This was a double-blind, randomized; placebo controlled 24-month trial. Men ≥40 and ≤95 years of age with idiopathic osteoporosis or osteoporosis due to hypogonadism were enrolled. Inclusion criteria included a LS or hip (TH, femoral neck (FN) or trochanter) T-score of ≤−2.5 to ≥−4.0 without prior vertebral fracture or ≤−1.5 to ≥−4.0 with one prior vertebral fracture. Participants were randomized (1:1) to 50mg ODN or PBO orally once-weekly, and all received vitamin D_3(5600IU/week) and calcium supplements (total intake including food of ~1200mg daily). The primary outcomes were the effect of ODN versus PBO on LS BMD assessed by DXA versus PBO at 24 months and safety and tolerability. Secondary outcomes included changes in BMD at the TH, FN, trochanter sites, and bone turnover markers (u-NTx, S-CTx, s-PINP and s-BSAP).

Results: A total of 292 men were randomized and received at least one dose of study medication. The average age was 68.8 years, and 5.8% had total testosterone levels below 250ng/dL. BMD increases from baseline at 24 months in the ODN group at the LS and all 3 hip sites (TH, FN and trochanter) were 6.9%, 1.9%, 1.7% and 2.8% respectively, and all were greater vs. PBO (LS, TH and trochanter $p<0.01$; FN $p=0.008$). ODN significantly decreased (vs. PBO) the bone resorption markers u-NTx/Cr and s-CTx (68% and 77%, both $p<0.001$) and also decreased bone formation markers, s-PINP and s-BSAP (16% and 8%, $p=0.001$ and $p=0.019$ respectively) compared to PBO at 24-months. The between group decrease of bone formation markers was maximal at 3 months, after which levels returned towards baseline by 24 months. The adverse events and overall safety profile were similar between ODN and PBO.

Conclusion: In this study, ODN increased spine and hip BMD in osteoporotic men. Changes in bone turnover markers suggest that ODN treatment decreases bone resorption while producing relatively small decreases in bone formation by the end of the study. ODN is a promising potential therapy for the treatment of osteoporosis in men.

Comparison of Infection Rates in Patients Receiving Denosumab, Denosumab and Biologics and Biologics Alone in a Suburban Rheumatology Clinic. Sajina Prabhakaran[1] and Charles Pritchard[2]. [1]Drexel University College of Medicine, Philadelphia, PA, [2]Drexel University College of Medicine, Willow Grove, PA.

Background/Purpose: Biologics including rituximab, abatacept and belimumab increase the risk of infection in patients. Denosumab, a RANK-ligand inhibitor used in the treatment of osteoporosis may theoretically make patients more susceptible to infections. RANK is a member of the tumor necrosis factor receptor (TNFR) superfamily so inhibition may cause immunosuppression. One pivotal trial showed an increase in cellulitis and erysipelas in patients on denosumab. We used a retrospective chart review of a patients in a sole specialty rheumatology practice to evaluate the infection rates and hospitalizations of patients on the combination of biologics with denosumab, biologic agents alone, and denosumab alone.

Methods: We reviewed the charts of 136 patients, 50 patients who received biologics only, 50 patients who received denosumab alone and 36 patients who received both simultaneously over the past 4 years. Biologics studied included infliximab, tocilizumab, rituximab, belimumab, abatacept, adalimumab, and golimumab. The primary end-point was to determine if there was a greater risk of infection, hospitalization, complication or discontinuation of biologic and/ or denosumab in the combined group versus the biologic alone. Percentage of incidence was calculated for each group and Chi-square and Fisher's Exact tests were used for analysis. Relative risks were calculated to compare infection risks between groups.

Results: There was no difference found in the risk of infection between the groups that received both biologic and denosumab compared to biologic alone, RR = 1.24, 95%, CI: 0.76 –2.04. There were statistically significant increases in the risk of infection in the groups that received both biologic and denosumab compared to the group that received denosumab; RR=7.87, 95% CI: 2.49–24.9 and biologic alone compared to denosumab, RR=6.33, 95% CI 2 – 20.1. Hospitalization rates were higher in the combination group compared to the denosumab (19.4% vs 12%, $p=0.038$). Statistically significant increases in the risk of infection with increased duration of exposure to biologics ($p<0.001$) were also noted.

Conclusion: We did not find an increased risk of infection with the combination of denosumab and a biologic compared to a biologic alone. The rates of infection and hospitalization of patients in the combination group were not significantly different between biologic medications.Secondary characteristics also did not affect the compared rates of infection.The duration of exposure to denosumab did not affect the infection rate. There did not seem to be any increased risk of infection in patients on combination non biologic DMARDs and denosumab. In summary this retrospective small study from a sole specialty rheumatology practice did not show a statistical increased risk of infection combining a biologic with denosumab vs a biologic. Hence it appears to be relatively safe to combine denosumab with a biologic agent.

A Potential Role for TLR4 Activation in Osteoarthritis Associated Pain. Rachel E. Miller[1], Shingo Ishihara[1], Phuong Tran[1], Richard J. Miller[2] and Anne-Marie Malfait[1]. [1]Rush University Medical Center, Chicago, IL, [2]Northwestern University, Chicago, IL.

Background/Purpose: Damage associated molecular patterns (DAMPs) result from cellular stress and extracellular matrix breakdown. They may contribute to osteoarthritis (OA) pathogenesis by promoting synovitis and cartilage degradation, via activation of pattern recognition receptors (PRR) on chondrocytes and synovial cells. We hypothesized that DAMPs play a direct role in OA pain through activation of dorsal root ganglia (DRG) neurons. We investigated the effects of three OA-associated DAMPs, S100A8, S100A4, and α2-macroglobulin (α2M) on cultured DRG cells.

Methods: DRG neurons (L3-L5) were isolated from adult C57BL/6 mice (wild type, *Tlr4* null or *Tlr2* null) and cultured prior to (1) MCP-1 stimulation or (2) Ca^{2+} mobilization assays. For stimulation assays, cultures were treated overnight with S100A8 (1 μg/mL), S100A4 (1 μg/mL) or α2M (50–100 μg/mL) and supernatants collected for MCP-1 ELISA. The proalgesic chemokine MCP-1 is a key mediator of pain in murine experimental OA. For Ca^{2+} mobilization assays, cultures were loaded with a Ca^{2+}indicator dye and responses to S100A8 (1 μg/mL) or α2M (50 μg/mL) were recorded. Further, destabilization of the medial meniscus (DMM) or sham surgery was performed in 10-week old male C57BL/6 mice. Mice were euthanized 8 or 16 weeks later and L3-L5 DRG were harvested for culture, with or without the selective TLR4 antagonist, TAK242 (Tocris, 1 μM). After 96 hrs, supernatants were analyzed for MCP-1 levels via ELISA.

Results: Stimulation of DRG cultures with α2M resulted in a concentration-dependent increase of MCP-1 production, where 100μg/ml α2M caused a 10-fold increase compared to unstimulated cells ($p<0.0001$). These effects are similar to those observed with IL-1. S100A8 was an equally potent inducer of MCP-1 ($p<0.0001$ compared to control), whereas S100A4 did not stimulate MCP-1 expression.

Responses to α2M or S100A8 were unaltered in DRG cultures of *Tlr2* null mice. In contrast, DRG cells from *Tlr4* null mice did not produce MCP-1 in response to α2M, whereas the response to S100A8 was 50% suppressed, suggesting that the effects of α2M are mediated through TLR4 whereas S100A8 may use other receptors as well. This was confirmed using a selective TLR4 inhibitor in wild type (wt) DRG cultures.

8 and 16 weeks after DMM, unstimulated DRG cells produced increased amounts of MCP-1 compared to naïve and sham. Addition of TAK242 to the culture medium significantly reduced MCP-1 levels produced by DMM DRG

cells, suggesting that TLR4 contributes to MCP-1 production observed after DMM surgery.

Since DRG cultures contain glial cells in addition to sensory neurons, we studied direct effects of α2M and S100A8 on neurons through assessing Ca^{2+}-mobilization responses. On average, 8% of wt DRG neurons responded to S100A8 and 23% responded to α2M, suggesting that DRG neurons can express excitatory receptors for these DAMPs. In *Tlr4*null DRG, 6% of all neurons responded to S100A8 and none responded to α2M.

Conclusion: These studies suggest a potential role for DAMPs in DRG activation, which may contribute to OA pain. TLR4 plays an important role in these effects but other receptors may also be involved. Our results suggest that PRR may be a novel therapeutic target in OA associated pain.

Phenotypes of Osteoarthritis-Related Knee Pain and Their Transitions over Time: The Osteoarthritis Initiative. Na Lu[1], Tuhina Neogi[1], K. Douglas Gross[1], Jingbo Niu[1], Hyon Choi[2] and Yuqing Zhang[1]. [1]Boston University School of Medicine, Boston, MA, [2]Harvard Medical School, Boston, MA.

Background/Purpose: The WOMAC questionnaire is one of most commonly used instruments to assess knee pain in persons with or at risk of knee osteoarthritis (OA). However, the summary score of the WOMAC pain subscale fails to distinguish pain experienced during activity from pain felt at rest. Yet these two symptomatic profiles may represent distinct phenotypes. If recognizable patterns of pain are, in fact, distinguishable as unique groupings of the individual WOMAC item responses, then their delineation could valuably inform distinct underlying mechanisms and the subsequent development of phenotype-specific treatments for OA-related knee pain.

Methods: The Osteoarthritis Initiative (OAI) cohort consists of adults ≥ 45 years of age that have or are at risk for knee OA. The WOMAC pain subscale was administered at baseline and each annual follow-up visit. Using a latent class model (SAS software PROC LTA), we identified distinct pain phenotypes based on participants' responses to each of the 5 WOMAC pain questions. The resultant pain phenotypes each consist of subjects with homogenous responses to the 5 WOMAC pain questions. We then examined the baseline characteristics of these pain phenotypes and estimated the transition probability of each pain phenotype to another over 24 months follow-up.

Results: Among 3,985 participants (7,906 knees) who had a WOMAC pain score available during the first 3 follow-up visits, we identified 5 distinct knee pain phenotypes at baseline: 1) No/minimal pain (No-Pain: 55.0%); 2) Mild pain during activity only (Mild-P-A: 20.0%); 3) Moderate pain during activity only (Mod-P-A: 12.3%); 4) Mild pain both during activity and at rest (Mild-P-A-R: 7.1%); and 5) Moderate pain both during activity and at rest (Mod-P-A-R: 5.8%). Age at baseline was similar across the 5 pain phenotypes; however women, higher BMI, higher depressive symptoms, and K/L score ≥3 tended to be higher among subjects with pain both during activity and at rest than pain during activity only. During follow-up, a majority of knees' pain phenotypes remain stable; ~11% of knees with No-Pain at baseline later developed Mild-P-A, ~20% of knees with Mild-P-A transitioned to the No-Pain group, and ~15% of knees with Mild-P-A transitioned to Mod-P-A. Among knees with Mild-P-A-R, ~43% improved to either No-Pain (~32%) or Mild-P-A (~11%). Among knees with Mod-P-A-R, ~26% had their pain improved to Mod-P-A, while the probability of transitioning to either No-Pain (9.5%) or Mild-P-A (7.2%) was small.

Conclusion: We identified 5 distinct knee pain phenotypes based on responses to the WOMAC pain questionnaire. While the pain phenotypes remained stable in the majority of knees over time, there was substantial transitioning both to better and worse pain phenotypes. These findings may have implications for identification of pain phenotype-specific risk factors and development of treatment for distinct pain phenotypes.

Characteristics of Pain Flares in Knee Osteoarthritis. Susan L. Murphy[1], Angela K. Lyden[1], Arnold Gammaitoni[2], David A. Williams[3], Daniel J. Clauw[1], J. Ryan Scott[1] and Kristine Phillips[1]. [1]University of Michigan, Ann Arbor, MI, [2]Zogenix, Inc, San Diego, CA, [3]Univ of MI Hlth System-Lobby M, Ann Arbor, MI.

Background/Purpose: For inclusion in osteoarthritis clinical trials, participants often need to have a pain 'flare', usually defined as a pain increase over a period of time prior to study entry. Outside of clinical trial settings, there is no consensus regarding what constitutes a pain flare. The purpose of this study was to examine how individuals with knee osteoarthritis experience pain flares and their impact on daily living.

Methods: 45 participants (64 + 10 years; 55% female) with knee osteoarthritis underwent a baseline clinic visit as part of a larger pharmaceutical trial. At this visit, symptom measures were collected and participants were trained in procedures to collect data using a wrist-worn accelerometer in a 7-day home monitoring period. Participants wore the Actiwatch-Score and entered ratings of pain severity (0–10 scale) eight times per day. They were also asked to provide information at the end of each day in a logbook. Participants were asked to provide a definition of a pain flare and used that definition to indicate in the logbook if they experienced a pain flare that day and what they were doing when it occurred. Pain variability was calculated as the standard deviation of the pain ratings over the 7 day period. We hypothesized that pain flares and pain variability would be strongly related.

Results: When asked to define 'pain flare', descriptors of 'sharp' and 'increase in pain' were used by 30% and 21% of the sample respectively. Other descriptors included 'intense/severe', 'electrical' and various descriptors (e.g., twinge, stabbing, pulsation). Pain flares were most often described to be of short duration. During the home monitoring period, 77% of the sample experienced at least one pain flare and the mean was 2.2 + 2.0. Pain flares were most strongly associated with their worst daily pain (r =.51), followed by weekly average pain severity (r =.42), pain interference on the Brief Pain Inventory (r=.39), and WOMAC pain scale (r=.37). When asked to describe what they were doing when a pain flare occurred, participants most frequently mentioned activity-related causes (stair climbing, walking, shopping), while very few mentioned stiffness due to inactivity or being awakened by night pain. Pain flares were not significantly associated with pain variability (r =.12) or with neuropathic pain as measured by the PainDetect (r=.09); however PainDetect was most strongly correlated with WOMAC Pain (r=0.60), WOMAC Physical Function (r=0.57), and BPI severity (r=0.60).

Conclusion: Pain flares occurred frequently over a week for people with osteoarthritis, were of short duration, and were most often experienced during activities. Interestingly, pain flares were not associated with pain variability. Although pain flares and pain variability may be activity-related, WOMAC subscales, which asked about pain or function during activities, were most strongly associated with a neuropathic component to pain. These findings provide further insight into the pain experience for people with knee osteoarthritis. Pain flares appear to be characterized by researchers and individuals with knee osteoarthritis in a variety of ways suggesting the need for additional research in this area.

Cortical Reorganization after Duloxetine Treatment-Related Pain Decrease in Knee Osteoarthritis. Pascal Tetreault, Marwan Baliki, Etienne Vachon-Presseau, Renita Evonne Yeasted, Thomas J. Schnitzer and A. Vania Apkarian. Northwestern University, Chicago, IL.

Background/Purpose: Structural brain properties of patients coping with chronic painful conditions are becoming better understood but knowledge on how pain treatment affects these properties is still sparse. Assessment of cortical modifications during chronic pain evolution now permits identifying regions critically involved in painful pathologies. In this study, we evaluate structural brain reorganization of knee osteoarthritic (OA) patients after four months treatment with duloxetine (DLX) or placebo (P).

Methods: OA patients (n=40) meeting standard inclusion/exclusion criteria with pain ≥ 5 on 11 point NRS scale were randomized to DLX (60 mg) or placebo. Pain measurements were made at week 0, 2, 3, 6 and 16 and anatomic MRI scans done at baseline and at end of treatment (week 16). The total gray matter volume of the brain was obtained using SIENAX tool from FSL and cortical gray matter density (GMD) changes were evaluated using a voxel based morphometry approach (FSL-VBM). To evaluate structural brain properties, longitudinal contrast was made by using a two-way repeated measure ANOVA design.

Results: Patients were categorized as responders (≥ 20% pain decrease from baseline) and nonresponders in both DLX and placebo groups. The total gray matter volume showed an interaction of time*treatment*response ($F=16.69$, $p < 0.001$). Following treatment, DLX responders had a borderline significant volume increase ($p=0.07$); in contrast, placebo responders had a significant volume decrease ($p < 0.05$). Whole-brain voxel-wise VBM contrast (before – after treatment) revealed that DLX-treated patients underwent modification in GMD in the left precentral gyrus, left middle frontal gyrus and bilateral ACC (figure 1A). Interestingly, when patients positively responded to their treatment, independent of compound received, difference in GMD was observed only in the left precentral gyrus (figure 1B). In addition, regions in the left middle frontopolar (figure 1C) and inferior temporal gyri showed GMD changes when DLX induced pain relief. We thus show that some cortical regions presenting GMD reorganization were shared among all 4 groups studied, suggesting that a proportion of gray matter structural modification may be naturally occurring in time while other regional changes are directly related to treatment received.

Conclusion: Understanding how pharmacological treatment affects structural brain properties is important to assess drug efficacy and its potential deleterious effects. We herein show that pharmacological treatment of OA pain is affecting cortical reorganization in a way that is dependent on treatment, response and the interaction of both.

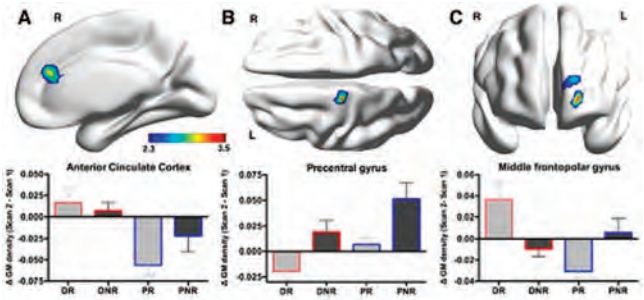

Figure 1. Treatment received, pain decrease and their interaction induce unique gray matter reorganization. Two-way repeated measure ANOVA revealed that **A)** DLX and P induce opposite GM modification in bilateral ACC. **B)** Response to the treatment is affecting cortical changes in a region in the left precentral gyrus (primary motor cortex) and **C)** Prefrontal cortex undergoes high GM reorganization for DLX-patients that show pain decrease. DR/NR=DLX responders/nonresponders, PR/NR=P responders/nonresponders

Does a Family History of Total Knee Replacement for Knee Osteoarthritis Influence Knee Pain and Structural Progression? a Prospective Longitudinal Cohort Study. Feng Pan[1], Hussain Khan[1], Changhai Ding[1], Tania Winzenberg[1], Johanne Martel-Pelletier[2], Jean-Pierre Pelletier[2], Flavia Cicuttini[3] and Graeme Jones[1]. [1]Menzies Research Institute Tasmania, University of Tasmania, Hobart,7000, Australia, [2]Osteoarthritis Research Unit, University of Montreal Hospital Research Centre (CRCHUM), Notre-Dame Hospital, Montreal, QC, [3]School of Public Health and Preventive Medicine, Monash University, Melbourne, Australia.

Background/Purpose: Genetic factors appear to play an important role in the pathogenesis of both knee pain and radiographic osteoarthritis (OA) based on cross-sectional studies but there are limited studies on the role of genetic mechanisms in the development of these factors over time. The aims of this study were to describe whether offspring having at least one parent with a total knee replacement for severe primary knee OA have an increased risk of worsening knee pain and knee structural progression over 8 to 10 years as compared to randomly selected controls with no family history of knee OA.

Methods: A total of 219 participants (mean age 48 years, range 29 to 61) with 115 offspring and 104 controls participated in this study. Knee pain was respectively assessed using a simple knee pain questionnaire at baseline and Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) at 2 years and 10 years. T1 or T2-weighted fat saturated magnetic resonance imaging of the right knee was performed to assess knee cartilage defects, bone marrow lesions (BMLs), meniscal extrusion and tears.

Results: Compared with controls, the prevalence of knee pain for offspring was higher at baseline (45% versus 20%, $P < 0.001$, assessed as yes/no), similar at 2 years (56% versus 54%, $P = 0.764$, WOMAC >0) and much higher at 10 years (74% versus 54%, $P = 0.002$, WOMAC >0). Over 8 years, offspring more frequently had an increase in knee pain (66% versus 41% ≥1 point increase, $P = 0.003$) and in all subscales apart from walking (all $P < 0.05$). In addition, they also had a greater increase in cartilage defect score (1.03 versus 0.52, $P = 0.007$), meniscal extrusion score (0.28 versus 0.10, $P = 0.027$), and meniscal tear score (0.40 versus 0.10, $P = 0.012$) in the medial tibiofemoral compartment. No significant difference in BML change was observed. In multivariable analysis, after adjustment for confounders and these structural factors, offspring still had an elevated risk of worsening knee pain (OR = 2.22, 95%CI = 1.17 to 4.22), as well as each subscale apart for walking and standing (OR = 2.01 to 3.36, all $P < 0.05$).

Conclusion: Offspring with family history of knee OA have an increased risk of worsening knee pain and progression of knee cartilage and meniscal pathology but not bony structural changes suggesting that genetic factors may be independently involved in the pathogenesis of knee pain and facets of structural progression. Intriguingly, the change in knee pain was independent of structural factors suggesting this effect is mediated by factors outside the knee.

Urate Crystal Induced Inflammation and Joint Pain Are Reduced in Transient Receptor Potential Ankyrin 1 (TRPA1) Deficient Mice – a New Potential Role for TRPA1 in Gout. Lauri J Moilanen, Mari Hämäläinen, Lauri Lehtimäki, Riina Nieminen and Eeva Moilanen. The Immunopharmacology Research Group, University of Tampere School of Medicine and Tampere University Hospital, Tampere, Finland.

Background/Purpose: In the gout, monosodium urate (MSU) crystals deposit intra-articularly and cause painful arthritis. In the present study we tested the hypothesis that Transient Receptor Potential Ankyrin 1 (TRPA1), an ion channel mediating nociceptive signals and neurogenic inflammation, is involved in MSU crystal-induced responses in gout by utilizing three experimental murine models.

Methods: The effects of pharmacological selective inhibition (HC-030031) and genetic depletion of TRPA1 were studied in MSU crystal-induced inflammation and pain by using 1) spontaneous weight-bearing test to assess MSU crystal-induced joint pain, 2) subcutaneous air-pouch model resembling joint inflammation to measure MSU crystal-induced cytokine production and inflammatory cell accumulation, and 3) MSU crystal -induced paw edema to assess acute vascular inflammatory responses and swelling.

Results: Intra-articularly injected MSU crystals provoked spontaneous weight shift off the affected limb in wild type but not in TRPA1 knock-out mice referring to alleviated joint pain in TRPA1 deficient animals. MSU crystal-induced cell infiltration and accumulation of cytokines MCP-1, IL-6, IL-1beta, MPO, MIP-1alpha and MIP-2 in subcutaneous air-pouch was attenuated in TRPA1 deficient mice and in mice treated with the TRPA1 inhibitor HC-030031 as compared to control animals. Further, HC-030031 treated and TRPA1 deficient mice developed tempered inflammatory edema when MSU crystals were injected into the paw.

Conclusion: TRPA1 mediates MSU crystal-induced inflammation and pain in experimental models introducing TRPA1 as a potential mediator and a drug target in gout flare.

ACR Concurrent Abstract Session
Pediatric Rheumatology - Clinical and Therapeutic Aspects: Juvenile Idiopathic Arthritis
Sunday, November 16, 2014, 4:30 PM–6:00 PM

928

A Multinational Study of the Epidemiology, Treatment and Outcome of Childhood Arthritis Preliminary Data from 6,940 Patients. Alessandro Consolaro[1], Amita Aggarwal[2], Troels Herlin[3], Olga Vougiouka[4], Rubén Burgos-Vargas[5], Ilonka Orban[6], Nahid Shafaie[7], Maria Trachana[8], Lidia Rutkowska-Sak[9], Ingrida Rumba-Rozenfelde[10], Dimitrina Mihaylova[11], Alberto Martini[1] and Angelo Ravelli[12]. [1]Istituto Giannina Gaslini, Genova, Italy, [2]Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India, [3]Aarhus University Hospital, Aarhus, Denmark, [4]P. A. Kyriakou Childrens Hospital of Athens University, Athens, Greece, [5]Hospital General de Mexico, Universidad Nacional Autonoma de Mexico, Mexico City, Mexico, [6]National Institute of Rheumatology and Physiotherapy, Budapest, Hungary, [7]Tehran University of Medical Sciences, Tehran, Iran, [8]Aristotle University, Thessaloniki, Greece, [9]Institute of Rheumatology, Warsaw, Poland, [10]University of Latvia, Riga, Latvia, [11]University Children Hospital, Sofia, Bulgaria, [12]Istituto Giannina Gaslini and University of Genova, Genova, Italy.

Background/Purpose: The epidemiology of juvenile idiopathic arthritis (JIA) is known to be variable worldwide and the therapeutic approach to JIA is not standardized. Moreover, the availability of the novel and costly biologic medications is not uniform throughout the world, with possible significant impact on disease prognosis. The EPOCA study is aimed to obtain information on the frequency of JIA subtypes in different geographic areas, the therapeutic approaches adopted, and the disease status of children with JIA currently followed worldwide.

Methods: So far, 124 centers in 55 countries have agreed to participate in the study. Participation in the study was proposed to the pediatric rheumatology center of all countries belonging to the Pediatric Rheumatology International Trials Organization (PRINTO), and to several centers in the US and Canada. Each centre was asked to enroll 100 consecutive JIA patients or, if less than 100, all consecutive patients seen within 6 months. Each patient received a retrospective and cross-sectional assessment. Parent- and child-reported outcomes were recorded through the administration of the Juvenile Arthritis Multidimensional Assessment Report (JAMAR). Participating countries were grouped into 6 geographic areas.

Results: Currently, 6,940 patients from 41 countries have been entered in the web database. Comparison of data from the different geographic areas is presented in the table.

	Africa N = 79	Asia N = 726	Eastern Europe N = 2171	Latin America N = 795	North America N = 243	Western Europe N = 2845
JIA onset age, yrs, median (IQR)	5.7 (2.8; 10)	5.9 (2.9; 9.5)	6.3 (2.8; 10.4)	6.6 (3.5; 10.3)	7.5 (3.2; 11)	4 (2; 8.7)
Systemic arthritis, N (%)	11 (13.9)	174 (24)	165 (7.6)	143 (18)	16 (4.9)	202 (7.1)
Oligoarthritis, N (%)	25 (31.6)	256 (35.3)	958 (44.1)	247 (31.1)	103 (31.8)	1398 (49.1)
Enthesitis related arthritis, N (%)	3 (3.8)	92 (12.7)	248 (11.4)	74 (9.3)	35 (10.8)	253 (8.9)
Uveitis, N (%)	4 (5.1)	40 (5.5)	232 (10.7)	51 (6.4)	38 (11.7)	495 (17.4)
JADAS10, median (IQR)	5 (1.5; 10)	3.5 (0.5; 10)	5 (1; 10.6)	3.5 (0; 10.8)	2 (0; 5.5)	2 (0; 6.3)
Inactive disease, N (%)	13 (16.5)	237 (32.6)	454 (20.9)	268 (33.7)	114 (35.2)	1070 (37.6)
JADI articular > 0, N (%)	27 (34.2)	136 (18.7)	531 (24.5)	257 (32.3)	60 (18.5)	352 (12.4)
Treated with biologics, N (%)	27 (34.2)	134 (18.5)	637 (29.3)	273 (34.3)	178 (54.9)	1067 (37.5)

Conclusion: Patients seen in Western Europe have a younger age at onset and a greater prevalence of uveitis. Systemic arthritis is more common in Asian patients, whereas enthesitis related arthritis is less frequent in African patients. Children from Africa and Eastern Europe have a higher level of disease activity and a lower frequency of inactive disease, and African and Latin American patients have a greater prevalence of articular damage. Biologic medication are administered more frequently in North America and less commonly in Asia.

Antibiotic Exposure and the Development of Juvenile Idiopathic Arthritis: A Population-Based Case-Control Study. Daniel B. Horton[1], Frank I. Scott IV[2], Kevin Haynes[1], Mary E. Putt[1], Carlos D. Rose[3], James D. Lewis[1] and Brian L. Strom[4]. [1]Center for Clinical Epidemiology and Biostatistics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, [2]Division of Gastroenterology, Hospital of the University of Pennsylvania, Philadelphia, PA, [3]Division of Rheumatology, Nemours A.I. duPont Hospital for Children, Thomas Jefferson University, Wilmington, DE, [4]Rutgers Biomedical and Health Sciences, Newark, NJ.

Background/Purpose: Dysregulation of the human microbiome has been implicated in the development of several autoimmune diseases, including rheumatoid arthritis and inflammatory bowel disease (IBD). Moreover, antibiotic exposure has been linked with the development of IBD in children. This study aimed to determine whether early antibiotic exposure increases the risk of incident juvenile idiopathic arthritis (JIA) in a general pediatric population.

Methods: A nested case-control study was conducted using The Health Improvement Network, a United Kingdom population-based medical records database with comprehensive diagnostic and outpatient prescription data. Children with incident JIA diagnosed before age 16 were identified by validated diagnostic codes (positive predictive value 86%). Age- and sex-matched control subjects were randomly selected with incidence density sampling in a 10:1 ratio from general practices taking care of at least 1 child diagnosed with JIA. Eligible subjects needed to be registered within 3 months of their birthdate. Individuals with prior IBD, immunodeficiency, autoimmune connective tissue disease, or vasculitis were excluded. The association between antibiotic prescriptions and JIA diagnosis was determined by conditional logistic regression.

Results: There were 153 children diagnosed with JIA in the study population (table 1). Any antibiotic exposure was associated with an increased risk of developing JIA after adjusting for confounders (adjusted OR 2.6, 95% CI 1.5,4.6) (table 2). This risk increased with the number of prescriptions in a dose-dependent manner. These results did not significantly change when adjusting for the number or type of infections. Age of exposure did not significantly modify this association. The relationship between antibiotics and incident JIA was similar across different antibiotic classes, although use of non-bacterial antimicrobial agents (e.g., antifungal, antiviral) was not associated with JIA. In sensitivity analyses excluding data up to 12 months before the index date, the association between antibiotics and incident JIA did not substantively change.

Conclusion: Antibiotic exposure was associated with an increased incidence of JIA in a dose-dependent fashion in a large pediatric population. This study implicates a role for antibiotic exposure in disease pathogenesis, perhaps mediated through alteration in the microbiome.

An Exploratory Analysis of Predictors of Response from 12-Weeks of Canakinumab Therapy in Patients with Active Systemic Juvenile Idiopathic Arthritis. Hermine I. Brunner[1], Nicola Ruperto[2], Isabelle Koné-Paut[2], Bo Magnusson[2], Seza Ozen[2], Flavio Sztajnbok[2], Jordi Anton[2], Judith Barash[2], Reinhard Berner[2], Fabrizia Corona[2], Karine Lheritier[3], Corine Gaillez[3], Alberto Martini[2] and Daniel Lovell[1]. [1]PRCSG, Cincinnati, OH, [2]PRINTO-Istituto Gaslini, Genova, Italy, [3]Novartis Pharma AG, Basel, Switzerland.

Background/Purpose: Systemic juvenile idiopathic arthritis (SJIA), an interleukin-1β (IL-1β)-mediated autoinflammatory disease, is characterized by recurrent flares of active disease. Canakinumab (CAN), a selective, human, anti- interleukin-1β monoclonal antibody, has been shown to be efficacious in the treatment of SJIA (Ruperto et al. N Engl J Med 2012). The present study aimed to explore baseline demographics and clinical characteristics that are most predictive of response to CAN in CAN-naïve SJIA patients during the initial 12 weeks of therapy.

