Cover photo

The scientific names for the seeds shown on the cover are identified by the key and photo below. Seeds 2 and 7 have had their wings removed by cleaning.

1. Green ash (Fraxinus pennsylvanica Marsh.)
2. Ponderosa pine (Pinus ponderosa P. & C. Lawson)
3. Northern red oak (Quercus rubra L.)
4. Witch hazel (Hamame lis virginiana L.)
5. Service berry (Amelanchier arborea (Michx. F.) Fern.)
6. Persimmon (Diospyros virginiana L.)
7. White fir (Abies concolor (Gord. & Glend.) Lindl. Ex Hildebr.)
8. Tulip poplar (Liriodendron tulipifera L.)

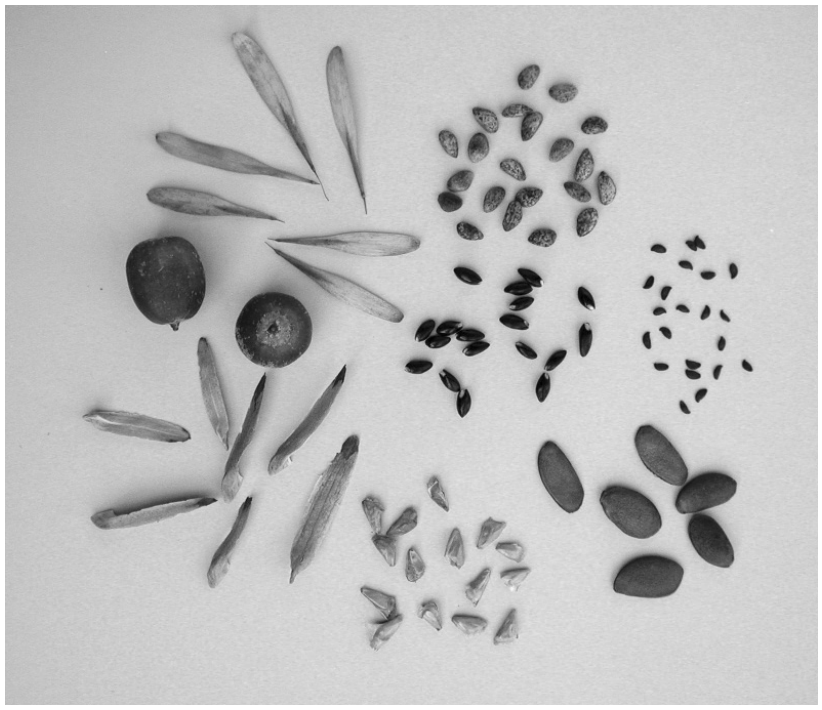
The Woody Plant Seed Manual



Franklin T. Bonner *editor*
USDA Forest Service, Scientist Emeritus, Southern Research Station (retired), Starkville, Mississippi

Robert P. Karrfalt *editor*
USDA Forest Service, National Seed Laboratory, Dry Branch, Georgia

This book is a revision of the USDA Forest Service's
1974 Agriculture Handbook 450, *Seeds of Woody Plants in the United States*
which was preceded by the USDA Forest Service's
1948 Miscellaneous Publication 654, *Woody-Plant Seed Manual*

Dedication

This handbook on the seeds of woody plants would not be possible if not for the pioneering work of many individuals in past years. They worked without the modern laboratory and information retrieval services that we now routinely use and take for granted. Their early efforts in the first half of the 20th century solved many seed problems and pointed the way for later research on numerous subjects. Without them, our body of knowledge about the seeds of woody plants would not be what it is today. Many contributed, but for their extensive work and leadership, we dedicate this book to the following pioneers:

George S. Allen *Canadian Forestry Service & University of British Columbia*
Henry I. Baldwin *New Hampshire Forestry Department*
Lela V. Barton *Boyce Thompson Institute*
Claude E. Heit *New York Agricultural Experiment Station*
Nikolas T. Mirov *USDA Forest Service*
Paul O. Rudolf *USDA Forest Service*
Charles F. Swingle *USDA Bureau of Plant Industry*
W. R. Van Dersal *USDA Soil Conservation Service*
Philip C. Wakeley *USDA Forest Service*

Acknowledgments

The development and publication of this book was supported by the USDA Forest Service's Research and Development (R&D) and State and Private Forestry (S&PF) National Offices as well as by R&D's Southern and Northeastern Research Stations, which supported Dr. Bonner and Ms. Nisley, respectively. We especially thank Drs. Jerry Sesco and Robert Lewis, Deputy Chiefs (retired) for Research and Development; Dr. Peter Roussopoulus, Director of the Southern Research Station; Dr. Michael T. Rains, Director of the Northeastern Research Station; and Debra Dietzman, Communications Director at the Northeastern Research Station, for their continued financial and personal support.

We also thank John K. Francis (retired after many years at the International Institute of Tropical Forestry), Robert P. Karrfalt (S&PF, Regeneration, Nurseries, and Genetics Resources National Team), Susan E. Meyer (Rocky Mountain Research Station), Peyton W. Owston (retired from the Pacific Northwest Research Station), and John C. Zasada (retired from the (North Central Research Station), the regional coordinators who solicited and organized the authors of the 236 genera.

We are grateful to Dr. Stanley R. Krugman for getting this effort going and sharing his experiences from the production of AH 450, *Seeds of Woody Plants in the United States* (1974). Sharon Friedman, Jacob L. Whitmore, Calvin Bey, Sam Foster, and Marilyn Buford served as our liaisons to the R&D National Office; Karl Dalla Rosa and Hal Brockman were the liaisons to S&PF; and Frank Burch to National Forest Systems. Becky Loth, at the National Seed Laboratory served admirably as the webmaster of our interim website, and Laura Cricco, Phyllis Grinberg, Jean B. Holland, Pamela Huntley, Barbara Johnson, and Kathy McManus, all of the Northeastern Research Station, provided much appreciated administrative and computer support.

Rebecca G. Nisley of the USDA Forest Service, Northeastern Research Station, Hamden, Connecticut, is acknowledged as principle editor for style and grammer.

Contents

Introduction

The first comprehensive handbook on the seeds of trees and shrubs produced by the USDA Forest Service was USDA Misc. Pub. 654, *Woody-Plant Seed Manual*. The manuscript was ready for publication in 1941, but World War II delayed publication until 1948. The boom in tree planting in the 1950s and 1960s created a large demand for seeds and exposed the gaps in our knowledge concerning production and quality of seeds of woody plants in general.

Realization of this condition led to the revision and considerable expansion of the manual, resulting in publication of USDA Agric. Handbk. 450, Seeds of *Woody Plants in the United States*, in 1974. Seed data were presented for about 800 species, varieties, and sub-species in 188 genera, considerable more than the 420 species and 140 genera in the 1948 edition. The 1974 Handbook proved to be very popular both in this country and abroad, leading to five printings and translations in several other languages. More than a quarter-century after its publication, however, numerous advances in tree seed technology have dictated that a new revision is needed; the result is the current volume.

The major audience for this book, as for its two predecessors, is those who are involved in the growing and planting of trees and shrubs. Their involvement can be collection and sale of seeds, production of nursery stock (both bare-root and container), or planting itself. Planting for commercial forest production is the traditional mainstay of tree planting, but planting for wildlife food, watershed protection, urban environmental improvement, ornamental enhancement, wetland mitigation, and carbon sequestration are all on the increase. Ecosystem management, now commonly used in the management of many federal and other governmental forest lands, has decreased the use of planting to regenerate the forests and has increased the role of natural regeneration. Those who apply these practices will find this book useful also in the data on flowering and seed production. Although the book is not intended to be a detailed textbook on seed ecology and physiology, there is sufficient scope and depth to the material included to make it useful to anyone who studies seeds. For additional information on these topics, readers should consult the recent works by Baskin and Baskin (2000) and Farmer (1997).

The organization of this book follows that of the earlier manuals. Part 1 comprises seven chapters that provide general principles on seed biology, genetic improvement, harvesting and conditioning, storage, testing, seed certification, and nursery practices. The chapter on genetic improvement combines two chapters from the 1974 Handbook but does not include the extensive technical information provided in 1974. Genetic improvement of tree and shrub species is now too common and widespread to be covered adequately in a chapter in a seed manual. For complete treatments on this subject, readers are referred to Zobel and Talbert (1984). In the same vein, pollen handling has been dropped; interested readers should refer to the handbook by Bramlett and others (1993). A chapter on nursery practices has been added to the current book, not to serve as a complete technical reference on the subject, but to point out the seed considerations in current nursery operations. Good technical manuals on nursery production of woody plants are those of Duryea and Dougherty (1991), Landis and others (1990–95), Liegel and Venator (1987), and Williams and Hanks (1976). Readers needing additional information on vegetative reproduction should consult Dirr and Heuser (1987).

Part 2 has been expanded to include almost 1,300 taxa in 236 genera. Most of the additions are either tropical species that are grown in Puerto Rico and the Virgin Islands, Hawaii, and the Pacific territories or native species that have increased in value for wildlife or environmental plantings in recent years. Many of these latter are shrubs from the western United States. Information is presented by genus in alphabetical sequence as before. Data have typically been grouped under the following headings: growth habit, occurrence, and use; flowering and fruiting; collection, extraction, and storage of seeds; pregermination treatments; germination tests; and nursery practices. For genera without much information, some of these headings have been combined. In general, the minimum standard for inclusion has been sufficient information to collect and germinate the seeds. Readers with wider interests in tropical species should consult Khullar and others (1991), Ng (1992), Schmidt (2000), Tompsett and Kemp (1996), and Vozzo (2002). An excellent reference on propagation of native plants of the Pacific Northwest is the work by Rose and others (1998).

If authors of the 1974 genus chapters were still working for the Forest Service, they were given the opportunity to write the updated version. Some did, and a number of retired authors also asked to be a part of the revision. If very little rewriting was done because of a dearth of new information about a genus since 1974 (and there were a few of these), names of the 1974 authors remain on the chapters. If new information required extensive rewriting, then the new authors got primary credit. In most cases, 1974 authors who are now deceased also got credit for their contributions. There were 95 authors engaged in the updating of this manual (page 1182), and they all deserve our thanks . Recruitment of authors and coordination of their activities were primarily carried out by a group of regional coordinators: Franklin T. Bonner, John K. Francis, Robert P. Karrfalt, Susan E. Meyer, Peyton Owston, and John C. Zasada.

One major change in the current book deals with nomenclature. A decision was made to use the nomenclature system under development by the USDA Natural Resources Conservation Service as part of a government-wide attempt to adopt standard nomenclature for plants, insects, etc. of North America. This on-line database (PLANTS 2004)

became the primary nomenclature resource. A second resource was needed for numerous non-native plants; for this purpose the USDA Agricultural Research Service Genetic Resources Program (GRIN 1999) was adopted. Other valuable data on plant nomenclature came from *Hortus third*, by the Liberty Hyde Bailey Hortorium at Cornell University (LHBH 1976). Use of these resources for nomenclature resulted in numerous name changes, which may be confusing in some cases. For example, *Libocedrus* (in the 1974 Handbook) is now *Calocedrus*; *Castanopsis* is now *Chrysolepis*. The Table of Contents for part 2 makes this transition easier by listing the old names where appropriate. Some genera have been divided or placed into different families also, and numerous species names have been changed. We have attempted to include all 1974 Handbook names that are now synonyms in the genus chapters. In addition, we have provided the scientific names and authorities for fungi from Farr and others (1989). Scientific names of insects, birds, and wild mammals have been taken from numerous accepted sources.

Another change in the current book is a shift from English to metric units. The metric system of measurements is now the "official" system of the United States, and it is commonly used in most USDA Forest Service publications. To assist users who are not yet comfortable with this, we have included both metric and English values for the most commonly used values in seedling production: number of seeds per unit weight (seeds per pound and seeds per kilogram), and number of seeds to sow per unit of bed area (seeds per square meter and seeds per square foot). A table of conversion factors is again included before the glossary (page 1193).

The vast majority of the line drawings and photographs used in the 1974 Handbook have been used again in this volume. For new species, efforts were made to collect specimens for new photographs that are similar in style and background to those of the 1974 Handbook. In most cases this was done, but samples were not available for every new species. As a result, line drawings from other publications were utilized.

The glossary has been expanded by several dozen terms; a few have been dropped. Others have been altered to reflect current usage. Most terms of seed biology and seed technology have been defined according to the glossary of the IUFRO Working Party S2.01.06 "Seed Problems" (Bonner 1984).

Those who use this book should realize that much new information on seeds of woody plants has appeared in print since the current chapters were finalized. Efforts to improve the utilization of our forest and range resources continue, and new information is constantly discovered and put to use. Like the seed manuals published before, this one will not be the last, although the next revision may be a digital data base. Until another revision takes place, however, genus chapters will be periodically updated with new information on the website that was established during the current revision: *www.nsl.fs.fed.us*.

Using This Book

Many difficult editorial problems developed as we worked on the Manual; some of them have no one best answer. The first was the metric versus "English" units question. This we resolved as discussed in the Introduction. Ironically, the English don't use these units anymore, having made the switch to metric.

The next one was the problem of using common versus scientific names in the text. Switching back and forth from one to the other in the text (as was done in AH-450) can be very confusing, so we decided to use common names for the species and genera as consistently as possible in the text. All scientific names are provided in the text at first mention or in various tables listing the taxonomy of the genera; the preferred scientific name (according to PLANTS or GRIN 2004) are in listed in boldface.

We have also designated a preferred common name for a species in boldface. Please note that we have chosen these preferred common names with care. Although the other common names in use or found in various references are listed as well, we worked to provide preferred common names that are grammatically logical. Only those common names for a "true" genus stand alone as one word. Common names connected with hyphens or closed up as one word—such as Douglas-fir, mountain-laurel, mountain-ash, Cooke-pine, and Atlantic white-cedar, for example—indicate that these species are not members of the true fir, true laurel, true ash, true pine, or true cedar genera, respectively. The modifiers false mock, and pseudo, also indicate that the species is not a true member of the specified genus. Common names that include a person's name are not in the possessive case; for example, Nuttall horsebrush, Gambel oak, Gardner saltbush, or Joshua tree. However, vernacular names such as eastern virgin's-bower, traveler's-joy, and squaw waterweed seemed best left as they were. Wonderful names like rubber rabbitbrush, tingiringy-gum, messmate stringybark eucalyptus, mountain misery and hearts-a-bustin' provided some much needed humor during the editorial process.

Sometimes the correct or preferred word choice for a procedure or process is controversial or not in common use. For example, many of our authors used the traditional term "stratification"; others used the more current terms "chilling" or even "pre-germination chilling" (which is often shortened to "pre-chilling").

Standard abbreviations for metric and "English" units are used throughout the book. Other words and units are shortened or abbreviated in the tables in the interests of saving space. The following abbreviations were used extensively in the references and text:

United States Government Departments and Agencies: USDA = United States Department of Agriculture, USDC = United States Department of Commerce, USDI = United States Department of the Interior. USDOE = United States Department of Energy. ARS = Agricultural Research Service, CFSTI = Clearinghouse for Federal Scientific and Technical Information, FS = Forest Service, OECD = Organization for Economic Cooperation and Development, NPS = National Park Service, NRCS = National Resources Conservation Service (formerly the SCS), NTIS = National Technical Information Service, SCS = Soil Conservation Service.

Non-governmental agencies and publishers: AOSA = Association of Official Seed Analysts, FAO = Food and Agriculture Organization of the United Nations, FNAEC = Flora of North America Editorial Committee, ISTA = International Seed Testing Association, IUFRO = International Union of Forestry Research Organizations, LHBH = Liberty Hyde Bailey Hortorium, NBV = Nederlandische Boschbouw Vereeniging, WFTSC = Western Forest Tree Seed Council.

Other: avg = average, dbh = diameter at breast height, max = maxiumum, min = minimum, mon = month(s).

In addition to the book, this Manual is being made available as a CD-ROM and can be read, downloaded, and printed at our website, which can be accessed at: *www.nsl.fs.fed.us*. There we plan to set up a system to update and add to the 236 genera that are included in the Manual.

Invasives

We remind our readers that listing species in this book is not necessarily a recommendation to use them! Many species that earlier in the twentieth century were recommended and even planted by various federal and state agencies as erosion control and wildlife plants—multiflora rose, autumn-olive, and Russian-olive, for example—are now considered invasive non-natives and are targets of eradication campaigns! Other plants that have escaped from horticultural uses—broom, burning bush, oriental bittersweet, Japanese barberry, etc.—are also members of this infamous company. Finally, there are invasive plants such as ailanthus and royal paulownia that arrived here accidentally. We sincerely hope that the information contained in this new manual may be of help in efforts to control woody invasives.

Part I Principles and General Methods of Producing and Handling Seeds

Part 2 Specific Handling Methods and Data for 236 Genera

Part I

Principles and General Methods of
Producing and Handling Seeds

Chapter 1

Seed Biology

Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Contents

Introduction

Seeds are the principal means of regeneration of most woody plants. They serve as the delivery system for the transfer of genetic materials from one generation to the next. The part of a tree's life cycle that involves seed formation, maturation, dissemination, and germination is a complex—yet fascinating—chain of events, many of which are still poorly understood. Yet some knowledge of these events is necessary for successful collection and utilization of seeds to produce the means for artificial regeneration. This chapter presents basic information on the biology of seeds and how this knowledge can be used in collecting, conditioning, storing, and sowing seeds.

Flowering Plants

The seed-producing organisms of the plant kingdom belong to the division Spermatophyta and are further classified into 2 sub-divisions—Gymnospermae (gymnosperms) and Angiospermae (angiosperms). Gymnosperms are further divided into orders. Only 2 are of interest here: Ginkgoales, which is represented by a single species, ginkgo (*Ginkgo biloba* L.), and Coniferales (conifers), by far the most important group of gymnosperms. The conifers contain 4 families in North America: Pinaceae, Taxodiaceae, Cupressaceae, and Taxaceae. These include economically important genera such as pine *(Pinus* L.), spruce (*Picea* A. Dietr.), sequoia (*Sequoia* Endl.), cypress (*Cupressus* L.), and yew (*Taxus* L.).

Angiosperms are divided into 2 classes—Monocotyledoneae and Dicotyledoneae. Monocotyledonous trees are not very common in North America, but they are represented in this book by the families Palmae (genera *Roystonea* O.F. Cook, *Sabal* Adans., and *Washingtonia* H. Wendl.) and Liliaceae (genus *Yucca* L.). Dicotyledonous species number over 30 families in North America and are by far the largest class of woody plants. This class includes such common genera as maple (*Acer* L.), acacia (*Acacia* Mill.), birch (*Betula* L.), ash (*Fraxinus* L.), holly (*Ilex* L.), oak (*Quercus* L.), and blueberry (*Vaccinium* L.).

Reproductive Cycles

The reproductive cycles of flowering plants begin with initiation of reproductive buds and end with maturation of the seeds. There are 3 types of reproductive cycles that have been recognized in trees of the temperate zone (Owens and Blake 1985).

The 2-year cycle is the most common type. Reproductive buds form late in the growing season of the first year; pollination occurs in the next spring, closely followed by fertilization. The embryo grows rapidly, and seeds are mature by summer or early fall of the second year. This is the cycle of most gymnosperms and angiosperms of North America. Detailed studies of individual species provide good descriptions of the cycle in birch (Macdonald and Mothersill 1987), larch (*Larix* Mill.) (Owens and Molder 1979), spruce (Owens and others 1987), Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco) (Owens and Smith 1964; Owens and others 1991a), thuja (*Thuja* L.) (Owens and Molder 1984a), and fir (*Abies* Mill.) (Owens and Molder 1977b).

The second type of reproductive cycle is the 3-year cycle that is common to most species of pines (Owens and Blake 1985). Buds form in late summer or early fall as before, followed by pollination the following spring. Pollen tube and ovule development then stop in mid- or late-summer and resume the following spring. Fertilization occurs that spring, and the seeds mature in the fall. Descriptive work on pines includes western white pine (*Pinus monticola* Dougl. ex D. Don) (Owens and Molder 1977a) and lodgepole pine (*P. contorta* Dougl. ex Loud.) (Owens and Molder 1984b). Other gymnosperms in this book that exhibit this type of reproductive cycle include araucaria (*Araucaria* Juss.) and sciadopitys (*Sciadopitys* Sieb. & Zucc.). Among angiosperms of North America, the 3-year reproductive cycle occurs only in the black oak group (Erythrobalanus) of oak (Mogensen 1965). Like that in pine, fertilization in black oak does not occur until 13 months after pollination.

The third type of reproductive cycle, found in members of the Cupressaceae family, is somewhat similar to the second type. The primary difference is that fertilization occurs within a few weeks of pollination during the second year, with embryo development going into a dormant phase in late summer or early fall (Owens and Blake 1985). This type of cycle has been described for Alaska-cedar *(Chamaecyparis nootkatensis* (D. Don) Spach) (Owens and Molder 1984a) and probably occurs in some juniper (*Juniperus* L.) species (Johnsen and Alexander 1974).

Flowering

Botanically speaking, angiosperms produce true flowers, but gymnosperms do not. Gymnosperm reproductive structures are actually strobili, but for this discussion, they will be considered flowers in the broad sense. All trees propagated from seeds pass through a period of juvenility before they acquire the capability of flowering and producing seeds of their own. The length of this juvenile period is extremely

varied among species, ranging from as little as 3 years for *Pinus gieggii Engelm*. (Lopez-Upton and Donahue 1995), to 40 years for sugar pine (*P. lambertiana* Dougl.) (Krugman and Jenkinson 1974). The majority of tree species in the temperate zone, however, begin flowering at the age of 10 to 15 and produce significant seedcrops by the age of 25 to 30 (Owens and others 1991b). Woody shrubs generally flower and fruit at earlier ages. Extensive data on seed-bearing ages are presented for all species in part 2 of this book.

Among species with unisexual flowers (flowers of one sex only, either staminate or pistillate), flowers of one sex may be produced long before flowers of the other sex. For example, Scots pine (*P. sylvestris* L.) may produce female strobili at age 5 to 7, but no male strobili until age 10 to 15 (Matthews 1970). Many other pines are the same. The extent of this phenomenon in angiosperms is not known, but it does occur in some species, for example, yellow birch (*Betula alleghaniensis* Britton) (Erdmann 1990).

The length of the juvenile period can be affected by many factors other than age. Physical size of the plant seems to be important in some cases (Hackett 1985; Schmidtling 1969). Genetic differences are often obvious in even-aged plantations where spacing and tree size are equal, and there is experimental evidence to confirm the genetic effect in a few species (Sedgley and Griffin 1989). Furthermore, tree improvement programs have demonstrated that selections for early flowering within species have the potential to produce clones with precocious flowering traits (Krugman and others 1974).

Initiation

In numerous woody plants, flower initiation and development is a lengthy process extending over several months. During this period, environmental factors and the internal physiological condition of the trees interact to produce the flower crops. The effects of some environmental factors have been observed through the years, and these relationships have been used to influence flowering and seed production in some species (see below). The internal factors involved are still poorly understood, as are their interactions with the environment.

Phenology. Flower buds on most trees and shrubs of the temperate regions are initiated late in the growing season of the year preceding flowering (table 1). In species with unisexual flowers, male flowers may start earlier and differentiate more rapidly as well. Flowers may bloom from late winter to fall, depending on the species and the location. In temperate trees, flowering is primarily seasonal, that is, production only occurs in certain times of the year. Most species bloom in the spring, but there are numerous exceptions to this rule. Witch-hazel (*Hamamelis virginiana* L.) flowers from September to mid-November; California-laurel (*Umbellularia californica* (Hook & Arn.) Nutt.) from December to May; September elm (*Ulmus serotina* Sarg.) *in* September; and deodar cedar (*Cedrus deodara* (Roxb.) Loud.) in September to October. The times reported in this book for flowering are typically expressed as a range of several months to allow for the latitudinal and elevational differences throughout the range of a given species. Local variations in weather may also affect the time of flowering from year to year on the same tree.

Table 1–Chapter 1, Seed Biology: times of flower initiation in selected species as determined from microscopic examination of buds

Species	Location	Time of initiation	
		Male	Female
Acer pseudoplatanus L.	Indiana	June	June
Betula papyrifera Marsh.	NW Ontario	Early May	Late June–early July
Carya illinoensis (Wangenh.) K. Koch	Georgia	May	Mar
Larix occidentalis Nutt.	British Columbia	June	June
Picea glauca (Moench) Voss	Ontario	Early Aug	Early Aug
Pinus elliottii Engelm.	Florida	Late June–July	Late Aug
P. monticola Dougl. ex D. Don	British Columbia	Late June–Aug	Mid-Aug
Populus tremuloides Michx.	Connecticut	Early July	Late June
Pseudotsuga menziesii (Mirb.) Franco	Oregon	Apr	Apr
Taxodium distichum (L.) Rich.	Florida	—	Aug
Thuja plicata Donn ex D. Don	British Columbia	Early June	July
Tsuga heterophylla (Raf.) Sarg.	British Columbia	June	July

Sources: Anderson and Guard (1964), Fraser (1962), Lester (1963), Macdonald and Mothersill (1987), Mergen and Koerting (1957), Owens and Molder (1974, 1977, 1979), Owens and Pharis (1971), Owens and Smith (1964), Takaso and Tomlinson (1990), Wetzstein and Sparks (1983, 1984).

In tropical species, the time period between initiation of floral buds and anthesis is relatively short, and flowering may occur once, twice, or several times a year or even continuously throughout the year (Kramer and Kozlowski 1979; Sedgley and Griffin 1989). Some species have 2 periods of flowering per year, 1 considerably heavier than the other. The irregularity of flowering is more evident in moist tropical forests, where seasonal changes are absent (or subtle), than in dry tropical forests (Willan 1985). Flowering patterns in dry tropical forests are usually related to rainfall patterns.

Influencing factors. The natural variations in flowering that are obvious to even casual observers are evidence that flowering must be affected by many factors. These factors can be either environmental or physiological (internal) in nature, and they all interact to influence the expression of flowering in woody plants.

Temperature. High temperatures during summer enhance formation of flower buds in many species of the temperate regions (Sedgley and Griffin 1989). Most flowering studies that show this effect have correlated weather records with records of fruit and seed production (Owens and Blake 1985), but the physiological reasons for this effect have not been elucidated. Most of the examples are of conifers: Norway spruce (*Picea abies* (L.) Karst.) (Lindgren and others 1977), Douglas-fir (Lowry 1966), ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) (Maguire 1956), and red pine (*P. resinosa* Ait.) (Lester 1963). Among hardwoods, European beech (*Fagus sylvatica* L.) has shown similar responses (Matthews 1955). High summer temperatures usually accompany drought conditions, however, and it is difficult to say which is the most important (see below).

There are important low temperature effects also, but they occur in the spring following bud initiation. For some species in the warmer portion of the temperate regions and for subtropical species, there is a moderate cold requirement for flowering. Examples are pecan (*Carya illinoensis* (Wangenh.) K. Koch) (Amling and Amling 1983) and olive (*Olea europaea* L.) (Hackett and Hartmann 1967). Another low temperature effect that is familiar to most people is the killing of flowers by late frosts in the spring. Citrus and other fruit crops are well-known for this, especially in the South, but native trees and shrubs suffer the same fate. Complete seedcrop failures may only occur in local stands or microsites, however, as some trees may always be protected from the cold or exposed to winds that prevent frost formation on the flowers.

Light. Unlike flowering in annuals, flowering in most woody perennials does not appear to be under strict photoperiodic control (Sedgley and Griffin 1989). Mirov (1956) and Lanner (1963) concluded that flowering in pines was not affected by day length. Other studies suggest that photoperiod may have some control on the sex of reproductive buds (Owens and Blake 1985). Experimental evidence of some type of control does exist, however, so it may be that the effect is difficult to define in woody plants. In azaleas (*Rhododendron* L.), for example, flower initiation was accelerated by short days of 8 hours light (Criley 1969), whereas flowering in some varieties of apple (*Malus* Mill.) was better under long days (14 hours) than short days (8 hours) (Tromp 1984). In western hemlock (*Tsuga heterophylla* (Raf.) Sarg.), pollen cone buds were favored by increasing daylengths, whereas seed cone buds were favored by decreasing daylengths (Owens and Molder 1974). In coniferous species where the photoperiod effect is different for male and female flower buds, there is a natural difference between the sexes in time of bud differentiation. In species without this difference, there may be an indirect effect of photoperiod through cessation of shoot elongation, which usually coincides with reproductive bud differentiation (Owens and Blake 1985). Clearly, photoperiodic effects on flower initiation for any species cannot be understood without knowledge of the timing of the reproductive cycle in that species.

Light intensity has a more demonstrable effect on flowering in trees than photoperiod. Open-grown trees with full crowns have more flowers than trees with shaded crowns, and this is not just an effect of more sites for bud formation on open-grown trees. Any collector of tree seeds can testify that, in northern latitudes, most of the crop will be found on the southern and western portions of open-grown crowns. Increased light intensity (or at least increased sunshine) is also reported to increase flowering in tropical trees (Nanda 1962; Ng 1977).

There are conflicting reports about the effects of light intensity on sexual differentiation. Higher light intensities of open stands were found to favor female flowers in walnuts (*Juglans* L.) (Ryugo and others 1980) and male flowers in striped maple *(Acer pensylvanicum* L.) (Hibbs and Fischer 1979).

Moisture. There have been many studies that showed increased flowering in trees subjected to moisture stress in late summer (Owens and Blake 1985; Sedgley and Griffin 1989). It is extremely difficult to separate the effects of temperature and light intensity from those of moisture stress, however, as the 3 conditions typically occur together. After careful examination of published data, Owens and Blake (1985) concluded that there was little evidence that moisture stress during the period of flower bud initiation led directly to increased flower production.

There are other effects of moisture besides drought, of course. A plentiful supply of moisture during peak growth periods will indirectly benefit flowering through increased shoot growth and crown development. Excess moisture during pollination, especially for wind-pollinated species, can be a problem, but this effect will be discussed later in this chapter.

Nutrition. In general, a favorable nutrient status is required for woody plants to produce good seedcrops. Many studies have shown increased seed production after the application of fertilizers, especially nitrogen and phosphorus, but the precise roles of these elements in flowering and seed production are not known (Owens and Blake 1985). Abundant flowering in fruit trees has long been associated with a high carbon to nitrogen ratio in the shoot tissues (Kramer and Kozlowski 1979). Although this condition may be explained in term of carbon partitioning within the plant, the controlling factors are still unknown. Fertilization to increase flowering and seed production may have 2 effects. There can be a short-term effect of direct impact on flower production and fruit/seed size, and there can be a long-term effect of more buds sites just by increasing crown size.

Physiology. The physiological status of woody plants is the most important factor of all in flower initiation, yet it is the factor that is most difficult to influence. Early plant physiologists searched for a single hormone that could turn flowering on or off (Kramer and Kozlowski 1979) but were not successful. Current knowledge suggests that the balance between gibberellins, cytokinins, and other natural bioregulators controls the change from juvenile to mature stage and also the amount of flowering in the mature stage. The weak link in this reasoning is that most of the evidence comes from results of experiments in which chemicals were applied to plants externally (Sedgley and Griffin 1989). The strong point of these experiments is that flowering really can be stimulated in a host of species (primarily gymnosperms) by chemical application. A considerable amount of research remains to be done before we can understand the internal controls on the flowering process in woody plants.

Manipulation of flowering. When speaking of manipulating the flowering process in trees, we must distinguish between forcing trees to flower while they are still in the juvenile phase, or treating trees that are already in the flowering phase to produce more flowers. In the first case, the interest is usually in speeding breeding programs. In the second, increased seed production for artificial regeneration programs is usually the goal.

Juvenile phase. Precocious flowering in conifers has been produced mainly with water-based foliar sprays of gibberellins (GA). A detailed review by Owens and Blake (1985) points out that GA_3 has been most successful with members of the Cupressaceae and Taxodiaceae, whereas non-polar $GA_{4/7}$ mixtures have provided successes with the Pineaceae. In Cupressaceae and Taxodiaceae, treatment with GA_3 alone is usually successful in stimulating flower bud production; this can be seen in the following genera: "cedar" (*Chamaecyparis* Spach.), cryptomeria (*Cryptomeria* D. Don), cypress, sequoia, baldcypress (*Taxodium* Rich.), and thuja (Owens and Blake 1985). Manipulation of other cultural treatments, such as drought, fertilization, or daylength, is not really necessary unless a change in the proportion of pollen to seed cones is the goal. For example, treatment of western redcedar (*Thuja plicata* Donn ex D. Don) seedlings with GA_3 under short days favored initiation of seed cone buds, whereas treatment under long days favored initiation pollen cone buds (Pharis and Morf 1972; Pharis and others 1969).

In Pineaceae, GA treatments are often combined with cultural treatments, because there is usually a strong synergistic effect. Precocious flowering has been induced in seedlings of jack pine (*Pinus banksiana* Lamb.) with a combination of moisture stress and $GA_{4/7}$ (Cecich 1981; Riemenschneider 1985) and in Douglas-fir seedlings with a combination of girdling and the same gibberellin treatment (Pharis and others 1980). Other Pineaceae genera for which success has been reported are larch, spruce, and hemlock (Owens and Blake 1985), although these results have generally not been as successful as those for Cupressaceae and Taxodiaceae. Other factors, such as timing of treatments, developmental stage of the plants, and method of application can also have significant effects. In loblolly pine, a combination of low temperatures and short photoperiods has been used to stimulate formation of strobili on potted stock as young as 3 years (Greenwood 1978). It should also be noted that the mechanisms for these treatment effects are still unknown, and much basic research is needed to fully understand them.

Mature phase. Stimulation of flower initiation in sexually mature trees is commonly practiced in seed orchards to increase seed production. Fertilization has been the most common and most successful treatment used. Owens and Blake (1985) summarized fertilizer tests on over 20 species of trees and found, that while many were successful, others produced variable results. Interactions with other factors, such as timing, method of application, rate, formulation, and moisture conditions following treatment have significant

effects (Schmidtling 1983). Most of the attention has been on nitrogen and phosphorus, but many trials used complete fertilizers. Current practice is to base fertilization levels on soil analyses of individual orchards. Typical fertilization prescriptions for seed orchards of southern pines have been annual application of about 400 kg/ha of nitrogen, 80 kg/ha of potassium, 40 kg/ha of phosphorus, and 50 kg/ha of magnesium (Zobel and Talbert 1984).

Another treatment widely used is manipulation of soil moisture levels. Irrigation of seed orchards in conjunction with fertilization is one practice, and in most cases the response is positive. Moisture stress has also been used, although this sort of treatment is difficult to apply in the field. In seed orchards, moisture stress has been created by root pruning the orchard trees to temporarily disrupt moisture uptake. The effect of moisture stress may be through its effect on carbon allocation in the tree, although other factors are sure to be involved. Ebell (1970) found that moisture stress increased the level of amino acids in Douglas-fir trees just as application of nitrate nitrogen did, and that both induced cone formation. When water was supplied to the trees, protein synthesis increased but cone formation did not.

Girdling and other wounding treatments have been popular as a means of increasing production in fruit trees. The theory behind these actions was that girdling prevented translocation of carbohydrates to the roots, thus raising the C to N ratio in the crown, which increased fruit production. Recent experimental evidence provides weak, if any, support for this theory, and a good explanation for the wounding effect is still lacking (Owens and Blake 1985). Despite the uncertainty, girdling is still used in seed orchards of Douglas-fir and other conifers.

Timing of wounding treatments seems to be important, at least in some species. Ebell (1971) girdled Douglas-fir trees at weekly intervals from April to mid-July. The optimal time of treatment was about 1 month before the vegetative buds burst. Many other studies of this nature have not controlled time of treatment as well, and timing effects cannot be determined (Owens and Blake 1985).

Thinning of seed stands is another commonly used practice to increase flowering. Thinning brings about increased light intensity to the crowns (see previous section) and less competition for moisture and nutrients. As one might expect, there is a delay before treatments are usually effective, ranging from 1 to 4 years (Allen 1953; Owens and Blake 1985). Flower and fruit production increases attributed to thinning have been documented for black walnut (*Juglans nigra* L.) (Ponder 1979), hoop-pine (*Araucaria cunninghamia* Sweet) (Florence and McWilliam 1956), loblolly pine (Bilan 1960; Allen and Trousdell 1961), longleaf pine *(Pinus palustri*s Mill.) (Allen 1953), and other conifers. Fertilization at the time of thinning enhanced cone production in Japanese larch (*Larix leptolepis* (Sieb. & Zucc.) Gord.) and Japanese red (*Pinus densiflora* Sieb. & Zucc.) (Asakawa and Fujita 1966) and ponderosa pines (Heidmann and others 1979).

Much less is known about stimulation of flowering in tropical and subtropical tree species. Many of the same treatments used on temperate species have been tested in the tropics also, and, as one would expect, results have not been consistent. Carbohydrate accumulation and an interruption of vegetative growth of the tree are the factors that have been most frequently associated with increased flower initiation (Dick 1995).

Structure and Development

Flower primordia are inconspicuous at first and rarely can be identified without careful microscopic examination of the tissues. Initially, there are no external features that serve to distinguish flower buds from vegetative buds. As flower buds grow and develop, they become distinguishable from vegetative buds by their general appearance and location. Variation among species is significant, but flower buds usually become wider and longer as they grow and may differ in color and shape from vegetative buds. In some species, such as flowering dogwood (*Cornus florida* L.), flower buds are distinctive in shape and large enough by late summer (July to August) for easy identification, thus providing a preliminary estimate of next year's flower crop.

Flower buds enlarge greatly as the flowering season nears and conditions become favorable for bud growth. Individual flowers of many species open rapidly once flowering begins. This is especially true if air temperatures are unseasonably high. Conversely, colder than normal temperatures will delay flower opening. Flower opening usually does not occur simultaneously over an entire inflorescence, over an entire tree, or even among plants of the same species in a stand, but it may be in progress for many days at any one location. The evolution of flowering in this way in wild populations is a distinct advantage in perpetuation of the species, as short-term events that destroy flowers or prevent pollination cannot destroy the entire crop.

Flowers of woody plants come in many different shapes, colors, odors, and sizes. They may be minute and inconspicuous, like the flowers of thuja, or they may be large, showy, and fragrant like the 1-foot wide, white, perfect flowers of bigleaf magnolia (*Magnolia macrophylla* Michx.) (Brown

and Kirkman 1990). The flowers of many species are sufficiently attractive to create a demand for their use in ornamental plantings. Well-known ornamental trees include serviceberries (*Amelanchier* Medic.), redbud (*Cercis canadensis* L.), dogwoods (*Cornus* L.), mountain-laurel (*Kalmia latifolia* L.), magnolias (*Magnolia* L.), and azaleas. Some woody vines included in this book are also used extensively for ornamental plantings because of their showy flowers: trumpet creeper (*Campsis radicans* (L.) Seem. ex Bureau), clematis *(Clematis* L.), and honeysuckle (*Lonicera* L.).

An angiosperm flower (figure 1) may have some or all of the following parts: a stalk or peduncle, a receptacle, a calyx composed of sepals, a corolla composed of petals, stamens with anthers and filaments, and 1 or more pistils, each with a stigma, style, and ovary. A flower is complete when it has a calyx, corolla, functional stamens, and 1 or more functional pistils. It may be considered incomplete when 1 or more of these parts is lacking or nonfunctional. Though lacking a calyx or corolla, a flower is perfect (or bisexual) when it has both stamens and pistil, and unisexual when only one or the other is present and functional. The calyx and corolla may be considered accessory parts, but stamens (which produce pollen) and the pistil or pistils (which contain the ovaries) are mandatory for normal seed production. The primary function of the calyx and corolla, both of which are modified leaves, is to enfold and protect the stamens and pistils while they mature. For entomophilous species, the color, odor, or nectar supply of the unfolded calyx and corolla play a role in attracting of the insects that are needed for pollination.

Many angiosperm trees and shrubs produce complete flowers, for example, cherry (*Prunus* L.), locust (*Robinia* L.), magnolia, and tuliptree (*Liriodendron tulipifera* L.). Other species bear incomplete flowers that lack a calyx as in some ashes, a corolla in silktassel (*Garrya* Dougl. ex Lindl.), or both calyx and corolla in willows (*Salix* L.) and hazels (*Corylus* L.). Some species bear separate male and female flowers on the same plant (monoecious); examples are alders (*Alnus* Mill.), birches, and oaks. Other species bear these separate flowers on different plants (dioecious); examples are maple and holly. In some species all floral parts are present but instead of being distinctly separate, some are more or less united, for example, sepals in viburnums (*Viburnum* L.), petals in catalpas (*Catalpa* Scop.), and pistils in azaleas (*Rhododendron*).

Some genera of angiosperms have polygamous floral habits. Bisexual as well as unisexual staminate and pistillate flowers may occur on the same tree, as in the hackberries (*Celtis* L.). This condition is defined as polygamo-monoecious, although the trees are functionally monoecious. If bisexual flowers occur with only staminate or pistillate flowers on separate trees, as in buckthorn (*Rhamnus* L.), the condition is defined as polygamo-dioecious, although the plant is functionally dioecious. In a few species, there are several flowering patterns. Silver maple (*Acer saccharinum* L.) and striped maple, for example, can be monoecious, dioecious, or sometimes polygamo-monoecious (Gabriel 1990; Hibbs and Fischer 1979).

Most coniferous gymnosperms are monoecious, but other genera—juniper and torreya (*Torreya* Arn.)—are dioecious. Coniferous gymnosperm flowers are strobili (small

Figure 1—Chapter 1, Seed Biology: structure of a complete angiosperm flower (from Krugman and others 1974).

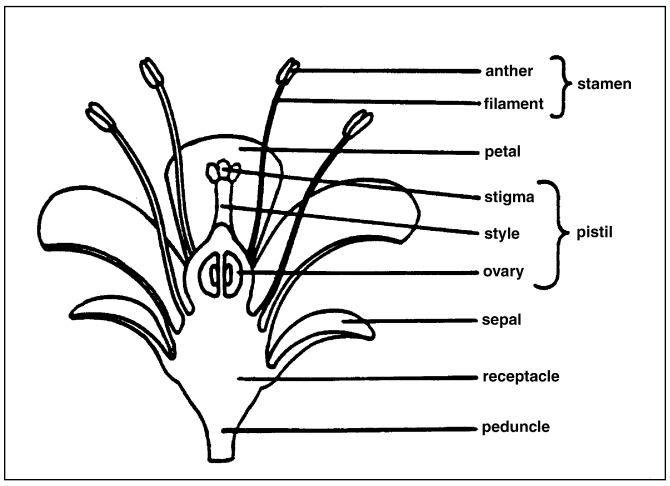

Figure 2—Chapter 1, Seed Biology: structure of a staminate flower typical of coniferous gymnosperms (Coniferales) (from Krugman and others 1974).

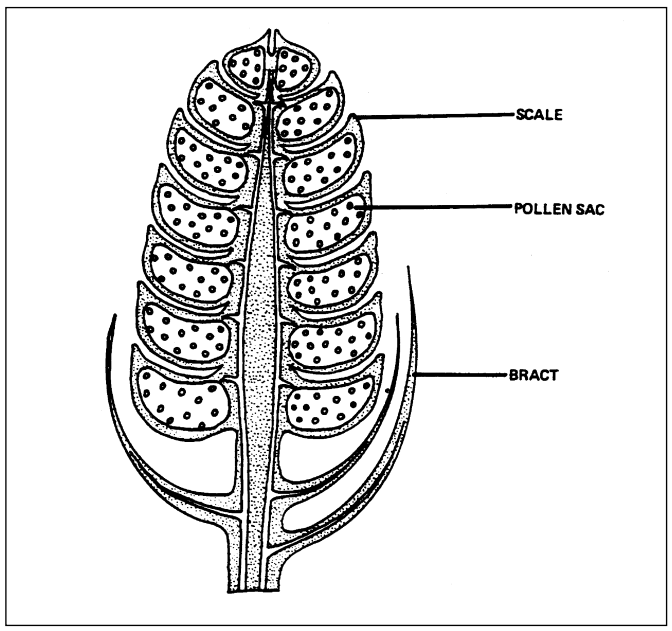
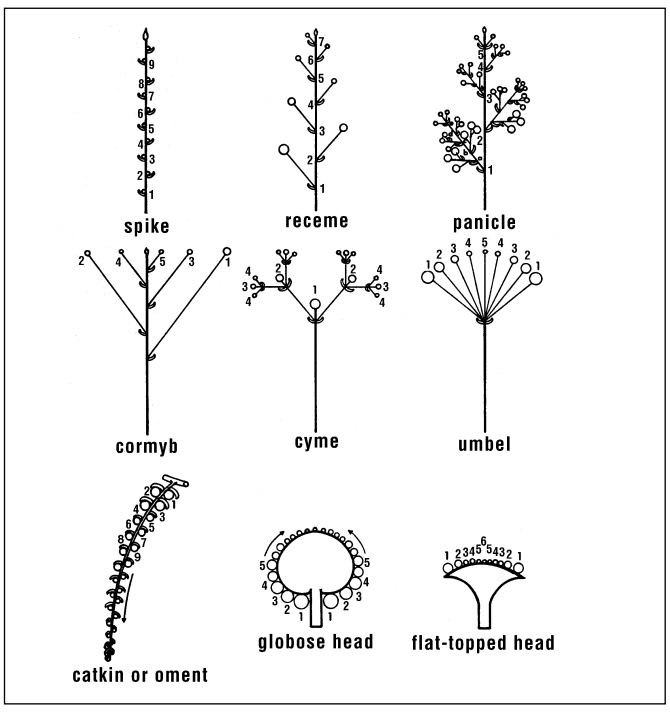


cones) without calyx, corolla, stamens, or pistils. These strobili characteristically have a central axis bearing a few to numerous distinctly shaped scales and bracts (figure 2). In staminate strobili, each scale (microsporophyll) bears 2 pollen sacs (microsporangia) on its lower surface. In ovulate strobili, 2 inverted ovules (megasporangia) form on the upper surface of each ovulate scale. Staminate strobili—often bright shades of yellow, red, or purple when fully developed—are numerous, short-lived, and highly productive of pollen. The less numerous, but infrequently colorful, ovulate strobili develop into woody, relatively durable structures (cones) that contain a varying number of seeds.

Coniferous strobili are similarly arranged around the central axes of cones (figure 2). Flowers of angiosperms, on the other hand, have varied and distinctive floral arrangements. Some species bear a single flower on each peduncle, for example, magnolia and tuliptree, but most others bear flowers in groups or clusters called inflorescences. The general structure of an inflorescence is a central stem, with or without branches, on which flowers, with or without pedicels, develop. Examples of the common forms of inflorescences of woody plants (figure 3) include catkin (ament), birch; raceme, serviceberry; spike, walnut (pistillate); head, sycamore (*Platanus* L.); cyme, viburnum; panicle, sumac (*Rhus* L.); and umbel, plum.

Figure 3—Chapter 1, Seed Biology: common forms of flower clusters, with individual flowers represented by circle and the order in which the flowers develop shown by numbers (#1 indicates the position of the oldest flower in the inflorescence) (from Krugman and others 1974).



On many woody plants, the flowers appear throughout the crown, but in some monoecious species, staminate or ovulate flowers tend to predominate or be restricted to certain parts of the crown. For example, in most pines, ovulate strobili are most numerous in the upper crown, whereas staminate strobili predominate in the lower crown. In true firs, ovulate strobili are found primarily on the tips of the uppermost branches, and staminate strobili are found below them, but still in the mid- to upper crown region.

In some species, flowering may occur on older branches or on the trunk itself. This phenomenon, called cauliflory, occurs frequently in tropical species, but rarely in temperate ones. Of the temperate woody plants in this book, redbud is the only genus for which cauliflory has been reported (Owens and Ewers 1991).

Pollination

Seed initiation by successful union of male and female reproductive elements is the culminating event in flowering. This union depends on 2 key steps: pollination and fertilization. Pollination is the transfer of male pollen grains from stamens in angiosperms, or staminate cones in gymnosperms, to pistils in angiosperms, or ovulate cones in gymnosperms. Fertilization occurs when subsequent pollen tube growth allows union of the sperm cell with the egg cell in the ovule. A detailed discussion of these processes is beyond the scope of this book, and the following sections will provide only brief descriptions. For additional information, readers should see the reviews by Owens and Blake (1985), Sedgley and Griffin (1989), and Marshall and Grace (1992).

Pollen grain development. Pollen grains are formed within structures called pollen sacs. In angiosperms, these sacs are found in the anthers at the tips of the stamens. Each pollen grain contains a tube cell and a generative cell, defined as the binucleate stage, and most angiosperm pollen is shed at this stage of development. The generative cell divides to form 2 male gametes, usually after shedding and germination, but before shedding in some species (Owens and Blake 1985). Pollen tube growth in most species occurs quickly after the trinucleate stage is reached. Detailed descriptions of this part of the sexual life cycle of angiosperm trees is very limited.

In gymnosperms, the pollen sacs are formed beneath each cone scale in the staminate cones. These sacs are initiated before winter in all conifers of the north temperate zone, but the rates of development after initiation vary greatly among species (Owens and Blake 1985). In the Pinaceae, the microspore division produces a large tube cell, a smaller generative cell, and 2 prothallial cells with no known function. In the Cupressaceae, Taxodiaceae, and Taxaceae, the pollen grains are binucleate, lacking prothallial cells (Owens and Blake 1985).

Pollen grains of trees are extremely varied in shape and size. Some examples of shape are spherical (hickory, *Carya* Nutt; and juniper), elongated (maple and Douglas-fir), triangular *(Eucalyptus* L'Herit.), and sac-like (pine and spruce). A few genera exhibit more than one shape: spherical or elongated (birch and mountain-ash, *Sorbus*) and triangular or tetrahedral (silk-oak, *Grevillea robusta* A. Cunn.). Pollen grains may range in size from 3 to 300 μm. Within a given genus, grain sizes are fairly uniform. Some reported ranges are 10 to 30 μm for birch and 70 to 103 μm for true firs (Sedgley and Griffin 1989). The outer walls of pollen grains (exines) are relatively thick and very resistent to degradation by external agents. The exine surfaces are furrowed and sculptured, which may play some role in pollination.

Pollen dispersal. Dispersal of tree pollen is primarily by wind (anemophily) and insects (entomophily), although birds (ornithophily) and animals (therophily) can also be dispersal agents, especially in tropical genera such as albizia, *Albizia* Durz.; bauhinia, *Bauhinia* L.; eucalyptus, and silk-oak (Sedgley and Griffin 1989). Pollen dispersal in conifers is mainly by wind, which is also the primary agent for angiosperms that lack floral parts (ash; casuarina, *Casuarina* L. ex Adans; sycamore; and elm, *Ulmus* L.), particularly if the flowers are catkins or aments (birch, hickory, walnut, oak, willow, and poplar, *Populus* L.). Species with brightly colored or scented flowers, such as dogwood, magnolia, apple, and tuliptree, often have heavy or sticky pollen grains. Their pollinating agents are almost always insects. Some species, notably maple, willow, and mulberry (*Morus* L.), are pollinated both by wind and by insects (Sedgley and Griffin 1989). Quite a few shrubs and understory plants depend on entomophilous pollination, as their positions within the stand preclude good wind movement. Some examples of this are azalea, mountain-laurel, and California-laurel.

Pollen dispersal must occur at the time of receptivity by the stigma of the pistil for pollination to be successful. This required synchronization occurs in many cases within and among perfect flowers or among monoecious flowers on a single plant. In other species, male and female organs mature at different times, creating a condition called dichogamy, in which pollen may be supplied by different perfect flowers on the same tree or by unisexual flowers from different trees. Dichogamy is strong in magnolia (Thien 1974). In southern magnolia (*Magnolia grandiflora* L.), stigmas are receptive in the morning before pollen is released (anthesis). The flowers close in the evening and reopen the following day. The stigmas are no longer receptive, but the anthers will now release pollen, which will only be "successful" in other flowers. Among dioecious species, dichogamy clearly will reduce self-pollination and encourage cross-pollination, thus promoting greater genetic diversity.

Weather conditions have a strong influence on pollination. Dry, warm weather will usually enhance pollen dispersal by wind. If winds are excessively dry, however, pollen of white oaks may be shed before maturity (Sharp and Chisman 1961). In contrast, rain or high humidity greatly hinders anemophilous pollination. Complete seedcrop failures can occur locally if heavy rains dominate the weather when anthesis is occurring. Late spring freezes can also kill staminate flowers and cones and prevent any dissemination of pollen in some species. Entomophilous pollination is not as greatly affected by the weather, but low temperatures and heavy rains will curtail the activities of insect pollinators.

Anemophilous pollen dispersal depends primarily on weather factors and stand structures. Under near-calm conditions, pollen of many pines and hardwoods can be expected to disperse only a few dozen meters (Sedgley and Griffin 1989), but in turbulent wind conditions, dispersal of pine pollen for 1 km and more is likely (Griffin 1980; Lanner 1966). Entomophilous pollen dispersal distances are not precisely known but probably are considerably less than anemophilous dispersals.

Pollen viability and flower receptivity. For pollination to be successful, the pollen grains must remain viable until they reach the stigma, and the female flowers or cones must be receptive when the pollen arrives. Not much is known about the length of viability of pollen in nature; some pollens survive for only hours and others for weeks. The pollen of many species, notably conifers, can be carefully dried to below 10% moisture content and stored below freezing for several years (Copes 1987; Wang and others 1993). Like pollen viability, flower receptivity varies greatly among species. For angiosperms, the receptive period for an individual flower may last for less than a day, as noted earlier for southern magnolia (Thien 1974), or it may continue for up to 10 days in some cherries (Stösser and Anvari 1982). Among gymnosperms, the receptive period ranges from less than a day in japanese larch, *Larix kaempferi* (Lam.) Carr. (Villar and others 1984) to 2 weeks or more in true firs, hemlocks, and pines (Owens and Blake 1985).

Pollination in angiosperms. When pollen grains reach the stigma of a receptive flower and germinate, the pollination process is set into motion. Pollen grains are captured on the stigmas due to their own sticky surface characteristics or the nature of the stigma surface. The stigma surface is naturally dry in some genera (maple; dogwood; sweetgum, *Liquidambar* L.; elderberry, *Sambucus* L.; and basswood, *Tilia* L.) and wet in others (hickory, eucalyptus, holly, plum, and serviceberry) (Sedgley and Griffin 1989), but there are no strong correlations between surface condition and other aspects of pollination and fertilization. Some have suggested that pollen germination rates are quicker on dry stigmas, but evidence for this is weak (Owens 1992). Germination is rapid, usually occurring within a few hours (Owens 1992), and is temperature-dependent. Luza and oth-

ers (1987) reported that pollen of English (*Juglans regia* L.) and black walnuts would not germinate at 40 °C or below 14 °C; maximum germination occurred at 28 to 32 °C.

Many of the pollen grains that reach stigmas may not germinate, and many that do will abort in the early stages of tube growth. Germinating grains form a microscopic tube that grows between the cell walls of the stigma and style toward an ovule. Usually only 1 pollen tube will penetrate an ovule; the others abort soon after germination.

Pollination in gymnosperms. In gymnosperms, the scales of the ovulate cones spread apart when the cones are receptive, and small drops of extracellular secretion (pollination drops) are formed. Pollen grains drift between the scales and are "captured" by the drops. Entry into the ovule through the micropyle is accomplished via these drops. The process differs among the gymnosperm families; Cupressaceae, Taxodiaceae, and Taxaceae have one mechanism, and Pinaceae another. These difference have been described in detail by Owens and Blake (1985) and Sedgley and Griffin (1989).

Fertilization

Fertilization occurs when the pollen tube enters the ovule and "delivers" the 2 sperm cells (gametes). In angiosperms, a typical ovule contains within its matured embryo sac 8 separate cells: an egg cell, 2 synergid cells, 2 polar cells, and 3 antipodal cells (figure 4). In the actual process of fertilization, 1 sperm (N) unites with the egg cell (N) to form a zygote that develops into the embryo (2N) of the seed. Generally, only 1 embryo develops, but multiple embryos are not uncommon in some species. The other sperm (N) unites with the 2 polar cells located near the center of the embryo sac, forming what will become the endosperm (3N). This process is commonly described as double fertilization. Endosperm tissue is triploid (3N) and functions as a source of nutrients available to the growing embryo and, in some species, to the young seedling that develops from the embryo at germination. As embryo and endosperm develop, the synergid and antipodal cells disintegrate.

Ovule and embryo sac formation in angiosperms may precede, occur synchronously with, or follow pollination. In tuliptree, the embryo sac is ready for fertilization by the time pollen is mature (Kaeiser and Boyce 1962). In sweetgum, sac development occurs 1 to 3 weeks after pollination (Schmitt 1966). Ovule development in oaks is extremely slow. It begins about 1 month after pollination in the white oak group, and 13 months afterwards in the black oak group (Stairs 1964). In all cases, development proceeds rapidly once it is underway. These time differences are also reflected in the elapsed times from pollination to fertilization. Most angiosperms require approximately 24 hours or less (Sedgley and Griffin 1989), but others require much longer: 60 hours in English walnut (Luza and others 1987), 8 to 9 days in *Rhododendron nuttallii* T.W. Booth (Palser and others 1989), 12 days in peach (*Prunus persica* Batsch) (Herrero and Arbeloa 1989), and 12 to 14 months in some species of oak (Kramer and Kozlowski 1979).

As the pollen tubes of gymnosperms elongate into the ovule, their generative cells divide into a stalk cell and a body cell. The body cell divides again to form 2 male gametes. One gamete fuses with the egg nucleus within an archegonium, a multicellular organ within the ovule, and the other usually disintegrates. Each gymnosperm ovule consists of an integument surrounding a multicellular body, the female gametophyte. The female gametophyte tissue is often incorrectly called "endosperm," a usage that should be discouraged. During later stages of ovule development, archegonia differentiate within the female gametophyte (figure 5). The number of archegonia varies by genus and by species. Florida torreya (*Torreya taxifolia* Arn) almost invariably has 1; the Pinaceae have 1 to 10; and sequoia may have up to 60 (Willson and Burley 1983). Occasionally more than 1 archegonium is fertilized, either by the second male gamete or by gametes from other pollen tubes, but normally only 1 embryo matures. Archegonia usually complete development less than 1 week before fertilization, but this interval is longer in some conifers. The elapsed time between pollination and fertilization in gymnosperms is generally much longer than that in angiosperms. These periods range from 3 weeks for Engelmann spruce (*Picea engelmannii* Parry ex Engelm.) (Singh and Owens 1981) to 15 months for Monterey pine (*Pinus radiata* D. Don) (Lill 1976).

Reproductive Abnormalities

Occasionally the physiological processes associated with sexual reproduction break down and abnormalities result. In woody plants these abnormalities seldom have an impact on seed production or seed quality, but their general nature should be understood.

Polyembryony. Polyembryony is the occurrence of more than 1 embryo per ovule. It is unusual in angiosperms (Sedgley and Griffin 1989), but more common in gymnosperms with multiple archegonia, where pollination and fertilization produce multiple embryos, all differing in genetic composition. This type of polyembryony is found in araucaria, cypress, and all Pinaceae (Chowdhury 1962; Haines and Prakash 1980; Konar and Banerjee 1963). Another type of polyembryony can be produced through cleavage or division of a developing embryo. It has been noted in many coniferous genera of the northern temperate zone (Sedgley and Griffin 1989).

Parthenocarpy. Parthenocarpy is the formation of fruit without fertilization and is a desirable trait for selection in genetic improvement of fruit crops. Parthenocarpy is not

common in forest species but has been noted in apples and pears (*Pyrus* L.) when adverse environmental conditions induce ovule abortion (Sedgley and Griffin 1989).

Agamospermy. Agamospermy, sometimes called apomixis when it occurs in trees, is the development of seeds without fertilization. Some forms of this phenomenon seem to require pollination, while others do not. Agamospermy has been reported in sugar maple (*Acer saccharum* Marsh.) (Gabriel 1967), several species of serviceberries (Campbell and others 1987), and hawthorns (Crataegus L.) (Dickinson and Phipps 1986).

Figure 4—Chapter 1, Seed Biology: longitudinal section through a typical pistil just before fertilization (from Krugman and others 1974).

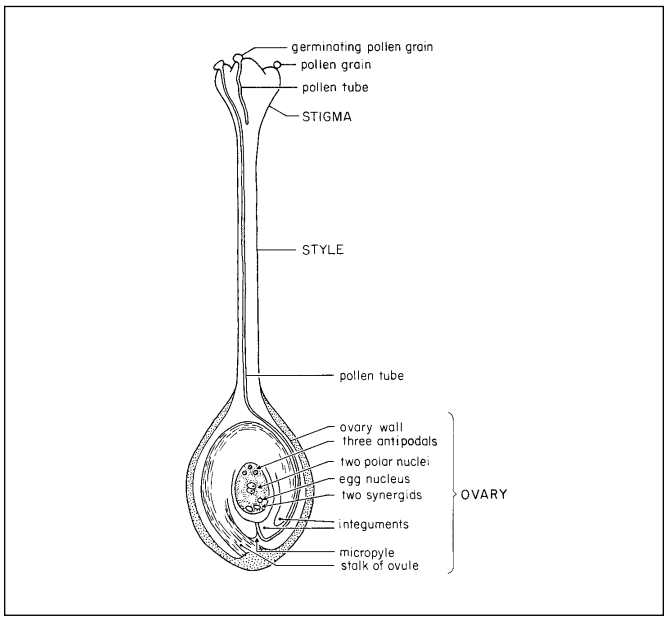


Figure 5—Chapter 1, Seed Biology: longitudinal section through an ovule of *Pinus ponderosa*. during the period of pollen tube development preceding fertilization.

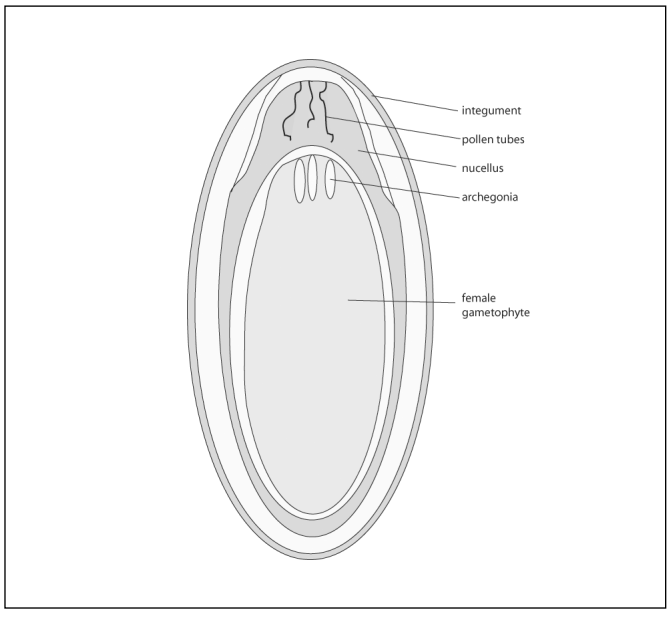

Fruit and Seed Development

Morphological Development

The life history of a fruit generally includes 4 distinct phases of growth and development:

1 Pre-anthesis cell initiation and multiplication within the floral buds and enlarging flowers
2 Anthesis, pollination, pollen tube growth, and fertilization
3 Post-fertilization growth, mostly by cell enlargement in the fruit and cell multiplication in the seed
4 Maturation of the fruit through ripening and senescence (Nitsch 1965)

In most species, phase 3 does not proceed unless pollination and fertilization of some ovules has occurred. If it does proceed without fertilization, parthenocarpy or agamospermy is taking place. This section will briefly outline the events of phases 3 and 4. More complete discussions can be found in reviews on embryology, development, and maturation (Bewley and Black 1994; Chowdhury 1962; Johri 1984; Maheshwari 1950; Sedgley and Griffin 1989).