Methods: Data from 3 trials were pooled for this analysis. CAN-naïve patients (pts; n=178) aged 2–19 years with active SJIA were enrolled and received sc CAN 4 mg/kg/month; Predictors of response (according to aACR* 30, 70, and Inactive Disease [ID]) at Days (D) 15, 29, 57 and 85 were explored using univariate and multivariate logistic regression analyses. The candidate predictors (categorical variables) of CAN-response considered were: Age group, Gender, Prior NSAIDs (no/yes), Prior MTX (no/yes), Steroids (0, >0 – ≤0.4; > 0.4 mg/kg/day), Number of Active Joints (≤10, 11-≤20, >20) and Joints with Limitation of Motion (≤10, 11-≤20, >20), CRP (elevated/normal) at baseline and at D15. All candidate predictors with p<0.1 in univariate analyses were included in the multivariate analysis. *ACR response plus absence of fever.

Results: By Week 2 there was substantial clinical benefit with 102 pts (57%) and 36 pts (20%) achieving aACR70 and ID, respectively; by Week 12, 108 pts (61%) had aACR70 and 50 pts (28%) ID. The multivariate analysis indicated that normal CRP at D15 is the only predictor significant (all p<0.05) for ID at all time-points (Table).

Table: Inactive Disease - Multivariate logistic regression analysis on 12-week data

	Odds Ratio (95% CI)			
Variable*	**Day 15**	**Day 29**	**Day 57**	**Day 85**
CRP at Day 15 (elevated vs normal)	**0.20 (0.07, 0.55)**	**0.14 (0.04, 0.41)**	**0.26 (0.10, 0.66)**	**0.31 (0.12, 0.82)**
Number of active joints (11-≤20 vs. ≤10)	0.22 (0.03, 1.66)	0.55 (0.09, 3.41)	**0.17 (0.031, 0.97)**	0.37 (0.06, 2.10)
Number of active joints (≤10 vs. >20)	2.56 (0.12, 55.39)	1.53 (0.06, 37.44)	**16.10 (1.00, 258.12)**	25.41 (1.60, 404.61)
Prior NSAID treatment (no vs. yes)	2.01 (0.71, 5.71)	**9.33 (2.44, 35.68)**	**3.10 (1.03, 9.31)**	**5.31 (1.66, 17.05)**
Steroid Level (0 vs. >0.4 mg/kg/day)	5.48 (0.97, 31.01)	**8.89 (1.26, 62.64)**	2.98 (0.51, 17.46)	**11.16 (1.72, 72.34)**
Steroid Level (>0.4 vs >0-≤0.4 mg/kg/day)	0.32 (0.08, 1.29)	0.41 (0.09, 1.82)	0.81 (0.25, 2.60)	**0.13 (0.03, 0.57)**
Prior MTX treatment (no vs. yes)	1.94 (0.75, 5.00)	2.78 (0.93, 8.33)	**2.79 (1.04, 7.51)**	1.77 (0.65, 4.83)
Prior anti-TNFs treatment (no vs. yes)	1.83 (0.52, 6.49)	3.62 (0.77, 17.00)	2.01 (0.63, 6.38)	**3.64 (1.04, 12.77)**

Values in bold are significant; *Significant in at least one time point

Conclusion: This exploratory analysis suggests that canakinumab-naïve patients with normal CRP (i.e. ≤10 mg/l) at Day 15, lower baseline steroid doses, low number of active joints, no prior NSAID use are most likely to achieve inactive disease up to 12 weeks.

Response to Canakinumab Treatment Is Maintained in Systemic Juvenile Idiopathic Arthritis Patients. N.M. Wulffraat[1], N. Ruperto[2], H.I. Brunner[3], S. Oliveira[2], Y. Uziel[2], K. Nistala[2], R. Cimaz[2], M. Ferrandiz[2], B. Flato[2], M.L. Gamir[2], I. Koné-Paut[2], C. Gaillez[4], K. Lheritier[4], K. Abrams[5], A. Martini[2] and D.J. Lovell[3]. [1]UMC Utrecht, Utrecht, Netherlands, [2]PRINTO-Istituto Gaslini, Genova, Italy, [3]PRCSG, Cincinnati, OH, [4]Novartis Pharma AG, Basel, Switzerland, [5]Novartis Pharmaceuticals Corporation, East Hanover, NJ.

Background/Purpose: Canakinumab, a selective, human, anti-interleukin (IL) −1β monoclonal antibody, is approved for the treatment of systemic juvenile idiopathic arthritis (SJIA) patients (≥ 2 years old). SJIA is an IL-1β-mediated autoinflammatory disease, which is characterized by recurrent flares of active disease. Canakinumab treatment in patients with SJIA, allows for successful steroid dose reduction/discontinuation and reduces risk to experience a flare. [1] We evaluated the maintenance of efficacy with continued canakinumab treatment in SJIA patients during the blinded randomized treatment withdrawal part of a large phase III trial.

Methods: Patients 2–19 yrs of age with active SJIA who had responded to open-label canakinumab treatment 4mg/kg/4wks sc, maintained a minimum adapted ACR Pediatric criteria [aACR] 30 for up to 32 weeks, and were steroid-free or had successfully reduced systemic steroids to a minimum dose, were randomized to either continue canakinumab or receive placebo until 37 flare events occurred. [1] Patients were considered to have completed the study if they entered clinical remission on medication (CRM), i.e. achieved 24 consecutive weeks of clinical inactive disease (CID). [2] A survival analysis of the time to worsening in aACR level, after randomization for the canakinumab and placebo groups was performed. Time to worsening is the time to fail to maintain at least the same level of aACR response seen at randomization. The change in the proportion in each group of those with CID was also evaluated.

Results: 100 pts were randomized to a canakinumab (n=50) or a placebo (n=50) group, of whom 26 (53%) and 27 (54%), respectively, had CID at the start of the randomization part. In the first 2 months, probability of maintaining aACR response was similar for both treatment groups. Thereafter, the probability of maintaining aACR response was greater in the canakinumab vs placebo groups. The median time to worsening in aACR level for patients in the placebo group was 141 days (95% CI: 85, 281), and could not be calculated for canakinumab as <50% of canakinumab group had a worsening in their aACR level by the end of this phase. The median duration of exposure

for the canakinumab group was 221.5 days (range: 8–617 days). There was a statistically significant relative risk reduction of 51% for the canakinumab vs placebo group to experience a worsening in aACR level (HR= 0.49; 95% CI: 0.27, 0.90; p=0.0131). CID was achieved by 31 (62.0%) vs 17 (34.0%) patients in canakinumab vs placebo at their last visit (OR= 3.4; 95% CI: 1.5, 8.0; p=0.0020) and CRM was reached by 20 (40%) canakinumab and 2 (4%) placebo patients by the end of the study.

Conclusion: A greater proportion of SJIA patients who continued canakinumab treatment maintained/improved their aACR response, achieved CID and CRM than pts who discontinued canakinumab by being switched to placebo, demonstrating maintenance of efficacy with continued canakinumab treatment over time.

MRP8/14 Serum Level As Predictor of Response to Starting and Stopping Anti-TNF Treatment in Non-Systemic Juvenile Idiopathic Arthritis. Janneke Anink[1], Marieke H. Otten[1], Lisette W.A. van Suijlekom-Smit[1], Marion A.J. Van Rossum[2], Koert M. Dolman[3], Esther P.A. Hoppenreijs[4], Rebecca ten Cate[5], Simona Ursu[6], Lucy R Wedderburn[7], Gerd Horneff[8], Thomas Vogl[9], Dirk Föll[10], Johannes Roth[9] and Dirk Holzinger[11]. [1]Erasmus MC Sophia Children's Hospital, Rotterdam, Netherlands, [2]Emma Kinderziekenhuis Academic Medical Center, Amsterdam, Netherlands, [3]St. Lucas Andreas Hospital and Reade Institute, Amsterdam, Netherlands, [4]Radboud University Medical Center, Nijmegen, Netherlands, [5]Leiden University Medical Center, Leiden, Netherlands, [6]Arthritis Research UK Centre for Adolescent Rheumatology at University College London, Great Ormond Street Hospital and UCLH, University College London, London, United Kingdom, [7]Arthritis Research UK Centre for Adolescent Rheumatology, University College London, London, United Kingdom, [8]Asklepios Klinik Sankt Augustin, Sankt Augustin, Germany, [9]Institute of Immunology University of Muenster, Muenster, Germany, [10]University Children's Hospital Muenster, Muenster, Germany, [11]University Hospital Muenster, Muenster, Germany.

Background/Purpose: Biological therapy has dramatically improved the treatment of patients with JIA. However, there is still a group of patients that shows a lack of clinical response to this treatment. Furthermore, when patients do respond to treatment with etanercept, it is unclear when they can discontinue this treatment. The use of robust predictive markers of response to identify individuals who are likely to respond to anti-TNF treatment (etanercept or adalimumab) and who are able to stop etanercept may provide guidance in optimizing treatment strategies. Our objective was to test the ability of baseline MRP8/14 serum levels to differentiate between responders and non-responders to anti-TNF treatment and to correlate longitudinal follow-up of this marker in response to treatment. A second objective was to test the ability of MRP8/14 to distinguish between patients who are likely to flare after discontinuing etanercept.

Methods: Samples were collected from 89 JIA patients (13 polyarthritis rheumatoid factor (RF) positive, 33 polyarthritis RF negative, 24 extended oligoarthritis, 5 persistent oligoarthritis, 4 enthesitis related arthritis, 10 psoriatic arthritis) included in the Dutch Arthritis and Biologics in Children Register, the German Registry for Biologics in Paediatric Rheumatology and Great Ormond Street Hospital for Children London treated with TNF blockers. The patients were categorized into responders (ACRpedi≥50 and/or inactive disease according to the Wallace) and non-responders (ACRpedi<50). Serum concentrations of MRP8/14 complexes were measured by ELISA at start of biologic treatment and if available also within 6 months after start of treatment. A flare was defined as having at least three of the following: VAS physician or patient ≥ 20 mm, ≥ 2 active joints, any worsening on the CHAQ and ≥30% worsening on ESR or limited joints. Non-parametric tests were used for analyses.

Results: Before initiation of etanercept treatment, responders (n=71) showed significantly higher levels of MRP8/14 serum complexes compared to non-responders (n=18) (p=0.004, median in responders: 1490 ng/ml (IQR 1020–3323 ng/ml), median in non-responders: 788 ng/ml (IQR 442–1233 ng/ml)). No significant correlation was found between baseline MRP8/14 and JADAS10 disease activity. In non-responders MRP8/14 levels did not significantly change after initiation of treatment whereas levels decreased in responders (p<0.001). Change in JADAS10 disease activity was significantly correlated to change in MRP8/14 levels (Spearman's rho: 0.4, p=0.03). Samples were available from 28 patients at the time of discontinuation of etanercept. Patients who flared within 6 months after the discontinuation of etanercept had higher MRP levels at discontinuation than patients who did not flare (p= 0.031, median 1025 ng/ml (IQR 588–1288 ng/ml) vs. 505 ng/ml (IQR 346–778 ng/ml)).

Conclusion: High levels of baseline serum MRP8/14 have prognostic value in predicting a subgroup of JIA patients who will respond well to anti-TNF treatment. Decrease of MRP8/14 after initiation of treatment is associated with response to treatment. High MRP8/14 serum levels at time of discontinuation of etanercept are associated with a higher chance to flare.

Background/Purpose: To assess efficacy and safety of SC golimumab (GLM) in polyarticular pediatric juvenile idiopathic arthritis pts (aged 2 to <18 yrs) with active arthritis despite MTX for ≥3months.

Methods: In GO-KIDS, a 3-part randomized double-blind, PBO-controlled, withdrawal trial in pts with active JIA with a polyarticular course (≥5 active joints) and disease duration of ≥ 6 months despite current MTX (10–30 mg/m^2/wk).In Part 1(wk0–12), all pts received open-label (OL) 30 mg/m^2 GLM SC(max 50mg) q4wks with stable MTX dose. At wk16, pts with ACR JIA 30 response entered Part 2 (wk16–48).In Part 2, pts were randomized to continue GLM or switch to PBO q4wks. Upon Part 2 completion at wk48 or ACR JIA flare in Part 2, pts received OL GLM in Part 3. Primary endpoint was proportion of ACR JIA 30 responders at wk16 without a JIA flare in Part 2 using wk16 as baseline measurement. Secondary outcomes were ACR JIA 30/50/70/90 response rates and inactive disease rates at wk16 and wk48 by group and safety.

Results: 173 pts (Caucasian 87.9%, 75.7% females; age [median/range] 12 yrs/2–17 yrs) with moderately active disease were enrolled (Table1); 19 (11%) were d/c in Part 1 (lack of efficacy n=14, AE n=4, withdrawal of consent n=1). In Part 1, 151 of 173 (87.3%) achieved an ACR JIA 30 response and 36.1% inactive disease status (Table2). In Part 2, 154 pts were randomized (PBO n=76; continued GLM n=78). The trial did not meet primary endpoint, as at the end of Part 2 groups did not differ in flare rates [PBO-grp vs. GLM-grp: 52.6% vs. 59.0%, p=0.41) nor were there differences for major secondary endpoints (Table2). Nonetheless, sustained JIA improvement was maintained in both groups (PBO, GLM) relative to wk 0 (Table1 and 2). Through wk48, AEs, serious AE (SAE), and serious infections were reported in 87.9%, 13.3%, and 2.9% of all randomized pts, respectively. Most common SAE was JIA exacerbation. No deaths, active TB or malignancies were reported. Proportion of pts with ≥ 1 injection site reaction was 8.1%. None of the reactions were serious, severe, or led to GLM d/c.

Conclusion: Children with active polyarticular JIA demonstrated rapid response to GLM during16 wks of OL treatment, resulting in inactive disease in 36% of the pts after 3 injections of OL GLM during part 1. The lack of differences in flare rates between GLM and PBO arms during the double-blinded part of the study among OL GLM responders needs further evaluation. Safety profile was acceptable and injections well tolerated.

Table 1

Values are medians (interquartile range)	At Baseline (All enrolled patients n=173)	At wk16 (All randomized patients prior to randomization, n=154)	At wk48	
			PBO + MTX (n=76)	GLM + MTX (n=78)
Physicians global assessment of disease activity	5.40 (3.90; 7.00)	0.50 (0.10; 1.30)	0.30 (0.00; 1.00)	0.30 (0.00; 1.30)
Patient/parent global assessment of well-being	4.50 (2.80; 6.10)	0.90 (0.30, 2.30)	0.60 (0.20; 1.65)	0.45 (0.10; 1.70)
Number of active joints	12.0 (8.0; 18.0)	1.0 (0.0; 3.0)	1.0 (0.0; 3.0)	0.0 (0.0; 2.0)
Number of joints with limited range of motion	8.0 (6.0; 15.0)	1.0 (0.0, 4.0)	0.5 (0.00; 4.0)	1.0 (0.0; 3.0)

Amelioration of Inflammatory Arthritis By Anti-TNF Therapy Is Associated with Restoration of Lymphatic Contraction. Echoe M. Bouta[1], Igor Kuzin[2], Karen de Mesy-Bentley[1], Ronald Wood[3], Homaira Rahimi[4], Rui-Cheng Ji[5], Christopher T. Ritchlin[3], Andrea Bottaro[2], Lianping Xing[1] and Edward M. Schwarz[1]. [1]University of Rochester, Rochester, NY, [2]Cooper Medical School, Camden, NJ, [3]University of Rochester Medical Center, Rochester, NY, [4]University of Rochester/Golisano Children's Hospit, Rochester, NY, [5]Oita University, Oita, Japan.

Background/Purpose: Rheumatoid arthritis (RA) is a chronic inflammatory joint disease with episodic flares. In tumor necrosis factor transgenic (TNF-Tg) mice, a model of inflammatory-erosive arthritis, the popliteal lymph node (PLN) enlarges during the pre-arthritic "expanding" phase, and then "collapses" with adjacent knee flare associated with the loss of the intrinsic lymphatic pulse. Thus, a critical question is whether loss of the lymphatic pulse can be recovered by standard RA therapies.

Methods: We tested the hypothesis that anti-TNF vs. irrelevant IgG (IgG); and methotrexate (MTX) vs. saline treatment ameliorates knee synovitis adjacent to collapsed PLN in TNF-Tg mice by restoring the lymphatic pulse using contrast enhancement MRI (CE-MRI), ultrasound, near infrared indocyanine green (NIR-ICG) imaging, transmission electron microscopy (TEM) and flow cytometry.

Results: Anti-TNF treatment significantly decreased normalized synovial volume compared to IgG (0.87±0.21 vs. 1.52±0.16; p<0.05), measured by CE-MRI. This decrease correlated with a lower power Doppler volume within the joint, a measure of inflammation, in both anti-TNF and MTX treated mice compared to placebo treated (0.04±0.01 vs. 0.20±0.03 mm^3 and 0.05±0.01 vs. 0.18±0.08 mm^3, respectively; p<0.05). Lymphatic pulse rate and clearance were measured via NIR-ICG imaging (Figure). As predicted, anti-TNF significantly increased the lymphatic pulse vs. IgG (2.63±0.68 vs. 0.99±0.36 pulses/min), and MTX also induced an increase vs. saline (1.38±0.21 vs. 0.38±0.38 pulses/min), although this effect was weaker than anti-TNF. Consistently, footpad clearance of ICG was higher in anti-TNF and MTX treated mice vs. placebos (64.53±6.08 vs. 30.84±12.26 and 64.54±6.20 vs. 42.49±5.69, respectively; p<0.05). To gain insight into the mechanism of lymphatic pulse restoration, TEM was performed on the lymphatic vessels. We found that placebo treated mice showed damaged lymphatic endothelial cells (LECs) and smooth muscle cells (LSMCs), while anti-TNF treated mice showed intact LECs and LSMCs apical to fibrotic tissue, suggestive of tissue repair. Interestingly, anti-TNF treatment resulted in a significant ~4-fold increase in monocyte numbers normalized to placebo vs. MTX (3.77±0.77 vs. 1.08±0.19 cells per PLN; p<0.05), via flow cytometry. We previously reported monocytes trafficking in afferent lymphatic vessels. Thus, these findings indicate increased transit of monocytes to the PLN from the inflamed joint.

Conclusion: These NIR-ICG, CE-MRI and flow cytometry results

demonstrate that anti-TNF increases lymphatic transport to a greater extent than MTX. Furthermore, our data suggest that the primary mechanism for monocyte (type 1 synoviocyte) removal from inflamed joints following anti-TNF treatment is through restoration of lymphatic pulse and cellular egress.

Targeting Glycolysis in Rheumatoid Arthritis. Monica Guma[1], Alessia Lodi[2], Ajit Divakaruni[1], Anne Murphy[1], Stefano Tiziani[2] and Gary S. Firestein[3]. [1]University of California, San Diego, La Jolla, CA, [2]University of Texas at Austin, Austin, TX, [3]University of California at San Diego School of Medicine, La Jolla, CA.

Background/Purpose: Many of the signaling pathways activated in inflammation have a profound effect on cell metabolism. However, little is known about metabolome in rheumatoid arthritis (RA), particularly in fibroblast-like synoviocytes (FLS). The shift from ATP generation through oxidative phosphorylation to glycolysis has been implicated not only in tumor cells growth but also in immune cell function upon activation. To determine the role of glycolysis in arthritis, we examined glucose metabolism in FLS and evaluated whether this pathway could play a role in inflammation and joint damage.

Methods: The glucose profile of FLS cells was determined by ^{1}H-MRS. Analysis of FLS oxygen consumption/extracellular acidification after LPS stimulation used Seahorse technology. FLS function using the glycolysis inhibitor 2-Deoxy-D-glucose (2-DG) in medium and platelet derived growth factor (PDGF) stimulated cells was evaluated by measuring 1) migration of cultured FLS monolayers (scratch assay); 2) proliferation using an MTT assay; and 3) protein expression by ELISA. For arthritis experiments, mice were injected with K/BxN sera on day 0. The glycolysis inhibitor bromopyruvate (BrPa; 5mg/kg) was injected daily i.p. beginning on day 0 after serum administration. Clinical arthritis scores were serially assessed. Joint histology was evaluated using a semiquantitative scoring system.

Results: One-dimensional ^{1}H MRS spectra of aqueous extracts revealed 39.8±5.2% higher intracellular lactate accumulation in RA FLS compared with osteoarthritis (OA) FLS ($p<0.01$) indicating increased glycolytic rate. Of interest, FLS also displayed an unusual mitochondrial response, decreasing mitochondrial respiration (pmol O_2/min) and increasing extracellular acidification (mpH/min) by 49.6±10.2% and 44±8.6% respectively after LPS stimulation. Glycolysis regulated key FLS functions that might contribute to cartilage damage in RA. For example, glycolysis inhibition with 2-DG (10 mM) reduced MMP3 and IL-6 secretion by 68±5.2% and 75±4.3%, respectively ($p<0.01$). Proliferation was reduced by 79±7.2% and migration by 63±15% ($p<0.05$). Finally, glycolysis inhibition by BrPa significantly decreased arthritis severity. Day 8 scores were 11.6±1.5 and 2±0.6 ($P<0.01$) for vehicle and BrPa-treated mice, respectively. Joint histology scores for vehicle and BrPa-treated mice for inflammation were 2.3±1.1 and 0.25±0.35 ($p<0.01$), bone erosion scores were 1.8±1.2 and 0.12±0.35 ($p<0.01$), and cartilage damage scores were 2.1±0.83 and 0.88±0.35 ($p<0.01$), respectively.

Conclusion: The metabolic profile in RA FLS suggests that glucose metabolism is abnormal and has shifted to ATP generation through oxidative phosphorylation to glycolysis. Blocking this pathway with a glycolysis inhibitor suppressed inflammatory arthritis in mice as well as the aggressive behavior of cultured RA FLS, including proliferation, cytokine secretion and cell migration. These data suggest that glycolysis inhibition may be disease modifying by directly modulating synoviocyte mediated functions and could be an effective strategy for arthritis.

Active Invasion of Periodontal Bacteria into Synovial Joint Exacerbates Collagen-Induced Arthritis in Disease-Prone B10 Riii Mice. Sasanka Chukkapalli[1], Mercedes Rivera-Kweh[1], Irina Velsko[1], Indraneel Bhattacharyya[1], S. John Calise[2], Edward Chan[1], Minoru Satoh[3] and Lakshmyya Kesavalu[1]. [1]College of Dentistry, University of Florida, Gainesville, FL, [2]University of Florida, Gainesville, FL, [3]Univ. Occupational and Environmental Health, Kitakyushu, Fukuoka, Japan.

Background/Purpose: Periodontitis (PD) is a chronic immunoinflammatory disease caused by complex subgingival periodontal bacteria. Rheumatoid Arthritis (RA) and PD both are chronic inflammatory disorders characterized by deregulation of the host inflammatory response. Both disease share risk factors and have pathological pathways in common, resulting in soft and hard tissue destruction of synovium and periodontium, respectively. In this study, we utilize an established murine PD model induced by chronic polybacterial infection of three major human periodontal bacterial pathogens: *P. gingivalis, T. denticola*, and *T. forsythia.* Our study was designed to examine whether the induction of PD enhance arthritis in the collagen-induced arthritis (CIA) mouse model.

Methods: CIA-prone major histocompatibility congenic B10 RIII mice were used in the study. These were divided into four groups (n=10 each). Group I mice were infected orally with a polybacterial mixture of *P. gingivalis, T. denticola, T. forsythia* for 24 weeks. Mice in group II were also orally infected with a polybacterial mixture followed by administration of collagen II (CII) emulsified in complete Freund's adjuvant (CFA) and boosted with CII in incomplete Freund's adjuvant (IFA) to induce arthritis. Group III mice were sham-infected controls. Group IV mice were administered CII emulsified in CFA and IFA as collagen control. After 24 weeks of infection, mice were examined for development of PD as well as for RA clinical signs; systemic spread of the infection, matrix metalloproteinase 3 (MMP3) levels, cytokine expression, anti-CCP (cyclic citrullinated peptide) antibodies, and autoimmune signaling molecules. Further, the tissue sections from mouse ankle joints and paws were evaluated for the presence of periodontal bacteria by fluorescence *in situ* hybridization (FISH).

Results: Group I and II showed oral colonization/infection with all 3 bacteria (100%), higher levels of anti-bacteria IgG antibodies ($P < 0.0005$) and greater significant alveolar bone resorption ($P < 0.0005$) than the sham-infected (Group III) and collagen control mice (Group IV). Group II mice showed exacerbated clinical signs of arthritis (10/10), systemic spread of periodontal bacteria, and significant serum MMP3 levels ($P < 0.05$) compared to Group IV. *In vivo* tomographic imaging of infected+collagen treated mice using MMP3 fluorescent probe showed intense MMP3 activity (fluorescence intensity=12) in arthritic lesions (4/4) compared to collagen control mice (fluorescence intensity=5). Histopathology of infected+collagen treated mouse ankle joints showed higher levels of characteristic inflammatory cellular infiltration, destruction of articular cartilage, pannus formation, and bone distortion (6/6) compared to collagen control mice. FISH showed the presence of *P. gingivalis* in the ankle joints of infected+collagen treated mice.

Conclusion: This is the first study to examine a causal relationship between PD and RA using two established disease models in mice. This study provides direct evidence for a causal association between major periodontal pathogens/PD and increased severity in induced arthritis.

A Unique Role for IL-18 Receptor-α in Monocyte Migration in RA and K/BxN Serum Transfer Arthritis. W. Alexander Stinson[1], Phillip L. Campbell[1], Jeffrey Ruth[1], Gautam Edhayan[1], Ray A. Ohara[1], Nicholas Lepore[1], Alisa E. Koch[2], David A. Fox[1] and M. Asif Amin[1]. [1]Division of Rheumatology, University of Michigan Medical Center, Ann Arbor, MI, [2]Department of Veteran's Affairs and University of Michigan, Ann Arbor, MI.

Background/Purpose: Rheumatoid arthritis (RA) is a chronic autoimmune disease characterized by monocyte (MN) recruitment. Proinflammatory cytokines and their corresponding receptors play an important role in the progression of RA by increasing MN infiltration. Soluble IL-18 receptor-α (IL-18Rα) is highly expressed in RA synovial fluids (SFs), synovial tissues (STs), ST fibroblasts, and CD4+ T cells. In this study, we determined the contribution of IL-18Rα in the pathogenesis of RA.

Methods: Western blotting was performed to examine IL-18Rα expression on tumor necrosis factor-α (TNF-α) stimulated MNs. We performed MN chemotaxis in modified Boyden chambers to determine the role of IL-18Rα in MN migration *in vitro*. To examine MN homing in the context of RA, we employed an RA ST-severe combined immunodeficient (SCID) mouse chimera using RA SFs with or without IL-18Rα neutralizing antibody. We harvested RA ST after 48 hours and examined tissue sections by immunofluorescence. K/BxN serum transfer arthritis was performed in IL-18Rα null and wild type (wt) mice to determine the role of the IL-18Rα in arthritis and MN recruitment. Cytokine levels were determined by enzyme linked immunosorbent assays (ELISAs) in ankle homogenates of IL-18Rα null and wt mice.

Results: TNF-α stimulated normal human MNs showed a marked increase of IL-18Rα expression. After finding increased expression in IL-18Rα, we determined its role in MN migration. IL-18Rα partially mediates TNF-α and RA SF-induced MN migration, as anti-human IL-18Rα antibody significantly inhibited TNF-α and RA SF mediated MN migration *in vitro* ($p<0.05$). We further investigated the importance of IL-18Rα to MN migration in human RA by using the RA-SCID mouse chimera. RA SF injected into the chimeric human ST resulted in MN recruitment to the ST, which was decreased in the presence of mouse anti-human IL-18Rα, suggesting that IL-18Rα is essential in RA SF-stimulated MN migration *in vivo*. We determined the contribution of IL-18Rα in inflammatory arthritis by performing K/BxN serum transfer arthritis. IL-18Rα null mice were resistant to K/BxN arthritis, showing a significant decrease in ankle circumference compared to wt mice ($p<0.05$). Mouse ankles harvested on day 9 of maximal arthritis showed a significant decrease in MN migration in IL-18Rα null mouse joint sections compared to wt mice, as determined by staining for F4/80, a MN/macrophage marker. To determine the mechanism of decreased MN ingress and defective arthritis in IL-18Rα null mice, ELISAs were performed for proinflammatory cytokines using mouse ankle homogenates. We found a >3 fold decrease in IL-1β levels in IL-18Rα null mouse ankles compared to wt mouse ankles ($p<0.05$), suggesting that the IL-18Rα is critical in inflammatory cytokine expression.

Conclusion: These studies suggest that IL-18Rα is inducible in MNs and plays an important role in MN migration *in vitro* and *in vivo*. IL-18Rα null mice have impaired MN recruitment and arthritis development in part due to decreased IL-1β. These results provide strong evidence that the IL-18Rα plays an important role in MN ingress in RA and in a rodent model of inflammatory arthritis and may be a novel therapeutic target for RA.

C1q Is Mandatory for Disease Development in Experimental Arthritis and Expression of Its Receptors Correlates with Disease Activity in Patients. Matthieu Ribon[1], Julie Mussard[1], Roxane Herve[1], Marina Botto[2], Marie-Christophe Boissier[3] and Patrice Decker[1]. [1]INSERM UMR 1125, Li2P, University Paris 13, Sorbonne Paris Cité and Rheumatology Department, Avicenne Hospital, Assistance Publique-Hôpitaux de Paris (AP-HP), Bobigny, France, [2]Imperial College, London, United Kingdom, [3]INSERM UMR 1125, Li2P, University Paris 13, Sorbonne Paris Cité, Bobigny, France.

Background/Purpose: The complement system is a major effector mechanism of innate and adaptive immunity. It is activated in rheumatoid arthritis (RA) patients but the pathway involved remains unclear. RA is associated with the production of autoantibodies with some of them, anti-citrullinated protein antibodies, representing a diagnosis and even a prognosis marker. Antibodies are known to activate the complement system via the classical pathway in a C1q-dependent manner. But some models suggest C1q-independent pathways in arthritis. Therefore, we have investigated whether C1q is necessary for disease development in a mouse model of RA based on (auto)immunization and we have analyzed C1q receptor expression in patients.

Methods: Disease development was studied in the collagen-induced arthritis (CIA) mouse model. The impact of C1q was evaluated by comparing wild-type (WT) mice and C1q-knockout (KO) true littermates. Arthritis was followed by clinical score evaluation. Inflammation and bone destruction were estimated by histology. Anti-collagen antibody, C3a and blood cytokine levels were measured by ELISA and Luminex. B/T lymphocytes and neutrophils were analyzed by flow cytometry. Osteoclastogenesis was analyzed by culturing bone marrow cells with M-CSF/RANKL and then counting TRAP-positive multinucleated cells by microscopy. In addition, whole blood cells from healthy donors and RA patients were used to estimate their C1q binding capacity ex vivo by flow cytometry.