Angiosperms. Following fertilization, the first tissue to develop in the embryo sac is the endosperm, which follows 1 of 2 patterns. A nuclear endosperm, in which there is no early cell wall formation, is most common in woody plants. In the latter stages of growth, cell walls do form in this endosperm. Examples can be found in silk-oak and plum. Cellular endosperm, as found in ash and fringetree (*Chionanthus virginicus* L.), develops cell walls in the first and all subsequent divisions (Johri 1984). Endosperm tissue provides nutrition for the developing embryo, and in some genera, such as persimmon (*Diospyros* L.), magnolia, gooseberry (*Ribes* L.), and snowberry (*Symphoricarpos* Duham.), it persists as the primary food storage tissue in the mature seeds. Such seeds are described as endospermic. The monocotyledonous palms are also endospermic. In other genera, such as acacia, hickory, catalpa, and teak (*Tectona grandi*s L.f.), the endosperm is consumed during embryo development and is absent or exists only as a very thin layer of tissue in mature seeds. The cotyledons of the embryo become the site of food storage, and these species are designated as nonendospermic. Still other genera have significant food storage capacity in both endosperm and cotyledons; examples are barberry (*Berberis* L.), ash, wintergreen (*Gaultheria* L.), and basswood (*Tilia* L.).

In most species, the perisperm, comprised of the maternal nucellar tissue in the ovule, fails to develop and is absorbed by the developing embryo. In a few species, the perisperm develops into a food storage tissue that is outside of the embryo sac. In these cases there is no endosperm development, and the perisperm becomes the major food storage tissue. In this book, yucca is the only genus with a fully developed perisperm.

Embryos differentiate and attain their full size in most species by the time the fruits or seeds are shed. In fact, relative length of the embryo can be a good maturity index for decisions on when to collect seeds of many species. In a few species, however—for example, American holly (*Ilex opaca* Ait.), European ash (*Fraxinus excelsior* L.), and common snowberry (*Symphoricarpos albus* (L.) Blake—embryos are still immature when seeds are shed from the trees, and full size is only attained following a period of after-ripening. This condition causes the very slow germination that is a major problem in nursery production of these species.

As endosperm and embryo grow, the surrounding maternal tissues develop into the seed-covering structures, collectively called the seedcoat. Most seedcoats are composed of a firm outer layer, the testa, and a generally thin, membranous inner coat called the tegmen. There are many variations of seedcoat structure, however, and many species do not fit the model described above. In some genera, the testa is thin and permeable, as in poplar (*Populus* L.) and willow. In others, it may be thick and bony, as in hawthorn and apple. Some hard seedcoats have special cutinized layers, as in redbud and honeylocust (*Gleditsia triacanthos* L.). In some genera both covering structures are membranous, as in elm; the outer layer partially membranous and the inner one bony, as in chastetree (*Vitex* L.); or the outer layer soft and fleshy and the inner layer hard, as in magnolia.

Many species develop extended tissues on their seedcoats that play a role in dissemination of the seeds. These extensions may be wings, as in ailanthus, *Ailanthus altissima* (Mill.) Swingle, and tuliptree; tufts of short, bristly hairs, as in baccharis, *Baccharis* L., and sycamore; long soft hairs, as in poplar and willow; wings with hairs, as in catalpa and desertwillow, *Chilopsis linearis* (Cav.) Sweet; or various other appendages, such as small points on sourwood (*Oxydendron arboreum* (L.) DC.; and long, feathery styles on cercocarpus, *Cercocarpus* H.B.K. Actually, the appendages on baccharis, sycamore, and cercocarpus are on the fruits, which are single-seeded achenes, commonly called seeds.

It is useful to define and classify fruit types, although all authorities do not completely agree on the results. The classification presented here (table 2) is based on that of Krugman and others (1974) and Sedgley and Griffin (1989), but with modifications.

Premature fruit shedding may occur late in phases 3 or 4. Premature shedding can seriously reduce the size of the potential seedcrop, especially in tropical fruit crops, where over 99% of the fruits may drop (Chaplin and Westwood 1980). Three periods of premature shedding in angiosperm fruit trees are recognized (Sedgley and Griffin 1989). The first occurs within 2 weeks of anthesis and usually involves unfertilized flowers. The second period (the most serious) occurs within 2 months of anthesis when young fertilized fruits are shed. The third shedding period is when immature, but full-sized, fruits are shed. Premature shedding can result from a number of conditions, but an imbalance of growth regulators and competition for nutrients are probably the most important (Sedgley and Griffin 1989).

Gymnosperms. Postfertilization growth of most gymnosperm cones is actually the continued enlargement of an existing structure, the ovulate cone. In most genera, for example, true fir, spruce, and hemlock, the young conelet develops into the mature woody cone in just a few months. In pine, the conelet is already more than a year old at fertilization. In other genera, such as juniper, the cone scales fuse together to form a berrylike structure around the seeds. Other fleshy gymnosperm fruits are found on yew and torreya, where the seeds develop within fleshy arils.

The food storage tissue in gymnosperms, the female gametophyte, is already present when fertilization occurs, so development from that point centers on the embryo. The embryo grows and differentiates into a miniature plant with radicle (rudimentary root), hypocotyl (stem), plumule (bud), and cotyledons. The cotyledons are usually quite small and range in number from 2 in thuja and sequoia to 18 in some pine (Chowdhury 1962).

In most gymnosperms, the embryo is both morphologically and physiologically mature at the time of seed dispersal from the cones. Exceptions to this are ginkgo and certain pines that grow at high altitudes and/or extreme northern latitudes. Examples of the latter include Swiss stone (*Pinus cembra* L.), Korean (*P. koraiensis* Sieb. & Zucc.), Japanese white (*P. parviflora* Sieb. & Zucc.), and Siberian stone pines (*P. sibrica* Du Tour) (Krugman and Jenkinson 1974). Like the angiosperm seeds that are shed with immature embryos, these species require special treatments for prompt germination.

Seedcoats of gymnosperms may be relatively thin and soft, as in true fir; thin to thick and woody, as in pine; or very hard, as in juniper. Some genera have resin vesicles on

Table 2—Chapter 1, Seed Biology: classification of fruits of woody angiosperms

Fruit type	Description and examples
DERIVED FROM SINGLE FLOWERS	
Dry, dehiscent—pericarp dry and splitting open at maturity to release seeds	
Capsule	Two or more fused carpels, as in *Aesculus, Eucalyptus, Kalmia*
Legume (pod)	Splits along 2 sutures, as in *Acacia, Gleditsia, Lupinus*
Follicle	Splits along 1 suture, as in *Grevillea, Magnolia*
Dry, indehiscent—pericarp dry, but not splitting open at maturity	
Achene	Small, 1-seeded fruit with seed attached to ovary wall at only 1 point, as in *Cowania*, *Eriogonum*; or pericarp fused with calyx tube and embryo completely filling the ovarian cavity, as in *Artemisia, Chrysothamnus*
Nut	One-seeded fruit with woody or leathery pericarp, as in *Quercus*, or generally partially or wholly encased in an involucre (husk), as in *Carya, Corylus*
Samara	One-seeded pericarp modified with a wing-like appendage, as in *Fraxinus, Ulmus*; sometimes with 2 samaras fused together, as in *Acer*
Fleshy–part of the fruit wall comprised of fleshy or pulpy tissue with relatively high moisture content	
Berry	Pericarp has a skin that encloses a fleshy or pulpy mass that contains 1 or more seeds, as in *Berberis, Diospryros, Ribes*
Drupe	One-seeded fruit with pericarp usually in 3 distinct layers; the exocarp forms a skin, the mesocarp a fleshy layer, the endocarp a hard, stony layer, as in *Cornus, Nyssa, Prunus*; the seed, enclosed in endocarp only, is sometimes called a pyrene.
Pome	A many-sided fruit with the seeds enclosed in a papery inner wall, as in *Crataegus, Malus*
Hesperidium	Many-seeded fruit with leathery exocarp and mesocarp, and thick, fluid-filled endocarp, as in *Citrus*
DERIVED FROM INFLORESCENCES	
Dry, dehiscent—pericarp dry and splitting open at maturity to release seeds	
Strobile	A dry, conelike fruit developing from pistillate catkins, as in *Alnus, Betula*
Head	A multiple fruit that forms a compact cluster of simple fruits; the shape may be globose, as in *Liquidambar*, or conelike, as in *Casuarina;* the simple fruits can be different types, such as achenes in *Platanus* or capsules in *Liquidambar*
Fleshy—part of the fruit wall comprised of fleshy or pulpy tissue with relatively high moisture content	
Synconium	A type of pseudocarp in which achenes are actually borne on the inside of a hollow receptacle, as in *Ficus*
Sorosis	A fruit derived from the ovaries of several flowers, as in *Morus*
Coenocarp	A fruit incorporating ovaries, floral parts, and receptacles of many flowers, as in *Artocarpus*

or within their seedcoats: true fir, hemlock, and incense-cedar (*Calocedrus* Endl.). The resin makes seeds sticky and more difficult to handle in all phases of extraction and cleaning. Most gymnosperm seeds are winged, but there are exceptions: baldcypress, yew, torreya, and some pines. These pines are often called the "nut" pines: Swiss stone pine, piñyon (*Pinus edulis* Engelm.), chilgoza pine (*P. geradiana* Wall.), etc. Wings may be loosely adhering structures that are easily separated from the seeds, as in most pines, or they may be integral parts of the seedcoat, as in Douglas-fir, longleaf pine, and incense-cedar.

Cones of gymnosperms that require more than 1 year to mature generally remain small during the first year after flowering in the interval between pollination and fertilization. In a few species, such as western juniper (*Juniperus occidentalis* Hook) and Alaska-cedar, the fruit grows before fertilization occurs and attains almost full size during the first growing season, a full year or more before the seeds are physiologically mature. Seed collectors must be aware of this condition to avoid collecting cones with immature fruits. In Alaska-cedar, there are distinct color differences between immature and mature cones (Harris 1990), and position of cones on the branches is an indicator for both species. Gymnosperm fruit classification is much simpler than that of angiosperms (table 3) (modified from Krugman and others 1974).

Table 3—Chapter 1, Seed Biology: classification of fruits of woody gymnosperms

Fruit type	Description and examples
DRY STROBILI	
Cone	Woody structures that generally open on the trees and release seeds at maturity, as in *Abies, Picea,* and most *Pinus*; some *Pinus* cones remain closed at maturity and open only in fires or disintegrate over time
FLESHY STROBILI	
Drupelike	Enclosing a single seed, as in *Ginkgo, Taxus, Torreya,* and some *Juniperus*, or multiple seeds in other *Juniperus*, that are shed from trees intact

Sources: Modified from Kregman and others (1974).

Premature cone shedding can also be important in gymnosperms. It is most common several weeks after anthesis, when pollination has not occurred, but can also result from damage from frost, hail, drought, insects, or pathogens (Owens and Blake 1985; Sedgley and Griffin 1989; Sweet 1973). There are also losses from what Bramlett (1972) described as "physiological drop," when there were no visible signs of external injury. In general, the physiology of immature cone abscission is much less understood than premature fruit shedding in angiosperms (Sedgley and Griffin 1989).

Physiological Development

The growth of fruits that starts soon after fertilization (or prior to fertilization in a few species) involves a complex array of physiological processes and conditions. These processes are generally similar for fruits of most temperate trees, and they produce comparable trends in size, weight, and moisture content. A typical pattern of development for dry fruits is provided by the single-seeded samaras of green ash (*Fraxinus pennsylvanica* Marsh.) (figure 6). Fresh weight, dry weight, and moisture content increase slowly through early summer. By the end of August, the embryo is 2 to 3 mm long. Over the next 6 weeks there are sharp increases in dry weight and significant decreases in moisture as embryo length increases 5-fold (Bonner 1973). In drupes of the temperate zone, weight trends are similar, but moisture changes are somewhat different. In black cherry (*Prunus serotina* Ehrh.), for example, moisture contents decrease during spring to early summer, then increase again as maturity approaches (figure 7). In temperate recalcitrant seeds, such as acorns, the patterns are more like those of dry fruits (figure 8). Similar trends occur in the maturation of most tropical tree fruits also, but the changes are not always correlated with the seasons as they are in temperate species.

Moisture content. Any discussion of seed moisture must be based upon the 2 physiological classes of seeds in respect to moisture: orthodox and recalcitrant. Orthodox seeds are seeds that can be dried to low moisture levels (below 10% of fresh weight) without losing viability. Recalcitrant seeds cannot be dried below rather high levels (25 to 50%, depending on the species) without losing viability. This sensitivity to desiccation has important implications in the storage of seeds, and chapter 4 contains a broader discussion of this subject.

Among orthodox seeds, the dry types (tables 2 and 3) are generally shed from the trees at rather low moisture contents. Exact measurements of the moisture levels at which shedding occurs are hard to find, but some preliminary data suggest a range of about 10 to 15% for sweetgum, green ash, and boxelder (*Acer negundo* L.) (Bonner 1996). The fleshy fruits (tables 2 and 3) also contain orthodox seeds, but because they are still enclosed in the fleshy tissues of the fruits, they are shed at higher moisture contents. Black cherry fruits, for example, are shed at fruit moisture contents of 70 to 75% (Bonner 1975). Seed moisture contents are not quite as high, but they are much higher than those that are found in species with dry fruits. Some examples of seed moisture contents from fleshy fruits at shedding are 34% for flowering dogwood, a drupe, and 50% for persimmon (*Diospyros virginiana* L.), a berry (Bonner 1996).

Moisture contents of recalcitrant fruits are also high at the time of shedding. Some representative values for temperate species are 40% for acorns of black oaks, 50% for those of white oaks (Bonner and Vozzo 1987; Finch-Savage and others 1992), 50% for horsechestnut (*Aesculus hippocastanum* L.) (Tompsett and Pritchard 1993), and 58% for planetree maple (*Acer pseudoplatanus* L.) (Hong and Ellis 1990). Similar values have also been reported for tropical recalcitrant species (Tamari and Jacalne 1984).

In orthodox species with dry fruits, the maturation drying that occurs on the plants prior to shedding is the final stage of development as the seeds enter their quiescent period. This stage is apparently necessary for the synthesis of

Figure 6—Chapter 1, Seed Biology: seasonal changes in fresh weight, dry weight, and moisture content during maturation of a dry fruit, green ash (*Fraxinus pennsylvanica* Marsh.) (from Bonner and others 1994).

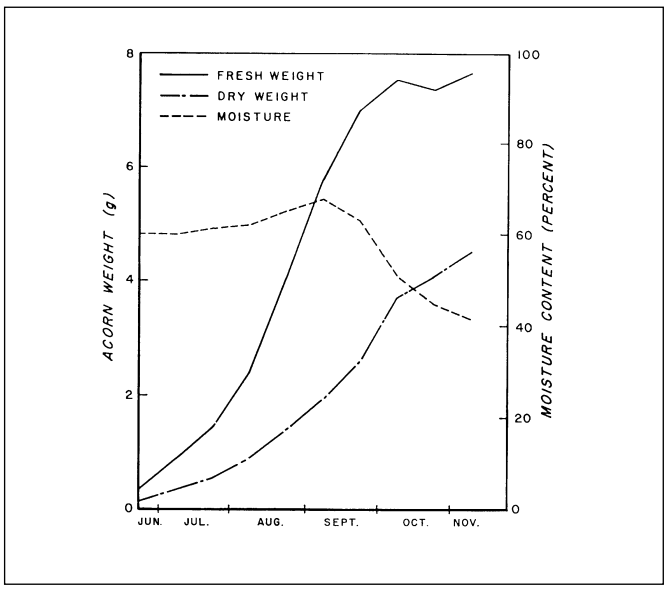
many enzyme systems, including those required for desiccation tolerance and germination when rehydration occurs (Bewley and Black 1994). There are some data for tree seeds (Finch-Savage and others 1994), but most of the work in this area has been done on castor bean (*Ricinis communis* L.) (Kermode and Bewley 1985) and cereal grains (Bewley and Black 1994). There is no reason to doubt, however, that the same physiological processes take place during maturation of orthodox seeds of woody plants. Conditions are different in orthodox seeds from fleshy fruits, however, as they are shed before complete desiccation. Desiccation occurs later after the fleshy covering has dried or been removed (eaten in many cases). Many of these species have complex dormancy periods, and it can be hypothesized that there are interactions between the dormancy and the delay in maturation drying of the seeds.

Figure 8—Chapter 1, Seed Biology: seasonal changes in fresh weight, dry weight, and moisture content during maturation of a recalcitrant fruit, Shumard oak (*Quercus shumardii* Buckl.) (from Bonner and others 1994).



In recalcitrant seeds, there is no pronounced maturation drying stage, because development never stops completely. There are slight decreases in moisture content that are apparently associated with shedding of fruits (figure 8), but there is no true quiescent period with recalcitrant seeds. Most species, especially tropical recalcitrant species, germinate soon after shedding, and some, including several *Quercus* species, will germinate while still on the tree, an event defined as vivipary.

Stored food reserves. As postfertilization growth proceeds, carbon fixed by photosynthesis is transferred to the seeds in the form of sucrose. In the seeds the sucrose is converted into many components, but most of it goes into stored food reserves of carbohydrate, lipid, or protein (Bewley and Black 1994). Many seeds have more than one type of food reserve, but one is usually predominant (table 4). The type of food reserve has implications for seed storage (see chapter 4), and it has been suggested that there are other important relationships. Korstian (1927), for example, suggested that dormancy in the black oak group was related to the high lipid content of these seeds, and that stratifica-

tion was needed to convert the lipid to soluble carbohydrates for germination. This conversion does take place during stratification of black oaks (Vozzo and Young 1975), but no direct connection to dormancy has been made. Also, some species with large lipid components, such as southern catalpa (*Catalpa bignonioides* Walt.) and winged elm (*Ulmus alata* Michx.), exhibit no dormancy, whereas some with high carbohydrate levels, such as sugarberry (*Celtis laevigata* Willd.) and eastern redcedar (*Juniperus virginiana* L.) are usually dormant.

Accumulation of food reserves follows similar patterns in most seeds. First there are slow increments of accumulation, then much more rapid accumulation as maturity and shedding are approached (figure 9). Soluble carbohydrates are converted to insoluble fractions in starchy seeds (figure 10), and the protein- nitrogen fraction increases at the expense of soluble forms (figure 11). During this period of development, seeds are strong sinks for current photosynthate, and vegetative growth is somewhat reduced (Bazzaz and Ackerly 1992; Owens and Blake 1985). The extent of growth lost in this trade-off in heavy seed years has not been accurately measured in woody plants, but estimates range from 30% in Norway spruce, *Picea abies* (L.) Karst, in Europe (Buyak 1975) to less than 5% in flowering dogwood in Mississippi (Bonner 1996). Rohmeder (1967) estimated that between the start of seed-bearing and the typical harvest age of forest trees, 10 to 30% of the potential volume yield may be used in seed production.

Some data on elemental concentrations in mature seeds are available (table 5). Such information is of great value to wildlife biologists in studies of the nutritive value of browse to wildlife.

Hormones. At the same time that the growing seeds are accumulating food reserves, there are certain hormonal changes that are taking place within the seeds. The major hormones in seeds are auxins, gibberellins, cytokinins, and abscisic acid (ABA) (Bewley and Black 1994). These hormones appear to play important roles in the growth and development of both fruits and seeds, but it is not always clear what these roles are. The major auxin in seeds, indoleacetic acid (IAA), is found in both free and bound forms. It has been extracted and identified from a number of tree seeds, for example, pecan (Lipe and others 1969), water oak (*Quercus nigra* L.) (Hopper and Vozzo 1982), English

oak (*Q. robur* L.) (Michalski 1969), apple, and plum (*Prunus cerasus* L.) (Bewley and Black 1994). Over 80 gibberellins are now known, and more than half of them have been identified in seeds (Bewley and Black 1994). Gibberellins or gibberellin-like substances have been identified in seeds of Jeffrey (*Pinus jefferyi* Grev. & Balf.), sugar, and ponderosa (Krugman 1967); and Monterey pine and Douglas-fir (Pharis and Kuo 1977); pear (*Pyrus communis* L.) (Martin and others 1977), water oak (Hopper and Vozzo 1982), and English oak (Michalski 1968).

Cytokinins have not been studied as much in seeds of woody plants, but they (or cytokinin-like compounds) have been found in English oak (Michalski 1974), apple, and sour cherry (Bewley and Black 1994). ABA has received much attention in seeds of woody plants, first for its possible role in dormancy, then for its possible role in tolerance of desiccation. ABA has been identified in developing seeds of English oak (Finch-Savage and others 1992), pear (Martin and others 1977), and peach (Piaggesi and others 1991).

The highest concentrations of gibberellins and cytokinins have been found in immature seeds during their most rapid phase of development, and both decline later as they apparently become bound up with other compounds. Immature seeds are also rich in auxins, and they are thought to be the source of this group of hormones needed for normal fruit growth. Removal of developing seeds will inhibit growth of the fruit (Bewley and Black 1994). In contrast to

the other hormones, ABA concentration is low in developing seeds and highest at maturity. In conjunction with maturation drying, ABA may prevent embryos from germinating while still on the tree (Bewley and Black 1994). These correlations do not prove a causal relationship between seed maturity and dormancy, however, and much research remains to be done.

Factors That Influence Seed Production

There are many factors that can reduce the size of a seed crop on woody plants no matter how abundant flower production may be. Flower abortion and premature fruit drop have been discussed earlier. This section will briefly review factors that reduce seedcrops well after fertilization and early development of fruits or cones has occurred.

Physiological factors. Most of the fruit and cone losses that can be attributed to physiological factors occur early in the fruiting season. On some occasions, however, fruits or cones will abscise late in the growing season. The exact mechanisms are not understood, but they may be related to competition for a shrinking supply of nutrients late in the season between reproductive structures and vegetative shoots. Early abscision of acorns as maturation is completed may appear to be physiological in nature, but the primary cause is often insect damage that triggers a physiological reaction.

Weather. Weather can influence seedcrops in a variety of ways. Interference with flowering and pollination through late freezes, rain during pollination, etc., have been discussed previously. Severe drought can have a noticeable effect on the size of many angiosperm seeds. This effect is particularly noticeable for large single-seeded fruits such as oak acorns (Bonner 1996). Other damaging effects of weather can be more direct. Strong winds and hail can destroy flowers and fruits, sometimes to the point that most of the crop is lost. Hurricanes along the coastal areas of the Southeast are infrequent but very serious, and they can create problems locally for longleaf pine, a species with large, heavy cones that are fairly easy to knock to the ground.

Biotic factors. Flowers, fruits, and seeds are susceptible to damage by many insects, pathogens, and animals. Flower damage, particularly by insects, often goes unnoticed in branch terminals and in the tops of trees. Much more is known about damage to fruits and seeds, because they are handled and observed closely when collected.

Insects. Little is known about insects that destroy flowers, as the damage is often not seen. Both larvae and young adults of treehoppers (Membracidae) destroy pistillate flowers of oaks (Cecich 1993). Thrips, both Phlaeothripidae and Thripidae, destroy young strobili on several pines, true firs, and Douglas-fir (Hedlin and others 1980). The most serious economic damage is done by *Gnophothrips fuscus* (Morgan) on slash pine (*Pinus elliottii* Engelm.). Other insects that damage pine strobili in the Southeast include Nantucket pine tip moth, *Rhyacionia frustrana (*Comstock); pine conelet looper, *Nepytia semiclusaria* (Walker); the Virginia pine sawfly, *Neodiprion pratti pratti* (Dyar) and other sawflies, *Xyela* spp.; leaffooted pine seedbug, *Leptoglossus corculus* (Say); cone midges, *Cecidomyiidae*; and several coneworms, *Dioryctria* spp. (Ebel and others 1975). Strobili damage in other conifers has been reported for *Xyela* spp. on lodgepole, Coulter (*Pinus coulteri*

D. Don), ponderosa, digger (*P. sabiniana* Dougl.), and Monterey pine; western conifer seed bug (*Leptoglossus occidentalis* Heidemann) on Douglas-fir, grand fir, incense-cedar, and several pine species; and the European pine shoot moth (*Rhyacionia buoliana* (Schiffermuller)) on red, Scots, eastern white (*Pinus* strobus L.), pitch (*P. rigida* Mill.) and other pines (Hedlin and others 1980).

Insect damage to fruits and seeds is much more common than damage to flowers and strobili. Most damage is caused by larvae that hatch from eggs deposited in young, developing fruits and devour the embryo tissues. In angiosperms, major damage is caused by *Curculio* spp., *Conotrachelus* spp., and *Melissopus* spp. in oaks (Gibson 1972, 1982; Vozzo 1984); *Thysanocnemis* spp. in ash (Solomon and others 1993); several species of seed beetles (Bruchidae) in acacias (Southgate 1983); and the fruit borers *Pagyda salvalis* Walk. and *Dichocrosis punctiferalis* Guenee in teak (Neelay and others 1983). There are numerous insects that cause minor damage to fruit- and seed-crops of other angiosperms, but they do not seriously threaten to decimate seed supplies.

Because most major commercial forest species are conifers, insect damage to their cones and seeds is more economically important than damage to fruits and seeds of angiosperms. Cones of many species can be heavily damaged by cone worms (*Dioryctria* spp.) and cone beetles (*Conophthorus* spp.). Lesser damage to cones is also caused by the cone borers *(Eucosma* spp.) and cone midges (Cecidomyiidae) (Hedlin and others 1980). The southern pine coneworm, *D. amatella* (Hulst), is a major pest in seed orchards of the southern pines and many control programs are designed to reduce its impact (Ebel and others 1975). Significant damage to other conifers has been recorded for red pine cone beetle (*Conophthorus resinosae* Hopk.) (Hard 1964), sugar pine cone beetle (*C. lambertianae* Hopk.) (Bedard 1968), and *C. monticolae* on western white pine (Graham 1990). The major seed damage in conifers has been attributed to seedworms, *Laspeyresia* spp.; seed chalcids, *Metastigmu*s spp.; seedbugs, *Leptoglossus* spp.; and *Tetyra bipunctata* Herrich-Schaeffer (Ebel and others 1975; Hedlin and others 1980; Kinzer and others 1972; Krugman and Koerber 1969; Scurlock and others 1982).

Control of seed insects in natural stands is normally not economical. In seed orchards, where considerable resources have been invested to produce seedcrops and many other cultural practices are being carried out, control programs are feasible. In recent years, however, environmental concerns are forcing stringent limitations on chemical application programs in seed orchards. Insect populations can be reduced with light and chemical attractant traps, but these methods have a limited impact.

Pathogens. Flowers, fruits, and seeds of woody plants are exposed to great numbers of microorganisms in their natural environments; some of these are pathogenic and some are beneficial. Of the 3 types of pathogenic microorganisms causing damage to woody plants—viruses, bacteria, and fungi—only fungi have serious effects on seed production.

The most important group of fungi is the cone rusts. These fungi attack first- and second-year cones on a wide range of conifers throughout North America (table 6). Degree of infection varies, but losses are often significant. Losses from southern pine cone rust and inland spruce cone rust have been sufficient to warrant spraying orchards with fungicides (Sutherland and others 1987). Other fungi that can reduce seed production in conifers include sirococcus blight (*Sirococcus strobilinus* Preuss) and pitch canker (*Fusarium moniliforme* Sheld. var. *subglutinans* Wollenw. & Reink.). Sirococcus blight is primarily a problem in nurseries and young stands, but it can kill branches in older trees

Table 6—Chapter 1, Seed Biology: major cone rust diseases of conifers

Disease	Fungal pathogen	Species infected
inland spruce cone rust	*Chrysomyxa pirolata* Wint.	*Picea engelmannii, P. glauca, P. mariana, P. rubens, P. pungens, P. sitchensis, P. abies*
coastal spruce cone rust	*Chrysomyxa monesis* Ziller	*Picea sitchensis*
southern pine cone rust	*Cronartium strobilinum* (Arth.) Hedgc. & Hahn	*Pinus elliottii, P. elliottii* var. *densa, P. palustris*
southwestern pine cone rust	*Cronartium conigenum* Hedgc. & Hunt	Many *Pinus* species from S Arizona, S into Central America
western gall rust	*Endocronartium harknessii* (J.P. Moore) Y. Hirat.	*Pinus banksiana, P. contorta, P. ponderosa,* and to a lesser. degree, many others in W US, Canada, & NE US

as well. It can be found on larch, spruce, pine, and Douglas-fir (Sutherland and others 1987). Pitch canker damages shoots, cones, and seeds of pines in the South and East. In a few short years, pitch canker has become a major disease problem in seed orchards of all southern pines (Barrows-Broaddus and Dwinell 1985; Blakeslee and others 1980).

With the exception of species that attack trees with edible nuts, such as scab disease—*Cladosporium caryigenum* (Ell. & Lang.) Gottwald—on pecan (Graves and others 1989), reduction of seedcrops in angiosperms by fungi is generally not serious. There are, however, numerous fungi that infect flowers and fruits and cause only incidental or local damage to the seedcrop (table 7). For additional information on seed pathogens and other microorganisms and the species on which they are found, readers are referred to Mittal and others (1990).

Birds. Birds feed on flowers, fruits, and seeds, especially the latter. Many small birds—such as finches, grosbeaks, and sparrows (Fringillidae), doves (Columbidae), and quail (Phasianidae)—feed on small seeds after they are shed, but these losses are incidental to the total seedcrop. Larger birds that feed on maturing fruits and seeds still on the trees can have serious, though usually local, impacts on seed yield. Acorns are a favorite of grackles (*Quiscalus* spp.), jays (Corvidae), and woodpeckers (Picidae). The California woodpecker *(Balanosphyra formicivora*) can devour enough acorns, its favorite food, to severely reduce the crop within its foraging range (Bent 1939). Pine seeds are a favorite of Clark's nutcracker (*Nucifraga columbiana*) and piñyon jays (*Cyanocephalus cyanocephalus*), which specialize in piñyon seeds and even young cones (Bent 1946). Berries of various juniper species are eaten in large numbers by jays, Clark's nutcracker, and robins *(Turdus migratorius*). Robins also are heavy feeders in the winter on Pacific madrone (*Arbutus menziesii* Pursh.) on the west coast (Bent 1949).

Losses of seeds are most serious when the birds feed in flocks. Heavy feeding of grackles on acorns has been mentioned previously in connection with seed dispersal. Flock depredation also occurs when robins or cedar waxwings (*Bombycilla cedrorum*) feast on cherries, eastern redcedar, hollies, and elms.

Not as many quantitative data or observational data have been collected for tropical and subtropical species, but it is certain that birds play a large role in the depredation and dispersal of tropical fruits and seeds (Terborgh 1990). A study of *Virola surinamensis* (Rol.) Warb. (Myristicaceae) in a moist, tropical forest in Panama by Howe (1990) found that more than 80% of the fruits were eaten or removed by birds.

Although less damaging to the total seedcrop, birds' feeding on flowers can have a local impact. Grouse (*Bonasa umbillas,* and *Dendragapus* spp.) are known to feed heavily on buds and flowers of alder and poplars and strobili of pines, spruces, firs, and larches (Bent 1932).

Mammals. Significant amounts of fruits and seeds are lost to mammal predation by many species. Squirrels (*Citellus* and *Sciurus* spp.) are heavy feeders on acorns of almost all species of oak throughout North America. Not only are many acorns eaten, but also many more are buried in the ground for winter retrieval. Squirrels are also heavy feeders on pines, usually dissecting or removing the green cones. Several western squirrel species cache the cones for winter retrieval, and these caches were once heavily utilized by cone collectors. Cone losses to squirrels can be very

significant. Fowells and Schubert (1956) reported that in 1 year in an area in California, the Douglas pine squirrel (*Tamiasciurus douglasii*) destroyed over 50% of the sugar pine and ponderosa pine cones. Squirrels may remove over 90% of the cone crops of white spruce (*Picea glauca* (Moench) Voss) in Alaska (Nienstaedt and Zasada 1990). Losses of cones of southern pines to squirrels in the Southeast are normally not nearly so severe.

Squirrels also reduce seedcrops by cutting and feeding on cambial tissues in branches in the spring, thus destroying buds, flowers, and strobili. There is evidence of this type of damage on ponderosa pine (Adams 1955), red pine (Roe 1948), sugar maple (Godman and others 1990), and American elm (*Ulmus americana* L.) (Bey 1990).

Minor fruit depredation also occurs from other animals, such as bears (*Ursus* spp.), raccoons *(Procyon lotor*), deer (*Odocoileus* spp.), and opossums (*Didelphis virginiana*). In tropical and subtropical forests, many more animals are fruit and seed predators than in temperate forests.

Maturity and Dispersal

As a general rule, fruits should be collected only after the seeds have reached full maturity. One problem with this rule is that full maturity is not easily defined. To some, dispersal from the tree of seeds with the ability to germinate and grow is a sign of full maturity, yet serotinous cones with germinable seeds remain on the some pine species for several years after others have dispersed and germinated. Other seeds are shed naturally but require an after-ripening period before they can germinate. These are examples of dispersal strategies that have been favorable for regeneration of these species but also seem to contradict the simple definition of maturity. Others propose that physical or chemical attributes of the seeds define maturity: minimum moisture content, maximum dry weight, maximum level of stored food reserves, or maximum germination performance. As in the previous definition, there are numerous apparent exceptions to all of the proposed criteria. Another problem with the general rule about collection at maturity is that, in actual practice, fruits and seeds must often be collected before full maturity, whatever that is, because of possible losses to predators, difficulties in collecting small wind-dispersed seeds, or time constraints in commercial collection operations. The solution to both of these problems is to develop practical indices of maturity for fruits and seeds so that collectors can tell when they can proceed without danger of gathering immature seeds that will not germinate properly and produce healthy seedlings.

Indices of maturity. In order to collect seeds at the optimum stage of their development, collectors need some sort of index of seed maturity to guide them in their choice of collection time. Indices of seed maturity should ideally be simple procedures that require little or no equipment and that can be administered in the field.

Physical. The most commonly used indices of fruit or seed maturity are those that are based on physical characteristics. Change of fruit color is widely used on both dry and fleshy fruits. The most common color changes are from a "vegetative green" to a shade of brown in dry fruits or to a bright or blue-black color in fleshy fruits. Common patterns are changes from green to yellow to brown (ash, maple, and white oak, *Quercus alba* L.); from green to red to purple or black (cherries and tupelos, *Nyssa* L.); from green to yellow to purple (for example, honeylocust); and from green to brown (conifers).

Embryo size is a simple maturity index. When embryo length reaches 75% of the length of the embryonic cavity, seeds of many species are considered mature enough to collect (Edwards 1979). The relative size of embryos can be easily seen on radiographs or determined from cross-sections of seeds.

Moisture content also is a simple indicator of maturity in some species, but overnight or 24 hours of drying of samples in ovens is required for accurate measurement. "Critical" samara moisture levels (percentage of fresh weight) were reported to be 16% for green ash (Cram and Lindquist 1982) and 59% for sugar maple (Carl and Snow 1971). Moisture content of cones is also a very good maturity index for many conifers, but instead of actually measuring it, most collectors estimate cone moisture content by measuring specific gravity of the cones. This can be accomplished easily in the field with a graduated cylinder of water

Table 8—Chapter 1, Seed Biology: cone specific-gravity values that indicate seed maturity in some conifers

Species	Specific gravity
Abies grandis (Dougl. ex D. Don) Lindl.	0.90
Cunninghamia lanceolata (Lamb.) Hook.	0.95
Pinus elliottii Engelm.	0.95
P. merkusii Junghuhn & Vriese ex Vriese	1.00
P. palustris P. Mill.	0.90
P. strobus (L.)	0.90
P. taeda (L.)	0.90
P. virginiana P. Mill.	1.00

(Barnett 1979). Cone weight is estimated by water displacement of the floating cone, and volume is estimated by water displacement of the submerged cone. Specific gravity is equal to weight divided by volume (examples of cone specific gravities used to judge maturity are listed in table 8).

Other physical indices of seed maturity are easy cup release from acorns of oak; a white, brittle embryo of some ash species that breaks when bent at a sharp angle; and white pine cone scales that flex open when cones are bent double. For details on maturity indices of individual genera or species, see part 2 of this book.

Chemical. Although chemical indices of maturity are biologically sound, they are seldom practical to use in collection. Most potential chemical indicators are based on the level of stored food reserves (table 9), but elemental phosphorus and IAA concentrations have been suggested as indices for green ash (Bonner 1973) and English oak (Michalski 1969), respectively.

Shedding and dispersal. The majority of temperate genera shed their fruits and seeds in the fall or winter, although many—for example, birch and poplar—shed theirs in the spring. In some genera—for example, maple, eucalyptus, willow, and elm—there are both spring-shedding and fall-shedding species. Other species have seeds that mature and are shed in mid-summer—for example, ceanothus (*Ceanothu*s L.).

The seeds of many species are shed or dispersed quickly (within a few days) after they mature, and collectors must be alert to the phenological characteristics of the species in order to collect what they need. Some species that shed fruits quickly when they mature are maples and elms. In others, the fruits are persistent on the tree but open to disperse the seeds quickly after maturity; examples include sweetgum, poplars, and willows. In still other species, fruit opening and seed dispersal are very dependent on the weather. Cones of loblolly pine, for example, open readily in warm, dry conditions and disperse their seeds. At night, they close back up again when humidity rises. If a weather front brings rain, the cones may close up completely and not reopen for dispersal for several days. The primary seed dispersal agent of all of the above species is wind.

Drupes, berries, and other fleshy fruits are not usually shed quickly, but they can be removed from the trees rapidly by birds and animals. This can be a major problem for seed collectors wishing to harvest the seeds of species such as pawpaws (*Asimina* Adans.), hollies, plums, and prickly-ash (*Zanthoxylum* L.). Seeds will usually have to be collected exactly at the time of maturity on the trees, or the entire crop may be lost. The same problem occurs for some fruits that are not fleshy, for example, hickories, walnuts, and oaks. These fruits are favorite foods of rodents, deer, and other animals, and they must be collected from the ground as soon as they are shed. Birds will also take many of these fruits before shedding; for example, a flock of grackles can completely strip a large willow oak (*Q. phellos* L.) of its acorn crop in several hours.

The cones of most conifers disperse their seeds soon after maturity. In true firs, dispersal occurs as the cone disintegrates on the trees, leaving the spike-like cone axis still upright on the branches. In some pines, cedars, and hemlocks, the cones are slow to give up their seeds, and dispersal may take 3 to 12 months. Serotinous cones of several species—such as jack (*Pinus banksiana* Lamb.), sand (*P. clausa* (Chapm. ex Engelm.) Vasey ex Sarg.), pitch (*P. rigida* Mill.), and lodgepole pines—do not normally open on the trees but open on the ground following fires that melt the resin seals on the cone scales. Other pines—Swiss stone and Siberian stone pines, etc.—shed their cones while still

Table 9—Chapter 1, Seed Biology: chemical levels that indicate seed maturity

closed or only partly open, and seed dispersal occurs only as the cones disintegrate on the ground over several months (Krugman and others 1974).

The major dispersal agents for seeds of woody plants are wind, animals, and water. Wind-dispersed species are mostly small, and many have hairs or other appendages that help to prolong their flight. Other seeds, such as those of ailanthus, catalpas, or ashes, are somewhat larger but have wings that are large in relation to the size of the embryos. Food value and color aid in dispersal by animals, which is very local if by rodents or widespread if by birds. Dispersal by water is usually by flotation and can be very important for wetland species such as tupelos, willows, and the 1 oak species that has floating acorns–the overcup oak (*Quercus lyrata* Walt.). At least 2 genera in this book—ceanothus and witch-hazel disperse seeds with an explosive force when drying fruits split suddenly and expel the seeds. For more detailed treatments of seed dispersal, readers should see Bawa and Hadley (1990) and Fenner (1992).

Dormancy

Once seeds have matured and been dispersed, survival of the species requires that they germinate at a time and place favorable for growth and survival of the seedlings. Plants have evolved many mechanisms and processes that ensure survival. Some species produce prodigious numbers of seeds, so that even if only a tiny proportion germinate and grow, some seedlings will survive. In others, germination at unfavorable times is prevented by a mechanism that is commonly described as dormancy. Dormancy is defined as a physiological state in which a seed disposed to germinate does not, even in the presence of favorable environmental conditions (Bonner 1984). Seeds are able to overcome dormancy and germinate when "triggered" by certain internal processes that are usually induced by environmental changes. There is a tremendous range in the degree of dormancy among woody species. Some seeds lie in the soil for years before germinating, whereas other are delayed for only a few weeks. The latter condition is sometimes described as "delayed germination" to indicate something less than true dormancy. In fact, the distinction between dormancy and delayed germination is not at all clear, and among the majority of species, the interval between maturity and germination (in natural conditions) is a continuum with no distinct gradation.

Types of Dormancy

Many different classifications of dormancy have been devised by seed scientists and there is no universal agreement on the subject. Most tree seed workers accept the definitions of the Seed Problems Working Party of the IUFRO—International Union of Forest Research Organizations (Bonner 1984)—and these definitions will be used in this discussion.

Seedcoat (or external) dormancy. Seedcoat dormancy has 3 primary modes of action. In the most common mode, the seedcoats (or other covering structures) are impermeable to the entry of moisture or gases. Members of the Leguminoseae—for example, acacia, albizia (*Albizia* Durazz.), honeylocust, mesquite (*Prosopis* L.), black-locust, sophora (*Sophora* L.)—usually display this characteristic, which is commonly called hardseededness by those who work with seeds. Members of other families also have seedcoats that impose a similar dormancy, but seedcoat structures are different; some examples include American beautyberry (*Callicarpa americana* L.), hollies, sumacs, and basswood.

The second mode of dormancy action attributed to seedcoats is the mechanical resistance to swelling of the embryo as it absorbs moisture. This resistance delays full imbibition and emergence of the radicle from within the seed. Mechanical resistance frequently contributes to dormancy and has been documented in big sagebrush (*Artemesia tridentata* Nutt.) (McDonough and Harniss 1974), pecan (Van Staden and Dimalla 1976), loblolly pine (Barnett 1976b), Korean pine (Hatano and Asakawa 1964), and water oak (Peterson 1983). It does not appear to be the primary factor in tree seed dormancy, however.

A third possible mode of seedcoat dormancy is the presence of germination inhibitors in the seedcoats (Bewley and Black 1994; Nord and Van Atta 1960; Peterson 1983) that may or may not play a significant role in dormancy. Some of the phenolic substances in seedcoats that could possibly be germination inhibitors could actually be beneficial by inhibiting the growth of pathogenic microorganisms (Mohamed-Yasseen and others 1994). In some herbaceous species, there are inhibitors that must leach from the embryo before germination can take place, and seedcoats prevent this leaching (Bewley and Black 1994). There is no conclusive evidence of this condition in seeds of woody plants, but success in stratifying seeds by placing them in porous sacks in running water suggests that it may occur.

Embryo (or internal) dormancy. Embryo dormancy arises from a condition within the embryo itself. The most likely cause of embryo dormancy is the presence of germination inhibitors in the embryonic axis or in the food storage tissues of the seed. For germination to occur, these inhibitors must be metabolically inactivated, or their effect

must be overcome by germination-promoting substances. Germination inhibitors have been isolated and identified in a number of woody plant seeds, with ABA the most common inhibitor. Species with ABA functioning as an internal inhibitor include sugar (Enu-Kwesi and Dumbroff 1978), Norway (*Acer platanoides* L.) (Tilberg and Pinfield 1982), and planetree maples (Webb and Wareing 1972); European hazel (*Corylus avellana* L.) (Williams and others 1973); white ash (*Fraxinus americana* L.) (Sondheimer and others 1968); apple (*Malus pumila* Mill.) (Singh and Browning 1991); and northern red (*Quercus rubra* L.) and English oaks (Szczotka 1977). Correlations of changing ABA levels with degree of dormancy in mature seeds is not evidence of cause and effect, however, and more detailed research is needed in this field. ABA also seems to play a role in preventing precocious germination in English oak (Finch-Savage and others 1992) and shedding of silver maple samaras (Tomaszewska 1973). Other germination inhibitors have also been found in dormant seeds of woody plants, but there is no good evidence for their modes of action in the seed.

In another type of embryo dormancy, called physiological immaturity, a critical enzyme system or other biochemical factor is not in place at shedding and afterripening is required for complete physiological maturation. Evidence for the existence of this type of dormancy is weak, so it probably is the same as morphological dormancy.

Morphological dormancy. Morphological dormancy results from the embryo not being completely morphologically developed when seeds are shed. Additional growth of the embryo is required in an afterripening period. Morphological dormancy has been documented in black (*Fraxinus nigra* Marsh.) and European ashes (Vanstone and LaCroix 1975; Walle 1987), American holly (Ives 1923), and several pines that grow at high altitudes or latitudes (Krugman and Jenkinson 1974).

Combined dormancy. Combined dormancy is a condition in which 2 or more primary factors, such as seedcoat dormancy and embryo dormancy, are present to the extent that each requires treatment to overcome. Some examples of combined dormancy in North American species are seeds of Mexican redbud (*Cercis canadensis* var. *mexicana* (Rose) Hopkins) (Tipton 1992), skunkbush (*Rhus trilobata* Nutt.) (Heit 1967b), and American basswood (Barton 1934). For basswood, seedcoat scarification with acid for 10 to 40 minutes, followed by moist stratification for 90 days is the recommended treatment to overcome dormancy (Heit 1967b).

Double dormancy. Double dormancy is a condition in which there is dormancy in both the radicle and the epicotyl of the embryo, but each require different conditions to overcome it. This type of dormancy is difficult to demonstrate, but it has been reported for viburnums (Giersbach 1937). A similar condition is found in some oaks, in which radicles are not dormant, but epicotyls are.

Secondary dormancy. Secondary dormancy results from some action, treatment, or injury to seeds during collection, handling, or sowing. Pine seeds can incur secondary dormancy if exposed to high temperatures and moisture at crucial times (McLemore and Barnett 1966). When stratified seeds are redried to storage levels (below 10%), they are often said to have incurred secondary dormancy. Germination can certainly be delayed under these conditions, but this is not a true secondary dormancy.

Overcoming Dormancy

Dormancy is a great advantage when one wants to store seeds, but a disadvantage when prompt germination in desired. With the exception of hardseeded species, years of research have revealed little about how seed dormancy really functions and how it can be overcome. Applied research and practical experience, however, have combined to provide ways to hasten the germination of dormant seeds.

Seedcoat dormancy. Treatments are designed to breach the seedcoat, or other covering structures, and remove barriers to moisture uptake, gas exchange, swelling of the embryo, and radicle emergence. Methods used to overcome seedcoat dormancy are collectively known as scarification treatments, and there are risks to seed viability inherent in all of them. In selecting a scarification treatment, the most gentle method should be tested first; then increasingly severe treatments until the desired effect is obtained. The methods below are listed in order of increasing severity. Complete details on how to apply them can be found in chapter 5 for small samples, as in seed testing, and in chapter 7 for large quantities. Suggested methods for individual species may be found in part 2 of this book.

Cold water soak. In some hardseeded species, the seedcoats are not completely impermeable to water. Soaking such seeds in water at room temperature for 24 to 48 hours may be sufficient for full imbibition and subsequent germination.

Hot water soak. Similar to the cold water soak, except that seeds are put into very hot or boiling water and left there as the water cools. The hot water softens the seedcoats or causes them to crack, and imbibition occurs as the water cools. Numerous leguminous species can be treated in this manner—for example, acacia, albizia, and prosopis.

Hot wire. This technique requires a heated needle or an electric woodburning tool to burn small holes through

seedcoats (Sandif 1988; Stubsgaard 1986). A belt-driven burner that scarifies seeds electrically shows promise for treatment of larger lots (Danida Forest Seed Centre 1993). "Burned" seeds can be shipped or returned to storage after treatment (Lauridsen and Stubsgaard 1987), something that other scarification methods normally do not allow.

Acid treatment. Treatment with concentrated sulfuric acid (or other mineral acids such as hydrochloric or nitric acids) is the method of choice for many species. Seeds should be in contact with the acid for 15 to 60 minutes, depending on species or individual seedlot, and washed thoroughly in running water afterward to remove any acid that remains on the seedcoats. Acid has been used in North America to treat honeylocust and Kentucky coffeetree (*Gymnocladus dioicus* (L.) K. Koch) (Liu and others 1981), black locust (Heit 1967a), and snowbrush ceanothus (*Ceanothus velutinus* Dougl.) (Heit 1967b).

Mechanical treatments. Mechanical scarification is used extensively for large lots of seeds. There are various scarifiers in use, from small cement mixers filled with rough rocks or pieces of broken concrete, to the impact seed gun developed in Denmark (Stubsgaard 1986). A mechanical device has also been developed to crack peach seedcoats (Reid and others 1979). For small samples, seedcoats can be scarified by hand with knives, files, clippers, sandpaper, etc.

Internal dormancy. Treatments to overcome internal dormancy are expected to bring about physiological changes within the embryo that will enhance rapid germination. The most successful treatments have been those that simulate natural conditions in a crucial time period in the reproductive life cycle of the plant. For temperate species, this is usually a moist, chilling period, commonly called stratification, because it was formerly done by alternating layers of seeds and sand or peat in a pit in the ground. Stratification in pits is seldom used anymore, but the principles are the same.

Stratification (chilling). The usual procedure for stratification is to refrigerate fully imbibed seeds at 1 to 5 °C for 1 to 6 months. This procedure simulates the natural winter conditions of temperate seeds that are lying on the forest floor. During stratification (1) enzyme systems are activated (Eichholtz and others 1983; Li and Ross 1990a&b; Michalski 1982; Slater and Bryant 1987); (2) stored foods are changed to soluble forms (Dumbroff and De Silva 1972; Kao and Rowan 1970; Pukacka 1986; Tylkowski 1986; Vozzo and Young 1975); and (3) the inhibitor/promoter balances change (Enu-Kwesi and Dumbroff 1978; Tillberg and Pinfield 1982; Webb and others 1973; Williams and others 1973). For a more detailed review of the biochemical changes during this period, see Bewley and Black 1994.

The optimum length of the stratification period varies greatly among species and among different seedlots of the same species. There may be differences even within the same lot if some portions are handled differently. In southern pines, dormancy often appears to increase during storage, and stored seeds require longer stratification than the same lots when fresh (Bonner 1991). Details on stratification procedures can be found in chapters 5 and 7. Recommendations for particular genera or individual species are provided in part 2 of this book.

One tremendous benefit of stratification for nurseries is an increased uniformity of emergence. The low temperatures used in stratification inhibit germination of the seeds that are no longer dormant while the remaining seeds are undergoing the needed internal changes. When the seeds are finally sown in favorable temperatures, there is a flush of uniform germination and emergence, which is crucial to even seedling development. This condition also explains why some non-dormant species appear to respond favorably to short periods (1 to 2 weeks) of stratification with faster and more complete germination.

There is a growing body of evidence that suggests that full imbibition is not the optimum moisture content for stratification. Careful regulation of seed moisture content at levels below full imbibition has produced improved seed performance and sowing options for both conifers (Edwards 1986; Poulsen 1996) and hardwoods (Muller 1993).

Incubation and stratification. A number of species that exhibit complex embryo dormancy or morphological dormancy will germinate quicker if given a warm, moist incubation period prior to cold stratification. The incubation period promotes embryo growth and other internal processes and is usually shorter than the stratification period. Species for which this treatment has been effective include cherry plum (*Prunus cerasifera* Ehrh.) (Tylkowski 1986), black ash (Vanstone and LaCroix 1975), and several species of juniper (Rietveld 1989; Van Haverbeke and Comer 1985).

Chemical treatment. Various studies have shown that some species will germinate quicker following treatment with exogenous chemical agents, such as hydrogen peroxide, citric acid, and gibberellins. Although these benefits can be demonstrated in the laboratory with small samples, they are rarely, if ever, used in production nurseries.

Combined treatments. Some species—such as American basswood—have seeds with combined dormancy charateristics that seem to require 2 types of treatment for good germination. Impermeable seedcoats must first be scarified before seeds are stratified (Brinkman 1974).

Variation in Dormancy

As noted earlier, there is widespread variation in the degree of dormancy, both among species, and within a species. For some species, there are patterns of dormancy that have been documented and that can have practical application. For example, degree of dormancy appears to increase with increasing elevation of seed source for black cherry and red maple (*Acer rubrum* L.) in Tennessee (Farmer and Barnett 1972; Farmer and Cunningham 1981). Seeds from more northern sources generally require longer stratification periods than seeds from southern sources. This relationship has been reported for sugar maple (Kriebel and Gabriel 1969), red maple (Farmer and Goelz 1984; Tremblay and others 1996), sweetgum (Wilcox 1968), and sycamore (Webb and Farmer 1968). In contrast, eastern white pine showed just the reverse in a range-wide study (Fowler and Dwight 1964): seeds from the southern sources are more dormant, but this phenomenon may be related to the higher altitudes of the natural stands of white pine at the southern extremities of its range. Warmer climates during seed maturation typically produce heavier and larger embryos in seeds (Durzan and Chalupa 1968), presumably because the growing seasons are longer. This conditions suggests that degree of dormancy (or delayed germination) is related to degree of physiological maturity in temperate seeds, but the evidence for this is lacking.

Variation in dormancy among individual trees at the same site has been documented for loblolly pine (McLemore and Barnett 1966) and sweetgum (Rink and others 1979), and can probably be assumed to occur in all woody plants. Partial genetic control of dormancy is also obvious, because most seed dormancy is related in some way to seedcoats or other covering structures, all maternal tissues. The best way to understand dormancy is to quantify it in mathematical terms. A number of studies have attempted this for temperate trees (Bonner and Harrington 1993; Donald 1987; Richter and Switzer 1982; Rink and others 1979; Sorensen 1983) and all of the proposed methods have application under certain conditions.

Germination

Germination is defined as "the resumption of active growth in an embryo which results in its emergence from the seed and development of those structures essential to plant development" (Bonner 1984). In another sense, it is the culminating event of seed maturation, the establishment of the seedling. It is useful to think of germination as occurring in overlapping events (Kramer and Kozlowski 1979):

1. Absorption of water
2. Increased respiration, enzymatic activity, and assimilation of stored foods
3. Increased adenosine phosphate and nucleic acids
4. Cell growth and division
5. Differentiation of tissues

All of these events are influenced by environmental conditions and events within the seeds themselves.

Environmental Factors

The most important environmental factors that influence germination are moisture, temperature, light, and aeration.

Moisture. The typical pattern of moisture uptake by seeds has 3 phases (Vertucci 1989): a rapid initial uptake, a short lag period of extremely slow uptake, and another rapid period of uptake just before germination. The first phase is primarily imbibitional in nature and occurs in dead seeds as well as live ones. It is a physical process of moisture moving from a substance with high water potential (soil) to one with a low water potential (dry seed). This uptake displaces gases from dry seeds (Simon 1984) and is visually evident in the bubbles that slowly escape from dry seeds when they are submerged in water. The length of the second phase is related to the degree of dormancy or delayed germination in the seeds. It can be practically absent in the rapidly germinating seeds of oak (Bonner 1968) or extended in the case of very dormant seeds. The third phase occurs when metabolism becomes very active, and the seedcoats split, leading to greater oxygen uptake.

There are minimum amounts of moisture required for germination to proceed, and several studies have sought to measure the moisture stresses that will retard or halt germination (table 10). Significant decreases in germination occurred, in general, from – 0.8 MPa and below, and germination was effectively stopped at stresses of – 0.3 to – 2.0 MPa. All of these studies used osmotic solutions to impose stress, and there are concerns that this method may hinder germination by inhibiting gas exchange. McDonough (1979) used thermocouple psychrometer chambers to impose moisture stress on seeds of quaking aspen (*Populus tremuloides* Michx.), however, and his results agree quite well with those reported with osmotic solutions. Comparisons among species should be made with caution, as methodology and equipment varied widely in these studies. There were also significant interactions with seed source, seed treatment, and temperature for some species (Bonner and Farmer 1966; Farmer and Bonner 1967; Moore and Kidd 1982).

Table 10—Chapter 1, Seed Biology: critical levels of water potential (MPa) for germination within a 20 to 30 °C range of temperatures as determined with osmotic solutions*

Species	Water potential (MPa)	
	Strongly decreased germination	Effectively stopped germination
Artemisia tridentata Nutt.	–0.1	–1.6
Acacia tortillis (Forsskal) Hayne	–0.29	–0.51
Cercocarpus montanus (Raf.)	–0.4	–1.3
Chrysothamnus nauseosus (Pallas ex Pursh) Britt.	–0.4	–1.6
Liquidambar styraciflua L.	–0.5	–1.52
Pinus contorta Dougl. ex Loud	–0.8	—
P. eldarica Medw.	–0.6	–1.2
P. elliottii Engelm.	–0.81	–1.82
P. palustris P. Mill.	–0.81	–1.82
P. ponderosa P. & C. Lawson	–0.4	–0.8
Picea engelmannii Parry ex Royle	–0.8	—
Populus ciliata Wall. ex Royle	–0.1	–0.3
P. deltoides Bartr. ex Marsh.	–1.01	–1.52
Quercus palustris Muenchh.	–0.5	–2.0

* Some data were converted from atmospheres and bars to MPa as follows: 1 bar = 0.1 MPa; 1 atm = 0.1013 MPa.

Temperature. Seeds of temperate woody plants can germinate over a wide range of temperatures, from a minimum of 2 or 3 °C, to a maximum of about 45 °C (Bonner and others 1994). Radicle emergence will occur in most species at 45 °C, but few will produce normal seedlings at this temperature. Low temperatures, on the other hand, are favored by some species. Northern red oak from Wisconsin, for example, germinated best at 1 °C in a trial reported by Godman and Mattson (1980). Some true firs and mountain hemlock (*Tsuga mertensiana* (Bong.) Carr.) will germinate in snowbanks in Oregon and Washington (Franklin and Krueger 1968). Many dormant temperate species will sometimes germinate in stratification bags at 3 to 5 °C if left for long periods. The major effect of temperature on germination, however, is on rate rather than total germination.

Natural seedbeds do not remain at constant temperatures, but experience diurnal fluctuations from lows at night to highs in the daytime. Most temperate woody plants have adapted to these conditions and germinate most rapidly at alternating temperatures of approximately 20 °C at night and 30 °C in the daytime. Other species germinate faster at lower temperatures regimes, for example, 15 to 25 °C or 10 to 20 °C, or at constant temperatures of 5 to 22 °C (Sabo and others 1979; Wang and Pitel 1991). Official seed testing prescriptions are based on the known optimum temperatures for each genus or species (ISTA 1993). Experiments with 2-way thermogradient plates suggest that germination of many temperate species will occur at a wide range of temperature regimes, and that an amplitude of change between day and night of 10 to 12 °C may be more important than the cardinal points (Bonner 1983; Mayer and Poljakoff-Mayber 1963; Sabo and others 1979).

In the tropics, pioneer species that invade forest gaps also respond to alternating temperatures with increased germination (Vázquez-Yanes and Orozco-Segovia 1982). Temperatures are more constant underneath canopies, and light becomes more of an important factor in germination in these conditions (Clark 1990; Vázquez-Yanes and others 1990.).

Light. Light plays a complex role in the germination of woody plants, in that it stimulates the germination of most species but is absolutely necessary for only a few. It is often difficult to separate the effects of light and the effects of temperature. Dry, dormant seeds normally do not germinate in the dark, but stratification at low temperatures or treatment with high temperatures can overcome the dark inhibition in some species.

The key to seed response to light is thought to be the phytochrome system. Phytochrome is a pigment that exists in 2 forms within the embryonic axes of seeds (Bewley and Black 1994). One form (Pr) has a maximum absorption at 660 nm, whereas the other form (Pfr) has a maximum absorption at 730 nm. Red light converts Pr to Pfr in imbibed seeds, which is associated with overcoming dormancy. Far-red light drives the process in the other direction, accompanied by a partial return of dormancy. The red/far-red reaction has been demonstrated in seeds of numerous temperate species: Virginia (*Pinus virginiana* Mill.) (Toole and others 1961), longleaf (McLemore and Hansbrough 1970), and Scots pines (Nyman 1963); red alder (*Alnus rubra* Bong.) (Bormann 1983); paper (*Betula papyrifera* Marsh.) (Bevington and Hoyle 1981), hairy (*B. pubescens* Ehrh.), and European white birches (*B. verrucosa* Ehrh.) (Junttila 1976); and northern catalpa (*Catalpa speciosa* Warder ex Engelm.) (Fosket and Briggs 1970). There is also evidence that the red/far-red system is operative in seeds of many tropical rainforest species (Vázquez-Yanes and Orozco-Segovia 1990). For a detailed discussion of phytochrome and its reactions, readers should see Bewley and Black (1994).

Phytochrome reactions require only a short exposure to the proper wavelength to take effect (Bewley and Black 1994). Other light responses that are related to daylength have been noted in seeds of woody plants. In terms of germination, eastern hemlock appears to have long-day light requirements of 16 hours at 27 °C, but shorter requirements of 8 to 12 hours at 17 °C (Stearns and Olson 1958). In many temperate species—for example, Fraser fir (*Abies fraseri* (Pursh.) Poir). (Adkins and others 1984); sweetgum (Bonner 1967), and ponderosa pine (Harrington 1977)—stratification decreases the light requirement for prompt germination. These responses may or may not be related in some way to phytochrome, but they demonstrate the complex nature of the relationship of light to seeds.

Aeration. Respiration supplies energy to germinating seeds, and oxygen is a primary electron acceptor in the process (Kramer and Kozlowski 1979). Insufficient oxygen is not usually a major barrier to germination, except when seeds are buried too deeply in the soil or are submerged in water. A few small seeds can germinate as they float on the surface of water—for example, willows, cottonwood (*Populus deltoides* Bartr. ex Marsh.), and sycamore—but oxygen is usually too limiting for germination when seeds are submerged. Poor oxygen supply is often a problem in seed testing when blotters are kept too moist. Moisture will actually form a film around seeds and inhibit the entry of oxygen (Gordon and Edwards 1991).

As seeds begin to germinate, the pattern of oxygen uptake is practically identical to that of water uptake (Kozlowski and Gentile 1959): (1) a short period of rapid uptake; (2) a period of very slow uptake; and (3) a second period of rapid uptake. Measurements of seedcoat permeability to oxygen in some herbaceous species suggest that the coats are much more permeable to water than to oxygen. Part of this may be due to the consumption of oxygen by the seedcoat itself in oxidative reactions (Bewley and Black 1994). There are lots of phenolic compounds in seedcoats, for example, and their oxidation could consume a considerable amount of oxygen.

Biochemical Changes

When non-dormant seeds are placed in environments that are conducive to germination, internal processes that drive the growth of the embryo start to take place. These processes are dominated by the conversion of storage foods into soluble forms and their translocation into the embryonic axis. In stratified seeds, these processes have already been initiated during the treatment period. In the past 25 years, there has been an enormous amount of research that has greatly advanced our knowledge of the biochemical mechanisms of seed germination. Although most of this research has been centered on seeds of agricultural crops, the basic processes are similar in most seeds and the conclusions drawn from this research can be readily extrapolated to include the seeds of woody plants. A detailed discussion of biochemical changes in seed germination is beyond the scope of this book. For additional information, readers should see Bewley and Black (1994), Murray (1984), and Pehap (1983).

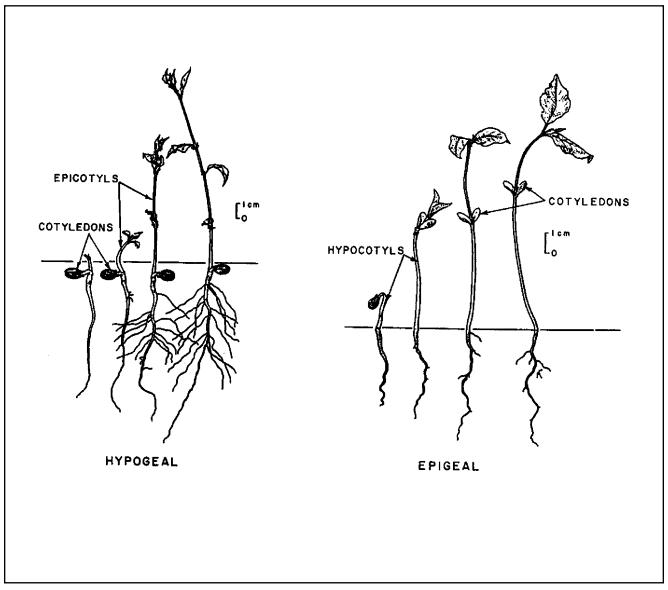
Most recent work on seeds of woody plants has been on oily seeds. In these seeds, lipid reserves are converted to starch, which is then hydrolyzed into soluble carbohydrates (mainly glucose) for embryo growth. Much of this change takes place within the storage tissues (endosperm, cotyledon, female gametophyte, or haustoria) before axis elongation signals the start of germination, so it is difficult to say if this change is part of dormancy removal or part of the germination process (Arce and others 1983; Li and Ross 1990a&b; Murphy and Hammer 1993;). Recent studies on gene expression and enzyme formation in several pine species should help in this regard (Gifford and others 1991; Murphy and Hammer 1993; Pitel and Cheliak 1988; Pitel and others 1984; Salmia 1981).

Other changes within germinating embryos include the hydrolysis of storage proteins to form amino acids and other soluble nitrogenous compounds for enzyme synthesis

(Bouvier-Durand and others 1984; Salmia 1981) and a large increase in soluble phosphorus compounds (Ching 1966).

The transfer of reserve foods from storage tissue to the axis is usually direct. In endospermic Leguminosae (which include honeylocust), however, the reserves are transferred from the endosperm to the cotyledons, then to the growing axis (Bewley and Black 1994). A similar transfer process may exist in other species that have both endosperm and cotyledons, but there is no evidence for it. In oil palm (*Elaeis guineensis* Jacq.), a slow-germinating monocot, the haustoria form at one end of the embryo and absorb the food reserves from the endosperm as they are broken down and pass the nutrients on to the developing plumule and radicle (Oo and Stumpf 1983).

Figure 12—Chapter 1, Seed Biology: the common forms of seed germination in temperate trees. These are hypogeal germination **(left)**, here that of American plum (*Prunus americana* Marsh.), with seedlings at 1, 3, 5, and 9 days after germination, and epigeal germination **(right)**, here that of common chokecherry (*P. virginiana* L.) seedlings at 1, 3, 7, and 11 days after.



Physical Development

Physical changes in germinating seeds are practically the same for all species. The first sign is usually swelling of the seed from water uptake. Embryo elongation occurs second, but unseen within the seed's covering structures. Then the seedcoat splits, and the emerging radicle elongates. At this point, germination in temperate species takes one of two forms. One form is epigeal germination, in which the hypocotyl elongates, arches upward, then straightens, pushing the cotyledons upward through the soil (figure 12). In many species the seedcoats are still attached to the cotyledons after emergence and are not shed until the cotyledons start growing. Genera that exhibit epigeal germination include pine, cedar, eucalyptus, juniper, magnolia, and mountain-ash.

In the second form, hypogeal germination, it is the epicotyl that elongates, pushing the young plumule through the soil while the cotyledons remain below ground (figure 12). There they remain attached to the seedling and supply reserve foods for weeks or more. Genera that exhibit hypogeal germination include buckeye, oak, walnut, chestnut (*Castanea* Mill.), and torreya.

Germination form is normally the same for all species in a genus, but like most things in seed biology of woody plants, there is an exception. In cherries and plums, both forms occur; common chokecherry (*P. virginiana* L.) is epigeal, but the remaining species of the genus are hypogeal (figure 12).

Some authorities recognize other forms of germination in tropical species. Bunya-pine (*Araucaria bidwillii* Hooker) and Parana-pine (*A. angustifolia* (Bert.) O. Kuntze) seeds germinate on the surface of the soil, then the cotyledonary stalks elongate and push the hypocotyl, plumule, and radicle into the soil. The hypocotyl subsequently develops into a tuber that serves to transfer the food reserves from the female megagametophyte to the growing seedling. This type of germination has been defined as cryptogeal (Burrows and Stockey 1994), and these araucarias are the only species in this book that exhibit this form of germination. Ng (1991) also has defined durian germination in which the hypocotyl elongates but the cotyledons remain within the seed. This form of germination occurs in common durian (*Durio zibethinus* Murr.), a popular, edible fruit of Southeast Asia that is cauliferous.

Chapter 2

Genetic Improvement of Forest Trees

Clark W. Lantz

Dr. Lantz retired from the USDA Forest Service, Southern Region's Cooperative Forestry Staff, Atlanta, Georgia, and is currently reforestation consultant in Granbury, Texas

Contents

2

Introduction

In this chapter, readers can gain a basic understanding of why certain procedures are used to improve forest trees. The references listed can be used as a source for obtaining more detailed information, both historical background and technical details. Examples are frequently cited from operational tree improvement programs to focus the chapter on an applied level. Although many of the examples are taken from the author's professional focus of over 40 years in the southern United States, the principles they exemplify can be used world-wide.

Terminology

Many of the terms used in this chapter are listed in the Glossary; a more detailed glossary may be found in Snyder (1972) and Wright (1976). Comprehensive references on forest genetics include Dorman (1976), Wright (1976) and Zobel and Talbert (1984).

"Forest genetics" is the general term often used for the study of inheritance in forest trees, whereas "forest tree improvement" usually refers to the applied use of forest genetics to actually improve the quality of the trees. "Tree breeding" is often used as a synonym for tree improvement, but it also may be found referring to specific activities such as controlled pollination. Zobel and Talbert (1984) define forest tree breeding as "activities geared to solve some specific problem or to produce a specifically desired product." Tree improvement will be the term used most frequently in this chapter.

It is important to understand that tree improvement is an integral part of silviculture. Tree improvement provides the raw material for artificial regeneration, which is one of the most important weapons in the arsenal of the silviculturist. Tree improvement provides a direct avenue to introduce genetically improved seedlings (or cuttings) into the reforestation system with no additional "handling fees." It costs no more to plant a genetically improved seedling than a "woods-run" seedling. (Note that although the costs of producing genetically improved planting stock are not insignificant, they can be viewed as an investment in future increased productivity. Dividends accrue in terms of increased growth, better form and wood quality, and improved insect and disease resistance).

Allocation of Resources

One of the key elements of land management is allocation of resources. An ever-expanding world population demands an ever-increasing supply of wood products. These must be produced on both private and public lands. The most productive sites should be devoted to maximum timber production. Maximum wood production on these acres relieves the pressure on other acres, which can be devoted to native vegetation, wildlife production, aesthetic considerations, and other uses not compatible with maximum timber production.

Even those acres devoted to maximum wood production via artificial regeneration with genetically improved planting stock are not lost to most aspects of good forest management practices. These acres will support strong wildlife populations, preserve watersheds, and provide many recreational opportunities. All these are fully compatible with timber production.

Monoculture

Critics of plantation forestry programs often cite the dangers of monoculture as reasons to reject these programs. The reasons quoted range from disease outbreaks to site deterioration, but usually focus on lack of biodiversity. In point of fact, there are few documented cases of severe problems, even in clonal plantations. Where there have been losses from pathogens, the increased productivity of the plantations usually greatly overbalances the losses. [It should be noted that most Forest Service restoration plantings after fire and logging are not monocultures. Seedlings of the various species that are planted are grown from seeds collected from areas near the new site.]

There can be interactions between intensive culture and diseases, as in the case of fusiform rust—*Cronartium quercum* (Berk.) Miyabe ex *Shirai* f. sp. *fusiforme* (Hedgc. & Hunt) Burdsall & Snow—which may be increased by site preparation procedures and fertilization (Miller 1972). Some clonal plantations such as those of cottonwood and eucalyptus have encountered disease problems, but these are often due to "off-site planting" (that is, growing a species on a site for which it is poorly adapted) rather than the lack of genetic diversity. Even the fabled case of "Saxony spruce" in which pure stands of Norway spruce—*Picea abies* L.—were blamed for "site deterioration" was actually due to off-site planting. This, in conjunction with poor management and poor seed source selection, led to drastically decreased productivity of the plantations (Lutz and Chandler 1946).

Gene Conservation

The fundamental concepts of gene conservation are an integral part of the tree improvement process. In the preservation of selected trees in seed orchards, clonal banks and progeny tests, valuable germplasm is not only preserved but

also replicated on different sites where it may enrich local tree populations via wind pollination. The planting of genetically improved seedlings on new sites likewise enriches the local gene pool of that species. Future populations of these trees can be expected to be more heterogeneous than the local stands as well as more productive (Namkoong 1974).

During the selection and breeding of forest trees, a tremendous volume of data is generated regarding species—site interactions, growth and tree quality information, and other physiological relationships. These data serve to increase our understanding of the importance of high-quality seedlings that are well-adapted to the planting site. Good forest stewardship requires vigorous, fast-growing trees as well as a diversity of flora and fauna.

The use of isozyme analysis has been adopted by many forest geneticists as a tool for estimating diversity in natural populations. For example, Shimizu and Adams (1993) used isozyme analysis in natural stands of Douglas-fir—*Pseudotsuga menziesii* (Mirbel) Franco—and found no evidence that planting nursery-grown seedlings contributed any less genetic diversity than natural regeneration.

Tree Improvement Versus Crop Improvement

The genetic improvement of forest trees has many similarities to the breeding of field crops. Most of the concepts are the same, namely the selection of above-average individuals from large populations, and subsequently breeding these individuals using a specified mating design. Following the breeding phase, the progeny must be tested on a variety of sites and under differing climatic conditions. Progeny tests are specially designed genetic tests that expose hereditary differences among trees, by bringing different genotypes together under a common set of environmental conditions.

When the progeny have developed sufficiently for a reliable assessment of their value, improved individuals or groups can be released for operational use and/or the breeding cycle can be repeated.

There are two major differences between working with field crops and forest trees. The first is time. Field crops such as corn and wheat reach reproductive maturity in a few months, while most trees require many years. Crop rotations with corn and wheat are also only a matter of a few months whereas trees may not produce a marketable crop for 25 to 100 years! Even in the tropics, it is rare to harvest a timber crop in less than 8 or 10 years. In practical terms, this means that a corn or wheat breeder can complete a breeding cycle in 2 or 3 years compared to the tree breeder's 8 to 10 years, at the very least (table 1).

Table 1—Chapter 2, Genetic Improvement of Forest Trees: the time factor

	Field crops	Trees
Reproductive maturity	1–2 months	5–20 years
Rotation length	4–6 months	10–100 years
Breeding cycle	1–2 years	8–20 years

The second major difference is that most field crop breeding is done with domesticated varieties that have been manipulated by humans for centuries and are often genetically homogeneous. Forest tree breeding, in contrast, usually starts with wild stands of trees that have been little-changed by humans. An exception here is "high-grading," the common logging practice of cutting the best quality trees and leaving the worst to regenerate the next generation. Unfortunately, tree improvement foresters are often forced to work with the results of one or more cycles of high-grading, namely trees of poor form and marginal value for breeding material. On the other hand, working with wild, unselected stands of trees does provide an opportunity to produce large gains in quality in the first few generations of breeding.

Field-crop breeding, therefore, usually involves working with well-known varieties that are often pure lines (genetically pure). With corn, for example, pure lines are crossed to produce heterozygous (genetically different) progeny that exhibit hybrid vigor (improved performance due to the interaction of different genotypes). Site considerations are also important here, as the corn will be planted on uniform, well-prepared sites while the trees may be planted on rough, cut-over sites with little or no site preparation. Adaptation is also a consideration as the corn is bred for a very narrow spectrum of soils, sites, and climatic zones. The trees, on the other hand, may be planted over a much wider range of soils, sites, and climatic zones.

The Biology of the Species

The genetic improvement of any crop will be effective only after a careful analysis of the biology of the species and how this influences the breeder's approach to the problem. For example, insect-pollinated species require special considerations from tree breeders. Genera such as maple (*Acer* L.), tuliptree (*Liriodendron* L.), magnolia (*Magnolia* L.), some species of willow (*Salix* L.), basswood (*Tilia* L.), and many tropical species are all insect-pollinated and, therefore, cannot be managed with the same techniques as

wind-pollinated species. The majority of commercial timber species are both wind-pollinated and monoecious, producing both male and female "flowers" (cones or stroboli) on the same tree. The location of these stroboli usually favors cross-pollination. For example, most conifers bear female cones in the upper areas of the crown with the male cones below, usually favoring cross-pollination rather than self-pollination.

Cross-pollination, in most plants, is an adaptation designed to increase heterozygosity, which is usually linked to vigorous growth, high fertility, and strong resistance to attack by pathogens. Conversely, self-pollination often leads to poor growth, weakness, and reduced fertility. Most breeding programs are designed to favor cross-pollination for these reasons.

Some tree species are dioecious, with the sexes separated on different trees. Members of the following genera are dioecious: ash (*Fraxinus* L.); holly (*Ilex* L.); juniper (*Juniperus* L.); poplar, cottonwood, and aspen (*Populus* L.); willow (*Salix* L.); and yew (*Taxus* L.). Fortunately, many of these genera can be propagated vegetatively. Also, in the case of the poplars, cross-pollination can be accomplished very quickly on a greenhouse bench by simply brushing pollen onto the receptive female flowers (Miller 1970).

Precocious (early flowering) species are adaptable to seedling seed orchards because they produce flowers at a young age and their seed production is abundant. Examples include Virginia pine (*Pinus virginiana* P. Mill.), sand pine (*P. clausa* (Chapman ex Engelm.) Vasey ex Sarg.), lodgepole pine (*P. contorta* Dougl. ex Loud.), and European black alder *(Alnus glutinosa* (L.) Gaertn.). Species that can be vegetatively propagated present unique opportunities because sexual reproduction is not necessary, and, therefore, the recombination of parental characteristics can be avoided. Species such as eastern cottonwood (*Populus deltoides* Bartr. ex Marsh.) can be produced vegetatively with unrooted stem cuttings planted directly in the field (figure 1). Other species require rooting under special conditions before they can survive field planting. These include Monterey pine (*Pinus radiata* D. Don), Norway spruce (*Picea abies* (L.) Karst.), tsugi (*Cryptomeria japonica* (L.f.) D. Don), Alaska-cedar (*Chamaecyparis nootkatensis* (D. Don) Spach), sweetgum (*Liquidambar styraciflua* L.), and sycamore (*Platanus occidentalis* L).

Figure 1—Chapter 2, Genetic Improvement of Forest Trees: hybrid poplar plantation in Oregon planted from unrooted cuttings.

Concepts of Genetic Improvement

Phenotype and Genotype

When we look at an individual Sitka spruce (*Picea sitchensis* (Bong.) Carr.), a cherrybark oak (*Quercus pagodafolia* Raf.), a Rocky Mountain juniper (*Juniperus scopulorum* Sarg.), or even an Angus bull, for example, we see a phenotype, a living organism with its own unique genetic constitution, as modified by its environment. In contrast, the genotype of the organism is encoded in its DNA. Each tree, therefore, has its own individual set of genetic blueprints. These are the instructions that will determine the genetic potential of its progeny.

The formula that "phenotype is the product of the genotype as affected by its environment" is often written as P = G + E. The phenotype is the organism that we see, measure, and with which we work. Life would be much simpler if the genotype was as obvious! Geneticists spend a great deal of their time and energy working to ascertain the actual genotype of their target organism. A major reason for progeny testing is to gain a better understanding of the genotypes of the selections that we are breeding. Recent advances in gene mapping with loblolly pine (*Pinus taeda* L.) (Sewell and Neale 1995) indicate that real progress is being made with the description of the loblolly genome. Some day we will understand the genomes of important commercial conifers as well as we understand common research bacteria and the common fruit fly.

The Genetic Code

The physical basis of genetic information is the DNA molecule, a long double helix of base pairs. This molecule is sufficiently stable to provide for the continuity of the species, yet flexible enough to allow for periodic changes. DNA therefore serves as both the blueprint for cell structure and metabolism and also the template for replication of many exact duplicates. These unique properties enable evolution to proceed in a remarkably stable universe. The evolutionary forces of mutation, migration, hybridization, and natural selection are responsible for the great variety of life that exists today.

New genotypes that result from mutations may move about (migration) and interbreed with other genotypes (hybridization). The new gene combinations that result are then sorted out by the process of natural selection. If these new genotypes are able to survive, reproduce, and leave more progeny than their competitors, they are "well-adapted." Therefore the tree species, races, and stands with which we are working are well-adapted to a specific site by virtue of their survival and reproduction in that environment.

Chromosome numbers. Chromosome numbers can change as a result of mutations. Polyploidy has been an important evolutionary factor in the plant kingdom. In most of the commercially important conifers, chromosome numbers range from n = 11 to 23 (Saylor 1972)(table 2). A notable exception is redwood—*Sequoia sempervirens* (Lamb. ex D. Don) Endl.—which is hexaploid (6n = 66). In contrast, chromosome numbers in the commercially important broadleaved trees vary widely, from n = 7 to 19, with a number of polyploids, including the genus alder (*Alnus* P. Mill.), birch (*Betula* L.), several *Prunus* species, and magnolias. A comprehensive table of chromosome numbers is found in Wright (1976).

Selection. Almost every process of genetic improvement starts with selection. This is true regardless if we are working with dairy cattle, winter wheat, or forest trees. The concept of selection involves the selection of a very small proportion of a population for one or more desirable characteristics. The difference between the proportion selected and the population mean (average) is called the selection differential.

Genetic gain or progress is measured by the product of the selection differential and the heritability (degree of genetic control) of the trait in question (for example height, straightness, and volume). Therefore by selecting individuals that are well above average in height, and assuming that the heritability (h^2) of height growth is sufficiently high to show progress, some gain in height should be expressed in the next generation. On the other hand, if the population in question is extremely uniform in height, and/or the heritability of height growth is low, selection may not be an effective approach. In some species, for example red pine—*Pinus resinosa* Soland.—the population is so uniform that selection for many traits is not cost-effective (Fowler and Morris 1977).

Hybridization

When populations are uniform and selection is not likely to be effective, one possible technique of genetic improvement is hybridization. Most of the successful hybrids in forestry have been interspecific (between species) hybrids. Examples include hybrid larch (*Larix leptolepis* x *decidua*), hybrid poplars (*Populus* spp. widely hybridized with many cultivars), the *Pinus rigida* x *taeda* cross in Korea (Hyun (1976), and the eucalyptus hybrids (Campinos 1980).

Heterosis (hybrid vigor) is a controversial topic among tree breeders. Many interspecific hybrids grow better than their parental species when planted in transitional environments. The actual quantitative documentation of heterosis is seldom published however.

A great deal of effort has been expended to produce a hybrid chestnut resistant to the chestnut blight—*Cryphonectria parasitica* (Murr.) Barr. Unfortunately, the American chestnut—*Castanea dentata* (Marsh.) Borkh.—which was devastated by the disease in the early 1900's, has little resistance to the disease. It is possible to cross American chestnut with Chinese chestnut—*C. mollissima* Blume—which is resistant to the blight. The hybrids produced are resistant, but unfortunately their form is so poor

Table 2—Chapter 2, Genetic Improvement of Forest Trees: chromosome numbers for some commercially important genera

# chromosomes	Genus
11	*Juniperus, Nyssa, Sequoia, Thuja*

19	*Liriodendron, Populus, Salix*
21	*Platanus*
23	*Fraxinus*

that they have little value as timber trees. There are two possible approaches to this problem. One is genetic engineering; the other is back-crossing to pure American chestnut. The American Chestnut Foundation has produced many successful back-crosses with the potential of restoring this grand tree to its former dominance in the eastern hardwood forest.

Many tree species that coexist on the same sites maintain their status as separate species primarily by a separation of flowering time. On transitional sites (ecotones) when one species is accelerated or retarded in flowering time, hybrids often result as in the case of the Coulter pine (*Pinus coulteri* D. Don) x Jeffrey pine (*Pinus jeffreyi* Grev. & Balf.) hybrids in California (Zobel 1951) and the pond pine (*Pinus serotina* Michx.) x loblolly pine (*P. taeda* L.) mixtures in North Carolina (Saylor and Kang 1973). Hybridization often occurs near the edge of the range where the species is losing its adaptive advantage. In southeastern Oklahoma and northeastern Texas, shortleaf (*P. echinata* P. Mill.) and loblolly pines occupy many sites together and hybrids are not uncommon (Abbott 1974).

Natural hybridization is a common phenomenon among the oaks (*Quercus* L.) (Muller 1952), some birches (Barnes and others 1974), and aspens (Pauley 1956).

Testing for Breeding Value

After the elite, select, or superior individuals have been selected, some system of testing their genetic value must be used. We have identified these trees as good phenotypes but we do not know their genotypes and therefore we are uncertain as to their value as breeding stock. Sometimes the outstanding trees in a stand may be taller than their neighbors due to an environmental advantage such as better soil or more moisture. It is important to use only trees with better than average genetic characteristics, as the environmental differences will not be passed on to future generations. In natural stands, it is critical to determine the age of individual trees. Trees growing together may have a similar size, yet be quite different in age. Obviously we would prefer that our select trees not be outstanding merely based on the fact that they are older than their neighbors.

The usual way to test vegetatively propagated trees is to plant them in blocks and compare performance with a standard population. This may be a clone of known performance, or in some cases seedlings from a standard seedlot may be used. Tests that are designed to evaluate the relative performance of a specific clone are called clonal tests.

Trees propagated from seed are usually progeny tested with one or more test designs modified from crop breeding. Early work with trees involved open-pollinated tests in which cones or seeds were collected from select trees and the half-sib progeny (female parent known, males unknown) were evaluated in plantations. As technology evolved, control-pollinated tests were developed that provided much better estimates of breeding values.

Most progeny tests are designed with row plots in field plantations, although single-tree plots have some advantages over row plots. A technique developed by the Western Gulf Forest Tree Improvement Cooperative uses greenhouse testing (Lowe and van Buijtenen 1989). This technique culls the poorest 17 to 20% of the progeny at about 5 months, based on shoot dry weight. This system reduces both the time and the cost of testing greatly.

Screening for Fusiform Rust Resistance

Due to the economic importance of fusiform rust with the southern pines, the USDA Forest Service established the Rust Testing Center at Bent Creek, North Carolina, in 1976. Forest Service pathologists developed a standardized inoculation system to screen loblolly and slash pine seedlings for susceptibility to fusiform rust (Knighten 1988). The Resistance Screening Center inoculates an average of 40,000 seedlings annually (figure 2). The southern tree improvement cooperatives routinely screen all new selections by sending seeds to the Rust Testing Center for evaluation. This is an essential part of the progeny testing procedure.

Screening for White Pine Blister Rust Resistance

Cooperative programs designed to develop resistance to white pine blister rust—*Cronartium ribicola* J.C. Fisch.—

Figure 2—Chapter 2, Genetic Improvement of Forest Trees: fusiform rust inoculation chamber at USDA Forest Service, Southern Station, Resistance Screening Center in North Carolina.

have been operating for a number of years in California and Idaho. For example, the USDA Forest Service, Pacific Southwest Region's program has identified 985 rust-resistant sugar pines—*Pinus lambertiana* Dougl.—for future tree improvement use. Family selection has been used as a breeding strategy.

Advanced Generation Breeding

Advanced generation breeding is usually designed with a combination of selections from first generation progeny test plantations in conjunction with new selections from operational plantations or other sources. A major advantage of selection in plantations is that the environment is usually more uniform than in natural stands. Tree age, spacing, and soils are often relatively uniform, with the result that the phenotype more closely approaches the genotype. In this case, selection is more efficient and gain can be increased. In most advanced generation breeding plans the best individuals are selected from the best families. It is important, however, to separate the production population from the breeding population to minimize the effects of inbreeding (Lowe and van Buijtenen 1986).

Starting a Tree Improvement Program

Establishing Objectives

Before a tree improvement program is begun, the situation needs comprehensive analysis. Tree improvement is long-term work, and a great deal of time and energy can be saved with some careful planning. The following factors should be considered.

1. **Desired products**
   - Wood properties necessary to produce the desired products
   - Required volume of wood
2. **Possible species**
   - Native or exotic (long-term consequences of using exotic species?)
   - Rotation length (shorter rotations give major improvements in gain per unit time)
3. **Chosen reforestation system**
   - Seed propagation or vegetative?
   - Bareroot or container seedlings?
   - Storage and distribution methods
   - Planting techniques and cultural procedures
4. **Plantation evaluation/survival system**
   - Required personnel
   - Numbers and skill levels
   - Required facilities and equipment
   - Required long-term budgets

Identifying the Raw Material To Be Used

Native versus exotic species. Are there native species available that are well-adapted to the planting sites to be used or would exotic species be more productive? The temptation to introduce an exotic species may be strong but there are a number of advantages of native species.

- They have evolved in harmony with their environment and usually have developed a mutual tolerance with competitors and pathogens. Exotics, on the other hand, may not perform well in a new environment—they have not been exposed to the stresses of this new environment and often have not had sufficient time to adapt to local conditions.
- Native species have well-defined management regimes that have been tested over time. Reforestation personnel have learned how to grow, ship, store and plant the seedlings or cuttings.

An exotic species introduced into a new environment does not necessarily produce wood with the same characteristics as in its place of origin. Excessive amounts of juvenile wood are common, as are wide bands of earlywood and narrow bands of latewood. These growth patterns lead to low-density wood and drying defects (Zobel 1981). There are notable exceptions, such as Monterey pines grown in New Zealand, but in general the wood quality of native species is more desirable than that of exotics.

Public opinion is running strongly in favor of native species both in the United States and overseas. Plantation forestry with exotic species has encountered strong public resistance in a number of locations.

Successful introductions of exotics. There have been many successful introductions of exotic species world-wide (table 3). Native U.S. species have been introduced into other countries, especially Monterey pine, a minor species in coastal California that has become the backbone of the forest products industry in New Zealand, a country with few conifers of economic importance. Monterey pine has also done well in Australia, Chile, and South Africa. Douglas-fir and Sitka spruce, both native to the Pacific Northwest, have been widely planted in Great Britain and northern Europe. Several of the southern pines have been widely planted in Australia, South America, and South Africa.

Land races. When the decision has been made to use a given exotic species, the question arises as to the source of material to be used. Often it is more efficient to select within a land race of the species rather than the original population in its native environment. A land race has become adapted to

its new environment by virtue of its survival there for a number of years. For example, Monterey pine has been growing in New Zealand for over 100 years. During that period, this species has weathered many storms and fought off many pathogens. Thus, natural selection has altered the population by gradually eliminating individuals not well adapted to their new environment. Selection of individual trees within this land race will be more cost-effective therefore than returning to the native populations in California.

Geographic variation. Philip Wakeley of the USDA Forest Service established one of the first definitive studies of geographic variation in the United States in 1926 and 1927. Wakeley collected loblolly pine seed from Arkansas, Georgia, Texas, and locally (Louisiana), grew the seedlings and planted them on a site near Bogalusa, Louisiana (table 4). This study was the first solid evidence that the source of seeds was important in the growth and rust resistance of loblolly pine. The trees grown from seeds collected locally produced almost twice the volume of wood as the other sources after 22 years. In addition, this was the first evidence that loblolly pine from Livingston Parish, Louisiana, had special merit as a rust-resistant source.

Following this test at Bogalusa, the Southwide Pine Seed Source Study was designed by Wakeley as a cooperative project involving 17 different agencies, with field plots established from Texas to the Atlantic coast. This study demonstrated that loblolly pines grown from sources west of the Mississippi River usually had better planting survival and greater rust resistance than those from eastern sources. On the other hand, seedlings grown from sources along the southern Atlantic coast had faster growth rates than those from western sources (Wells 1969; Wells and Wakeley 1966; Wells 1983).

The results of this study have led to widespread planting of Livingston Parish loblolly seedlings throughout the southeastern coastal plain, leading to major reductions in fusiform rust infection (Wells 1985). Likewise, forest industry has planted seeds from Atlantic coast sources of loblolly in Arkansas and Oklahoma with impressive gains in volume growth on the better sites (Lambeth and others 1984) (figure 3).

On the Pacific coast, the Eddy Tree Breeding Station was established in California in 1925. This later became the Western Institute of Forest Genetics and played a major role in the development of forest genetics in the West.

The 2 varieties of Douglas-fir (coastal and interior) (figure 4). have been studied extensively (Kung and Wright 1972). The coastal variety has been widely planted in Great Britain and northern Europe. Other western species with pronounced racial differentiation are ponderosa pine, and grand (*Abies grandis* (Dougl. ex D. Don) Lindl.) and white firs (*A. concolor* (Gord. & Glend.) Lindl. ex Hildebr.). In the Northern United States, white spruce (*Picea glauca* (Moench.) Voss) occupies an extensive east–west range with considerable racial variation (Nienstaedt 1968).

Utilizing the Raw Material

Seed production areas. Time is a critical factor in determining the route to follow in a tree improvement program. A useful expedient is the seed production area (seed stand). This is a high-quality stand that can be thinned to remove the lower quality individuals and then managed for seed production (Cole 1963; Rudolf 1959). Although the gain from these stands is not high, (Easley 1963), the time saved can be more important than the degree of improvement. These stands can be managed by prescribed burning, fertilized, and sprayed for insect control. Seeds can be collected by climbing, shaking, tarping, or felling trees. An efficient seed collection system can be designed where the felling of trees is planned to coincide with good seedcrops.

Although natural stands are preferred sources for seed production areas (figure 5), plantations are often used where the seed source can be verified. In these cases, the plantation is treated like a land race, and good performance over a

* Located in Bogalusa, Louisiana.

given time is evidence that this plantation has adaptive value on this site.

Clonal seed orchards. The most common tree improvement system is the clonal seed orchard (figure 6). These have been established for many outcrossing species worldwide. The procedures used involve selection of individual trees, progeny testing to determine their breeding value, and replication of the ortets (selections) in an orchard environment. In actual practice, the orchard is usually established by grafting and the progeny testing is done by controlled pollinations within the orchard or in clonal banks.

Seed production usually begins before progeny testing is completed, resulting in the production of improved seeds that cannot be certified as genetically superior (seed certification is covered in chapter 6) until progeny testing is completed and the orchard can be rogued (that is, trees with low breeding value are removed).

Selecting Plus Trees

Selection of plus trees from wild stands that are pure (single species) and relatively even-aged usually involves grading candidate trees in comparison with the best adjacent crop trees (of similar age) in the stand. Characteristics compared with southern pine (for timber) are straightness, height, DBH, volume, form class, crown size, branch diameter, branch angle, natural pruning and wood quality. Any evidence of insect or disease susceptibility usually calls for rejection of the candidate. Acceptance of the candidate tree depends on the numerical rating of the tree, its wood quality, age class, geographic location, and any special attributes.

Figure 6—Chapter 2, Genetic Improvement of Forest Trees: loblolly pine clonal seed orchard in Arkansas.

Selecting Orchard Sites

All seed orchards require good access, level topography, and well-drained soils. Because vehicular traffic is essential in the management and harvesting of orchards, a coarse-textured soil is mandatory. Subsoiling is practiced in many seed orchards to fracture any hardpans formed from compaction by vehicles. Even in sandy soils, compaction can seriously reduce root growth of the trees. Establishment of a year-round ground cover is important to stabilize the soil and prevent or reduce erosion (Jett 1986).

Establishment

Most clonal orchards are established by grafting, although at least one slash pine orchard has been planted with cuttings (Bengston 1969). Rootstock planted in the field can be grafted in-place (field-grafting) or potted stock grown in a greenhouse, lath-house, or nursery bed can be grafted. Grafting on potted stock is more cost-effective, but field-grafting is preferred by some orchard managers because of the often shorter time to reach commercial cone production.

Graft incompatibility occurs in many species, including most conifers. This is a problem in roughly 22% of southern pine clones (Lantz 1973) and it is particularly serious in Douglas-fir, where up to 67% of the clones may be affected (Wheat 1967). There is some evidence that clonal root stocks from related material may reduce incompatibility rates (Bower and McKinley 1987) but the data are not conclusive. Copes (1967) has developed a tissue sampling technique that can be used to predict incompatibility in Douglas-fir.

Management

Most seed orchards are fertilized to promote flowering and some are irrigated to reduce the impact of moisture stress. Insect control is essential for maximum seed production. In the absence of cone and seed insect control, Belcher and DeBarr (1975) have estimated that 11% of the loblolly cones were attacked by cone worms (*Dioryctria* spp.). In their report on 26 seed orchards surveyed over 3 years, an average of 9.9% of the collected seeds were damaged by insects. There was a large amount of clonal variation, as the range of cone worm attack was from 0 to 67%, depending on clonal susceptibility.

More recently, Jett and Hatcher (1987) reported that cone worms can cause losses exceeding 90% of loblolly cones when pesticides are not used.

Pollen Contamination

Most seed orchards are located with some consideration for pollen contamination. Unfortunately economics often

dictates locations that cause a major problem with pollen contamination. Early seed orchard establishment in the South carried a recommendation of at least 122-m (400-ft) isolation zones surrounding the orchard (Squillace 1967). Later studies indicated that vegetation formed a more effective barrier than either soil or sod.

Pollen contamination in seed orchards was estimated by Adams and Birkes (1989) using isozyme analysis. In seed orchards of Douglas-fir, loblolly pine, and Scots pine (*Pinus sylvestris* L.), they estimated that as much as 50% of the pollination within the orchards was due to outside pollen. The amount of self-fertilization within the orchards was estimated as less than 10%, with considerable variation by clone.

An additional study by Smith and Adams (1983) also indicated that pollen contamination was in the 40 to 52% range for 2 Douglas-fir seed orchards in Oregon. Suggestions for reducing contamination included more complete geographic isolation, water spraying to retard flower development, and supplemental mass pollination.

Supplemental Mass Pollination

Supplemental mass pollination (SMP) has been used effectively in southern pines, Douglas-fir, and Scots pine (Bridgwater and others 1993). The authors have summarized their recommendations for success with SMP:

1. The goals of SMP must be clear.
2. Orchard phenology must be monitored in order to apply SMP prior to maximum pollen flight in the orchard.
3. Fresh pollen or high viability stored pollen must be used.
4. The pollen application system must be effective.
5. The success of the SMP can be monitored with isozymes or other procedures.

Harvesting

Cones, seeds, and fruits may be harvested by climbing or with bucket trucks, aerial lifts (figure 7), tree shakers, or seed collection nets. Seed collection nets as developed by the Georgia Forestry Commission are effective when bulk collections are harvested from the orchard (figure 8). When individual tree (or clonal) collections are needed, the other systems must be used. The USDA Forest Service Missoula Technology Development Center refined the net retrieval system concept (McConnell and Edwards 1984), which has been widely copied and modified. This system is an effective method of harvesting southern pine seeds on nets when orchard mix collections can be used.

Figure 7—Chapter 2, Genetic Improvement of Forest Trees: cone collection with JLG lift in South Carolina.

Genetic Gains

Realized genetic gains in volume growth from first generation southern pine clonal seed orchards have ranged from 6% with un-rogued loblolly and slash pine orchards to 17% for rogued orchards of these species (Squillace 1989). The gains from advanced generation loblolly orchards have been predicted at 25% greater volume than unimproved material for the second generation, 35% for the third generation, and 45% for the fourth generation (Zobel and Talbert 1984).

Advanced-Generation Breeding

Advanced-generation breeding often is designed to combine the best individuals from the best families in the first generation with unrelated individuals from a separate breeding population. The Western Gulf Forest Tree Improvement Program has developed a sub-line system separating the breeding population into breeding groups that are crossed to produce seeds only when a production orchard is established (Lowe and van Buijtenen 1986). With this system, inbreeding is restricted to the breeding populations and the production populations are not affected.

A similar system has been used with northern red oak—*Quercus rubra* L.—in Indiana. Coggeshall and Beineke (1986) have designed 6 sub-lines with 30 clones in each for a total of 180 clones. These sub-lines will be crossed only when the production seed orchard is established.

Figure 8—Chapter 2, Genetic Improvement of Forest Trees: seed collection nets deployed on floor of Georgia Forestry Commission seed orchard.

Figure 9—Chapter 2, Genetic Improvement of Forest Trees: accelerratedd breeding orchard in North Carolina.

Seedling Seed Orchards

When working with precocious species, considerable time can be saved by collecting open-pollinated seed from select trees, growing the half-sib progeny in a nursery, and establishing a progeny test/seed orchard with the seedlings. A major problem with this system is designing a plantation that is effective for progeny testing and will also permit effective seed production after the poor performers are removed. Effective designs have been developed by Wright (1976) and Hodge and others (1995).

A recent report by Hodge and others (1995) indicated a gain of 10.7% in volume for a seedling seed orchard of longleaf pine (*Pinus palustris* Mill.) at 8 years. In this case the heritability of volume growth was calculated at 0.21 and there was a moderate genotype × environment interaction related to geographic regions.

Accelerated Breeding

Accelerated breeding techniques developed in recent years can substantially reduce the breeding cycle. One of the most direct methods is selection at younger ages. A pilot-scale accelerated breeding study was developed by van Buijtenen and others (1986). This study used a 3-phase procedure with half of the loblolly pine families eliminated in each test. The tests measured dry weight, root growth potential, and resistance to heat stress. The survivors of these tests were then subjected to flower-induction techniques.

Potted seed orchards growing in greenhouses can reduce the length of the breeding cycle by at least 20% (Zobel and Talbert 1984) (figure 9). In this case, a 20-year cycle can be reduced to 16 years by accelerating flowering in the greenhouse as compared to a conventional outdoor seed orchard. The trees can be maintained in 20- to 40-gallon tubs with a drip irrigation system. McKeand and Weir (1983) calculated that a reduction of 6 years in the breeding cycle with a 30,000 seedlings per year regeneration program would amount to a savings of $2 million. A similar system has been reported for western hemlock (Bower and others 1986). In this case, potted ramets produced about 10 times the amount of seeds as field-grown trees.

With a potted orchard, several techniques can be utilized to increase both male and female flowers. Water stress and applications of gibberelic acid ($GA_{4/7}$) will promote early female flowers (Todhunter 1988), whereas out-of-phase dormancy (Greenwood 1981) will speed up the development of male flowers. Wire girdling is also an effective way to promote male flowering.

Top-working grafted loblolly ramets has also accelerated flower production (Bramlett and Burris 1995). In this case, both male and female flowers were produced in the year following grafting.

Deployment of Genetically Improved Material

Seed Zones

Seed zones have been established for most of the major commercial forest species. These are areas that are environmentally similar and within which a given source can be expected to perform uniformly. When reforestation is needed within the zone, seeds should be collected from that zone. In some cases, when seeds are not available from that zone, seeds from an adjacent zone may be substituted.

In the Western United States, seed zones can be quite narrow, depending on the topography. For example, seed zones for Douglas-fir in Oregon are delineated on 152-m (500-ft) elevation intervals (Ching 1978). Restricted zones have also been recommended in the northern Rocky Mountains for western white—*Pinus monticola* Dougl. ex D. Don—and ponderosa pines (Rehfeldt and Hoff 1976).

In the South, seed zones for most species are much broader, reflecting the larger geographic provinces and more uniform topography (Lantz and Kraus 1987)(figure 10). The Western Gulf Forest Tree Improvement Program has defined specific seed deployment zones for areas west of the Mississippi River (Byram and others, 1988), and the North Carolina State University—Industry Cooperative Tree Improvement Program has adopted a more flexible approach for areas to the east (McKeand and others 1992)

Genotype x Environment Interactions

Progeny tests of the first and second generation select trees have highlighted some outstanding families in the southern pines. Some of these families perform well on dry sites, some on wet sites, and some do well across-the-board. The famous International Paper clone 7-56, for example, seems to be a top performer wherever it is planted.

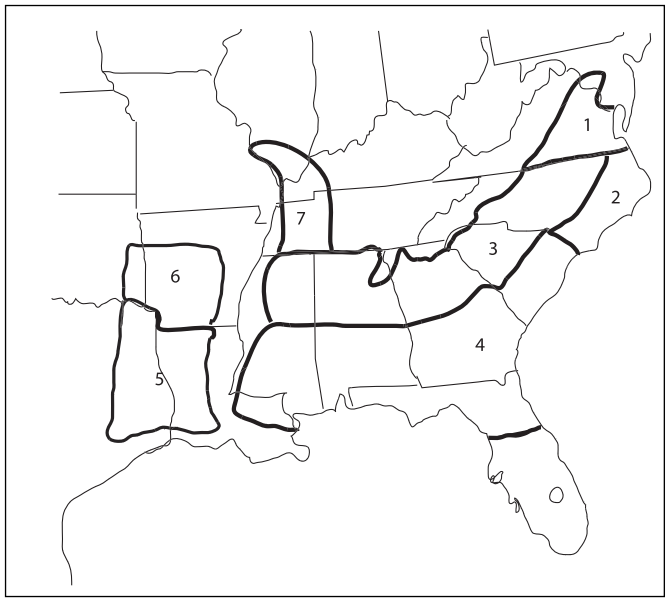
In general the genotype × environment interaction (change in relative rank among tested families) of most improved material has been unimportant. However, the University of Florida Cooperative Forest Genetics Research Program has reported a strong genotype x environment interaction for growth with some recent loblolly pine tests (Hodge and others 1995).

Single-Family Block Plantations

Many forest industries in the South routinely establish single-family block plantations and often record a growth advantage compared to mixed family blocks (Williams and others 1983). Using block plantings rather than progeny tests, Gladstone and others (1987) recorded 16% greater stand volumes for single-family plantings than for woods-run material. Mixed family blocks had only 11% greater volume than the checks.

Although single-family blocks may perform well on company land for short rotations, few non-industrial private forest landowners understand the risks involved. When a single family is planted on private land where long rotations are used and where natural regeneration may be employed, genetic diversity can be reduced to a low level. In only 1 or 2 cycles of natural regeneration, inbreeding could seriously reduce growth and productivity.

Figure 10—Chapter 2, Genetic Improvement of Forest Trees: seed zones for loplolly pine.



Molecular Biology

Isozymes

Brewbaker (1967) was one of the first scientists to propose the study and use of isozymes in forestry. Since then, isozymes have been widely used for taxonomic work, pollen contamination estimates, heterozygosity estimates, and a number of other uses. In isozyme analysis, a single gene codes for production of a single protein that can be visually distinguished as one band on an electrophoretic gel. The band pattern on a stained gel may be interpreted as a direct reflection of the genotype of the tree. Cotyledons, needles, or embryos (all diploid tissues) may be used or pollen grains and female gametophytes (haploid tissues) may be used.

Isozymes have been used to compare the rates of heterozygosity and outcrossing (El-Kassaby and others 1986) with Douglas-fir. These authors found no significant differences between clonal and seedling seed orchards in outcrossing rates. There were, however, significantly greater proportions of homozygous progeny from the seedling orchard.

Although isozyme analysis has been an effective tool for many forest genetics studies, Libby and others (1997), summarizing a southern meeting on genetic diversity, found that isozyme data have a number of limitations when used to estimate the genetic variation within a single species. However, isozyme analysis has been widely used to estimate the amount of pollen contamination in seed orchards (Adams and Birkes 1989).

The USDA Forest Service has established a National Forest Genetics Electrophoresis Laboratory in Camino, California, where genetic variation studies, taxonomic determinations, "DNA fingerprinting," and the effect of silvicultural and management procedures can be evaluated. This laboratory served an important role after Hurricane Hugo demolished the longleaf pine seed orchard on the Francis Marion National Forest in coastal South Carolina. Isozyme and DNA analyses were used to identify the surviving ramets in the orchard and facilitate reconstruction of the orchard.

Gene Mapping

New techniques such as RFLPs (restriction fragment length polymorphisms) (Nance and Nelson 1989) and RAPDs (random amplification of polymorphic DNA) (Sewell and Neale 1995) have paved the way for significant advances in gene mapping of QTLs (quantitative trait loci). Conkle (1981) produced linkage maps for several *Pinaceae* species and Sewell and Neale (1995) constructed a "consensus" map for loblolly pine. Another technique for mapping genes using PCR (polymerase chain reaction) markers has been developed for pines by Harry and Neale (1993). Other mapping work has been done with *Eucalyptus* spp. and *Populus* spp. These mapping techniques are resulting in a great deal of data on the genome of loblolly pine. This information will allow more efficient selection procedures (marker-assisted selection) to be employed in the future.

In addition to the work done on pollen contamination and heterozygosity using isozymes, RAPD markers have been used to assess genetic variation in aspen following the 1988 Yellowstone fires (Tuskan 1995).

Fingerprinting

Electrophoresis has been used for a number of years to "fingerprint" clonal material in seed orchards. Now PCR techniques have been used to identify Douglas-fir seedlots produced in a seed orchard in British Columbia and RAPD markers have been used to identify Norway spruce clones in Austria (Neale 1995).

Genetic Engineering

Genetic engineering has received a considerable amount of attention from the media, but few examples of forest tree applications are available. There has been a case of gene transfer in hybrid poplar that conferred resistance to glyphosate (herbicide). There is also interest in transfer of DNA with resistance to chestnut blight (Carraway and others 1993). In this case, somatic embryogenesis could be used to establish ovules and zygotic embryos on culture media. Transfer of this material would be accomplished by bombardment with plasmid DNA containing the resistant gene or genes.

Tree Improvement Cooperatives

Tree improvement cooperatives have been established in the major timber-growing regions of the United States and Canada, including California, the Pacific Northwest, the Inland Empire (also known as the intermountain region or the Great Basin), the Great Lakes region, and the South. Advantages of these cooperatives include a long-term breeding plan, often developed by forest geneticists at a land grant university, statistical support for progeny test design and analysis, laboratory facilities for wood-quality determinations and soil tests, and pollen and seed processing facilities. Technology transfer of new developments in the field of tree improvement and training is also an important function of these cooperatives.

Often select trees, pollen, seed, and grafting material are shared among members of the cooperative. Some cooperatives share orchards and even nursery sites. Duplication of effort is minimized and cooperative members gain significant economies of scale as they share breeding and testing workloads. Separate staffs are not needed by the individual organizations as the scientists and support personnel employed by the cooperatives are shared by all member organizations.

The South

Bruce Zobel started tree improvement cooperatives in the United States in 1951 at Texas A&M University. A few years later, Tom Perry began the University of Florida Cooperative Forest Genetics Research Program. Zobel later moved to the North Carolina State University and organized the NC State University Industry Cooperative Tree Improvement Program. J.P. van Buijtnen reorganized the Texas A&M Cooperative as the Western Gulf Forest Tree Improvement Coop in 1969. In the Spring 1988 Society of American Foresters Tree Genetics and Improvement Working Group newsletter, Tim White reported that in 1987 these 3 cooperatives involved 28 forest industries, 12 State forestry agencies, and 3 seed companies. Average annual seed production over all members at that time ranged from 60,000 to 90,000 kg (70 to 100 tons) of pine seed and the average annual hectares planted with seedlings was 728,000 (1.8 million acres). Recent divestitures of industrial forest land dramatically decreased cooperative membership. This may seriously and negatively impact future seed production.

The Pacific Northwest

Tree improvement activities began in the Pacific Northwest in the 1950's when the Industrial Forestry Association coordinated the establishment of clonal seed orchards for coastal Douglas-fir. In the 1960's, forest industry started hiring forest geneticists and individual programs were started by several companies. About this time, the USDA Forest Service started a tree improvement program for Douglas-fir; western hemlock (*Tsuga occidentalis* (Raf.) Sarg.); and ponderosa, western white, and sugar pines on national forest lands in Oregon and Washington (Daniels 1994). The Forest Service program was followed in the 1970's by the USDI Bureau of Land Management's tree improvement program for Douglas-fir in western Oregon.

From 1967 to 1985, Roy Silen at the USDA Forest Service's Pacific Northwest Forest and Range Experiment Station and Joe Wheat of the Industrial Forestry Association developed 20 cooperatives for Douglas-fir and 2 for western hemlock. These "progressive tree improvement programs" featured low-intensity selection of large numbers of roadside trees followed by open-pollinated progeny tests (in contrast to the high-intensity selection practiced in most of the southern pine programs). In 1986, the Industrial Forestry Association's Pacific Northwest Program was reorganized and named the Northwest Tree Improvement Cooperative of the Western Forestry and Conservation Association. This organization currently has 37 members, with a land base of 2.8 million hectares (6.9 million acres) and more than 80 breeding zones (Daniels 1994).

The overall Pacific Northwest region had a total of 282 seed orchards with a total of 1,389 ha (3,473 ac) in western Washington, western Oregon, and northern California in 1994 (Daniels 1994). Federal agencies manage 64% of this area; industry, 30%; and States and other cooperative groups, 6%.

The Inland Empire

The Inland Empire Tree Improvement Cooperative membership has 20 separate organizations, including forest industry, State forestry agencies, tribal councils, Federal agencies, universities, and other private organizations. Lauren Fins established the cooperative in 1978 at the University of Idaho to serve Idaho, western Montana, and eastern Washington. The cooperative has established 16.8 ha (42 ac) of western white pine and ponderosa pine orchards which have produced an average of 322 kg (710 lb) of seed annually. In addition to these cooperative orchards, many member organizations have established their own orchards.

California

The California Tree Improvement Association, organized in 1978 with 26 members, manages over 9 million acres of forestland. Ponderosa pine was the first species selected, followed by Douglas-fir and sugar pine. Members include forest industry, the State of California, and the USDA Forest Service. Local tree improvement associations were formed to focus on one or more of the California tree seed zones. The main objectives of the association are the selection of superior trees, the establishment of clone banks, the establishment of progeny test sites, and the establishment of a ponderosa pine seed orchard.

The Great Lakes Region

The Minnesota Tree Improvement Cooperative was established in 1980 and currently has 18 full members and 7 supporting members. The cooperative is working with black (*Picea mariana* (Mill.) B.S.P) and white spruces, and jack, red, and white pines. There are 35 seed orchards occupying about 50 ha (125 ac). In 1995, about 30 hl (84 bu) of cones were collected from 3 of these orchards. Six orchards were approved for production of certified seed in 1995. Gains in height growth have ranged from 3 to 9%.

The Future

The demand for wood products will continue to increase worldwide. Computer and printing paper will be in great demand, particularly in Southeast Asia where population growth is expanding exponentially (Kellison 1997).

In the United States, timber harvesting on the forest land base is being progressively restricted, which dictates that wood production be concentrated on less land area each year. This requires management for maximum wood growth on our most productive sites. Fortunately this will result in reduced pressure on average and marginal sites which often have high value for recreation and aesthetic pursuits.

Tree improvement programs, combined with intensive management, have dramatically increased wood yields. In the Southeastern United States, genetically improved loblolly pine on good sites, under maximum cultural care, can be expected to yield 10.8 to 14.4 m^3 (3 to 4 cords) per 0.4 ha (1 ac) per year. On the Pacific Coast, vegetatively propagated hybrid cottonwood grown under maximum culture on 6- to 7-year rotations is producing 25.2 m^3 (7 cords) per 0.4 ha (1 ac) per year (Kellison 1997). In South America, southeast Asia, and South Africa, plantations of acacia, eucalyptus, and Gmelina from genetically improved sources are expected to yield about 25.2 m^3 (7 cords) per 0.4 ha (1 ac) per year. Many of these plantations can be managed with coppice rotations to further increase their economic value.

Tree breeding techniques must be fine-tuned in order to provide these increased yields of wood. Vegetative propagation procedures can be improved to provide more propagules at lower cost. Accelerated breeding will shorten generation intervals. Marker-assisted selection using molecular biology technology will result in both more efficient selection and shorter breeding cycles.

Continued research is needed to identify those parameters that predict the performance of specific genotypes on specific sites and work is needed to quantify genotype × environment interactions over a wide range of sites.

Public education will assume even greater importance in the future as competition for land increases. Engagement with many diverse groups will be required for making progress based on sound scientific principles. Many different approaches and mixes of objectives are possible and the consequences, both positive and negative, will have to be weighed in the balance of public opinion. Topics such as the long-term effects of using biotechnology in the forest, planting selected families on large land areas, and preservation of non-commercial species must be openly discussed.

Chapter 3

Seed Harvesting and Conditioning

Robert P. Karrfalt

Mr. Karrfalt is director of the USDA Forest Service's National Seed Laboratory, Dry Branch, Georgia.

Contents

3

Introduction

Most forest trees and shrubs grown for artificial regeneration purposes, and some grown horticulturally, are reproduced from seeds. Seed quality is, therefore, of critical importance in determining the many options and outcomes in producing a crop of seedlings. Only high-quality seeds that can be planted by machinery permit bareroot seedlings to be grown at the uniform and controlled bed densities needed to produce the desired seedlings at the most economical cost. Uniform and controlled bed densities facilitate more efficient and mechanized methods of weed control, root-pruning, and lifting of seedlings. Adverse consequences occur in both labor costs and the genetic makeup of the seedlings unless high-quality seeds are used and properly managed. Therefore, a poor job of seed handling at harvest and conditioning can have serious negative impacts on the quality and availability of seedlings. However, a good job at this point will have positive impacts on seedling status. It also makes sense economically to focus effort at this point in the process, because more efficiencies can then be realized at later stages.

This chapter begins with what to consider in planning a seed harvest, how to harvest, how to temporarily store seeds, and how to extract, clean, and upgrade the finished seeds. A discussion of quality control concludes the chapter.

Harvesting

Seed harvest is the first step in producing a high-quality seedlot. This statement assumes that genetic considerations have been properly addressed in planning the seed harvest (see chapter 2). Quantities of seeds to collect, initial seed quality, and the timing of collections are the key quality factors in seed harvest. Timing is important because maximum seed viability and vigor occur at physiological maturity (figure 1). Collecting too early results in lower seed quality due to seed immaturity and reduced yield. Collecting too late can also be detrimental, because seeds may be lost to seed shed, predation by animals or insects, or seed deterioration. However, some species mature after natural seedfall; these include various ash species (*Fraxinus* spp.) and ginkgo (*Ginkgo biloba* L.). The initial seed quality must be assessed to avoid collecting seeds that are empty, malformed, or damaged. Quantity of seeds to collect influences quality because the seeds must be processed before deterioration becomes measurable.

Planning and preparation

Quantities to collect. The quantity of seeds to collect can be computed from nursery records and seed-plant production records of past harvests (table 1). If this information is not available, then general averages can be taken from the tables in the generic chapters of this handbook. Determining the number of cones or fruits needed to give this desired amount of seed can be predicted by cutting open a sample of cones or fruits. Because of variation from crop to crop, location to location, and even tree to tree, it is wise to always cut a few fruits to be sure of the quality and not waste collection effort on poor crops. Figure 2 shows a cutting method for assessing the number of filled seeds in a conifer cone; table 2 lists a good average seed count for 4 western conifers. When the desirable number of seeds per cone is found on the cut face, then collections are made. Usually a minimum number of good seeds must be found when cutting before the crop is accepted. This minimum number will vary with the need for the seeds, the cost of collection, and the quality of alternative collection sites. Douglas (1969) suggests that 50% of the seeds exposed on the cut face of true fir (*Abies* spp.) cones should be full, and Schubert and Adams (1971) set this percentage of good seeds at 75% for pines (*Pinus* spp.).

How the number of seeds on the cut face of a cone corresponds to the total number of seeds in the cone is shown in table 3. Such a table is constructed by making longitudinal cuts on the cones, counting the number of seeds on the cut face, and then opening the cone by drying or dissection to determine the total number of good seeds in the cone. For example, the authors of the data in table 3 found in their samples that when 8 good seeds appeared on the cut face of longleaf pine (*Pinus palustris* P. Mill.) cones, there would be, on the average, 59 seeds per cone. In figure 3, cutting ash seeds to determine the percentage of filled seeds is an example of a way to examine the quality of a hardwood fruit. Such cutting procedures provide an estimate of the amount of good seed that can be expected from a given quantity of fruits or cones.

Positive species identification. Another vital step is making a positive identification of the species. Sometimes this is relatively easy. For example, there may be no close relatives to the species in the area. Douglas-fir—*Pseudotsuga menziesii* (Mirbel) Franco—is the only species in its genus in the coastal western United States and has a unique cone. It thus presents little problem in species identification. Oaks (*Quercus* spp.), on the other hand, overlap in their range in many parts of the country and often hybridize, making positive identification more challenging. An addi-

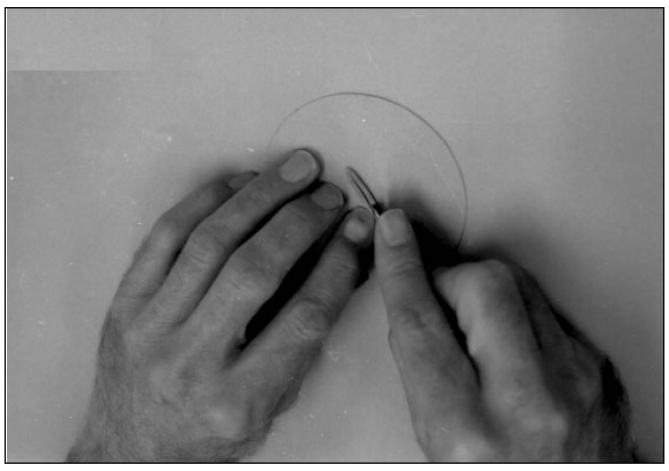
Question	Value	Calculated quantity of seeds needed	Example
How many plants are to be produced?	200,000	—	—
How many years of production is this?	3	200,000 x 3	600,000
What is the ratio of seedlings to viable seeds?	80%	600,000 ÷ 0.8	750,000
What is the viability of the seeds?	80%	750,000 ÷ 0.8	937,500
How many seeds are there per unit weight*?	99,000	937,500 ÷ 99,000	9.5 kg
What is the purity?	95%	9.5 ÷ 0.95	10 kg
What volume of the "raw collection unit" (that is, seeds, fruits, or cones) must be collected to obtain the desired weight* of pure seeds?	0.8 kg/hl	10 kg x 0.8 kg/hl	12.5 hl
Is there sufficient capacity for post-harvest storage & timely conditioning for the desired volume of seeds?			

* Weight in kilograms (kg) or pounds (lb).

tional challenge is presented when the scientific names are debated by taxonomists. Genera such as locust (*Robinia* L.) and blueberry (*Vaccinium* L.) have gone through extensive reclassifications. Therefore, careful attention to nomenclature and good record keeping are very important in maintaining control over regeneration work. This is especially true when many diverse species are involved. The finished seeds of many related species are impossible to identify and separate. Without good collection records, the true identity of a seedlot can easily be lost. Collecting and preserving leaf, bud, and twig samples along with a seedlot can serve as an excellent check on species identity. Collecting these vegetative parts is important for seed collectors who lack knowledge of botany. Later, knowledgeable persons can verify the identity of a seedlot from the vegetative parts.

Careful seed-source identification is also vital. Not properly documenting the source of a seedlot can be as disastrous as misidentifying the species, perhaps even more so,

Figure 3—Chapter 3, seed Harvesting and Conditioning: cutting ash samaras open will tell if the fruits are filled and if the embryos are mature.



because the mistake might not be known until an outplanted crop fails because of poor adaptation. Seed certification procedures are a good way to track seed-source identity.

Seed structures. Accurate and complete knowledge of seed and fruit structures is essential for making accurate estimates of initial seed quality. When beginning work with an unfamiliar species, workers should dissect some fruits and seeds in order to become familiar with the normal seed structures. The condition of the embryo cannot be evaluated if its location and shape are not known. Workers also need to recognize the outside appearance of seeds. Seeds, especially small ones, can be confused with trash or other floral parts if their true shape is not known. Chapter 1 provides a general discussion of flowering and seed formation. Detailed descriptions and drawings showing the seed structure and maturity indices are presented for each genus in part 2 of this manual.

Seed maturity. Fruits and cones should be collected only when seeds are sufficiently mature. Properly timing the collection of seed depends on correctly estimating seed maturity, which is often difficult because it is influenced by weather, genotype, site quality, site aspect, and location on the plant. Seasonal events and location cause wide variability in timing and length of the collection period. For example, if snow is deep and melts late at a high-elevation site, trees may flower so late that seedcrops do not even mature. Conversely, an early spring and dry summer can cause seeds to ripen and disperse very early. When drying winds occur in the autumn, most seeds of several western conifers and eastern white pine (*Pinus strobus* L.) will disperse in a few days. Conversely, rainy conditions may result in cones retaining most of their seeds for weeks or months. A high wind or a rainstorm may rapidly disperse an entire crop of mature seeds of some shrubs. Cones generally ripen first at lower elevations and south and west slopes, later at higher elevations and north and east slopes (Schubert and Adams 1971). Maturity may be reached several weeks earlier on hilltops than in nearby bottoms (Cobb 1959). The write-ups for the individual genera in part 2 should be consulted for maturity indices. Judging maturity, however, requires experience; in lieu of experience, careful observation and experimentation are essential to properly apply maturity indices or to develop them. Fortunately, for many species, there is a week or more between seed maturity and seed shed or fruit

Table 2—Chapter 3, Seed Harvesting and Conditioning: minimum average number of good seeds on cut face of cones needed to justify collection of cones of some western conifers

Species	Seed count
Pseudotsuga menziesii (Mirb.) Franco	6
Tsuga heterophylla (Raf.) Sarg.	8
Pinus ponderosa P.&C. Lawson	10
Picea sitchensis (Bong.) Carr.	14

Table 3—Chapter 3, Seed Harvesting and Conditioning: sound seed yield per cone for 4 pine species as estimated from the number of sound seeds exposed when cones are bisected longitudinally

Sound seeds exposed	*Pinus palustris* (Louisiana)	*Pinus taeda* (Louisiana)	*Pinus elliottii* (Louisiana)	*Pinus elliottii* (Georgia-Florida)	*Pinus echinata* (Virginia)
2	23	31	20	31	12
4	35	44	35	50	22
6	47	57	50	69	31
8	59	70	65	87	41

Sources: Derr and Mann (1971).

drop. This delay provides some margin for error in estimating maturity. Prompt action is, however, necessary once maturity has been reached.

Immature fruits may be collected by mistake from species having fruits that require 2 or 3 years for development. Alaska-cedar (*Chamaecyparis nootkatensi*s (D. Don) Spach) and western juniper (*Juniperus occidentali*s Hook.) are examples of species that bear immature seed structures that are nearly equal to mature ones in color and size. Collecting intermingled mature and immature fruits should be avoided, because these fruits are difficult to separate (Stoeckeler and Slabaugh 1965). At the other extreme is the possibility of collecting empty conifer cones. Cones that have recently shed their seeds will close during rainy weather (Allen and Owens 1972), and workers must be careful not to collect these closed empty cones by mistake.

Maturity for collection is most often judged subjectively from the appearance of the cones, fruits, or seeds. Green color changes to yellow-green, yellow, brown, reddish, or purple. Fruits begin to soften. Scales or bracts begin to crack or flex. A few early-maturing individuals begin to drop their seeds. Such subjective indicators have a variety of shortcomings (Schubert and Adams 1971). The color changes may not be the same with every individual or population of plants. Weather can accelerate or modify the appearance of the indicator. On the whole, however, these indicators have proven to be reasonably practical. Their chief drawback is their dependence on the experience and judgment of collectors. When in doubt, it is generally better to shorten the collection period than to collect immature seeds that will have low viability and the tendency to produce low-vigor, deformed seedlings (Heit 1961, Schubert 1956).