Results: C1q is absolutely required for arthritis development as C1q-KO mice did not develop clinical signs of arthritis in contrast to WT mice. Both WT and KO mice developed anti-collagen antibodies and particularly similar levels of pathogenic IgG2a anti-collagen antibodies. Moreover, neither inflammation nor joint destruction was observed in C1q-KO mice. Importantly, the level of complement activation, estimated by C3a production, was similar in WT and C1q-KO mice. Surprisingly, no statistical difference was observed between WT and KO mice regarding the percentage or the activation of lymphocytes and neutrophils in the blood, spleen and lymph nodes. As a recent study suggested that C1q might influence osteoclastogenesis in vitro, we have shown that C1q deficiency does not alter development of osteoclasts from CIA mice. The impact of C1q on cytokine secretion in vivo is currently being analyzed. In RA patients, we have shown that the percentage of neutrophils able to bind C1q is significantly and positively correlated with the disease activity estimated by the DAS28.

Conclusion: C1q-KO mice are protected from arthritis development and thus C1q plays a key role in the CIA model. Although the complement system is activated, the classical pathway cannot be compensated by the alternative/lectin pathways in this model. Our results strongly differ from those reported in the serum-transfer model where C1q is not necessary for disease development, suggesting that C1q might be involved at different steps, maybe before antibodies are produced, for example in the response to DAMPs. In patients, the expression of total C1q receptors by neutrophils reflects disease activity, supporting the potential role of C1q in RA.

Prenatal Methyl-Rich Diet Decreases Inflammation in Collagen Induced Arthritis. Sanjay Garg[1], Dipak R. Patel[2] and Raymond Yung[2]. [1]University of Michigan, Ann Arbor, MI, Ann Arbor, MI, [2]University of Michigan, Ann Arbor, MI.

Background/Purpose: Early-life nutrition can have a profound effect on late-life disease development. Most current studies focus on macro-nutrition (calorie, carbohydrate, fat, and protein), and much less is known about the role that early life micro-nutrition plays in diseases of adults. One notable exception is that prenatal folic acid supplementation dramatically decreases the incidence of spina bifida and other neural tube defects. In mouse models, supplementing 'methyl donors' in the diet of pregnant mice (dams) affects the incidence of diabetes and obesity in their offspring. These changes have been attributed to changes in the DNA methylation status of selected genes.

Previously, we have demonstrated that feeding dams a prenatal diet supplemented with methyl donors (MDS) during mating and pregnancy decreases the levels of selected CD4+ T cell pro-inflammatory chemokines and cytokines in F1 mice by changing the DNA methylation pattern of those genes. $CD4^+$ T cells are critical in arthritis pathogenesis, and many of the pro-inflammatory cytokines and chemokines required for arthritis development are regulated by DNA methylation. Recent studies have shown that RA is characterized by a perturbed extracellular redox environment. Based on our preliminary data, we hypothesize that the prenatal MDS diet will decrease inflammation in the collagen-induced arthritis (CIA) model of RA by modulating redox metabolites and $CD4^+$ T cell function.

Methods: Female DBA/J mice received either a control diet or MDS diet during pregnancy and lactation. Pups borne to these mice (F1 Control or F1 MDS) were maintained on those diets after birth and until they were weaned at 4 weeks. After weaning, all mice were fed a standard (NIH 31) diet. Arthritis was then induced, and paw swelling was measured. Cytokines and redox metabolites were measured in the serum at specified time points, and mice were sacrificed for in vitro analysis of CD4+ T cell function.

Results: Both F1-MDS and F1-Control mice developed arthritis 30 days after collagen injection, and the mean arthritis score was decreased by at least 2 points at day 45 after injection ($p<0.05$). At 55 days after injection, $CD4^+$ T cells from F1-MDS mice expressed decreased levels of TNF-α ($p=0.04$), IL-17 ($p=0.04$), and IL-6 ($p=0.02$) protein. Levels of the chemokine CCR7 were also decreased

in $CD4^+$ T cells from F1-MDS mice ($p=0.02$). The serum redox potential in CIA mice is more oxidizing (−77 mV) than in non-CIA mice (−83 mV) ($p<0.01$). After CIA induction, the redox potential was maintained at a more homeostatic level (−85 mV) in F1-MDS mice, and the redox potential was more oxidizing (−77 mV) in F1-Control mice ($p<0.01$).

Conclusion: The pre-natal MDS diet decreases disease severity, as measured by paw swelling in the CIA model of RA. The diet caused decreases in serum levels of pro-inflammatory cytokines and expression of pro-inflammatory genes in CD4+ T cells. Many of these genes are methylation sensitive. These results demonstrate that a pre-natal diet enriched in methyl donors can decrease disease severity in a mouse model of RA.

ACR Concurrent Abstract Session
Rheumatoid Arthritis - Clinical Aspects II: Remission and De-escalation of Therapy
Sunday, November 16, 2014, 4:30 PM–6:00 PM

940

Reducing Therapy in Rheumatoid Arthritis Patients in Ongoing Remission. Judith Haschka[1], Jürgen Rech[1], Matthias Englbrecht[1], Stephanie Finzel[1], Michaela Reiser[1], Axel J. Hueber[1], Arnd Kleyer[1], Hans-Peter Tony[2], Martin Fleck[3], Karin Manger[4], Wolfgang Ochs[5], Jörg Wendler[6], Hanns-Martin Lorenz[7], Hubert Nüßlein[8], Rieke Alten[9], Winfried Demary[10] and Georg Schett[1]. [1]University of Erlangen-Nuremberg, Erlangen, Germany, [2]University Hospital Würzburg, Würzburg, Germany, [3]Asklepios Medical Center Bad Abbach, Bad Abbach, Germany, [4]Rheumatology Practice Bamberg, Bamberg, Germany, [5]Rheumatology Practice Bayreuth, Bayreuth, Germany, [6]Rheumatology Practice Erlangen, Erlangen, Germany, [7]University of Heidelberg, Heidelberg, Germany, [8]Rheumatology Practice Nuremberg, Nuremberg, Germany, [9]Schlosspark-Klinik, University Medicine Berlin, Berlin, Germany, [10]Rheumatolgy Practice Hildesheim, Hildesheim, Germany.

Background/Purpose: Due to improved therapeutic management a steadily increasing number of rheumatoid arthritis (RA) patients reach stable remission of disease. Data on withdrawal of medication after sustained remission are limited, though it is important for economic and safety reasons. The RETRO study represents a real-life study addressing different strategies of reduction of DMARD therapy in RA patients in disease remission. The aim of the study was to evaluate the possibility of tapering and even discontinuation of DMARD therapy in RA patients in stable long-lasting remission and to determine predictors for recurrence of disease.

Methods: RETRO is a phase 3, multicenter, randomized, controlled, open, prospective, parallel-group trial (EudraCT Number: 2009–015740–42). Patients, fulfilling the ACR/EULAR2010 criteria for RA with disease history of ≥12 months, were enrolled into the study if they were in clinical remission (DAS28-ESR < 2.6) at stable dose of DMARDs for more than 6 months. Patients on ≥1 conventional and/or biological DMARDs were included and randomized into three trial arms: Arm 1 (control group) was continuing full-dose conventional and/or biological DMARD treatment for 12 months; arm 2 was reducing the dose of all conventional and/or biological DMARD treatment by 50% for 12 months and arm 3 was reducing the dose of all conventional and/or biological DMARD treatment by 50% for 6 months before entirely stopping DMARD. In case of recurrence of disease (DAS >2.6) the original therapy was restarted.

Results: 101 patients (61.4% females, 60% ACPA positive, 63% RF positive; 37.6% biologic therapy, 80.2% MTX, 7.9% other DMARDs) finished the one year endpoint: 38 patients in arm 1 (age 55.8±13.9y, disease duration 6.8±5.9y, remission 20.9±16.7mo), 36 patients in arm 2 (age 54.1±13.1y, disease duration 8.6±7.7y, remission 14.5±12.7mo) and 27 patients in arm 3 (age 54.8±12.3y, disease duration 5.6±7.0y, remission 17.6±19.5mo). Of 101 patients, 66.3% were still in remission at 12 mo. Trial arms 2 (38.9%, $\chi^2(1)=5.0$, $p=0.036$) and 3 (51.9%, $\chi^2(1)=9.6$, $p=0.003$) significantly differed from the control group (15.8% flare rate) with more patients flaring in reduction arms. However, there was no significant difference between the two reduction arms ($\chi^2(1)=1.1$, $p=0.443$). A multivariate logistic regression identified ACPA positivity (Wald $\chi^2=4.5$, $p=0.03$) and treatment reduction compared to the control group (arm2: Wald $\chi^2=6.6$, $p=0.01$, arm3: Wald $\chi^2=8.8$, $p=0.003$) as predictors for subsequent flares. Sex, disease duration, remission duration, age, RF, biologic DMARD and remission depth (defined by fulfilling Boolean remission criteria yes/no) failed to predict recurrence of disease in this study.

Conclusion: This study is a prospective real life treatment strategy study investigating the effect of reduction and discontinuation of DMARD therapy in RA patients in stable remission. Interestingly neither remission depth, nor disease duration at baseline or biological DMARD therapy predicted the recurrence of disease. Presence of ACPA but not RF was the only predictor for recurrence of disease. The data indicate that treatment reduction and even discontinuation is feasible in a subset of RA patients in stable remission.

Biologic De-Escalation in Rheumatoid Arthritis: Cost Savings and Clinical Success. Tarun S. Sharma[1], Lyudmila Kirillova[2], Andrea Berger[3] and Eric D. Newman[2]. [1]Geisinger Medical Center, Danville, PA, [2]Geisinger Health System, Danville, PA, [3]Center for Health Research, Geisinger Health System, Danville, PA.

Background/Purpose: Economic considerations and clinical risks of prolonged biologic use in Rheumatoid Arthritis (RA) have emerged as concerns. In this study, we measured the clinical outcomes and cost savings of biologic de-escalation in patients with well-controlled RA.

Methods: We reviewed the electronic health records of all RA patients treated with a biologic medication from 01/01/13 to 12/31/13 (n= 940) and evaluated biologic de-escalation (decreased dose, frequency, or discontinuation). Baseline demographics were recorded for all patients. Successful de-escalation was defined as a de-escalation where the dose of biologic on 12/31/13 was lower than the pre-de-escalation dose and the efficacy was maintained until 12/31/13. Flare was defined as addition or increase in dose of steroid or Disease Modifying Anti-Rheumatic Drug or a switch in the biologic medication. We compared the de-escalated and non-de-escalated groups, the outcomes of de-escalation, and financial benefits of de-escalation. Predictors of successful de-escalation were evaluated using two-sample t or Wilcoxon rank sum tests for continuous variables and Pearson's chi-square or Fisher's exact tests for categorical variables.

Results: Of the 940 RA patients treated with biologics, 87 (9.3%) underwent biologic de-escalation. Successful de-escalation was achieved in 74 RA patients (85.1%) at the end of the study period. Using the CDAI (Clinical Disease Activity Index) to define disease activity, the de-escalated patients had a median duration of 501.5 days in low disease activity or remission prior to a de-escalation attempt. There was no significant difference in the baseline characteristics between the de-escalated and non-de-escalated patients, except the de-escalated patients were more likely to be RF positive (83.1% vs. 67.7%, $p=0.015$). Results of a univariate analysis showed that the successfully de-escalated patients were more likely to be on their biologic for ≥2 years prior to de-escalation (70.3% vs. 38.5%, $p=0.054$, marginal significance). The unsuccessful group was more likely to have a RA flare during the observational period (53.8% vs. 6.8%, $p<0.001$).

Cost Analysis of successful de-escalations revealed savings of $719,702 and projected annualized savings of $1,256,886 if the successfully de-escalated patients remained at their latest biologic dose for 1 year.

Conclusion: This is the largest observational study analyzing clinical outcomes and cost savings of biologic de-escalation in RA. In our cohort of 940 RA patients on a biologic in the year 2013, 85% of the de-escalations were successful. The only predictor of successful de-escalation was biologic use ≥ 2 years prior to de-escalation. Significant cost savings from biologic de-escalation were achieved. Biologic de-escalation in RA is a sound methodology for improving value of care delivery - maintaining clinical disease control while reducing cost.

ACR/EULAR Remission in RA patients in Clinical Practice - Does Substitution of Patient Global with Pain Score Change Remission Rates? Data from the Danish Danbio Registry. Merete Lund Hetland. The Danish Rheumatologic Database (DANBIO), Glostrup Hospital., Copenhagen, Denmark.

Background/Purpose: Modern treatment strategy in RA aims at remission. In 2011, new ACR/EULAR remission criteria were published for patients with RA. Of four Boolean criteria, one is a patient-reported outcome:

The patient's global score (PATGL), which reflects how much the disease affects the patient's life at the present. It has been criticized that patient's pain score (PAIN) is not included, since pain is the single largest problem for patients with RA. Our aim was to investigate how such a modification of the remission criteria, replacing PATGL with PAIN, would impact achievement of remission in patients treated in routine care.

Methods: The DANBIO registry is a nationwide, Danish database that is used by all public hospital departments of rheumatology and many rheumatologists in private practice. Patients are followed prospectively and PATGL.PAIN, as well as doctor's global (DOCGL) and FATIGUE scores are collected routinely at all visits. For the present study, the latest visit for each patient was selected.

Results: A total of 16,154 patients with RA were included (age: 65 years (55–73) (median(25–75%)), disease duration: 8 years (3–16), 28.4% men, 86.5% IgM-RF positive, 25.0%/75.0% treated with biologics/sDMARD, HAQ: 0.625(0.125–1.375), DAS28CRP: 2.5 (1.8–3.4)).

16.5% of the patients fulfilled the Boolean criteria for remission (SJC≤1, TJC≤1, CRP≤10mg/L, and PATGL ≤10mm). PATGL and PAIN were closely correlated (Spearman's rho=0.86, p<0.0001).

If PATGL was substituted by PAIN, the remission rate was largely similar: 18.0%, but 5% (680/13,485 pts) changed status from no remission to remission, and 16.7% (446/2,669 pts) from remission to no remission.

If PATGL was substituted by FATIGUE, the remission rate was 13.2% (with 3% of patients (400/13,178) changing status from no remission to remission, and 36% of patients (946/2627) from remission to no remission.

If PATGL≤10 mm was substituted by PATGL≤20mm, the remission rate increased to 25.7%.

If PATGL was substituted by DOCGL, the remission rate increased to 45.4%, and 35.6% of patients (4,598/12,928) changed from no remission to remission, and 5.3% (138/2584) from remission to no remission.

Conclusion: In >15,000 RA patients treated in routine care in a treat-to-target setting, 16.5% fulfilled the 2011 ACR/EULAR Boolean remission criteria at their latest visit. Substitution of patient's global with pain score only changed the remission rate marginally. In accordance with this, the two scores were highly correlated. In contrast, substituting patient's global with doctor's global score almost tripled the fraction of patients in remission. The finding underscores the importance of inclusion of patient-reported outcomes in the remission criteria, but PATGLO and PAIN seemed to capture largely the same patients as being in remission.

Disclosure: M. L. Hetland, None.

Improvements in the Proportion of Patients Achieving DAS, CDAI, and SDAI Remission By Omitting the Patient Global Assessment (PtGA): an Analysis from a Prospective, Observational Registry. Philip Baer[1], WG Bensen[2], Carter Thorne[3], Boulos Haraoui[4], Denis Choquette[5], Regan Arendse[6], John Kelsall[7], Maqbool Sheriff[8], John S. Sampalis[9], Emmanouil Rampakakis[9], Francois Nantel[10], May Shawi[10], Allen J Lehman[10], Susan Otawa[10] and Edward Keystone[11]. [1]Private Practice, Scarborough, ON, [2]St Josephs Hospital and McMaster University, Hamilton, ON, [3]Southlake Regional Health Centre, Newmarket, ON, [4]University of Montreal Hospital Centre, Montreal, QC, [5]Institut de rhumatologie de Montréal (IRM), Montréal, QC, [6]University of Saskatchewan, Saskatoon, SK, [7]The Mary Pack Arthritis Centre, Vancouver, BC, [8]Nanaimo Regional General Hospital, Nanaimo, BC, [9]JSS Medical Research, Montreal, QC, [10]Janssen Inc., Toronto, ON, [11]Mount Sinai Hospital, University of Toronto, Toronto, ON.

Background/Purpose: PtGA is included in the formula of all disease activity indices despite the fact that it may not accurately reflect RA disease activity, but rather reflect symptoms related to fibromyalgia (FM), low back pain, osteoarthritis, depression or other conditions. A high disease activity score based on FM could mislead the physician to overestimate disease activity of RA patients and thereby to initiate therapy not indicated. (1) We previously assessed the impact of the PtGA on the ability to achieve Boolean ACR/EULAR remission state. (2) The aim of this analysis was to assess the proportion of patients failing to achieve DAS, CDAI and SDAI remission based on a real-world, routine clinical care setting in Canada, and the implications of constructing new disease activity indices omitting the PtGA.

Methods: BioTRAC is an ongoing, prospective registry of patients initiating treatment for RA, AS, or PsA with IFX or GLM. In this analysis, RA patients treated with infliximab from 2002–2014 or with golimumab from 2010–2014 were included. Modified versions of DAS28 (mDAS28), CDAI (mCDAI), and SDAI (mSDAI) were calculated by omitting PtGA from the formulas. Correlation of the standard and modified versions of each index was assessed with the Pearson's correlation coefficient. In the absence of validated thresholds for remission and LDA for the modified versions, the standard definitions were considered as the gold standard and ROC curve analysis was used to identify new thresholds for the modified versions. Cross-tabulations with the Chi-square test were used to assess the agreement between the standard and modified definitions of remission and LDA.

Results: One thousand nineteen RA patients with a mean (SD) age of 56.1 years (13.5) and disease duration of 8.5 years (9.1) were included in the analysis.

A strong correlation was observed between the standard and modified versions of DAS28 (r=0.98; P<0.001), CDAI (r=0.99; P<0.001), and SDAI (r=0.99; P<0.001). Based on ROC analysis the new thresholds for remission and LDA were: mDAS28 (remission=2.6, LDA=3.1), mCDAI (remission=2.5, LDA=10.5), mSDAI (remission=3.3, LDA=10.9). Cross-tabulation of the standard and modified thresholds showed that an additional 10.1%, 10.6%, and 17.8% of non-remission cases for DAS28, CDAI and SDAI, respectively, would be classified as remission with the modified definitions. Similarly, an additional 11.5%, 21.2%, and 20.6% of non-LDA cases for DAS28, CDAI and SDAI, respectively, would be classified as LDA.

Conclusion: The results of this analysis have shown that PtGA could account for up to 10% of non-remission cases and up to 20% of non-LDA cases as measured by DAS, CDAI and SDAI. Further analyses are required to identify the determinants of patient global assessment.

Predict the Chance of Remission for Your RA Patient in Real Life. Till Uhlig[1], Vibeke Norvang[1], Elisabeth Lie[1], Erik Rødevand[2], Knut Mikkelsen[3], Åse S. Lexberg[4], Synøve Kalstad[5] and Tore K. Kvien[1]. [1]Diakonhjemmet Hospital, Oslo, Norway, [2]St. Olavs Hospital, Trondheim, Norway, [3]Revmatismesykehuset, Lillehammer, Norway, [4]Vestre Viken Hospital, Drammen, Norway, [5]University Hospital of Northern Norway, Tromsø, Norway.

Background/Purpose: Clinical remission (REM) is the treatment target in rheumatoid arthritis (RA), and there are several composite REM criteria available. Knowledge on how disease duration affects REM in daily clinical practice, and whether predictors of REM depend on the method for assessment of REM, is limited.

Objective: To study the rates of REM after 3 and 6 months with DMARD treatment applying different criteria, and to study predictors of REM after 6 months.

Methods: Data from 4992 patients in the NOR-DMARD study, representing real life rheumatology practice, were analysed. All patients started with a synthetic or biological DMARD and had 6-month follow-up data available,. Mean (SD) age was 54.6 (14.9) yrs, disease duration was 8.5 (7.9) yrs, 73.2% were females. Disease duration (mean 7.9 [9.6] yrs) was grouped into: <0.5 yrs (n=1329), >0.5–1 yr (n=321), >1–5 yrs (n=992), >5–10 yrs (n=750), and >10 yrs (n=1532).

The applied definitions for clinical REM were Disease Activity Score28 (DAS28) <2.6, Simplified Disease Activity Index (SDAI) <3.3, Clinical Disease Activity Index (CDAI) <2.8, Routine Assessment of Patient Index Data (RAPID3, range 0–10) <1, and the Boolean ACR/EULAR REM definition (BOOL) <1, with additional BOOL for practical use (BOOLP) <1.

Results: Overall REM rates (%) after 3 (6) months were for DAS28 22.5 (26.0)%, CDAI 10.3 (12.6)%, SDAI 9.8 (11.8)%, RAPID3 20.3 (21.3)%, BOOL 8.7 (10.1)%, and BOOLP 10.3 (12.2)%. Both at 3 and 6 months REM rates were highest for disease duration <0.5 yr for all six composite definitions (ANOVA all <0.001), varying from BOOL 12.5% (3 mths) to DAS28 34.3% (6 mths), with lower rates and minor changes across higher disease duration groups.

The table shows odds ratios (*p<0.05 **p<0.01 ***p<0.001) for achieving 6-month REM in separate logistic regression models for each remission definition, adjusting always for age, respective baseline disease activity as well as other covariates (the latter were included in the multivariable model if p<0.10).

	DAS28	SDAI	CDAI	RAPID3	BOOL	BOOLP

Fatigue VAS	0.99*	0.99***	0.99***	0.99***	0.99***	0.99***
Invest global VAS	1.01*				1.01	1.01

Conclusion: In clinical practice REM within 6 months of start/change of therapy was most frequently achieved if baseline disease duration is <6 months. REM at 6 months is further independently predicted by use of biologic DMARDs, lower age, higher education, non-smoking, absence of erosions, lower baseline disease activity, lower fatigue score, and better physical function. These real life findings inform clinicians on optimal patient treatment, including the need for very early use of DMARDs.

Disease Remission Reduces Risk of Heart Failure in Rheumatoid Arthritis Patients Independent of Treatment Strategy. Thomas Schau[1], Michael Gottwald[2], Christian Butter[1] and Michael Zaenker[2]. [1]Cardiology Dept., Immanuel Klinikum Bernau Heart Center Brandenburg, Bernau, Germany, [2]Immanuel Klinikum Bernau, Rheumatology Center Northern Brandenburg, Bernau, Germany.

Background/Purpose: Risk of heart failure (HF) is increased in patients with RA, however there is great variance in reported prevalence rates due to different diagnostic standards and underestimation of diastolic HF. Besides traditional risk factors, systemic inflammation and persistent RA-activity are thought to be independent contributors to increased HF risk. This study was to determine influence of RA-activity on prevalence of HF in a community-based RA-cohort compared to age- and gender-matched controls by using the European Society of Cardiology (ESC) diagnostic guidelines.

Methods: A prospective, cross-sectional study including 157 consecutively recruited RA-patients from our outpatient clinic during a 3 months period. Inclusion criteria were written consent and diagnosis of RA fulfilling ACR/EULAR-criteria. Blinded to any health information, an age- and gender-matched control group (n=77) was recruited from a district office and veterans of our hospital staff. Data were obtained using standardized questionnaire, clinical investigation, lab tests including NT-proBNP (Roche), and echocardiography containing tissue doppler and strain imaging.

Results: The RA and control cohorts were comparable in age (mean (SD) 61 years (±13) vs. 59(±12) and gender distribution (67% vs. 69% females). In RA, median HAQ was 1.1 (Interquartile range (IQR) 0.8–2.0), median DAS28 was 2.8 (IQR 2.0–3.4), with remission (DAS28<2.6) in 45%, low disease activity (DAS28 2.6–3.2) in 25% and higher disease activity (DAS28 >3.2) in 30% of the patients. Prevalence of HF was significantly higher in RA vs. controls (38(24%) vs. 5(6%), p<0.001). Of all diagnosed HF, only 2 RA patients showed reduced ejection fraction. Comparing RA and control group, traditional risk factors were not significantly different except mean BMI (29±5 vs. 27±4, p<0.001) and prevalence of hypertension (59% vs. 40%, p=0.019). No significant differences were found for diabetes, chronic kidney disease, hyperlipidaemia. Subgroup analysis revealed 37% prevalence of HF in patients with DAS28 >3.2 (RR 5.7, p<0.001 compared to controls), 30% in patients with DAS28 2.6–3.2 (RR 4.6, p=0.0015) and 13% in patients with DAS28-remission (RR 1.95, p=0.264). In multivariate analysis adjusted for age and gender, remaining risk factors for HF in RA were DAS28≥2.6 (OR 3.4, 95%CI 1.3–9.8), RA-duration >10years (OR 2.6, 95%CI 1.2–5.8), CRP median >10mg/l (OR 4.8, 95%CI 1.1–21), and ESR >16mm/h (OR 5.4, 95%CI 2.1–16). We found no influence of treatment type.

Conclusion: Compared to age and gender matched controls, prevalence of mostly diastolic HF was found 4–6fold increased in active RA but only 2fold increased in states of disease remission. We conclude that optimal control of RA and awareness for diastolic HF more than type of treatment are crucial for adequately addressing cardiovascular risk in RA patients.

Rheumatoid Arthritis - Small Molecules, Biologics and Gene Therapy II: Novel Therapies in Rheumatoid Arthritis - Early in Development

Sunday, November 16, 2014, 4:30 PM–6:00 PM

946

Phase 1 Study of Immunotherapy Using Autoantigen-Loaded Dendritic Cells in Patients with Anti-Citrullinated Peptide Antigen Positive Rheumatoid Arthritis. Young Bin Joo[1], Jun-Eui Park[2], Chan-Bum Choi[3], Jeongim Choi[1], Jin-ah Jang[2], Minkyu Heo[2], Hak-yeop Kim[2], Hye-Soon Lee[1], Yong-Soo Bae[4] and Sang-Cheol Bae[5]. [1]Hanyang University Hospital for Rheumatic Diseases, Seoul, South Korea, [2]JW CreaGene Research Institute, JWCreaGene Inc., Seongnam-si, South Korea, [3]Hanyang University Hospital for Rheumatic Diseases, Clinical Research Center for Rheumatoid Arthritis (CRCRA), Seoul, South Korea, [4]Sungkyunkwan University, Suwon, South Korea, [5]Department of Rheumatology, Hanyang University Hospital for Rheumatic Diseases, Seoul, South Korea.

Background/Purpose: To date, no dendritic cell (DC) immunotherapy has been shown to give a benefit in patients with rheumatoid arthritis (RA). In this prospective phase I study, we evaluated the safety and clinical efficacy of autologous tolerogenic dendritic cell (DC) administration (CreaVax-RA) in patients with RA.

Methods: Twelve RA patients (six for low dose vaccination, 0.5×10^7 cells/injection and remaining six for high dose vaccination, 1.5×10^7 cells/injection) were administrated five times at 2 to 4 week intervals subcutaneously (around inguinal lymph nodes) with each CreaVax-RA, autologous semi-mature DCs pulsed with recombinant PAD4, RA33, citrullinated-filaggrin (cit-FLG) and vimentin antigens. Safety and clinical benefits together with associated immune responses were evaluated as primary and secondary outcomes, respectively, at 14 and 24 weeks after first administration. The major clinical outcomes were assessed by European League Against Rheumatism (EULAR) response.

Results: Among a total of 12 adverse events (AEs) in eight patients, 11 events (91.7%) were restricted in patients treated with low dose (0.5×10^7 cells/inj) while 1 event in patients with high dose (1.5×10^7 cells/inj). All of the AEs were grade 1 or 2 without over grade 3 AE. In ELISPOT assay, the number of IFN-γ-secreting T cells decreased in 91.7% (n = 11/12). The level of antigen-specific autoantibodies significantly decreased in 55.6% (n=5/9) among the autoantibody-positive patients against more than one autoantigen ($p < 0.001$). The percentage of patients who achieved a good-to-moderate EULAR response ranged over 58.3% (n = 7/12) at 14 weeks after initial administration. The response rate was much higher in high dose group than in low dose group (83.3% vs 33.3%, respectively). The patients without any autoantibodies showed no clinical efficacy.

Conclusion: DC administration (CreaVax-RA) was safe and well tolerated in patients with RA in the present phase I study. Preliminary, but clinical outcomes were in good agreement with doses and immune responses. These phase I results warrant further clinical study of high dose CreaVax-RA (1.5×10^7/inj) in patients with RA.

Efficacy and Safety of NNC01140006, an Anti-IL-21 Monoclonal Antibody, in Patients with Active Rheumatoid Arthritis. Juan D. Cañete[1], Piotr Leszczynski[2], Rikke Riisbro[3] and Klaus S. Frederiksen[3]. [1]Hospital Clínic of Barcelona, Barcelona, Spain, [2]Department of Rheumatology and Rehabilitation, Poznan Medical University, Poznan, Poland, [3]Novo Nordisk A/S, Søborg, Denmark.

Background/Purpose: A phase 2, randomised, double-blind, placebo-controlled, parallel-group trial was conducted to evaluate the efficacy and safety of NNC0114-0006 in patients with active rheumatoid arthritis (RA) on background methotrexate (MTX) therapy.

Methods: Patients (N=62; 82% female) with RA (mean duration 6.9 years; 77% RF positive; 82% anti-CCP positive; mean DAS28-CRP 5.7) and on MTX (mean duration 3.9 years; mean dose 14.3 mg/week) were enrolled. Patients were randomised to i.v. NNC0114-0006 (12 mg/kg; n=41) or placebo (n=21); two doses given 6 weeks apart. The primary endpoint was change in DAS28-CRP from baseline to Week 12. ACR 20/50/70 and EULAR response at Week 12, adverse events (AEs), changes in laboratory safety measurements, antibodies against NNC0114–0006 (ADAs) and pharmacodynamic (PD) parameters were also evaluated.

Results: There were no significant differences between treatment groups with respect to baseline. Four patients in the NNC0114-0006 group withdrew (3 withdrew informed consent, 1 was lost to follow-up). A significant improvement in mean DAS28-CRP was observed with NNC0114-0006 versus placebo at Week 12 (–0.65, p=0.04; Fig. 1), due largely to reductions in swollen and tender joint counts. The reduction in DAS28-CRP at week 12 was supported by improved disease activity in terms of ACR20/50/70 and EULAR response, although these endpoints did not reach statistical significance. An expected increase in total (both free and antibody-bound) IL-21 levels after treatment with NNC0114-0006 was observed. While no change in absolute B cell numbers was observed at Week 1, about one third of patients treated with NNC0114-0006 had increased percentages of plasma cells, plasmablasts and short-lived plasmablasts, with decreased percentages of naïve B cells. They also showed increased transcript levels of Ig-Lambda light chain (IGLV7–43) and other plasma-cell signature genes in whole blood analysis. However, the DAS28-CRP response in these patients was comparable to placebo and those who did not exhibit this B cell alteration. Nevertheless, following treatment, DAS28-CRP and ACR-N outcomes appear to be related to baseline CTX-I – a marker of bone resorption – but not baseline DAS28-CRP. In NNC0114-0006-treated patients, 43 AEs were observed in 22/41 (54%) patients, while 24 AEs occurred in 11/21 (52%) placebo patients. Four serious AEs occurred in 3 placebo patients. A higher number of patients reported infections (24% vs 10%) and skin disorders (12% vs 5%) in the NNC0114-0006 group versus placebo. No treatment-related ADAs were detected. No clinically significant changes were observed in laboratory safety parameters.