Some attempts have been made to develop more-objective maturity indices. Chemical constituents have been analyzed and related to maturity for Douglas-fir and noble fir (*Abies procera* Rehd.) (Rediske 1968). This type of approach has not been widely used, mostly because of the difficulty of getting samples to a laboratory and then returning the information on a timely basis to the field.

Measuring specific gravity is used to evaluate the maturity of conifer cones. As a cone matures, it loses water and its specific gravity decreases. The flotation procedure to measure specific gravity can be done in the field by collectors. Cones placed in a liquid with the appropriate specific gravity will sink if immature and float if mature. The specific gravity values for ripe pine and fir cones are listed in tables in part 2 of this manual. Although simple in application, this version of the flotation procedure requires finding a fluid with the correct specific gravity and carrying supplies of it into the woods. Many of these fluids are potentially polluting substances such as ethanol, kerosene, motor oil, or linseed oil and they and the tested cones, which have become contaminated, must be carried out of the woods. Thus, this version of the flotation method is rarely used today.

Instead, specific gravity values of cones can be calculated from values obtained by using water in a graduated metric cylinder with increments marked at 1-ml intervals. The cylinder should be the smallest size that the cone will fit into and made of lightweight plastic. Water obtained in the field can be used, thus minimizing the amount of material to transport.

Specific gravity estimates must be made immediately after the cone is removed from the tree. A few minutes delay, even in a moisture-proof container, will allow the cone to dry slightly, causing the specific gravity to be estimate below (lower s.g.) than it actually was on the tree.

Early collection, that is, before natural maturity date, is possible with the following species:

- sweetgum *(Liquidamber styraciflua L.)* (Bonner 1970a; Wilcox 1966)
- loblolly pine (*Pinus taeda L.*) (Cobb and others 1984; Waldrip 1970)
- Douglas-fir (*Pseudotsuga* menziesii (Mirbel) Franco) (Silen 1958)
- eastern white pine (*Pinus strobus* L.) (Bonner 1986)
- grand fir (*Abies grandis* Dougl. ex D. Don Lindl.) (Pfister 1966)
- white spruce (*Picea glauca* (Moench) Vozz) (Winston and Haddon 1981)
- red pine (*Pinus resinosa* Ait) (Winston and Haddon 1981)
- blue spruce (*Picea pungens* Engelm.) (Fechner 1974)

For these species, the cone or fruit is dried in a strictly controlled manner to allow for proper maturation of seeds, fruits, or cones. Those who wish to attempt to collect cones or fruits early and after-ripen them should consult the literature and do some test runs of the procedure. For further references on after-ripening and other seed maturation topics, check the review by Edwards (1980) on maturity and quality of tree seeds.

FLOTATION PROCEDURE

The flotation procedure to measure specific gravity begins with partially filling an appropriately sized graduated cylinder with water, leaving enough room so that the entire cone can be submerged in the water without raising the water level above the graduations. The volume of water placed in the cylinder should be recorded, and the cone then placed in the water. If it sinks, the specific gravity is greater than 1, and the cone is immature.

If it floats, the new water level should also be recorded. The increase in water level is caused by the cone pushing the water up. Because the specific gravity of water is 1 (1 ml of water weighs 1 g), the volume of water displaced (usually measured in milliliters) is approximately equal to the weight of the cone (usually measured in milligrams). Therefore, subtracting the original volume of water from the second volume of water gives the weight of the cone.

Next, the cone should be pushed down until the water just fully covers it. A worker's finger or stick can help push the cone down, but only the cone should be pushed below the water. Only the cone should be measured, not the finger or the stick! This last measurement is the weight of the volume of water displaced by the cone. Dividing the weight of the cone by the weight of the displaced water yields the specific gravity of the cone.

A large cylinder is needed for larger cones. As the graduations of larger cylinders will represent 10 or 20 ml each, water levels will often fall between marks. Estimating the exact water displacement is then required, resulting in greater error in the readings. To control this error, a 2-cylinder system can be used. One cylinder, large enough to hold the cone and water, is equipped with a side spout that can direct any displaced water into a smaller cylinder (figure 4). The second cylinder should be a 100-ml graduated cylinder, which eliminates any need to estimate the exact displacement. To operate this system, the larger cylinder is filled with water until water freely spills out the spout into the smaller cylinder. The water is allowed to drain to its natural level. The small cylinder is then emptied and returned to the spout. The cone is placed into the water, and the overflow collected in the smaller container. Once the dripping stops, which may take a while, the weight of the cone is read directly from the water level in the smaller cylinder. For example, the displaced water volume might be 40 ml. Next, the cone is pushed completely below the water surface. This is best done with a wire, perhaps with a small cradle bent into the end to hold the cone and keep it from rolling. The wire should be kept in the larger container during initial water fill to avoid any bias from its volume. The final amount of displaced water is read after dripping stops. Continuing the example, assume this water volume is 41 ml. This final displacement equals the total volume of the cone. The first displacement divided by the second displacement is equal to the specific gravity. Finishing the example, we divide 40 by 41, which results in a specific gravity of 0.976.

Figure 4—Chapter 3, Seed Harvesting and Conditioning: two-cylinder system for measuring specific gravity of pine cones.

Seed Acquisition

Seed harvesting can begin once a seedcrop of appropriate genetic make-up, adequate quality, adequate quantity, and proper maturity has been identified. However, seed quality must be monitored at the time of collection, for the situation may have changed since first determinations were made. Unexpected seed dispersal, insect-feeding, or other animal predation may have occurred. Certain seeds, such as acorns, can dry out or germinate shortly after they are shed (Bonner and Vozzo 1987; McDonald 1969; Olson 1957). Cones, fruits, and seeds should be cut open and examined again. Sometimes a 10 x hand lens is useful in making a quick evaluation. Prompt collection reduces losses to fungi, insects, and larger animals and birds. Some caution is advised in collecting the first fruits or seeds to be shed from the plant, which may be of poor quality and dropping because of death rather than maturation (Aldhous 1972; Stoeckler and Jones 1957).

Collection. The actual gathering of the seed or fruit from the plant takes many forms depending on the botanical characteristics of the mother plant. The first characteristic important to seed conditioning is the seed-bearing structure. In gymnosperms (for example, pines, spruces, firs, and ginkgo), this is the female strobilus or cone; in angiosperms (for example, all the hardwood trees), it is the fruit. If this structure is not easily removed from the plant or shed naturally, it is classified as persistent. Persistent cones and fruits require more effort to remove them from the plant. Either hard twisting and pulling, or a sharp cutting tool such as pruning shears is needed to sever the connection (figure 5). Alternatively, the seeds are allowed to shed naturally and caught on netting (figure 6). When not persistent, the cones or fruits can be quickly picked by hand or pulled off with rakes, hooks, or vacuum. Another method is to gather cones or fruits from the ground after shaking them from the plant or after natural drop (figures 7 and 8). Yard tools such as rakes, leaf blowers/vacuums, forks, and shovels can be useful in gathering seeds from the ground or off of low plants (figure 8).

In some loblolly, shortleaf (*Pinus echinata* P. Mill.), and eastern white pine seed orchards an extensive system of nets is used to collect seeds. Loblolly cones are very persistent, and much labor and equipment expense is saved by gathering seeds that shed naturally rather than using lift trucks or other devices to pick cones. Problems related to seed maturity are almost totally avoided by relying on natural shedding of the seeds. Avoiding such problems is the strongest attraction of the system in white pine orchards, because the window of time to collect is quite narrow for white pine. The system has several disadvantages, however. There must be enough dry weather during the collection period for natural seed shed to finish by the desired collection date. Predation from insects and larger animals can occasionally be too great, and weed seeds can enter the seedlot from ground plants and vines in the orchard and from droppings of birds that roost in the orchard. Also, family identities are lost in the bulk collection of seeds. This system can be used only for seeds with at least moderate levels of dormancy; non-dormant seeds germinate on the netting, resulting in great loss of quality and quantity.

The netting is carpet backing with UV light inhibitors. It is used in widths equal to the distance between rows of trees in the orchard. The individual strips are then drawn together at the edges and fastened with standard wire staples commonly used for paper (figure 9). If the ground is soft, tree shakers are used to shake the seeds from the open cones of loblolly pine, which has a hard seedcoat. As the trees are shaken twice, the shaker actually drives over some seeds that fell on the netting during the first shake. For this reason, shakers cannot be used for eastern white pine, for their seedcoats are too fragile and can be mechanically damaged when the seeds are driven over. Totally natural seed shed must be used in this case. Alternatively, overflights with helicopters can be used, although these are usually too expensive.

Figure 5—Chapter 3, Seed Harvesting and Conditioning: persistent cones or fruit can be cut from the branch with pruning shears.

Figure 6—Chapter 3, Seed Harvesting and Conditioning: seeds from persistent cones or fruits can be caught on netting after natural seed shed as an alternative to cutting the fruit from the branch.

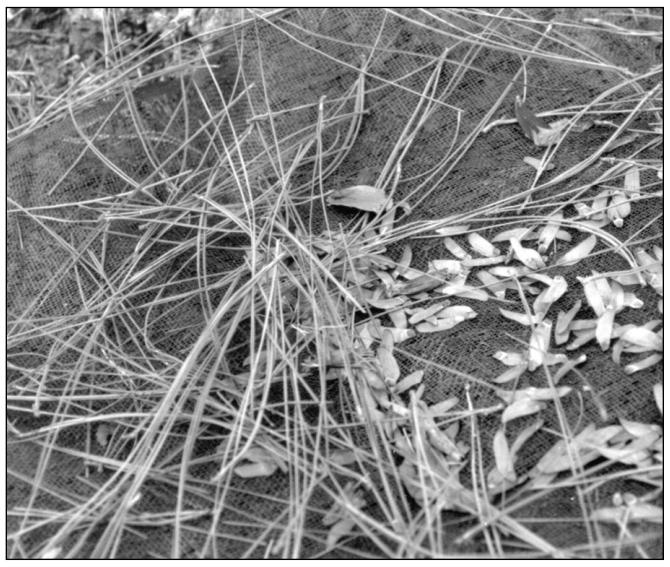

Figure 7—Chapter 3, Seed Harvesting and Conditioning: non-persistent fruits and cones can be shaken from the plant using tree shakers.

Once the seeds are shed from the trees, the netting is rolled up. This is done by a net retrieval machine or simply by drawing the net over itself and piling the seeds in a windrow. The windrow is then combined with a peanut combine to separate the seeds from the bulk of the needles

Figure 8— Chapter 3, Seed Harvesting and Conditioning: fruits such as acorns can be gathered from the ground after natural drop.

(figure 10). Large quantities of needles are gathered with the seeds, because needle drop occurs at the same time as seeds are shed. The staples holding the netting together pull free easily when the netting is rolled up.

Location on the plant is another factor determining the method of collection. Cones or fruits near to the ground are generally easily accessible to pickers. Those high in the air require some other means of reaching them. Using cone rakes carried by helicopters (Baron 1986; Haddon 1981) and shooting branches out of trees with a high-powered rifle are methods that are generally safer, faster, and more economical than climbing. Helicopter or rifle harvesting is restricted to species were the cones are clustered on a branch or at the top of a relatively narrow crown such as with spruce or true firs. Shooting the top out of a tree will of course deform the tree; both the rifle and cone rake techniques reduce cone production for a year or 2 at least, because the branch tips that would bear the next crop are removed with the cones. Therefore, climbing is still sometimes the best choice for collecting from tall-growing species. On relatively level land that is accessible by trucks, or in seed orchards, bucket trucks are widely used to lift workers into the crown quickly and with a minimum of personal danger. Another method for obtaining seeds from tall trees is collect them from the tops of trees felled for harvest or fallen over from storm damage (Bonner 1970b). It is important, however, to make certain that the seeds are sufficiently mature when falling occurred. The cones or fruits may appear mature, but the

appearance could be due to the general drying of the whole treetop rather than a true maturation. Collection may be necessary promptly after felling to forestall cone opening from high temperatures or losses to birds or mammals. Collecting from felled trees does not always prove cost effective. In some instances fruits or cones shatter or become deeply covered by limbs, tops, and foliage.

Squirrel caches have in the past been used as major sources of cones. This method is now generally avoided because the squirrels cut the cones before they mature, and the cones become heavily infected with fungi in the cache. Both these factors frequently lower seed quality more than is usually considered acceptable.

Purchase. Purchasing cones or fruits from independent collectors is an alternative to collecting the material directly. Independent collectors can range from the general public to professionally trained consultants. The relationship between collector and buyer may be totally informal, with people walking in off the street on the day of purchase, or it may involve a formal written contract that describes specifics of the harvest. The explicit formal arrangement provides the greatest guarantee of correct genetic source, species identity, and seed quality. However, successful collections have been made by buying from the general public. Whatever system is used to acquire cones and fruit, the important point is that there must be reasonable assurance that the correct species, genetic source, and quality are acquired. If any doubt exists about these factors, it is absolutely essential to modify the procedures to provide reasonable assurance.

Cones or fruits, especially those purchases from the general public, who may not be as knowledgeable or committed to quality as might be desired, must be inspected thoroughly. Containers of fruits or seeds need to be emptied for inspection. A rough cleaning can be done at this point to remove leaves, sticks, stones and other tramp items to obtain a truer volume or weight. A grading table is useful for making this inspection and for quick repackaging. A table for cones and larger fruits can be made from wooden slats measuring 2.5 by 5 cm (1 by 2 in) placed 2.5 cm (1 in) or less apart (Lott and Stoleson 1967). Litter can fall through the slats and the fruits can roll down the table to be repackaged (figure 11). Larger pieces of trash can be hand picked. Cutting or x-raying fruits and seeds is also necessary at this time to verify proper development and maturity.

No matter how the seeds, cones, or fruits were collected, it is best to minimize the amount of trash that is brought in with them. Needles, leaves, grass and other debris that are collected with the fruits will fragment during drying and handling and generally increase the difficulty of cleaning the seed. Such debris should be separated during collection if feasible, or, when not feasible at collection, upon arrival at the seed plant. Tumblers and large flat screens have been successfully used to do this mechanically.

Figure 9—Chapter 3, Seed Harvesting and Conditioning: edges of seed collection netting are stapled together at center of rows of trees in a seed orchard.

Figure 10—Chapter 3, Seed Harvesting and Conditioning: a windrow of needles and seed in one method of gathering loblolly pine seed from netting.

Lot identity. Maintaining the identity of the seedlot is critical. All the work of collection can come to nothing if the identity of the seedlot is lost. Therefore, all containers need to be precisely and carefully labeled. A unique seedlot (identification) number needs to be written on tags placed both inside and outside of the containers. The outside tag is usually enough and is accessible for easy inspection. The inside tag is easy insurance in case the outside tag is removed. Identification numbers should be simple; a long complicated number increases the chance that error will occur as the number is transcribed. The species name or initials, the year, and an accession number should be sufficient. Additional information should be kept in a record book, rather than incorporated into a complicated code. One aid to maintaining seedlot integrity is the use of official seed certification. This system (see chapter 6) and Karrfalt 1996) is most useful if seedlots are being bought and sold among many parties. It is particularly useful when seed buyers do not have first-hand knowledge of the collections or the seed company.

Transportation. A variety of rigid and nonrigid containers are available to transport fruits. Cones are shipped in bulk, in sacks, or in wire-bound boxes. New containers or ones that can be thoroughly cleaned should be used to prevent physical or pathological contaminants from getting into the seed. Bags may be completely filled when cones are to be in them for only a short time; however, for any temporary storage, bags should be filled only half-way. One bushel of cones goes well in a 2-bushel sack. Space is thus left for expansion of scales as cones dry. Otherwise, scales may dry in the closed position or partially closed position, severely impairing seed extraction. This condition can sometimes be overcome by wetting or soaking the cones and redrying. However, allowing scales to dry in a closed position results, at best, in extra work and time delays that can be completely avoided by leaving more space in the bags. Bags made of material having a tighter weave than burlap may be needed for small dry fruits or seeds. Never use an unventilated bag, such as one made of plastic, for cones or fruits that need to dry. Unventilated bags lead to loss of seed quality, because of molding and heating. Wire-bound boxes make good transport containers. Their main advantage is that they can be handled mechanically. They also hold a relatively large amount of seeds but not so much that aeration is inadequate for maintaining seed quality. These boxes are widely used for southern pines.

Figure 11—Chapter 3, Seed Harvesting and Conditioning: a grading table for quick inspection and cleaning of cones or fruits (Lott and Stoleson 1967).

Seed Cleaning and Conditioning

Post-Harvest Storage

Post-harvest storage is the period between collection and the preparation of the seed for planting and long-term storage. (For a discussion of long-term storage, see chapter 4.) At this stage, seeds are grouped according to their ability to be dried and whether the fruit is fleshy or not fleshy. Seeds that cannot be dried are called recalcitrant. These include the seeds of oaks, chestnuts (*Castanea* spp.), buckeyes (*Aesculus* spp.), many tropical hardwoods, and some maples (*Acer* spp.). These seeds cannot be allowed to dry. Premature germination or deterioration can occur as a consequence of the high moisture. Therefore, these species require cool storage or, if the species is injured by chilling, immediate planting. Storage near freezing is often best with temperate species, as long as ice does not form, which would cause cell damage and death. If controlled near-freezing storage is not available, seeds may be hold in a cellar, air-conditioned room, or shaded spot. To maintain the high moisture content of recalcitrant species, it is helpful to seal them in moistureproof containers, usually plastic sacks, or to add moisture to compensate for drying losses (Bonner 1973; Bonner and Vozzo 1987; Tylkowski 1984).

Those seeds that can be dried are referred to as orthodox. Orthodox seeds are broken into 2 groups:

- fleshy fruits—for example, those of dogwoods (*Cornus* spp.), cherries (*Prunus* spp., and junipers (*Juniperus* spp.)
- non-fleshy fruits—for example, those of ash, elm (*Ulmus* spp. L.), and pine

Fleshy fruits must be prevented from drying until the pulp is removed, otherwise the pulp hardens and is then not easily or adequately removed. Pulp is generally removed to make handling easier and to control fungi or bacteria that can grow in the pulp. As with recalcitrant species, the fleshy-fruited orthodox seeds must be kept cool and ventilated to prevent the buildup of heat and subsequent deterioration. They may be treated basically the same as the recalcitrants; however, fleshy-fruited orthodox seeds might require more ventilation because of higher moisture content.

The dry-fruited (also referred to as non-fleshy) orthodox species should be allowed to dry to prevent deterioration. High moisture in these fruits usually leads to heating, molding, and subsequently, loss of viability. Spreading the seeds on screen racks is an economical way to dry these fruits. Minimal drying is necessary during post-harvest storage when the seeds are collected dry. Post-harvest storage conditions usually need to allow for the loss of moisture at a gradual rate and to protect the seeds from the weather. If the fruit expands upon drying (for example, a pine cone), sufficient space must be allowed for expansion. Otherwise the fruit will become case-hardened and the seed locked inside the fruit as discussed previously. Figure 12 shows wire-bottom racks for air-drying cones under shelter. Alternatively, moisture must be maintained at a high level to prevent the expansion of cones. Because high moisture can lead to seed deterioration, it is important to evaluate a system that keeps orthodox seeds moist to be sure there is no loss of seed quality. Cones in full sacks or in bulk must be re-bagged into half-full sacks or placed in ventilated storage. Drying racks with cones spread out about two cones deep are very good. Cones have also been successfully stored in temporary cribs of snow fencing 8 to 10 feet in diameter. Storing cones in this type of crib or in 35-liter (20-bushel) wire-bound boxes ventilates the cones but also keeps them from drying and loosing their seed. Both cribs and boxes are used out of doors. Cones should never be stored in a large pile as this will result in heating. Smaller piles will cause many surface cones to open and the seeds will be lost. Also, piling cones on the ground invariably leads to stones in the seedlot.

Fruiting structures (that is, cones) that are serotinous require additional consideration; such cones require a brief period of very high temperature to melt resin seals that prevent cones from opening. In nature, this happens after forest fires. In North America, lodgepole pine, jack pine, sand pine, and black spruce have serotinous seeds. Black spruce seeds require a high initial kiln temperature only. The pines generally need a hot water dip or a steam treatment. This operation must often be done immediately after harvest, because not all trees will produce serotinous cones or the same degree of serotinony. Therefore, some cones will begin to open without the heat treatment, exposing some of the seeds to lethal temperatures when the treatment is done. The heat treatment can be delayed if it is absolutely certain that all cones will remain closed. The treatment cannot be done on seedlots with some open cones without losing seeds. The treatment must be hot enough and long enough to release all cones, otherwise, the undesirable situation of some cones open and some completely closed will be created artificially. Generally, the treatment is for 30 seconds or less, with boiling water or live steam. As the seal is broken, the cones often crackle. When the crackling has stopped, the cones are adequately treated. If the operator lacks experience in this procedure or faces new conditions, it is best to run a small trial batch to be sure the procedure is properly timed. Germination of the seeds should be tested to evaluate the procedure. The discussion on quality control later in this chapter explains how to do this.

Figure 12—Chapter 3, Seed Harvesting and Conditioning: screen bottom trays under shelter for air-drying dry fruits.

Species vary considerably in tolerance to high moisture and the length of time that they can be at high moisture. This tolerance is related to the degree of dormancy to germination. Some species—such as cottonwoods and aspens *(Populus* spp. L.) and red maple (*Acer rubrum* L.)—are all orthodox but require rapid drying and processing to maintain highest viability. Species with dormancy to germination—such as white pine, white ash (*Fraxinus* americana L.), and tuliptree (*Liriodendron tulipifera* L.)—can be held for relatively longer periods without loss of viability. How long a species can remain in post-harvest storage is the critical factor in determining the work schedule. Those without dormancy must be dealt with first and dealt with rapidly enough to preserve their viability.

Seed Extraction

Extraction is the first step after post-harvest storage. In terms of extraction, fruits are classified as being single or in clusters, fleshy or non-fleshy, dehiscent or indehiscent. Seeds in clusters (for example, those of ash and maple) must be singularized so they will flow easily through cleaning and planting machines. Fleshy fruits—for example, those of cherry and dogwood—are usually de-pulped for ease of handling and to control pathological problems. Indehiscent or unopened fruits—for example, those of black locust (*Robinia pseudo-acacia* L.) and manzanita (*Arctostaphylos* spp.—can be hulled to remove the seed from the fruit. The dehiscent dry fruits—for example, those of sweetgum and spruce—can be tumbled or shaken to separate the seeds from the fruit following drying.

Fleshy fruits. De-pulping fleshy fruits, such as those of magnolia and chinaberry, is done using a macerator, grinder, or mill that is carefully adjusted to avoid seed damage. It does not matter if the fruits are in clusters or single– de-pulping also singularizes the seeds. Macerators are most often used to depulp fruits (figure 13). The most common design uses a flat spinning plate on the bottom of a roughly 26-liter (7-gallon) can. The plate has 4 bars arranged in a 90-degree cross on the bottom. These bars strike the fruits and burst them. The abrasion of fruit against fruit also breaks up the fruits. Water is run into the can while macerating to wash away the separated pulp. Some machines have an angled baffle just above the spinner plate to force the fruit against the plate, creating a squeezing motion. Another refinement involves lining the can with hardware cloth or striking the outside of the can with a punch to create bumps on the inside. A 3.8-liter (1-gallon) can is then bolted to the spinner plate with the retainer nut for the spinner plate. This can is also wrapped with hardware cloth (figure 14). The addition of these rough surfaces decreases maceration time by 50 to 75%. The flow of water into the can is also improved by installing a ball valve directly to the side of the can. Water is then added to the seed simply by attaching a water hose to the valve and turning the valve (figure 15). This feature saves time and prevents pulp from being splashed on the operator.

A food blender can be used as a small-scale version of a macerator. Cover the blades with rubber or plastic tubing to prevent the seeds from being cut. About 240 ml (1 cup) of fruit at a time can be cleaned with this small macerator. The pulp must be rinsed and floated away in a separate operation.

A grinder (figure 16) can also be used to de-pulp fleshy fruits such as those of dogwood, blackberry, and cranberry. This grinding step is followed by a separate washing operation to rinse the pulp away. The grinder must be adjusted carefully to avoid crushing or cracking the seeds.

The pulp is easiest to remove if softened first. The flesh is ideally ready when it can be smashed between thumb and fingers. A 3- to 10-day running water soak will usually soften the fruit to the desired condition. Changing the soak water daily is an acceptable alternative to having running water. Some fruits—such as crabapple (*Malus pumila* P. Mill.)—are very hard and require more severe treatment. Crushing under vehicle tires or a fruit crusher or freezing followed by a storage period for fruit deterioration are needed for these hard fruits. However, it is vital to avoid any

Figure 13—Chapter 3, Seed Harvesting and Conditioning: a common type of macerator for de-pulping fleshy fruited seeds.

Figure 14—Chapter 3, Seed Harvesting and Conditioning: maceration time is reduced by adding to the macerator a hardware cloth liner and a can wrapped with hardware cloth.

Figure 15—Chapter 3, Seed Harvesting and Conditioning: a water Chapter 3, valve installed on the side of the macerator improves ease of operation.

heating or fermentation during these steps to soften the fruit, for any buildup of high temperatures or alcohols from fermentation can be lethal to the seeds. However, regular exchange of soak water will easily prevent this problem.

Dry fruits. Non-fleshy, or dry, orthodox fruits or seed-bearing structures—for example, those of pine, larch, and sycamore—usually require drying as a first step for both dehiscent and indehiscent types. The most common way to achieve this is to heat ambient air to temperatures that result in the relative humidity dropping to about 30%. Some locations have air that is naturally dry and require little or no heat to achieve the necessary drying conditions. Other locations may have high ambient relative humidities, which must be measured to be certain an adequate drying temperature is used. In many locations the ambient conditions can fluctuate, and the drying temperature should be adjusted to meet the current conditions for best economy and efficiency of drying. Always using the same drying temperature could result in using a temperature higher than necessary, wasting fuel, or a temperature that might not dry the air enough.

Figure 16—Chapter 3, Seed Harvesting and Conditioning: a grinder can also be used to crush fleshy fruits for seed extraction.

Table 4 shows what the maximum ambient relative humidity can be for a given drier temperature and ambient air temperature combination, while maintaining relative humidities of 30% or less in the drier. The numbers in the body of the table are the maximum ambient relative humidities. For example, at 20 °C and 65% RH, a drier temperature of 30 °C is too low, because the maximum permissible ambient RH is shown as 58. In this case, it would be necessary to use a drier temperature of 35 °C , for which the maximum permissible ambient RH is 71%, as shown in the table. The maximum drier temperature that should be used is 43 °C. If this temperature must be exceeded to obtain dry air, first dry

the air by cooling with an air conditioner. When treating serotinous or semiserotinus cones (for example, lodgepole pine or black spruce), it might be necessary to use temperatures in excess of 43 °C.

A well-constructed pressurized drier is needed to effectively use the dry air produced by heating. A laboratory model of a pressurized drier is shown in figure 17. The fan on this drier forces air into the box or plenum and the screen that holds the seeds is laid on top of the box. The drier becomes pressurized once the screen is covered evenly with seeds, causing the air to be uniformly forced through the seeds. The box containing the seeds must fit on the plenum with an airtight seal to provide the pressurized condition. If the drier were not pressurized, the air would take the path of least resistance and go around the seeds, drying only the surface layer of seeds. Inner layers would dry much more slowly. Pressurizing ensures that the seeds inside the seed mass are drying as well as seeds on the surface and that all the air is used for drying rather than simply passing by.
Pressurizing the drier, therefore, gives more uniform, rapid, and efficient drying. Without pressurizing, the seeds, cones, or fruits need to be spread loosely so that air can easily pass over and among the material. Alternatively, the material can be stirred several times an hour, but this is not practical during the night or with large quantities.

After drying, dehiscent fruits and cones such as sweetgum or pine can be tumbled or shaken to remove the seed from the fruit (figure 18). Indehiscent fruits can be hulled to remove fruit walls or wings or to singularize. Removal of fruit or wings and singularization are done usually in a single step. Some fragile fruits (for example, those of red maple) can only be singularized and not de-winged. Hammer mills or scarifiers have been used for hulling but

Figure 17—Chapter 3, Seed Harvesting and Conditioning: laboratory model of a pressurized seed drier.

might be too destructive (Young and others 1983). Tough legumes—for example, those of honey-locust (*Gleditsia triacanthos* L.)—have also been successfully broken up in a concrete mixer by adding small pieces of broken-up concrete. Debearders are also used. One that has been found to be very versatile and safe for the seed is the brush machine (figure 19) (Karrfalt 1992). In this machine, the fruit is rubbed against a slightly ovoid wire sleeve by rotating brushes. This sleeve is called a shell and can be made of coarse wire for much abrasion or fine wire for less abrasion. The brushes can be of varying degrees of stiffness ranging from very fine hair brushes to stiff nylon. Adjustments can also be made for the speed at which the brushes turn, how

Table 4—Chapter 3, Seed Harvesting and Conditioning: maximum recommended ambient relative humidity values for drying seeds, cones, and fruits with heated air at various drier temperatures from 24 to 43 °C

tightly they press against the shell, and how long the seeds are retained in the machine. The fruits need to be dry for the hulling operation to work well. The effect of hulling with a brush machine can be seen in figure 20. A partial list of genera and species that can be successfully de-winged or hulled with the brush machine includes ash, maple, tuliptree (*Liriodendron tulipifera* L.), southern catalpa (*Catalpa bignonioides* Walt.), black locust, sycamore, big sagebrush (*Artemisia tridentata* Nutt.), mountain-mahogany (*Cercocarpus montanus* Raf.), and winterfat (*Krascheninnikovia lanata* (Pursh) A.D.J. Meeuse & Smit)

Conifer seeds. Conifer seeds are usually de-winged after tumbling from the cone. De-winging can be done either wet or dry. Some species, white pines, for example, separate easily when tumbled in a drum such as a concrete mixer. Others—for example, hard pines and spruces—require adding a small amount of water to the seeds as they are tumbled to release the wings. In other machines, pressure can be applied with brushes or paddles to remove wings from dry seeds. A mortar mixer is an example of a machine commonly adapted to the dry de-winging of conifer seeds with a modest amount of pressure. However, using pressure increases the chance of mechanical damage. To minimize the amount of mechanical injury, the paddles should be slowed by changing gears on the mixer and de-winging the seeds for only a limited time. A timer switch can be used to easily control de-winging time. The Missoula small-lot pine seed de-winger (figure 21) is another commonly used machine that rubs wings off. It has been particularly widely used in the West and has de-winged millions of pounds of seed. However, if liners are improperly installed, liners or flaps selected improperly, or flaps turned too fast, serious seed damage can result. As always, proper use of equipment is essential.

Figure 18—Chapter 3, Seed Harvesting and Conditioning: a tumbler can be used to extract seed from dehiscent cones or fruits.

Figure 19—Chapter 3, Seed Harvesting and Conditioning: brush machine used for hulling indehiscent fruits, de-winging, and singularizing seeds.

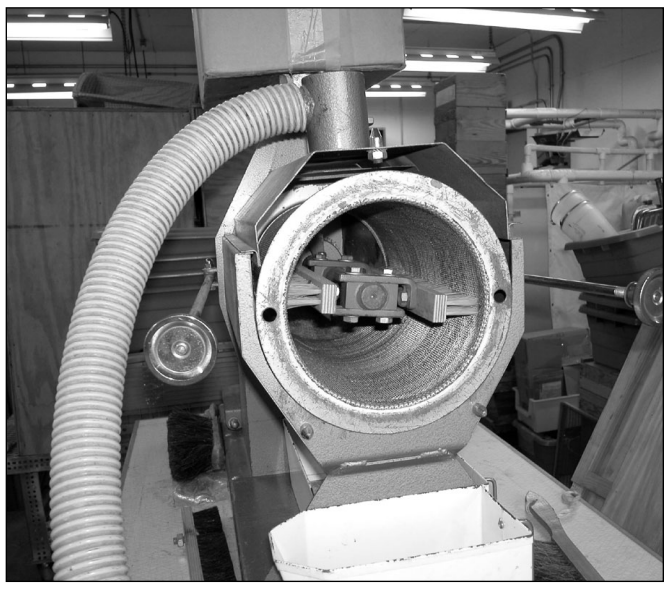

Figure 20—Chapter 3, Seed Harvesting and Conditioning: tuliptree and green ash seeds after treatment with the brush machine.

Because wet de-winging presents minimal chance of mechanical damage, it is the preferred procedure when appropriate. Wet de-winging is accomplished generally by tumbling the seeds in a rotating drum in the presence of an intermittent fine water mist. The drum can be simply a small concrete mixer (figure 22) or it can be a special-order machine (figure 23). The water can be added by computer-controlled valves or sprayed on with a hand sprayer. Intermittent compressed-air spray can be used to partially dry the seeds and blow the wings out of the drum. The compressed air and the water are alternated with each other until the de-winging is finished. Without the compressed air in the drum, the seeds need a quick pass through an air cleaner to blow out the wings. Wet de-winging requires immediate drying after de-winging to prevent deterioration. The drying is brief, because the moisture is near the surface of the seeds. The pressurized drier described previously is also best for this drying.

Some conifer seeds (longleaf pine and true firs, for example) have a wing that is one structure with the seedcoat. These wings must be removed with care; for some particularly fragile species such as true firs, the seed plant operators sometimes opt not to de-wing.

If the wings need to be rubbed from the seeds it might be necessary to remove large or abrasive trash from the seedlot first. This is called scalping and is done with a screen machine.

Another factor to keep in mind before de-winging is the separation of particles from the seedlot that are of equal size and weight to the finished seeds. These are sometimes all but impossible to remove from the finished product.

Figure 21—Chapter 3, Seed Harvesting and Conditioning: small-lot pine-seed de-winger developed by the USDA Forest Service's Missoula Technology and Development Center, Missoula, Montana.

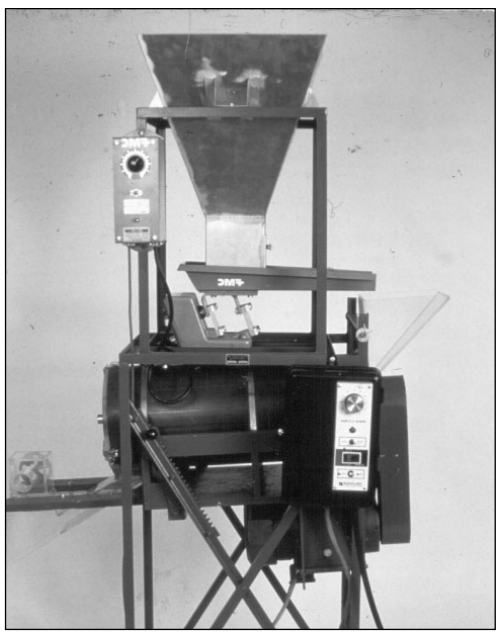

Figure 22—Chapter 3, Seed Harvesting and Conditioning: small mixer for tumbling seeds for wet and dry de-winging; the spray bottle is used to apply water for wet de-winging.

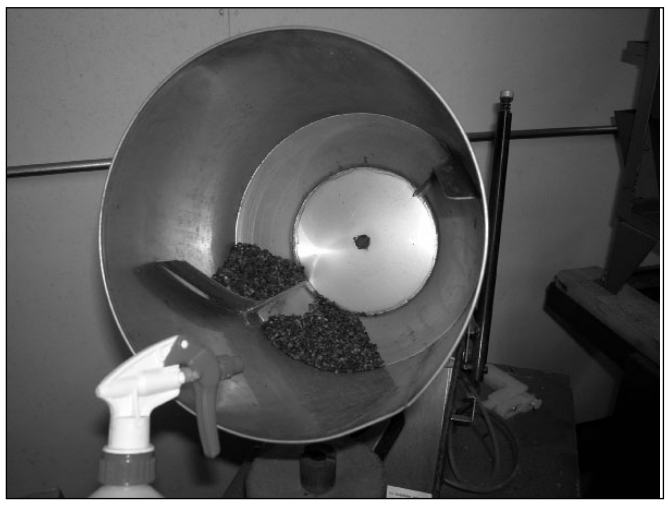

Figure 23—Chapter 3, Seed Harvesting and Conditioning: commercially made wet pine-seed de-winger.

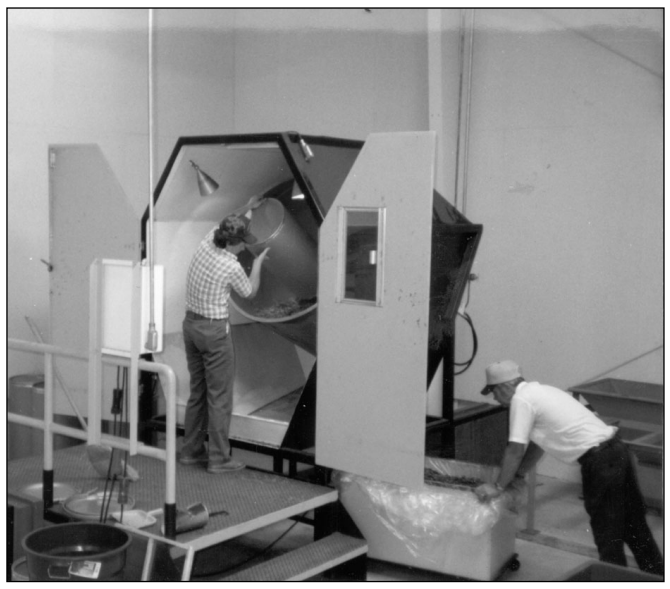

However, before the wing is removed, the seeds will be very much lighter than the trash in an air column. This is the case with species that have a great deal of pitch in them such as western larch. A sensitive air column can blow the seeds up and let the pitch or other trash fall, giving a perfect separation.

Cleaning and Upgrading

Basic cleaning and upgrading steps for orthodox hardwoods, shrubs, and conifers become similar once the seeds are extracted, de-winged, and dried. Basic cleaning is accomplished with air-screen machines, screens, aspirators, and blowers (figures 24–27). These devices have historically been the workhorses of seed cleaning.

Removing trash with air. Air can be used to remove particles that are either lighter or heavier than the seeds. Dust, small pieces of pine needles, leaves, and wings are examples of lighter materials that can be taken out of seeds using air. The removal of pitch from conifer seeds is an example of using air to remove seeds from heavier particles. Aspirators use negative pressure by having the fan placed above the seeds. Blowers, on the other hand, use positive pressure by placing the fan below the seeds. Either approach works well if the air can be applied uniformly, constantly, with enough force, and varied precisely so that a high level of control over the force of the air is acheived. Without precise control, only the coarsest separation would be possible. The more refined the air control, the more refined the separation. Air-screen machines, blowers, and aspirators can all accomplish good air separations, but not all models of machines have the same degree of control over the air and, therefore, different quality of work can result.

Removing trash with screens. While air is used to clean seeds by weight, screens separate seeds from trash according to width and thickness. Screens are made either by punching holes in sheet metal to make perforated metal screens or by weaving wire together to make screens that resemble those used for home windows. The perforated metal screens are most common, the woven wire (figure 28) less common, being used generally for very fine seeds such as those of eucalyptus (*Eucalyptus* spp.) and grass. The perforations are mostly made in round or oblong hole sizes (figure 28). Screens made in the United States are measured in 64ths of an inch; screens made in other countries are measured in millimeters. As an example, the holes in a U.S.-made number 8 round-hole screen are 8/64 of an inch in diameter. [Note: Some authors have described using soil screens, which have an entirely different size description system, for extracting seeds from fleshy fruits.]

Figure 24—Chapter 3, Seed Harvesting and Conditioning: air-screen machines come in many sizes and are used for basic seed cleaning; a small-seedlot cleaner is in front of a very large capacity cleaner.

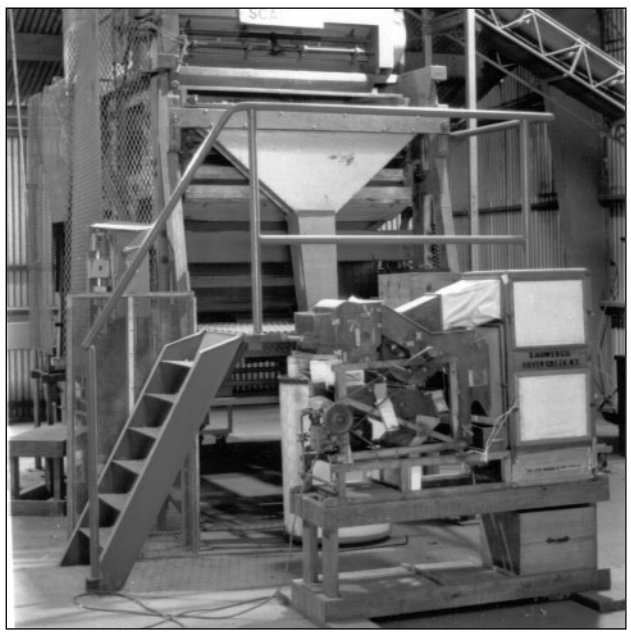

Figure 25—Chapter 3, Seed Harvesting and Conditioning: cleaner–sizer machine has 5 screens to give 6 separations at once.

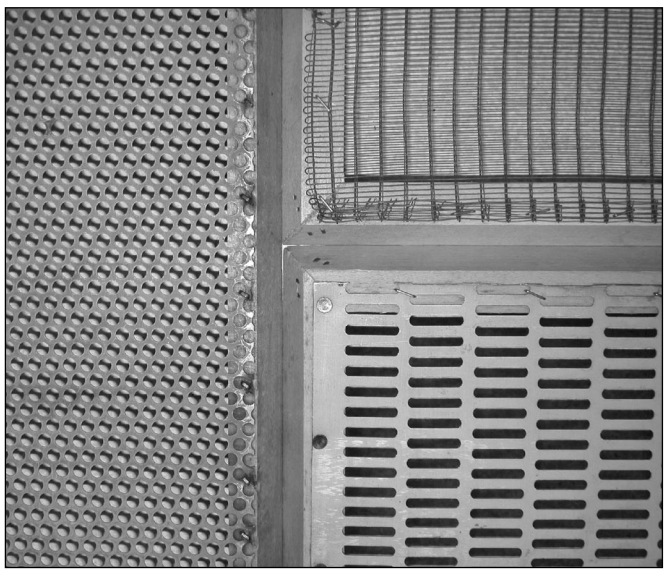
A proper selection of screens is necessary to get the desired separations. First, it must be determined if seeds need to be separated by their width or thickness. In cross-sections of seeds or trash particles, the dimension that is greater is the width and the lesser dimension is the thickness. Round-hole screens sort for difference in width,

Figure 26—Chapter 3, Seed Harvesting and Conditioning: a laboratory aspirator removes trash with vacuum.

Figure 27—Chapter 3, Seed Harvesting and Conditioning: a laboratory blower removes trash with positive pressure.

oblong-hole screens for difference in thickness. An example of a thickness separation is the sieving of flattened immature seeds out of redbud (*Cercis canadensis* L.). Slotted screens easily remove the wire staples that get into pine seeds when net collection systems are used. The separation of cone scales from pine seeds is another example of separation by width.

Figure 28—Chapter 3, Seed Harvesting and Conditioning: hand screens showing the 3 main types of screens used to clean seedlots (**counter-clockwise from left**): perforated metal round hole, perforated metal oblong holes, and woven wire.



After the correct type of hole has been determined, the proper size of hole is selected. Several screens are stacked on top of each other with the largest size screen on top and each successive screen the next size smaller. As an example, screens could be stacked from top to bottom in this order: 12, 11, 10, 9. The next step is to pour a sample of seeds on the stack of screens and shake the stack back and forth. Disassembling the stack reveals which sizes made the best separation. Typically, one size will hold both seeds and trash. A decision must be made whether to keep some trash in the seeds, discard some seeds with the trash, or take the mixed fraction and separate it in some other manner. When trash is left in the seeds, we are saying that we can live with that level of contamination. When some seeds are discarded with the trash, we are saying that we can afford to loose some seeds because the higher level of purity is worth the cost of the lost seeds. When the mixed fraction is cleaned, we are saying we need all the seeds but cannot afford the lower purity and are willing to pay for extra cleaning.

Once the screens have been selected, the air-screen or screen machine should be set up. In a 2-screen machine, the top screen would be the one that held the most trash and the bottom screen the one that passed the desired amount of small trash. Remember that there might be a few seeds in the large trash or the small trash so that purity is higher, or some trash may be left in the seeds to keep every seed possible. For machines with 3 or more screens, additional fractions can be created. The effectiveness of the screen in the

machine is determined by the speed of the shake of the screen, how well the screens are kept from blinding, and the feed rate; in some machines the slope of the screen is also adjustable.

Blinding occurs when the seeds or trash particles drop into a hole and can neither fall through nor bounce out (figure 29). This of course reduces the effective area of the screen. There are 3 types of devices to clear the holes: tappers, brushes, and ball decks. A tapper hits the screen to jar out any particles. Brushes are pressed against the bottom of the screen and pulled back and forth by ropes or cables. The brushes directly push the seeds out of the blinded holes. Ball decks consist of a cage attached to the bottom of the screen that contains small rubber balls. These balls bounce against the bottom of the screen and jar the seeds out of the blinded holes. Ball decks are now generally used on new machines, because they are easier to maintain than other devices and increase the capacity of the screen. They can also be put on many older machines to replace brushes and tappers.

Air and screens can be used to separate by particle width, thickness, and weight. However, they are generally unable to separate by particle length. Only the riddler screen (figure 30) can separate by length; this screen is used with a pulsing shake instead of the more steady shake of the standard air-screen machine. The holes in this screen have a right-angle bend in them. The long particles are unable to turn the corner and are walked up the screen by the shake. Short particles make the turn and pass through. The riddler screen is used principally in making dockage tests (a type of purity test) on grain, but has been used on a limited basis to clean trashy lots of tree and shrub seeds. Needle fragments can be removed from loblolly pine seeds with this type of screen.

Removing sticks and needles. Removal of sticks, stems, or needles from seeds is an example of length separation. Length separations are usually done using indent discs or indent cylinders (figure 31). An indent cylinder can remove stems from hardwood seeds that are not removed by basic cleaning. Seeds in an indent separator settle into the indents of the cylinder and are lifted as the cylinder is rotated. The stem piece also fits into the indent, but because it is longer its center of gravity is outside of the indent and subsequently it falls out of the indent before the seeds will (figure 32). The stem falls back to the bottom of the cylinder while the seeds are carried up and dropped into a collection trough. The indents need to be large enough to let the seeds seat completely. The speed of cylinder rotation and the angle of the collection trough are also adjusted to obtain the separation.

There are a few ways to perform length separation when an indent cylinder is not available. These techniques usually do not work as effectively but can be helpful. The first is to use flat screens with the upper portion of the screen covered with a sheet of paper (figure 33). The paper allows the seeds and long trash to travel parallel to the screen before encoun-

Figure 29—Chapter 3, Seed Harvesting and Conditioning: the seeds caught in the screen holes are said to have "blinded" the screen.

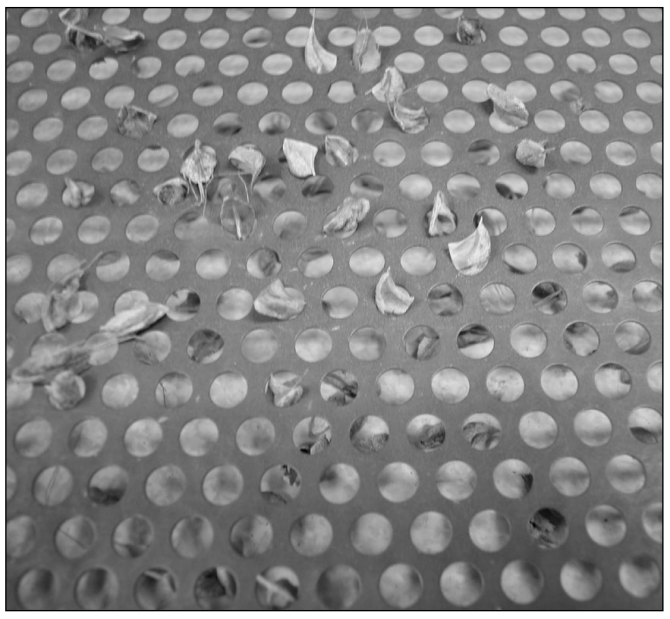


Figure 30—Chapter 3, Seed Harvesting and Conditioning: pine needles separated from seeds using a riddler screen.

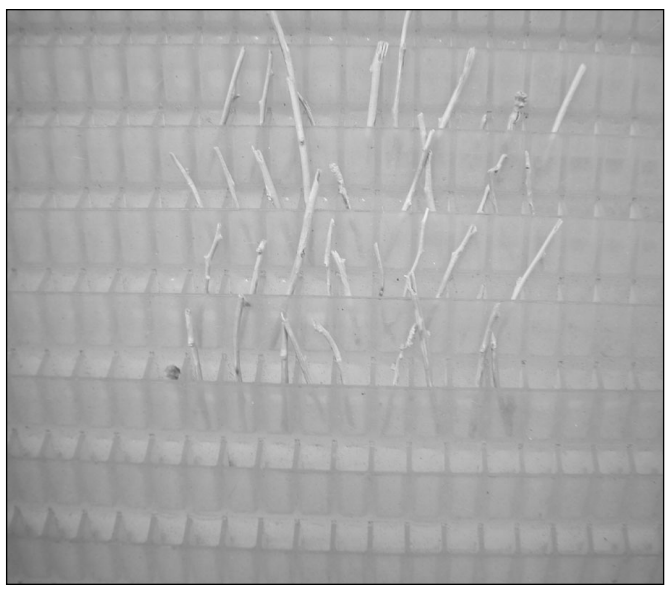

tering a hole. As a result, the long particles, the sticks, tend to ride over the hole while the short seeds fall through. Without the paper, the sticks come endways towards the hole and, having a small dimension, their diameter, in line with the hole, drop straight through. Several passes will usually be required for this procedure to remove most of the sticks.

Sometimes the sticks will be removable with air because of their aerodynamic properties. Even though they may be heavier than the seeds, they catch the air well and can be lifted away. Similarly, the sticks may float to the bottom of the specific-gravity table by the process described below.

Removing trash with static electricity. Electrostatic separators also separate by weight using the force of an electrostatic field instead of air to make the separation. Charges on the particles cause them to be drawn to a negatively charged plate. Picking up small pieces of paper with a piece of plastic that has been vigorously rubbed with a dry cloth is a simple example of using an electrostatic force to pick up a light particle. One type of electrostatic separator is shown in figure 34. Electrostatic separation has had little application with trees and shrubs and only with light-seeded species (Karrfalt and Helmuth 1983). A glass beaker rubbed on the inside with a nylon or other synthetic cloth makes a simple type of electrostatic cleaner for very small seedlots. Uncleaned seeds are poured into the rubbed beaker and rolled against the sides of the beaker. After the trash has clung to the sides of the beaker, the clean seeds can be poured out. Plastic cups can substitute for the glass beaker.

Removing trash by rolling and sliding. Another characteristic that can be used to separate seeds and trash is surface texture, or the ability to slide or roll down a slope. Conifer seeds, especially larch or white pines, can contain a

Figure 31—Chapter 3, Seed Harvesting and Conditioning: indent cylinder machine for removing needles, sticks, and stems from seeds.

Figure 32—Chapter 3, Seed Harvesting and Conditioning: seeds are caught in indent cylinder while pine needles slide away

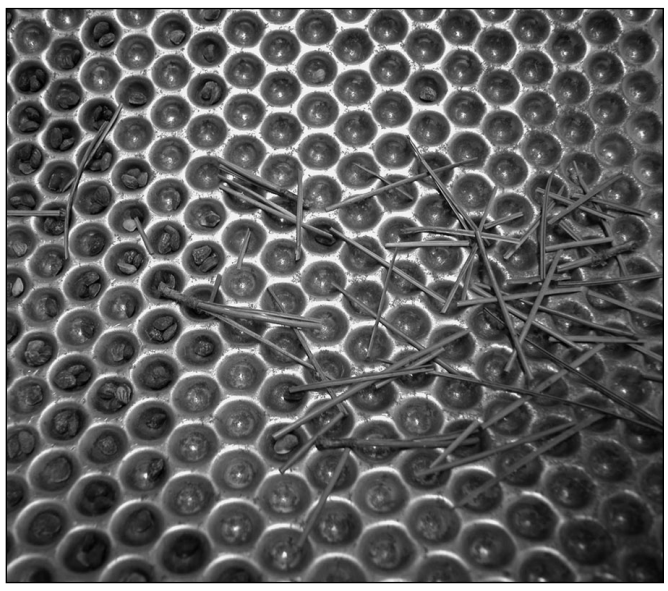

Figure 33—Chapter 3, Seed Harvesting and Conditioning: paper on screen aids in screening-out needles and sticks.

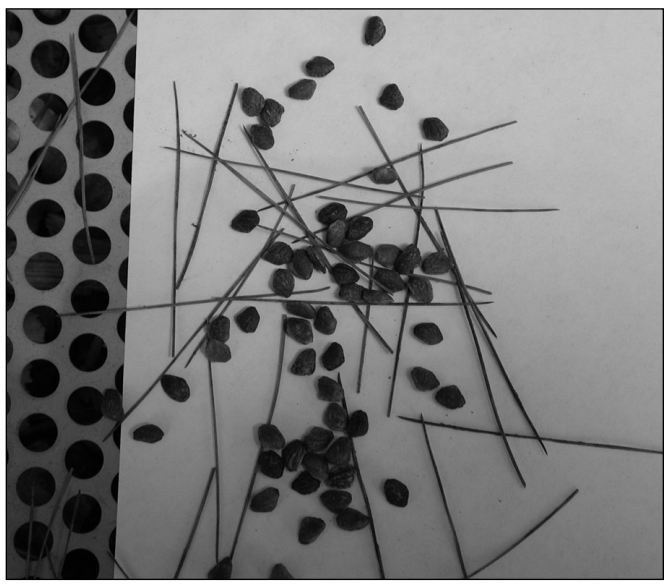

large amount of pitch. The pitch particles have a sticky surface whereas the seeds are relatively smooth. The vibratory separator (figure 35) is often able to use this difference to remove the pitch. This separator consists of a 22.9-cm-square (9-inch-square) deck mounted on a variable-speed vibrator. The deck has adjustable side and end tilt. The vibration causes the pitch, which grips the deck surface because it is tacky, to walk up the slope while the seeds, which are smoother, slide down the slope. The rate at which seeds are fed onto the deck, the speed of deck vibration, the roughness of the deck, the degree of side and end tilts, and the arrangement of the cut gates are all important. Trial and error determine what adjustments are necessary to get a separation.

Not all pitch will separate on the vibratory separator. Some may be too dry and, therefore, too smooth to stick to the deck well enough. Other pieces of pitch may be too round. Screening will sometimes work in these cases.

Another approach to surface texture is to modify it. Sometimes pitch can be removed with a gravity table (see section below on gravity tables), but only after it has been very well dried or stiffened by placing the seedlot in a cooler or freezer (Zensen 1980). This drying or cooling keeps the seeds from balling up around the pitch particles.

Another type of machine that separates by particles' ability to roll is the inclined draper (figure 36). This machine is a variable speed belt that can be set at different slopes. Particles that are round, or able to slide more easily, go down the slope while the flatter particles with greater friction ride up the hill on the moving belt and are placed in the upper collection box. Separating juniper berries from juniper leaves is an example of a separation that can be done with the draper. A board with a piece of cloth over it makes a simple draper for a small quantity of seeds. A handful of seeds can be cleaned at one time with this board. The seeds are allowed to roll down the board and then the needles are manually dumped off.

Spiral separators also use rollability. These are made of two concentric metal spirals. Seeds are poured into the top of the inner spiral. As they slide down the spiral, the round particles roll and gain momentum, causing them to fly out of the inner spiral into the outer spiral. Trash can be removed from dogwood and juniper berries in this manner (Delany 1998).

Improving quality with specific gravity tables. Specific gravity tables are another class of machine that separates by weight (figure 37). Gravity tables can be used on almost any species of seed that flows freely. They have been very successful in cleaning true firs, longleaf pine, tuliptree, and sycamore when other methods have not provided the desired results. The separations are made in the following manner. Seeds are fed onto a wire or cloth deck that has air blowing through it from below. This air is just enough to cause the seed mass to fluidize, with the lighter material floating to the top. Only enough air is applied to slightly lift

Figure 34—Chapter 3, Seed Harvesting and Conditioning: diagram of one type of electrostatic separator.

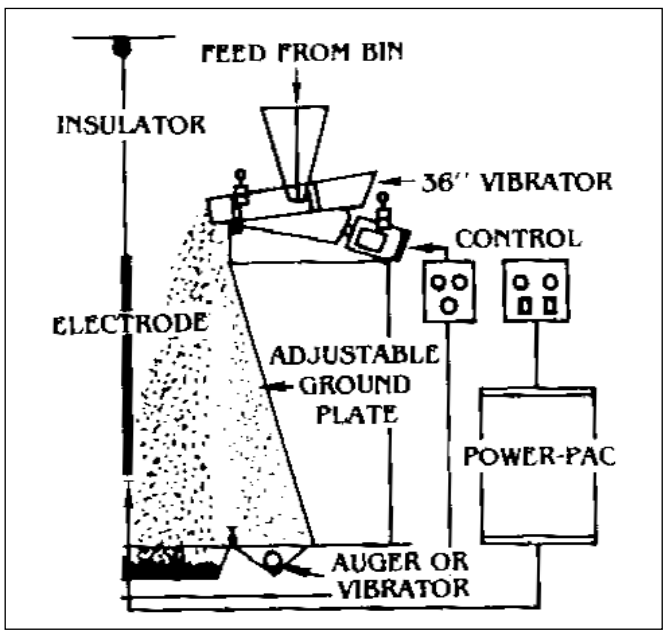

Figure 35—Chapter 3, Seed Harvesting and Conditioning: the vibratory separator removes trash from seeds by differences in surface texture.

Figure 36—Chapter 3, Seed Harvesting and Conditioning: the inclined draper separates particles on their ability to roll or slide down the inclined belt.

Figure 37—Chapter 3, Seed Harvesting and Conditioning: a specific gravity table for separating seeds and trash by weight.

the lighter material, not toss it into the air. This more gentle air flow results in a finer stratification of particles by weight than is possible in the air columns of blowers and aspirators. To pull the light and heavy particles apart, the deck shakes back and forth and is tilted sideways to oppose the direction of the shake. The shake of the deck pushes the heavy particles up the hill while the light particles drift down the slope, floating on top of the heavier seeds and pulled down the slope by gravity. This stratification of particles by weight and separation by the use of the shake and slope continues as the seed mass works its way across the deck, giving a continuous gradation of particle weights until the heaviest are at the top, intermediate weights are in the middle, and the lightest are at the bottom. When seedlots are upgraded on gravity table, the lightest particles can be empty seeds, cone particles, straw, partially filled seeds, or even good-quality seeds that are lower in weight. The heavier particles are usually the heaviest good-quality seeds but might also be pitch, stones, dirt balls, or tramp metal that has fallen into the seeds.

Dimensional grading of seedlots before using the gravity table improves the effectiveness of the table and may even be essential. Grading should be done both by width, thickness, and, if possible, length. The more dimensional grading is done, the better the table will work. The table sorts by density or dimension but never effectively for both at the same time. For example, partially filled large-diameter seeds and same-weight seeds that are completely filled but smaller in diameter sort to the same location on the gravity table.

A final point on gravity table operation is the need for seedlots need to be clean of light trash. Otherwise a great deal of dust will be blown into the operator‘s face and create an unhealthy, unpleasant, and difficult working situation.

Upgrading quality with liquids. Fluid separations based on difference in specific gravity are another way to upgrade seeds. The separation sorts lighter seeds from heavier, but because differences in specific gravity are used, the problems of dimensional sorting are avoided. Fluid separations can be very precise separations based on weight. Water flotation, the simplest version of this, for example, can be used to remove insect-damaged acorns. The good seeds, being high in moisture content, will have specific gravities greater than 1.0 and will sink. Seeds that have been damaged significantly by insects will contain air and therefore will float (figure 38). Water can also float empty stony-coated seeds such as loblolly pine or cherries; the full seeds of these species will sink. Mixtures of hexane and chloroform have been used to separate lighter seeds from empty or partially filled seeds (Taylor and others 1982). However, phytotoxicity needs to be tested before broadly adopting fluid separation using organic solvents (Barnett 1970).

In Sweden, the fluid separation of Scots pine (*Pinus sylvestris* L.) and lodgepole pine has reached a highly sophisticated level in the processes called PREVAC (“prevacuum”) and IDS (incubate, dry, separate) (Simak 1984; Bergsten 1993). The PREVAC system removes seeds with

damaged seedcoats. The seeds are placed in water in a vacuum chamber and a vacuum is then drawn on the chamber to break the surface tension and allow the water to wet the surface of the seeds. Water will enter seeds with damaged seedcoats rapidly, increasing their weight and causing them to sink. These sinkers are discarded, for they have damaged seedcoats and will be dead. The seeds that float are drawn off the top and kept. Conducting the PREVAC procedure before IDS prevents the mechanically damaged seeds from sorting out with the good seeds in the IDS procedure.

The IDS procedure uses the fact that dead or weak seeds lose water faster than living or more vigorous seeds. In the first step, all seeds are allowed to imbibe water. With Scots pine, this is done at 15 °C for 8 to 12 days. Then the seeds are dried in super-dry air with a relative humidity ranging from 5 to 15%. The extremely rapid drying resulting from the super-dry air maximizes the difference in drying rates between viable and nonviable seeds. The living tissue in the viable seeds holds water more tightly than the nonliving tissue in the nonviable seeds. Eventually, however, the viable and nonviable seeds will both dry to the same moisture content. Meanwhile, though, samples of seeds are drawn at set intervals through the drying period and placed in water to determine the best length of time to dry. When the number of seeds floating equals the number to remove, all the seeds are placed into the water. The floaters are nonviable and are discarded; the sinkers are viable and are kept (figure 39). Unless sown immediately, the sinking seeds must be dried thoroughly to a proper storage moisture content. The process has been completely automated in Sweden using sophisticated machines. However, the basic principle can be followed using pans of water and a kitchen sieve. The key is proper incubation and very rapid rate of drying. In extremely cold climates, it is possible to simply heat ambient air to near 40 °C to achieve the desired relative humidity. However, it may be necessary to dehumidify the air further by cooling it with an air-conditioner before heating. The IDS process is protected by patent in Canada and the United States, and royalties must be paid to use the process commercially (Downie and Bergsten 1991). Successful upgrades have been reported for seedlots of Douglas-fir (Sweeney and others 1991) and *Pinus roxburghii* Sarg. (Singh and Vozzo 1990). Attempts at upgrading seedlots of white spruce, sitka spruce (*Picea sitkensis* (Bong.) Carr.), and ponderosa pine (*Pinus ponderosa* P. & C. Lawson) gave mixed results (Downie and Bergsten 1991; Downie and Wang 1992; Karrfalt 1996).

Figure 38—Chapter 3, Seed Harvesting and Conditioning: water flotation of acorns for separating good seeds from damaged seeds and trash.