Conclusion: Treatment with NNC0114-0006 significantly improved DAS28-CRP versus placebo at Week 12. Changes in B cell subsets detected at Week 1 may be due to altered distribution of homing of plasma cells/plasmablasts. No safety concerns were identified.

Fig 1. Mean change in DAS28-CRP over time

A Phase 2b, Randomized, Double-Blind, Parallel-Group, Placebo-Controlled, Dose-Finding, Multi-Center Study to Evaluate the Safety and Efficacy of ASP015K in Moderate to Severe Rheumatoid Arthritis Subjects Who Have Had an Inadequate Response to Methotrexate. Alan J. Kivitz[1], Anna Zubrzycka-Sienkiewicz[2], Sergio R. Gutierrez-Ureña[3], Jeffrey Poiley[4], Rita Kristy[5], Kathyjo Shay[5] and Jay P. Garg[5]. [1]Altoona Center for Clinical Research, Duncansville, PA, [2]ARS Rheumatica sp. Zo.o, Reumatika, Warszawa, Poland, [3]Hospital Civil de Guadalajara FAA, CUCS UdG, Guadalajara, Mexico, [4]Arthritis Associates, Orlando, FL, [5]Astellas Pharma Global Development, Northbrook, IL.

Background/Purpose: ASP015K is a novel oral Janus kinase (JAK) inhibitor in development for the treatment of rheumatoid arthritis (RA). ASP015K inhibits JAK 1/3 with relative selectivity over JAK2 and can be dosed once daily (QD). This study evaluated the efficacy, safety and dose response of ASP015K QD in patients (pts) with moderate to severe rheumatoid arthritis (RA) with an inadequate response to methotrexate (MTX) (Clinical Trials Registration: NCT01554696).

Methods: In a 12-week, double-blind, placebo (PBO)-controlled study, pts 18 years or older who met ACR criteria for RA, were on MTX ≥ 90 days, and had active RA (CRP ≥ 0.8 mg/dL or ESR ≥ 28 mm/hr and ≥ 6 tender/swollen joints on a stable dose of MTX) were randomized 1:1:1:1:1 to ASP015K 25 mg, 50 mg, 100 mg, 150 mg or PBO, stratified by prior anti-TNF use and geographic region. Pts continued stable MTX therapy during the study. The primary endpoint was ACR20 response at week 12.

Results: 378 pts (83% female; mean age 53 years) were randomized and dosed. 43% of subjects were enrolled in Europe, 39% in U.S., and 18% in Latin America. 26% had used a TNF-inhibitor. Mean baseline values: tender joint count 23.0 (of 68), swollen joint count 13.6 (of 66), CRP 1.17 mg/dL, ESR 39.86 mm/hr, DAS28-CRP 5.54, and DAS28-ESR 6.36. Concomitant MTX dose was similar among groups. Dose-response on ACR20 was not shown. Numerically greater ACR20 responses than PBO were seen in the ASP015K 50 mg and 150 mg groups, with statistical significance shown in the 50 mg group. A statistically significant dose response was demonstrated in change in DAS28-CRP and DAS28-ESR, with effects seen as early as week 1. Pre-specified analyses by geographic region showed significant responses in ACR20 in the ASP015K 100 mg and 150 mg dose groups as compared to PBO in Europe but not in the other regions (Table). The incidence of adverse events (AEs) was similar between combined ASP015K groups and PBO (47.7% vs 47.2%). The most frequently reported AEs in the combined ASP015K groups vs PBO were headache (2.9% vs 1.4%) and hypercholesterolemia (2.0% vs 1.4%). The overall incidence of infections and serious adverse events (SAEs) were similar between ASP015K and placebo (18.3% vs 26.4% and 1.0% vs 0%, respectively). No meaningful differences in absolute neutrophil and lymphocyte counts and hemoglobin were seen between ASP015K and PBO. The safety profile was comparable among the ASP015K dose groups, although more AEs leading to study drug discontinuation and all 3 SAEs occurred in the 100 mg and 150 mg groups.

Conclusion: In this study of active RA subjects with an inadequate response to MTX, ASP015K did not demonstrate a dose-response on the primary endpoint of ACR20, with differential placebo response rates seen by region. Significant effects on inflammatory markers and DAS28 were shown, warranting further evaluation. ASP015K was well tolerated with no meaningful differences in safety measures from placebo noted.

Safety and Efficacy of CF101 in Rheumatoid Arthritis Patients: A Phase II Study. Rumen M. Stoilov[1], Rodina N. Licheva[2], Mariyana K. Mihaylova[3], Tatiana Reitblat[4], Emil A. Dimitrov[1], Krasimira M. Shimbova[1], Girish Bhatia[5], Amit Pispati[6], Alexandra Gurman- Balbir[7], B R Bagaria[5], Boytcho A. Oparanov[2], Sari Fishman[8], Zivit Harpaz[8], Motti Farbstein[8], Shira Cohen[8], Michael H. Silverman[8] and Pnina Fishman[8]. [1]Multiprofile Hospital for Active Treatment "Sv. Ivan Rilski" - EAD, Clinic of Rheumatology, Sofia, Bulgaria, [2]Diagnostic Consulting Center, Rheumatology office, Sofia, Bulgaria, [3]3Diagnostic Consulting Center, Rheumatology office, Sofia, Bulgaria, [4]Barzilai Medical Center,, Ashkelon, Israel, [5]Malpani Multispeciality Hospital, mumbai, India, [6]Bhatia Hospital Medical Research Society, mumbai, India, [7]Rambam Medical Center, Haifa, Israel, [8]CanFite Biopharma Ltd, Petah Tikva, Israel.

Background/Purpose: CF101, is a highly selective A_3 adenosine receptor (A_3AR) agonist, demonstrated safety and anti-inflammatory effect in Phase 2 clinical studies of rheumatoid arthritis (RA) and Psoriasis. A_3AR has been defined as a biological predictive marker, based on a significant correlation found in a former Phase II study, between its over-expression at baseline and positive patients' response to CF101 treatment.

Methods: This was a Phase 2, multicenter, randomized, double-blind, placebo-controlled, parallel-group study designed to assess the efficacy and safety of CF101 1mg, administered orally twice daily to patients with active RA for 12 weeks. Primary efficacy endpoint was ACR 20 response at week 12, with all-cause dropouts considered as non-responders, in the Intent-To-Treat (ITT) population. Secondary efficacy included: ACR 20/50/70 by visit, ITT, using non-responder imputation.

Seventy nine patients were enrolled for the study based on inclusion criteria of A_3AR > from 1.5 units and were randomized for two groups receiving CF101 1 mg (n = 42), or Placebo (n = 37).

Results: CF101 achieved ACR20 of 48.6%, statistically significantly higher than in the Placebo group (25.0%) at week 12 (P=0.0352). CF101 showed superiority in ACR50 and ACR70 values vs. placebo although not statistically significant, most probably due to the low number of patients. Interestingly, ACR20, ACR 50 and ACR 70 response rate at week 12 in patients with no prior systemic therapy, i.e., naïve patients were significantly higher compared to the response of the whole patient population treated with CF101.

The proportion of patients experiencing any adverse event (AE) was similar for both groups (16.7% for the CF101 group and 16.2% for the Placebo group). Two AEs, RA and rash, were considered possibly related to CF101. The majority of AEs were considered to be mild.

Conclusion: CF101 was very well tolerated and reached the primary endpoint in the current study demonstrating clear evidence of efficacy as a monotherapy for 12 weeks in patients with active RA.

Multiple Mechanisms of Tolerance Characterize the Immune Response to Autologous Modified Dendritic Cells Exposed to Citrullinated Peptides in Patients with Rheumatoid Arthritis. Soi-Cheng Law[1], Hendrik Nel[2], Ahmed Mehdi[2], Kim-Anh Le Cao[2] and Ranjeny Thomas[1]. [1]Univ of Queensland, Brisbane, Australia, [2]University of Queensland, Brisbane, Australia.

Background/Purpose: We carried out a phase I clinical trial of tolerising autologous peripheral blood DCs exposed to 4 citrullinated self-peptides ("Rheumavax") in 29 HLA-DR shared epitope (SE)+ anti-citrullinated peptide antibody+ DMARD-treated rheumatoid arthritis (RA) patients, of whom 18 received Rheumavax. This study aimed to evaluate immune biomarkers of treatment and of clinical response to Rheumavax.

Methods: Frozen peripheral blood mononuclear cells (PBMC) were analysed for T cell, B cell, monocyte and DC subsets by flow cytometry (FACS) at baseline, 6 days, 4, 8, 12 and 24 weeks after Rheumavax, and Luminex and ELISA assays were used to measure 108 serum analytes. PBMC were stimulated ex vivo for 5 days with each of the delivered citrullinated peptides, or with control citrullinated aggrecan peptide or tetanus toxoid antigens. Proliferation and cytokine production were measured. To identify relevant markers of change, we used sparse partial least squares linear multivariate approach, multilinear regression, ANOVA and t tests.

Results: Median disease duration of recruited patients was 2 years. At baseline, 9 of 18 patients assigned to Rheumavax had an incomplete response to DMARDs with a swollen joint count (SJC) of at least 1; 9 had minimal disease activity. One month after Rheumavax, SJC of patients with active disease at baseline reduced by a mean of 5 joints and SJC of those with inactive disease did not change. Immune effects of Rheumavax were first expected 6 days after administration. Using a multiple linear regression to model the effect of changes in PB cells at day 6 on clinical response, we found that reduction in the proportions of CD25+CD127+ activated CD4+ T cells and CD14loCD16- monocytes, and increased proportions of CD25-CD127+CD4+ naive cells, CD56+CD16+ NK cells and Foxp3+CD127loCD25hi Treg cells predicted the reduction in SJC 1 month after Rheumavax with R^2 of 0.85 (p=0.0001). Relative to controls, treated patients had an increased proportion of PB CD25+CD127-CD4+ induced (i)Treg from 6 days until 8 weeks after Rheumavax. Specific increase in IL-10 production in response to delivered cit-peptides occurred ex vivo in 4 patients, increased iTreg in 8 patients and an increase in IL-10 and iTreg in 4 patients post-Rheumavax treatment. Reduction in 12 pro-inflammatory cytokines, chemokines and metabolic factors in serum discriminated the 1 month response in Rheumavax treated and untreated patients. Consistent with their clinical and inflammatory improvement, treated patients had an increased proliferative response to tetanus toxoid ex vivo within 6 days of Rheumavax.

Conclusion: These data suggest that autologous tolerising DCs exposed to citrullinated peptides improved disease control in RA patients with prior partial response to DMARDs through reduction in circulating activated T cells and dendritic cell precursors, induction of Treg and lytic NK cells, and suppression of systemic inflammation, thereby restoring regulatory balance and immune function.

Safety, Tolerability, and Functional Activity of ABT-122, a Dual TNF- and IL-17A–Targeted DVD-Ig™, Following Single-Dose Administration in Healthy Subjects. Heikki Mansikka[1], Melanie Ruzek[2], Margaret Hugunin[2], Alexander Ivanov[2], Alyssa Brito[2], Anca Clabbers[2], Carolyn Cuff[2], Chung-Ming Hsieh[2], Martin Okun[1], Renee Heuser[1], David Carter[1], Barbara Hendrickson[1], Dipak Pisal[1], Sandra Goss[1], Jia Liu[1], Charles Locke[1], Nasser Khan[1] and Robert Padley[1]. [1]AbbVie, Inc, North Chicago, IL, [2]AbbVie, Inc, Worcester, MA.

Background/Purpose: Several lines of evidence indicate that greater clinical efficacy and protection of joints may be possible in patients with RA by neutralizing TNF and IL-17 concurrently, compared with neutralizing either alone. ABT-122 is a novel Dual Variable Domain immunoglobulin (DVD-Ig™) protein incorporating two sets of selective binding domains, with one pair targeting TNF and one pair targeting IL-17A. The safety, tolerability, and dual functionality of ABT-122 was investigated in a single ascending dose study in healthy subjects.

Methods: This was a first-in-human, double-blind, placebo-controlled study with single dose ABT-122 administration by intravenous (IV) or subcutaneous (SC) route in 64 healthy volunteers. Each ABT-122 dose was evaluated in a group of 8 subjects, 6 receiving active drug and 2 receiving placebo. Groups 1 through 5 received ABT-122 at 0.1, 0.3, 1, 3, and 10 mg/kg IV, respectively, and Groups 6 through 8 received 0.3, 1, and 3 mg/kg SC, respectively.

Dual binding capacity of ABT-122 for IL-17 and TNF in vitro was determined by sequential binding of human TNF and IL-17 to ABT-122 by surface plasmon resonance (SPR). Functional activity of recombinant ABT-

122 or of serum from subjects receiving ABT-122 was determined using an in vitro assay of inhibition of TNF- and IL-17–induced IL-6 production by human fibroblast-like synoviocytes (FLS), derived from RA patients.

Results: Following IV or SC administration there was no significant difference in the adverse event (AE) profile between subjects receiving ABT-122 or placebo. There were no serious AEs or premature discontinuations due to AEs reported in this study. No subject had an infusion reaction, systemic hypersensitivity reaction or an injection site reaction. No clinically relevant changes in laboratory parameters, vital signs, or ECG parameters occurred. All AEs were mild or moderate in intensity. The most frequently reported adverse event was upper respiratory infection for both subjects given ABT-122 or placebo.

ABT-122 simultaneously bound a similar amount of TNF per ABT-122 molecule independent of the occupancy of the IL-17 binding sites and vice versa by SPR. ABT-122 in the functional assay fully inhibited IL-6 release from FLS stimulated by the combination of TNF and IL-17, whereas individual monoclonal antibodies only partially blocked the IL-6 production. Serum from subjects receiving ABT-122 demonstrated comparable potency (IC_{50} and IC_{90}) to that defined by ABT-122 in the assay and was consistent across dose groups. Full neutralization was time- and dose-dependent through 21 days, and up to 10mg/kg, respectively.

Conclusion: These data demonstrate that ABT-122 can simultaneously bind and neutralize TNF and IL-17 in vitro and functional levels of dual TNF and IL-17 inhibition with ABT-122 are maintained for up to three weeks after a single dose in healthy subjects. ABT-122 demonstrated an acceptable safety profile following single dose administration up to 3 mg/kg SC and 10 mg/kg IV. These study results support continued development of ABT-122 for immune mediated inflammatory diseases.

ACR Concurrent Abstract Session
Spondyloarthropathies and Psoriatic Arthritis II - Novel Treatments Psoriatic Arthritis
Sunday, November 16, 2014, 4:30 PM–6:00 PM

952

A Phase IIb, Randomized, Double-Blind, Placebo-Controlled, Dose-Ranging, Multicenter Study to Evaluate the Efficacy and Safety of Clazakizumab, an Anti-IL-6 Monoclonal Antibody, in Adults with Active Psoriatic Arthritis. Philip Mease[1], A B Gottlieb[2], A Berman[3], E Drescher[4], J Xing[5], S Banerjee[5] and R Wong[5]. [1]Swedish Medical Center and University of Washington, Seattle, WA, [2]Tufts Medical Center and Tufts University School of Medicine, Boston, MA, [3]Centro Médico Privado de Reumatología, Tucuman, Argentina, [4]Csolnoky Ferenc Hospital, Veszprém, Hungary, [5]Bristol-Myers Squibb, Princeton, NJ.

Background/Purpose: New treatment options for psoriatic arthritis (PsA) are needed and interleukin-6 (IL-6), a cytokine with a central role in chronic inflammation, is a potential therapeutic target. This Phase IIb study evaluated the efficacy of 3 doses of SC clazakizumab (CLZ) – a potent, selective antibody to the IL-6 cytokine – with or without MTX versus placebo (PBO) in patients (pts) with PsA.

Methods: Pts with PsA according to the Classification Criteria for Psoriatic Arthritis (CASPAR) and active disease, who had an inadequate response to NSAIDs and/or DMARDs, were randomized to 1 of 4 treatment arms: CLZ 25, 100, or 200 mg, or PBO, with or without MTX, every 4 wks for 24 wks. The primary endpoint was ACR20 response rate at Wk 16. Additional secondary endpoints evaluated at Wk 24 include ACR20/50/70 and Psoriasis Area and Severity Index 75 (PASI75) response rates; changes in HAQ-DI and DAS28 (CRP); and dactylitis and enthesitis scores. All pts who discontinued or received rescue treatment prior to Wk 16 were imputed as non-responders at the Wk 16 analysis and all subsequent visits.

Results: A total of 165 pts were treated and analyzed. Baseline characteristics were balanced, including use of background MTX in ~70% of pts, except mean body weight (approximately 8 kg lower in PBO and CLZ 25 mg arms) and disease duration (3–5 yrs less in CLZ 100 and 200 mg arms). The study primary endpoint was met, with ACR20 response rates significantly higher in the CLZ 100 mg arm vs PBO (52.4 vs 29.3%, p=0.039) and numerically higher in the CLZ 25 and 200 mg arms (46.3 [p=0.101] and 39.0% [p=0.178], respectively) at Wk 16. The table shows secondary endpoints. ACR20/50/70 response rates were higher than PBO for all CLZ treatment arms at Wk 24, but no clear dose response was seen. Mean decreases from baseline to Wk 24 in DAS28 (CRP), HAQ-DI, the number of dactylitic digits and Spondyloarthritis Research Consortium of Canada (SPARCC) enthesitis score were greater in all CLZ treatment arms compared with PBO. PASI75 response rates were 12.2% in the PBO arm and between 12.2 and 28.6% in the CLZ arms at Wk 24. Through Wk 24, the rates of serious adverse events (SAEs) were similar across PBO, CLZ 25 and CLZ 100 mg arms (4.9, 4.9 and 4.8%, respectively) and higher for the CLZ 200 mg arm (9.8%), which was associated with more discontinuations. No serious infections, tuberculosis, malignancies, gastrointestinal perforations or unusual SAEs, were observed during the study period. Consistent with IL-6 blockade, non-clinically significant liver enzyme elevations and reductions in platelet and neutrophil counts were observed in the 3 CLZ treatment arms.

Week 24 results	PBO (n=41)	CLZ 25 mg (n=41)	CLZ 100 mg (n=42)	CLZ 200 mg (n=41)

CFB=change from baseline; LEI=Leeds Enthesitis Index *Calculated based on mean values at baseline and Week 24.

Conclusion: Clazakizumab is effective in controlling clinical features of PsA such as arthritis, enthesitis and dactylitis, with modest skin benefits. The safety profile was acceptable and consistent with IL-6 blockade. This is the first demonstration of a beneficial effect of targeting IL-6 in PsA and further studies are warranted.

Secukinumab, a Human Anti–Interleukin-17A Monoclonal Antibody, Improves Active Psoriatic Arthritis and Inhibits Radiographic Progression: Efficacy and Safety Data from a Phase 3 Randomized, Multicenter, Double-Blind, Placebo-Controlled Study. Philip Mease[1], Iain B. McInnes[2], Bruce Kirkham[3], Arthur Kavanaugh[4], Proton Rahman[5], Désirée van der Heijde[6], Robert Landewé[7], Peter Nash[8], Luminita Pricop[9], Jiacheng Yuan[9], Hanno Richards[10] and Shephard Mpofu[10]. [1]Swedish Medical Center and University of Washington, Seattle, WA, [2]University of Glasgow, Glasgow, United Kingdom, [3]Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom, [4]UCSD School of Medicine, La Jolla, CA, [5]Memorial University of Newfoundland, St. John's, NF, [6]Leiden University Medical Center, Leiden, Netherlands, [7]Academic Medical Center, University of Amsterdam, Amsterdam, Netherlands, [8]University of Queensland, Brisbane, Australia, [9]Novartis Pharmaceuticals Corporation, East Hanover, NJ, [10]Novartis Pharma AG, Basel, Switzerland.

Background/Purpose: Secukinumab has demonstrated significant and rapid efficacy in the treatment of psoriasis in two phase 3 studies. We present the first randomized, multicenter, double-blind, placebo (PBO)-controlled phase 3 study to assess the efficacy and safety of secukinumab in patients (pts) with PsA (FUTURE 1; NCT01392326).

Methods: 606 adults with active, moderate to severe PsA were randomized to secukinumab or PBO. Pts on secukinumab received 10 mg/kg i.v. loading dose at baseline, Week (Wk) 2 and Wk 4, then either 75 mg s.c. (10

IV→75 SC) or 150 mg s.c. (10 IV→150 SC) every 4 wks from Wk 8. PBO was given on the same schedules. Patients naïve to anti-TNF therapy (~70%) and those intolerant of or inadequate responders to anti-TNF therapy (TNF-IR; ~30%), were stratified across groups. Statistical analyses for the primary and multiple secondary endpoints used non-responder imputation (binary variables), mixed-effects repeated measures model (continuous variables), and linear extrapolation (radiographic data), following a pre-defined hierarchical hypothesis testing strategy to adjust for multiplicity.

Results: Demographics and baseline characteristics were balanced between groups. Both 10 IV→75 SC and 10 IV→150 SC demonstrated significantly higher ACR20 responses vs. PBO at Wk 24 (50.5% and 50.0% vs. 17.3%, respectively; $P< 0.0001$ vs. PBO). All pre-specified secondary endpoints, including dactylitis, enthesitis, SF36-PCS, HAQ-DI, DAS28-CRP, ACR50, PASI 75, PASI 90, and mTSS score were achieved by Wk 24 and reached statistical significance; active dose separated from PBO as early as Wk 1 for ACR20, DAS28-CRP, and HAQ-DI. Drug exposure levels were similar in the secukinumab groups up to the primary endpoint due to i.v. loading. Improvements in all primary and secondary endpoints were sustained through Wk 52. At Wk 52, ACR 20/50/70 responses, using an observed analysis, were 66.9%, 38.4% and 25.6% for 10 IV→75 SC and 69.5%, 50.0% and 28.2% for 10 IV→150 SC. In both TNF-naïve and TNF-IR groups, secukinumab demonstrated superiority at Wk 24 in ACR20/50/70, PASI 75/90, HAQ-DI, SF36-PCS, dactylitis and enthesitis at both doses and the effect was maintained through Wk 52. Secukinumab significantly inhibited radiographic structural joint damage at Wk 24 vs. PBO. AEs at Wk 16: 60.4% (10 IV→75 SC), 64.9% (10 IV→150 SC) and 58.4% (PBO); non-fatal SAE rates: 2.5%, 4.5% and 5.0%, respectively. Mean, median, and maximum exposures: 438.5, 456.0 and 721 days; AE/non-fatal SAE rates: 78.1%/8.6% and 82.4%/12.9% in pts who received secukinumab 75 mg s.c. or 150 mg s.c., respectively, at any point in the study.

Table Summary of selected 24-week efficacy results

Week 24 Data	Secukinumab 10 mg/kg IV → 75 mg SC	Secukinumab 10 mg/kg IV → 150 mg SC	PBO
ACR20 (% responders)	50.5*	50.0*	17.3
ACR50 (% responders)	30.7*	34.7*	7.4
ACR70 (% responders)	16.8*	18.8*	2.0
DAS28-CRP (mean change from BL) Overall (n=606)	–1.67*	–1.62*	–0.77
[a]Dactylitis (presence of, %) Overall (n=324)	43.3*	51.9*	84.5
[a]Enthesitis (presence of, %) Overall (n=372)	51.2*	54.0*	87.2

*P <0.0001 vs. PBO; [a]Data from pts with dactylitis (n = 324) and enthesitis (n = 372) at baseline. ACR, American College of Rheumatology response criteria; BL, baseline; DAS28-CRP, Disease Activity Score 28 using C-reactive protein; IV, intravenous; pts, patients; SC, subcutaneous

Conclusion: In this first phase 3 trial to evaluate highly selective IL-17A inhibition in pts with PsA, secukinumab provided rapid, clinically significant and sustained improvements in signs and symptoms, and inhibited joint structural damage. Secukinumab was well tolerated through 52 wks.

Secukinumab, a Monoclonal Antibody to Interleukin-17A, Provides Significant and Sustained Inhibition of Joint Structural Damage in Active Psoriatic Arthritis Regardless of Prior TNF Inhibitors or Concomitant Methotrexate: A Phase 3 Randomized, Double-Blind, Placebo-Controlled Study.

Désirée van der Heijde[1], Robert B. M. Landewé[2], Philip Mease[3], Iain B. McInnes[4], Philip G. Conaghan[5], Luminita Pricop[6], Gregory Ligozio[6], Hanno Richards[7] and Shephard Mpofu[7]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]Division of Clinical Immunology and Rheumatology, Academic Medical Center / University of Amsterdam & Atrium Medical Center, Amsterdam, Netherlands, [3]Swedish Medical Center, Seattle, WA, [4]University of Glasgow, Glasgow, United Kingdom, [5]NIHR-Leeds Musculoskeletal Biomedical Research Unit and Leeds Institute of Rheumatic and Musculoskeletal Medicine, University of Leeds, Leeds, United Kingdom, [6]Novartis Pharmaceuticals Corporation, East Hanover, NJ, [7]Novartis Pharma AG, Basel, Switzerland.

Background/Purpose: Approximately two-thirds of patients (pts) with psoriatic arthritis (PsA) experience progressive joint damage associated with varying degrees of disability. Here we present the 1-year effect of IL-17A inhibition with secukinumab on radiographic progression in pts with active PsA enrolled in a 2-year, multicenter, randomized, double-blind, placebo (PBO)-controlled, phase 3 trial (FUTURE 1; NCT01392326).

Methods: 606 adults with moderate to severe PsA were randomized to PBO or one of two secukinumab treatment arms: secukinumab 10 mg/kg i.v. followed by 75 mg s.c. (10 IV→75 SC) or 150 mg s.c. (10 IV→150 SC). All pts were assessed for joint response at Week (Wk) 16 (based on ≥ 20% improvement in tender and swollen joint counts). PBO-treated pts were re-randomized to secukinumab 75 or 150 mg s.c. at Wk 16 (non-responders) or Wk 24 (responders). The van der Heijde total modified Sharp scores (mTSS), and erosion and joint space narrowing (JSN) scores were determined at baseline, Wks 16/24 (depending on response) and Wk 52. The effect of secukinumab on radiographic progression from baseline to Wk 24 was evaluated using a non-parametric ANCOVA model, with linear extrapolation for pts who had x-ray assessments at Wk 16. Exploratory analyses assessed the proportion of pts with no structural progression (defined as change from baseline in mTSS ≤ 0.5) and maintenance of this effect over time.

Results: The changes from baseline in mTSS, erosion and JSN scores demonstrated that secukinumab-treated pts had significantly less progression from baseline to Wk 24 compared with PBO-treated pts, regardless of whether pts had received prior therapy with a TNF inhibitor, were on secukinumab monotherapy, or were receiving concomitant methotrexate (MTX; Table). Inhibition of joint structural damage was sustained with secukinumab through Wk 52. Analysis of PBO pts who switched to secukinumab showed a greater mean change from baseline in mTSS for the PBO group from baseline to Wk 24 (mean increase of 0.48) vs. the period from Wk 24 to Wk 52 when pts had been switched to secukinumab (mean decrease of –0.03), providing additional support for efficacy. Analyses of pts who had x-rays at both Wk 16/24 and 52 showed that the proportion of pts who experienced no progression from randomization to Wk 24 vs. the period from Wk 24 to Wk 52 was consistently high in the secukinumab groups: 92.3% vs. 85.8%, respectively, for 10 IV→75 SC and 82.3% vs. 85.7% for 10 IV→150 SC. In pts initially randomized to PBO, 75.7% had no progression from randomization to Wk 24 and this increased to 86.8% for the period from Wk 24 to Wk 52 following active treatment with secukinumab ($P<$ 0.05).

Table

Radiographic progression at Week 24 by treatment group

Week 24 (Mean change from baseline)	Secukinumab 10 mg/kg IV → 75 mg SC n = 202	Secukinumab 10 mg/kg IV → 150 mg SC n = 202	PBO n = 202
mTSS	0.02[†]	0.13[†]	0.57
Erosion score	0.08[†]	0.04[‡]	0.35

Apremilast, an Oral Phosphodiesterase 4 Inhibitor, in Patients with Psoriatic Arthritis: Pharmacodynamic Results of a Phase 3, Randomized, Controlled Trial. Peter Schafer[1], Peng Chen[2], Lorraine Fang[2], Andrew Wang[2] and Rajesh Chopra[1]. [1]Celgene Corporation, Summit, NJ, [2]Celgene Corporation, Warren, NJ.

Background/Purpose: Apremilast (APR) is a phosphodiesterase 4 inhibitor that helps regulate the immune response that causes inflammation and skin disease associated with psoriatic arthritis (PsA). PALACE 1 compared the efficacy and safety of APR with placebo in patients with active PsA despite prior conventional DMARDs and/or biologics. In this phase 3 trial, APR demonstrated significant efficacy, including improvement in signs and symptoms and physical function related to PsA, and demonstrated maintenance of response through Week 52. This exploratory analysis evaluated the pharmacodynamic effects of APR on plasma biomarkers associated with inflammation in a subset of patients.

Methods: Patients were randomized (1:1:1) to receive placebo, APR 20 mg BID (APR20), or APR 30 mg BID (APR30) stratified by baseline DMARD use (yes/no). Peripheral blood plasma samples were collected from consenting patients at baseline and at Weeks 4, 16, 24, and 40 for analysis in a multiplexed cytometric bead array assay measuring 47 proteins (Human Inflammation MAP, Myriad RBM, Austin, TX). The statistical analysis identified significant differences ($P<0.05$; rank ANCOVA) in the percent change from baseline among the treatment groups. Logistic regression analyses assessed the association between the percent change of the biomarkers and the achievement of an ACR20 clinical response.

Results: The biomarker subset included 150 patients (placebo: n=51; APR20: n=51; APR30: n=48). Subjects in the biomarker subset had demographics and disease characteristics comparable with those of the full analysis set, with the exception of prior exposure to a biologic DMARD such as a TNF blocker, which was higher in the biomarker subset (48.8%) than in the full analysis set (23.6%). In the APR20 and APR30 treatment arms, there were significantly lower percent changes from baseline, compared with placebo, for the following markers: at Week 4, interleukin-8 (IL-8), tumor necrosis factor-alpha (TNF-α), and macrophage inflammatory protein beta (MIP-1β); at Week 16, IL-8, TNF-α, IL-6, and ferritin; and at Week 24, IL-8, TNF-α, IL-6, MIP-1β, MCP-1, and ferritin. Logistic regression analyses indicated that clinical responses correlated with the percent changes in TNF-α in the APR20 and APR30 treatment groups. A significant increase in von Willebrand Factor (vWF) was observed at Weeks 16 and 24 (although all vWF values remained within the normal range [<120 μg/mL] and returned to baseline levels by Week 40). After 40 weeks of APR30 treatment, there were significant decreases in IL-17, IL-23, IL-6, and ferritin from baseline levels, and significant increases in IL-10 and IL-1 receptor antagonist from baseline levels.

Conclusion: Treatment with APR for 4 to 24 weeks was associated with significant reductions in circulating levels of IL-8, TNF-α, IL-6, MIP-1β, MCP-1, and ferritin, representing components of pro-inflammatory innate Th1 immunity. After 40 weeks, there was significant inhibition of IL-6, IL-23, and IL-17 on APR30 treatment, suggesting that long-term APR therapy inhibits components of the systemic Th17 immune response in patients with PsA.