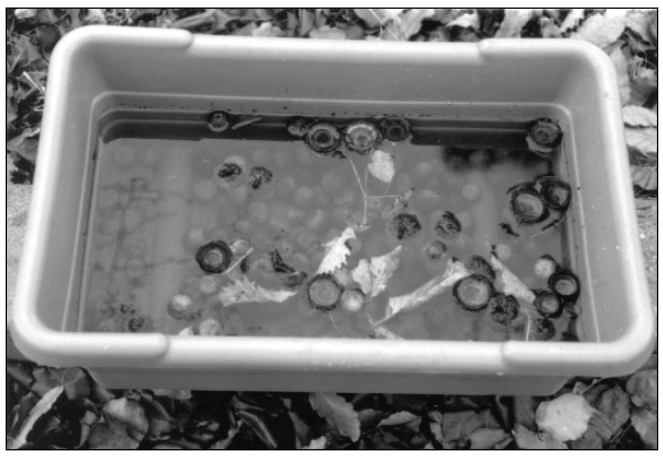

Figure 39—Chapter 3, Seed Harvesting and Conditioning: incubate-dry-separate (IDS) separation chamber; the floating seeds are discarded because of low viability and vigor, and the sinking seeds are kept because they have higher viability and vigor.

The final stage of conditioning seeds is preparation for storage, which is discussed in chapter 4. Those wishing to study further the mechanical methods and principles of seed cleaning are referred to Brandenburg (1977) and Brandenburg and Park (1977).

Conveying seeds. Moving seeds in forest seed processing plants is usually best accomplished by batch movement. In most cases, this means that a 4.5-liter (5-gallon) pail must be lifted and emptied into a hopper that feeds a conditioning machine about every 15 to 20 minutes. Larger amounts are sometimes moved with a hopper and forklift. The advantages of batch movement are greater control and flexibility of seed flow, easier clean-out, and a simpler, less expensive design. Greater control is provided because the seeds can be seen more easily for continual inspection. If the desired result is not obtained on one pass, the seeds can be immediately rerun. In continuous flow systems the seeds must flow to the next machine. Batch processing also provides greater flexibility, because the order of conditioning can be altered to match the lot and kind of seeds. In continuous flow the order of processing is relatively fixed. Bucket elevators have been used frequently in the past to move seeds, but these can be difficult to clean out. With many elevator designs, as much as 0.45 to 2.3 kg (1 to 5 lb) of seeds remain in the bottom or boot of the elevator and must be cleaned out by hand. This is much work and highly impractical with lots of less than 23.7 kg (50 lb). Because of this clean-out problem, the bucket elevator might present a major threat to lot integrity. A continuous bucket elevator (figure 40) eliminates the clean-out problem but can add to the cost of the plant. Vacuum elevators also eliminate clean-out problems but can seriously damage seeds; they move seeds very fast and sometimes stop them too quickly against hard surfaces, causing mechanical damage. Bucket elevators have also been found to damage seeds when not properly installed. The damage may not be immediately visible to the naked eye or even in a radiograph (see chapter 5). The softer the seedcoat, the easier damage can occur. Seeds of true firs would be most easily damaged; those of longleaf pine and red maple would be slightly more resistant; whereas those of ponderosa pine, loblolly pine, and dogwoods would be most resistant but still easily damaged if too much force is applied in conveying the seed. Not having elevators in the seed processing plant results in lower equipment cost, more available floor space, less noise, and lower maintenance cost.

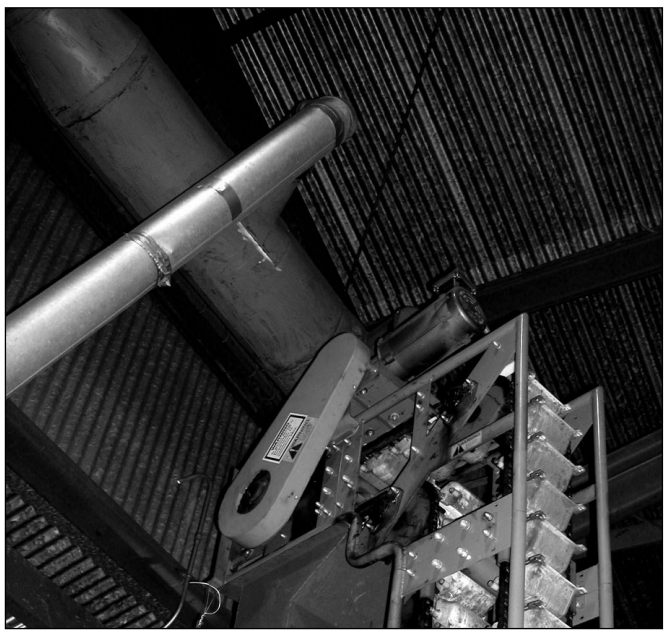
Scooping seeds by hand must also be done with proper consideration. Even a hand scoop if thrust into the seeds too hard or rapidly will cause damage and lower viability. Seed

Table 5—Chapter 3, Seed Harvesting and Conditioning: the application and interpretation of various seed tests to seed conditioning

Test	Observation	Interpretation/action
Moisture content (MC)	Orthodox seeds	
	Above 10% MC	Dry seeds immediately to prevent deterioration
	Below 10% MC	Safe for storage; seal seeds in moisture-proof container
	Recalcitrant seeds	
	Above 25%	MC high enough to preserve viability usually
	Below 25%	Seeds likely are non-germinable
Purity	Low (trash present will clog a seeder)	Seedlot needs to be re-cleaned
Germination, tetrazolium staining, or Excised embryo	95% or better	Best quality for container seedlings & precision sowing for bareroot seedlings
	90% or better	Good quality for container & bareroot seedlings
	80%	Minimum quality for bareroot seedlings
	Below 80%	Generally more difficult to achieve good seedling densities in the nursery; to improve results, determine if empty, insect-damaged, or filled nonviable (see x-ray test below) seeds are cause for low germination
Seed weight*	High number/weight	Smaller seeds
	Low number/weight	Larger seeds
X-radiography	Cracked seedcoat	Modify handling to eliminate damage
Standard	Broken embryo	Water soak or use PREVAC to remove damaged seeds
	Empty seeds	Remove with air separators, fluid separation, &/or gravity table
	Partially filled, insect-or fungus-damaged	IDS, Dimensional grading in conjunction with specific-gravity table separation
Contrast agent	No darker (more radio-opaque) spots on image	No damage to seeds from handling
	Darker spots on image	Seeds bruised in handling; reduce number, severity, & length of drops; remove damaged seeds with IDS

* Measured in either kilograms or pounds.

Figure 40—Chapter 3, Seed Harvesting and Conditioning: continuous bucket elevator for gentle handling of seeds.



should be gently gathered onto the scoop. If time does not permit gentle scooping, then another means of conveying should be arranged.

Quality Control

Quality control is very important in conditioning seeds. Seed conditioning can be a highly complex operation, usually involving many steps and many different persons. A procedures manual is crucial, so that the role of everyone involved can be clearly identified and thought out. Writing out the steps in detail, from preparing for collection through storage and planting, provides an opportunity for a careful examination of all steps to identify potential problems and inefficiencies. Also, when procedures are fully documented, the same steps can be followed if there is a change in personnel. Many good techniques and small nuances gained through years of seed conditioning can be lost if not documented in permanent form. Typically, plant managers are not expected to publish their techniques, and knowledge is lost at retirement or job transfer. It is therefore imperative that the manager document all procedures used, in detail, either on the manager's own initiative or with the manager's supervisor. Sometimes an interview with someone who has good writing ability will help a manager get thoughts on paper.

The procedure manual should indicate all the types of records to be kept and what to do when an error occurs. Sooner or later a mistake inevitably will occur, and procedures need to be in place to handle these errors. Quality control involves more than preventing mistakes; mistakes will occur despite the best precautions. Quality control also consists of making sure that mistakes do not go undetected and that reasonable effort is made to rectify the mistake. To aid in this, records should be kept in detail showing time spent, inputs, outputs, conditions during the work, and who did the work. Who did the work is often an important factor when trying to unravel a mistake. The people who did the work will be the ones who know the most about it and have the best chance to explain what happened. A third-party review of procedures can also be of great help. Preparing to explain a process to someone else encourages a more thorough review of the work. A properly administered seed certification or seed plant accreditation program can provide this type of review.

Constantly monitoring seed quality is necessary for a high-quality conditioning operation. The specifics of testing are discussed in more detail in chapter 5. The application of the tests (table 5) is discussed here. Testing begins before harvest with cutting and x-ray tests to judge the maturity and quality of seeds. Unless it is determined that good seeds are present, a crop of totally empty or damaged seeds can be collected.

Moisture testing is critical to monitor how well we are maintaining seed moisture in all types of storage. The electronic moisture tester (figure 41) is adequate for most orthodox seeds but needs to be periodically (annually, for example) verified by a laboratory oven test. The electronic meters also must have conversion charts developed; they do not give direct readings for tree and shrub seeds. These conversion charts are made by regressing (comparing) meter readings with oven moisture tests over a range of seed moisture values. Recalcitrant seeds do not test well in electronic meters, but the procedures used to handle them should be checked at least initially to be sure moisture is kept at sufficiently high levels. This is done by drawing samples and having them tested for moisture. Otherwise, the problem might not be discovered until the seed is bought, sold, tested for germination, or, worst of all, planted in the nursery and a poor germination occurs. Following wet de-winging of conifer seeds, de-pulping of fleshy fruits, or water separation of seeds, it is necessary to dry and then test the moisture content before moving to the next step. Seeds held at high moisture even overnight could begin to respire too rapidly and begin heating. Some seeds (for example, those of longleaf pine) are shed from the cone or fruit at a high moisture content, and moisture needs to be checked and reduced if too high for safe storage.

Figure 41—Chapter 3, Seed Harvesting and Conditioning: electronic moisture testers are used to monitor seed moisture content.

Figure 42—Chapter 3, Seed Harvesting and Conditioning: radiography of pine seedlots quickly and accurately shows how many bad seeds to remove.

Visual inspection, cutting tests, and, ideally, x-radiography is used to monitor the conditioning operation. Visual inspection leads us in improving purity. Cutting tests and x-radiography reveal how many bad seeds still need to be removed. X-radiography is the better method, for it can easily show mechanical damage to the seeds, is very fast, and is more accurate than cutting tests in differentiating between good and bad seeds. If an x-ray shows that 20% of the seeds are bad and must be removed, the cleaning equipment should then be adjusted to remove 20% of the seeds by number or volume (figure 42). A second check can then be made of the seeds after the machine has been adjusted to ensure the adjustment has removed all the bad seeds it should without removing too many good seeds. The separation may not be able to be completed with one setting.

In addition to daily monitoring, the conditioning procedures need to be verified as correct by full laboratory tests, to be sure no harm is coming to the seeds and that the desired quality is achieved. Purity tests tell how much of the seed by weight is pure seed and how much is trash. A low purity value means that a better job of cleaning needs to be done. Periodically, and after any modifications of procedures, it is critical to test each step in the process for its effect on viability. Samples should be taken before and after every step in the process. X-radiography and germination tests need to be run on these samples. The x-ray will help detect mechanical damage that causes cracks in the seeds, and, if used with a contrast agent, smaller bruises on the seeds. Germination tests detect any step that stresses the seeds. Two germination tests need to be run on each sample, one on the fresh sample and one on a sample after storage. The first test will pick up the immediate problem areas. The test after storage will be more effective in detecting latent damage. Some damage is not immediately obvious in the germination test but requires time for deterioration to develop to the point at which a drop in germination can be measured.

Chapter 4

Storage of Seeds

Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Contents

Introduction

In the simplest form of seed storage, mature seeds are held for a short period until weather or other factors permit sowing or planting. In the more comprehensive view, there are at least 3 objectives for storing seeds, and each of them dictates different strategies and procedures. These objectives may be described as storage for the following periods:

1. Very short periods (overwinter) between collection and sowing
2. Several years (10 or less) to ensure a reliable supply of seeds in the absence of annual crops
3. Long periods (10 to 50+ years) for germplasm conservation

The strategies employed will depend on all of the factors that influence seed longevity. Some of these factors have been discussed in chapter 1, but now they will be explored in the context of seed storage only. Following this, recommendations will be made for storage procedures to achieve the objectives listed here.

Factors Affecting Longevity of Seeds

Seed Characteristics

Basic seed physiology. In his classic paper, Dr. E. H. Roberts (1973) divided seeds into 2 groups based on their storage characteristics: orthodox and recalcitrant. Orthodox seeds are those that can be dried to moisture contents of 10% or less; in this condition they can be successfully stored at subfreezing temperatures. Recalcitrant seeds, on the other hand, are those that cannot be dried below relatively high moisture levels (25 to 45%) and therefore cannot be stored below freezing. Current knowledge of seed physiology can allow additional classification of tree seeds into the following groups (Bonner 1990): (1) true orthodox, (2) sub-orthodox, (3) temperate-recalcitrant, and (4) tropical-recalcitrant. In addition, Ellis and others (1990) have proposed an intermediate storage class that falls between orthodox and recalcitrant.

True orthodox seeds can be stored for relatively long periods at subfreezing temperatures—if their moisture contents are reduced to about 5 to 10% (wet weight basis). [Throughout this chapter, seed moisture will be expressed as a percentage of wet weight in keeping with the international protocol (ISTA 1993).] Most species of the economically valuable tree genera of the Northern Temperate Zone are classified as having true orthodox seeds: fir (*Abies* P. Mill.), alder (*Alnus* P. Mill.), birch (*Betula* L.), ash (*Fraxinus* L.), larch (*Larix* P. Mill.), spruce (*Picea* A. Dietr.), pine (*Pinus* L.), sycamore (*Platanus* L.), cherry and plum (*Prunus* L.), Douglas-fir (*Pseudotsuga* Carr.), hemlock (*Tsuga* Carr.), etc. Many valuable genera of the tropics and subtropics are also true orthodox: *Acacia* L., *Albizia* Durz., many other Fabaceae, *Casuarina* Rumph. ex L., *Eucalyptus* L' Her., mesquite (*Prosopis* L.), and teak *(Tectona* L.f.). The time limits for storage of true orthodox seeds under optimum conditions is not really known. Eliason and Heit (1973) reported 86% germination in red pine (*Pinus resinosa* Soland.) samples stored for 42 years. Martin (1948) found that herbarium samples of velvet mesquite (*Prosopis velutina* Woot.) germinated quite well after 44 years. Barnett and Vozzo (1985) found that slash pine (*P. elliottii* var. *elliottii* Engelm.) still germinated at a rate of 66% after 50 years of storage at 4 °C. Other examples of storage data for true orthodox tree seeds are found in table 1.

Sub-orthodox seeds can be stored under the same conditions as true orthodox seeds, but for much shorter periods. The reasons for their decreased longevity are not completely known. However, indirect evidence suggests that some causes are high lipid contents—as in hickory (*Carya* Nutt.), beech (*Fagus* L.), walnut (*Juglans* L.), and some pines (*Pinus* L.) and thin fruits or seedcoats, including some maples (*Acer* L.), poplars (*Populus* L.), and willows (*Salix* L.) (Bonner 1990). Retention of viability for more than 10 years would be rare for sub-orthodox species with current storage technology (table 2).

Temperate-recalcitrant seeds cannot be desiccated but can be stored at or slightly below freezing. Genera with temperate-recalcitrant seeds include buckeye (*Aesculus* L.), chestnut (*Castanea* P. Mill.), oak (*Quercus* L.), and redbay (*Persea* P. Mill.). Some, but not all, of these species can be stored for 3 to 5 years at near-maximum moisture contents (30 to 50%) and low temperatures (–3 to +4 °C) (table 3).

Tropical-recalcitrant seeds have the same desiccation sensitivity of temperate-recalcitrant seeds and are also sensitive to low temperatures. Even short periods of exposure to temperatures below 10 to 15 °C can cause loss of viability (Berjak and Pammenter 1996; Chin and Roberts 1980). Included in this group of species are *Araucaria* Juss., *Hopea* Roxb., *Shorea* Roxb., ex C.F. Gaertn., and *Theobroma* L. Longevity of these seeds is usually measured in months, not years (table 4).

Intermediate seeds can be dried to moisture levels almost low enough to meet orthodox conditions (12 to 15%) but are sensitive to the low temperatures typically employed for storage of orthodox seeds. Viability is retained usually only for a few years. The research that led to the concept of

intermediate seed behavior was done with coffee (*Coffea arabica* L.) (Ellis and others 1990), and although no forest tree species have been identified as intermediate as yet, there is a very good chance that some will fit this classification.

There are several genera that contain both orthodox and recalcitrant species. In the Northern Temperate Zone, maple (*Acer*) is such a genus. Silver maple (*Acer saccharinum* L.) is clearly temperate-recalcitrant in nature (Tylkowski 1984), but red maple (*A. rubrum* L.) can be dried to 10% seed moisture content and is either true orthodox or sub-orthodox. Among tropical species, the genus *Araucaria* Juss. has a similar distinction. *Araucaria cunninghamii* Aiton ex D. Don is orthodox in nature, and *A. hunsteinii* K. Schum. &

Hollrung is tropical-recalcitrant (Tompsett 1982). There are undoubtedly other genera, still unidentified, with these characteristics.

Placing seeds into these precisely defined groups of storage behavior is often tenuous, however, because recalcitrance is not an all-or-nothing characteristic (Berjak and Pammenter 1996). There is a great deal of natural variation, and species should be viewed as lying somewhere along a spectrum that stretches from extreme orthodoxy to extreme recalcitrance. Furthermore, as technology improves, a species may not be what it was once thought to be. *Fagus* L. was once thought to be recalcitrant, but with carefully controlled drying, seeds of this genus can attain low moisture contents and an extended storage life at subfreezing temperatures (Bonnet-Masimbert and Muller 1975; Suszka 1975) and should now be considered as sub-orthodox in storage behavior.

Seed morphology. Seed morphology is important to the storage life of seeds in the context of protection for the embryo. The hard seedcoats of species of the Leguminosae help maintain the low level of metabolism in these dry orthodox seeds by excluding moisture and oxygen. Hard, thick seedcoats, such as those of *Carya* Nutt., *Cornus* L., and *Nyssa* L., help protect the embryos from mechanical damage during collection and conditioning. The thinner or softer a seedcoat may be, the more likely that the seed has a shorter storage life because of rapid moisture uptake or bruising of internal seed tissues. Thin seedcoats may be a significant factor in storage difficulties of *Acer rubrum* L., *Pinus palustris* P. Mill., and *Populus* L. spp., but there is no direct evidence of this.

Chemical composition. General observations of seed behavior in storage has suggested that chemical composition is an important factor in longevity; for example, oily seeds do not store as well as starchy seeds. One can find support for this concept with the relatively poor performance in storage of *Carya* Nutt. spp., *Juglans* L. spp., and *Sassafras albidum* (Nutt.) Nees, all oily seeds, and the relatively good performance of *Celtis laevigata* Willd., *Fraxinus* L. spp., and *Platanus occidentalis* L., all starchy seeds (Bonner 1971). Exceptions to this rule abound, however. Oily seeds of *Liquidambar styraciflua* L. as well as *Pinus taeda* L., and many other conifers keep very well in proper storage. Within *Quercus* L., acorns of the black oaks, which are somewhat oily with very little carbohydrate, store longer than acorns of the white oaks, which are full of carbohy-

drates and very little lipid. Even among the black oaks, species with the highest lipid contents seem to store better, even though there is no evidence of cause and effect. One must conclude that among a wide range of species there is no compelling argument for gross chemical composition as the critical factor in seed longevity under proper storage conditions. There is some evidence, however, that suggests that the relative concentrations of particular carbohydrates play key roles in desiccation tolerance, a critical property in determining storage behavior of seeds (Lin and Huang 1994). This topic is obviously one that deserves more research.

Seed maturity. Seeds of many orthodox species that are immature when collected (or extracted from fruits) are likely to fare poorly in storage (Stein and others 1974). Experimental evidence has demonstrated this fact for Scots (*Pinus silvestris* L.) (Kardell 1973), loblolly (*P. taed*a L.), longleaf *(P. palustris* P. Mill.), and eastern white *(P. strobus* L.) pines (Bonner 1991). The physiological basis for this effect is not known, but it seems logical that immature seeds have not been able to complete the normal accumulation of storage food reserves, develop all needed enzymes and/or growth regulators, or complete their full morphological development and cell organization. For species with seeds that are naturally dispersed while still physiologically immature, such as *Fraxinus excelsior* L., there is no apparent damage to storage longevity (Willan 1985). The ability to complete maturation naturally after separation from the mother tree has apparently evolved with these species. For conifers like the pines noted above, storage of immature cones for several weeks prior to extraction of the seeds appears to enhance seed maturity and viability retention during storage (Bonner 1991).

Seed Handling Prior to Storage

Poor fruit or seed handling that damages seeds will often lead to reduced viability in storage, especially in orthodox seeds. The most common example of this is impact damage to seeds during extraction and conditioning. Seeds can be bruised by excessive tumbling of cones, running dry dewingers too fast or too full, or poor transport systems (Kamra 1967). During kiln drying of conifers, excessive heat while seed moisture is still high can easily lead to damage that will show up later as reduced vigor and viability in stored seeds (see chapter 3).

Another factor to consider in damage to seeds during extraction and conditioning is cracks or other breaches of the seedcoats that will allow microorganisms to enter. Cracks in seedcoats that occur during seed conditioning are usually not visible to the naked eye but can be detected on radiographs (see chapter 5). This is one reason why hard-seeded legumes are usually not returned to storage after mechanical scarification. An exception to this is when seed burners are used for scarification (Lauridsen and Stubsgaard 1987). Seed burners tend to cauterize the breach in the seedcoat and kill surface contaminants.

Recalcitrant seeds, with their high moisture contents, are potentially very susceptible to damage during handling, but they seldom are subjected to rigorous cleaning or conditioning procedures. Furthermore, the most important group of recalcitrant species in North America—the oaks (*Quercus* L.)—have single-seeded fruits with rather strong outer covering structures and rather well-protected embryonic axes. Silver maple *(Acer saccharinum* L.), on the other hand, has recalcitrant seeds with a large embryo that is protected by a soft and pliable pericarp and is very susceptible to bruising during seed handling.

Storage Environment

Storage environment is obviously very important in extending the life of seeds. The general objective is to reduce the metabolism of the seeds as much as possible without damaging them and to prevent attack by microorganisms. The ideal metabolic rate in storage will conserve as much of the stored food reserves in the seeds as possible, yet operate at a level that maintains the integrity of the embryos.

Moisture. Seed moisture is the most important factor in maintaining viability during storage; it is the primary control of all activities (table 5). Metabolic rates can be minimized by keeping seeds in a dry state. For true orthodox and sub-orthodox seeds, optimum moisture contents for storage are 5 to 10%. The normal practice with all orthodox tree seeds is to dry them to these levels and store them in moisture-proof containers that maintain them at these levels. Moisture in seeds (or any objects) will come to an equilibrium with the moisture in the storage atmosphere based on the differences in the vapor pressures and the chemical nature of the seeds (table 6). Proteins are the most hygroscopic, followed by carbohydrates, then lipids. These differences are reflected in the equilibrium moisture contents (the seed moisture content when equilibrium is reached) of various seeds (figure 1). Starchy seeds have higher equilibrium moisture contents than fatty seeds. For this reason, seed managers should know the dominant chemical constituents of the seeds they are storing.

Recalcitrant seeds equilibrate in a similar fashion, but their naturally high moisture contents and rapid metabolism

make it difficult for a true equilibrium to be reached with the atmospheric moisture. The large differences in chemical makeup of various species of oak lead to large differences in their equilibrium values (figure 2). Because all recalcitrant seeds are stored at high moisture contents, their equilibrium moisture contents are not as important in seed storage management as they are for orthodox seeds.

Temperature. Metabolic rates can also be minimized with low temperatures, both for orthodox and for recalcitrant seeds. The storage moisture content determines just how low temperatures can be set for seed storage. From freezing to –15 °C, 20% is the approximate upper moisture limit. Below –15 °C, the limit is about 15%; and in cryogenic storage in liquid nitrogen (–196 °C), 13% is the limit. Therefore, true orthodox seeds maintained at moisture levels of 5 to 10% can be safely stored at just about any temperature. The longevity of orthodox tree seeds in liquid nitrogen is really not known, but short tests with several species suggest that they can survive for long periods just like orthodox agricultural seeds (table 7). It is not known if sub-orthodox seeds have this same tolerance of low temperatures, but it is known that they can be stored for a few years at temperatures as low as –20 °C (table 2).

Table 5—Chapter 4, Storage of Seeds: potential moisture damage thresholds

Moisture content (%)	Potential effect
> 30	Germination can occur
10–18	Active fungal growth
< 8–9	Insect activity reduced
5–8	Best range for sealed storage
< 5	Desiccation injury possible in some species

Figure 1—Chapter 4, Storage of Seeds: equilibrium moisture contents at 25 °C for 3 orthodox species: American sycamore (*Platanus occidentalis* L.) has the lowest lipid content; sweetgum (*Liquidambar styraciflua* L.) the highest (from Bonner and others 1994; Bonner 1981).

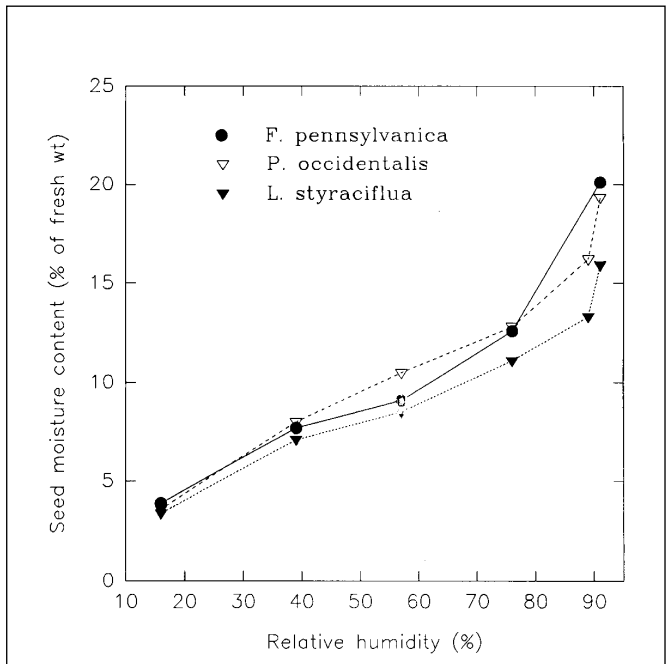

Table 6—Chapter 4, Storage of Seeds: equilibrium moisture content at 4 to 5 °C and 3 relative humidities for some seeds

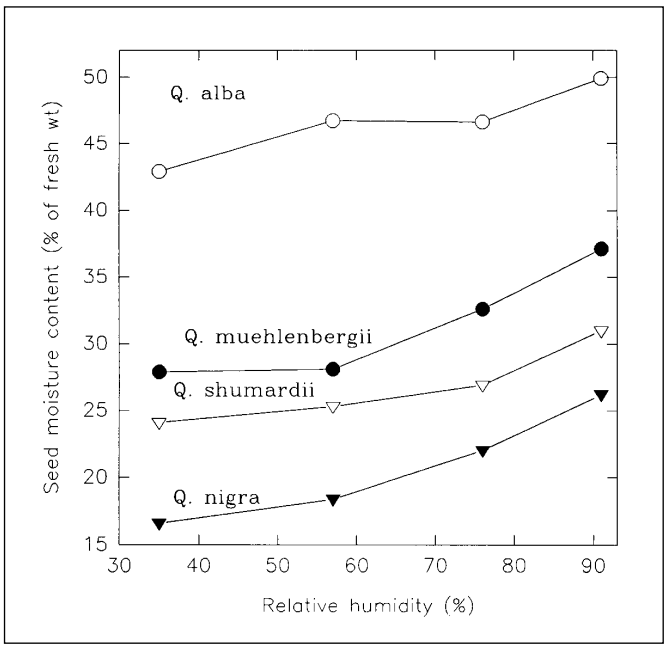
Figure 2 —Chapter 4, Storage of Seeds: equilibrium moisture contents at 25 °C for 4 recalcitrant oak (*Quercus* L.) species. White oak (*Q. alba* L.) has the lowest lipid content; water oak (*Q. nigra* L.) the highest (adapted from Bonner and others 1994).



If seeds have impermeable seedcoats that will inhibit the uptake of moisture and oxygen from the surrounding atmosphere, they can be stored for a number of years at room temperature. The primary examples of such storage come from seeds of the *Leguminosae* (Bonner 1990).

Recalcitrant seeds require different conditions. Temperate recalcitrant seeds can be stored at or just below freezing (–3 °C) (table 3), but lower temperatures for just a few months will kill them (Bonner 1973), apparently due to intracellular ice formation. The lethal exposures for temperate-recalcitrant seeds are poorly defined and appear to be a function of both temperature and length of exposure. On at least one occasion, sub-freezing temperatures for a week killed all *Quercus* acorns that were on the ground or still on the trees in central Louisiana. On the other hand, exposure to sub-freezing temperatures for 3 days on the ground, with a minimum of around –10 °C at night, did not kill acorns of *Quercus pagoda* Raf. in Mississippi (Bonner 1992). This question will require research to provide a satisfactory answer.

Tropical-recalcitrant seeds have a much higher lethal minimum temperature than temperate species. Chilling damage and death will occur below 12 to 20 °C, depending on the species. Among the species included in this book, only certain *Araucaria* Juss. can be considered as tropical-recalcitrant species. Because there are no ice crystals formed at these temperatures, the chilling damage in these seeds must have a different physiological basis than damage in temperate-recalcitrant seeds.

A number of conifer species can be partially redried after stratification and returned to storage when planting is delayed. Seed moisture contents may be over 20% in such cases, so subfreezing temperatures cannot be used. Good results have been obtained by storing stratified seeds of ponderosa pine and Douglas-fir with seed moisture contents of around 26% at 2 °C for 9 months (Danielson and Tanaka 1978).

Atmosphere. Reduction of oxygen levels will slow metabolism and increase longevity of seeds, but it is not practical to regulate this factor precisely in operational storage situations. In past years, seeds of *Populus* L. species were often stored in vacuum desiccators to extend storage life; the beneficial effect in this case was reduction of oxygen for metabolism. (Proper drying and refrigeration have replaced vacuum storage for *Populus* now.) Recalcitrant

seeds, with their active metabolisms, require oxygen to such a degree that it is quickly depleted in airtight storage containers, and the seeds die. Any recalcitrant seeds must be stored in containers that afford free access to the surrounding atmosphere.

There have been extensive trials with storage of seeds in inert gases (Justice and Bass 1978), primarily crop species, but these procedures show no long-term advantage over good standard temperature and moisture conditions. One advantage of gas manipulation may be for transport of seeds in tropical regions where refrigeration may not be available. Success of this nature has been reported for shipment of Monterey pine (*Pinus radiata* D. Don) seeds sealed in atmospheres of nitrogen or carbon dioxide (Shrestha and others 1985).

Carbon dioxide can also be used to kill insect larvae in storage. Dry orthodox seeds can be placed in atmospheres that are 60 to 80% CO_2 for 4 weeks at room temperature to kill larvae. If seed moisture is below 8%, there should be no damage to the seeds for at least several years (Stubsgaard 1992). If there is enough moisture in the seeds to stimulate metabolism, the seeds will absorb the CO_2. In small sample bags, the absorption will collapse the bag around the seeds as if a "heat-shrink" packaging process were in use. This same condition is often observed in plastic bags of seeds in moist stratification.

Storage Facilities

Cold Storage

Facilities for seed storage will vary by the amount of seeds to be stored and the projected length of storage. Small seedlots—a liter (quart) or less—can be stored in household refrigerators and freezers. Larger seedlots and quantities will require a walk-in refrigerator or freezer (figure 3). These units are usually assembled from prefabricated insulated panels and can be made almost any size to fit the owner's needs. A suggested size for a nursery operation is one large enough to hold a 5-years' supply of seeds. The cold storage at the USDA Forest Service's W. W. Ashe Nursery in Brooklyn, Mississippi (figure 3) has a capacity of 1,584 m^3 (52,800 ft^3). One cubic meter will hold from 125 to 140 kg (275 to 310 lb) of seeds. Many orthodox and sub-orthodox seeds show declining germination and vigor after a few years in storage at temperatures just above freezing (Bonner 1991; Zasada and Densmore 1977), so freezers maintained at about –18 to –20 °C are preferred for any storage of sensitive species longer than 3 or 4 months. Because it would be inconvenient to have separate facilities, most users just place all orthodox species in freezers. For reasons discussed earlier, recalcitrant species must be stored at temperatures no lower than –3 °C. It is usually convenient to store recalcitrant seeds in the same facility used for stratification and seedling storage. Short-term storage of any redried stratified seeds as noted earlier should be done here also. All of these facilities should have backup generators and safety alarms in case of power failure.

For cryogenic storage, special tanks must be employed to hold the liquid nitrogen, and special equipment is needed to maintain its level. The tanks (figure 4) in place at the USDA National Seed Storage Laboratory in Fort Collins, CO, each have a capacity of 2,600 to 5,500 samples, depending on the size of the sample container. Samples are stored in sealed glass tubes and suspended above the liquid nitrogen in its vapor (temperature approximately –150 °C).

Containers

Orthodox seeds should be dried to safe moisture contents (5 to 10%) and stored in sealed containers that prohibit absorption of moisture from the atmosphere. The containers used most commonly for tree seeds are fiberboard drums with a thin plastic coating on the inside (figure 5). These drums are available in sizes of about 0.5 and 1.0 hl (1.5 and 3 bu); they hold approximately 25 and 50 kg (55 and 110 lb) of loblolly pine seeds. Any large, rigid container can be used, as long as it can be sealed. The best practice is to insert a polyethylene bag liner for this purpose. It is also a good idea to do this with fiberboard drums, as repeated use of the drums over a number of years will cause breaks in their interior plastic lining. Glass containers, very popular in pre-plastic days, should not be used because of the danger of breakage. If they are used, plastic bags should be inserted to hold the seeds in case the glass is broken.

Figure 3—Chapter 4, Storage of Seeds: a large walk-in refrigerator for seed storage.

Figure 4—Chapter 4, Storage of Seeds: liquid nitrogen tanks for long-term storage of seeds for germplasm conservation at the USDA National Seed Storage Laboratory, Fort Collins, Colorado.

Figure 5—Chapter 4, Storage of Seeds: fiberboard drums that are commonly used for storage of tree seeds.

Small seedlots can be stored in polyethylene bags or bottles (figure 6). All plastic is not the same, however; low-density polyethylene with water vapor transmission rates of 4 g/m^2/day or lower at 25 °C is good for seeds (Lauridsen and others 1992). This requirement is met by polyethylene bags with a wall thickness of 0.075 to 0.1 mm (3 to 4 mils). As temperature is lowered, permeability of these materials decreases (Stubsgaard 1992). The common household freezer bags in the United States meet this thickness requirement, but most sandwich bags do not. Bags thinner than 0.075 mm should not be used, because they are too permeable to moisture vapor. For recalcitrant seeds, maximum bag wall thickness is 0.25 mm (10 mils); thicker plastics can limit gas exchange because they are impermeable to oxygen and carbon dioxide. There is no maximum thickness for orthodox seeds. Seeds with sharp points or appendages, such as *Fraxinus* L., *Taxodium* L.C. Rich, or *Carya* Nutt., can cause problems by piercing the bag walls and allowing moisture to enter. When storing these types of seeds, double bags can be used to reduce the problem. The same steps can be taken when emerging insect larvae from oak acorns eat holes in the bags. Information on vapor transmission rates of other packaging materials can be found in Lauridsen and others (1992).

Figure 6—Chapter 4: Storage of Seeds, polyethylene bags and bottles that are commonly used for storage of small samples of tree seeds.

Moisture Control

Refrigerated storage units can be made with controlled humidity so that orthodox seeds can be stored in unsealed containers without danger of moisture absorption. At the low temperatures usually employed for tree seeds, however, this feature would be very expensive. It is much cheaper to dry the seeds and store them in sealed containers. If recalcitrant seeds are stored in the same facility as orthodox seeds, dehumidification could not be used because of desiccation damage to the recalcitrant seeds. Dehumidification is also a factor when seeds are stored in household refrigerators. Most currently manufactured refrigerators are frost-free, which means that the moisture has been removed from the inside atmosphere. In such units recalcitrant seeds will quickly become desiccated if care is not taken.

Storage Recommendations

Orthodox Seeds

All orthodox seeds should be stored in moisture-proof, sealed containers with seed moisture contents of 5 to 10%.

If the period of storage will be 3 years or less for true orthodox species, or 2 years or less for sub-orthodox species, temperatures of 0 to 5 °C are sufficient. For longer periods of storage for both types of orthodox species, freezers (–18 to –20 °C) should be used.

Temperate-Recalcitrant Seeds

Temperate recalcitrant seeds should be stored with moisture contents at least as high as that present when the mature seeds were shed from the tree. (Refer to genus chapters in this manual for information on individual species.) This moisture level must be maintained throughout storage, which may require occasional rewetting of the seeds. Temperatures should range from 0 to 5 °C, although 1 or 2 degrees below freezing will not harm most species. Containers should be basically impermeable to moisture loss, but must allow some gas exchange with the atmosphere. Polyethylene bags with a wall thickness of 0.075 to 1.0 mm (3 to 7 mils) are suitable. Some oak acorns can be stored for 3 years in this fashion (table 3), but some viability will be lost. For other recalcitrant species, few data are available.

Tropical-Recalcitrant Seeds

Storage of tropical recalcitrant seeds is done in the same manner as storage of temperate species, except that temperatures must be kept at a high level. There are differences among species but the lower limits are generally 12 to 20 °C. Successful storage for more than 1 year should not be expected.

Cryogenic Storage

For long-term germplasm conservation programs, true orthodox and sub-orthodox seeds can be dried to moisture contents of 5 to 10% and stored in liquid nitrogen. Such programs require special equipment and procedures and are beyond the scope of this book.

Other Management Considerations

The first step in planning for seed storage facilities or programs is to consider the objectives of storage. If storage is only needed for periods of 6 to 30 months, freezers may not be needed. If storage will be for longer periods, then at least some freezer capacity will be needed. If recalcitrant seeds will make up the bulk of the stored materials, then freezers will not be needed. If seeds and seedlings will be stored in the same facility, then space requirements will be very large. Overestimating storage needs can be a problem, but underestimating them is an even bigger one.

Germination should be retested on seedlots that will be stored for more than 5 years. After the initial test, tests should be carried out after 3 years and every fifth year thereafter. Seed vigor will decline before germination percentage (Hampton and TeKrony 1995), so tests on stored seedlots should include some measure of vigor or germination rate (see chapter 5). When total germination has declined 15% from its original level, plans should be made to use the seeds as soon as possible.

In long-term storage for germplasm conservation, genetic damage or shifts are always a consideration. A few studies have demonstrated some chromosome damage during storage of tree seeds of the following species: *Fraxinus americana* L. (Villiers 1974), *Pinus echinata* P. Mill (Barnett and Vozzo 1985), and *P. sylvestris* L. (Simak 1966). There is no evidence yet, however, that these aberrations cause damage that is transmitted to the next generation. While more research should be done on this question, especially in seeds stored cryogenically, there seems to be no cause for alarm.

Introduction

Seed testing is the cornerstone of all other seed technologies. It is the means by which we measure the viability and all the physical factors that regulate the use and maintenance of seeds. Everything that is done with seeds should have some test information to guide the work and ensure high quality. Seed tests tell if a crop of seeds is worth collecting, if handling procedures are correct, and how many potential seedlings are available for regeneration.

The earliest form of seed analysis, the cut test, is still often used today. Before seeds are collected in the field, some seeds are cut open with a knife or razor blade to see if their internal tissues are fully developed and undamaged. This analysis is made more accurate in some cases by the use of a hand lens. It is also used for simple analysis during extraction and cleaning, or after germination to determine if the ungerminated seeds have deteriorated or remained dormant. Although the cut test is often very good at producing some information quickly, it is limited in the amount of information it can supply and it lacks accuracy compared to more sophisticated procedures. Therefore, it should never be taken as a substitute for a formal laboratory analysis.

Sampling

Formal seed analysis begins with the sampling of the seedlot. The Rules for Testing Seeds (AOSA 1996) and the International Seed Testing Rules (ISTA 1996) both give instructions on how to draw samples from a seedlot so that the sample is representative of the entire seedlot. Representative means that any tests conducted on this sample will accurately estimate the mean value of the lot quality.

Sampling can be done with the hand or with a seed probe, also known as a trier (figure 1). If a probe is used, it must be long enough to reach to the farthest edge of the container. A probe has gates that prevent seeds from entering until the probe is inserted the full dimension of the container. The probe should be inserted into the seed container with these gates closed. Otherwise, seeds from the upper layers will fill the probe as it is inserted and the bottom layers will not be sampled. Once the tip reaches the bottom or far side of the container, the gates should be opened and the probe gently turned back and forth to help the seeds fall in. Then the gates should be closed gently, not forced, so that any seeds that are caught in the opening and are preventing the gates from closing fully (figure 2) are not crushed. (Mechanically damaged seeds would bias the sample.) After the probe has been withdrawn from the seed container, it should be held horizontally, with the gates facing upward. Then the gates should be opened gently and the probe shaken gently back and forth, so that seeds caught in the gates will slip down into the probe and the gates can be safely closed. Finally, the probe should be emptied by pouring the seeds out the top of the probe and into a second container (figure 3). This sample is the first primary sample.

If there is only 1 container, primary samples should be taken until there are 5 of them. When more than 1 container holds the seedlot, at least some of the other containers must be sampled. When there are between 1 and 5 containers, all containers should be sampled, at least 1 probe from each container. When there are more than 5 containers, 5 of the containers plus 10% of the remaining ones should be sampled. It is never necessary to sample more than 30 containers. (It would be rare that a forest seedlot would need 30 containers or more, or possibly even 20.) All of the primary samples are then placed together to make up the composite sample.

Sampling by hand is sometimes necessary when the seeds will not flow into the probe because of their size, shape, or surface texture. Sampling by hand can be done by inserting the open hand (figure 4) into the seeds, closing it once the point of sampling is reached, and then withdrawing it closed. The seeds are then placed in a second container to form the composite sample, just as in sampling with the probe. At least 5 handfuls must be taken, and all levels must be sampled. When the hand cannot be inserted into the seedlot, the seeds can be poured from one container into a second. The tester then should stop at a minimum of 5 evenly spaced intervals and remove a handful of the seeds for the composite sample.

The composite sample, whether taken with a probe or by hand, is usually too large to submit to a seed laboratory for analysis. The composite sample is, therefore, mixed and divided to obtain a submitted sample. This procedure is very important and must be done correctly for the results to be accurate.

The composite sample can be mixed either mechanically or by hand with rulers. Hand-mixing the composite sample is done by pouring the seeds into a cone on a flat, clean surface. An open file folder makes a good work surface that can be picked up to return the seeds to a container. With one ruler held stationary against the seeds, the second ruler is used to pull the outer edge of the pile up to the top of the pile, allowing the seeds to roll down the sides and over the top of the stationary ruler (figure 5). The full pile is thoroughly turned over and all layers mixed together. This procedure should be repeated for 1 full minute. Then the pile should be divided by cutting the cone in half and then into

Figure 1—Chapter 5, Seed Testing: seed probes are used to sample free-flowing seeds.

Figure 2—Chapter 5, Seed Testing: seeds caught in the gates of the seed probe must not be cut when the gates are closed.

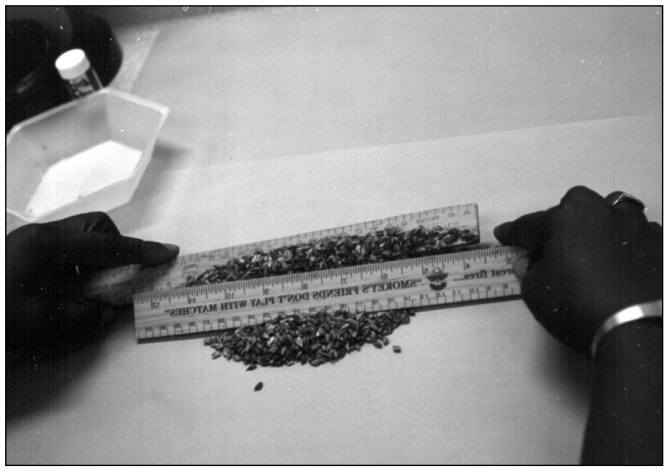
quarters. The quarter is then weighed to see if it is enough for the sample. If not, then another quarter, an eighth, or a smaller fraction is taken until the minimum weight is obtained (figure 6).

Hand-mixing can be replaced by mixing with either a soil divider or a gamet divider (figure 7). These devices can save a substantial amount of time and also, by reducing the tedious nature of the work, increase the likelihood of doing a quality job. The seedlot needs to be poured through the divider 3 times. When the gamet divider is used, the motor must not be turned on until the seeds have been poured completely into the hopper. Once the seeds are cleared out of the machine, the motor must be turned off before the seeds are poured back into the hopper for the next pass. The seedlot is then divided in half, then quarters, eighths, and so forth, to obtain the correct weight for the submitted sample, just as in the hand mixing and dividing.

The size of the submitted sample for some species is stated in the Rules for Testing Seeds (AOSA 1996) and is twice as large as the minimum amount for the purity test.

This amount is different for each species and the rules need to be consulted to be sure the correct amount is submitted for purity tests that are to be done according to the rules. A smaller sample of seeds can be submitted, but the test will not be according to the rules and the accuracy cannot be assured to the same degree as a test that is done according to the rules. If a species is not listed in the rules, an amount that contains 2,500 seeds should be taken. This amount can be estimated by counting out 100 seeds and multiplying their weight by 25. Under the AOSA rules, samples can be as small as 600 seeds when only germination is tested. It is important to work quickly when drawing the sample, if the submitted sample is to be tested for moisture content. This will prevent the gain or loss of moisture from the air. Once obtained, the submitted sample should be put in a moisture-proof container to maintain its true moisture content until it is sampled and tested at the laboratory. Plastic bottles with tight-fitting lids or tightly closed plastic bags of at least 0.1 mm (4 mil) thickness are adequate. Metal containers can be used but are harder to find. Glass containers should not be used; they easily break in transport, allowing the samples to be exposed to the air or, worse, mixed together.

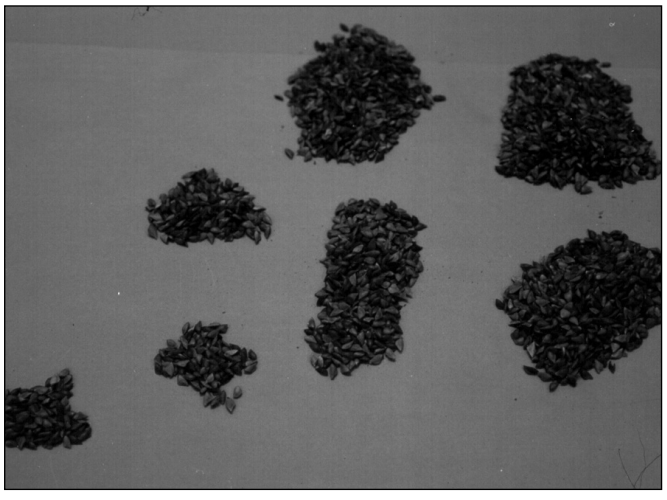
Figure 5—Chapter 5, Seed Testing: seed can be hand-mixed before withdrawing a submitted sample from a composite sample.



Sample Identification

Assignment of a test number is the first step in handling every seedlot that is received in the laboratory. This number allows for the orderly tracking of the test sample among the other samples in the laboratory. A typical test number indicates the test year and an accession number. For example, the 300th test conducted in 2005 would have a number such as 05-300.

Figure 6—Chapter 5, Seed Testing: the composite sample is divided systematically into quarters, eighths, sixteenths, and smaller fractions to obtain the submitted sample at the seed storage plant or the working sample in the laboratory.



Moisture Tests

Moisture tests must be the first tests conducted on samples when they arrive at the seed laboratory. Once a sample container is opened and work begun, the seeds will likely

Figure 7—Chapter 5, Seed Testing: a soil divider (**left**) and a gamet divider (**right**), devices that systematically mix and divide seed samples.

gain or lose moisture in exchange with the ambient air. The standardized laboratory test for moisture content is the oven method (ISTA 1996). This procedure was determined, after many years of research, to be a best estimate of moisture for general testing work (Bonner 1972, 1981, 1984, 1992; Buszewicz 1962; Hart and Golumbic 1966). This test is made on 2 subsamples containing 3 to 5 g of whole seeds. These 2 samples are placed in containers with lids and weighed to determine the wet weight (figure 8). Then they are placed in a forced-draft drying oven (figure 9) for 16 to 18 hours at 105 ± 2 °C. The lids are removed during drying but are also placed in the oven. The samples are then placed in a desiccator to cool for about 20 minutes before being weighed a second time to determine their dry weight. The lids are placed on the cans while cooling and weighing. The loss of weight represents the weight of water in the undried sample. This water weight is divided by the wet weight to obtain the percentage moisture content on a wet-weight basis. The percentage moisture is expressed on a wet-weight basis because this value most accurately represents how much of the seedlot is water. Therefore, the buyer knows the weight of seeds and the weight of water that are purchased. For example, when the price per weight is the same, a pound of seeds at 7% moisture content is a better value than a pound of seeds at 9% moisture content. For example, a 100-kg seedlot (or a 100-lb seedlot) at 7% moisture contains 93 kg of seeds, whereas the lot at 9% moisture contains 91 kg of totally dry seeds, 2 kg less.

Figure 8—Chapter 5, Seed Testing: 2 seed samples are tested to measure the moisture content of a seedlot.

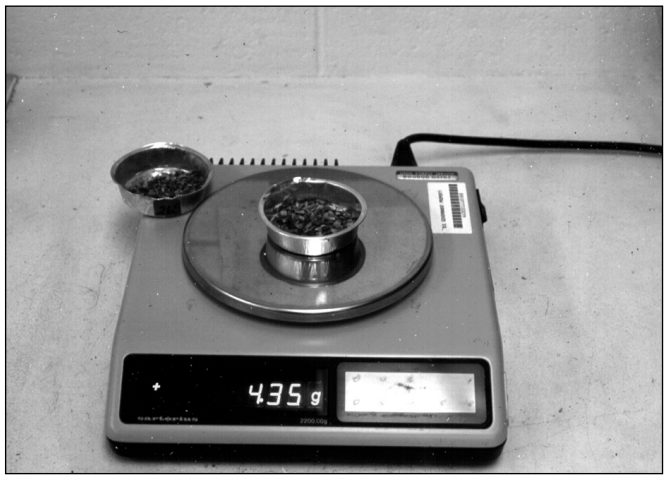


Figure 9—Chapter 5, Seed Testing: a convection oven and desiccator are used to conduct a seed moisture test.

Some larger seeds and seeds with impermeable seedcoats need to be cut to make an accurate test (Bonner 1974, 1981, 1992). If the seed is not cut open, the moisture is not freely released, and the moisture content is underestimated (figure 10).

The oven method is not a direct measure of the content of water. It measures weight loss that is assumed to be due to the loss of water. A basic analytical procedure is required to verify the temperatures and length of drying. The currently accepted procedure is the Karl Fisher procedure (figure 11) (Hart and Golumbic 1962). The moisture committee of the ISTA uses this procedure in its work to standardize and validate the oven procedures.

Another widely used method to measure seed moisture is the electronic moisture meter. Although there are numerous brands of electronic moisture meters on the market, not all of them will work for tree and shrub seeds (figure 12), and those that do will not have calibrations for tree seeds. Therefore, conversion charts must be developed for them by testing samples with high to low moisture contents with both the meter and the oven. A linear regression between the oven and meter readings is calculated, and the conversion chart predicted from this regression (Bonner 1981; Hart and Golumbic 1966; Jones 1960; Karrfalt 1987; Lanquist 1965). These meters provide quick results, are nondestructive to the seed, and are usually accurate to within ±1% of the moisture estimated by the oven method.

Figure 10—Chapter 5, Seed Testing: cutting large seeds open before drying them in the moisture test is necessary to release all the moisture.

Figure 11—Chapter 5, Seed Testing: the Karl Fisher apparatus is used as the analytical standard for determining seed moisture content.

Purity, Noxious Weed Content, and Seed Weight Tests

Purity, noxious weed content, and seed weight tests are sometimes called physical tests because they do not relate to viability. These tests are described individually as follows.

Purity Analysis

After samples for the moisture-content test are withdrawn, the remainder of the submitted sample should be mixed and divided to obtain the working sample, which

Figure 12—Chapter 5, Seed Testing: electronic moisture testers can give a quick and reasonably accurate estimate of seed moisture.

contains the minimum weight for conducting a purity analysis. Each species has its own specified minimum weight, which has been determined to contain 2,500 seeds. The mixing and dividing should be done in the same way as described in the sampling section for drawing the submitted sample from the composite sample. However, at this point it is necessary to be very close to the minimum weight for 2 reasons. First, the analyst does not want to examine more seeds than necessary, and second, the accuracy of the test is evaluated using tolerance tables that were developed using these minimum weights. Using substantially more seeds than the minimum will invalidate the use of these tables.

Purity is determined differently by each of the 2 major testing organizations. The ISTA rules specify a 3-part purity and the AOSA rules specify a 4-part purity. The ISTA purity values report percentages of pure seeds, other seeds, and inert materials. The AOSA purity values report percentages of pure seeds, weed seeds, other crop seeds, and inert materials. The pure-seed fraction consists of all those seeds that are of the kind specified on the seedlot's label. Specific descriptions in the rules define "pure seeds," but basically the pure-seed fraction comprises whole seeds and seeds that are not more than half broken away. "Other seeds" in the ISTA rule are all kinds of seeds other than those listed on the label. The AOSA rule makes a distinction between "crop seeds" and "weed seeds" and uses a detailed list (AOSA 1995) to specify when a species is a weed and when it is a crop. Weed seeds are mainly a problem in lots collected from nets or directly from the ground. Contaminated cleaning equipment can also result in weed seeds entering a seed-

lot. “Inert matter” is all other material that is not classified as crop seeds or other seeds. It could include soil particles, stones, wire, small pieces of broken seeds, or other plant parts. Purity is calculated by dividing the weight of the of pure seeds by the total weight of all the fractions in the sample (figure 13) and is expressed as a percentage.

Purity work can often be tedious and very technical. Devices such as the mechanical purity board (figure 14) can speed up the procedure. The analyst must understand important taxonomy principles and accurately use the seed herbarium (figure 15) to identify all the kinds of seeds in the sample.

Noxious Weed Examination

The noxious weed exam is a specialized purity examination. It is not a test traditionally associated with forest seeds but may become more common as the commercial exchange of native plants increases. A noxious weed is a highly aggressive competitor or a plant with other highly objectionable characteristics, such as being poisonous. It is so offensive it has been put on a noxious weed list compiled by an individual state or the federal government. A noxious weed exam is made solely to identify the number of noxious weed seeds found in the sample. Nothing else is noted in this exam. The presence of any noxious weed seeds makes it illegal to sell the seeds until the noxious weeds have been removed. The sample size for a noxious weed examination is 25,000 seeds.

Seed Weight Determination

The number of seeds per unit weight (kilogram and gram or pound and ounce) is determined on the pure-seed fraction from the purity test. This test is called the seed weight determination in the ISTA rules. It is made by counting out 8 replicates of 100 seeds and weighing them to the same precision as the weights for the purity test. The coefficient of variation for these 8 values is computed. This coefficient cannot be greater than 6 for chaffy seeds or greater than 4 for all other seeds. Otherwise, an additional 8 replications need to be counted and weighed and combined with the first 8 weights. All 16 weights are then used to compute the mean. Any weight diverging from the mean by more than 2 standard deviations is discarded; only the remaining weights are used to compute the number of seeds per unit weight.

Seeds can be counted by hand, with a counting tray, a shutter box, or a vacuum counter (figure 16). When seeds are counted by hand, it is usually best to count out the appropriate number of piles of 10, 20, or 50 seeds, in order not to lose one’s place. A counting tray is simply a block of wood

Figure 13—Chapter 5, Seed Testing: a purity sample is divided into its component parts.

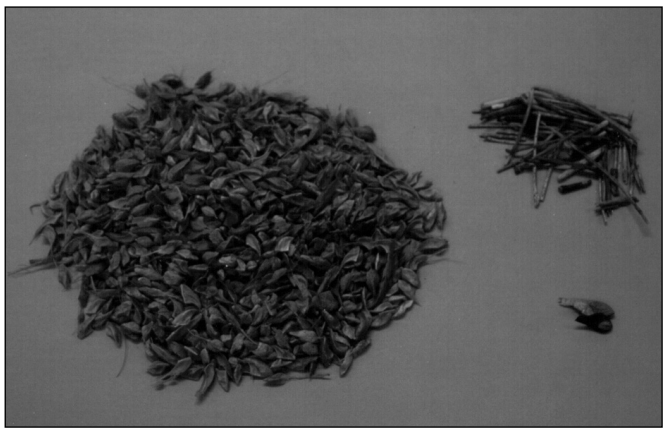

Figure 14—Chapter 5, Seed Testing: a mechanical purity board can reduce the time required to conduct a purity analysis.

Figure 15—Chapter 5, Seed Testing: seed herbaria are used to make positive identification of the species of seed tested.

or plastic with impressions drilled into it to hold the seeds as they are poured across the plate. The counting tray may or may not be faster than counting by hand, depending on the seeds' size and shape, which determine how many double- or triple-seeded holes must be thinned by hand. Using the shutter tray is similar to using the counting tray, but the shutter tray is emptied by sliding the bottom tray rather than turning it over. For uniformly sized seeds, using either the counting tray or the shutter tray can speed up counting considerably.

The vacuum counter is probably the fastest and one of the most common ways to count seeds in the laboratory. The vacuum counter is made of an acrylic (or sometimes metal) plate that is drilled with 25, 50, or 100 holes and attached to a hollowed-out second plate. A vacuum line is attached to the head and a shut-off valve controls the application of the vacuum. To use the vacuum counter, the seeds are spread out loosely in a 1-seed-deep layer, the counter is placed on top of the seeds, and the vacuum is then turned on. Moving the counting head back and forth for about the diameter of a seed will bring the seeds into contact with a vacant hole. With the vacuum still on, the seeds can be transferred to a dish for weighing or to a germination container (figure 17). Some users of vacuum counters report a tendency for lighter seeds, such as empty or partially filled seeds, to be picked up in preference to heavier seeds. To eliminate this problem, this device must be used according to the procedure described above.

Seed weights are sometimes determined with an electronic counter (figure 18). The ISTA rule calls for counting all pure seeds in the working sample when this is done. No error-check is then made. A recent internal report made by the Seed Count Committee of the Association of Official Seed Analysts, augmented by the author's personal observations, suggests caution in the use of electronic counters for seed weight determinations. A high potential for error in counts exists. If carefully calibrated, these machines can count quite accurately, but the machines need to be adjusted and used correctly. A thorough evaluation of the degree of desired accuracy and the amount of time required to achieve it needs to be made before deciding to use the electronic counter.

Germination Testing

Germination testing is designed to estimate the maximum number of seeds that will produce a normal seedling and to give results that are as repeatable as possible. Without uniform procedures, there would be no standard on which to base the value of seedlots for commercial transactions and the seed trade would be chaotic and filled with dispute. Germination also tells a grower about a seedlot's potential. A seedlot with 80% germination cannot produce more than 80 seedlings per 100 seeds. Therefore, if 100 seedlings are needed, a minimum of 125 seeds must be planted (100/0.80 = 125). How to use test data to compute sowing rates is presented in detail in chapter 7 (Nursery Practices) and later in this chapter in the section on the use of test data.

Figure 16—Chapter 5, Seed Testing: seeds can be counted sometimes more quickly using a counting tray, a shutter box, or a vacuum counter.

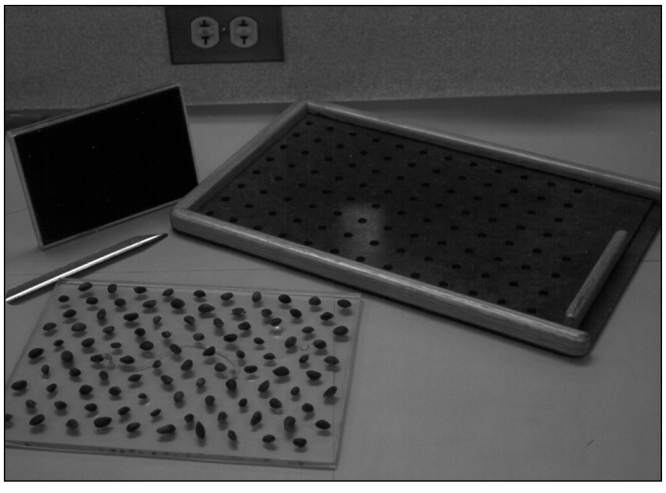

Figure 17—Chapter 5, Seed Testing: a vacuum counter is often used to count out seeds for weight determinations and for planting germination tests

The germination test is conducted on the pure-seed fraction from the purity test. Both the AOSA and ISTA prescribe the use of 4 replications of 100 seeds. These replications can either be planted 1 to a container (figure 19), 2 to a container, or all on 1 tray. Alternatively, the 4 replications can be further divided into smaller replications, but the total number of seeds tested must remain 400 to remain in compliance with the rules. If fewer than 400 seeds are available, then the number of seeds per replication should be reduced so that an equal number of seeds is present in each of the 4 replications. Using fewer than 100 seeds in a replication is not according to the rules, and the test would thus be unofficial. However, it is better statistically to have 4 replications of 50 seeds each rather than 2 replications of 100 seeds each. The 4 replications are then placed under optimal germination conditions for the period specified in the rules. Germination is the number of normal seedlings produced from 100 pure seeds expressed as a percentage. A normal seedling has all the essential plant structures necessary for the plant to continue to grow normally under favorable conditions (AOSA 1996; ISTA 1996).

Seeds can be planted in a number of ways. They can be scattered or placed one at a time with forceps, although more generally a vacuum counter or other type of planting plate is used for speed and to ensure even spacing of the seeds. The vacuum counter is the most expedient technique, because it can handle a variety of seed sizes (figure 17). Counting devices are described in the seed weight discussion above. Seeds should be hand-planted only when counting devices cannot be used in order to save time.

Seeds can be germinated on various media. Sand, sand and perlite mixtures, potting mixtures, soil, and various papers—blue blotters, white blotters, or crepe-cellulose papers (such as Kimpak®)—can be used (figure 20). Testing rules, however, specify what is an acceptable medium for the kinds of seeds tested. Specifying the medium helps assure uniformity in test results. The blotters resist penetration by the roots of the plants, whereas the crepe-cellulose paper allows for root penetration. Blotters offer the advantage of keeping the roots where the analyst can actually see them for evaluation, but if a seedling is very large it will fall over and tangle with other seedlings, making counts difficult. The media also differ in their water-holding ability. Blotters usually need to be watered several times during the test, whereas crepe-cellulose paper, sand, sand mixtures, potting soils, and soil are absorbent enough to hold all the water the seeds need for up to 3 months, if kept in a moisture-proof container. Watering the medium can be done by hand or by machine. Watering by hand is usually done using a squeeze bottle or a small hose from the tap and requires subjectivity on the analyst's part to estimate that the correct amount of water has been applied. Too much or too little is harmful, but in most cases there is wide latitude in the amount that will give optimal results (Belcher 1975).

Figure 18—Chapter 5, Seed Testing: an electronic seed counter is sometimes used to estimate the number of seeds per weight (in either kilograms or pounds).

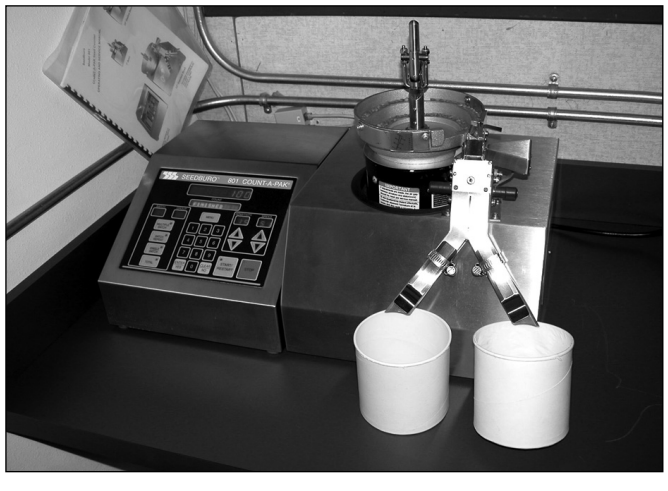

Figure 19—Chapter 5, Seed Testing: 2 germination tests, each composed of 4 dishes containing 100 seeds each, the dishes are stacked for transport and prechilling.

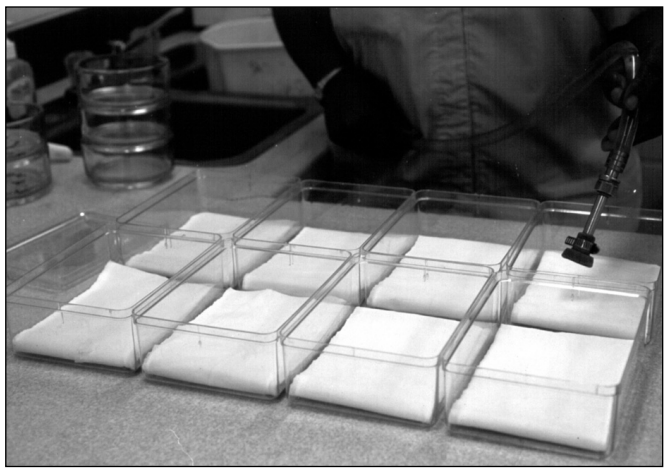
Machines for watering include automatic pipetting machines (figure 21) or small traveling spray booms. Both save a great amount of time if many tests are conducted and, once adjusted, take all the guesswork out of applying the correct amount. These machines should be checked periodically, however, to verify that they are in fact applying the desired amount of water.

Germination tests should be run in cabinets or rooms that meet exacting requirements for temperature and light control in order to make accurate and repeatable estimates. Temperatures should be carefully checked throughout the chamber at the level of the substrate to be sure there are no places that deviate from the desired temperature by more than 1 °C. Poor air circulation and hot spots from lights or light ballasts are the most common causes of temperatures that are too high or too low. The temperature at which the germination chamber is set depends on the species being tested. Many species do well at an alternating 20 and 30 °C. For this regime, the chamber is held for 16 hours at 20 °C and for the remaining 8 hours of the day at 30 °C. Other possibilities are constant temperatures of 15, 20, or 22 °C, with light usually supplied for either 8 or 16 hours. When temperatures alternate, the light is provided during the higher temperature to follow a natural cycle of light and temperature. Sources of light need to contain abundant amounts of blue and/or red light but not far-red light because far-red light is known to inhibit germination. Cool white flourescent lamps are most commonly used. The temperature/light regime used for a germination test is determined by experiments that germinate the same seedlot at different temperature/light combinations. The combination that supports the highest percentage of germination in the most reasonable time is the one that is then adopted in the rules for testing.

Dormancy is the condition of a seed that prevents it from germinating when it is placed in conditions that are favorable for germination. (For a discussion of dormancy, see chapter 1.) Dormancy must be overcome in order to conduct the germination test, just as when trying to grow seedlings. Pre-germination chilling (commonly called "prechilling" and traditionally called "stratification") is the procedure most used for breaking dormancy in forest seeds. The seeds are held in moist conditions at temperatures between 0 and 3 °C. Pre-germination chilling can be accomplished in 1 of 3 basic ways. In the first, the seeds can be planted on moistened germination medium in sealed containers and then put in the cold. In the second, the seeds can be placed in a moist medium, placed in the cold, and then at the end of the prechilling period, planted on the germination medium. In the third method (similar to the second), the seeds are soaked for 16 to 48 hours in water to become fully imbibed, placed in a moisture-proof container, held in the cold for the specified period, and then planted on the germination medium. This last procedure is sometimes called naked stratification, because no moisture-holding medium is used (figure 22). How long seeds are held in prechill varies widely by species and genetic source of the seedlot. The period can range from 10 days to many months. For some species, a warm period preceding the cold period is required. This is called "warm stratification" or "warm incubation." Western white pine (*Pinus monticola* Dougl. ex D. Don) (Anderson and Wilson 1966) and European ash (*Fraxinus excelsior* L.) (Piotto 1994) have been reported as requiring this warm-cold stratification .

Figure 20—Chapter 5, Seed Testing: seeds are germinated on various media, from right to left: crepe-cellulose paper (such as Kimpak®), blue blotters, sand–perlite mixtures, and potting soil.

Figure 21—Chapter 5, Seed Testing: an automatic pipetting machine can help to uniformly and rapidly water germination dishes.



A species that does not require prechilling is called nondormant. If 10 to 14 days of prechilling are needed, the dormancy would be considered light. If 30 to 60 days of prechilling are required to break the dormancy, it would be considered moderate. More than 60 days of prechilling classifies the seedlot as highly or strongly dormant. The degree of dormancy varies within the seedlot of even lightly dormant species; some seeds germinate without prechilling, whereas other seeds in the same lot will not germinate until they are prechilled. However, the term variable dormancy is usually reserved for seedlots in which some seeds germinate during prechilling, whereas other seeds in the same lot will not germinate even after being placed in favorable germination conditions. Species that fit the deep and variable dormancy category are Rocky Mountain juniper (*Juniperius scopulorum* Sarg.) and basswood (*Tilia americana* L.).

Because of the above-mentioned variation in dormancy, seedlots will often be tested with and without prechilling or with varying lengths of prechilling. Such tests are referred to as paired or double tests; usually only 2 tests are done. More tests, of course, can be and are done with some seedlots. This type of testing can determine the presence of dormancy, the strength of dormancy, or a weakness in the seeds (Belcher 1995). When the seedlot has the same germination with and without prechilling, it is said to be nondormant. When the germination is increased with prechilling, the seedlot is classified as dormant; the longer the prechilling period needed, the stronger the dormancy is said to be. A decrease in germination with prechilling is an indication of weakness in the seeds. This last condition is similar to the situation of the type of vigor test known as the cold test, which is described in the following section.

Prechilling is not the only treatment to break dormancy. Light is useful to break dormancy and can reduce the need for prechilling. Birches (*Betula* L.) and loblolly pine (*Pinus taeda* L.) are prime examples where light helps break dormancy. Seedcoat dormancy is treated by scarifying the seedcoat with either acid, bleach or mechanical means. Chemical stimulates such as gibberellins or potassium nitrate have been little used with forest tree seeds.

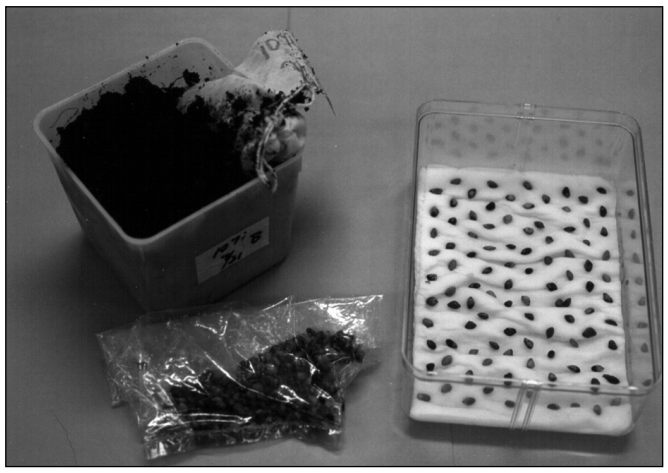
Vigor Testing

Sometimes standardized laboratory germination procedures are criticized as not predicting field performance very well (Moreno 1985; Stein 1967). These critics suggest using a variety of test conditions to find an optimum for each seedlot. The problem in predicting field germination is that it is impossible to predict the weather with the necessary precision. Vigor testing is one possible solution. The vigor test does not predict performance for a particular set of fluctuations; rather, it predicts the general ability of a seedlot to germinate normally over a range of adverse conditions. Its purpose is to differentiate seedlots, with essentially equal germination, according to their ability to germinate well in spite of adversity. Figure 23 illustrates the relationship between vigor and germination. As seeds age and begin to weaken and die, vigor declines before germination test results decline (Belcher 1978; Justice and Bass 1978).

Like germination tests, vigor tests are conducted under standardized conditions in order for the results to be repeatable and useful in the field. A vigor test cannot make up for poor practices that unnecessarily increase environmental variation in the field; such poor practices can be major sources of disparity between laboratory and field germination. Uniform sowing depth and watering, as well as sowing only on soil at the minimum acceptable soil temperature—all help make field germination more predictable.

The most common vigor tests in agriculture are the cold test, the accelerated aging test, the conductivity test, and the tetrazolium test. These 4 tests have not been used very much for forestry. In addition to these tests, speed of germination as expressed in a number of formulas has been put forward for use in forestry as a vigor test. Despite the potential benefit for tree seed nurseries, the science and technology are not advanced enough to permit the practical application of vigor testing with forest species.

Figure 22—Chapter 5, Seed Testing: seeds can be prechilled on a germination medium, in separate medium, or in a plastic bag.



The cold test is done by planting seeds in damp soil and then holding the germination tray at 10 °C for 7 days. This test mimics the cool damp conditions of soil in early spring. At the end of the period, the germination trays are transferred to the appropriate temperature for germination. The higher the percentage of germination, the more vigorous the seedlot is said to be. High-germinating lots have the needed strength or vigor to pass the period of stress and still have energy for high germination when conditions are favorable. This is analogous to the case of the tree seedlot that drops in germination following prechilling. Those that drop in germination after prechilling are weak.

The accelerated aging test is conducted with the stress of high temperature and moisture. The given weight of seeds is placed in a small box with a screen tray that suspends the seeds over a reservoir of water (figure 24). These boxes are then placed in an aging chamber at 40 to 43 °C for 72 to 288 hours, depending on the species. Whichever temperature is chosen in this range, the variation must be virtually nil to ensure repeatability of the results. The water-jacketed incubator has been determined by organized tests among laboratories to be the best device to give this necessary strong control over the test conditions. At the end of the period, the seeds are planted and tested for germination under the standard conditions.

The electrical conductivity test has been widely tested in agriculture but has not been adopted as routine practice except in a few specialized areas. In this procedure, seeds are soaked individually or in bulk. Deteriorated or dead seeds leak electrolytes more readily than high-vigor seeds. This greater leakage causes the water to have a higher conductivity, which can be measured with a conductivity meter (figure 25). Bonner and Agmata-Paliwal (1992) reported on the use of conductivity for tree seeds and found that results have poor repeatability for precise estimates but possibly would work for general estimates of classes as poor, low, intermediate, or high viability.

Several statistics have been put forward to use speed of germination as an indicator of vigor. The faster a seedlot completes germination or reaches its peak, the more vigorous it is said to be. The simplest indicator is days to 90% of total. For example, if the final germination is 88%, the indicator would be how many days it takes to reach 79% germination. A lot that reaches 79% in 12 days would be more vigorous than one that takes 16 days. To use this statistic, counts must be made quite frequently, even daily, or the data must be interpolated to determine the number of days to the specified germination.

Czabator's factor (1962), developed for use with southern pines, combines the maximum daily average germination, called the peak value, and the average daily germination at the end of the test to form one statistic called the germination value. Germination is counted frequently, at least every third day, and the cumulative germination on each day is divided by the number of days that the test has been run in order to compute the mean daily germination for that day. For example, if on day 22 the cumulative germination is 88, the mean daily germination is 4. This mean

Figure 23—Chapter 5, Seed Testing: as seed viability decreases, the proportion of live low-vigor seeds increases.

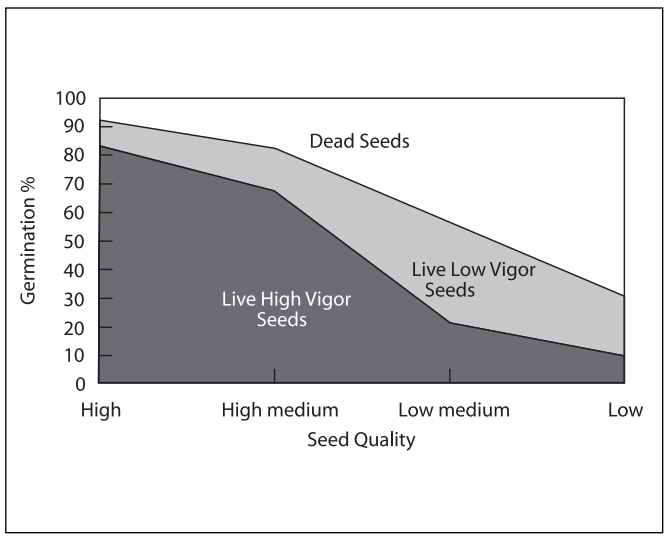


Figure 24—Chapter 5, Seed Testing: the accelerated aging test is conducted by placing seeds in a plastic box with a water reservoir and holding them at 40 °C for 72 hours.

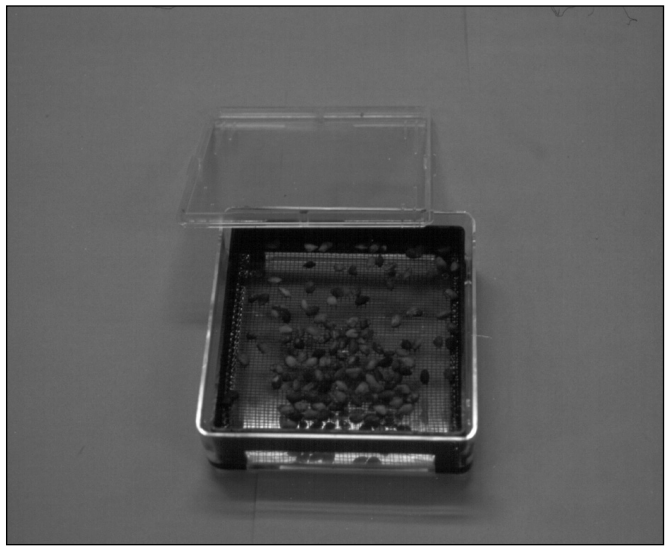

daily germination increases with each day of germination until the period of maximum germination has ended and then decreases. The largest value of the mean daily germination is called the peak value. Figure 26 shows a graph of a typical germination. Initially only a few seeds germinate, followed by a period of rapid progress, and finally a slow-down period and an end of germination altogether. Germination value is computed by multiplying the peak value by the mean daily germination. Lots that have higher germination values are generally considered more vigorous.

Another characteristic of more vigorous lots is that they store for longer periods of time without loss of germination. Therefore, if 2 seedlots have equal germinations, the one with the lower vigor might be considered for first use, because the germination of this lot will likely decrease faster than the lot with higher vigor. This approach would give the greatest potential number of seedlings. Lower vigor seedlots will loose viability even under ideal conditions in the freezer.

Tetrazolium staining has been tried also as a vigor test (Moore 1976). Because of the highly subjective nature of this test and the great amount of experience it requires to administer, it has never been widely used as a vigor test and never successfully with forest plants. As stated in the next section, tetrazolium staining can be used to successfully estimate viability for very dormant species or for other hard-to-germinate species.

The problem with vigor analysis is that it has proven to be difficult to standardize, apparently because the test conditions are so exacting. In tests involving germination, the temperature must be very tightly controlled. Just a degree or two difference in temperature can change the speed of germination, effecting the value of those statistics that rely on germination speed. The accelerated aging test was difficult to standardize until chambers were developed that had virtually no variation in temperature. Difficulty in standardizing laboratory tests and the lack of clear and consistent interpretation to the field has prevented the operational use of vigor testing.

For a more complete list of literature references and a detailed explanation of the vigor testing procedures, refer to the Association of Official Seed Analysts' Seed Vigor Testing Handbook (AOSA 1983) and the International Seed Testing Association's Handbook of Vigour Test Methods (ISTA 1995). Bonner (1998) has also made a thorough review of vigor testing specifically for tree seeds.

Chemical Staining for Viability

The tetrazolium staining procedure mentioned in the vigor section is useful in estimating the viability of dormant seeds, especially very dormant ones. This test involves soaking the seeds first in water so that they imbibe fully and soften for cutting. A moistened seed will take up the stain more rapidly. A variety of methods are used to open seeds. It is extremely important that no damage occur to the embryonic axis when a seed is cut. The embryonic axis is the radical and the plumule. The meristematic regions are here, and their condition needs to remain unaltered until they are carefully examined. These are the areas where the embryo must

Figure 25—Chapter 5, Seed Testing: the conductivity meter is used to measure seed viability or vigor by estimating the amount of cations lost from deteriorating seeds.

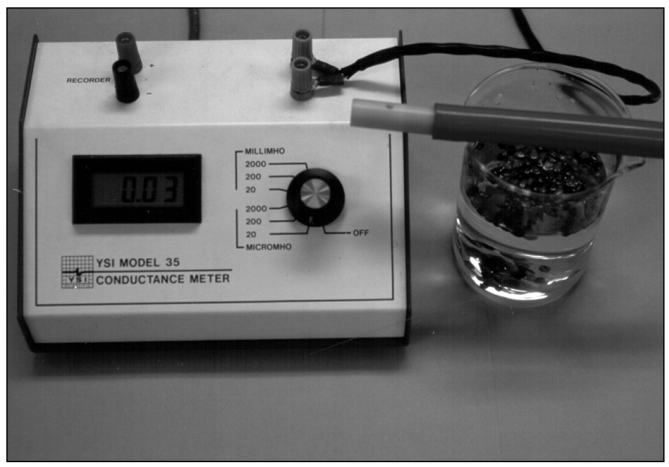

Figure 26—Chapter 5, Seed Testing: germination curves of 3 pairs of seedlots, with high, moderate, and low germination values. The upper curve in each pair represents the more vigorous lot in the pair because the germination is completed sooner.

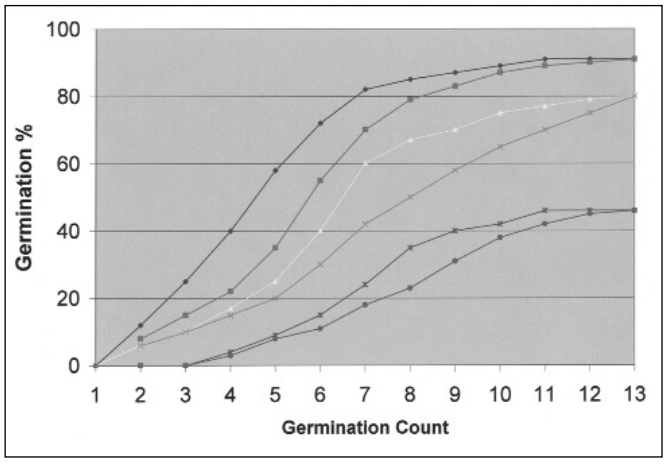

grow in order to produce a normal seedling. Usually forceps and sharp single-edged razor blades are used to cut open the seeds (figure 27). For seeds with harder or stony seedcoats, a variety of vises, hammers, and clippers are used to cut through or remove the seedcoat (figure 28).

The solution that is used to make a tetrazolium (TZ) test is colorless. It is made by dissolving 2,3,5-triphenol tetrazolium chloride in a phosphate buffer at pH 7.4, which is the optimum pH for the TZ reaction. The buffer is necessary to compensate for any pH imbalance in the TZ salt, the water, or possibly the seeds. The colorless solution is taken up by the prepared seeds and then reacts with respiratory enzymes (that is, dehydrogenases) to form an insoluble light pink (magenta) precipitant. Tissues that are alive and respiring will stain, and those that are not alive will not. For a detailed discussion of this procedure, refer to the AOSA Handbook on Tetrazolium Testing (AOSA 2000). The TZ test can be completed in 4 to 48 hours, depending on the amount of preparation time required and the rate of staining.

Tetrazolium staining has proven useful with many species that have deep dormancy, including tuliptree (*Liriodendron tulipifera* L.), baldcypress (*Taxodium distichum* (L.) Rich.), Rocky Mountain juniper, and sumac (*Rhus* L.) species. However, for a few species with very deep dormancy, there will be no staining (Vivrette 1995) unless the seeds are prechilled.

Figure 27—Chapter 5, Seed Testing: seeds are cut open carefully to prepare them for tetrazolium staining.

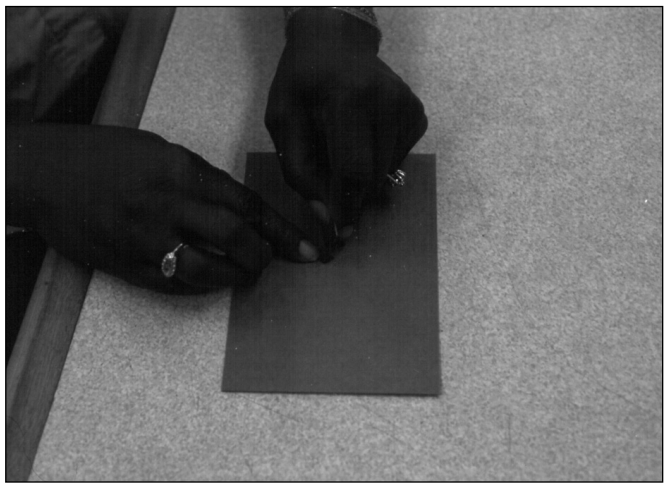

Figure 28—Chapter 5, Seed Testing: vises, hammers, or clippers are used to cut through or remove hard or stony seedcoats for conducting tetrazolium or excised embryo tests.

Excised Embryo Testing

The excised embryo test is done on the embryo after it is removed from the seed (Flemion 1948; Heit 1955). In this germination test, the embryo has been freed from the restriction of the seedcoat and nutritive tissue (figure 29). Therefore, a germination that would take many months and be incomplete can be complete in 10 to 14 days. The ashes (*Fraxinus* L.), maples (*Acer* L.), and cherries and plums (*Prunus* L.) are some of the genera that are tested by embryo excision. Because the embryos are very vulnerable to infection once excised, the test must be done under strictly clean (axenic) conditions. The work surface and all tools, hands, and germination dishes should be washed carefully, perhaps with absolute ethanol. If "clean" embryos mold easily, then cleaning procedures must be reviewed for effectiveness and the work area examined for sources of microbial contamination. Generally, however, sterilization procedures such as autoclaving are not required. The procedures for excising the embryos are similar to those used in preparing seeds for tetrazolium. Greater care is needed, however, because the embryo must be removed intact without any significant injury or broken apart. The main advantage of this method over the TZ test is that the evaluation is less subjective; the growing embryo is actually observed in most cases. Therefore, a direct reading on the growth potential of the seedlot can be obtained.

A complete excision is not always required. Russian-olive *(Elaeagnus angustifolia* L.) (Belcher and Karrfalt 1979) and western white pine (Hoff and Steinhoff 1986) respond well to only partial removal of the seedcoat. However, white pine seeds require prechilling before their seedcoats are cut open.

X-Radiography

X-radiography is very useful in forest seed analysis. It provides a very rapid and accurate analysis of the internal structure of seeds, identifying empty, insect-damaged, or poorly developed seeds (figure 30). It is an immense help in judging maturity, determining how many bad seeds should be remove, and detecting any mechanical injury. It is more accurate than cutting tests in many cases, requires much less time, and is nondestructive (AOSA 1979; Simak and others 1989). X-radiography was first applied to tree seeds by Simak in Sweden. The use of contrast agents has improved the ability of the x-ray test to discriminate between viable and nonviable seeds with some species (Kamra 1963; Simak 1957; Vozzo 1978). A contrast agent enters damaged areas of the seed differentially from nondamaged areas, making the damaged areas more radiopaque. They will then appear as bright areas on the radiograph. Aqueous solutions of heavy salts such as iodine or barium chloride and vaporous agents such as chloroform have been used as contrast agents.

Radiographs can be made on Polaroid® film, x-ray paper, or x-ray film. Polaroid film is useful if no darkroom is available, because the film is developed in the light, just like a Polaroid photograph. The disadvantages of Polaroid are high cost, short shelf life, and lack of detail. X-ray paper is fast to use but does require a simple darkroom. It is less expensive than Polaroid, has a shelf life of several years in cold storage (3 °C), and much better resolution. The best resolution is obtained with x-ray film. X-ray film, however, is more expensive and slower to develop (over 45 minutes) and a light table is required to see the images. Usually the film or paper is placed in a paper or vinyl cassette so that it may be handled in the light. This cassette can result in some loss of clarity of the image, especially with small seeds; using the film in the dark where the seeds can be laid directly on the emulsion gives a noticeably superior image.

Seed work is usually done with x-rays in the range of 10 to 30 kvp (that is, kilovolt potential), which is is the amount of penetrating power the x-rays have. The exact kilovolt potential depends on the equipment and the seeds in question. Trial and error is necessary to find the best combination. Too high a kilovolt potential and the seeds will not be visible or will appear too dark. Too low a kilovolt potential, and the image will lack detail and be too light. Some small seeds need to be x-rayed at a low kilovolt potential to give the correct penetration but need a long exposure to produce a radiograph with enough density to provide good contrast. X-ray inspection cabinets are manufactured that operate in this very low kilovolt potential range for examining small items such as seeds. They are designed for total protection of the operators, with complete lead shielding and safety interlocks on the door (figure 31).

X-radiography has proven useful for studying the seeds from many wild species, which often can be empty or poorly formed. Some laboratories test every lot of seeds they receive with x-rays and get a good initial evaluation. X-radiography can be of great value in evaluating germination test results, because it is much faster than cutting open

Figure 29—Chapter 5, Seed Testing: embryos of peach (*Prunus persica* L.) have been removed from their seedcoats for an excised embryo test of viability.

Figure 30—Chapter 5, Seed Testing: x-radiography can be used to quickly determine how many seeds are empty, damaged, or poorly developed.

seeds that failed to germinate. Empty seeds will never germinate, and damaged or poorly developed seeds will seldom germinate. The excised embryo or tetrazolium test for difficult-to-cut seeds can be speeded up by x-radiography. The seeds are first placed on the x-ray film or paper in a manner that will allow the comparison of the exact image to the exact seed. This is done by placing the seeds on an additional piece of paper before placing the paper on the x-ray film or paper. If orientation of the seed is important, as in double-seeded fruits such as dogwood, the seeds can be placed on adhesive tape and that then laid on the paper. The seeds should be oriented so that both seeds in the fruit can be viewed and the tape prevents them from turning. After the radiograph is made, the seeds are gently slipped off the x-ray paper so that the seeds are kept in order for cutting. Only those seeds that are morphologically sound in the radiograph need to be cut.

Other Quick Tests

As stated in the introduction, cutting tests are very limited in their application. However, they can provide useful information on full seed percentages and the condition of the internal structures. For example, color of the tissue cannot be determined in a radiograph, which is only black and white. Seeds that are cut and found to be dark are not likely to germinate. New and unfamiliar images in a radiograph require cutting the seed to determine what is actually in the seed. With slash and longleaf pines, cutting can reveal embryos that have initiated chlorophyll (turned green), a result of a seedlot having been held too long at high moisture. This is a sure sign of a weakened seedlot.

Hydrogen peroxide (H_2O_2) has been used as a quick test for western conifers (Ching and Parker 1958). In this test, the seeds are floated in solution of 1.0% hydrogen peroxide overnight. The radicle ends are then clipped and the seeds incubated in the dark at 20 to 30 °C for 10 to 12 days. Counts of germinates are made at 3 to 4 days and at 10 to 12 days. The hydrogen peroxide solution is changed at the first count.

Figure 31—Chapter 5, Seed Testing: a cabinet x-ray system is a safe and simple way to make radiographs of seeds.

Sowing Rates

A sowing rate is the amount of seeds sown in a unit area of nursery bed to produce the desired number of seedlings. The following formulas show how seed test data are used to determine this rate.

Weight of seeds to sow in a nursery bed (width x length) is equal to

(bed width x bed length x seedlings desired per area) ÷ (germination x seeds per weight x purity x survival factor)

Number of seeds needed to sow per area of nursery bed is equal to

(seedlings desired per area) ÷ (germination x survival factor)

In both of these formulas, the survival factor is the ratio of the number of seedlings expected to the number of viable seeds planted. It is derived from experience in the given nursery and should be constantly updated with new information collected from history plots. History plots are permanent sample plots in a nurserybed used for carefully monitoring the number of seeds sown and the number and quality of seedlings produced (Landis and Karrfalt 1987). For example, if 100 seeds are sown on a square foot, germination is 80% in the laboratory, and 60 seedlings actually grow on the square foot, then the survival factor is 60 ÷ 80 or .75 (75%).

Computing sowing rates for containers is somewhat different, because we must predict the probability of an empty cell in the container. The probability that a container cell is empty is equal to 1 minus the probability that at least 1 seedling is in the cell. Sowing 1 seed per cell, this probability is 1 minus germination. With a 90% germination, the probability of an empty cell following single-seed sowing is 0.1. In sowing 2 seeds per cell, the probability of no

seedling in a cell drops to .01, but now there are 81 cells (.90 × .90) out of 100 that will have 2 seedlings per cell. Double seedlings per cell requires thinning to 1 seedling per cell for proper growth. Thus, in container nurseries it is necessary to choose between empty spaces and thinning. In this example, to go from 10 empty cells to 1 empty cell per 100 cells, 81 seeds were wasted. For 10,000 seedlings, 8,100 seeds would be wasted, which would be 112 to 224 g (3.9 to 7.8 oz) of seeds when the seeds number 72,300/kg (32,900 seeds/lb). Thinning also requires more labor and may be dysgenic by favoring early germinating genotypes. Sowing extra containers is another strategy followed to compensate for empty cells. The empty cells are still present but enough seedlings are produced without the problems of thinning.

The purity and seed per weight are still important to the container grower, because they will be used to compute the amount of seed to prepare. The following formula can be used to calculate how many seeds are in a unit weight of seeds:

weight of seeds × purity × no. of seeds per unit weight

Example: 1 kg of seeds at 98% purity, 33,000 seeds/kg:
1 kg x 0.98 x 33,000 pure seeds/kg =
32,300 pure seeds

or 1 lb of seeds at 98% purity, 15,000 pure seeds/lb:
1 lb x 0.98 x 15,000 seeds/lb =
14,700 pure seeds

To sow 10,000 cells with 1 seed each, 10,000 seeds are needed, which is 10,000 seeds divided by 32,300 seeds/kg = 0.31 kg (10,000 divided by 14,700 = .69 lb). Double sowing 10,000 cells would take 2 x 0.31 = 0.62 kg (2 x .69 = 1.4 lb). Combining these steps yields the following formula:

(number of seeds to sow per cell x number of cells to sow) ÷ (purity x seeds per unit weight)

In the double-sowing example, this would be 2 × 10,000 ÷ .98 x 33,000 seeds/kg (.98 × 14,700 seeds/lb) for a total of 0.62 kg (1.4 lb) of seeds required.

Buying and Selling Seeds

Current test data are essential. To be current, the data should not be more than 9 months old. The more recent the test, the more likely it is to reflect the true condition of the seedlot when the buyer takes possession of it. Ideally the tests should be run by a disinterested third-party laboratory that is well qualified to do the tests. The results of informal analysis, such as the cut test, should never be accepted as the true measure of the worth of a seedlot.

Which tests are important to request, and how should they be used? Moisture content is important for 2 reasons. First, the seeds need to be at a proper storage moisture content to ensure viability. Orthodox seeds need to have a moisture content below 10% and recalcitrants usually above 25%. Second, it must be remembered that extra water can be added to the seeds and distort the true value of the lot. One kilogram of a seedlot with 10,000 seeds/kg (22,000 seeds/lb) at 7% moisture content would contain 70 g (2.5 oz) of water and 930 g (32.6 oz) of dry seeds. A similar lot of 10,000 seeds/kg at 9% moisture would have 90 g (3.2 oz) of water and 910 g (31.9 oz) of dry seeds. In an accurate comparison between the lots (that is, dried to equal moisture content of 7%), the mass of the seeds in the second lot is 20 g (2%) less than that of the first. Although both seedlots might appear to have seeds of the same size, the lot with higher moisture would actually have slightly smaller sized seeds. Because the water is free, adding extra moisture can be a good way for the seller to increase profits.

The number of pure live seeds per weight is a calculation that is often helpful in assessing the value of a seedlot. In this procedure, germination, purity, and seed weight are all considered. Consider a seedlot with germination of 90%, purity of 98%, seed weight of 18,600 seeds/kg (8,500 seeds/lb). The number of pure live seeds per kilogram is then .90 × .98 × 18,600 = 16,400 seeds/kg (7,500 seeds/lb). This is the same value as a lot that has 95% germination, 96% purity, and 18,000 seeds/kg (8,200 seeds/lb) (.95 × .96 × 18,000 = 16,400) but a higher value than a lot with 97% germination, 84% purity, and 17,400 seeds/kg (7,900 seeds/lb) (.97 × .84 × 17,400 = 14,200). Number of pure live seeds per weight tells the grower the potential number of seedlings and removes at least some ambiguity in comparing the value of different seedlots. If the maximum number of potential plants is the most important factor, the first 2 lots are superior to the third, although the third has a higher viability. Alternatively, as might be the case for a container nursery, the high germination could be the most important factor, and the third lot would be chosen over the first two, even though potentially fewer trees can be produced from it.

Minimum standards are usually set for all quality values. Those minimums depend on the type of nursery, the generally available quality for a species, the desirability of the seed source, and other factors. In general, the higher its quality, the more a seedlot is worth in the nursery. High germination

is of great value in a bareroot nursery but indispensable to the container grower, who seeks to avoid wasting seeds by double-sowing or having empty growing space in single sowing. However, for some species, 60% germination might well be typical and expecting 98% germination is not reasonable.

Test Limitations and Variation

Standardized laboratory tests are designed to give maximum values with minimum variation, allowing the results to be repeated. Without repeatability, there would be no standard by which to compare different seedlots. Assessments would become even more difficult if seed tests were conducted in random fashion to mimic field conditions. Although the correlation between laboratory and field germinations is frequently low, experience has shown that seedlots with higher germination scores will, over time, give more germination in the field. Further improvement in predicting field performance may result from improvements in the techniques of vigor testing.

Because seeds are biological, they usually are quite variable in size and performance. Natural things simply show more variation than is usually seen in manufactured items. Test results, therefore, can vary more than perhaps is expected and still be accurate. For example, a seed weight of 16,000 seeds/kg (7,300 seeds/lb) might be reported as 15,600 (7,100) in a second test, and both results are in fact accurate. Tolerance tables can guide decisions on whether test results are comparable. Some of these tables are suitable for all types of seeds, whereas others vary depending on the type of test and the kind of seeds tested.

Scheduling Seed Tests

When should a seed test be conducted? Tests are needed to formally determine the quality of the seedlot upon completion of the conditioning process. All variables then need to be measured: germination, seed weight, purity, and moisture content. Moisture needs to be monitored during storage to be sure it is being properly maintained. If there are no changes in moisture content, then seed weight and purity will not change and viability will change very slowly, if at all. Some annual monitoring of seed moisture is necessary to ensure that storage conditions are being adequately maintained. The viability can be retested at 3- to 5-year intervals with a current test always done no more than 6 to 9 months before sowing. If a longer time passes before sowing, some deterioration could occur, resulting in changes in germination. Determining viability in some seeds takes a long time, and thus it is important to schedule adequate lead time into the production schedule.

Commercial Trade of Tree, Shrub, and Native Plant Seeds

Official rules for testing seeds developed by the International Seed Testing Association or the Association of Official Seed Analysts are very important to the orderly buying and selling of seeds. These rules give standardized procedures that can be repeated with acceptable variation no matter what laboratory conducts the test. In addition, the seed testing associations conduct comparative tests among themselves to verify that the procedures are being applied uniformly and within tolerable limits of error. Such a system is important: it assures sellers that they are offering good seedlots for sale, and it reassures buyers by giving them reliable information on which to base their purchases. There are also consumer protection seed laws in some countries or states requiring that seeds offered for sale meet certain minimum standards or be accurately labeled as to their quality. Without a repeatable system of testing procedures, such laws would be impossible to enforce. Both the consumer and the reputable seed dealer would suffer. Uniformity of the rules combined with uniformity in applying the rules equals order in the marketplace.

Introduction

Seed certification is a system that provides assurance to buyers that the seeds being purchased are what they are represented to be by the producer or seller. This certification of identity (and sometimes quality) is typically provided by an independent third party for a fee that is charged to the producer and becomes part of the production costs. The system is simple and effective; it is used all over the world in various, yet basically similar, forms for agricultural, horticultural, and forestry seeds or other propagules. This chapter will briefly describe how seed certification developed in forestry and how it is practiced today with seeds of woody plants. More detailed historical accounts of agricultural and forest tree seed certification in the United States can be found in Hackleman and Scott (1990) and Rudolf (1974).

Certification in Agriculture

Certification of agricultural seeds has been practiced in the United States since the early 1900s (Copeland and McDonald 1995; Hackleman and Scott 1990) and has been a positive force in the development of modern agriculture. Certification in individual states is typically controlled by an agency that is authorized by the state to carry out the procedures. The agencies are commonly called crop improvement associations, but some carry other designations. The organizational structures of these agencies may vary, but their goals are similar and they act cooperatively through the Association of Official Seed Certification Agencies (AOSCA 1994). AOSCA establishes minimum certification standards for all types of plant materials. The member state certification agencies may develop their own certification standards for different materials, but their standards must equal or exceed those of AOSCA. Agricultural seed certification is an assurance of the varietal (genetic) identity of the material, but it is also normally a *de facto* assurance of genetic quality. Developers of improved varieties of agricultural species (state land grant universities or private seed companies) widely publicize the results of their field trials, and the expected performance of new varieties is well known and documented before they reach the market. Seed buyers want the assurance from certification that their seeds are really the variety that the producer says they are. The slightly higher cost required for this assurance is gladly paid.

Certification in Forestry

Certification of forest reproductive material has developed in a slightly different manner from that of agriculture in this country. Most forest landowners do not have ready access to the performance data from field trials of selected forest materials. There are two primary reasons for this. First, field trial results in forestry are not as widely published as those in agriculture, and the publication outlets that are used are not widely seen by the general public. Second, much of the genetic improvement in forestry has been done by large forest industries and the USDA Forest Service, all of which originally intended that the improved materials would be planted on their lands only and not sold on the open market. So other than technical reports in forestry journals and a few government publications, these results have not been widely disseminated, although they are available.

The first efforts in genetic improvement in forest reproductive materials in this country came about through recognition that some seed sources were more suitable for planting in certain areas than others. Application of this principle in the 1930s and 1940s led to the establishment of seed control policies and seed zones to ensure that seeds and seedlings for reforestation came from the best origins

Figure 1—Chapter 6, Certification of Tree Seeds and Other Woody Plant Materials: current tree seed zones for Douglas-fir in western Oregon (adapted from Randall 1996).

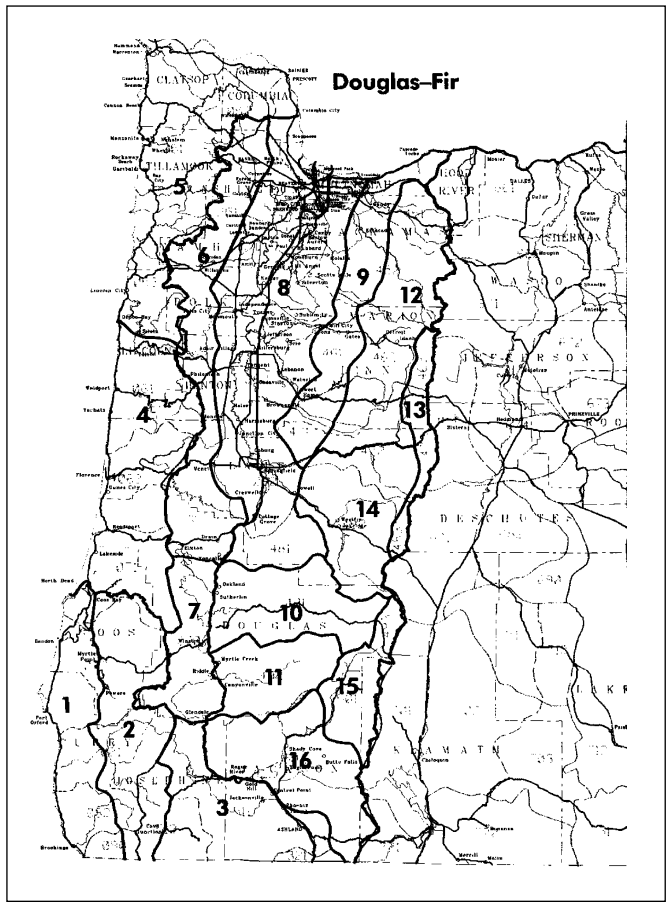

Figure 2—Chapter 6, Certification of Tree Seeds and Other Woody Plant Materials: current tree seed zones in use in Washington (adapted from Rudolf 1974).

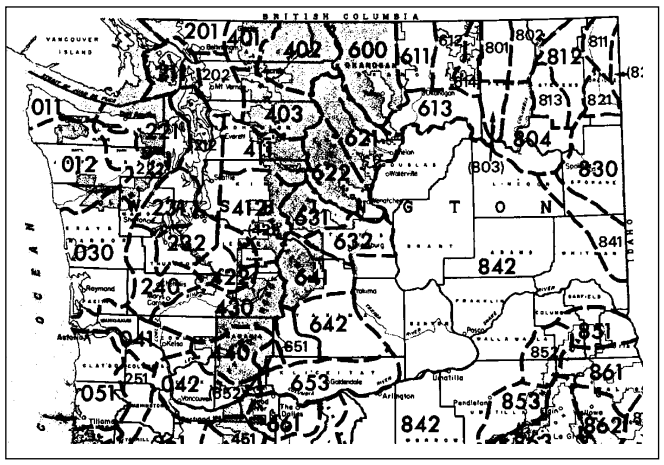

Figure 3—Chapter 6, Certification of Tree Seeds and Other Woody Plant Materials: geographic districts for source-identified certification of forest reproductive material in Mississippi (courtesy of MSIA 1979).

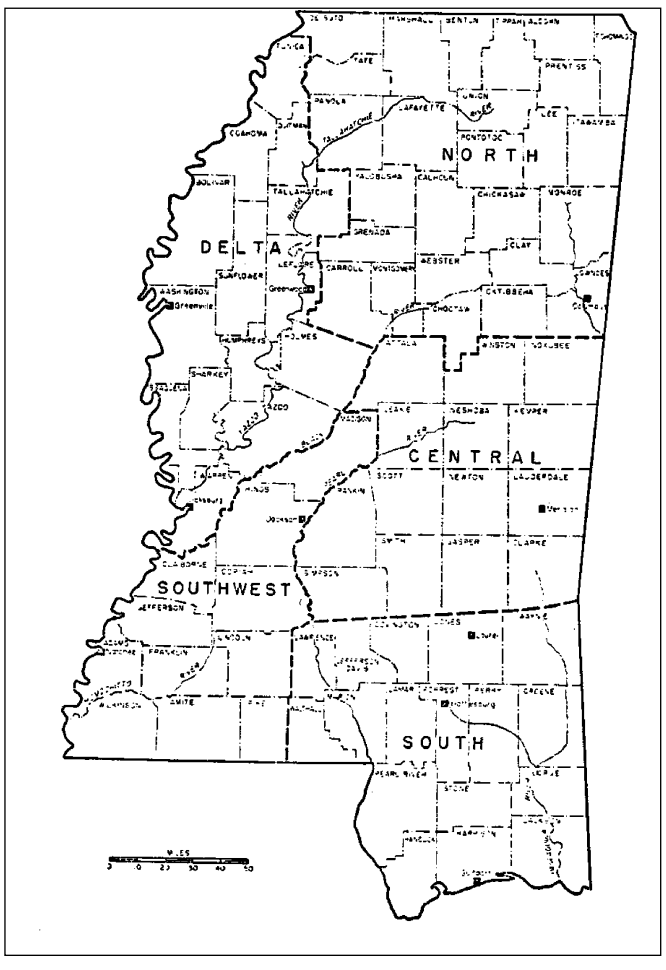

Figure 4—Chapter 6, Certification of Tree Seeds and Other Woody Plant Materials: the 5 seed collection and planting zones for longleaf pine (from Lantz and Kraus 1987).

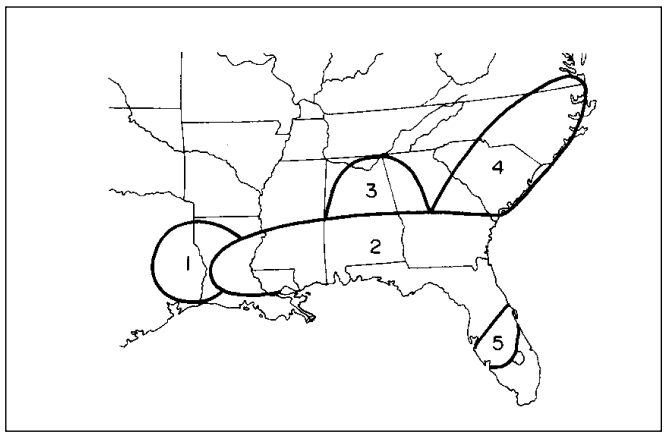

(Rudolf 1974). The use of seed zones (figures 1–4) has been very effective, and they are still widely used today. The major impetus for forest seed certification, however, came from the expanded reforestation programs and rapidly developing tree improvement programs in the 1950s and 1960s. Establishment of seed orchards of major species with selected phenotypes and the subsequent progeny tests with their offspring has led to wide-scale use of improved families and clones in forest regeneration. When foresters wanted certification of this material, they turned to the state crop improvement associations, because these agencies were the only ones legally permitted in most states to perform certification services. As these services were extended to forestry material, the mechanisms for implementation developed differently in different parts of the country.

South Dakota established the first forest tree certification program in 1952 for stock selected for shelterbelt use (Rudolf 1974). Georgia established the next program in 1959 with comprehensive certification standards for tree seeds (GCIA 1959). The AOSCA (then known as the International Crop Improvement Association) adopted almost identical standards also in 1959 (Rudolf 1974), with later revisions in 1962, 1966, and 1970 (Hackleman and Scott 1990). Other states were not far behind. In 1994, AOSCA widened the scope of its tree seed certification standards to allow certification of material from all native plants—trees, shrubs, vines, forbs, and grasses (AOSCA 1994). These standards were designated for pre-variety germplasm certification and will be explained in a later section.

Pacific Northwest

An organized effort to improve tree seed supplies in the Pacific Northwest came about in the mid-1950s with the formation of the Northwest Forest Tree Seed Committee at Corvallis, Oregon (Edwards 1981). This group later became the Western Forest Tree Seed Council in affiliation with the Western Forestry and Conservation Association. The bumper cone crop of 1966 underlined the need for certification programs (Hopkins 1968), and the council and the Western Reforestation Coordinating Committee of the Western Forestry and Conservation Association took action. Through their efforts, the Northwest Forest Tree Seed Certifiers Association (NWFTSCA) was formed in 1966 to promote seed certification. This organization developed seed zone maps for Washington and Oregon and the framework for a seed certification system (Edwards 1981).

Certification was jointly administered by the Washington State Crop Improvement Association and the Oregon Seed Certification Service, a division of the Department of Crop and Soil Science at Oregon State University. The NWFTSCA provided review and advice to the agencies. Their system recognizes the following categories of reproductive material, which are indicated by standardized color-coded labels affixed to seed containers.

Audit class. Certifying authorities have reviewed records indicating seed lot origin and collection documentation on where and when the seeds were collected. Origins are usually less specifically identified than those in the source-identified class. ***Labels placed on the seed containers are brown and white.***

Source-identified class. Reproductive material comes from a seed zone defined by a legal description and from within a 154-m (500-ft) elevation band. The seed zones were defined on the Tree Seed Zone Map issued by the Western Forest Tree Seed Council in 1973. They are based on physiographic and geological provinces of Washington and Oregon as defined by Franklin and Dyrness (1973). Two subclasses are recognized: (a) *personally supervised production*—both the producer and the certifying agency have personal knowledge of the seed zone from which the seeds were collected and (b) *procedurally supervised production*—only the buyer and not the certifying agency determines if the collections are properly identified. ***Labels for both subgroups are yellow.***

Selected class. Reproductive material comes from trees that were selected for a specific character(s). Two classes are recognized: (a) *reproductive material obtained from selected trees* recognized to be superior for any number of traits, such as volume, form, or disease resistance and (b) *material from untested seed orchards and from seed production areas, and open-pollinated seeds* from individual selected trees. In this class, only the female parent is known. This class of material has promising traits that may be superior in the offspring, but such superiority has not been determined by testing. Details of the parents must be recorded. ***Labels are green.***

Tested class. Reproductive material comes from selected trees that have been tested for performance of specific characteristics, as determined by progeny or other applicable tests under specified conditions. The material from this class that performs best in the tests is presumed to be the ultimate in promised genetic superiority and is similar to the agricultural class "certified seed," indicating the highest degree of improvement. ***Labels are blue.***

To be able to sell certified material, the producer or collector must submit an application to the appropriate seed certifying agency, along with a fee, stating what material is to be certified. The application must spell out how the material will be produced or collected. The certifying agency will then notify the applicants if their plans are acceptable or in need of modification. The agency performs field and seed plant inspections, seed storage inventory audits, and whatever additional steps are necessary to ensure that the materials meet the agency's standards and can be tagged with the official agency labels. Cone collectors and buyers have slightly different registration and inspection procedures than seed orchard producers, but the agency controls are comprehensive. Procedures may be amended from time to time, so interested parties should check with their respective state certifying agencies to get the current regulations.

The species of greatest interest for certified collections have traditionally been Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco), western white pine (*Pinus monticola* Dougl. ex D. Don), ponderosa pine (*P. ponderosa* P. & C. Lawson), sugar pine (*P. lambertiana* Dougl.), and lodgepole pine (*P. contorta* Dougl. ex Loud.). Another dozen or more species, both hardwoods and conifers, are occasionally certified.

Most of the tree seeds sold in the Pacific Northwest are exported to countries in northern Europe that are members of OECD (Organization for Economic Cooperation and Development), a United Nations–based international economic development organization that has set up the Scheme for Control of Forest Reproductive Material Moving in International Trade. European countries that import tree seeds from the Pacific Northwest are required to have OECD certificates on their seeds; consequently, procedures were established in the Northwest to implement this scheme

(which varied only slightly from the standards already in place). The major importers have been Germany (Douglas-fir), the United Kingdom (Sitka spruce, *Picea sitchensis* (Bong.) Carr.), and Sweden (lodgepole pine) (Piesch 1977), with total presently somewhere around 4,500 kg/year (Pfeifer 1997). Because tree seeds are not covered under the Federal Seed Act, there are no officially collected data on the total amount of tree seeds exported from the United States. Details of the OECD Scheme and how it operates in the United States are provided in a later section of this chapter.

Southeast

Standards for tree seed certification in the Southeast began in the late 1950s as more and more attention was focused on seed source and the potentially superior material that could come from the newly established seed orchards. Much of this interest was in response to the results of a seed source study of southern pines established by Phillip Wakeley of the USDA Forest Service. His early results showed that these species could be greatly improved by careful selection of seed source (Wells and Wakeley 1966). Later results showed still more potential for genetic improvement programs (Wells 1983). Some seed zones for selected species were established within states (figure 3), and regional zones for the southern pines were established later (figure 4) (Lantz and Kraus 1987).

Instead of a collective effort, individual states developed their own standards, usually through committees of state, federal, and industrial interests under the aegis of state chapters of the Society of American Foresters. These committees then turned to their respective state seed certification agencies to administer the systems. Georgia and Florida were the first states to develop standards. Other states followed, basing their standards and procedures primarily on those of the states that had gone before. The following 3 classes of certified material were recognized by all states.

Source-identified material. Reproductive materials that can be from (a) *natural stands*, including seed production areas with known geographic origin or (b) *plantations of known provenance*. This class is equal to the source-identified class of the Pacific Northwest. ***Labels are yellow***.

Selected material. Reproductive materials must be from rigidly selected trees or stands that have promise but not proof of genetic superiority; progeny tests to supply the proof are not complete. This class is equal to the selected class of the Pacific Northwest. ***Labels are green.***

Certified material. These reproductive materials must be of known genetic identity obtained from trees of proven genetic superiority. This material must have proven its genetic superiority through progeny tests. This class of material is the same as the tested class in the Pacific Northwest system. ***Labels are blue.***

Most states wrote their standards to apply to seeds and seedlings of southern pines only, but Mississippi and Alabama also included sweetgum (*Liquidambar styraciflua* L.), sycamore (*Platanus occidentalis* L.), and eastern cottonwood (*Populus deltoides* Bartr. ex Marsh.). Standards for cottonwood were for unrooted cuttings only (ACIA nd; MSIA 1979). The demand for certified material varied among states in subsequent years but was particularly strong in Georgia, where the state forestry commission vigorously promoted the use of certified seeds and seedlings of southern pines. Like the system used in the Pacific Northwest, certification in the Southeast requires application to the certifying agencies, fees, inspections, and possible audits. Most state systems in the Southeast are very similar, but details may vary. For more information, contact the respective state certification agencies.

Overseas sales of southern pine seeds were brisk in the 1950s and 1960s, but few, if any, of the lots were certified. In the 1980s the export market for southern pine seeds had decreased somewhat; however, new customers who wanted more assurance of quality were coming on the scene. This development stimulated interest in certification of these exports. Following the lead of the Pacific Northwest, producers and government officials in the Southeast turned to the OECD Scheme for Forest Reproductive Material, which was becoming a certification model acceptable throughout most of the world. Under the aegis of AOSCA, a committee comprising state and federal officials, seed producers and merchants, and university researchers was formed in 1986 to produce uniform regional standards that would meet (or exceed) both AOSCA and OECD standards of certification of forest materials. This action would also remove differences in state standards, thereby making cooperative action easier. In some cases, southern pine seeds were produced in orchards in one state, extracted and cleaned in another, and sold in still another. State certifying agencies had reciprocal agreements that allowed inspectors in one state to approve practices for seeds sold in a neighboring state, but differences in small details could cause problems. After 5 years of deliberations, agreement was reached on uniform standards, but apparently none of the states implemented the new standards. Certification in the Southeast continues to be carried out on demand by the respective state agencies, according to the standards adopted 20 or 30 years ago. Because the anticipated large demand for OECD-certified

material from the Southeast did not develop, seed producers and merchants have not been adversely affected by the lack of uniformity.

Organization for Economic Cooperation and Development

The United Nations Organization for Economic Cooperation and Development (OECD) was organized in 1960 to facilitate economic development in member countries. Membership included most of western Europe, Canada, the United States, Japan, Australia, and Turkey (Piesch 1977). The OECD Scheme for Control of Forest Reproductive Material Moving in International Trade was first published in 1967 and amended in 1974 (Hoekstra 1976). Additional revision is currently underway. The unit of approval for reproductive material is 1 of 7 kinds of "basic material": seed source, stand, seed plantation, seed orchard, parents of family(ies), clonal mixtures, and clone. All materials are tagged and accompanied by a certificate of provenance. The scheme describes the following 4 categories of certification possible for the materials.

Source-identified materials. Basic requirements are (a) the region of provenance where the material is collected and the origin of the basic material (indigenous or non-indigenous) shall be defined and registered by a Designated Authority and (b) the seed shall be collected, processed, and stored, and plants shall be raised under the control of a Designated Authority. This category is equal to the source-identified class of systems in the United States. ***Labels are yellow.***

Selected materials. Selected materials must conform to the 2 requirements above, and also they will be derived from basic material that conforms to certain requirements and has been approved and registered by a designated authority. The requirements pertain to selection criteria, uniformity, quality, isolation, and origin. This category is similar to the selected class of the systems in the United States. ***Labels are green.***

Materials from untested seed orchards. This material consists basically of seeds that are produced by a seed orchard of selected trees (category 2) for which progeny tests are not yet complete. These materials are potentially more valuable than those from category 2 because the mother trees are pollinated (it is hoped) by other selected trees. The original systems of the Pacific Northwest and Southeast did not contain this class but included these materials in the selected class. ***Labels are pink.***

Tested materials. This material is the same as class 3, except that progeny testing has been completed and (a) *the genetic superiority of the material is proven by the tests* and (b) *the results of the tests shall be registered by a designated authority.* This class generally corresponds to the tested class of the Pacific Northwest system and the certified class of most state systems in the Southeast. ***Labels are blue.***

The OECD scheme is virtually identical to the standards established in the United States except for class 3, the material (seeds) collected from orchards of selected material prior to completion of progeny tests. Oregon and Washington, wishing to continue export sales to OECD countries, added class 3 to their standards for the purpose of issuing OECD certificates. The USDA Forest Service has been appointed as the designated authority to implement the scheme in the United States. Because tree seeds are not covered in the Federal Seed Act, the Forest Service re-delegated its authority to implement the scheme to the states of Oregon and Washington under cooperative agreements with their seed certifying agencies (Hoekstra 1976). California, Ohio, and perhaps other states now have similar agreements in place (Karrfalt 1998). The same procedure would have been followed in the Southeast with the uniform regional standards if an agreement had been reached among all parties. This pathway is still open, of course, to individual states that wish to pursue separate cooperative agreements with the USDA Forest Service.

The OECD scheme is widely used as a model for certification standards in many non-member countries. It is currently being revised again; interested parties should contact the Cooperative Forestry Office of the USDA Forest Service in Washington, DC, for the latest information on the scheme.

European Union

The European Union (EU) also has a certification requirement for forest seeds imported into the member countries. All of these countries also participate in OECD and require both OECD and EU certificates and labels. Although the United States is not a member of EU, its seed dealers are affected when seedlots are exported to EU countries. The EU scheme differs from both OECD and North American systems in that only 2 categories of certification are recognized: selected and tested materials. The EU scheme does not recognize source-identified and audit classes from the Pacific Northwest system or source-identified class from the southern systems. Because the United States is not a member nation and because source-identified seed is the most common export from this country to Europe, these

seeds must receive a derogation (special exemption) and a special white label to signify their classification. Seed exports from the United States to Europe would be greatly simplified if the OECD and EU schemes were the same. Discussions are currently underway to revise the EU scheme, so there is hope that this harmonization will be realized in the near future.

Native Shrub and Grass Seeds

In the 1980s and 1990s, a surge of interest in rehabilitating rangelands arose in the western portion of the United States. The majority of the plant materials used in these projects are grasses and shrubs, not trees. Although some selection programs are underway to produce genetically superior materials within a limited number of species, practically all of the material being planted at present comes from general collections from natural stands. Because good results are obtained with local ecotypes, there is now a strong demand for source-identified certification of this material (Young 1994, 1995). Young (1994) listed 34 commercial seed dealers that were interested in collecting or producing certified grass or shrub seeds for reclamation and restoration plantings.

Although shrub seeds could conceivably come under certification standards for tree seeds, native grasses do not make a good fit in this regard. To meet this growing demand for certification, AOSCA has replaced their old tree seed certification standards with new pre-variety germplasm certification standards (AOSCA 1994). These standards allow certification of material from all natural plant populations of indigenous or non-indigenous species before any varieties that are developed in improvement programs are released. The standards recognize the following 3 types of materials.

Source-identified seeds:	***Labels are yellow***
Selected seeds:	***Labels are green***
Tested classes:	***Labels are blue***

All of these types are defined very much like the corresponding classes in tree seed standards that were described earlier. To satisfy OECD export standards, AOSCA will allow a pink label to go on Selected material if it is equal to the OECD class untested seed orchard. This class of material is collected from orchards for which progeny tests are not yet complete. Even though the current demand is for source-identified materials, the mechanism now already exists for certification of any improved native plant materials when producers are ready. For information on certification of native plant materials, including trees, consult the AOSCA Certification Handbook (AOSCA 1994) or state certification agency.

Federal Seed Act and Labeling Laws

The Federal Seed Act of 1939 is basically a truth-in-labeling law that governs interstate commerce and importation of agricultural seeds (Copeland and McDonald 1995). Movement of seeds within state boundaries is not covered under the act, therefore all states have their own seed labeling laws to govern intrastate sales. Presently fewer than 20 states include tree seeds under their labeling laws, and in most that do, enforcement is not strict. Because tree seeds are seldom, if ever, sold over the counter at retail stores, the public does not demand stricter enforcement. Laws do exist in some states, however, providing legal recourse for buyers who feel wronged. Label requirements differ; some states require only the species and date of collection, whereas others require germination test results and provenance data.

There has always been some confusion among foresters about the differences between certification and labeling (Zobel and Talbert 1984). Many believe that correct labeling is all that certification will deliver. Under labeling laws, seed officials normally step in to correct wrongs *after* they have caused damage to the buyer. The mere existence of inspections and penalties, however, promotes honesty in labeling. In certification programs, officials are on the scene to confirm identity and production of the material *before* it is delivered to the buyer. This certification activity has a cost, which is passed along to the buyer; it is, however, the best assurance that a buyer will receive what is being paid for.

Outlook for Certification

The outlook for certification of tree seeds, other forestry materials, and native shrubs and grasses is uncertain. Demand for tree seed certification in the Pacific Northwest formerly fluctuated with the size of the cone crops; large cone crops meant heavy demand for certification services. Currently, greatly reduced timber harvests on federal lands in the West have sharply cut the demand for seedlings from federal agencies and therefore for seeds. Demands for planting increase when large areas were denuded by wildfire, but this factor is not predictable. Forest industries are, for the most part, meeting their needs from their own seed orchards and are not applying for certification. The export market to Europe for seeds of western conifers would decline if European seed orchard production increases or if European environmental groups continue to effectively pressure foresters to plant only species native to Europe.

Tree seed certification in the South is quite dormant at the present. Export markets for southern pine seeds still exist, although not to the extent as in the 1960s, but most of these customers are not members of OECD or EU and do not require those certificates. Many of the pine seeds now sold overseas come from overseas seed orchards, primarily first-generation orchards that now produce excess seeds surplus to the producers' own needs. Among private forest landowners in the South, very little demand for certification is evident. The USDA Forest Service and forest industries that use most of their own improved seeds for planting are infrequent customers for certification services, and the Southern Region of the Forest Service's National Forest System is undergoing a reduction in timber harvest and replanting, much the same as the western regions.

The best potential for future certification of tree or other native plant seeds is in restoration or reclamation planting programs. These programs require relatively small seedlots from an extraordinarily large number of species, many of which have not been grown in nurseries before. There is also a trend toward wanting only local ecotypes for restoration planting (Young 1995) and source-identified certification to provide the assurance that proper seed sources are being used. The large number of shrub and grass seed dealers that are willing to get their products certified for source (Young 1994) and the increasing number of seed dealers that are selling tree seeds (at least 58 offering over 1,800 species) (USDA FS 1995) indicates that commercial sources are ready and willing—customers simply have to ask for certified materials. State certification agencies now have the standards and procedures to certify any or all of this material. From this perspective, there appears to be a promising future for certification of seeds and other materials from trees and other native plants.