Real-World Validation of the Minimal Disease Activity Index in Psoriatic Arthritis: An Analysis from the Prospective, Observational, Biological Treatment Registry Across Canada. Proton Rahman[1], Saeed Shaikh[2], Michael Starr[3], William Bensen[4], Denis Choquette[5], Wojciech Olszynski[6], Maqbool Sheriff[7], Michel Zummer[8], Emmanouil Rampakakis[9], John S. Sampalis[9], Allen J Lehman[10], Susan Otawa[10], Francois Nantel[10], Vincent Letourneau[10] and May Shawi[10]. [1]Memorial University of Newfoundland, St. John's, NF, [2]McMaster University, Hamilton, ON, [3]Montreal General Hospital, Montreal, QC, [4]Division of Rheumatology, McMaster University, Hamilton, ON, [5]Notre Dame Hospital, Montreal, QC, [6]University of Saskatchewan, Saskatoon, SK, [7]Nanaimo Regional General Hospital, Nanaimo, BC, [8]Université de Montréal, Montreal, QC, [9]JSS Medical Research, Montreal, QC, [10]Janssen Inc., Toronto, ON.

Background/Purpose: A definition of minimal disease activity (MDA) in PsA was derived from the opinion of 60 PsA experts including fulfillment of ≥5 of the 7 following criteria: tender joint count (TJC) ≤1, swollen joint count (SJC) ≤1, PASI ≤1 or body surface area ≤3%, pain (VAS) ≤15, patient global disease activity (PtGA) (VAS) ≤20, HAQ ≤0.5, and tender entheseal points ≤1 (1). The aim of this analysis was to describe the rate of MDA achievement over time and to assess the association between MDA achievement and DAS28 remission in PsA patients treated with anti-TNF in a routine clinical practice setting.

Methods: BioTRAC is an ongoing, prospective registry of patients initiating treatment for rheumatoid arthritis (RA), ankylosing spondylitis (AS), or PsA with infliximab or golimumab as first biologics or after having been treated with a biologic for <6 months. Data from PsA patients treated with infliximab (enrolled in 2005–2013) or golimumab (enrolled in 2010–2013) who had available MDA information at baseline, 6 months, and/or 12 months were included. Improvement in patient parameters over time was assessed for statistical significance with the paired-samples t-test. Agreement between MDA and remission as defined by the DAS28 (<2.6) criteria was assessed with the sensitivity, specificity, as well as the positive (PPV) and negative (NPV) predictive value

Results: A total of 123 PsA patients with mean (SD) age of 50.5 (10.5) yrs and mean (SD) duration since diagnosis of 6.1 (7.3) yrs were included in this analysis, providing information from 340 assessments. At the time of enrollment in the registry, mean (SD) patient parameters were: DAS28 =4.2 (1.5), PASI =2.7 (4.8), SJC28 =4.1 (3.5), TJC28 =6.1 (5.6), morning stiffness =45.4 (43.0) min, health assessment questionnaire (HAQ-DI) =1.09 (0.65), physician global assessment of disease activity (MDGA) =5.3 (2.1), patient global assessment of disease activity (PtGA) =49.3 (27.3) mm, and pain =46.5 (25.2) mm. By 6 mos of treatment, statistically significant (P<0.05) improvements were observed in all clinical and patient outcome parameters studied, which were sustained or further enhanced over 12 months of treatment.

The proportion of patients with MDA significantly increased from 12.3% at baseline to 45.0% after 6 months of treatment (P<0.001), and 41.9% at 12 mos (P=0.021). Similarly, DAS28 remission was observed in 15.9%, 47.8% and 45.1% of patients at baseline, 6 mos, and 12 mos, respectively. Using DAS28 as reference standard, sensitivity was 69.8%, specificity 93.0%, NPV 88.2%, and PPV 80.4%.

Conclusion: MDA has high discriminatory power for remission as defined by the DAS28 criteria, while being more rigorous than DAS28. Furthermore, treatment with anti-TNF is effective in inducing MDA in 45% of patients as early as 6 mos from treatment initiation.

Long-Term Evaluation of NT-Probnp Levels in Ankylosing Spondylitis Patients Under TNF Blockers: A Marker of Persistent Disease Activity?

Debora Russo[1], Carla G.S. Saad[2], Ana C.M. Ribeiro[1], Cláudia Goldeinstein-Schainberg[2], Percival D Sampaio-Barros[2], Celio R. Gonçalves[2], Eloisa Bonfá[1] and Julio C. B. Moraes[2]. [1]University of Sao Paulo, Sao Paulo, Brazil, [2]Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil.

Background/Purpose: N-terminal pro-brain natriuretic peptide (NT-proBNP) is a strong marker of cardiovascular risk with recent evidence that short-term inflammation control reduces its levels in ankylosing spondylitis (AS) patients under TNF blockers. There are no data regarding long-term NT-proBNP assessment in AS patients using TNF blockers. Therefore, we evaluated longitudinally NT-proBNP in AS patients pre- and post-long-term TNF blockage therapy and its possible association with sustained disease activity.

Methods: Forty-eight consecutive AS patients (NY criteria) without previous/current cardiovascular disease or systolic myocardial dysfunction in echocardiography, who were eligible to anti-TNF therapy, were prospectively enrolled. All patients received TNF blockers (infliximab, adalimumab or etanercept) and they were evaluated for circulating NT-proBNP levels, clinical and laboratory parameters of disease activity including BASDAI, ASDAS, ESR and CRP, traditional cardiovascular risk factors including blood pressure, body mass index, waist circumference and treatment data at baseline (BL), 12 (12M) and 24 months-after (24M). Statistical analysis included: ANOVA test or Friedman test to observe differences at BL, 12M and 24M evaluations; Mann-Whitney test or t-test to observe differences between patients with inactive/moderate active and high/very high disease activity at 24M; and multivariable linear regression analysis. All analyses used significance level of 0.05.

Results: At BL, all patients had active AS. NT-proBNP levels had a median (IQR) of 23.5(8–53.7) pg/ml and 6.2% had high levels without any evidence of cardiac systolic dysfucntion. Multiple linear regression analysis revealed that this peptide, at BL, was independently correlated with ESR (p=0.003) and pulse pressure (p=0.025). Longitudinal evaluation after 12M and 24M showed that all disease parameters improved (p<0.05) and NT-proBNP levels significantly reduced [19(5–38) pg/mL and 14(5–35) pg/mL respectively, p=0.011]. Of note, NT-proBNP levels were higher in patients with persistent high/very high disease activity (ASDAS-CRP >2.1) at 24M (p<0.001) compared to inactive/ moderate active disease patients (ASDAS-CRP<2.1) at same time. Reinforcing this finding, this difference between these groups was present also at BL (p=0.024) and 12M (p=0.03). Further comparison of BL parameters of patients that persists with ASDAS-CRP >2.1 at 24M identified that these patients are older (44.6±12.7 vs. 35±9.9 years-old, p=0.007), more often female (53.3% vs. 21.2%, p=0.043) and they have higher body mass index (29±5.0 vs. 25.7±4.7 kg/m2, p=0.028), BASDAI (6.6±2.4 vs.5.1±1.9, p=0.02) and ASDAS-ESR (3.9±1.0 vs.3.1±0.9, p=0.006) at BL. Multivariate analysis did not show any independent factor related to higher ASDAS-CRP at 24M.

Conclusion: The novel finding of sustained higher long-term NT-proBNP levels in AS patients with persistent high/very high disease activity during anti-TNF therapy and without systolic alteration suggest that this parameter may reflect longitudinal inflammatory status. (ClinicalTrials.govnumber: NCT01072058).

Background/Purpose: Very longterm data are rarely reported in lupus nephritis (LN) trials, despite their pivotal importance to detect late poor renal outcomers and to identify early prognostic markers. Here we report the 10-year followup of the MAINTAIN Nephritis Trial, a randomized European-based open trial comparing azathioprine (AZA) and mycophenolate mofetil (MMF) as maintenance therapy of proliferative LN.

Methods: 105 patients suffering from Class IV or V LN were randomly assigned to receive AZA or MMF after induction therapy with glucocorticoids and intravenous (IV) cyclophosphamide (CY) (Euro-Lupus protocol; 6 × 500mg fortnightly). The primary endpoint was time to renal flare. After a mean followup of 48 months, we reported that 25 and 19% of patients experienced a renal flare in the AZA and MMF group, respectively (NS) (Houssiau *et al*., ARD 2010). In March 2014, we collected the 10-year data. Survival curves were drawn according to Kaplan-Meier method and statistically tested by logrank test. Other statistical methods were used as appropriate.

Results: Five patients died (3 MMF, 2 AZA), of whom 2 (1 MMF, 1 AZA) had reached ESRD. Two additional MMF patients developed ESRD. Out of the 105 patients, 41 suffered from at least one renal flare, without difference between the two groups (22 AZA, 19 MMF). Proteinuric and nephritic flares were equally distributed between groups. Time to renal flare (all, proteinuric and nephritic) did not differ (p=0.77; p=0.39; p=0.50). Out of the 100 living patients, 13 were lost-to-followup. For the 87 remaining patients, the mean (±SD) followup was 115 (±17) months. Additional IVCY was prescribed in only 17% of the patients, somewhat more frequently in the AZA group, although the difference was not statistically significant (p=0.2). Further use of MMF in the AZA group and further use of AZA in the MMF group occurred in 33 and 26% of the patients, respectively. Patients were classified as good or poor longterm renal outcomers if their creatinine at last followup was ≤120% (n=83) or >120% (n=21) of baseline value, respectively. Interestingly, while their baseline 24-h proteinuria did not differ, patients with good longterm renal outcome had a much lower 24-h proteinuria at 3, 6 and 12 months compared to patients with poor outcome (p<0.0001 by ANOVA). Results were similar if different definitions of poor longterm renal outcome were used (eGFR below 60ml/min/1.72m^{2}BSA, creatinine ≥1.0mg/dl or ≥1.4mg/dl). The positive predictive value of a uP/C ratio <0.5mg/mg at 3, 6 and 12 months for a good longterm renal outcome was excellent (89, 90 and 92%, respectively). By contrast, the negative predictive value was low (21, 29 and 32%, respectively), since many patients without an early proteinuria drop also achieved a good longterm renal outcome.

Conclusion: The longterm followup data of the MAINTAIN Nephritis Trial do not indicate that MMF is superior to AZA for renal flare prevention in a Caucasian population suffering from proliferative LN. Moreover, we

confirm the excellent positive predictive value of an early proteinuria drop for longterm renal outcome.

Background/Purpose: Early data derived from small selected samples suggest that discoid lupus erythematosus (DLE) is negatively associated with renal involvement in patients with SLE. Recent findings from two large transversal studies are controversial, and the prognosis value of DLE on renal disease remains unclear. We used a longitudinal design to examine whether DLE onset protects against the development of LN in patients with systemic lupus erythematosus SLE from a large multiethnic Latin-American cohort.

Methods: We studied SLE patients enrolled in GLADEL, an inception longitudinal cohort from 34 centers in 9 Latin American countries. The main predictor was DLE onset, which was defined as physician-documented DLE that occurred before the diagnosis of SLE. The outcome was time from the diagnosis of SLE to LN during the followup. LN was defined by clinical or histological documentation of lupus glomerulonephritis or renal insufficiency secondary to LN. Kaplan-Meier analysis and Cox proportional hazard models were used to examine the association between DLE onset and time to LN.

Results: We examined 891 GLADEL SLE patients at risk (91% females and 56% non-Caucasians). The mean age at SLE diagnosis and mean duration of follow-up were 30.8 years (SD 12.6) and 4.3 years (SD 2.3), respectively. Overall, 56 patients had DLE onset, and 329 developed LN during the followup. Among the LN group, only 10 (3.0%) had DLE onset, compared to 46 (8.2%) in the group that remained free of LN ($p<0.0023$). The cumulative proportion of LN at 1- and 5-year since SLE diagnosis was 12% and 24%, respectively in the DLE onset group, compared to 23% and 42% in those without DLE ($p<0.0019$) (Figure). Table 1 shows that DLE onset was negatively associated with time-to-LN after controlling for potential confounders. The final predictive model shows that the hazard ratio (HR) of LN in patients with DLE onset was 0.47 (95% CI 0.23–0.96) after controlling sociodemographic factors and disease severity at diagnosis.

Conclusion: Our data from the largest Latin-American SLE cohort indicate that the presence of DLE before the diagnosis of SLE protects against further LN, independently of other contributing factors such as age, ethnicity and SLE severity. These findings have relevant prognosis implications to SLE patients and their clinicians. Further studies are warranted to unravel the biological and environmental pathways implicated in the protective role of DLE against renal disease in patients with SLE.

Allogeneic Mesenchymal Stem Cell Transplantation for Lupus Nephritis Patients Refractory to Conventional Therapy. Dandan Wang, Huayong Zhang, Xuebing Feng and Lingyun Sun. The Affiliated Drum Tower Hospital of Nanjing University Medical School, Nanjing, China.

Background/Purpose: Allogeneic mesenchymal stem cell transplantation (MSCT) has been shown to be clinically efficacious in the treatment of various autoimmune diseases. Here we analyzed the role of allogeneic MSCT to induce renal remission in patients with active and refractory lupus nephritis (LN).

Methods: This is an open-label and single-center clinical trial conducted from 2007 to 2010 in which 81 Chinese patients with active and refractory lupus nephritis were enrolled. Allogeneic bone marrow- or umbilical cord-derived mesenchymal stem cells (MSCs) were administered intravenously at the dose of one million cells per kilogram of bodyweight. All patients were

then monitored over the course of 12 months with periodic follow-up visits to evaluate renal remission, as well as possible adverse events. The primary outcome was complete renal remission (CR) and partial remission (PR) at each follow-up, as well as renal flares. The secondary outcome included renal activity score, total disease activity score, renal function and serologic index.

Results: During the 12-month follow-up, the overall rate of survival was 95% (77/81). Totally 60.5% (49/81) patients achieved renal remission during 12-month visit by MSCT. Eleven of 49 (22.4%) patients experienced renal flare by the end of 12 months after a previous remission. Renal activity evaluated by BILAG scores significantly declined after MSCT (mean±SD, from 4.48±2.60 at baseline to 1.09±0.83 at 12-month), in parallel with the obvious amelioration of renal function. Glomerular filtration rate (GFR) improved significantly 12 months after MSCT (mean±SD, from 58.55±19.16 mL/min to 69.51±27.93 mL/min). Total disease activity evaluated by SLEDAI scores also decreased after treatment (mean±SD, from 13.11±4.20 at baseline to 5.48±2.77 at 12 month). Additionally, the doses of concomitant prednisone and immunosuppressive drugs were tapered. No transplantation-related adverse event was observed.

Conclusion: Allogeneic MSCT resulted in renal remission for active LN patients within 12 months visit, confirming its use as a potential therapy for refractory LN.

Background/Purpose: Improved immunosuppressive therapies have changed the treatment of lupus nephritis (LN) over the past decade. We examined the outcome of LN with current standard of care in an inception cohort of SLE patients.

Methods: An observational study of new onset SLE was performed by an international network of 32 centers. Patients were evaluated at enrollment and annually. LN was identified as "renal disorder" (ACR classification criterion) and/or biopsy confirmation. Data included medications, estimated glomerular filtration rate (eGFR) and proteinuria (ePrU), end-stage renal disease (ESRD), SLE disease activity index-2000 (SLEDAI-2K) and Systemic Lupus International Collaborating Clinics (SLICC)/ACR damage index (SDI). GFR states were defined: state 1 (eGFR: >60 ml/min); state 2 (eGFR: 30–60 mL/min); and state 3 (eGFR: <30 ml/min). Similarly, PrU states were defined: state 1 (ePrU: <0.25 gr/day); state 2 (ePrU: 0.25–3.0 gr/day); and state 3 (ePrU: >3.0 gr/day). HRQoL was determined by SF-36 subscale, mental (MCS) and physical (PCS) component summary scores. Statistical analyses included analysis of variance or equivalent t-tests, Chi-squared test, regression and Kaplan-Meier curves.

Results: Of 1,827 SLE patients, 89% were female, 49.2% Caucasian with mean±SD age 35.1±13.3 years. At enrollment, mean SLE duration was 0.5±0.3 years, SLEDAI-2K was 5.4±5.4, SDI was 0.3±0.7. The mean follow-up was 4.6±3.4 years. LN occurred in 700/1,827 (38.3%) patients: 566 (31%) at enrollment and 134 (7.3%) during follow-up. It was more common in Hispanics (49.3%), African ancestry (39.9%) and Asians (36.8%) compared to Caucasians (20.3%) ($p<0.001$). Renal biopsies from 395 (56.4%) patients revealed ISN classes (%): I: 9 (2.4), II: 36 (9.5), III: 101 (26.8), IV: 163 (43.2), V: 121 (32.1) and VI: 3 (0.8); 21 and 34 biopsies had class III/V and IV/V respectively. At presentation, impaired renal function (eGFR <60 ml/min) occurred in 12.9% and proteinuria (ePrU of >0.25 gr/day) in 55.1% of patients with LN. Medications in LN patients were corticosteroids 651/700 (93%), antimalarials 517/700 (73.9%) and immunosuppressive (cyclophosphamide, azathioprine, mycophenolate mofetil) drugs in 614/700 (87.7%). At final follow-up 113/685 (16.5%) patients with LN had impaired renal function and 417/671 (62.1%) had proteinuria. Following LN the estimated 10 year incidence of ESRD was 10.1% (95%CI: (6.6%, 13.6%)) and there was a higher risk of death (HR=2.98, 95%CI (1.48, 5.99), $p=0.002$). Patients with eGFR <30 ml/min at diagnosis had lower SF-36 PCS scores ($p<0.01$) and lower Physical function, Physical role and Bodily pain scores. Over time, patients with abnormal eGFR and ePrU had lower SF-36 MCS ($p \leq 0.02$) scores compared to patients with normal values.

Conclusion: LN occurred in 38.3% of SLE patients, frequently as the initial presentation, in a large multi-ethnic inception cohort. Despite current standard of care, nephritis was associated with ESRD and death, and renal insufficiency was linked to lower HRQoL. New strategies are required to improve outcomes of lupus nephritis.

A Systematic Review and Network Meta-Analysis of the Risk of Serious Infections with Immunosuppressives for Lupus Nephritis. Jasvinder Singh[1], Alomgir Hossain[2], Ahmed Kotb[2] and George Wells[3]. [1]University of Alabama at Birmingham, Birmingham, AL, [2]University of Ottawa, Ottawa, ON, [3]University of Ottawa Heart Institute, Ottawa, ON.

Background/Purpose: To compare the risk of serious infections of immunosuppressive medications used for the treatment of lupus nephritis.

Methods: We performed an up to date systematic review and network meta-analysis (NMA) by performing an updated search for randomized trails of immunosuppressive medications for lupus nephritis up to September 2013 with the help of Cochrane and ACR librarians. We updated the data from the systematic review for the 2012 ACR lupus nephritis treatment recommendations and the published Cochrane Review on lupus nephritis. We abstracted data related to infections from these trials. Bayesian network meta-analyses (NMA) were conducted. A binomial likelihood model, which allows for the use of multi-arm trials was used. Informed priors were assigned for basic parameters and odds ratios, as well as risk ratios and risk differences, and 95% credible intervals were modeled using Markov chain Monte Carlo methods. Brooks-Gelman-Rubin plots were used to assess model convergence. Model fit was examined using the deviance information criterion (DIC) and the residual deviance. The degree of inconsistency was assessed by comparing statistics for the deviance and deviance information criterion in fitted consistency and inconsistency models. In further sensitivity analyses, fixed effects models and models using vague priors were also conducted.

Results: 31 RCTs with 2, 442 patients provided data. There were twenty-five 2-arm, five 3-arm and one 4-arm trial. We found that tacrolimus was associated with significantly lower risk of serious infections compared to prednisone, cyclophosphamide, mycophenolate mofetil and azathioprine with a risk approximately one-third (**Table 1**). We also found that MMF-AZA (MMF followed by AZA) was associated with significantly lower risk of serious infections as compared to low dose CYC, high dose CYC or high dose prednisone, although this was based on fewer data (**Table 1**). Other differences between immunosuppressives did not reach statistical significance.

Conclusion: Tacrolimus and MMF-AZA combination were associated with lower risk of serious infections serious infections compared to other treatment options for lupus nephritis. These numbers can help patients make informed decisions about treatment options for lupus nephritis.

Table 1 Comparison of various drugs for the risk of infections in patients with lupus nephritis showing statistically significant results

Treatment	Reference	Odds Ratio (95% Credible Interval [CrI])	Relative Risk (95% CrI)	Risk Difference % (95% CrI)

Reduction in Proteinuria and Normalization of C4 Complement Levels Predict Response to Treatment of Lupus Nephritis with Low-Dose Pulse Cyclophosphamide and Abatacept. Sarah Goglin[1], David Wofsy[1], Miriam G. Cisternas[2] and Maria Dall'era[1]. [1]University of California, San Francisco, San Francisco, CA, [2]MGC Data Services, Carlsbad, CA.

Background/Purpose: The response to treatment of lupus nephritis is unpredictable. There is a need to identify clinical and biochemical characteristics that can predict treatment outcome in lupus nephritis. To do this, we utilized data from the Abatacept and Cyclophosphamide Combination: Efficacy and Safety Study (ACCESS) to identify predictors of renal response at 6 months in patients with lupus nephritis.

Methods: 134 subjects with class III or IV lupus nephritis were randomized to low-dose intravenous cyclophosphamide (IVC) or low-dose IVC with abatacept. Renal response was assessed at 24 weeks. Complete renal response (CR) was defined as: urine protein-to-creatinine ratio (UPCR) <0.5; serum creatinine (Cr) normal, or if abnormal, within 25% of baseline; and adherence to steroid taper regimen. Partial renal response (PR) was defined as: $>50\%$ improvement in UPCR; with the same parameters for serum Cr and steroid taper as CR. For the purposes of this analysis, we defined renal response as a composite of CR and PR. We identified possible predictors of renal response, including baseline demographic, clinical, laboratory, and histologic characteristics, as well as clinical and laboratory data obtained within the first 3 months of therapy. We calculated univariate odds ratios (ORs) and 95% confidence intervals (CIs) for renal response for each putative predictor, in the sample as a whole and within each treatment arm. We then conducted a multivariable logistic regression analysis, including all significant predictors (defined as $p<0.05$) from the univariate regressions.

Results: Reduction in proteinuria by at least 25% by week 12 was the strongest predictor of CR or PR at week 24 (OR 8.1; $p<0.05$). Normalization of C4 and normalization of C3 and C4 by week 12 were also predictive of renal response at week 24 (ORs 4.5 and 4.6 respectively; $p<0.05$). Reduction in proteinuria by at least 25% and normalization of C4 remained significant independent predictors in the multivariate analysis (ORs 13.3 and 3.6 respectively; $p<0.05$). This was independent of the treatment arm. None of the baseline characteristics was predictive of renal response.

Conclusion: This study demonstrates that a reduction of at least 25% in proteinuria at 3 months and normalization of C4 levels at 3 months independently predict renal response to therapy with low-dose IVC, with or without abatacept, at 6 months in patients with lupus nephritis. This supports previous findings from the Aspreva Lupus Management Study (ALMS), although reduction in proteinuria was a stronger predictor in this analysis. In contrast to the ALMS analysis, we did not find that time since lupus nephritis diagnosis or baseline eGFR were predictors of renal response. Future studies should address these and other, novel biomarkers so that we can more accurately predict which patients will respond well to treatment.

Skin Collagen Synthesis Rates Distinguish Between Early and Late Diffuse Scleroderma Patients. Claire Emson[1], Martin Decaris[1], Michelle Gatmaitan[1], Flora Luo[1], Dan Holochwost[1], Simplicia FloraCruz[1], Thomas Angel[1], Kelvin Li[1], Marc Hellerstein[1], Fredrick M. Wigley[2], Scott Turner[1] and Francesco Boin[2]. [1]KineMed Inc., Emeryville, CA, [2]Johns Hopkins University School of Medicine, Baltimore, MD.

Background/Purpose: The synthesis and degradation of extracellular matrix (ECM), particularly collagen, is one of the central mechanisms perturbed in scleroderma (SSc). Understanding the kinetics of this process can be of great value to define disease activity during the course of SSc and to develop better tools to assess with precision response to therapeutic interventions.

Methods: Using a stable isotope (deuterium) labeling method and a new kinetic proteomic approach designed to enrich for ECM, we assessed the turnover of collagen in the skin of SSc subjects. Moreover, we pursued the extraction of different collagen pools based on their solubility to measure kinetics of collagen subtypes and other matrix molecules. Three subpopulations were studied: limited (n=6), diffuse early-active (n=5) and diffuse late-stage SSc (n=6). Subjects were given heavy water for 3 weeks prior to a skin biopsy. Protein, lipid and cell kinetics were measured and correlated to gene array and histology from adjacent biopsies.

Results: Total collagen synthesis rates (% new collagen after 3 weeks of labeling) were significantly higher in late-stage diffuse SSc subjects (5.052%±1.953) compared to early-active (1.986%±0.8226; p=0.0031) or normal subjects (2.237%±0.6365; p=0.0031) demonstrating that fibrotic tissue in these subjects undergoes active remodeling. The microarray data showed that the higher collagen synthesis detected in late diffused patients is significantly associated with the expression of genes involved with fibrosis and cell cycle. When compared to total collagen synthesis rates, kinetic analysis of individual collagen pools revealed that the guanidine soluble collagen (corresponding to recently synthetized uncross-linked collagen and immature matrix) represented a greater proportion of the total collagen pool in the late diffuse subjects that have more established fibrosis.

Conclusion: This study shows that cutaneous fibrosis in late-stage SSc is not a static hypodynamic scarring but rather undergoes active remodeling with a pool of newly synthesized, uncross-linked collagen. These data emphasize that the biological processes and pathogenetic networks driving SSc skin involvement likely change over time with the different stages of the disease.

Blockade of TLR4 Signaling By TAK242 Ameliorates Experimental Organ Fibrosis. Swati Bhattacharyya[1], Wenxia Wang[1], Zenshiro Tamaki[1], Yasuhiro Tsukimi[2], Masashi Yamasaki[2] and John Varga[3]. [1]Northwestern University, Feinberg School of Medicine, Chicago, IL, [2]Takeda Pharmaceutical Company Limited, Kanagawa, Japan, [3]Northwestern University Feinberg School of Medicine, Chicago, IL.

Background/Purpose: Our recent studies implicate innate immune signaling through Toll like receptor 4 (TLR4) in scleroderma pathogenesis. Aberrant production and accumulation of the endogenous TLR4 ligand Fn-EDA drives TLR4-dependent persistent fibroblast activation and progressive fibrogenesis in scleroderma. The goal of these studies is to evaluate the antifibrotic potential of pharmacological TLR4 blockade in organ fibrosis.

Methods: For this study, we used TLR4 intracellular signaling inhibitor TAK242. The effect of TAK242 was investigated in normal dermal fibroblasts activated with TLR4 ligands or scleroderma fibroblasts by Western blot analysis, immunofluorescence and real-time qPCR; and in 3-D organotypic human skin equivalents reconstituted with scleroderma fibroblasts. The effect of TLR4 inhibition by TAK242 was examined *in vivo* by local subcutaneous injection of bleomycin (BLM) to induce dermal and pulmonary fibrosis in 6- to 8-week-old female mice (C57BL/6J).

Results: TAK242 treatment ameliorated dermal and pulmonary fibrosis and reduced the expression of pro-inflammatory and pro-fibrotic mediators in the skin of BLM-treated mice compared to vehicle-treated wildtype control mice. Importantly, TAK242 induced the regression of pre-established organ fibrosis. In vitro, TAK242 abrogated TLR4-induced stimulation of collagen synthesis and myofibroblasts differentiation in explanted normal skin fibroblasts, and in constitutively active scleroderma fibroblast populating 3D skin equivalents. The antifibrotic effects of TAK242 were accompanied by reduced activation of TLR4 signaling.

Conclusion: Our results provide evidence that specific TLR4 inhibitor TAK242 attenuates organ fibrogenesis both *in vitro* and *in vivo*. These findings identify TAK242 as a potential novel strategy for breaking the cycle of progressive fibrosis in scleroderma and other fibrotic diseases.

Adiponectin Is an Endogenous Anti-Fibrotic and Target in Systemic Sclerosis: Novel Link Between Fibrosis and Metabolism. Feng Fang[1], Roberta G. Marangoni[1], Xingchun Zhou[2], Wen Hong[2], Boping Ye[2], Asano Yoshihide[3], Shinichi Sato[3], Yuri Masui[3], Chengning Zhang[1], Katja Lakota[1], Jun Wei[1], Monique E. Hinchcliff[1], Philipp Scherer[4], Laszlo Otvos[5] and John Varga[6]. [1]Northwestern University, Feinberg School of Medicine, Chicago, IL, [2]China Pharmaceutical University, Nanjing, China, [3]University of Tokyo, Tokyo, Japan, [4]University of Texas Southwestern Medical Center, Dallas, TX, [5]Temple University, Philadelphia, PA, [6]Northwestern University Feinberg School of Medicine, Chicago, IL.

Background/Purpose: Systemic sclerosis (SSc) skin fibrosis is associated with attenuated cutaneous adipose tissue and adipogenic gene expression. Levels of the adipose-derived cytokine adiponectin (APN) and its receptors, are both reduced in SSc, and inversely correlated with extent of skin involvement. We investigated the role of APN in pathogenesis of skin fibrosis in mice with genetic APN gain- and loss-of-function, and determined the effects, mechanism and therapeutic potential of APN-derived synthetic peptides on the fibrotic process in vitro and in vivo.

Methods: Fibrotic responses were examined in human and mouse fibroblasts, skin organ cultures and 3D skin equivalents. Novel APN-derived peptides targeting APN receptors were designed and synthesized. Genetic and pharmacological manipulation of APN signaling was evaluated in mouse models of scleroderma.

Results: Mice lacking APN developed exaggerated cutaneous fibrosis and intradermal adipose loss upon bleomycin challenge. In contrast, ΔGly-APN mutant mice that have ~2-fold elevated levels of circulating APN were protected from fibrosis, and showed preferential expansion of intradermal adipose tissue. To directly evaluate the role of APN signaling in SSc fibrosis, recombinant APN, as well as synthetic APN-derived peptides were used. APN treatment of skin fibroblasts resulted in suppression of collagen synthesis, myofibroblast transformation and other fibrotic responses that were mediated via the energy-sensing enzyme AMP kinase. Synthetic APN-derived peptides targeting the APN receptors abrogated fibrotic responses in explanted fibroblasts, skin organ cultures and in 3D human skin equivalents. Daily treatment of mice with APN-derived peptides induced potent activation of AMP kinase in target organs in the absence of toxicity. Significantly, peptide treatment prevented, as well as reversed, bleomycin-induced cutaneous fibrosis.

Conclusion: We identified an important homeostatic role for the adipocyte-derived cytokine APN in negative regulation of collagen deposition and myofibroblast accumulation, highlighting a novel link between metabolism and skin fibrosis. Restoring impaired APN signaling in SSc (scleroderma) using synthetic APN-derived peptides might therefore represent a pharmacological approach to fibrosis therapy.