Chapter 7

Nursery Practices

Thomas D. Landis

Dr. Landis retired from the USDA Forest Service, State and Private Forestry's Reforestation, Nurseries, and Genetics Research National Team

Contents

Introduction

Plant propagation is both a science and an art. In this chapter, we examine the science of plant propagation, which consists of a knowledge of plant physiology, nursery cultural practices, and the biological characteristics of the particular plant that we want to grow. The art of plant propagation cannot be taught, however, because it consists of certain technical skills that must be acquired through experience and often requires a certain "feel." This special quality is expressed in the saying that people who seem to be able to grow plants have a "green thumb" (Landis and others 1999). But before we get into the specific details of plant propagation, we first need to cover some basic nursery terms.

Terminology

A seedling is a plant grown from a seed, but the term is commonly used generically for many types of nursery stock, including transplants, rooted cuttings, and emblings (plants that are produced through micropropagation). Forest and conservation seedlings are traditionally divided into 2 basic stocktypes, depending on how they were propagated: bareroot seedlings and container seedlings. Bareroot stock is grown in soil in open fields (figure 1A), and the seedlings are removed from the soil during harvesting (figure 1B). Container seedlings are grown in an artificial growing medium in a controlled environment, such as a greenhouse (figure 2A), where most or all of the growth-limiting factors can be manipulated. Because the volume of growing medium in containers is relatively small, roots bind the medium into a cohesive "plug" by the time the seedlings are harvested (figure 2B). Therefore, container-grown stock are sometimes called "plug seedlings."

Another stock type is the transplant, a seedling that has been physically removed from its seedbed or container and then replanted in another location for additional growth. Traditionally, most transplants are bareroot seedlings that were grown for 1 or 2 years and then replanted into a transplant bed and allowed to grow for another year or two. Recently, container transplants are becoming much more popular. This new stock type, also called a plug transplant, is produced by transplanting a small container seedling into the bareroot nursery for an additional year or two of growth.

Bareroot seedlings have been traditionally described with a numerical code. The first number corresponds to the number of years in the seedbed, and the second number refers to the number of years in the transplant bed. Bareroot seedlings are generally produced in 1 to 3 years (1+0 to 3+0), and transplants require 2 to 4 years (for example, 1+1 or 2+2). The sum of the numbers gives the total number of years needed to produce that stock type. For example, a 1+2 transplant takes 3 years to produce.

There is no standard nomenclature for describing container seedlings, and each nursery and region uses its own system. Because most container seedlings are grown in a season or less, they are generally defined by the type and

Figure 1—Chapter 7, Nursery Practices: bareroot seedlings are grown in outdoor beds where they are exposed to local weather (**A**). During harvesting, the soil is removed from the roots and they are shipped to the outplanting site in the bareroot condition (**B**).

Figure 2—Chapter 7, Nursery Practices: container seedlings are grown in artificial growing media in a controlled environment where seedling growth is accelerated (**A**). By the end of the growing season, the roots have formed a cohesive "plug" (**B**).

volume of the growth container. For example, a "Styro " refers to a seedling that has been produced in a Styrofoam® block container with cells that are approximately 65 cm^3 (4 in^3) in volume. Plug transplants are described by the number of years in the transplant bed, so that a container seedling that is transplanted for an additional year of growth is called a "plug+1."

The Target Seedling

There is no one ideal type of seedling suitable for all purposes, and the ultimate use of the stock will control many aspects of the nursery program. Management objectives determine whether the seedlings will be used for plantation forestry or for ecosystem management purposes. Forest products companies demand plants that are genetically selected for commercial objectives: fast growth and desirable attributes such as fiber length or the ability to "self-prune." On the other hand, seedlings used in ecosystem management must reflect broad genetic diversity because they will be used to restore or maintain natural ecosystems. This distinction is critical because it not only affects target seedling specifications but the entire propagation system.

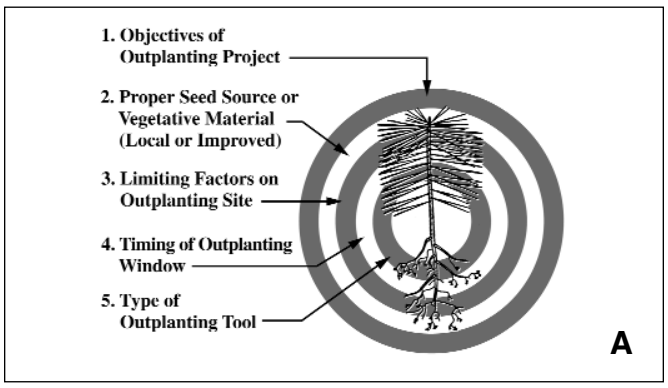
The true measure of seedling quality is performance on the outplanting site—both initial survival and subsequent growth. Because both the seedling user and the nursery manager are jointly responsible for successful plantations, they must work together to define the target seedling for that particular outplanting project (figure 3). Conditions on the outplanting site will determine both what to plant, and when and how to plant it. For example, the seedling user must specify the proper genetic origin for the seedlings (the seed source) and which environmental factors on the outplanting site will be most limiting to survival and growth. A very hot and dry site will require a different target seedling than an outplanting site in a rainy climate. Climate will also determine when to outplant. Planting windows are time periods when stresses are low and the chances for seedling survival and growth are optimal (figure 4).

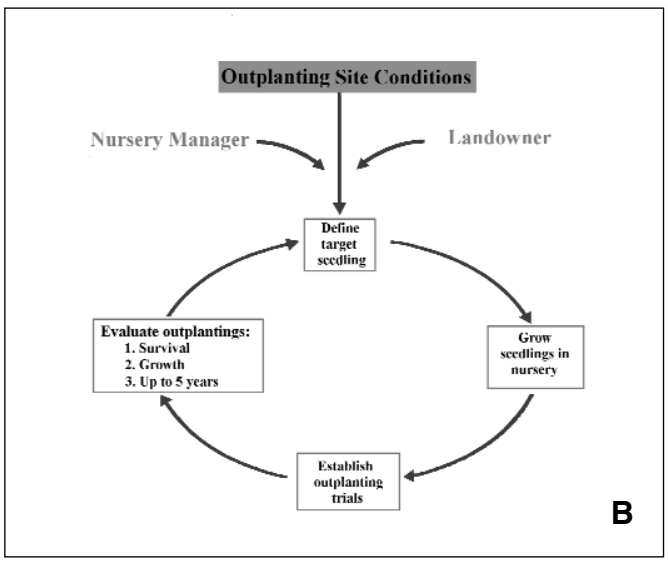
Target seedlings can be described in terms of (1) morphological factors, such as height and stem diameter, (2) physiological factors, such as root growth capacity and cold hardiness, and (3) genetic factors, such as seed source.

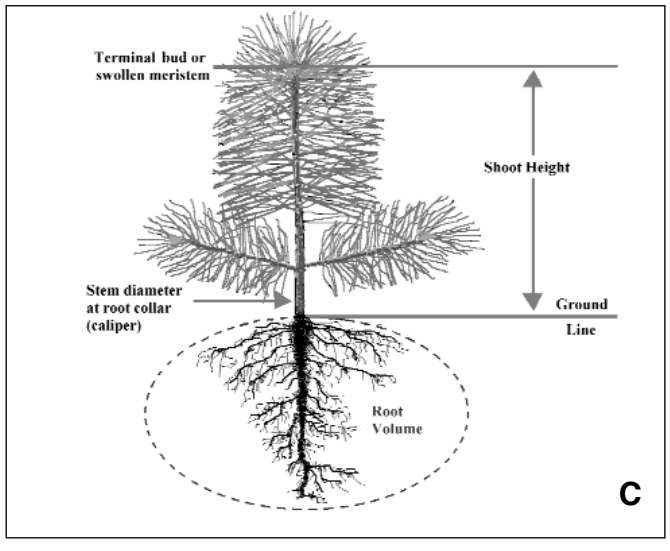
Morphological Specifications

Forest and conservation seedlings are described by traditional morphological dimensions, which are used by both nursery personnel and seedling users. The most common dimensions are shoot height and stem diameter. Shoot height is the vertical distance from the ground line to the tip of the terminal meristem or bud. Stem diameter, often called "caliper" or "root collar diameter," is the diameter of the main stem at the base of the shoot (figure 3C). Other seedling morphological specifications include root volume or length, ovendry (OD) weight, and shoot-to-root ratio (S:R). Though they require destructive sampling, seedling dry weights are useful indices of crop development. The S:R is a relative comparison of the size or weight of the shoot to

Figure 3—Chapter 7, Nursery Practices: the best species and stock type of seedling depends on customer objectives and especially conditions on the outplanting site (**A**). This ideal plant is known as the "target seedling" and has traditionally been described by morphological characteristics (**B**). This prototype seedling must be tested with outplanting trials and these survival and growth results are then used to fine-tune target seedling characteristics (**C**).







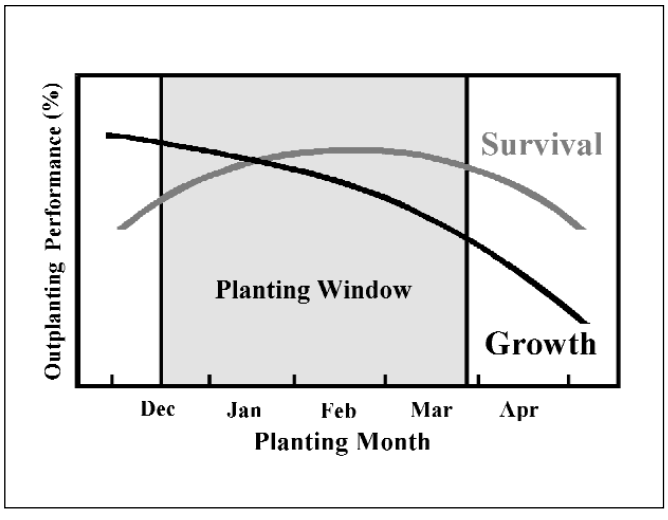
the root system and is sometimes specified by seedling users to match the stock type to conditions on the outplanting site.

Physiological Qualities

The most common measures of the physiological condition of forest and conservation seedlings are dormancy and hardiness. Dormancy refers to the state of relative metabolic activity, and seedlings reach maximum dormancy during the early winter. Hardiness is a general term for resistance to stress. Although cold hardiness is the most common type, hardiness can also refer to resistance to all types of stress, including high temperatures, dehydration, and physical handling.

Recently, nursery managers and foresters have been using 2 criteria to measure seedling quality. Root growth potential (RGP) measures a seedling's ability to produce new roots when growing in an ideal environment, such as a greenhouse. RGP tests are used operationally to establish lifting windows in the nursery and to help predict outplanting performance. The other common measure of physiological quality is the cold hardiness test, which measures the minimum temperature to which a seedling can be exposed without suffering observable cold injury. Because of their strong correlation with general stress resistance, cold hardiness tests have been used to establish nursery lifting windows and predict seedling tolerance to operational stresses such as dehydration and mishandling.

Figure 4—Chapter 7, Nursery Practices: seedling survival and growth is greatest during the "planting window," which is determined by conditions on the outplanting site, especially moisture and temperature (modified from South and Mexal 1984).



Genetic Considerations

Most seedlings grown for forest and conservation purposes are ordered by species, stock type, and seed zone or seed source. A seed zone is a geographic area that is relatively similar in climate and soil and often is described by a numerical code. Seed zones in mountainous terrain are also stratified by elevation (figure 5A). For example, the geographically diverse state of California has more than 80 different seed zones, with numerous elevation bands within each zone. All seeds and cuttings collected in a particular zone are labeled with that source code so that all seedlings produced from them will be planted back into the zone of origin. When a seedling order is sown in the nursery, information on species, seed zone, and elevation is included into a seedlot identification number. The seedlot number remains with this group of seedlings throughout their entire nursery tenure and is marked on the storage container when the seedlings are harvested for outplanting (figure 5B).

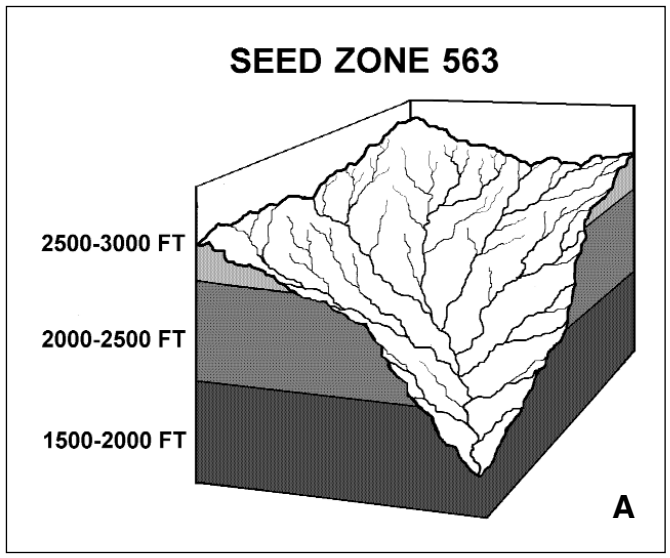
Types of Nurseries

Once the target seedling has been defined, the next step is to decide how best to grow it. Forest and conservation stock is propagated in either bareroot or container nurseries, and the choice is determined by several factors:

1. **Cost.** Container seedlings traditionally have been more expensive than bareroot stock, although, in recent years, the costs are becoming more comparable. Container nurseries also are more cost-effective at low seedling production levels.
2. **Species characteristics.** Most forest and conservation species can be grown as bareroot seedlings, although some do better in containers.
3. **Production time**. Because container seedlings can be produced more quickly than bareroot seedlings, they are often used to reforest burns and other sites that need to be planted quickly.
4. **Outplanting site condition.** Bareroot seedlings are used on typical reforestation sites, but container seedlings often are preferred for the more severe, hard-to-plant sites. Container stock has a wider outplanting window than bareroot stock.
5. **Personal preference.** Some customers tend to prefer one stock type over the other.

Because bareroot seedlings are grown in open fields, the soil, water supply, and climate of the nursery site must be suitable for propagation. The growth rate of bareroot seedlings and the length of the growing season are largely

Figure 5—Chapter 7, Nursery Practices: because plants are genetically adapted to local environmental conditions, forest and conservation nurseries use "seed zones" to ensure that seedlings will be ecologically adapted to the outplanting site (**A**). The seed zone and elevation are included in the seed source code, which will remain with the seedling throughout the nursery cycle (**B**).



controlled by the climate at the nursery site. Quality nursery soils are difficult to find in convenient locations, and good agricultural land is often expensive. Compared to container nurseries, bareroot nurseries usually require considerable capital to develop but have lower operating costs. A comprehensive discussion of site selection factors that should be evaluated when locating a bareroot nursery is presented in Duryea and Landis (1984) and Lantz (1985).

Container nurseries can be constructed on land with low agricultural value that would be unsuitable for bareroot seedling production. The amount of capital investment and

operating costs vary with the type of nursery. For example, fully controlled greenhouses require expensive structures and environmental controls, whereas open growing compounds are much less costly. Because container seedlings are grown at high densities, less land is required than for a bareroot nursery.

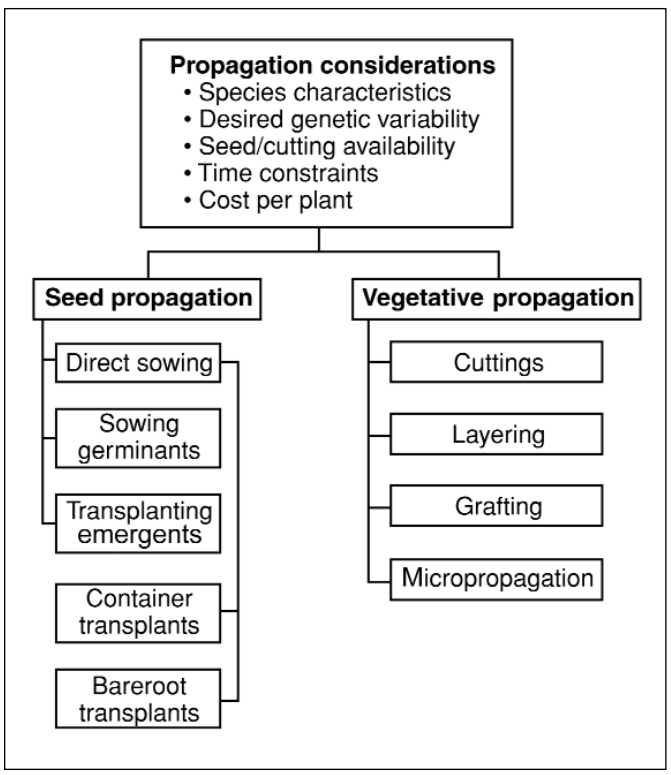
The decision whether to start a bareroot or container nursery must be carefully thought out because there are many considerations. It is helpful to list the various factors side-by-side for ease of comparison. A decision-making process is presented in the first chapter of volume one of the Container Tree Nursery Manual (Landis and others 1994).

Propagation Options

To determine which type of propagation method will be most effective and economical, both the biology of the plant and the objectives of the outplanting project must be considered (figure 6). As mentioned in the target seedling section, management objectives have a critical influence on the selection of propagation system. Most of the commercially important tree species used in plantation forestry can be grown from seeds, but a few are vegetatively propagated on a large scale to multiply selected clones. For example, on commercial forest land in the southeastern United States, southern pines are grown from genetically improved seeds. In the Pacific Northwest, forest product companies are vegetatively propagating fast-growing species such as redwood (*Sequoia sempervirens* (Lamb. ex D. Don) Endl.) and poplars (*Populus* spp.). Because biodiversity is a primary objective in ecosystem management and restoration, seed propagation is usually used, because it better captures and preserves natural genetic variation (table 1).

The availability of propagation material can also have an influence. Some species, such as western larch (*Larix occidentalis* Nutt.), produce seedcrops very irregularly; other species, such as Alaska-cedar (*Chamaecyparis nootkatensis* (D. Don) Spach), produce seeds of poor quality. Availability is critical for emergency planting projects, such as fire restoration, when the crops must be grown in a very short time. As for economics, seed propagation is almost always much less expensive than vegetative propagation. All vegetative propagation techniques involve more hand labor than does seed propagation and also require special equipment and structures (table 1).

Figure 6—Chapter 7, Nursery Practices: nursery managers must consider many biological, operational, and economic factors before deciding on the best propagation system for a given plant species. The first and most important decision is whether to use seed or vegetative propagation.



Seed Propagation

Seed propagation is the most common means of producing forest and conservation seedlings in North America because of its many advantages (table 1):

1. **Cost.** Plants grown from seed are inexpensive.
2. **Ease of propagation.** Seed propagation is simpler and easier than vegetative propagation.
3. **Seedling vigor.** Plants grown from seeds often grow faster than those produced from cuttings.
4. **Phytosanitary restrictions.** It is easier to import and export seeds than vegetative material or whole plants.

There are 4 major ways to produce plants from seeds (table 2). Only direct seeding and transplanting are used in bareroot nurseries, but container seedlings have been produced by all 4 methods.

Direct seeding. Direct seeding is the most common and most economical method. After any required pretreatment, seeds can be sown directly into containers or seedbeds. Seeds are always sown by seedlot, and each lot is immediately labeled with some sort of marker that contains all pertinent information. The seedlot location is also permanently recorded in case the markers are lost. Seedlot identity is carefully maintained during the entire nursery operation to ensure that the seedlings are returned to the environment to

Table 1—Chapter 7, Nursery Practices: operational considerations when choosing propagation methods

Considerations	Seeds	Cuttings	Micropropagation
MANAGEMENT OBJECTIVES			
Fast growth	Most species, using genetically selected seeds from orchards	Good for certain fast growing species	Relatively new but offers enormous potential
Biodiversity	Best	Low, but can be increased with extensive collections	
Availability of propagules	Varies seasonally & yearly; some can be stored for long periods, others not	Collection is seasonal with most species	Collection from stock plants at nursery
EASE OF PROPAGATION			
Difficulty	Relatively easy	Some species root easily; others not	Currently possible for a few species
Specialized equipment & training	Minimal	Moderate (rooting benches)	Definitely
Timing	BR = seasonal C = year-round	BR = seasonal C= year-round	Year-round
Cost per plant	Low	Moderate	High

Note: BR=Bareroot nursery C=container nursery

which they are adapted. In the Pacific Northwest, some nurseries sow literally hundreds of different seedlots each year, reflecting the many diverse environments in that mountainous terrain. In the South, some nurseries propagate by families and the seedlots from each family are sown and cultured separately.

Many forest and conservation seeds have some type of seed dormancy that keeps them from germinating when placed under unfavorable environmental conditions. Growers need to understand the dormancy characteristics of the seeds that they are trying to germinate, because the type of presowing treatment differs for each. For example, some plants exhibit seedcoat dormancy, which means that the seeds are impermeable to the water and/or oxygen that the embryos need to initiate germination. Culturally, there are a couple of ways to overcome this problem. Scarification—any treatment that breaks down the seedcoats to allow penetration of water and oxygen—can be either mechanical or chemical. Mechanical scarification consists of physically scratching the seedcoat to reduce its thickness, and chemical scarification involves dissolving the seedcoat with caustic chemicals such as acids. Hot water or steam can also be used to soften hard seedcoats.

Another common presowing seed treatment is chilling or stratification, which consists of keeping seeds under a cool, moist environment for a specified period of time. The term stratification comes from the practice of placing layers of seeds between layers of insulating material that keep them moist and cool. A more popular form of stratification is called "naked stratification" because bare seeds are soaked and then placed in a plastic bag without any accompanying material. Bags are kept in a refrigerator for a specified period of time according to the requirements of the individual species. The plastic bag maintains the moisture around the seed but also allows oxygen to enter. Some nurseries place a tube in the mouth of the bag to stimulate better air exchange (see chapter 1 on seed treatments).

Planting germinants. The second method for sowing seeds is to pregerminate the seeds and sow the germinants directly into containers. This technique is particularly helpful with seeds that require long or variable cold, moist stratification treatments; seeds from large-seeded species; and seeds from lots of variable quality (table 2). For seeds that need cold, moist stratification, seeds can be mixed with a moisture-retaining material such as peat moss and placed in a plastic bag in a refrigerator. Another option is to place seeds on moisture-retentive material in a covered tray and keep them refrigerated. Stratifying seeds are checked every few days to see if the seeds have split and germination begun. It is very important to keep seeds moist but not too wet, because mold can develop. Spraying the germination tray with a hand sprayer works well. Germinating seeds are individually picked out of the tray, sown into a container, and then promptly covered with a seed mulch such as white grit to keep them from drying out. Seeds that require warm, moist stratification can be germinated in a greenhouse by

Table 2—Chapter 7, Nursery Practices: characteristics of seed propagation methods for forest and conservation species

Propagation method	Type of nursery	Best use	Advantages	Disadvantage
Direct seeding (seeds are sown with or without pretreatment)	Bareroot or container	Seeds of high quality with viability test information; uniformly shaped seeds with smooth seedcoats	Quick; minimizes seed handling; mechanical seeding possible; most labor efficient; sowing all at once	Requires seed of known high quality; dormant seeds must be pre-treated; Containers require thinning and/or consolidation
Planting germinants or "sowing sprouts" (pregerminated seeds are sown from stratification trays or bags)	Container	Very large or irregularly shaped seeds; seeds of unknown quality or low purity; valuable or scarce seedlots	Good use of growing space; efficient use of seed; can adjust for unknown seed quality	Slower & more labor intensive; sowing can take weeks or months to complete; irregular crop development due to staggered sowings
Transplanting emergents or "pricking out" (seeds are sown into trays & then young emergents are transplanted)	Container	Small or fragile seeds; seeds of unknown quality or low purity; valuable or scarce seedlots	Good use of growing space; efficient use of seeds can adjust for unknown seed quality; more uniform crop development	Slower & more labor intensive; poor technique results in stem deformation; potential disease problems in seed flats
Transplanting seedlings (established seedlings are re-planted into a transplant bed or container)	Bareroot or container	Producing stock with more caliper & larger root systems; hold-over stock	Transplants are more resistant to pests & weeds; increased yields per unit area	Increases cost of stock; requires more bed space than seedlings; "J" or "L" roots result from poor technique

Source: modified from Landis and Simonich (1984).

covering them with a moist layer of burlap. It is important to moisten the seeds frequently during this warm stratification period and then plant them as soon as they crack.

The timing of sowing and seed placement are critical; seeds sown too late or improperly placed may develop weak stems. Germinants must be sown before the radicle becomes too long and begins to curve and must be positioned with the radicle pointing downwards. It is best to dibble a small hole in the growing medium prior to sowing the seed so that the root can be oriented properly.

Transplanting emergents. This method involves growing seedlings to the primary leaf stage and then transplanting them to a container (often called "pricking out"). Transplanting emergents works best for seeds that have complex dormancy, are small in size, or come from lots of variable quality (table 2). In some container nurseries, seeds are sown in special trays and placed in a greenhouse to germinate. Small seeds are covered with a thin layer of sand as a mulch. After the seeds germinate and the young seedlings begin to emerge from the germination medium, they are carefully removed one at a time with a pointed instrument and transplanted into a hole made with a dibble in another container. The growing medium is firmed around the transplant to ensure good root contact, and then the seedlings are allowed to grow into shippable size.

When planting emergents, proper technique is extremely important so that seedlings do not become "J-rooted." One option is to clip off the bottom of the root to make planting easier. Another technique is to use a sharp, forked tool to insert the seedling into the container and then to cut off the root tip after the seedling is placed into the growing medium.

Transplanting seedlings. This propagation technique is used in both bareroot and container nurseries (table 2). Through the 1950s, transplanting was the principal way of producing bareroot seedlings because precision sowing equipment was unavailable. Today, transplanting is again growing in popularity because of the demand for larger seedlings with more-fibrous root systems.

Transplants are more expensive to produce than seedlings, but this expense can usually be justified under the new "free-to-grow" reforestation regulations that mandate quick establishment and growth.

Some bareroot nurseries grow seedlings specifically for transplanting, whereas others use smaller-grade stock from harvested seedbeds. Most nurseries transplant bareroot seedlings in the spring, but container seedlings are often transplanted in the summer or early fall. Mechanical transplanters use a vertical "shoe" to open the soil and a

wheel with clips to place the transplant into the slit at the proper spacing. Transplant beds have the same physical dimension as seedbeds but seedlings are planted in fewer rows and at much lower densities. Once they become established, transplants are fertilized and irrigated and are given the same root culture treatments as bareroot seedlings.

The first container transplants were made from surplus stock but now seedlings are grown specifically for this purpose. Typically, seedlings are grown in 33- to 66-cm^3 (2- to 4-in^3) containers for 4 to 6 months and are then transplanted to the beds. Miniplugs, the newest type of plug transplant, are grown in very small containers (around 16 cm^3 or 1 in^3) specifically for transplanting. Plug transplants are cultured and harvested in exactly the same manner as are bareroot transplants. Another new larger container stock type is made by transplanting miniplugs into much larger containers—for example, 328 cm^3 (20 in^3).

A complete discussion of seed propagation is provided in Landis and others (1999).

Vegetative Propagation

The second major plant propagation technique is vegetative propagation, which also is called asexual propagation because 2 parents are not required. A clone is defined as a group of genetically uniform individuals that were originally derived from a single parent by asexual propagation. The major benefit of vegetative propagation is that the offspring will very closely resemble the parent because their genetic code is identical (figure 7). Other benefits of vegetative propagation include the following:

1. The ability to obtain a high degree of crop uniformity.
2. The elimination of problems with seed availability, dormancy, and viability.
3. The ability to perpetuate genetically superior plants, such as fast-growing or disease-resistant clones.
4. The ability to "bulk-up" valuable, genetically improved seedlots.

In forest and conservation nurseries, rooted cuttings are the most common type of vegetative propagation, and there are 3 different types that are named for the type of tissue used. Hardwood cuttings (figure 8A) are collected during the dormant period from the last season's growth, stratified in cold storage, and planted ("stuck") in containers or bareroot beds. Semi-hardwood cuttings are collected after the active growth period from hardened woody tissue of the current season's growth. Softwood cuttings are collected from soft succulent new shoots of woody plants that have just begun to harden, normally in spring, but also at any time of the year in species having multiple flushes. Cuttings can be collected from plants in the wild or from mother plants established in the nursery for that purpose; rows of these mother plants are called stool beds. In bareroot nurseries, cuttings are planted in rows in formed seedbeds and cultured just like seedlings (figure 8B). In container nurseries, cuttings can be rooted in special trays and then transplanted into the growth containers or stuck directly into the containers (figure 8C). Rooting hormones are used to promote new root formation in recalcitrant species. Some nurseries sell unrooted cuttings of such easy-to-root genera as poplar (*Populus*) or willow (*Salix*).

Root cuttings are another type of vegetative propagation source that has been used for some species, such as quaking aspen (*Populus tremuloides* Michx.). Sections of lateral aspen roots, which are actually modified stems, are collected from trees in the wild and placed in growing medium in the greenhouse. After several weeks, shoots form on the roots and can be cut and stuck into growth containers.

Other vegetative propagation methods include air layering, grafting and budding, and micropropagation. Layering is uncommon but can be used for species such as those in the *Rubus* genus that grow as vines. Grafting and budding are normally used for fruit trees; they are too labor intensive

Figure 7—Chapter 7, Nursery Practices: plants propagated from seed appear different from their parents, because they contain a mixture of genetic characteristics **(Top).** Vegetative propagation, on the other hand, produces exact duplicates of the parent plant **(Bottom).**

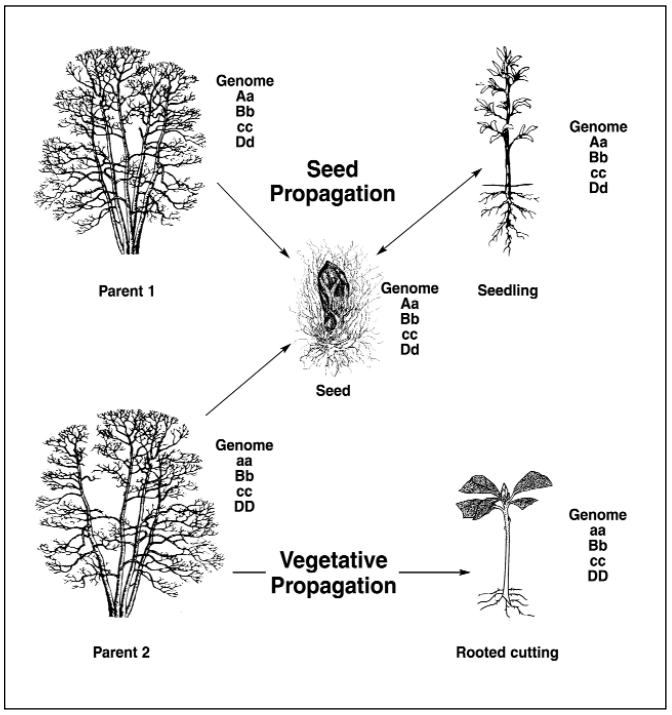


Figure 8—Chapter 7, Nursery Practices: hardwood cuttings are the most common vegetative propagation method used in forest and conservation nurseries (**A**). Hardwood or semi-hardwood cuttings are typically treated with rooting hormones and planted into bareroot beds (**B**) or containers (**C**).

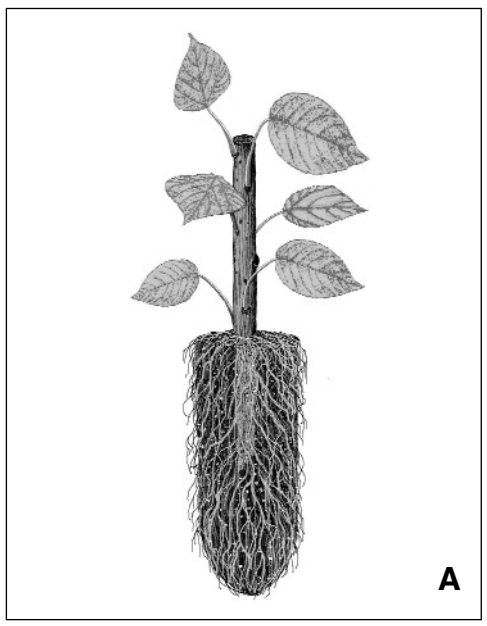
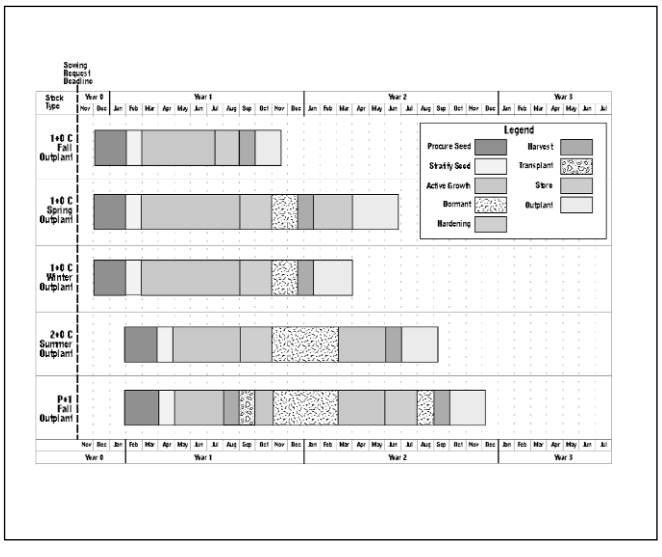


and thus too expensive to use for reforestation stock. Grafting is used in tree improvement programs to develop seed orchards. Micropropagation or tissue culture has been used for some forest species, but it requires specialized equipment and is therefore not currently practical for most species used in reforestation. A complete discussion of vegetative propagation is provided in Landis and others (1999).

Bareroot Nursery Cultural Practices

Bareroot seedlings take from 1 to as many as 4 years to produce, depending on the species, nursery climate, and stock type (figure 9). Southern pine seedlings are produced in 1 year, whereas some northern spruce transplants require 2 years in the seedbed and 2 more years in the transplant bed. Crop rotation requires at least 1 year longer to allow time for soil management. A typical crop rotation for a 2+0 ponderosa pine crop is 2 years with seedlings growing in the seedbed, followed by a 1-year rest or fallow period for the bed. The most comprehensive references on bareroot nursery management include Duryea and Landis (1984), Lantz (1985) and Williams and Hanks (1976). A complete discussion of the equipment needed to produce bareroot seedlings can be found in the *Bareroot Nursery Equipment Catalog* (Lowman and others 1992).

Figure 9—Chapter 7, Nursery Practices: growing schedule are used in crop planning to illustrate the time required for each phase of the nursery cycle from seed procurement to outplanting.



Soil Management and Seedbed Preparation

The bareroot nursery crop cycle starts with soil preparation. Next to water quality, the most important site quality factor in a bareroot nursery is the soil; maintaining or improving soil quality is an ongoing process. The best soil type for a forest and conservation nursery is sand to sandy loam at least 46 cm (18 in) deep.

A typical nursery crop cycle starts with either a cover crop, a green manure crop, or a year of leaving the soil fallow, depending on the objectives of the nursery manager. If the objective is to protect soil from wind and water erosion and control weeds, then cover crops are sown. Green manure crops are primarily grown to supply organic matter to the soil; they also serve as "catch crops" to capture mineral nutrients such as phosphorus and iron in a readily available form. The cover or green manure crop is plowed down in late summer to allow time for the organic matter to decompose (figure 10). If the objective is to eliminate weed growth and lower soil pathogen levels, then the land is kept fallow by repeated cultivation.

In addition to the organic matter supplied by the cover or green manure crop, many nurseries add organic amendments and fertilizers during the fallow year. Sawdust is a good soil amendment if nitrogen fertilizer is also added to promote decomposition; if no fertilizer is supplied, soil microorganisms will cause a nitrogen deficiency in the subsequent seedling crop. Many growers also add preplant fertilizers such as phosphorus or organic fertilizers during the rest or fallow year. Soil pH can be adjusted to the ideal range of 5.5 to 6.5 by adding dolomite to raise the pH or sulfur to lower it. Because phosphorus is immobile in the soil, phosphorus fertilizers are often incorporated into the soil at this time instead of as a top dressing during the growing season.

Figure 10—Chapter 7, Nursery Practices: the bareroot nursery cycle starts with soil preparation. Many nurseries sow a cover crop or green manure crop during the fallow year to protect the soil and maintain the organic matter level.

Seedbeds are prepared for sowing with a series of sequential cultivations, until the soil is worked into the proper crumb-like structure. Because of the frequent use of heavy equipment under wet conditions, soil compaction is a serious and recurring problem in forest and conservation nurseries. Many nurseries "deep rip" or "subsoil" their fields with long shanks during the rest or fallow year to a depth of 46 to 61 cm (18 to 24 in). Ripping is often done immediately after organic matter is applied so that it can be incorporated throughout the soil profile and prevent formation of hard, impermeable layers ("pans").

Many bareroot nurseries fumigate their seedbeds with soil sterilants such as methyl bromide/chloropicrin or methyl isothiocyanate. Fumigation is expensive, but eliminates all common nursery pests: pathogenic fungi, insects, nematodes, and weed seeds. The fumigants are either injected into or mixed with the soil and then covered with a plastic tarp or sealed with irrigation, allowing the gas to permeate throughout the soil. After several days, the tarp is removed or the soil seal broken to allow the gas to dissipate. Due to environmental concerns that have led to the phasing out of methyl bromide under the Montreal Protocol, nurseries are looking for alternatives to soil fumigation. One of these is encouraging the growth of beneficial microorganisms to make the soil suppressive to pathogens.

Sowing

Fall-sowing has been used to allow seeds to stratify naturally over the winter, but most nurseries sow in the spring as soon as soil temperatures are warm enough. In either case, the seeds are sown into preformed, raised seedbeds that are approximately 10 to 15 cm (4 to 6 in) high and 1.2 m (48 in) wide, a standard dimension that corresponds to all mechanized equipment. Seedbeds are laid out side-by-side between irrigation lines (figure 11).

The amount of seed to sow is calculated with a formula that takes both seed characteristics and "seedling factors" into consideration (figure 12):

Seed sowing rate = (desired seedbed density) ÷ (seed viability x nursery factor x seeds per weight)

Figure 11—Chapter 7, Nursery Practices: bareroot seedlings are grown in raised seedbeds that provide better drainage and warmer soil temperatures. Bed width is standardized to allow cultivation by tractor-drawn equipment (modified from *Bareroot Nursery Equipment Catalog* by Lowman and others 1992).

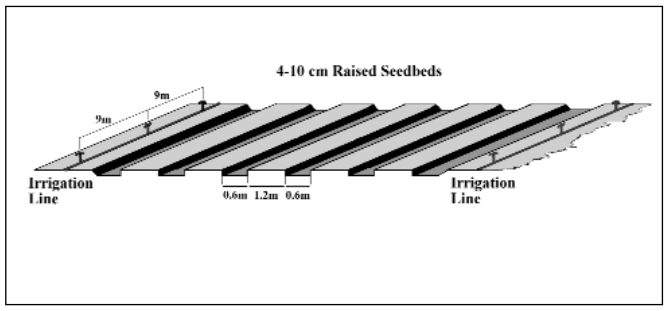


Figure 12—Chapter 7, Nursery Practices: seed use efficiency, the ratio of seeds sown to seedlings harvested, is a function of both seed quality and seedling losses during the growing season (from Thompson 1984).

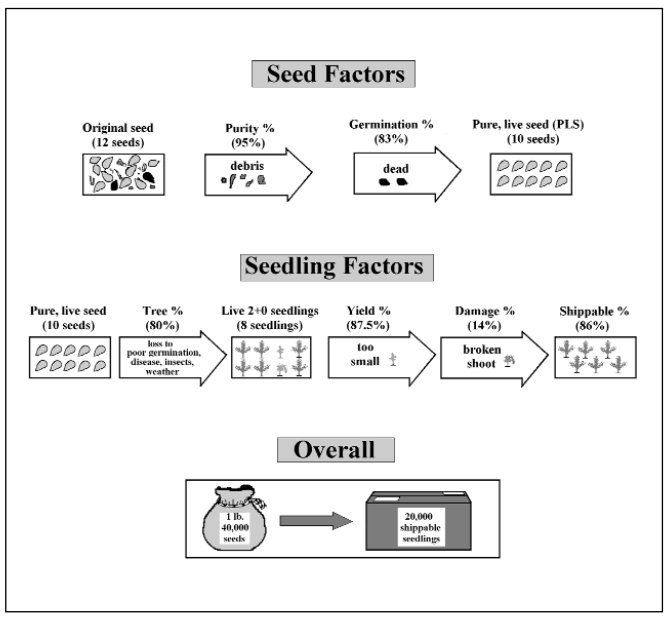


Sowing seeds at the proper density is one of the most important cultural operations in a bareroot nursery because it controls the quantity and quality of the crop. Seedlings sown at too low a density grow large and out of proper shoot-to-root balance and thus waste valuable growing space. On the other hand, seedlings planted at too high a density often become stunted and spindly and are more susceptible to disease.

Seeds can be broadcast-sown by hand, but this is a critical operation and requires training and practice. Seeds are sown by making quick sideways movements with the hand, pressed into the seedbed with a roller, and then covered with a mulch. Seeds can be mechanically broadcast with a drop spreader, such as a fertilizer spreader, which is calibrated to distribute the proper amount of seeds per area of seedbed. Very small seeds are often mixed with a carrier, such as sand or sawdust, so that they will be distributed more evenly.

Most bareroot nurseries use mechanical seed drills that sow seeds in 6 to 8 rows per seedbed. To control seedling growing density, precision drills are capable of accurately placing seeds at specific distances in the row. Some seed drills automatically cover the seeds with soil, whereas others leave seeds exposed so that they can be covered with mulch, such as sawdust, pine needles, or hydromulch. Mulches serve several functions, including controlling soil erosion, retarding moisture loss, and reducing soil temperature.

Many nurseries apply chemical herbicides immediately after sowing. These pre-emergence herbicides selectively kill germinating weed seeds but do not harm the tree seedlings. Newly sown seedbeds are kept moist until germination occurs, which usually takes 3 to 4 weeks.

Irrigation and Fertilization

The ability to supply water and mineral nutrients for accelerated seedling growth is one of the most important cultural activities in forest and conservation nurseries. Nurseries have used both wells and surface impoundments as water sources; both are adequate as long as they are properly designed to deliver the right amount of water at the right pressure at the right time. Total nursery demand must be calculated to include water for other cultural activities such as cooling or frost protection as well as for seedling growth. The quality of irrigation water is critical and should have been checked before the nursery was ever developed. High pH values of water can be controlled with acid injection but high salt levels cannot be corrected economically.

Most bareroot nurseries pump water through semi-permanent sprinkler systems to keep the seedbeds at the proper soil moisture level. The amount of water to apply can be estimated from soil moisture measurements and predictions of evapotranspirational demand, but successful irrigation requires both good judgement and practical experience. Sprinkler irrigation also is used to cool the soil surface while new germinants are still succulent and to provide protection against late spring or early fall frosts.

Bareroot nurseries apply mineral nutrients needed for rapid seedling growth with chemical or organic fertilizers. Maintaining a slightly acid soil pH is important to ensure that all nutrients remain available. A presowing application of sulfur to lower pH or dolomite to raise it were discussed earlier, along with incorporation of phosphorus. Unless soil tests show other nutrient deficiencies, nitrogen and potassium are the only fertilizers that are typically applied during the growing season. These applications are called "top dressings," because they are applied over the top of the crop. Application rates are determined by experience or from chemical tests of the soil and seedling foliage, and the fertilizers applied by drop or rotary spreaders. Some nurseries inject soluble fertilizer solutions into the irrigation system or apply them through a spray boom behind a tractor. Suspected nutrient deficiencies, as indicated by symptoms such as chlorosis ("yellowing"), should always be confirmed by soil or foliage tests because symptoms can be caused by many factors.

Root Culturing and Top-Pruning

Root culturing is critically important. A tree seedling is only as good as its root system, because forest and conservation species need fibrous roots to absorb water quickly after outplanting. Root-pruning consists of undercutting seedbeds with a stationary or oscillating horizontal blade to sever the dominant tap root and promote new, more-fibrous root growth. Wrenching is a special type of undercutting that uses a thicker angled blade to shatter the soil profile and increase soil permeability and aeration (figure 13). During the hardening period, wrenching also is used to induce a temporary seedling moisture stress that retards shoot growth and induces dormancy. Lateral root pruning with a vertical blade or coulter is used to cut the lateral roots between the seedling rows. This piece of equipment is sometimes "belly-mounted" under the tractor, which allows precise placement by the tractor operator.

Some nurseries top-prune their seedlings to control shoot height and increase crop uniformity. The timing of this operation is extremely critical to ensure that the seedlings are not injured or stimulated to produce abnormal shoot growth. The window for top pruning usually lasts only a few weeks and must be scheduled each year based on seedling development.

Harvesting

Harvesting, or lifting, is done during the dormant period when seedlings are in a state of maximum dormancy and hardiness. This time period, known as the "lifting window"

Figure 13—Chapter 7, Nursery Practices: root culturing is important to develop a fibrous root system. These pine seedlings are being wrenched with a sharp-angled blade that is being pulled under the seedbed.

occurs during the late fall, winter, or early spring, depending on the climate of the nursery. Nurseries in milder climates can lift all winter, but nurseries located where the ground freezes have only 2 narrow lifting windows: one in the fall and another in the spring. Because the weather is often too wet in the spring, some nurseries must lift a significant portion of their crop in the fall.

The lifting operation consists of drawing an inclined, vibrating blade under the seedlings, usually at a depth of about 25 to 30 cm (10 to 12 in). The inclined blade lifts seedlings out of the seedbed and the vibrating action loosens soil from around their roots (figure 14A). Some nurseries hand-lift their stock after the seedlings are loosened: the seedlings are pulled from the seedbeds, the loosened soil shaken from the roots, and the seedlings placed in a box. The lifting boxes often are lined with wet burlap to keep the roots from drying out. Several different types of mechanical harvesters are also used to lift seedlings. Most use a digger blade to lift the entire seedbed onto a moving, vibrating belt that shakes soil from the roots; others have rubber gripper belts that pull the seedlings from the soil and transfer them to the work platform. Boxes or larger totes of seedlings are quickly transported to a pre-storage cooler to await grading and processing. In the South, some nurseries "field-pack" their seedlings, which involves bagging seedlings immediately after they are lifted and weighing them. The number of seedlings per bag is estimated from a ratio between the weight of seedling samples and the seedling count.

The time period from when seedlings are lifted until they are outplanted is one of the most critical in the entire

reforestation sequence. Tiny fibrous roots are especially prone to drying and can be killed by a few minutes of exposure to heat, direct sunlight, or drying wind. The lifting crew includes several people who are assigned to keep the seedling boxes wet until they can be moved to the pre-storage cooler (figure 14B). Progressive nurseries monitor seedling quality during the seedling harvesting/outplanting operation. The pressure chamber directly measures seedling moisture stress and is used to determine when weather conditions are too dry to lift and to identify potential problems.

Grading, Packing, Storing, and Shipping

Boxes of seedlings that are not field-packed are brought into the packing shed where they are graded and counted. Graders visually rate each seedling according to predetermined grading standards (figure 14 C and D). Bundles of "shippable" seedlings are placed on a moving belt and "culls" are discarded onto the floor and destroyed. Seedlings grown especially for transplanting are also graded in this manner, and some nurseries use a multiple grading system: shippable seedlings, transplants, and culls. Grading standards often are specified by the customer, depending on the intended use. Usually, the nursery manager negotiates these standards with the customer when the seedling order is taken. Grading standards usually consist of a range of acceptable shoot heights, a minimum acceptable stem diameter (caliper), and the length and fibrosity of the root system. Each seedlot is processed separately during the grading process and each box is marked with the proper seed source code (figure 5B).

Shippable seedlings are placed in moisture-retaining boxes or bags. The root systems of southern species are dipped in a clay slurry that coats them and prevents desiccation. For northern species, sphagnum moss or cedar shavings ("shingle toe") is sometimes added to the storage container to keep roots moist. These storage containers are transported to a cooler where they are kept at temperatures near freezing to maintain dormancy and cold hardiness. Cold storage facilities keep the ambient temperature near freezing, but it is important to monitor the temperature inside the storage container. The type of storage depends on the cold tolerance of the species and the length of the storage period. Southern pines will not tolerate freezing and can be cold-stored at slightly above freezing for only 1 to 2 weeks. Cold storage is prescribed for northern species when the storage period is 3 months or less. If the storage period exceeds 3 months, seedlings need to be kept in frozen storage with temperatures kept slightly below freezing. Research has shown that frozen storage can maintain high seedling quality for more than 6 months and also retards the development of storage molds. Hardwood seedlings are cold-stored in open bins under very high humidity. Sometimes, when cold storage is not available, hardwoods are "heeled-in" in outside beds until they can be outplanted. Heeling-in is effective because dormant hardwoods have lost their leaves and therefore lose little moisture through transpiration.

The period between leaving the storage area to outplanting of seedlings is one of the most critical in the entire nursery and reforestation process. Seedlings are susceptible to many abuses; desiccation and warm temperatures are the most serious. Cold is the primary environmental factor that maintains seedling dormancy, and even fully dormant seedlings can begin to grow after relatively short exposures to warm temperatures. Ideally, seedlings will always be shipped and stored on the outplanting site in refrigerated vans. If seedlings must be shipped in non-refrigerated trucks, then they should be covered with white or reflective tarps to keep them cool and retard desiccation. An excellent guide to all aspects of seedling handling that pertains to all species—not just southern pines—is provided by Lantz (1989) in *A Guide to the Care and Planting of Southern Pine Seedlings*.

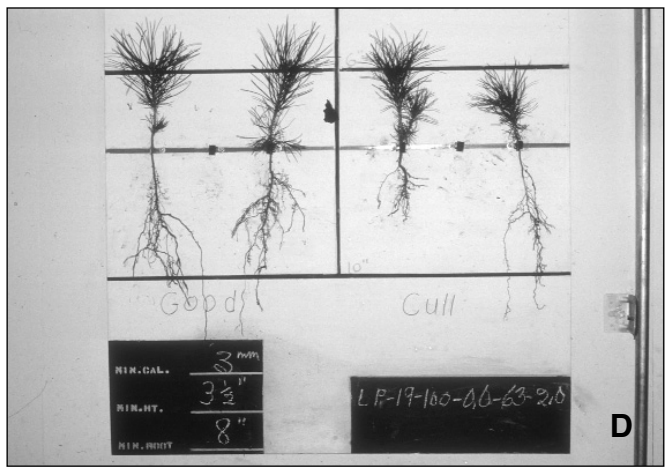
Container Nursery Cultural Practices

Container seedlings are grown in relatively small-capacity containers in special growth-promoting environments that can produce a shippable seedling in as little as 9 to 12 months (figure 2B). In the temperate zone, container crops are scheduled around the summer solstice, when solar energy and temperatures are at levels that promote rapid growth. Although many container nurseries typically grow just 1 crop per season, some can raise 2 or 3 crops by careful scheduling. The first crop is sown in late winter and grown in the greenhouse until outdoor conditions are mild enough to move seedlings outside. The second crop is sown just before the summer solstice so that the seedlings can still benefit from the intense sunlight of early summer and are left in the greenhouse through fall. In semitropical and tropical climates, container seedlings can be grown year-round and the growing schedule is primarily determined by moisture conditions on the outplanting site.

Propagation Environments

Several different types of growing environments are used to produce container seedlings. Fully controlled environments, such as the traditional greenhouse, are popular in colder climates and feature permanent sides and a full range of environmental control equipment. Semi-controlled environments, called shelterhouses, have sides that can be rolled up to promote better cross ventilation (figure 15A).

Figure 14—Chapter 7, Nursery Practices: harvesting equipment lifts bareroot seedlings by undercutting them and loosening soil from around the roots with vibration (**A**). During hand-lifting, workers pull seedlings from the seedbed and place them in tubs, being careful to avoid excessive exposure and desiccation (**B**). Seedlings are then taken to the packing shed where they are counted and graded (**C**) to predetermined morphological specifications that were agreed upon by the nursery manager and the customer: shoot height, stem diameter (caliper), and some measure of root size and fibrosity (**D**). Finally, the "shippable" seedlings are sealed into moisture-retentive bags or boxes for refrigerated storage (**E**).



Shelterhouses produce one crop per season, and the seedlings benefit from exposure to ambient conditions during the hardening phase. In milder climates, container seedlings can be grown in outdoor compounds (figure 15B). The type of growing environment will determine which cultural options are available and the resultant seedling growth rate. To reach the genetic potential of the crop, greenhouses and shelterhouses supply heating, ventilation, photoperiodic lighting, irrigation, fertilization, and even supplemental carbon dioxide. In open compounds, the ground is covered with weed barrier cloth and gravel to control weed growth, and the seedlings are raised on tables. Although temperatures cannot be controlled, the crop has the benefit of irrigation, fertilization, and sometimes even photoperiodic lighting.

Figure 15—Chapter 7, Nursery Practices: container seedlings are grown in a variety of propagation environments ranging from traditional greenhouses, to shelterhouses (**A**), and open growing compounds (**B**).

Types of Containers

There are many different types of containers, with capacities ranging from as small as 16 cm^3 (1 in^3) to more than 492 cm^3 (30 in^3). The most commonly used container types include Styrofoam® blocks, book planters, and several types made of molded hard plastic. Other growing containers, such as peat plugs and plastic bags, are sometimes used, but these lack vertical ribs on their insides for controlling root spiraling. The best type of container depends on available nursery equipment, the species of plant, and conditions at the outplanting site. Hardwood species must be grown in relatively larger containers than conifers because their large leaves intercept irrigation and create more shade competition with their neighbors. Foresters prefer seedlings grown in smaller containers for moist outplanting sites, but demand larger container stock for harsh dry conditions or sites with heavy brush competition. New container types are continually being developed. One of the newest innovations involves lining the container cavity with copper compounds that "chemically prune" the root system. Most containers can be used for more than 1 growing season and thus must be cleaned and sterilized between crops with hot water or chemical disinfectants.

Growing Media

Almost all container nurseries use some type of artificial growing medium instead of native soil. An ideal medium should be sterile, lightweight, porous, and consistent in quality. Several different brands of media are commercially available, and most are composed of sphagnum peat moss, vermiculite, and sometimes perlite, composted bark, or sawdust. Some nurseries mix their own growing media. Larger nurseries have specially designed mixers for blending the components, and some have customized equipment using cement mixers and so forth. Some components of growing media, such as vermiculite and perlite, are inherently sterile; sphagnum moss, however, may contain pathogenic fungi. Chemical fumigants or steam heat are typically used to sterilize media. Fertilizers or other chemical amendments are sometimes added to growing media during the mixing process. Dolomitic limestone is used to supply calcium and magnesium and raise the low pH. Slow-release fertilizers, such as Osmocote®, are composed of resin-coated pellets that release mineral nutrients in response to temperature and moisture.

Containers are filled with growing medium in several different ways. Smaller nurseries fill containers by hand. Automated filling machines that do everything from filling and tamping the medium to sowing and covering the seeds can also be used. A complete discussion of container types and growing media can be found in Landis and others (1990).

Sowing and Thinning

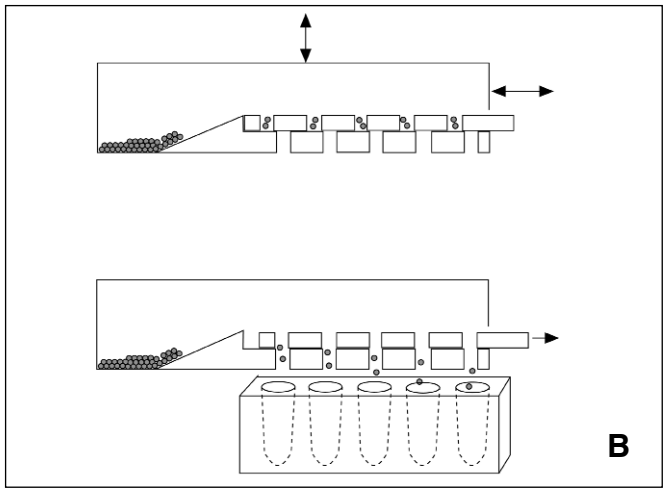
The number of seeds to sow per container cavity is calculated using the seed germination percentage, with the objective of having no empty cavities. Containers can be sown by hand, which is necessary for very large or irregularly shaped seeds, or with various sowing machines. The shutterbox (figure 16A) consists of a template with a set of predrilled holes that correspond to the pattern of the individual container cavities. The size of the holes in the shutter control the sowing rate, usually from 2 to 6 seeds per hole depending on seed quality (figure 16B). Vacuum seeders have plates or drums that hold a certain number of seeds until they are released into the containers. Precision sowing machines can accurately control the sowing density down to

1 seed per cavity. Although expensive, this equipment saves valuable seeds and eliminates the need for thinning.

The final stage in the sowing process consists of covering the sown seeds with some type of mulch such as perlite, grit, or coarse vermiculite. Light-colored mulches are preferred because they reflect sunlight and thus do not heat up as much as darker materials. Seed mulches restrict the growth of algae, mosses, and liverworts and also prevent weeds from becoming established. The depth of seed covering is very critical—if it is too deep, the seeds will not germinate; if it is too shallow, the seeds will dry out. The recommended depth is 2 to 3 times the width of the seeds.

Sown containers are moved into the growing area where they are placed on specially designed pallets or benches that promote air-pruning of the root system. Some benches are constructed on rollers so that they can be moved together when access is not required. This feature is popular because it saves valuable growing space. As in bareroot nurseries, the identification of each seedlot and its location is carefully monitored during the nursery process.

Figure 16—Chapter 7, Nursery Practices: shutterbox seeders are custom-made for each type of container (**A**). Sowing consists of filling the precisely spaced holes in the shutter with seeds (**B, top**) and then moving it laterally to allow the seeds to drop into the containers (**B, bottom**).



After 3 to 4 weeks, when seed germination is complete, workers thin multiple germinants down to 1 per cavity and remove any weeds that may be present. Extra seedlings are either pulled or clipped, depending on their size. Larger seedlings must be clipped because pulling them may uproot the crop seedling. If the sowing calculations were inaccurate, some containers may be empty. Resowing is an option, but late-sown seedlings would rapidly be overtopped by their neighbors and usually remain stunted. Single-cell containers such as the Ray Leach® system can be consolidated to remove empty cavities, saving valuable growing space.

Irrigation and Fertilization

Water quality is the most critical site selection factor for container nurseries, but because these nurseries can use a well-drained, slightly acid growing medium, they are better able to manage marginal water quality than are bareroot nurseries.

Eliminating water stress is crucial to achieving good seedling growth, and container nurseries use either stationary overhead sprinklers or mobile boom irrigation systems. Stationary systems consist of sprinkler heads set in a regular pattern that distribute water in a circular pattern (figure 17A), whereas mobile systems have a horizontally mounted boom that moves back and forth to deliver a uniform amount of water to the crop (figure 17B). Determining when and how much to irrigate is particularly difficult in a container nursery because seedlings use up water quickly in the small containers and it is difficult to directly observe moisture conditions. The best irrigation monitoring technique is to weigh containers between irrigations, as the relative wetness of the growing medium can be correlated to container weight.

Most container nurseries fertilize through the irrigation system, a process sometimes called "fertigation." Liquid fertilizer solutions are injected into the irrigation lines in the headhouse and applied to the crop through nozzles. The ability to supply all 13 essential mineral nutrients allows seedlings to grow at an exponential rate, and nutrient injection systems can supply the proper nutrient concentration and ratio at exactly the right time.

Hardening

When container seedlings have reached their desired height, the nursery manager changes the growing environment to initiate hardening. The most critical environmental

Figure 17—Chapter 7, Nursery Practices: container seedlings are typically irrigated either with stationary sprinklers (**A**) or moving irrigation booms (**B**).

factors for inducing hardiness and dormancy are cooler temperatures, mild moisture and nutrient stress, and shortened photoperiod. Seedlings in fully enclosed greenhouses are often moved to a shadehouse at this time, where the change in temperature and humidity aid the hardening process. Growers with shelterhouses permanently raise the sides to expose the crop to ambient conditions. At the same time, the photoperiod lights are shut off and the fertilizer mix changed to a special low-nitrogen hardening formula.

Harvesting, Grading, Storing, and Shipping

The harvesting method is related to the type of seedling storage. Some nurseries store their container seedlings outside to overwinter in sheltered storage, being particularly careful to insulate the root systems against cold. Seedling roots are much less cold-tolerant than shoots and can be damaged or even killed at temperatures that are only a few degrees below freezing. Other nurseries grade their seedlings and ship them directly to the outplanting site in the growth container. This procedure is necessary where freezer storage facilities are not available, but the seedlings still must be protected and maintained at the outplanting site.

Refrigerated storage is becoming increasingly popular. Like bareroot seedlings, container stock is usually harvested during the dormant period unless conditions on the outplanting site require otherwise. Cold hardiness tests can be used to determine when seedlings are ready for harvesting. Research has shown that these tests are a good indication of overall hardiness and dormancy. Nurseries pull seedlings from the growth container and wrap or bag them in bundles (figure 18A). The bundles are placed in moisture-proof boxes and stored under refrigeration (figure 18B). Container seedlings of cold-tolerant species can also be freezer-stored and treated essentially the same as bareroot stock. Container stock should be shipped to the outplanting site in refrigerated vans whenever possible and always kept out of direct sunlight and protected from drying winds.

Pest Management

The objective in both bareroot and container nurseries is to optimize the potentially limiting factors that control seedling growth to create the perfect propagation environment. Like all things in life, however, there is a trade-off. In this case, there is an increased risk of pests and abiotic stresses—increased succulence means greater risk of abiotic injury (frost injury is a prime example). The perfect propagation environment is also, unfortunately, a perfect breeding ground for many fungi, insects, and other pests.

A disease occurs anytime a seedling is not completely healthy. Both biotic pests and abiotic stresses can cause disease. Typical nursery pests include fungi, insects, and even weeds or moss, which compete with the seedling for light, nutrients, and water. Abiotic stresses include temperatures that are too high or too low and moisture and nutrient stresses. Although most people would think that biotic pests cause the most injury in nurseries, that is not the case (figure 19). Abiotic diseases are actually more common, especially in bareroot nurseries and open growing compounds, where seedlings are subject to the vagaries of the weather.

All pest problems can be prevented much more easily than they can be cured, so nurseries should set up a regular monitoring program. Nursery workers should constantly be on the lookout for anything unusual and notify the manager immediately if they notice a potential problem. Careful monitoring can distinguish between biotic and abiotic diseases (table 3) and make control much more effective. There

Figure 18—Chapter 7, Nursery Practices: many container seedlings are harvested by pulling them from the containers (**A**), wrapping them in plastic film or placing them in bags, and then storing them under refrigeration (**B**).

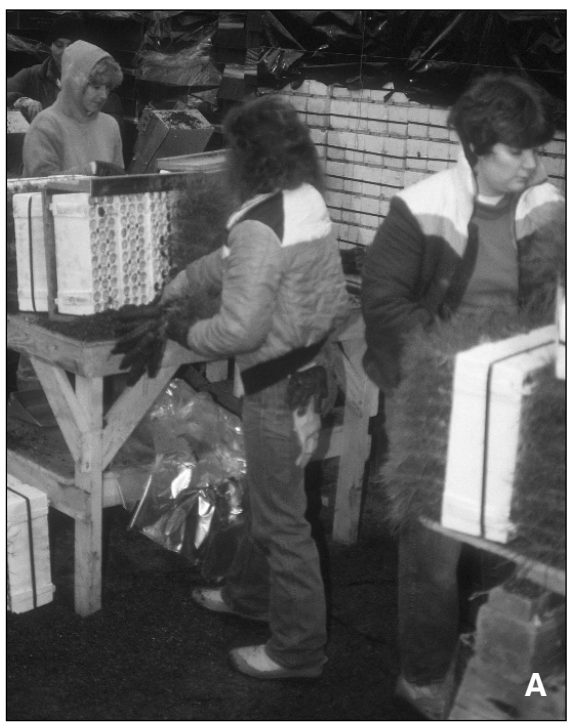


Figure 19—Chapter 7, Nursery Practices: abiotic diseases are usually more common than damage from biotic pests in forest and conservation nurseries (modified from Sutherland and others 1982).