Mir-145 Protects Against Skin Fibrosis *in Vivo* by targeting TGF-β Signaling. Serena Vettori[1], Christian Beyer[2], Matthias Brock[1], Naoki Iwamoto[1], Britta Maurer[1], Michelle Trenkmann[1], Astrid Jüngel[1], Renate E. Gay[1], Maurizio Calcagni[3], Gabriele Valentini[4], Steffen Gay[1], Joerg H. W. Distler[2] and Oliver Distler[1]. [1]Zurich University Hospital, Zurich, Switzerland, [2]Department of Internal Medicine III and Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany, [3]Division of Plastic Surgery and Hand Surgery, University Hospital Zurich, Zurich, Switzerland, [4]Second University of Naples, Napoli, Italy.

Background/Purpose: *In vitro*, miR-145 exerts anti-fibrotic effects in systemic sclerosis (SSc) by downregulating TGF-β signaling. In turn, ectopic TGF-β downregulates miR-145 thereby optimizing TGF-β signaling pathways. In this study, we aimed to investigate whether therapeutic application of miR-145 could prevent fibrosis *via* regulation of TGF-β *in vivo*.

Methods: We used miR-145$^{-/-}$ (n=7–8), and mouse models of dermal fibrosis induced by either bleomycin (n = 6) or by adenoviral overexpression

of constitutively active TGF-β receptor type I (n = 3). MiR-145$^{-/-}$ mice and wild type controls were also treated with intradermal bleomycin, while a subset of bleomycin-induced dermal fibrosis mice were simultaneously treated with intradermal injections of a synthetic miR-145 designed for *in vivo* transfection. Dermal thickness, myofibroblast count (α-SMA staining on paraffin-embedded skin sections), and collagen content (hydroxyproline assay), were analyzed as outcomes of skin fibrosis. The expression of miR-145 and of miR-145 targets, TGFBR2 and SMAD3, was analyzed in mice treated with the synthetic miR-145 and in the mouse model of skin fibrosis induced by the constitutive activation of TGF-β receptor type I by real-time PCR.

Results: We found that miR-145$^{-/-}$ mice were more sensitive to the effects of bleomycin than wild type controls, as shown by a stronger increase of dermal thickness (2.04 versus 1.7 fold), α-SMA count (4.4 versus 3), and collagen content (1.82 versus 1.34; all $p < 0.01$). According to the anti-fibrotic effects shown by miR-145 *in vitro*, we expected to counteract bleomycin effects in C57BL/6 mice by the simultaneous administration of synthetic miR-145. Indeed, all explored outcomes improved in these mice, as compared to controls injected with a synthetic miR-scrambled: dermal thickness reduced from 1.7 to 1.27 fold, α-SMA count from 3.7 to 1.9, collagen content from 3.6 to 2.9; all $p < 0.01$. MiR-145 expression in mice injected with the synthetic miR-145 increased by 37 fold ($p < 0.01$) confirming the efficiency of the *in vivo* transfection. Accordingly, the downregulation of the previously identified direct miR-145 targets, TGFBR2 and SMAD3, by 0.21 and 0.10 fold ($p < 0.05$) supports the hypothesis that the anti-fibrotic effects of miR-145 are mediated by the downregulation of these TGF-β signaling components. Finally, in mice overexpressing constitutively active TGF-β receptor type I, miR-145 was strongly down-regulated by 0.55 fold in fibrotic skin as compared to mock-transfected controls, confirming the existence of a regulatory feedback loop between miR-145 and TGF-β *in vivo* and further proofing the relevance of the miR-145/TGF-β interaction *in vivo*.

Conclusion: Here we show for the first time that the therapeutic application of miR-145 protects against skin fibrosis *in vivo*, thus opening the road to new therapeutic targeted approaches to SSc and other fibrotic disorders. We also confirm on the *in vivo* level, that the anti-fibrotic effects of miR-145 are mediated by the downregulation of the TGF-β signaling components TGFBR2 and SMAD3, and that the abnormal miR-145 expression that is observed in SSc is dependent, at least in part, on activation of TGF-β.

Priming of WNT Signalling during Fibrosis Is Mediated By TGF-β Induced Axin-2 Downregulation. Justin Gillespie[1], Emma C. Derrett-Smith[2], Michael McDermott[1], Paul Emery[3], Christopher P Denton[2] and Francesco Del Galdo[3]. [1]Leeds Institute of Rheumatic and Musculoskeletal Medicine, University of Leeds, Leeds, United Kingdom, [2]UCL Medical School Royal Free Campus, London, United Kingdom, [3]Leeds Institute of Rheumatic and Musculoskeletal Medicine, University of Leeds and NIHR Leeds Musculoskeletal Biomedical Research Unit, Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom.

Background/Purpose: Systemic Sclerosis (SSc) is characterized by autoimmune activation, vasculopathy and tissue fibrosis. Recently, activation of the Wnt/β-catenin signaling pathway in SSc fibroblasts has been linked to the pathogenesis of SSc. However, the relative role of crosstalk between TGF-β and Wnt Pathways in SSc is still to be determined. Here we have aimed to evaluate the Wnt pathway in SSc fibroblasts and the effects of TGF-β on canonical Wnt signalling.

Methods: Dermal fibroblasts from 3 early diffuse cutaneous (dc)-SSc patients and 3 healthy controls (HC) were stimulated with recombinant human (rh)TGF-β and/or rhWnt-3a. mRNA stability was investigated using actimomycin D. mRNA levels were quantified by qRT-PCR and protein expression was measured by western blotting or immunohistochemistry. Canonical Wnt signaling was evaluated by TOPFlash luciferase reporter activity. *In- vivo*expression studies were performed on TGF-β-RII DeltaK transgenic mice, which have constitutive activation of the TGF-β pathway in fibroblasts, and wild-type littermates.

Results: In basal conditions, SSc fibroblasts did not show any increase in TOPFlash reporter activity compared to HC. On the contrary, the expression of *Axin2*, a Wnt target gene and negative regulator of the Wnt pathway, was reduced at both mRNA (58%; $P<0.01$) and protein levels. Indeed, SSc fibroblasts had an increased response to rhWnt-3a compared to HC fibroblasts (11.6 fold increase in TOPFlash activity and 2.5 fold in *Axin-2*mRNA vs. 4.2 and 1.8 fold, respectively, in HC). TGF-β treatment of HC fibroblasts decreased Axin-2 expression to levels similar to SSc fibroblasts, both at mRNA (38.7%; [$p<0.001$]) and protein levels. This effect was associated with a 3.7 fold increase in mRNA decay. Concordantly, TGF-β-RII DeltaK transgenic mice displayed a reduced expression of Axin-2 in the dermis. Similar to SSc, pretreatment of HC fibroblasts with TGF-β increased their responsiveness to Wnt-3a (16.1 vs. 7.7 fold increase in TOPFlash activity; $P<0.01$). Depletion of Axin-2 by siRNA was sufficient to mimic the effect of TGF-β pretreatment ($P<0.05$). Accordingly, XAV939-mediated Axin-2 stabilization ablated the Wnt-3a-induced canonical hyperactivation in 'TGF-β primed' fibroblasts.

Conclusion: TGF-β stimulation primes dermal fibroblasts to increase their responsiveness to Wnt ligand-induced canonical signaling. TGF-β mediates the downregualtion of Axin-2, which is required for canonical Wnt signaling hyperactivation in dermal fibroblasts. Our data suggest that the increased Wnt signaling observed in SSc is a consequence of TGF-β signaling and therefore targeting of the TGF-β pathway may also help to resolve the aberrant Wnt signaling observed in SSc.

Caspase-8 Prevents Lung Fibrosis in a Murine SSc-like Disease Model By Preventing Macrophage Differentiation. Alexander Misharin[1], Carla M. Cuda[2], Luisa Morales-Nebreda[3], Gokhan Mutlu[1], GR Scott Budinger[3] and Harris R. Perlman[2]. [1]Northwestern University, Chicago, IL, [2]Northwestern University Feinberg School of Medicine, Chicago, IL, [3]Northwestern University, Feinberg School of Medicine, Chicago, IL.

Background/Purpose: Pulmonary fibrosis has emerged as the leading cause of death in patients with Systemic Sclerosis (SSc). Currently available therapies are only marginally effective in treating this devastating complication and even patients who respond to therapy are left with significant respiratory morbidity. Alternatively activated M2 macrophages have been demonstrated to be the key players in development of pulmonary fibrosis. Caspase-8 is a cysteine-aspartic acid protease was originally identified as a key initiator of the apoptotic death receptor pathway and was later found to suppress programmed necrotic cell death (necroptosis) by inhibiting the receptor-interacting serine/threonine kinase 1/3 (RIPK1/3). We have previously shown that mice deficient in caspase-8 specifically in macrophages and DCs have markedly less lung fibrosis than their littermate controls following intratracheal treatment with either bleomycin or an adenovirus encoding an active form of TGF-β. We now examined specific mechanisms, responsible for this protection.

Methods: Mice lacking caspase-8 specifically in DCs or macrophages were generated ($Cre^{CD11c}Casp8^{flox/flox}$ and $Cre^{LysM}Casp8^{flox/flox}$) and examined using the bleomycin and adenoviral TGF-β models of lung fibrosis. Flow cytometric analysis was used to characterize macrophages and DC. Luminex-based QuantiGene assay was used to determine gene expression profiles and polarization of FACS-sorted macrophages.

Results: We found that in the wild type mice, monocytes, recruited into the lung from the bone marrow after instillation of bleomycin, transition through the interstitial macrophage phase into alveolar macrophages, which are virtually indistinguishable from tissue-resident alveolar macrophages. However, unlike the tissue-resident macrophages, which do not exhibit profibrotic M2 phenotype, these bone marrow-derived alveolar macrophages were M2-polarized. Mice, deficient for caspase-8 in macrophages had similar number of interstitial macrophages to WT mice, but were lacking profibrotic M2 bone marrow-derived alveolar macrophages. Moreover, expression *Pparg*, *Tgm2*, *Shpk* and *Mertk*, which are important for mature alveolar macrophage phenotype, was decreased in Caspase-8-deficient bone marrow-derived alveolar macrophages.

Conclusion: Our data identified bone marrow-derived alveolar macrophages and not interstitial macrophages or tissue-resident alveolar macrophages as key players and perspective target for pulmonary fibrosis in patients

with scleroderma. Moreover, these data reveals a novel role for Caspase-8 in macrophage differentiation and polarization.

Risk of Developing Antiphospholipid Syndrome Following Infection: A Systematic Review and Meta-Analysis of Observational Studies. Noha Abdel-Wahab[1], Maria A. Lopez-Olivo[1], Saurabh Talathi[2] and Maria E. Suarez-Almazor[1]. [1]The University of Texas, MD Anderson Cancer Center, Houston, TX, [2]The University of Texas Health Science Center at Houston, School of Public Health, Houston, TX.

Background/Purpose: Infection has been increasingly reported in the literature as an environmental trigger inducing the development of anti-phospholipid antibodies or antiphospholipid syndrome in genetically predisposed individuals. We conducted a systematic review and meta-analysis of observational studies to evaluate the risk of developing positive antiphospholipid (aPL) antibodies following infection compared to controls and determine whether these antibodies are associated with any clinical consequences.

Methods: We conducted a literature search using Medline, EMBASE, Web of Science, and the Cochrane CENTRAL databases with no language restriction to identify observational studies reporting on patients who develop positive aPL antibodies after infection from inception up to October 2013. Two independent reviewers assessed the studies for inclusion and for quality, and extracted relevant data. We extracted data on the related infection, profile and prevalence of aPL antibody, and patient clinical outcomes. We performed a meta-analysis and estimated relative risks (RR) with 95% confidence intervals (CI) of developing antibodies after an infection compared to controls

Results: From 2,257 unique citations, 320 publications met our inclusion criteria; from these, we selected 216 studies with controls to estimate risk. The most commonly reported infections were viral and bacterial. Compared to controls, patients with an infection were 10.9 times more likely to develop positive IgG anticardiolipin (aCL) antibodies after the infection (95% confidence Intervals (CI) 5.6–21.2). The highest risk ratio (RR) was observed after infection with tuberculosis (47.5; 95% CI 3.0–753.8), Q fever (44.0; 95% CI 2.8–702.5), and Hepatitis C virus infection (21.4; 95% CI 3.6–127.1). After an infection with Epstein Bar virus individuals were 33 times more likely to develop positive IgM aCL (95%CI 1.9–586.2) compared to controls. The RRs for developing lupus anticoagulant or and anti-β2 glycoprotein-I (GPI) antibodies were 2.4 (95% CI 1.3–4.5), and 2.3 (95%CI 1.2–4.4), respectively. For studies without controls (104), the pooled incidence of positive IgG aCL after infection was 36% (95% CI 27%-45%). The highest incidence was found in individuals with human immunodeficiency virus (HIV) (51%; 95% CI 38%-63%). Development of clinical manifestations of aPL syndrome was reported in 52.3% of the included studies. The most common manifestations were thromboembolic events or pregnancy related complications, occurring in 23.1% of individuals.

Conclusion: Various viral and bacterial infections can frequently induce the development of aPL antibodies, and can cause thromboembolic manifestations fulfilling the diagnosis of APS.

The Long-Term Efficacy of an Anti-Pneumococcal Polysaccharide Vaccine (PPSV23, Pneumovax) Among Autoimmune Inflammatory Rheumatic Patients. Adi Broyde[1], Uri Arad[2], Noa Madar-Balakinski[2], Daphna Paran[3], Ilana Kaufman[4], Ira Litinsky[5], David Levartovsky[6], Irena Wigler[2], Dan Caspi[7] and Ori Elkayam[8]. [1]Tel Aviv medical center, Tel Aviv, Israel, [2]Tel Aviv Sourasky Medical Center and the Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel, [3]Tel-Aviv Medical Center, Sackler Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Israel, [4]Tel Aviv Sourasky Medical Center and the Sackler Faculty of Medicine, Tel Aviv University, Tel-aviv, Israel, [5]Tel Aviv Sourasky Medical Ctr, Tel-Aviv University, Tel Aviv, Israel, [6]Department of rheumatology. Tel Aviv Medical Center, Tel Aviv, Israel, [7]Tel Aviv Sourasky Medical Center, Tel Aviv, Israel, [8]Tel-Aviv Medical Center, Sackler Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Israel.

Background/Purpose: Vaccination with Pneumovax is recommended for adult patients with auto-immune inflammatory rheumatic diseases (AIIRD). Re-vaccination is recommended after 5 years in this population although reports on the long term efficacy of the vaccine are scarce.The objective of this study was to estimate the long term efficacy of anti-pneumococcal vaccine (PNEUMOVAX) using the surrogate marker of humoral response in patients with AIIRD on immune-suppressing therapy and the effect of clinical and demographic factors as well as treatment on the long term efficacy of the vaccine.

Methods: One hundred and forty five consecutive AIIRD patients (rheumatoid arthritis (RA) (48.5%), psoriatic arthritis (PsA) (22.3%), ankylosing spondylitis (AS) (21/5%), and IBD associated arthritis) (2.3%), (mean age 54.6, 61/5% women) treated with biologic therapy (TNF α or Il-6 receptor inhibitors) or Methotrexate (MTX) participated in this study. Data including the day of vaccination, demographic, clinical charasteristics and treatment was collected. Blood samples were drawn from each patient and tested for anti-pnemococcal antibody level

Results: 67.7% had received PNEUMOVAX, with a mean time from vaccination of 45 months. Treatment included TNF α inhibitors (73.9%), Il-6 receptor inhibitors (13.1%), or MTX without a biological treatment. (13%). The uptake of vaccination was significantly higher in the elderly population (>65 y). Vaccinated patients had significantly higher antibody levels compared with unvaccinated patients. After 10 years, we did not observe a decrease in the antibody levels. The use of MTX was associated with significant lower antibody levels whereas biologics – both TNF α blockers and tocilizumab-and low dose steroids showed not such tendency.

Conclusion: The long term efficacy of Pneumovax vaccination seems to be preserved among AIIRD patients for at least 10 years and its long term effect is not affected by the use of biologics while MTX might slightly impair it.. The actual recommendation for revaccination after 5 years should be reconsidered.

Racial, Gender and Geographic Differences in Systemic Lupus Erythematous and Lupus Nephritis Mortality Rates in the Unites States, 1968–2010. Eric Y Yen[1], Magda Shaheen[2], Jennifer MP Woo[1], Deborah K. McCurdy[1] and Ram Raj Singh[3]. [1]UCLA Division of Pediatric Rheumatology, Los Angeles, CA, [2]Charles R. Drew University of Medicine and Science, Los Angeles, CA, [3]UCLA Division of Rheumatology, Los Angeles, CA.

Title: Racial, Gender and Geographic Differences in Systemic Lupus Erythematous and Lupus Nephritis Mortality Rates in the Unites States, 1968–2010

Background/Purpose: Many epidemiologic studies of systemic lupus erythematosus (SLE) mortality in the United States (US) utilize patient registries that are regional and may not be applicable to the general population. Our approach is to analyze comprehensive mortality data in the US over the past 43 years. We aimed to determine the variation of SLE and lupus nephritis (LN) mortality by race, gender, and geographic location.

Methods: Using county-level national mortality data from the National Center for Health Statistics from the period of 1968–2010 divided into 3 cohorts based on International Classification of Diseases periods for version 8 (1968–1978), 9 (1979–1998) and 10 (1999–2010), we estimated age-adjusted morality rates (AMR) per 100,000 persons and stratified results by gender, race, and geographic locations. We selected cases where the underlying cause of death was SLE (734.1, 710.0, M32) and further identified LN cases to include glomerular disease and renal failure.

Results: Of the 93,245,807 death records reviewed, we identified 46,786 cases of SLE. AMR-SLE were 3–5-fold higher in females than in males: 0.628 (95% CI 0.613–0.644), 0.748 (95% CI 0.737–0.759), and 0.700 (95% CI 0.688–0.712) among females; and 0.162 (95% CI 0.154–0.170), 0.176 (95% CI 0.170–0.182) and 0.134 (95% CI 0.128–0.140) among males for the periods of 1968–1978, 1979–1998, and 1999–2010 respectively. Intriguingly, while the AMR-SLE decreased among white males (from 0.149 in 1968–1978 to 0.107 in 1999–2010, $p<0.0001$) and remained stable among white females (0.496 to 0.499, $p=0.7$) over the last 43 years, it increased among black females and males (1.601 to 1.959 in females, $p<0.0001$; and 0.270 to 0.335 in males, $p=0.004$). Thus, black females had ~6-fold higher AMR-SLE than black males and ~10–18-fold higher than white males. To test whether differences in LN, a severe common manifestation of SLE, contributed to these differences, we analyzed mortality trends among 3,307 deaths (1999–2010) ascribed to LN. Black females had the highest AMR-LN at 0.473 (95% CI 0.445–0.501), which was ~5-fold higher than AMR-LN in black males and white females and 36-fold higher than in white males. Analyses of regional differences in AMR-LN showed even more dramatic racial trends, with black females living in the South census region with the highest AMR-LN of 0.507 (95% CI 0.468–0.547) and white males living in the Northeast census region with the lowest AMR-LN of 0.006, a 85-fold difference. While no regional differences in AMR-LN were observed for black males, AMR-LN was higher in the South than in the Northeast for white males, white females, and black females.

Conclusion: Overall SLE mortality has not substantially decreased from the 1968–1978 to the 1999–2010 periods, except in white males. In fact, SLE mortality has increased ~1.2-fold in blacks. Black females experience up to 18-fold higher mortality than white males. Increased deaths ascribed to LN in black females, particularly in southern states, might account for the profound racial differences in SLE outcome.

Relation of Pelvic Drop during Walking to Risk of Incident Medial Knee Osteoarthritis: The Multicenter Osteoarthritis Study. K. Douglas Gross[1], Emily K. Quinn[2], Michael C. Nevitt[3], James C. Torner[4], Cora E. Lewis[5] and David T. Felson[1]. [1]Boston University School of Medicine, Boston, MA, [2]Boston University, Boston, MA, [3]UCSF (University of California, San Francisco), San Francisco, CA, [4]University of Iowa, Iowa City, Iowa City, IA, [5]The University of Alabama at Birmingham, Birmingham, AL.

Background/Purpose: During walking, the contralateral pelvis tends to drop as the weight bearing limb enters midstance. If excessive, pelvic drop (PD) can result in increased loading of the medial knee. We previously reported an increased prevalence of medial knee OA in persons with greater PD, but while some rehabilitation strategies target reduction of PD in hopes of preventing knee OA onset, it is not yet known whether PD is actually a cause or a consequence of medial knee disease. The purpose of this longitudinal case-control study was to assess the causal relation of PD to 2-year risk of incident medial knee OA. We also determined the effect of trunk lean on this relationship.

Methods: The Multicenter Osteoarthritis Study (MOST) consists of middle aged and older adults living in Iowa or Alabama that have or are at risk of knee OA. Among knees with no medial OA at the 60-month exam, readers identified incident cases at 84 months as having Kellgren & Lawrence grade ≥ 2 with medial $>$ lateral joint space narrowing (0–3 scale) on fixed flexion knee x-ray (kappa > 0.80). Two control knees per case were randomly selected (1 per subject), and cases and controls underwent video assessment of PD during walking at the 60-month visit. Using synchronized frontal and sagittal cameras (60 Hz) and surface markers on the anterior superior iliac spines (ASISs), a physical therapist measured mean PD and mean trunk lean during the midstance phase of a mid-trial step over two self-paced walking trials. PD was measured as the frontal angle between the horizontal and a line joining left and right ASIS markers (ICC= 0.93), while trunk lean was measured as the frontal angle between the horizontal and a line joining left and right acromion processes (ICC= 0.98). Quartiles of PD were formed using the sex-specific distribution among cases, and logistic regression estimated the relative odds of incident medial knee OA in each quartile while controlling for covariates. Analysis was repeated within strata of ipsilateral ($\leq -0.1°$), neutral (0.0° to 6.4°), and contralateral ($\geq 6.5°$) trunk lean.

Results: 199 subjects contributed 64 case and 135 control knees. Mean +/− sd age, BMI, and walking speed was 66.8 +/− 8.3 yrs, 29.4 +/− 5.0 kg/m^2, and 1.18 +/− 0.17 m/sec, respectively. 60.3% were female, 85.4% were white, and 48.2% were seen in Alabama. Mean +/− sd PD was slightly greater in women, but comparable among case and control knees (2.5° +/− 2.6° vs. 2.3° +/− 2.8°, p= 0.66). Relative odds of incident medial knee OA did not change across PD quartiles (p trend = 0.89), and trunk lean did not modify the results (p = 0.92).

Conclusion: These findings do not confirm a longitudinal association between pelvic drop during walking and 2-year risk of incident medial knee OA. Previous reports of a cross-sectional association could indicate that pelvic drop is a frequent consequence of existing medial knee OA rather than an antecedent cause of incident knee disease.

Table. Relative Odds of Incident Medial Knee OA in Categories of Increasing Pelvic Drop During Walking

Pelvic Drop During Walking (sex-specific case-based quartiles)	Cases N = 64 n (%)	Controls N = 135 n (%)	Adj* Odds Ratio (95% CI)
Least Pelvic Drop (−3.9°, 1.0° men; −6.5°, 1.1° women)	15 (34.1%)	29 (65.9%)	1.0 (Reference)
2nd (1.1°, 1.9° men; 1.2°, 2.7° women)	16 (30.2%)	37 (69.8%)	0.8 (0.3, 1.9)
3rd (2.0°, 3.4° men; 2.8°, 3.9° women)	17 (33.3%)	34 (66.7%)	1.0 (0.4, 2.4)
Most Pelvic Drop (3.5°, 9.4° men; 4.0°, 10.2° women)	16 (31.4%)	35 (68.6%)	1.0 (0.4, 2.4)

* Adjusted for age, sex, BMI, race, clinic site, and walking velocity.

Obesity Paradox in Osteoarthritis Progression – What Effects Are We Measuring? Qiong Louie-Gao[1], Hyon K Choi[1], David T. Felson[2], Tuhina Neogi[1], Uyen Sa D.T. Nguyen[1], Na Lu[1] and Yuqing Zhang[1]. [1]Boston University School of Medicine, Boston, MA, [2]University of Manchester, Manchester, United Kingdom.

Background/Purpose: While obesity is a well-established risk factor for incident knee osteoarthritis (OA), it has a null association with OA progression. Among various potential explanations for such a paradox, one is a lack of precision in the research question. While investigators are interested in the total effect of BMI on OA progression among OA patients, most studies have instead measured a direct effect of BMI in the general population (Figure). This is because in these studies, data on BMI were assessed prior to OA diagnosis, or BMI measured after OA diagnosis has remained mostly unchanged compared with that prior to OA incidence. We have demonstrated this potential mechanism underlying the paradoxical findings of BMI in OA progression by decomposing its effect components (Figure) using mediation analyses.

Methods: Knee radiographs were taken at baseline and each annual follow-up visit, and severity of knee radiographic OA was assessed using Kellgren/Lawrence (KL) criteria among participants in the Osteoarthritis Initiative. We identified subjects who had no OA on either knee at baseline (i.e., KL <2) and used KL scores measured at 24-month and 36-month visits to assess radiographic OA progression. Baseline BMI was categorized as: <25, 25 –29.9 (i.e., overweight), and ≥ 30 kg/m^2 (i.e., obese). We first assessed the total effect of BMI on KL grade worsening at Month 36 (Figure). We then decomposed the effect into the indirect effect of BMI (i.e., the pathway through its effect on KL grade at Month 24) and the direct effect (i.e., the pathway not through its effect on KL grade at Month 24) (Figure), using marginal structural model mediation analyses. All analyses were adjusted for age, sex, knee injury, and education.

Results: Of 1930 subjects without knee OA on either knee (56% women, mean age 59 years) at baseline, 186 knees developed OA (e.g., 144 with KL=2, 41 with KL=3, and 1 with total knee replacement therapy) over 36 months. Compared with those with BMI <25, overweight and obese subjects had a 1.40 (95% CI: 1.13–1.73) and 1.95-fold (1.54–2.46) increased risk of KL grade worsening, respectively, after adjusting for potential confounders. Conditioning on the KL grade at Month 24, the indirect effects of being overweight and obese on OA progression were 1.38 (95% CI: 1.35–1.42) and 1.80 (1.75–1.86), respectively; however, the corresponding direct effects were 1.02 (0.81–1.29) and 1.10 (0.86–1.41), indicating that the effect of BMI on OA progression at Month 36 is entirely through its effect on OA progression at Month 24.

Conclusion: Our findings demonstrate that the paradoxical findings of BMI on the risk of OA incidence and OA progression are due to a mismatch between an intended total effect of BMI on OA and its direct effect in the

general population. To obtain the intended total effect of BMI on OA progression, one could use the change in BMI after OA diagnosis as an exposure for the outcome of OA progression.

Figure

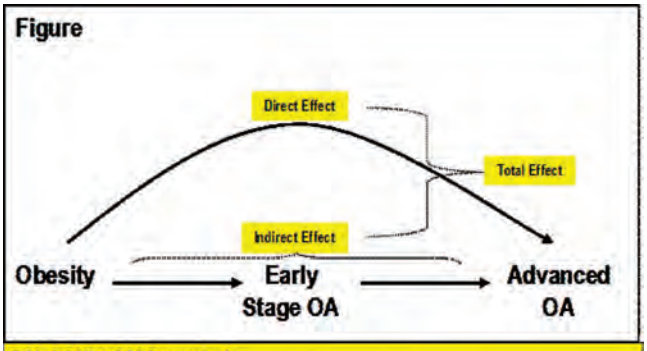

Table 1. BMI and OA Progression*

BMI	Baseline	Month 24	Month 36	Total effect	Direct effect	Indirect effect
< 25	1362	13(0.95%)	35(2.57%)	1.00	1.00	1.00
25-29.9	1540	54(3.51%)	81(5.26%)	1.40(1.13,1.73)	1.02(0.81,1.29)	1.38(1.35,1.42)
≥ 30	958	52(5.43%)	70(7.31%)	1.95(1.54,2.46)	1.10(0.86,1.41)	1.80(1.75,1.86)

Chronic Pain Predicts Reduced Physical Activity in a Large Population Cohort Study. Kathryn Remmes Martin, Marcus Beasley, Gary J. Macfarlane and Daniel Whibley. University of Aberdeen, Aberdeen, United Kingdom.

Background/Purpose: Chronic musculoskeletal pain (CP) is associated with reduced levels of physical activity (PA), however few studies have examined the prospective nature of CP on PA at the population level. The aim of this study is to examine whether CP independently predicts a reduction in PA.

Methods: Data are from the UK Biobank, a large prospective cohort designed to support investigation of risk factors for major diseases of middle and old age. More than 500,000 men and women aged 40–69 were recruited between 2006–2010 (baseline); approximately 20,000 repeat assessments were conducted between 2012–2013 (follow-up). Participants answered questions on health and lifestyle by touch-screen questionnaire. CP is defined as self-reported pain lasting at least three months either all over the body or related to the neck or shoulder, back, abdomen, hip or knee, as well as facial pain or headache. Questions on PA and sedentary behaviour were asked using a modified short-form of the International Physical Activity Questionnaire at baseline and follow-up. PA was categorized as low, moderate or high according to frequency/duration of moderate and vigorous activity; PA change was calculated and dichotomized into same or improved activity category or worsened activity category. Hours spent watching TV and in non-work computer use were combined to estimate time in sedentary behaviour. Descriptive, linear and logistic regression analyses were conducted on 14,391 men and women with complete data on a priori covariates (age, gender, ethnicity, highest educational attainment, work status at follow-up, change in BMI status, baseline self-rated health, self-reported depression at follow-up and time-to-follow-up).

Results: Mean length of follow-up was 4 years (range 2.1–6.5). 5,567 participants (39%) had CP at baseline. Of those without CP at baseline, 20% (n=1,793) had developed it at follow-up. At baseline, fewer individuals with CP were categorized with moderate or high levels of PA (χ^2=12.5, p=0.002). Overall, the majority of participants maintained the same PA category, while 21% had an improved activity classification and 20% had a worsened activity classification. Individuals with CP at baseline were more likely to deteriorate in activity status, than those without, who were more likely to stay the same or improve activity status (χ^2=9.2, p=0.002). This relationship remained in multivariate logistic regression after adjustment for covariates, with baseline CP predicting a negative change in PA category (OR: 1.13; 95% CI: 1.04–1.23). Individuals with CP spent more time in sedentary behaviour than those without CP (B=0.07, 95% CI: 0.01–0.13) in linear regression analysis adjusted for covariates and baseline sedentary behaviour.

Conclusion: CP predicts a negative change in PA over an average four-year follow-up period. Given the prevalence and persistence of CP, attention should be given to supporting and encouraging physical activity so as to prevent deterioration of PA levels and the spiral of pain-related inactivity within middle-age and early old age adults with CP.

Measurement Properties of the Health Assessment Questionnaire Disability Index (HAQ-DI) in Patients with Generalized Osteoarthritis (GOA). Nienke Cuperus[1], Elien A.M. Mahler[1], Thea Vliet Vlieland[2], Thomas Hoogeboom[3] and Cornelia H.M. van den Ende[1]. [1]Sint Maartenskliniek, Nijmegen, Netherlands, [2]Leiden University Medical Center, Leiden, Netherlands, [3]CAPHRI school for public health and primary care, CCTR centre for Care Technology Research, Maastricht University, Maastricht, Netherlands.

Background/Purpose: The involvement of multiple joints is common in osteoarthritis (OA), often referred to as generalized OA (GOA). Individuals with GOA typically suffer from limitations of both upper and lower extremity function. However, existing instruments measuring functional limitations in OA focus on a specific localization; limiting their use in GOA. We hypothesized the Health Assessment Questionnaire Disability Index (HAQ-DI), originally developed for inflammatory arthritis, to be appropriate to measure functional limitations in GOA. Therefore we evaluated the measurement properties (content validity, construct validity and reliability) of the HAQ-DI in patients with GOA.

Methods: Data were used from a randomized clinical trial comparing the effectiveness of two multidisciplinary treatment program for patients with GOA. 137 patients completed a standardized set of questionnaires before and directly after treatment. The measurement properties of the HAQ-DI were assessed according the Consensus Based Standards for the Selection of health Status Measurement Instruments Checklist. Floor and ceiling effects for each HAQ-DI category at baseline were considered present if >15% of patients scored the worst (3) or best (0) possible score. For the content validity, 17 health professionals experienced with GOA were asked to judge the relevance of each HAQ-DI item. Construct validity was assessed by computing associations (Pearson r) between HAQ-DI scores and scores on other clinical (un)related measures. Reliability was assessed by Cronbach's alpha and intra-class correlation coefficient (ICC). The minimal important change (MIC) score was calculated using an anchor based method.

Results: Of 137 patients (mean age 60(SD 8) years; (85%) female), 93% reported to have complaints in both the upper and lower extremities. Floor and ceiling effects were present: 20%-30% of patients reported the best possible score on the HAQ-DI categories eating, dressing and gripping; 16% reported the worst possible score on the category hygiene. The content validity was questionable since according to the health professionals the HAQ-DI encompasses 9 (out of 20) activities that are not relevant or too easy to perform for GOA patients. Construct validity was rated positive given the moderate to strong associations with related constructs and weak associations with unrelated constructs. Cronbach's alpha was 0.90, confirming internal consistency and the ICC was 0.81, reflecting good reliability. The MIC was 0.25 points and the smallest detectable change was 0.60 indicating that important changes cannot be distinguished from measurement error in individuals.

Conclusion: The HAQ-DI showed a good construct validity and reliability to measure functional limitations in patients with GOA. Given the unsatisfactory content validity, we recommend an update of the HAQ-DI items when using the HAQ-DI in future clinical practice and research focusing on functional limitations in GOA. This update might also be worthwhile for RA and all other rheumatic diseases.

Randomized Clinical Trial of a Patient and Provider Intervention for Managing Osteoarthritis in Veterans. Kelli D. Allen[1], Hayden B. Bosworth[2], Amy Jeffreys[1], Cynthia Coffman[2], Santanu Datta[2], Jennifer McDuffie[3], Eugene Oddone[2], Jennifer Strauss[3] and William S. Yancy Jr.[3]. [1]Durham VA Medical Center, Durham, NC, [2]Durham VA Medical Center and Duke University Medical Center, Durham, NC, [3]Duke University Medical Center, Durham, NC.

Background/Purpose: Adequate management of osteoarthritis (OA) requires both medical and behavioral strategies. However, some recommended therapies are under-utilized in clinical settings, and there is low use of behavioral strategies among patients. Consequently, interventions at the provider and patient levels both have potential for improving outcomes. The objective of this trial was to examine the effectiveness of a combined patient + provider intervention for managing OA in a primary care setting.

Methods: 300 patients with diagnoses of hip and / or knee OA at the VA Medical Center in Durham, NC (mean age = 61, SD = 11; 91% male; 50% non-white) were randomized to a combined patient + provider intervention for managing OA versus usual care. The 12-month, telephone-based patient intervention focused on weight management, physical activity and cognitive behavioral pain management. The provider intervention involved delivery of patient-specific recommendations for OA treatments (based on multiple sets of published guidelines and including non-pharmacological treatments such as physical therapy), delivered in the electronic medical record. The primary outcome was the Western Ontario and McMasters Universities Osteoarthritis Index (WOMAC), including the overall score (range: 0–96) and pain and function subscales. Secondary outcomes were objective physical function (Short Physical Performance Battery; SPPB, range: 0–20), weekly hours of any exercise and moderate or greater intensity exercise (Community Healthy Activities Model Program For Seniors or CHAMPS questionnaire) and depressive symptoms (Patient Health Questionnaire; PHQ-8, range: 0–24). Linear mixed models (LMM) were used to assess the difference in improvement in outcomes between the intervention and usual care groups, adjusting for clustering within physicians.

Results: At 12-month follow-up, WOMAC scores were 4.2 points lower in the intervention group vs. usual care [95% confidence interval (CI) = −7.2, −1.1; p=0.008], indicating improvement in symptoms and function. The WOMAC function subscale was 3.4 points lower in the intervention group compared to usual care [95% CI = −5.7, −1.0; p=0.005], but there was no significant difference in WOMAC pain subscale scores between groups (p=0.12). SPPB scores were 0.6 points higher in the intervention group than the usual care group [95% CI = 0.1, 1.2; p=0.02], indicating improvement in function. Weekly hours of exercise were also higher in the intervention group relative to the usual care group at 12-month follow-up: any exercise = 3.7 hours [95% CI = 1.5, 5.8; p=0.001] and moderate or greater intensity exercise = 1.6 hours [95% CI = 0.3, 2.9; p=0.02]. There was no significant difference between groups in PHQ-8 scores.

Conclusion: This combined patient and provider intervention improved physical function (self-reported and objectively assessed) and physical activity levels in patients with hip and knee OA. The telephone-based patient intervention is relatively low-cost and could be disseminated widely, and the provider intervention could be integrated in an automated manner within electronic medical record systems.

Socioeconomic Status Measures Are Associated with Increasing Pain, Stiffness and Physical Function Among Individuals with Knee and Hip Osteoarthritis. Rebecca Cleveland[1], Jordan B. Renner[2], Joanne M. Jordan[3] and Leigh F. Callahan[4]. [1]University of North Carolina at Chapel Hill, Chapel Hill, NC, [2]University of North Carolina Department of Radiology, Chapel Hill, NC, [3]University of North Carolina Dept of Epidemiology, Chapel Hill, NC, [4]University of North Carolina, Chapel Hill, NC.

Background/Purpose: The determinants of disability progression (DP) among those with knee and/or hip osteoarthritis (OA) are not well known. Our aim was to explore whether socioeconomic status (SES) measures were associated with DP at follow-up (FU) in the Johnston County Osteoarthritis Project (JoCo OA).

Methods: Analyses were carried out among individuals with radiographic knee and/or hip OA (rOA) aged ≥45 years who participated in TIME 1 (T1; 1999–2004), which included those who entered the cohort during the original study enrollment who returned for their first follow-up, and new enrolls recruited for cohort enrichment. Follow-up was assessed at TIME 2 (T2 FU; 2006–2010). DP was assessed using the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) which includes Pain, Stiffness and Physical Function Subscales. DP was defined as an increase from T1 to T2 FU of ≥10 in the WOMAC total score, or any increase in a subscale score. SES measures were education (no high school diploma [<HS] vs HS diploma or more [≥HS]), occupation (non-professional vs professional) and block group poverty (≥20% vs <20%). Odds ratios (OR) and 95% confidence intervals (CI) for associations between SES and DP were estimated using logistic regression simultaneously adjusting for other SES measures plus age, gender, hip and/or knee injury, BMI and smoking.

Results: There were 796 individuals with knee and/or hip rOA from T1 who returned at T2 FU. The mean age was 64.6 years, 66.3% were female, 30.7% African American, and mean BMI was 31.8 kg/m^2. At T2 FU, there was increased disability in 26.8% of individuals with knee rOA and 21.8% of individuals with hip rOA. Analyses including all individuals with knee and/or hip rOA showed that individuals with <HS education were more likely to have developed disability by T2 FU (OR=1.96, 95% CI=1.28–3.00) when compared with those ≥HS education (Table 1). Slightly stronger associations were seen when evaluating the effect of education among those with only knee rOA, where those with <HS education had nearly a three-fold increase in odds of having an ≥10 point increase in WOMAC score at T2 FU (OR=2.86, 95% CI=1.45–5.67). Among those with only hip rOA, having a non-professional occupation was associated with an increase in WOMAC disability, an association that narrowly missed statistical significance (OR=1.96, 95% CI=0.98–3.91). Across individual subscales, education was consistently associated with all subscales among those with only knee rOA, and occupation was associated with subscales among those with only hip rOA.

Conclusion: We report that individuals with lower education and non-professional occupation were more likely to have DP from T1 to T2 FU, associations that remained after adjustment for other SES measures. Our results suggest that SES may have an influence on DP, findings which may help clinicians in develop personalized OA management programs for individuals with low SES measures.

Genome-Wide Association Study for Severe Radiographic Knee Osteoarthritis. Youfang Liu[1], Michelle Yau[2], Laura Yerges-Armstrong[3], Braxton Mitchell[3], Rebecca D. Jackson[4], Marc C. Hochberg[3], Shad Smith[1], William Maixner[1], Luda Diatchenko[5] and Joanne M. Jordan[6]. [1]University of North

Carolina, Chapel Hill, NC, [2]University of Maryland, Baltimore, MD, [3]University of Maryland School of Medicine, Baltimore, MD, [4]The Ohio State University, Columbus, OH, [5]McGill University, Montreal, QC, [6]University of North Carolina Dept of Epidemiology, Chapel Hill, NC.

Background/Purpose: Knee osteoarthritis (OA) is a heritable common joint disorder. In previously reported genetic studies, cases were usually defined with a radiographic Kellgren and Lawrence (K/L) grade ≥2. Since more severe knee OA is more likely to have greater medical and public health impact, we searched for genetic variations associated with severe radiographic knee OA (rKOA) of K/L grade 3 or 4.

Methods: Caucasian participants with knee radiographic grade from the Johnston County Osteoarthritis Project (JoCo) were included in this analysis. Cases were defined as the subjects with KL grade ≥3 in at least one knee, while the controls were defined as the subjects with KL grades = 0 in both knees. Genome wide genotyping was completed using the Illumina Infinium 1M-Duo array and imputed into 2.5M using HapMap II Caucasian as the reference data. Genome-wide association analysis was performed using logistic regression with adjustment for age and sex, with and without additional adjustment for BMI.

Results: Of 672 participants [64% women, mean age = 64.2 (SD=10.6), mean BMI = 30.3(SD=6.4)], 353 were cases and 319 were controls. Although no SNPs reached genome-wide significant p-values at 5E-8, we identified two SNPs with p-values less than E-06 in the model without BMI adjustment (table). After BMI adjustment, associations were attenuated but still statistically significant (table). Both SNPs, rs11196174 and rs11196175, are located in the TCF7L2 gene which encodes a T-cell specific transcription factor participating in the Wnt signaling pathway, which has been shown to be related to OA.

Conclusion: Two SNPs, rs11196174 and rs11196175, located in the TCF7L2 gene were associated with severe rKOA, supporting the possibility that the pathogenesis of severe rKOA may be through the Wnt signaling pathway. Further studies will need to validate this finding in other populations.

							W/O BMI adjustment		With BMI adjustment	
SNP	Gene	A1	A2	Freq1	Chr	Position	Beta	P-value	Beta	P-value

Annual Medical Care Expenditures Among US Adults with Osteoarthritis, 2008–2011. Miriam G. Cisternas[1], Louise Murphy[2], David J. Pasta[3], Daniel H. Solomon[4] and Charles G. Helmick[2]. [1]MGC Data Services, Carlsbad, CA, [2]Centers for Disease Control and Prevention, Atlanta, GA, [3]DMA Corporation, Palo Alto, CA, [4]Brigham and Women's Hospital, Boston, MA.

Background/Purpose: As the US population ages, concerns continue to grow about the cost of medical treatment for osteoarthritis (OA). We estimated all-cause medical care expenditures and OA-attributable expenditures among US adults with OA age ≥ 18 years.

Methods: We identified adults with OA in the 2008–2011 Medical Expenditure Panel Survey (MEPS). Adults were defined as having OA if (1) ICD-9-CM 715 was present, or (2) ICD-9-CM 716 or 719 was present along with self-reported doctor-diagnosed arthritis that excluded rheumatoid arthritis. We estimated annual national total (aggregate) and mean per-person all-cause and OA-attributable expenditures overall and for four expenditure categories: ambulatory care (office-based and hospital outpatient); inpatient care; prescriptions; and other (emergency room visits, home health care, vision aids, dental visits, and medical devices). OA-attributable expenditures were calculated using multi-stage regression models that adjusted for demographics (age, sex, race, Hispanic ethnicity, and education), health insurance coverage (any private, public only, or none), and 9 costly comorbid conditions. The increment was our estimate of expenditures that would be expected if those with OA did not have the condition by applying the parameter estimates from the models of those without OA to the data from those with OA. Estimates are in 2011 US dollars.

Results: National total all-cause medical care expenditures among the 30.8 million adults reporting OA were $328.2 billion; mean per-person expenditures among US adults with OA were $10,654, compared to $4,884 for all adults. Across expenditure categories, all-cause mean per-person expenditures were: ambulatory care ($3,354), inpatient ($3,320), prescriptions ($2,546), and other ($1,434). National OA-attributable expenditures totaled $62.1 billion (mean per person=$2,017) and accounted for 6% ($62.1 billion/$1,122.0 billion) of all medical expenditures for US adults. Mean per-person OA-attributable expenditures followed the same order as all-cause expenditures: ambulatory care ($754), inpatient ($544), prescriptions ($348), and other ($185).

Conclusion: Mean per-person all-cause medical expenditures were more than double for adults with OA compared to the entire adult population. Total annual national medical expenditures attributable to OA were $62.1 billion, accounting for 6% of medical expenditures for US adults. The increasing prevalence of obesity and continued aging of the population suggest that medical expenditures for treating OA will increase in the future. Underused interventions such as weight management, physical activity, and self-management education may mitigate its adverse effects on symptoms and function.

The Effect of Compression Gloves in Hand Osteoarthritis: A Pre-Post-Test Trial. Alison Hammond[1], Yeliz Prior[1], Vivienne Jones[1], Mary Dooley[2], Yvonne Hough[3] and Angela Jacklin[4]. [1]University of Salford, Greater Manchester, United Kingdom, [2]Southport & Formby District Hospital, Southport, United Kingdom, [3]St Helens Hospital, St Helens, United Kingdom, [4]Stepping Hill Hospital, Stockport, United Kingdom.

Background/Purpose: Compression gloves are used in Hand Osteoarthritis (HOA) to reduce pain (day and/or night), stiffness and improve hand function. A systematic review identified only two trials (sample sizes n= 2 and 5), with inconclusive results [1]. The commonest compression gloves provided in the UK are Isotoner gloves. The aim was to evaluate effects of compression gloves on hand pain, stiffness and function.

Methods: A pre-post-test trial was conducted. Participants were recruited from 10 Rheumatology Occupational Therapy (OT) departments; had a doctor diagnosis of HOA and no steroid injections or new/changed medication within the previous 4 weeks. Assessments at 0 and 4 weeks included: hand pain on activity and at night, hand stiffness (all 0–10 numeric rating scales: none to very severe); Measure of Activity Performance of the Hand [MAP-HAND, 2]; Grip Ability Test [GAT, 3]; and composite finger flexion to distal wrist crease (CFF). OT assessors were trained in standardised hand assessment procedures. Assessor inter-rater reliability (ICC,10) was good: CFF (0.76–0.93); GAT (0.98) [4]. All participants received Isotoner ¾ finger gloves. Data were analysed using paired t-tests and effect sizes calculated using eta-squared (values of 0.14+ = large effect, 5).

Results: 30 people with HOA participated: 28 women, 2 men); average age = 61.23(SD 8.35) years; time since diagnosis 4.71(SD 6.47)years. (Right hand data presented below).

Mean(SD)	0 weeks	4 weeks	p	Effect size
Hand pain on activity	7.30 (1.61)	6.22 (1.99)	0.008	0.24
Hand pain at night	6.56 (2.10)	4.19 (2.20)	0.000	0.45
Hand stiffness	7.22 (1.74)	5.85 (2.14)	0.01	0.44
MAP-HAND	25.33 (7.08)	24.03 (7.87)	0.14	0.07
GAT	40.05 (12.04)	33.14 (13.10)	0.000	0.50
CFF Index (cms)	6.84 (2.17)	6.44 (2.33)	0.05	0.14
CFF Middle (cms)	5.72 (2.23)	5.29 (2.25)	0.03	0.17

Conclusion: This study demonstrates, for the first time, that compression gloves used by people with HOA led to significant improvements in: pain during the day and night, stiffness, hand function and finger motion, with moderate to large effect sizes. A limitation was the lack of a control group meaning we cannot be certain benefits were due to compression gloves. A randomised controlled trial needs to be conducted, including longer follow-up.

Identification of Potential SERUM Autoantibody Biomarkers in Rheumatic Diseases Using a New Generation of Protein Arrays. Lucia Lourido[1], Juan Fernandez-Tajes[1], Valentina Calamia[1], Carolina Fernandez-Costa[1], Beatriz Rocha[1], Patricia Fernandez-Puente[1], Jesus Mateos[1], Carlos Fernandez-Lopez[1], Natividad Oreiro-Villar[1], Manuel Fuentes[2], Francisco J. Blanco Garcia[1] and Cristina Ruiz-Romero[1]. [1]Grupo de Proteomica-PBR2-ProteoRed/ISCIII-Servicio de Reumatologia. Instituto de Investigación Biomédica de A Coruña (INIBIC), Complexo Hospitalario Universitario de A Coruña (CHUAC), Sergas. Universidade da Coruña (UDC). As Xubias, 15006., A Coruña, Spain, [2]Centro de Investigación del Cáncer/IBMCC (USAL/CIC), IBSAL, Departamento de Medicina, Unidad de Proteomica Servicio general de Citometría, Universidad de Salamanca, Salamanca, SPAIN., Salamanca, Spain.

Background/Purpose: Osteoarthritis (OA) is characterized by the loss of structural components from the extracelullar matrix (ECM) of articular cartilage. The progressive release of proteins from the tissue and an abnormal metabolic activity can be specifically detected by the immune system, leading to a humoral immune response producing immunoglobulins against these proteins (autoantibodies). Autoantibodies are stable circulating proteins, easily measurable in serum, and may be the signature before clinical manifestations of the disease. Protein microarrays have emerged providing a tool for the identification of disease immunosignatures. The aim of this study was to detect the presence of autoantibodies in OA serum samples and compare these results with those obtained from healthy (CTRL) and rheumatoid arthritis (RA) sera using nucleic acid programmable protein arrays (NAPPA).

Methods: Antibodies were detected using NAPPA constructed as previously described by Ramachandran *et al*. 2008, containing 80 sequence-verified full-length human genes obtained from the Center for Personalized Diagnostics at the Arizona State University (www.dnasu.org) and selected by their possible relevance in OA disease. Once the 80 different proteins were displayed by *in situ* protein expression system, NAPPA arrays were incubated in optimized conditions with 20 OA, 20 RA and 18 CTRL serum samples. The autoantibodies were detected using an antibody against human IgGs fluorescently labelled. Array images were obtained and processed by Genepix4000B and GenePix Software 6.0. For data analysis, normalization across all the arrays was performed.

Results: Significantly ($p<0.05$) 4 different autoantibodies against four different proteins have been observed to be higher in OA compared to CTRL samples. Of note, 2 of these proteins are related to the metabolism of ECM (CHST14, PCOLCE); the others are associated to cell adhesion (CD44) and bone mineralization (LEP). We also observed that IL6 autoantibody levels distinguish RA and CTRL samples. Most interestingly, this approach allowed the differential classification of RA and OA patients by the detection of 3 specific autoantibodies against proteins involved in cell proliferation (IGFBP4, IGFBP6); and bone mineralization processes (LEP) whose levels are increased in OA compared to RA, one of these proteins (LEP) also distinguishing between CTRL and OA subjects.

Conclusion: We have identified the presence of specific autoantibodies in OA allowing to characterize differential autoantibody profiles between OA and CTRL patients and most interestingly, between OA and RA patients. These autoantibodies released to the serum might have a biomarker value to more accurate diagnosis and prognosis of OA patients in clinical routine.

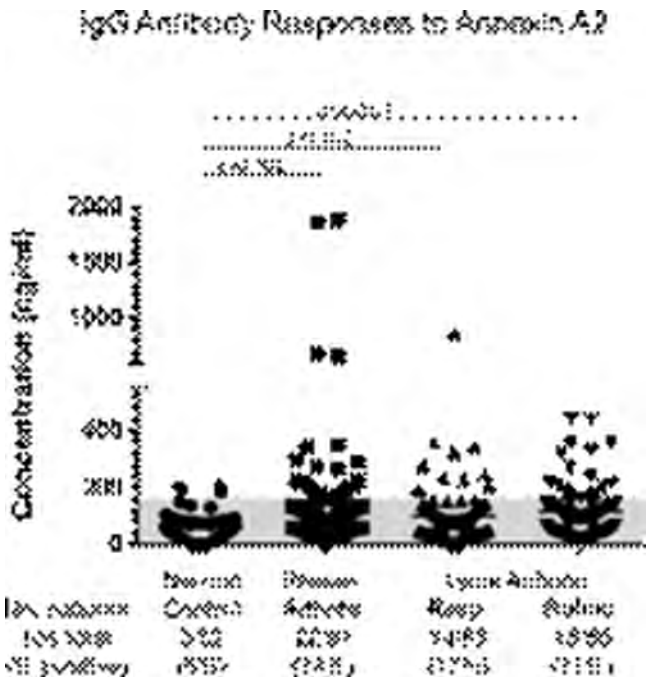
Identification of Annexin A2 As an Autoantigen in Rheumatoid Arthritis and in Lyme Arthritis. Annalisa Pianta[1], Elise E. Drouin[1], Sheila Arvikar[2], Catherine E. Costello[3] and Allen C. Steere[1]. [1]Massachusetts General Hospital, Harvard Medical School, Boston, MA, [2]Massachusetts General Hospital, Boston, MA, [3]Boston University School of Medicine, Boston, MA.

Background/Purpose: Disease-associated HLA-DR molecules are the greatest genetic risk factor for rheumatoid arthritis (RA) and for antibiotic-refractory Lyme arthritis (LA). We have developed a novel approach to identify disease-relevant HLA-DR-presented peptides in synovial tissue using discovery-based proteomics and translational research. Using this approach, we previously identified endothelial cell growth factor (ECGF) as the first autoantigen known to be a target of T and B cell responses in antibiotic-refractory or antibiotic-responsive LA, but not in RA. In this study, we continued to characterize the repertoire of naturally presented HLA-DR peptides in synovial tissue in patients with RA or LA.

Methods: HLA-DR-presented peptides were eluted from synovia, identified by tandem mass spectrometry, synthesized, and tested for reactivity with the matching patient's PBMC. Immunoreactive peptides or their source proteins were then tested for T cell reactivity by IFN-g ELISpot assay or for antibody responses by ELISA. All RA patients met the 2010 ACR/EULAR criteria for RA and the LA patients met the CDC criteria for Lyme disease.



Results: In one RA patient who lacked positive tests for rheumatoid factor (RF) or anti-citrullinated protein antibodies (ACPA), 1 of 86 non-redundant HLA-DR-presented peptides identified from her synovial tissue induced her PBMC to secrete IFN-g. The peptide was derived from the protein annexin A2 and others had shown that ~10% of RA patients make autoantibodies against this self-protein. We tested serum samples from our cohort of RA patients for anti-annexin A2 autoantibodies, and for comparison, from healthy control subjects or from patients with antibiotic-responsive or antibiotic-refractory LA. In our RA cohort, sera from 24% of 91 patients had antibody responses to annexin A2 that were >3SD above the mean value in healthy control subjects (Figure). Surprisingly, about 20% of the patients with antibiotic-responsive or antibiotic-refractory LA also had antibody reactivity with this autoantigen. In annexin A2-positive RA patients, the magnitude of antibody responses to ACPA or RF were less than in annexin A2-negative patients. Studies to look for linked T and B cell responses to annexin A2 are currently in progress in both the RA and LA cohorts.

Conclusion: We confirm that annexin A2, a phospholipid-binding protein that protects damaged endothelial cells, is a potential autoantigen in a subgroup of patients with RA. Moreover, we report for the first time that this protein may serve as an autoantigen in a subgroup of patients with LA. As with reactivity to ECGF, autoantibody responses to annexin A2 in Lyme disease seem to occur as a part of the immune response to the infection, whereas additional factors, such as immune dysregulation, are required for refractory arthritis.

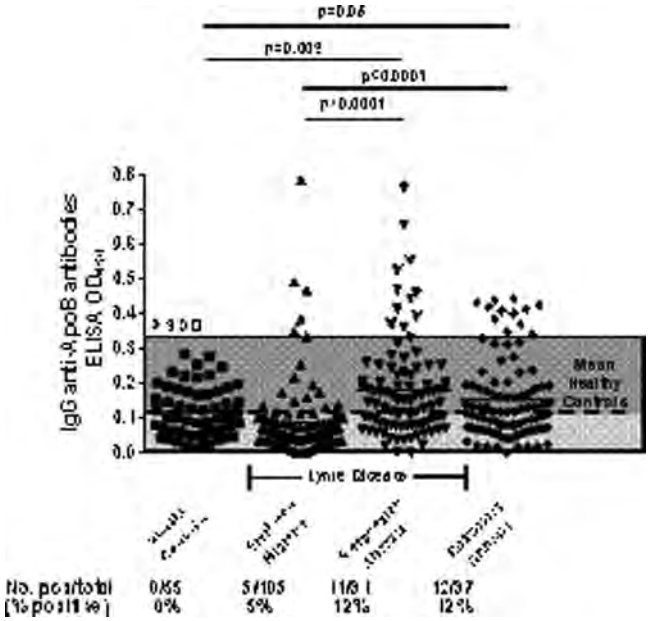
Apolipoprotein B Is a Target of T and B Cell Responses in a Subgroup of Patients with Lyme Disease. Jameson T. Crowley[1], Elise E. Drouin[1], Qi Wang[2], Gail McHugh[3], Catherine E. Costello[2] and Allen C. Steere[1]. [1]Massachusetts General Hospital, Harvard Medical School, Boston, MA, [2]Boston University School of Medicine, Boston, MA, [3]Massachusetts General Hospital, Boston, MA.

Background/Purpose: *Borrelia burgdorferi*-induced autoimmunity in affected joints has been hypothesized to be a contributing factor to antibiotic-refractory Lyme arthritis (ARLA). Our prior study, which combined proteomics and translational research, identified endothelial cell growth factor (ECGF) as the first known target of T and B cell responses in ~20% of patients with antibiotic-refractory or antibiotic-responsive arthritis and in ~10% of patients with erythema migrans (EM), the initial skin lesion of the disorder. Using this same approach, we identified apolipoprotein B (ApoB) as another novel autoantigen in Lyme disease.

Methods: HLA-DR presented self-peptides were isolated from ALRA patients' synovia, identified by tandem mass spectrometry, synthesized, and tested for reactivity with the matching patient's PBMC using an IFN-γ ELISpot assay. Immunoreactive peptides and their full-length source proteins were then tested for T and B cell reactivity using large numbers of patient and control cells and sera. Samples from patients with antibiotic-responsive arthritis were seen prior to antibiotic therapy, when the infection was still active, whereas those from patients with antibiotic-refractory arthritis were collected after antibiotics, during the presumed autoimmune phase of the illness. Antibody responses were quantified by ELISA.



Results: From the synovial tissue of one ALRA patient, 141 non-redundant HLA-DR-presented self-peptides were identified and tested. One peptide derived from ApoB caused significant secretion of IFN-γ by ELISpot. Additional testing of 25 patients showed ~10–30% patients with early or late manifestations of Lyme disease had T cell responses to ApoB.

To look for linked T and B cell responses, patients' serum samples were also tested for anti-ApoB IgG antibodies. By definition, none of the 55 healthy control subjects had a positive response (defined as >3 SD above the mean value in these subjects) (Figure). In comparison, 5% of patients with EM and 12% each of patients with responsive or refractory arthritis had positive responses for anti-ApoB IgG autoantibodies. Compared with the EM group, the values were significantly higher in both arthritis groups ($P<0.0001$), particularly in those with responsive arthritis, a group still actively infected.

Conclusion: We report for the first time that ApoB is a target of T and B cell responses in a subset of patients with Lyme disease. Although the molecular mechanisms are not yet known, *B. burgdorferi*, an organism with sequences for >100 lipoproteins and multiple membrane glycolipids containing cholesterol, may contribute directly to the development of this autoimmune response. As with reactivity to ECGF, autoantibody responses to ApoB seem to occur as part of the immune response to the infection, whereas additional factors, such as immune dysregulation, are also required for refractory arthritis.

Labial Salivary Gland Antibody-Secreting Cell Specificity and Characteristics in Sjögren's Patients. Kristi A. Koelsch[1], Jacen Maier-Moore[2], Kenneth Smith[3], Christopher Lessard[3], Astrid Rasmussen[3], Biji Kurien[3], Umesh Deshmukh[3], A. Darise Farris[3], Judith A. James[3], Kathy L. Moser Sivils[3], R. Hal Scofield[4] and Mark Coggeshall[3]. [1]Oklahoma Medical Research Foundation, Okalahoma City, OK, [2]University of Texas at El Paso, El Paso, TX, [3]Oklahoma Medical Research Foundation, Oklahoma City, OK, [4]US Department of Veterans Affairs Medical Center, Oklahoma City, OK.

Background/Purpose: Studies were approved by the OMRF and the University of Oklahoma Health Sciences Center Institutional Review Boards. Samples and data were obtained from 9 subjects following written, informed consent and evaluated in the OMRF Sjögren's Research Clinic. Four subjects met American/European combined and American College of Rheumatology criteria for SS. One of these also met the American College of Rheumatology criteria for SLE. Five subjects that did not meet disease criteria served as sicca controls. ASCs were isolated from labial SGs by single-cell-sorting for hmAb production. hmAbs were produced by the OMRF Human Monoclonal Antibody Core. Serum Ab and hmAb profiles of patients and controls were evaluated by various assays to determine specificities including ELISA, immunofluorescence ANA and *Crithidia luciliae* testing, INNO-LIA™ and BioPlex2200™, and double immunodiffusion (sera only) assays.

Methods: Studies were approved by the OMRF and the University of Oklahoma Health Sciences Center Institutional Review Boards. Samples and data were obtained from 9 subjects following written, informed consent and evaluated in the OMRF Sjögren's Research Clinic. Four subjects met American/European combined and American College of Rheumatology criteria for SS. One of these also met the American College of Rheumatology criteria for SLE. Five subjects that did not meet disease criteria served as sicca controls. ASCs were isolated from labial SGs by single-cell-sorting for hmAb production. hmAbs were produced by the OMRF Human Monoclonal Antibody Core. Serum Ab and hmAb profiles of patients and controls were evaluated by various assays to determine specificities including ELISA, immunofluorescence ANA and *Crithidia luciliae* testing, INNO-LIA™ and BioPlex2200™, and double immunodiffusion (sera only) assays.

Results: From the 72 hmAbs analyzed to date (52/patient; 20/control), we found diverse antigen specificities, with hmAbs from SS patients more often binding self-antigens. While 56% of the hmAbs from SS patients bound Ro and/or La, only 19% from sicca controls did ($p = 0.001$). We found hmAbs from SS patients to be more often polyreactive (binding more than one antigen) than the controls (29% vs. 12%, respectively). In addition, 3 hmAbs were reactive to the bacterial antigen, peptidoglycan (PGN) (patient = 2, control = 1). The anti-PGN hmAbs also bound common self-antigens. We found correlation between patient serum and SG hmAbs specificities.

Conclusion: In this ongoing study, we show correlations between glandular and serum antibody specificities, demonstrate that ASCs other than anti-Ro or anti-La are present in SS salivary glands and produce Ab *in situ*. Furthermore, we observed that the SGs are representative of the systemic immune response and that glandular ASC specificities were consistent with co-morbid disease presentation. We have also identified SG derived hmAbs that have cross-reactivity to bacterial- and self-antigens, supporting the theory of an infection-triggering event that leads to development of disease. Finally, these are the first fully human, antigen-specific monoclonal antibodies produced from SS salivary gland ASCs and therefore, may have clinical or diagnostic importance.

Integrated Comprehensive Analysis of Immune Cell Subsets and Serum Protein Profile Identifies the Role of Pre-Germinal Center B Cells in Sjogren's Syndrome Pathogenesis. Yoshiaki Kassai[1], Katsuya Suzuki[2], Rimpei Morita[3], Maiko Takiguchi[1], Rina Kurisu[1], Takahiro Miyazaki[1], Akihiko Yoshimura[3] and Tsutomu Takeuchi[2]. [1]Takeda Pharmaceutical Company Limited, Kanagawa, Japan, [2]Keio University School of Medicine, Tokyo, Japan, [3]Department of Microbiology and Immunology, Keio University School of Medicine, Tokyo, Japan.

Background/Purpose: Whole blood flow cytometric analysis and serum protein profiling were commonly utilized to characterize disease-specific alterations in a wide variety of autoimmune diseases. However, precise mechanisms underlying their pathophysiological conditions were still obscure because each experimental approach was carried out independently and not well integrated. Therefore, we performed comprehensive flow cytometric analysis by multi-colored staining in combination with serum protein profile to fully understand pathophysiological aspects in rheumatoid arthritis (RA) and primary Sjogren's syndrome (pSS).

Methods: Heparinized peripheral blood was collected from untreated RA patients (N = 51), pSS patients (N = 60), and healthy controls (N = 36). Fresh whole blood was immediately stained with fluorescent-labeled antibodies and analyzed with 3-laser, 8-color FACS equipment. Over a thousand of serum protein profile were also obtained with aptamer technology from SomaLogic, Inc. Serum immunoglobulin concentrations were evaluated by ELISA and gene expression levels were analyzed using quantitative real-time PCR.

Results: Among over 40 immune cell subsets we investigated, surface IgD+ CD38++ B cells, called pre-germinal center B (pre-GC B), were significantly increased in both RA and pSS patients. Interestingly, serum IgG but not IgM and IgA was positively correlated with the number of pre-GC B cells in pSS but not RA, suggesting their distinct role in pSS pathogenesis. Consistent with this, GC-related serum proteins such as PD-L2, SLAMF2, and CD30 ligand were significantly elevated and correlated with pre-GC B in pSS but not RA. Furthermore, pre-GC B cells isolated from pSS patients exhibited higher GC-related gene expressions including *XBP1* and *BACH2* than those from healthy controls.

Conclusion: Our findings suggest possible role of pre-GC B in pSS pathogenesis through IgG production and germinal center formation. By integrating multiple comprehensive analyses, we identified a novel immune cell phenotype, indicating this strategy as a useful tool to highly impact on better understanding of autoimmune diseases.

987

Novel Auto-Antigen in Aortic Aneurysms of Large Vessel Vasculitis. Ritu Chakravarti[1], Karishma Gupta[2], Jaclyn Scholtz[3], Edward Soltesz[4], Eric Roselli[4], Gosta Pettersson[4], Lars Svensson[4], Douglas Johnston[4], Belinda Willard[4], Michifumi Yamashita[5], Thomas Daly[6] and Gary S. Hoffman[7]. [1]Assistant Prof/ Project Staff, Cleveland, OH, [2]Technician, Cleveland, OH, [3]Student, Cleveland Clinic, cleveland, OH, [4]Cleveland Clinic Foundation, Cleveland, OH, [5]Resident, Cleveland, OH, [6]Director,, Cleveland, OH, [7]Center for Vasculitis Care and Research, Cleveland Clinic Foundation, Cleveland, OH.

Background/Purpose: Large Vessel Vasculitides (LVV) are a group of autoimmune diseases characterized by injury and anatomic modifications of large vessels that may include the aorta and its branch vessels. Disease etiology is unknown. Using samples from aorta root, ascending aorta and aorta arch surgical specimens, we sought to identify antigen targets within affected vessel walls in patients with LVV, including giant cell arteritis (GCA), Takayasu's arteritis (TA) and isolated focal aortitis (IFA).

Methods: Thoracic aorta aneurysm specimens and autologous blood were acquired from consenting consecutive patients in whom aorta reconstruction procedures were indicated. Aorta tissues from patients with both LVV and age-, race- and gender-matched patients with non-inflammatory aneurysms, were lysed and resolved on SDS-polyacrylamide gels. Sera from study groups were used to probe antigen-antibody reactivity on western blots followed by MS analysis to identify antigen. Additional sera samples tested included sera from diseases including medium to small vessel vasculitis, sepsis etc.

Results: We found that patients with LVV (n=17) produce antibodies to 14-3-3 proteins in the aortic wall, whereas patients with non-inflammatory matrix disorders (n=17) rarely do so. Most of the sera from other immune diseases were also negative. Anti-14-3-3 antibody production was demonstrated in all 3 forms of LVV. In each, sera contained autoantibody that was sufficient to immunoprecipitate 14-3-3 protein(s) from the aortic lysates. Antibodies to 14-3-3 were not found in sera of additional controls. Three out of seven known isoforms of 14-3-3 were found to be upregulated in LVV aortas. Most 14-3-3 Ag was found to co-localize within granulomas, chronic inflammatory cells and smooth muscle cells in LVV.

Conclusion: This study is the first to utilize sterile, snap frozen tissue from aortic reconstruction surgeries in an attempt to identify autoantigens in LVV. 14-3-3 protein(s) appears to be a novel auto-antigen in aortic aneurysms caused by LVV. The precise role of these antibodies and 14-3-3 proteins in LVV etiology and pathogenesis deserves further study.

Serum CXCL13 As a Biomarker of Disease Activity and Severity in Rheumatoid Arthritis: Comparison with Acute Phase Reactants and the Autoantibody Profile. Antonio Manzo, Serena Bugatti, Barbara Vitolo, Francesca Benaglio, Elisa Binda, Martina Scarabelli, Roberto Caporali and Carlomaurizio Montecurcco. Rheumatology and Translational Immunology Research Laboratories (LaRIT), Division of Rheumatology, IRCCS Policlinico S.Matteo Foundation/University of Pavia, Pavia, Italy.

Background/Purpose: The B cell chemoattractant CXCL13 has recently emerged as a new candidate biomarker of disease activity capable of identifying patients with persistent synovitis and worst radiographic outcomes in early rheumatoid arthritis (RA). However, whether CXCL13 reflects underlying disease processes or simply represents another non-specific marker of inflammation is currently unknown. The current study aimed at analysing the clinico-pathologic significance of serum CXCL13 in comparison to routine laboratory markers of disease activity and severity in patients with RA.

Methods: Baseline serum levels of CXCL13 were measured by colorimetric ELISA in 205 consecutive early untreated RA patients with disease duration <12 months (median 3 months, IQR 2–5.5). Disease activity was assessed by a comprehensive set of subjective, semi-objective and objective clinical features. Changes in CXCL13 levels were evaluated in 87 patients after 2 months of treatment with methotrexate and low-dose prednisone. An additional study population of 60 RA patients (n=22 with disease duration <12 months) in whom paired serum and synovial samples were collected on the same day was used to assess the pathologic correlates of circulating CXCL13.

Results: In cross-sectional analyses at baseline, CXCL13 was moderately correlated with the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) (rho 0.35 and 0.36 respectively, $p<0.001$). Similarly to acute phase reactants, CXCL13 correlated with overall disease activity as measured by the DAS28, in particular with physician-derived measures, as well as with ultrasonographic scores for Gray Scale and power Doppler signals. In contrast to ESR and CRP, no correlation was found with patient-derived measures and functional status. Although increased CXCL13 levels were found in ACPA(+) patients, high CXCL13 and ACPA were not synonymous. CXCL13 levels in the 3rd tertile (>100 pg/ml) were found in 27.9% of ACPA(-) patients, and, in turn, 53.4% of ACPA(+) patients had CXCL13 <100 pg/ml. Similar results were observed for RF. After 2 months of treatment, CXCL13 levels were not significantly changed from baseline, as opposite to the significant reduction observed for acute phase reactants (standardised response mean 0.04, 0.52 and 0.66 for CXCL13, ESR and CRP respectively). In paired serum and tissue samples, circulating CXCL13 was

significantly correlated with synovial CXCL13 protein (rho 0.30, p=0.04) and mRNA (rho 0.56, p=0.02) expression. Similarly to ESR and CRP, serum CXCL13 was related to synovial inflammatory features such as the degree of sublining macrophage infiltration (rho 0.34, p=0.01). Serum CXCL13, but not acute phase reactants, showed further correlation with the presence and density of large B cell aggregates (rho 0.28, p=0.03), expression levels of the B cell enzyme activation induced cytidine deaminase (AID) (rho 0.4, p=0.046), and the receptor activator of nuclear factor κB ligand (RANKL)/ osteoprotegerin (OPG) ratio (rho 0.72, p<0.01).

Conclusion: Serum CXCL13 in RA reflects an immunologically active and potentially persistent pattern of synovial inflammation beyond the levels of conventional inflammatory markers and the ACPA status.

989

Fcgamma Receptor IIb Facilitates Rapid Internalisation of Rituximab (type 1 anti-CD20 antibody) in B Cells from Patients with RA and SLE and Contributes to Less Efficient B Cell Lysis Than Type 2 Anti-CD20 Antibodies, *in Vitro*. Venkat Reddy[1], Geraldine Cambridge[2], David A. Isenberg[2], Mark Cragg[3] and Maria J. Leandro[2]. [1]Centre for Rheumatology Research, Division of Medicine, University College London, London, United Kingdom, [2]Centre for Rheumatology, Department of Medicine, University College London, London, United Kingdom, [3]Southampton University, Southampton, United Kingdom.

Background/Purpose: Incomplete B-cell depletion using rituximab (RTX) is associated with poor clinical response in some individuals with RA and SLE, in particular. However, the precise mechanisms of resistance to depletion with RTX (type1 anti-CD20 monoclonal antibodies, mAbs) are poorly understood. Improving depletion may augment clinical response. Newer mAbs such as GA101 (type2) are more potent than RTX at deleting malignant B cells.

Methods: We included 5 healthy controls (HC), 15 patients with RA and 16 with SLE. An *in vitro* autologous whole blood depletion assay was used to compare BHH2 (type2, glycosylated GA101) with RTX (type1) and B cell lysing potential of mAbs was defined as cytotoxicity index (CTI). Briefly, 100μl of heparinised blood was incubated with either RTX, BHH2 or without antibody, at a concentration of 1μg/ml at 37oC, 5% CO2for 24hours. Samples were analysed by flow cytometry for CD45+ lymphocytes, CD3+ Tcells and CD19+ Bcells. The CTI was calculated using the formula:CTI of mAb=100-[(number of B:Tcells in sample without mAb-number of B:Tcells with mAb)/number of B:T cells in sample without mAb) × 100]. Surface fluorescence quenching assay using isolated B cells was performed to assess for the internalisation of mAbs. Paired "t' test or Mann-Whitney U test was used to compare groups, as appropriate.

Results: *Whole Blood Depletion:* BHH2 (type2 mAb) was significantly more efficient than RTX (type1 mAb) at lysing B cells, *in vitro*, in all groups. The mean±SD CTI of BHH2 vs RTX in HC was 65±13 vs 45±24(p=0.04); in RA, 61±12 vs 28±18 (p<0.0001); and in SLE, 38±17 vs 13±10 (p<0.0001). Thus, a hierarchy of B cell susceptibility to lysis by RTX was noted with HC > RA >SLE. BHH2 lyses the RA cells as well as controls - i.e. it fully overcomes the defect in RA whereas it doesn't in SLE.

Internalisation: We performed a surface fluorescence-quenching assay at 6 and 24 hours. At both time points, a significantly greater % of BHH2 was accessible on surface when compared with RTX, in all groups. The mean±SD % surface accessible mAbs, after 6 hours of incubation for BHH2 vs RTX was 72±6 vs 57±11, 68±8 vs 57±12(p<0.005) and 71±10 vs 63±12(p<0.005) whereas after 24 hours of incubation it was 47±15 vs 28±12, 45±25 vs 36±15 and 59±9 vs 42±14(p<0.005 for all), for HC, RA and SLE, respectively. Prior incubation with AT10 (a mAb directed against Fcgamma receptor II, CD32) significantly reduced internalisation of type1 mAbs to a greater extent than type 2 mAbs, a mean reduction of 12% vs 4%, respectively (p<0.005). Further, a significant variability was noted between patients in the extent to which internalisation of RTX, but not BHH2, was reduced by AT10.

Conclusion: Type 2 anti-CD20 antibodies are more efficient than type1 (rituximab) at lysing B cells from patients with RA and SLE. B cells from patients with SLE may be less susceptible to lysis *in vitro* by rituximab when compared with B cells from patients with RA and healthy individuals. Fcgamma receptor IIb facilitates rapid internalisation of rituximab, but not type2 mAbs, by B cells from patients with RA and SLE, which may contribute to its inferior ability to lyse B cells. This study provides a mechanistic basis for considering type2 mAbs for clinical use in RA and SLE.

The Alternative CD20 Transcript Variant Is Not a Factor for Resistance to Rituximab in Patients with Rheumatoid Arthritis. Cecile Gamonet[1], Marina Deschamps[2], Sandrine Marion[3], Philippe Saas[4], Gilles Chioccha[3], Christophe Ferrand[4] and Eric Toussirot[5]. [1]Etablissement Français du Sang / Université de Franche Comté, Besançon, France, [2]INSERM UMR1098 / Etablissement Français du Sang/ Université de Franche Comté, Besançon, France, [3]Université Versailles Saint Quentin, Montigny le Bretonneux, France, [4]INSERM UMR1098, Besançon, France, [5]Rheumatology Department, Univesity Hospital, besancon, France.

Background/Purpose: the identification of predictive factors for the response, or alternatively factors for resistance to biological agents is a relevant goal in the management of patients with rheumatoid arthritis (RA). Rituximab (RTX) is a chimeric monoclonal antibody directed against the membrane CD20 protein expressed by B cells. Predictive factors for good response to RTX therapy in RA have been previously determined, and included presence of rheumatoid factors and anti -CCP antibodies. A spliced mRNA transcript of CD20 (D393-CD20) has been observed in tumoral B cells from patients with lymphoma and leukaemia (1). This transcript is coding for a non-anchored membrane protein and its expression may be associated with resistance to RTX in patients with haematological malignancies.

Objectives: we previously reported that this alternative D393-CD20 transcript is not expressed in B cells and synovial tissue from patients with RA. In this study, we aim to determine whether D393-CD20 is expressed by circulating B cells from patients with RA who are refractory to RTX and whether it could be a factor for non-response to this treatment.

Methods: selected patients were from the SMART study (2). We included those who did not respond to RTX treatment (EULAR response). 24 RA patients (21 F, age [mean ± SD]: 57.6 ± 11.2 years; disease duration: 8.7 ± 6.7 years, positive rheumatoid factors: 13/24; positive anti- CCP antibodies: 13/24) were evaluated. All the patients had concomitant MTX and low corticosteroids (< 10 mg/j; 21/24). CD20 mRNA expression study was performed using RT-PCR assay allowing to discriminate full length CD20 (membrane CD20) from D393-CD20 transcripts. A more sensitive RT-PCR assay, using a specific primer spanning the splice fusion area was then used to detect specifically only the D393-CD20 transcript. This analysis was performed on peripheral blood B cells from patients with RA.

Results: RA patients had high disease activity at baseline (DAS28: 5.8 ± 0.8). Disease activity remained elevated after one course of RTX 1000 mg × 2 (DAS 28 at week 24: 5.5 ± 0.8). Among all the 24 RA samples, although full length CD20 expression was always detected, we were unable to detect D393-CD20, even with the more sensitive RT-PCR assay permitting to identify the spliced transcript form. We did not identify a subgroup of patients who display positive D393-CD20.

Conclusion: the present study showed that, on the contrary of leukemic or lymphoma B cells, RA B-cells from RA patients who did not respond to RTX do not express D393-CD20. This result, together with our previous data (lack of expression of this alternative transcript in cross-sectional analysis of RTX-naïve RA patients and in synovial tissue from RA patients) indicate that D393-CD20 may only be a molecular marker of malignancies rather than a factor predictive to RTX responses in auto-immune diseases like RA.

Differential Antigen-Presenting B-Cell Phenotype from Synovial Microenvironment of Rheumatoid Arthritis and Psoriatic Arthritis Patients. Estefania Armas-Gonzalez[1], Ana Diaz-Martin[1], María Jesús Dominguez-Luis[2], Maria Teresa Arce-Franco[1], Ada Herrera-Garcia[1], Vanesa

Hernandez[1], Alicia Usategui[3], Jose L. Pablos[4], Juan D. Cañete[5], Sagrario Bustabad[1] and Federico Díaz-González[1]. [1]Hospital Universitario de Canarias, La Laguna. Tenerife, Spain, [2]Center of Biomedical Research of the Canary Islands, University of La Laguna, Tenerife, Spain, [3]Instituto de Investigación Hospital 12 de Octubre (i+12), Madrid, Spain, [4]Instituto de Investigación Hospital 12 de Octubre (I+12), Madrid, Spain, [5]Hospital Clínic of Barcelona, Barcelona, Spain.

Background/Purpose: The systemic depletion of B cells induced by mabthera, a monoclonal antibody against human CD20, has shown to be an effective therapy for controlling disease activity in rheumatoid arthritis (RA), but not in psoriatic arthritis (PsA) patients. This strongly suggests that B cells play a different role of in the pathogenesis of these diseases. It has been suggested that B cells participate in the pathogenesis of chronic synovitis through several mechanisms, including T-cell activation by acting as antigen-presenting cells.

Objective: To study the potential differences in antigen-presenting phenotypes of B cells present in the synovial microenvironment of RA and PsA patients.

Methods: The surface expression levels of CD27, CD23, class II molecules (HLA-DP, -DQ and -DR), CD40 and CD86 were assessed by double- or triple-staining flow cytometry on CD20+ cells from peripheral blood (PB) and synovial fluid (SF) of 13 RA and 15 PsA patients. Flow cytometry analysis data are presented as relative mean fluorescence intensity with respect to cells in PB, which was considered 100%. The expression of interferon-induced protein IFIT-4, which is involved in the differentiation of monocytes into dendritic cells, was assessed by quantitative RT-PCR in negatively immunoselected CD19+ B cells from SF and PB of RA patients.

Results: Analyzing all patients included in this study, the percentage of mononuclear CD20+ cells in SF (2.24±0.37%) was significantly lower than in PB (8.59±1.26%, $p<0.01$). When these data were compared in RA versus PsA patients, the percentages of CD20+ cells in PB and SF were similar in both range and tendency. B cells from SF of RA and PsA patients showed an activated phenotype (down-regulation of CD23) and seem to have had in contact with the antigen (up-regulation of CD27). Flow cytometry analyses showed an increased expression of HLA-DR and -DQ in CD20+ cells from SF compared to those from PB, in both RA (277.84±65.66; 262.20±108.81) and PsA (267.86±88.53; 311.08±116,65) patients. HLA-DP was also elevated in rheumatoid SF B cells (1009.48±335.70), although conversely, a significantly lower expression of this class II molecule was observed in SF from PsA patients (46.38±19.73). Surface expression of CD86 was higher in SF than in PB B cells from both pathologies (RA: 629.79±172.24; PsA: 326.46±138.77). CD40 expression was significantly lower in SF compared to PB in B cells from RA patients (66.31±12.21); however, this was not the case in PsA patients (243.76±71.18). Interestingly, CD20 surface expression was 35% lower in B cells (CD19+, CD138-) from SF with respect to PB in RA patients. Finally, qRT-PCR showed approximately a 5-fold increase in IFIT-4 mRNA content in B cells from SF compared to PB in RA patients.

Conclusion: These data show that B cells in the synovial microenvironment of RA and PsA patients show a differential phenotype respect to molecules involved in antigen presentation and co-stimulation, which suggest that B cells play a different role in the pathogenesis of these two pathologies. This could have implications for the understanding of the dissimilar clinical response to B cell-depleting treatment observed in RA and PsA.

Anti-Citrullinated Proteins Antibodies Promote Synovial Fibroblast Migration in Rheumatoid Arthritis. Meng Sun[1], Vijay Joshua[1], Aase Haj Hensvold[1], Sergiu-Bogdan Catrina[2], Lars Klareskog[3], Vivianne Malmström[4], Heidi Wähämaa[1] and Anca I Catrina[1]. [1]Rheumatology Unit, Karolinska University Hospital, Karolinska Institutet, Stockholm, Sweden, [2]Molecular Medicine and Surgery, Karolinska University Hospital, Karolinska Institute, Stockholm, Sweden, [3]Karolinska Institute, Stockholm, Sweden, [4]Rheumatology Unit, Karolinska University Hospital, Solna, Karolinska Institutet, Stockholm, Sweden.

Background/Purpose: The presence of anti-citrullinated proteins antibodies (ACPAs) in RA is associated with aggressive disease phenotype and bone destruction. As synovial fibroblasts (SFs) are considered key players of both synovial inflammation and bone destruction in rheumatoid arthritis (RA), we studied the effect of ACPAs on fibroblasts migration.

Methods: Human dermal fibroblasts (HDFs) were obtained from PromoCell. SFs were isolated from synovial tissue of RA patients (RASFs) by enzymatic digestion. ACPA positive and negative IgGs were separated from plasma of RA patients and monoclonal anti-citrullinated antibodies were generated from RA synovial fluid by single B-cells[1]. Migration scratch assays were performed using either RASFs or HDFs to test the effect of ACPAs, anti-citrullinated monoclonal antibodies and appropriate negative controls. The effect of a phosphatidyl inositol-3-kinase (PI3K) inhibitor (wortmannin) and a focal adhesion kinase (FAK) inhibitor (PF-573228) was tested. Light microscopy images were taken at baseline and after 6 hours incubation and analyzed using NIH ImageJ to calculate migration index. Cytotoxicity and proliferation assays were done in parallel with migration assays.

Results: ACPAs but not control IgGs induced a 3.9±0.5 (mean±SD) fold increase in HDFs and a 2.6±0.5 (mean±SD) fold increase in RASFs migration ($p<0.05$). PI3K but not FAK inhibition almost completely abolished ACPAs effects, with minimal fold migration increase of 1.4±0.4 (mean±SD). No difference in either cytotoxicity or proliferation rate were observed between different treatments. One out of three different anti-citrullinated monoclonal antibodies displayed similar mig.

Conclusion: We describe a novel effect of ACPAs, providing a link between synovial fibroblasts and the adaptive immune system. We further suggest that different fine specificities of ACPAs might have distinct impact on disease pathogenesis.

IL-7 Modulates B Cell Immunoglobulin Isotype Production and Increases B Cell Activating Factor of the Tumor Necrosis Factor Family (BAFF) in Synovial Fibroblasts from Osteoarthritis (OA) and Rheumatoid Arthritis (RA) Patients. Georg Pongratz, Stephan Kuhn, Madlen Melzer, Torsten Lowin and Rainer Strraub. University Hospital Regensburg, Regensburg, Germany.

Background/Purpose: Interleukin(IL)-7 is increased in synovial fluid from rheumatoid arthritis (RA) patients as compared to osteoarthritis (OA) patients and has been attributed a proinflammatory role, especially due to its well established influence on T cells. However, B cells and synovial fibroblasts (SFs) also possess functional IL-7 receptors and stimulation of IL-7 receptors on B cells increases disease severity in collagen-induced arthritis. However, the mechanisms involved in this proinflammatory effect are not known. We therefore wanted to further characterize the effect of IL-7 on B cell antibody production and on the production of B cell activating factor of the tumor necrosis factor family (BAFF) and IL-6 in synovial fibroblasts (SFs).

Methods: Naive splenic mouse B cells were cultured in the presence of different activating stimuli (LPS, anti-IgM, anti-CD40, anti-CD40 + IL-4, antiCD40 + IFN-γ) in the absence or presence of IL-7 added at different timepoints (with the initial stimulus or three days after start of culture) and different concentrations (0.1, 1.0, 10 ng/ml). Levels of antibody isotypes (IgA, IgM, IgG1, IgG2a, IgG2b, IgG3, IgE) and light chains (lambda, kappa) were determined in supernatant by ELISA after 5 days. SFs were isolated from OA (n=15) and RA (n=7) knee joints and cultured in the presence or absence of IFN-γ at different concentrations (0.1, 0.5, 1.0, 5.0, 10, 50 ng/ml) to induce BAFF and IL-6 in the absence or presence of different concentrations of IL-7 (0.01, 0.1, 1.0, 10 ng/ml). BAFF and IL-6 were determined in culture supernatants by ELISA.

Results: IL-7 shows a differential effect on B cell antibody production, depending on the co-stimulus used and the isotype analysed. Most prominent effects were observed when IL-7 was present from the beginning of B cell culture. IL-7 increased IgG2a ($p=0.038$), IgG3 ($p<0.001$), and lambda light chains ($p=0.024$) and decreased kappa light chains ($p<0.001$) in the presence of concomitant stimulation with IL-4 and anti-CD40. IL-7 further increased LPS-induced IgG3 ($p<0.001$) and IgE ($p<0.001$). IL-7 alone was able to induce IgE in B cells to some extent without any additional stimulus ($p<0.001$). IFN-induced BAFF was increased by IL-7 in a concentration dependent manner in RA ($p<0.001$) but not OA SFs ($p=0.078$). However,

under hypoxic conditions (O2 2%) both, RA ($p<0.001$) and OA ($p=0.008$) SFs increased IFN-induced BAFF production in the presence of IL-7 in a concentration dependent manner. In contrast, IFN-induced IL-6 was not altered in SFs in the presence of IL-7.

Conclusion: Effects of IL-7 on the B cell compartment in arthritis can be direct by modulation of isotype production or indirect by increasing BAFF production in SFs. Therefore, IL-7 not only plays a role in modulating T cells but also modulates B cell function in arhtritis and therefore might be a valuable drug target.

Rheumatoid Arthritis Patients Have Alterations in Inherently Autoreactive 9G4+ B-Cell Subpopulations in Peripheral Blood. Rita A. Moura[1], Maria J. Leandro[2], Venkat Reddy[1], João E. Fonseca[3] and Geraldine Cambridge[2]. [1]Centre for Rheumatology Research, Division of Medicine, University College London, London, United Kingdom, [2]Centre for Rheumatology, Department of Medicine, University College London, London, United Kingdom, [3]Rheumatology Research Unit, Instituto de Medicina Molecular, Faculdade de Medicina da Universidade de Lisboa, Lisbon, Portugal.

Background/Purpose: B-cells utilizing the VH-region immunoglobulin gene VH4–34 produce natural autoreactive antibodies. The rat monoclonal antibody 9G4 recognizes B-cells with VH4–34-encoded B-cell receptors (9G4+ B-cells) and also secreted immunoglobulins. In healthy individuals, 9G4+ B-cells present in splenic marginal zones and tonsils are excluded from germinal centre (GC) reactions, whereas in autoimmune diseases such as systemic lupus erythematosus, 9G4+ B-cells expand in the post-GC memory compartment, suggesting defective 9G4+ B-cell censoring mechanisms. In rheumatoid arthritis (RA) patients, the distribution of tonsil 9G4+ B-cells is similar to healthy individuals, but only limited phenotypic analyses have examined 9G4+ B-cells in peripheral blood. The aim of this work was to perform an extensive phenotype characterization of 9G4+ B-cell subpopulations in peripheral blood in RA patients and healthy controls (HC).

Methods: Blood samples were collected from established RA patients ($n=12$) and age and sex-matched HC ($n=15$). Peripheral blood mononuclear cells were isolated by density gradient centrifugation and 9G4+ B-cells (gated in CD19+ B-cells) were characterized by flow cytometry. 9G4+ B-cell subpopulations were defined using combinations of IgD, CD27 and CD38. The expression of CD5, CD24, IgM, BAFF-R and CXCR5 was analyzed in total 9G4+ B-cells. Statistical analysis was performed with Mann-Whitney test.

Results: The frequency of total 9G4+ B-cells in circulation was similar between RA patients and HC (median values: 3.83% and 4.68%, respectively). We found that RA patients had a higher frequency of 9G4+IgD-CD27- B-cells than HC ($p=0.04$). No significant differences were found in other 9G4+ subpopulations based on IgD/CD27 classification, although there was a tendency for higher levels of 9G4+ switched memory B-cells (IgD-CD27+). RA patients also had significantly lower levels of 9G4+ transitional B-cells (IgD+CD38+++) ($p=0.004$) and 9G4+ plasmablasts (IgD-CD27+++CD38+++) ($p=0.004$) and increased frequencies of 9G4+ naïve B-cells (IgD+38++) ($p=0.04$) when compared to HC. A tendency for higher levels of 9G4+ post-GC memory B-cells (IgD-CD38+) was also observed in RA patients. Furthermore, BAFF-R expression was significantly increased in 9G4+ B-cells from RA patients (both frequency and mean fluorescence intensity values) compared to HC ($p=0.04$ and $p=0.006$, respectively). There was a significant decrease in levels of 9G4+CD5+ B-cells ($p=0.004$) in RA patients, but no other significant differences were found in 9G4+ B-cells expressing CD24, IgM and CXCR5.

Conclusion: RA patients have alterations in the frequency of 9G4+ B-cell subpopulations when compared to healthy individuals. The significant reduction in the frequency of 9G4+ transitional and 9G4+CD5+B-cells and the increased levels of 9G4+ naïve B-cells suggests a more rapid maturation of 9G4+ B-cells in RA patients following entry into the peripheral pool. This could be influenced by the antigen specificity of the B-cell receptor. Furthermore, the increased BAFF-R expression by 9G4+ B-cells observed in RA patients might support an increased survival mechanism for these already inherently autoreactive B-cells.

Memory B Cell Subtype Modulation in Patients with Rheumatoid Arthritis. Zafar Mahmood[1], Marc Schmalzing[1], Thomas Dörner[2] and Hans-Peter Tony[1]. [1]University of Würzburg, Würzburg, Germany, [2]Charité Universitätmedizin Berlin and DRFZ, Berlin, Germany.

Background/Purpose: Memory B cells have been shown to play important roles in the pathogenesis of rheumatoid arthritis (RA). With the advent of B cell targeted therapies the modulation of memory B cells seems to be a prime target. Human peripheral memory B cells can be classified into three major subtypes by the phenotypic expression of CD27 and IgD: CD27+IgD+ preswitch, CD27+IgD- postswitch and CD27-IgD- double negative (DN) memory B cells. We aimed in this study to analyze different subsets of memory B cells in patients with RA under cytokine inhibition.