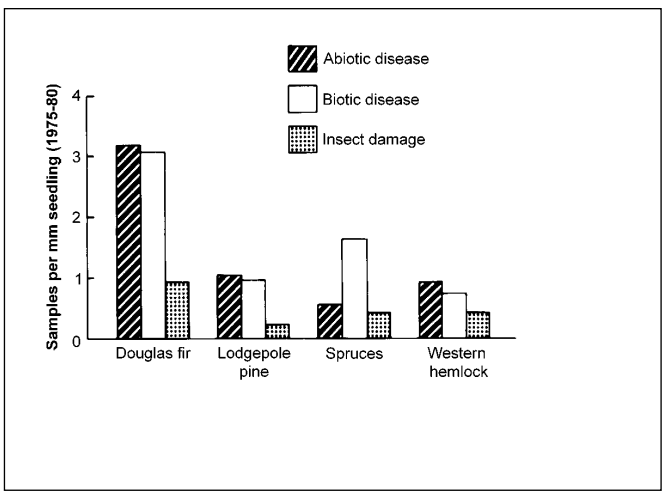

are a couple of good references that can help improve diagnostic skills. For bareroot seedlings, readers are referred to *Forest Nursery Pests* (Cordell and others 1989), and for container seedlings, to volume five of the *Container Tree Nursery Manual* (Landis and others 1989).

Once a pest has been confirmed and the population has exceeded the allowable limit, growers should take immediate action. All controls should be part of an integrated pest management (IPM) program that uses cultural as well as chemical controls. Many pest problems, such as *Botrytis* blight, can be almost completely controlled using proper irrigation and sanitation measures. Fungicides and insecticides are often needed however, especially when a problem has gotten out of hand. Pesticides are usually injected through the irrigation system in container nurseries or with tractor-drawn sprayers in bareroot beds. In recent years, some new biocontrol agents have proven useful in controlling insect pests, such as fungus gnats in greenhouses.

Weeds are a much more serious concern in bareroot nurseries, where they must be controlled either mechanically

Table 3—Chapter 7, Nursery Practices: careful observation of disease development can aid in diagnosis

Characteristics	Abiotic disease	Biotic disease
HOSTS	Often affects several species, or ages of seedlings	Usually restricted to one species or age class
SYMPTOMS		
Patterns	Regular: spatially related to some environmental factor	Random locations at first
Rate of development	Rapid & uniform	Relatively slow & uneven
Signs	No evidence of a pest	Pests or indirect evidence present
Spread	Related to one incident, with no secondary spread	May spread over time under favorable conditions

Source: modified from Sutherland and Van Eerden (1980).

and chemically. Hand-weeding and mechanical cultivation can keep weed populations low and are especially effective if done before weeds are allowed to go to seed. Most nurseries apply a pre-emergence selective herbicide immediately after sowing and then at intervals during the growing season. Another option is to apply non-selective contact herbicides directly to the weeds with wick applicators or shielded sprayers.

Beneficial Microorganisms

Mycorrhizae develop from a symbiotic relationship between a beneficial fungus and the roots of the host seedling. Although mycorrhizae have been a popular topic for many years, there seems to be a variety of opinions as to their value in forest and conservation nurseries. Some people believe that mycorrhizae are essential for both nursery culture and successful outplanting, whereas other nursery and reforestation specialists are more skeptical. Almost 50,000 research studies have been done on mycorrhizae, and most confirm the benefits of reducing root disease and increasing seedling tolerance to drought and other environmental extremes. Results of operational nursery and field trials have been more variable, however, depending on the species of mycorrhizal fungus used and soil fertility and types of indigenous fungi on the outplanting site.

Inoculation with mycorrhizal fungi can be worthwhile, but the timing of inoculation and species of fungus should be matched to nursery and outplanting objectives (table 4). In particular, the fungal species should be selected for either the nursery or the outplanting site. There is no "all-purpose" fungus that will perform well under all conditions. Most fungal species that are adapted to wildland conditions will not survive under the high moisture and high nutrient nursery environment and vice versa. However, some genera of fungi, including *Thelephora, Laccaria,* and *Rhizopogon*, have strains or ecotypes that are adapted to either nursery or forest soils.

The species of fungus, type of inoculum, and timing of the inoculation will vary with the objectives of the treatment (table 4). Inoculants that are meant to prevent diseases or increase seedling growth in the nursery should be applied to seeds, incorporated into the soil or growing medium or applied as a spore suspension (figure 20). However, if the objective is to increase seedling survival and growth after outplanting, then a species of fungus adapted to the outplanting site should be applied late in the growing season or as a root dip during processing (table 4).

Therefore, when considering inoculation, it is extremely important to define objectives. Mycorrhizal fungi and other beneficial microorganisms can make a good seedling better but they shouldn't be expected to be a "cure-all" that will solve every nursery and outplanting problem.

Summary

Anyone considering propagating forestry and conservation species must be familiar with the unique characteristics of these plants. Unlike most other crops, seedlings from forest nurseries are typically outplanted on relatively harsh sites without subsequent care. This difference is significant because seedling quality is defined by environmental conditions on the outplanting site. There is no such thing as an "all-purpose" tree seedling. Bareroot and container seedlings have different applications, and the choice of approach depends on the available resources, the nursery climate, and the conditions on the outplanting site.

Table 4—Chapter 7, Nursery Practices: nurseries and seedling customers must consider their reasons for inoculating with mycorrhizal fungi because their objectives determine the species of fungus and the type and timing of inoculation

Type of mycorrhizal inoculation	Timing in the nursery crop cycle	Objectives of inoculation *	
		Nursery	Outplanting
Coating seeds with spores	Before sowing	1) Increased growth 2) Disease prevention	None
Incorporating mycelia into the growing medium	Before sowing	1) Increased growth 2) Disease prevention	None
Liquid drench with spores	Establishment or rapid growth phases	1) Increased growth 2) Disease prevention	None
Liquid drench with spores	Hardening phase	1) Disease prevention 2) Increased growth	1) Increased survival
Root dip with spores	During packing or before outplanting	None	1) Increased survival 2) Increased growth

* Regardless of the biological objectives, mycorrhizal inoculation may have marketing advantages.

Figure 20—Chapter 7, Nursery Practices: seedlings can be inoculated during the growing season with a liquid suspension of spores from a beneficial mycorrhizal fungus.

Forestry and conservations plants are typically propagated by seed, although vegetative propagation is used for some species. Direct seeding is by far the most common, although sowing germinants or transplanting is used for species that have complex germination requirements or other operational restrictions. Although specific practices differ for container and bareroot seedlings, a successful cultural regime must be designed to reflect the biological requirements of the species and the available resources of the nursery.

Seedlings must be properly handled and stored from the time they are harvested until they are outplanted. Exposure of the root system is particularly damaging to seedling quality. Because warm temperatures rapidly bring seedlings out of dormancy, refrigerated storage is recommended whenever possible. The time between removing the seedlings from the storage area and outplanting them is one of the most critical in the entire nursery and reforestation process. Seedlings are susceptible to many abuses, with desiccation from exposure to direct sun and overly warm temperatures the most serious. Seedling users need to understand that seedling quality only decreases after the seedlings leave the nursery and all mistakes and abuses are cumulative.

Data for 236 Genera

Pinaceae—Pine family

Abies P. Mill.

fir

D. George W. Edwards

Dr. Edwards retired from the Canadian Forest Service's Pacific Forestry Centre

Growth habit, occurrence, and use. The name *Abies* is derived from "abed," the Old World Latin name for the silver fir (Dallimore and Jackson 1967; Weber 1987). Theophrastus (371–286 BC) wrote of "silver firs" from Mt. Ida (today's Kaz Dag, Turkey) being used in shipbuilding, which may have been the lumber of *A. equi-trojani* (Thanos 2003b), but also may have been in reference to *A. cephalonica* Loud. and/or *A. pectinata* DC. (now *A. alba* P. Mill.) (Amigues 1993, cited in Thanos (2003b). The name *Abies* first appeared in Pliny the elder's *Historiae Naturalis* from about AD 77 (Liu 1971).

Firs are long-lived, on average achieving reproductive maturity at 20 years, with an average life-span of 60 years (Jacobs and others 1984). Fir trees in excess of 400 years old have been recorded in several species (Earle 1999), and noble firs 600 to 700 years old are known (Arno and Hammerly 1977; Franklin 1979; Franklin and Dyrness 1973), but such life spans are modest compared to those of other tree genera. Siberian fir (table 1) rarely, if ever, survives more than 200 years because the main stem decays out (Vidakovic 1991). In numbers of species, fir is second only to pine but lags behind spruce (*Picea* spp.) and Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco) in terms of overall importance (Franklin 1982a).

All fir species are indigenous to the Northern Hemisphere (table 1), being widely distributed over the Eastern and Western Hemispheres (Liu 1971) chiefly in the temperate and frigid regions, from sea level to altitudes of 4,700 m. More than 70 species have been variously described (Liu 1971), although the number of those currently recognized is between 39 (Liu 1971) or 40 (Vidakovic 1991), 46 (Farjon 1990), ~50 (Welch 1991), and 55 (Rushforth 1987), depending on placements into varietal categories. Firs are found in 4 extensive regions (Franklin 1974b; Liu 1971; Miller and Knowles 1989; Welch 1991; Young and Young 1992):

- North America (Alaska to the Mexican border)—9 species
- Central America (Mexico, Guatemala, Honduras, and El Salvador)—8 species (Martinez 1948) or 6 species (Liu 1971)
- Mediterranean Basin, as well as lands bordering it, including southern and central Europe to the north, western Asia (Asia Minor, Caucasia, Syria, and Lebanon) to the east, and northwestern Africa (Morocco, Algeria, and Tunisia) to the south—8 species
- Siberia and eastern Asia (Amur, China, Korea, Japan, Taiwan, and the Himalayas)—17 species

The latitudinal range stretches some 53 degrees, from north of the Arctic Circle (north of 67°N, almost to Arkhangel'sk, Russia, on the White Sea) with Siberian fir (Liu 1971), to south of the Tropic of Cancer (south of 15°N, in El Salvador) with Guatemalan fir (FAO, in Anon. 1986). Fir has a long history in Mexico, with pollen from the middle Pleistocene Epoch (5 million years ago) (Graham 1999). The most widely distributed species is Siberian fir, then balsam fir, followed by subalpine fir (Liu 1971). Globally, some species—including Algerian fir (FAO, in Anon. 1986), bristlecone fir (Legg 1953; Little 1975; Talley 1974), Bulgarian fir (see table 1 footnotes for scientific name), Grecian fir, Spanish fir, (FAO, in Anon. 1969), Sicilian fir (Arena 1959a&b, 1960; FAO, in Anon. 1986); Gramuglio 1962; Köstler 1957) and Guatemalan fir (Anon. 1986; Donahue and others 1985; FAO, in Anon. 1986; Salazar 1991; Veblen 1978)—have restricted ranges or are rare and, in some ecosystems, endangered and threatened with extinction. No longer found on the island of Corsica, "silver fir" was described by Theophrastus (Thanos 2003b) as growing taller and better there than anywhere else in central and southern Italy. In 1986, 21 wild trees of Sicilian fir, a species that was considered extinct in 1900, were reported growing at Monte Scalone, Sicily; other plants grown from

* Spelling of Chinese place names has changed over time. This name is given as Hopeh in Liu (1971) but is currently Hebei.
† Formerly spelled Szechuan or Szuchuan (Liu 1971).

Note: The following recognized fir species are not included in the table for lack of sufficient data (common names are given when known):

CENTRAL AMERICA: *A. colimensis* sp. nov. Rushf. & Nar.; *A. durangensis* Mart. (Durango fir); *A. flinckii* sp. nov. Rushf.; *A. hickelii* Flous et Gauss. (Hickel fir); *A. hidalgensis* sp. nov. Debr., Rácz & Guíz.; *A. neodurangensis* sp. nov. Debr., Rácz & Salaz.; *A. zapotekensis* sp. nov. Debr., Rácz & Ramír.; *A. vejarii* Mart. (Vejar fir).

EAST ASIA: *A. beshanzuensis* Wu (Baishan fir); *A. chengii* Rushf. (Cheng fir); *A. chensiensis* Van Tiegh. (Shensi fir); *A. delavayi* (Van Tiegh.) Franch. (Yunnan fir, or Delavay fir); *A. densa* Griff. (Sikkim fir); *A. fabri* (Mast.) Craib (Faber fir, sometimes also Yunnan fir); *A. fanjingshanensis* Huang, Tu et Fang (Fanjingshan fir); *A. fargesii* Franch. (Farges fir); *A. forrestii* Coltm.-Rog. (Forrest fir); *A. kawakamii* (Hay.) Ito (Taiwan fir); *A. spectabilis* (D. Don) Spach (east Himalayan fir or Webb fir); *A. yuanbaoshensis* Lu et Fu (Yuanbaoshan fir); *A. ziyuanensis* Fu et Mo (Ziyuan fir).

MEDITERRANEAN BASIN: *A.* x *borisii-regis* Mattf. (Bulgarian fir, sometimes Macedonian fir, or King Boris fir); *A. marocana* Trab. (Moroccan fir); *A. tazaotana* Cheval. (Tazaotan fir).

seeds or grafts have been established in various parts of Europe (FAO, in Anon. 1986). Bristlecone fir is found in sufficient numbers, and is distributed widely enough, that the potential for extinction remains low (Smith and Berg 1988), and research on genetics and population viability is underway (USDA FS 1992). The sacred fir, or *oyamel*, of Mexico is logged heavily. However, since 1975 has it become generally known that the bulk (the populations east of the Rocky Mountain crest) of North American monarch butterflies (*Danaus plexippus* L.) overwinter on the cool slopes of the transvolcanic ranges west of Mexico city forested with *oyamel* (Pyle 1992, 1999). Thus, the *oyamel*s may be preserved to protect the monarchs. The arboreal altitude record, 4,700 m, is held by flaky fir, with its distinctive reddish-brown bark that exfoliates in thin papery scales, found in the very dry regions of China near Tibet (Rushforth 1987).

Firs are easily distinguished from all other conifers by their disk-like leaf scars and erect, oblong-cylindrical, or cylindrical seed cones. These are borne in the uppermost regions of the crown and are essential to species identification (Farrar 1995). At maturity, the terminally winged seeds, ovuliferous scales, and bracts are shed (Dallimore and Jackson 1967; Farrar 1995), leaving the cone axis—the rachis—as a persistent, erect spike, a unique and distinctive feature of all firs (Hosie 1969). *Abies* is considered to be most closely related to the genus *Keteleéria;* species of this genus have upright, cylindrical cones that resemble those of firs, but *Keteleéria* cones do not disintegrate at maturity (Rehder 1958).

Nine fir species are native to North America; 7 introduced Asiatic and European species have become common in their use as ornamentals or Christmas trees (table 1) and others are being tested (Girardin 1997a). Table 1 is not a complete list of all fir species but covers only those firs for which widely accepted cone and seed information was available at the time of this revision. Brief descriptions, including cone and seed morphology, for nearly 2 dozen other firs found outside North America are available in a website maintained by Earle (1999). Older, still-valid descriptions of fir species with dates of introduction into North America (Rehder 1958) are used frequently by growers of exotic conifers, but readers should be aware that species nomenclature has changed in numerous cases. Information on 22 fir species recognized in China can be found in the *Flora of China* (Cheng and Fu 1987).

Firs play an important role in European forestry, although only European silver fir is distributed widely enough to be of more than local value (Handley 1982). Several North American firs, including white, grand, and noble firs have been planted in Europe but are only locally important (Handley 1982); subalpine fir is grown in Scandinavia (Dietrichson 1971), especially at high elevations in Norway (Hansen and Leivsson 1990). Introduction of the genus to New Zealand began in the mid-19th century; of some 30 fir species now grown there, white, grand, California red, Nordmann, Spanish, noble, and sacred firs have been suggested as "contingency" species, that is, alternatives to Monterey pine (*Pinus radiata* D. Don) (Miller and Knowles 1989).

It is in western North American that firs attain their greatest ecological and economic importance (Franklin 1982a). They are major vegetation components, especially in the boreal, Pacific Coast coniferous, and western montane/alpine coniferous forests. They are critical as cover for watersheds where heavy winter snowpack accumulates—this cover modifies snowmelt so that runoff continues throughout the spring and into summer (Franklin and others 1978; Laacke and Fiske 1983)—and the maintenance and regulation of high-quality streams (Hunt 1993). Firs provide cover, and their seeds and leaves are important as food for various birds, including northern spotted owl (*Strix occidentalis*) (Ripple and others 1991), osprey (*Pandion haliaetus*), and bald eagle (*Haliaeetus leucocephalu*s) (Hopkins 1979) and mammals including mule (*Odocoileus hemionus*) and white-tailed (*O. virginianus*) deer , elk (*Cervus elaphus*), and black (*Ursus americanu*s) and grizzly bears (*U. arctos*), moose (*Alces alces*), and mountain goat (*Oreamnos americanus*) (Agee 1982; Cooper and others 1987; Leach and Hiele 1956; Peek 1974; Steele and others 1981). Some of these animal species are sensitive, rare, or endangered (Laacke and Fiske 1983). Excellent sources of information on wildlife-cover values of fir forests are available (FEIS 1996).

Firs are found at all elevations, from sea level (grand fir on the Pacific Coast and balsam fir on the Atlantic Coast) to timberline (noble and subalpine firs); they attain their maximal development on relatively cool, moist sites (Franklin 1974b). Noble fir is one of the most windfirm trees (Earle 1999). The form, texture, and color of fir trees add to the high scenic values of their growing locations, many of which have become important recreation areas. Their attractive, highly symmetrical appearance make many species, particularly Fraser and Pacific silver firs, valuable in urban horticultural plantings, where their slow growth can be an advantage. Whereas the original *Woody-Plant Seed Manual* (USDA FS 1948) mentioned only 5 fir species used "to a very small extent" in reforestation in the United States,

9 species—Pacific silver, balsam, white, Fraser, grand, subalpine, red, Shasta red and noble firs—are now in regular use throughout their native ranges.

With 2 exceptions—Fraser fir, the remaining stands of which are extremely valuable for watershed protection as well as for their scenic beauty (Beck 1990), and the rare bristlecone fir—all North American firs have become commercially valuable as timber and/or pulp species. In general, fir wood is soft, odorless, and light in color and weight; it lacks resin ducts and usually kiln-dries without checking or collapse (but tends to warp). It is easily worked and finished to a good surface, and it takes paint and polish well (Dallimore and Jackson 1967). Although generally of low durability (Franklin 1982a) unless treated with preservative, fir wood can be used in projects that do not require high structural strength; balsam fir is used extensively for cabin logs. Noble fir wood (sometimes marketed as "Oregon larch") is the strongest (along with red fir) of fir woods and is more durable than that of most firs. The frames of Royal Air Force Mosquito fighter planes of World War II were build with noble fir (Pojar and MacKinnon 1994). Grand fir knots, steamed and carved, were made into fish hooks (Turner 1998). The many other products made in North America of fir wood include quality veneers, paneling, construction plywood, crates, container veneers, poles (after preservative treatment), moldings, window sash and door stock, Venetian blinds, ladder rails, and aircraft framing (because of its high strength-to-weight ratio) (Bakuzis and Hansen 1965; Frank 1990; Franklin 1974b, 1982a, 1990; Smith 1982). In the late 19th century, clear lumber of red fir was known as "butter wood" because, when made into boxes for cheese and butter, it did not influence their flavor (Young and Young 1992).

Japan, which imports large quantities of noble and Pacific silver firs for construction (Franklin 1982a), uses its indigenous Japanese fir for making boards, roof shingles, door plates, matches, wooden clogs, musical instruments, household utensils (furniture, packing boxes, and coffins), as well as using it in ship-building and cooperage (Liu 1971). The Yunnan and Faber firs (*A. delavayi* and *A. fabri*, see table 1 footnotes) are used for temple construction in the high mountains of Sichuan Province, China (Earle 1999). European silver fir is widely used throughout Europe also for construction, joinery, musical instruments, and (after preservative treatment) for poles. Guatemalan fir faces extinction in parts of its range (Donahue and others 1985; Salazar 1991) through overuse for building materials, roof shingles, interior paneling, weaving looms and "low-density" furniture, shipping crates, charcoal, firewood (Anon. 1998; Donahue and others 1985; Salazar 1991), and Christmas trees and boughs (FAO, in Anon. 1986). In Guatemala, sheep and other livestock destroy nearly all regeneration (Veblen 1978).

Fir pulp is used extensively for making printing papers and high-grade wrapping paper, with Pacific silver fir the mainstay in the Pacific Northwest and balsam fir in the northeastern United States. Red fir is preferred for sulfite and thermomechanical pulping (Laacke 1990b; Smith 1982). Wood residues not utilized elsewhere are considered to be an energy source (Smith 1982).

Fraser fir (in the East) and Pacific silver, white, red, and noble firs (in the West) are prized also for Christmas trees (Hopkins 1982; Laacke 1990a&b) and typically command high prices (Franklin 1974b; Young and Young 1992). The farm-gate value of Fraser fir Christmas trees cut in North Carolina in 1993 was 80 to 100 million dollars (Blazich and Hinesley 1994, 1995). Noble fir boughs account for some 75% of fir bough harvest in the Pacific Northwest (Douglass 1975; Murray and Crawford 1982), as well as in Denmark (Bang 1979 & Holstener-Jorgensen and Johansen 1975, both cited by Murray and Crawford 1982; Franklin 1982a). Guatemalan fir also provides yuletide greenery and Christmas trees in its native range (FAO, in Anon. 1986; Salazar 1991). The sacred fir, or *oyamel*, is so named because of its heavy use as greenery for celebrating religious events in Mexico. Throughout Europe, but particularly in Denmark, Nordmann fir is prized as an ornamental, for its decorative foliage, and for Christmas tree production (Gosling and others 1999; Poulsen 1996); seeds from sources from the northern Caucasus (Republic of Georgia) are preferred (Godwin 1997).

From bark resin blisters, oleoresin (known commercially as Canada balsam and Strasbourg turpentine) is obtained for varnishes, the mounting of light microscopy specimens and medicinal purposes (Dallimore and Jackson 1967; Frank 1990; Lanner 1983). After distillation to yield fine turpentine oil, the crude residue is sold as rosin (Liu 1971). The pitch and bark of subalpine fir were a very important source of medicines for native peoples of the interior of British Columbia (Pojar and MacKinnon 1994); the pitch also made an effective insect repellent (Turner 1998). The fragrant needles of balsam fir are stuffed into souvenir pillows sold in New England (Frank 1990). North American native peoples pulverized fir needles for use as a body scent (sometimes to mask their human scent to reduce the risk of being attacked by large predators) or as a perfume for clothing; used powdered fir needles (particularly those of subalpine fir) mixed with deer grease as a hair tonic and tint; sprinkled

finely ground needles on open cuts; boiled white fir needles to make a tea; and boiled bark resin to make an antiseptic for wounds or as a tea for colds (Hart 1976; Hopkins 1982; Pojar and MacKinnon 1994; Turner 1998). The Straits Salish of Vancouver Island made a brown dye for basketry of grand fir bark and a pink dye by combining it with red ochre (Turner 1998). Cone scales of east Himalayan fir (see table 1 footnote) have been used to make a purple dye (Rushforth 1987).

Most commercial "pine" scents are essential oils distilled from fir foliage (Hunt 1993); foliar loppings of European silver fir in Czechoslovakia yield 1,380 tonnes (13,612 tons) per year of essential oils (Cermak and Penka 1979). "Pine" aromatherapy and other perfumery oil is steam-distilled from Siberian fir foliage (Luebke 1994–2000). The essential and fatty oil contents of west Himalayan fir seeds are suitable also for commercial exploitation in India (Jain and others 1988). Oil chemistry of other fir seeds has been studied intensively (Carrillo and others 1994; Guo and others 1984; Hasegawa and others 1987; Iwai and Nishioka 1945; Kaneko and others 1985; Rutar and others 1989).

Geographic races. The genus *Abies* was established by Miller in 1754, but Spach, in 1842, made the first attempt at a generic classification (Farjon and Rushforth 1989). Taxonomically, it is a difficult genus (Liu 1971), with extensive genetic variation (Libby 1982) that is reflected in at least 14 formal classification attempts (and several other groupings of species) made in the past 160 to 175 years. Two earlier, more-notable monographic revisions of *Abies* (Franco 1950; Gaussen 1964) were superceded in the early 1970s by a more widely accepted classification (Liu 1971) using 2 subgenera. In this scheme, the subgenus *Pseudotorreya* has a single section for the species *A. bracteata*, while the subgenus *Abies* is divided into 14 sections, 3 of which contain continuously variable forms. Section Grandes contains the North American species *amabilis, concolor*, and *grandis*; section Nobiles contains *magnifica and procera;* and section Balsameae contains *balsamea, fraseri,* and *lasiocarpa*. However, this scheme has been criticized for its unrestrained use of geographical and ecological characters that grouped species merely because they occur together, producing artificial associations (Farjon and Rushforth 1989).

More recently, a new classification scheme based on the morphology of fruiting and vegetation that puts together species with similar ecological preferences from adjoining geographical regions has been proposed. This scheme divides the genus into 10 sections, 4 of which are further divided into a total of 9 subsections, including 3 new subsectional names (Farjon and Rushforth 1989); an historical review plus an evaluation of other attempts to classify firs are included. The new scheme is diagrammatically represented in table 2.

For North American firs, section Bracteata retains the single species *A. bracteata* as the type species, whereas section Amabilis includes *A. amabilis* as the type species. Section Balsameae, subsection *Laterales* (type *A. kawakamii),* includes *A. balsamea, A. bifolia,* and *A. lasiocarpa,* whereas subsection Medianae (type *A. sachalinensis*) includes *A. fraseri*. Section Grandes includes *A. grandis* (type) and *A. concolor*, as well as the Central American species *A. guatemalensis, A. durangensis,* and a new species *A. flinckii* (Rushforth 1989). Section Nobiles include*s A. procera* (type) and *A. magnifica*. Section Oiamel, which is divided into subsections Religiosae and Hickelianae, includes the other known Central American firs, including another new species *A. colimensis* (Rushforth 1989).

Note that this scheme places Fraser fir (*Abies fraseri)* in subsection Medianae and balsam fir *(A. balsamea*) in subsection Laterales; this separation is based on whether bract scales are exserted and the seed scales reniform (Medianae, Fraser fir), or bract scales are included and seed scales are cuneate-flabellate (Laterales, balsam fir) (Farjon and Rushforth 1989). Natural hybrids between these 2 species have been reported (see below) and bracts in balsam fir are not always completely "included" (hidden) (Lester 1968), so this separation does not appear to be justified.

Detailed taxonomy (as well as descriptions of cones, pollen, seeds, and seedlings) of 11 European fir species can be found in a recent monograph (Schutt 1991), whereas a more general text (Vidakovic 1991) includes 26 fir species. Other descriptions and drawings are available (Cope 1993; Rehder 1958; Rushforth 1983, 1984, 1986; Farjon 1990; Debreczy and Rácz 1995).

In North America, 2 sets of genetic complexes—grand and white firs, and noble and California red firs—create significant taxonomic confusion for students, foresters, and land-managers (Franklin 1982a). The geographic variation of the first set—grand fir and white fir (section Grandes, Farjon and Rushworth 1989; section Grandes, Liu 1971)—has been extensively studied. Although these 2 species are morphologically, ecologically, and chemically distinct, they are genetically plastic and intergrade and hybridize freely over a wide area (Daniels 1969; Foiles and others 1990; Hamrick 1966, cited by Franklin 1974b; Hamrick and Libby 1972; Klaehn and Winieski 1962; Laacke 1990a; Lacaze 1967; Steinhoff 1978). The variation can be continuous—

Table 2—*Abies*, fir: schematic of new infragenetic classification system

11 Includes *A. durangensis* var. *coahuilensis*.
12 *A. mexicana* = *A. vejarii* var. *mexicana*.
13 Includes *A. hickelii* var. *oaxacana*.

hybrids between grand and white firs are intermediate in most characteristics—and white fir is usually referred to as "grandicolor" from northwestern California through central Oregon. However, regional races have evolved (Daniels (1969) and the major geographical units have been summarized (Franklin 1974b) as follows:

Species	Geographical location
A. grandis	Coastal lowlands of southern British Columbia, Washington, Oregon, and California, including lower elevations on the western slopes of the Cascade Range
A. grandis	Eastern slopes and higher elevations in the Cascade Range north of about 44° to 45°N latitude
A. grandis	Northern Idaho and interior of southern British Columbia
Intergrade	Klamath Mountains and Cascade Range of southwestern Oregon and northern California
Intergrade	Blue, Ochoco, and Wallowa Mountains of northeastern Oregon, west central Idaho
*A. concolor**	Sierra Nevada, California
A. concolor	Southern Rocky Mountains and southern California

*Now recognized as Sierra white fir (table 1).

No varieties of grand fir have been established, but 2 forms—the green coastal and the gray interior (Foiles and others 1990), reduced from the 5 climatic forms (Muller 1935, 1936, cited by Franklin 1974b)—are usually recognized. White fir is a highly variable species, the variation being significantly correlated with latitude of seed source for most morphological and growth characteristics (Hamrick and Libby 1972). At least 4 major morphological divisions—(a) central Oregon and northwestern California, (b) south-central Oregon and central and northeastern California, (c) southern California and Arizona, and (d) eastern Nevada and western Utah—have been designated (Hamrick and Libby 1972).

White and grand firs, as well as red and noble firs, are chemically distinguishable by their seedcoat terpenoids (von Rudloff 1976; Zavarin and others 1978, 1979), a method useful for identifying seed provenances (Zavarin and others 1979). Other chemo-systematic comparisons of leaf- and twig-oil terpenes have expanded the knowledge of geographic variation of Pacific silver, balsam, grand, and subalpine firs (Hunt and von Rudloff 1974; von Rudloff 1976; von Rudloff and Hunt 1977), and Greek (or Grecian) fir (Koedam 1981; Mitsopoulos and Panetsos 1987).

Noble, California red, and Shasta red firs form the second important interfertile complex of species (Franklin and others 1978; Sorensen and others 1990). Noble and California red firs readily produce hybrids (Barbour 1988; Little 1979) with seed and seedling characteristics similar to Shasta red fir where the ranges overlap (Franklin and others 1978; Sawyer and Thornburgh 1977; Silen and others 1965; Sorensen and others 1990). Populations in southern Oregon and northwestern California may represent hybrid swarms between the 2 species (Franklin and others 1978). Phenotypically, trees in southern Oregon to northwestern California often resemble noble fir but behave ecologically as Shasta red fir (Løfting 1966 and 1967, cited by Franklin 1974b). A latitudinal gradient in the Cascade Range, with a major discontinuity around 44°N, has been discerned (Franklin and Greathouse 1968a). The 2 species can be artificially cross-pollinated without difficulty as long as red fir is the female (ovuliferous) parent (Zavarin and others 1978). Noble fir exhibits high self-fertility that does not appear to affect germination but which can depress height growth (Sorensen and others 1976). Although no races of noble fir are known within its natural range, population differentiation and variation is reported (Maze and Parker 1983). Three horticultural varieties—cv. *glauca,* cv. *prostrata,* and cv. *robustifolia*—are recognized (Franklin 1990). When noble, Sakhalin, Maries, Japanese, and Grecian firs were used as female parents, height, dbh, and crown area were greater in the interspecific crosses than in intraspecific crosses (Mergen and Gregoire 1988).

Of all the interspecific crosses, progeny of Maries fir (as the female parent) showed the greatest growth; this species also had the least, whereas Sakhalin fir had the greatest, inbreeding depression (Mergen and Gregoire 1988). Effects of these crosses on seed and seedling characteristics were reported earlier (Mergen and others 1965). Geographic similarity (especially among Japanese, Korean, Maries, and Sakhalin firs) was suggested as a positive influence on hybrid survival and performance (Mergen and Gregoire 1988). Earlier, it had been suggested that a geographical, rather than genetic or physiological, separation occurred as the genus *Abies* evolved (Klaehn and Winieski 1962). Possible causes for incompatibility and results from other European inter- and intraspecific crossing experiments are reported (Kantor and Chira, 1965, 1971, 1972). However, many of the reported artificial crosses between noble fir and other true firs including balsam, white, subalpine, Min (or Min-kiang), and Sakhalin firs have not been repeated, and

their validity is questionable (Franklin 1990). Unsuccessful attempts to hybridize white and grand firs with European silver, Algerian, Nordmann, and Grecian firs indicate strong reproductive isolation between the North American representatives of the genus and their European counterparts (Kormutak 1997).

Pacific silver fir has an extensive range, occupying many soil types, and it can exist in areas of deep snow and minimal summer droughts (Packee and others 1982). Yet it is not a highly variable species, and no artificial hybrids with any other species have been described, although there is a cultivated dwarf form, Pacific silver fir var. *compacta* (Crawford and Oliver 1990). Despite this apparent lack of variation, strong family differences in germination responses among populations of Pacific silver fir on Vancouver Island, with important implications for maintaining genetic diversity in nursery seedling crops, have been reported (Davidson 1993; Davidson and others 1996).

For balsam fir, the most widely distributed fir in North America, apparently-continuous variation along altitudinal and geographic gradients has been reported (Lester1968; Myers and Bormann 1963) in which the putative variety *phanerolepis* (bracted balsam fir) is most important (Myers and Bormann 1963), but var. *fraseri* and var. *balsamea* have also been recognized (Frank 1990). The variety *phanerolepis* is most common in maritime Canada, the St. Lawrence Valley, and at higher elevations in mountains of the northeastern United States (Fernald 1909; Myers and Bormann 1963), although its taxonomic validity has been questioned (Myers and Bormann 1963). Natural hybrids have been discerned between balsam and Fraser firs (Myers and Bormann 1963; Robinson and Thor 1969), 2 closely related relics of an ancestral taxon (Robinson and Thor 1969; Jacobs and Werth 1984) that may have exhibited north–south clinal variation, although balsam fir var. *phanerolepis* is unlikely to be of hybrid origin (Robinson and Thor 1969; Jacobs and Werth 1984). Balsam fir var. *phanerolepis* and Fraser fir have been shown to be closely related and recently segregated taxa, with balsam fir var. *phanerolepis* being more closely related to balsam than to Fraser fir (Clarkson and Fairbrothers 1970). Using viable seed production as the criterion, balsam × Fraser fir and reciprocals, Fraser × bracted balsam fir and reciprocals, and bracted balsam × subalpine fir were found to be fully crossable (Hawley and Dehayes 1985a). This suggests that geographical rather than genetic isolation is likely more responsible for the taxonomic variation in these 2 firs (Hawley and Dehayes 1985a). After growing for 7 months indoors, hybrids from all these combinations were verifiable, with the hybrid seedlings not being characteristically intermediate between parents, but mostly resembling—but still distinguishable from—the paternal parent (Hawley and Dehayes 1985b). Interspecific crosses between balsam fir (as the maternal parent) and 10 other fir species (as paternal parents) have been claimed (Chiasson 1967), even though subsequent germination was very poor. A cultivar of balsam × Fraser fir (Fraser fir var. *prostrata*) is a dwarf shrub with horizontally spreading branches that is used ornamentally (Beck 1990).

Subalpine fir, the second most widely distributed fir in North America (covering 32 degrees of latitude), exhibits considerable variation, so much so that an (unsuccessful) proposal was made to reclassify it as a subspecies of balsam fir (Boivin 1959). In the West, subalpine fir was previously recognized as a separate, single species possessing 2 varieties, var. *arizonica*, the corkbark fir found only at the southern end of the range, and var. *lasiocarpa,* the typical subalpine fir, the remaining non-corky-barked trees (Fowells 1965; Little 1953). Differences in morphology, foliar volatile oils, and other factors have been cited as reasons for returning to the original designations of alpine fir as 2 species—that is, the subalpine fir (*A. lasiocarpa* Hooker) growing in the Cascade Range and the Rocky Mountain fir (*A. lasiocarpa* var. *arizonica*), growing in higher elevations in the interor—which are believed to have hybridized extensively (Hunt and von Rudloff 1979, 1983). It has been suggested (Hunt and von Rudloff 1979) that at the southernmost end of its range, coastal subalpine fir possibly hybridizes with noble fir, but no evidence for this has been reported.

Currently, corkbark fir is included under Rocky Mountain fir; corkbark fir seeds are about 70% larger than subalpine fir seeds (Fowells 1965). In central Alberta, on its eastern boundary where the range of Rocky Mountain fir meets and overlaps with that of balsam fir (Fowells, 1965, Hosie 1969), some studies obtained evidence of hybridization (Moss 1955; Roller 1967), whereas others suggested Rocky Mountain fir is a variety of balsam fir (Bakuzis and Hansen 1965). The controversy over the subalpine fir–Rocky Mountain fir–balsam fir complex (Hunt and von Rudloff 1979, 1983; Parker and Maze 1984; Parker and others 1981) continues.

The only unique populations of coastal subalpine fir are found in Alaska, at lower elevations, and appear to be isolated with no reported introgression between them and coastal mainland populations (Harris 1965; Heusser 1954). The Prince of Wales Island population has distinctive terpene patterns, but it is not known how, or if, these differ from those of neighboring populations (Hunt 1993). Three horti-

cultural and ornamental varieties of subalpine fir have been recognized—subalpine fir cv. *beissneri* (a dwarf tree with distorted branches and twisted needles), subalpine fir cv. *coerulescens* (with intensively blueish needles), and subalpine fir cv. *compacta* (a dwarf tree of compact habit) (Alexander and others 1990). Other fir varieties are described by Welch (1991).

Based on the mean yield of germinable seeds per cone as the crossability criterion in a study of 6 firs native to California (not including noble fir), plus 4 Eurasian and 2 Mexican firs, the long-held view that western true firs hybridize freely was challenged by Critchfield (1988). The only truly successful cross was white × sacred fir (from Mexico), species from 2 different taxonomic sections (independent of the classification scheme). Seedlings from white × grand fir were easily identified as hybrids, but crosses with Eurasian firs were uniformly unsuccessful. Nevertheless, the white × sacred fir cross, like several other successful crosses mentioned above, suggests that taxonomic sections in firs are not separated by reproductive barriers (as in *Pinus*), and that fir classifications should be reconsidered (St.-Clair and Critchfield 1988).

European experiences have been similar. In Germany, combinations of Veitch × European silver fir, white × Nordmann fir, white × grand fir, and white × noble fir showed marked hybrid vigor (heterosis effect) that was obtained almost always when white fir was a parent. Hybrids with long, green needles had the greatest growth vigor, needle color being a criterion of growth vigor even in seedlings (Rohmeder 1960a; Rohmeder and Eisenhut 1961; Rohmeder and Schönbach 1959). Seedlings from white × grand fir, Grecian × Nordmann fir, and Spanish × European silver fir crosses outgrew the offspring of the maternal species after 1 year (Kormutak 1991). Several of these crosses are between species from different taxonomic sections, providing support for the absence of reproductive barriers and/or the need to reconsider taxonomic sections (mentioned earlier). As in noble fir in North America, relative self-fertility of European silver fir in Germany is very high (0.72) (Moulalis 1986). Successful controlled crossings, unsuccessful controlled crossings, natural hybrids, intermediate populations, putative spontaneous hybrids, and putative controlled hybrids in firs have been summarized by Vidakovic (1991). The genetics and breeding of European silver fir have been thoroughly reviewed by Korpel and others (1982) and genetic variation in this species was further reported on by Bergmann and Kownatzki (1987). Since the 1980s, studies on fir genetics have gained momentum in Central America (Furnier and other 1996; Aguirre-Planter and others 2000), Europe (Fady and Conkle 1992, 1993; Fady and others 1991, 1992; Giannini and others 1994; Kormutak and others 1982, 1993; Mitsopoulos and Panetsos 1987; Parducci and others 1993, 1996, 1999, 2000; Parducci and Szmidt 1997, 1998, 1999) and Asia (Kawamuro and others 1995; Suyama and others 1992, 1996, 1997; Tsumura and others 1994; Tsumura and Suyama 1998). All of the reports cited here and throughout this chapter refer to other studies that are too numerous to include.

Elsewhere, Turkey fir (*A. bornmuelleriana*); the possible Grecian × Turkey fir hybrid (*A. equi-trojani*) (Liu 1971); and Nordmann fir are so variable in Turkey that *A. bornmuelleriana* and *A. equi-trojani* should be regarded as only races or ecotypes of *A. nordmanniana* (Arbez 1969a&b). Nordmann and Turkey fir can be distinguished in the nursery based on needle and bud characteristics (Arbez 1967). Bulgarian fir is recognized as one of several spontaneous hybrids (European silver × Grecian fir), as is Cilician fir (Grecian × European silver fir) (Korpel and others 1982). A monograph on Grecian fir is available (Panetsos 1975). Two varieties of European silver fir, var. *chlorocarpa* and var. *erythrocarpa*, are recognized in Bulgaria (Doikov 1973). Populations of Siberian fir in the former USSR have been differentiated on the basis of cone scale morphology (Vetrova 1992). Four species—west Himalayan fir, east Himalayan fir, Sikkim fir (often included with east Himalayan fir but quite distinct [Farjon 1990]), and Yunnan fir—are common in the Himalayas. A fifth—Faber fir, a Chinese species discovered in northeast Myanmar (Burma) on the Burma—Yunnan border, possibly a form of Yunnan fir—is not so common (Puri and Gupta 1968). Faber and Yunnan firs are closely related and were previously regarded as different forms of the same species (Dallimore and Jackson 1967) or as synonyms for the same species (Liu 1971). However, they have currently been given separate-species status (Farjon and Rushforth 1989). Other species have been described, such as Webb fir, which may be the western, high-altitude form of Sikkim fir, adding to the confusion (Puri and Gupta 1968). The high-altitude east Himalayan fir and the low-altitude west Himalayan fir are known to hybridize freely, forming intermediate populations with introgression at middle altitudes (Jain 1976).

Fir taxonomy in Mexico also is confused. Although *A. hickelii* has been suggested to be a synonym for *A. guatemalensis* (Dvorak 1997), others (Farjon and Rushforth 1989; Farjon 1990) classify it as a distinct species. Three more new species from western Mexico have been described (Debreczy and Rácz 1995). Levels and patterns of genetic variation in the firs of southern Mexico and

Guatemala have been reported (Aguirre-Planter and others 2000).

Because taxonomy remains confused in several instances, and because hybridization is probable, until the patterns of variation are better understood, the use of fir seed sources local to the reforestation site is the best practice. However, the specific or varietal name applied to the local population should not be relied on (Franklin 1974b). Geographic source has long been known to affect cone and seed characters in many fir species. Numerous studies have reported—sometimes contradictorily—that cone dimensions and (to a lesser extent) seed weight, germination, and seedling yields (as well as mineral contents in some species) may be under strong genetic control and related to provenance (Gambi and Stradajoli 1971; Giannini and Marinelli 1977; Gvozdikov 1980; Kociova 1974a&b; Laffers 1979; Singh and Singh 1981; Singh and others 1991; Ujiie and others 1991). For seeds of noble and Shasta red firs, the strong latitudinal gradients (or clines) in cotyledon number and in seed weight were considered promising indices of seed source/provenance (Franklin and Greathouse 1968b). Provenance selection is a key issue in Christmas tree production of noble, grand and Shasta red firs (Hupp 1984).

Isozyme analysis has effectively identified provenances of European silver fir (Konnert 1991) and has been used to study geographic variation of firs in Europe and to make comparisons with North American fir species (Konnert 1991; Kormutak 1988; Moller 1986; Schroeder 1989a,b&c). Thus, it was concluded that although European silver fir survived the last glaciation in 5 refugia, the species migrated to its present range from only 3 of them (Konnert and Bergmann 1995). By use of enzyme systems, Pascual and others (1993) showed that there is genetic divergence between Spanish and Moroccan populations of Spanish fir and that several true varieties of this species may exist. Enzyme linkages in balsam fir similar to those in other conifers might be used for taxonomic purposes (Neale and Adams 1981). A mating system study in balsam fir was described by Neale and Adams (1982). An isozyme study of Fraser fir on Mt. Rogers in Virginia revealed little or no population differentiation (Diebel and Feret 1991). Isozyme markers have revealed low levels of genetic variation within and high levels of genetic differentiation among Central American populations of Guatemalan fir, sacred fir, *A. flinkii*, and *A. hickelii* (see table 1 footnotes) (Aguirre-Planter and others 2000).

Flowering and fruiting. Fir strobili are unisexual and are typically borne on the uppermost branches. Both male (microsporangiate) and female (megasporangiate) strobili in grand fir develop from axillary buds (Owens 1984). The minimum age for production of female strobili is 20 years, that of male strobili, 35 years (Eis 1970). Usually, female strobili occur singly or in small groups on the upper side of the previous year's twigs on the highest branches, whereas male strobili cluster densely along the undersides of the previous year's twigs lower down in the crown. This arrangement promotes cross-fertilization but may reduce pollination (Singh and Owens 1982). However, both male and female strobili may be found on the same branchlet. Seed production in most fir species typically begins on trees 20 to 30 years old (table 3), although individual trees may produce some cones at a younger age, for example, 12 years in noble fir (Franklin 1974b) and 15 years in balsam fir (Roe 1948a). However, heavy cone production in noble fir begins when trees are 30 to 35 years old (Franklin 1982b). Seed production by Spanish fir in Czechoslovakia does not begin until trees are 50 years old (Holubcik 1969).

All firs require 2 years to complete their reproductive cycles; detailed descriptions of the cycles have been published for balsam, Pacific silver, grand, and subalpine firs (Owens and Molder 1977a&b, 1985; Powell 1970; Singh and Owens 1981, 1982), as well as descriptions of factors affecting seed production (Owens and Morris 1998). In Pacific silver fir, microscopic primordia are initiated in the axils of leaves inside vegetative buds during May of the first year; bud differentiation occurs about 2 months later, with bract initiation in mid-July and ovuliferous scales in mid-August; seed-cone buds become dormant in November. Microsporophyls are initiated between mid-July and early September, whereas microsporangia begin differentiation in September and are dormant by mid-October. Development of pollen-cone and seed-cone buds resumes early in April of the second year. While the single, large megaspore mother cell in each ovule is undergoing meiosis in early May, mature 5-celled pollen is forming (Owens and Molder 1977a&b).

Strobilus production, male and female, in balsam fir has been related to shoot vigor, the lowest number of female strobili occurring on whorl branches, and the most male strobili on internodal branches (Powell 1972). Even where the zones of male and female bearing overlap, the 2 sexes usually occur on different types of branch; when on the same branch, male strobili are confined to the weaker shoots. As the trees age, they appear to maintain a potentially female zone of constant size (number of whorls and internodes), while the uppermost boundary of the potentially male zone rises with increasing tree height. If the leader is lost, the male zone continues to rise while the female zone gets smaller, and the apical part of the crown can eventually become male (Powell 1972).

Table 3—*Abies*, fir: phenology of flowering and fruiting, and major characteristics of mature trees

A

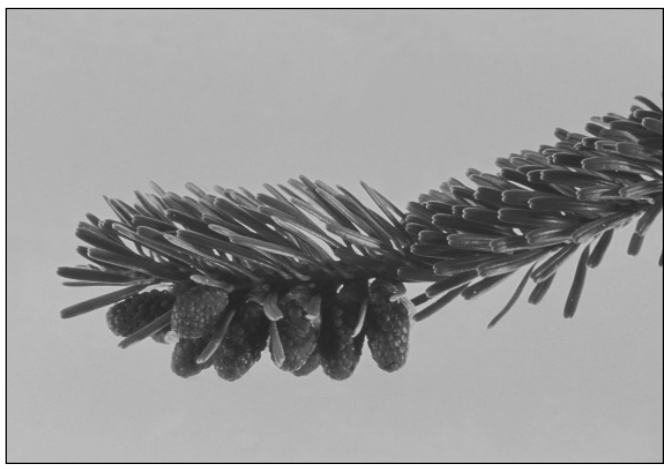
Thinning promoted fruiting in 150- to 170-year-old stands of Siberian fir in Siberia (Zelenin 1991), and best Sakhalin fir seeds occurred after heavy thinning (Sato 1940). In contrast, after a commercial thinning in a younger Siberian fir stand, the remaining trees produced such small amounts of pollen that seed quality was greatly reduced (Okishev and Pugachev 1983). Strobilus production in a Nikko fir seed orchard in Japan increased slightly following application of gibberellins $GA_{4/7}$ and GA_3, but girdling at the branch base was ineffective (Katsuta and others 1981).

Following bud burst in early spring, female strobili quickly elongate, and initially the bracts are highly conspicuous (figure 1). Enlarging male strobili have a miniature raspberry-like form (figure 2) until pollen is shed, when they become elongated and tassel-like. Wind-pollination in Pacific silver fir occurs by late May (Owens and Molder 1977a&b). Pollination durations may vary widely, from 18 days in a Nikko fir seed orchard in Japan (Itoo 1975) to a month in a Spanish fir forest in Spain (Arista and Talavera 1994a). Fir pollen is relatively heavy, so that pollination distances greater than 60 m may be the limiting factor for viable seed production in fir (and other coniferous species); although isolated trees may show an apparently good cone crop, the seedcrop may be poor (Anon. 1950a; Arista and Talavera 1994b). Parthenocarpy is known in balsam fir (Anon. 1950a) and Siberian fir (Nekrasova 1978a); without pollen, cones can be of normal size but what seeds form are without embryos. Controlled pollination techniques have been described for Fraser fir (Miller 1983), and fir pollen can be stored for at least 2 years under carefully controlled conditions (Kravchenko and others 1974; Lowe 1974).

For Pacific silver fir on Vancouver Island, development of the female gametophyte is complete at the end of June and fertilization occurs in mid-July. Embryonic meristems

Figure 1—*Abies amabilis,* Pacific silver fir: female strobili at the receptive stage (courtesy of D. Pigott).

Figure 2—*Abies procera, noble* showing the typical "raspberry" form (courtesy of Y. Tanaka.) fir: male strobili prior to pollen shedding (courtesy of D. Pigott).

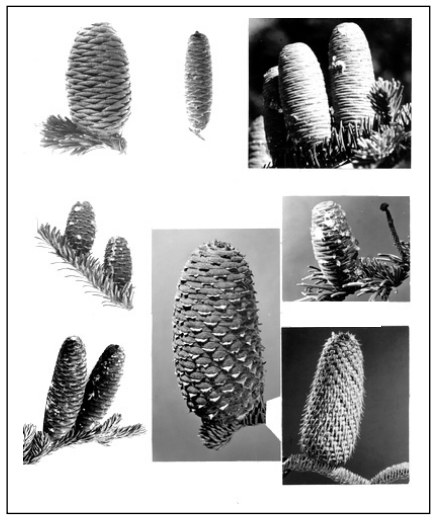


and cotyledons develop in early August and embryos mature late the same month or September. Seed dispersal usually begins mid-late September and most seeds have been shed by November (Owens and Molder 1977a&b). Similar phenologies have been described for grand fir on southern Vancouver Island (Owens 1984) and for Spanish fir in Spain (Arista and Talvera 1994b).

Mature fir cones are 7.5 to 25 cm long and typically ovoid to oblong-cylindrical. In many fir species, the fan-shaped ovuliferous scales outgrow the bracts early in the season, but the bracts remain highly conspicuous in noble fir, nearly covering the entire surface of the cone at maturity (figure 3). Typically, Shasta red fir bracts are also visible on the surface of mature cones, which makes them distinguishable from cones of California red fir, which have bracts that are shorter than the scales (Laacke 1990b). However, north of Mt. Lassen, where red and noble firs hybridize, red fir has exserted bracts (similar to those of noble fir). Adding to the confusion, exserted bracts are found also on a large southern Sierra Nevada population of red fir (Laacke 1990b). The bracts remain so prominent in bristlecone fir as to give this species its name.

Each scale bears 2 seeds on its adaxial (upper) surface, the ovules forming at the base of the scale near the attachment to the cone axis. The membranous wings form over the outer part of the scale. Scales near the tip and base of the cone usually lack fertile seeds. At maturity, seeds separate from the scale on which they form—a useful diagnostic in judging advancing ripeness—and seed dissemination involves abscission of the cone scales from the axis, leaving the rachis, the spike-like axis on the tree (figure 4) that may persist for several years. In Pacific silver fir, the scales become greatly distorted during drying in late summer, and

Figure 3—*Abies*, fir: mature female cones of *A. amabilis*, Pacific silver fir (**top left**); *A. balsamea*, balsam fir (**top middle**); *A. concolor*, white fir (**top right**); *A. fraseri,* Fraser fir (**middle left**); *A.* x *shastensis*, Shasta red fir (**middle center**); *A. grandis*, grand fir (**middle right**); *A. lasiocarpa*, subalpine fir (**lower left**); *A.procera*, noble fir (**lower right**).

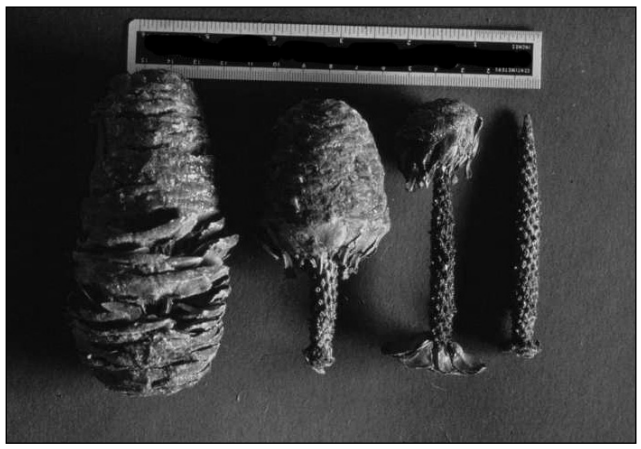


this twisting actively tears them from the axis. No such distortion occurs in noble fir, and seed dissemination requires branch movement by the wind or other agents to disturb the cone (Franklin and Ritchie 1970). Cone disintegration of other species such as grand fir and subalpine fir are intermediate.

Thus, pollination, fertilization, seed ripening, and dissemination all occur in the same season—in as little as 90 to 120 days—following the year of strobilus initiation (Franklin and Ritchie 1970). The chief agent of seed dispersal is the wind; seed rain density decreases as a function of distance from the parent tree, seedling mortality increases, and smaller-seeded species travel further (Carkin and others 1978; Franklin 1982b; Hofmann 1911; Houle 1992, 1995; Isaac 1930b; McDonald 1980; Savcenko 1966; Wolfenbarger 1946).

The majority of fir seeds are normally shed in October/November (table 3). Frequently these have the highest seed weight, maximum germination capacity and lowest occurrence of empty and immature seeds, plus higher seedling survival rates, than seeds shed earlier/later. In several firs, seed dispersal may extend well into winter (Anon. 1950b; Aussenac 1966; Hetherington 1965; Houle and Payette 1991; Roe 1946), the seeds becoming buried in, and germinating in, snowbanks (see also Pregermination treatments). Up to 50% of a Maries fir seedcrop may lodge in the foliage and only fall to the ground over winter (Smirnov 1991). The date of seed-fall of European silver fir in Italy

Figure 4—*Abies grandis*, grand fir: four stages in the abscision of ovuliferous scales from the cone axis (courtesy of D. Pigott)



became later with increasing altitude, but the amount of seeds fallen per square meter was greatest at intermediate altitudes of 900 and 1450 m and lowest at 800 and 1600 m. Seed quality in this species improved with increasing altitude because of a decrease in the percentage of empty and dead seeds (Giami 1970).

Fir seeds are large compared to most conifers, averaging 29, 46 and 83 seeds/g for Pacific silver, grand, and subalpine firs, respectively (Kolotelo 1997). In mature seeds (figure 5), the membranous wings are large—20 to 23.5 mm long in Manchurian fir (Voroshilova 1983)—ovoid or oblong, 1 to 1.5 times the length of the seed, and up to twice the seed width. The wing is usually translucent, uniformly light brown or tan, sometimes with a magenta edge. Seeds are completely covered by the wing on the adaxial face, but only on 2 margins on the abaxial face (Cermak 1987) by narrow flaps (figure 6). The soft seedcoat is brown, tan, or rarely cream and, in the outer, softer parts (sarcotesta) (Cermak 1987) where the seed is covered by the wing, large resin vesicles develop from cavities that differentiate in the outer layers of the integument (Owens and Molder 1977b). Vesicles appear on the seed surface as small, dark patches, their number, character, and placement varying with the species. Vesicle position (figures 7–9) and chemical contents in European silver fir have been described (Cermak 1987). The seedcoat of white fir is thinner than that of red fir and contains more vesicles, the number varying between 5 and 12/seed, although 7 to 9 are more common (Kitzmiller and others 1975). About 20% of the fresh weight of European silver fir seeds is resin (Cermak 1987), 90 to 95% of which is monoterpene hydrocarbons (principally limonene) (Cermak 1987; Cermak and Penka 1979; Penka and others 1977).

A

Figure 5—*Abies*, fir: mature seeds of *A. amabilis*, Pacific silver fir (**top left**); *A. balsamea*. balsam fir (**top center**); *A. fraseri*, Fraser fir (**top right**); *A. grandis*; grand fir (**bottom left**); *A. lasiocarp*a, subalpine fir (**bottom center**); *A. magnifica*, California, red fir (**bottom right**).

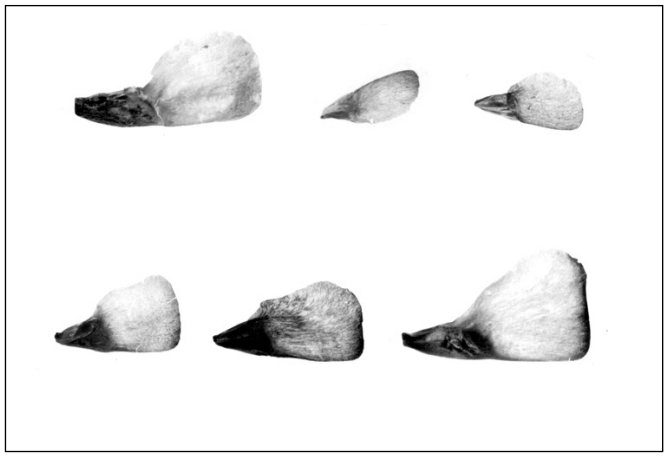


Figure 6—*Abies procera,* noble fir: abaxial view of seed showing (**left**) a seed with wing, but with integument still attached (indicated by the prominent flaps wrapping around the long margins) and which would be regarded as a "pure seed" commercially; a naked seed (**center**) without wing or integument; and the intact integument (**right**) removed from the seed at center. This wing attachment to the seed is typical for fir (Edwards 2002); scale bar is in millimeters.

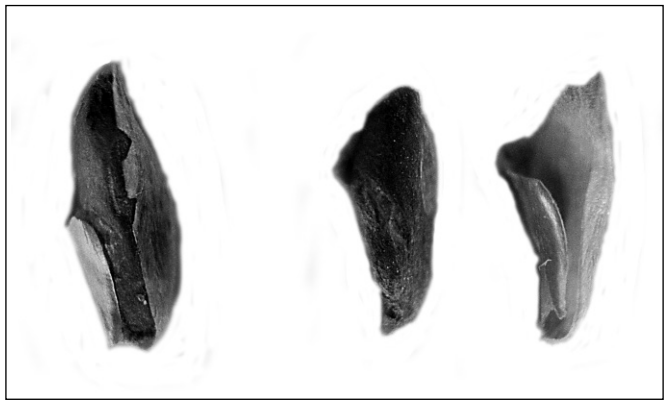

The role of resin has been linked to inhibiting precocious germination, that is, to promoting dormancy, of mature fir seeds at the time of seedfall (Rohmeder 1951). It might also provide some form of protection for the embryo and megagametophyte against excessive drying (Gunia and Simak 1970). Germination of non-stratified European silver fir seeds was increased after resin removal by low-temperature vacuum distillation (Zentsch 1960), and resin extracted from this species inhibited germination in pine and spruce seeds (Dässler and Zentsch 1959; Rohmeder 1951). Damaging the vesicles during processing of fresh European silver fir seeds and allowing the resin to "contaminate" undamaged seeds reduced their germination (Gunia and Simak 1970). The germination-reducing effect of resin leakage in other species was greater when damage occurred before the seeds had been stratified (Arista and others 1992; Kitzmiller and others 1973, 1975), lending support to the suggestion that the resin may be chemically transformed during chilling rather than simply being evaporated (Gunia and Simak 1970). Leaking resin quickly oxidizes and may then be toxic to the embryo (Bouvarel and Lemoine 1958), and/or provide a good medium for mold development (Gunia and Simak 1967, 1970; Kitzmiller and others 1973). Whatever the precise role of the resin, fir requires careful handling of cones and seeds from the time they are picked (Dalskov 1960; Gunia and Simak 1970). Although fragile, the seedcoat can account for up to 60% of the total dry weight in noble fir seeds (Kandya and Ogino 1986).

Most of the bulk in a mature fir seed is occupied by the fleshy, nutritive megagametophyte tissue. Whereas the seedcoat proportion does not vary greatly, the weight of the megagametophyte and embryo varies widely among individual seeds and is more closely correlated with how quickly the seeds germinate (Kandya and Ogino 1986). The embryo extends almost the length of the megagametophyte (figure 10), and this extension—relative to the megagametophyte length—is a good index of seed ripening (Dobbs and others 1976; Oliver 1974) (see also table 6). Embryonic cotyledons, which may vary in number from 3 to 14, are well-differentiated, but the radicle apex is difficult to discern as it is encased by the protective root cap.

Seedcrops large enough to justify commercial collections generally occur every 2 to 4 years (table 3), but inter-

Figure 7—*Abies alba*, European silver fir: diagrammatic view of the adaxial surfaces of a pair of seeds on an ovuliferous scale. **CA** = cone axis; **OS** = ovuliferous scale; **Br** = bract; **S1, S2** = seeds; **W1, W2** = wings. A cross section through the seeds (indicated by the dotted line) is shown in figure 8 (after Cermak 1987).

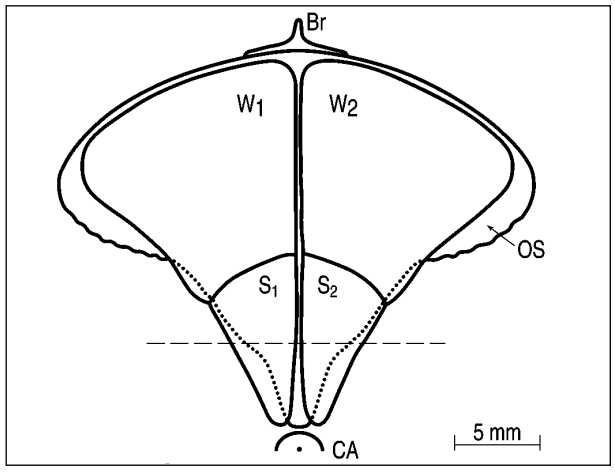

Figure 8—*Abies alba*, European silver fir: diagrammatic cross section of a seed (**S1** in figure 7). **OS** = ovuliferous scale; **Br** = bract; **W** = wing; **m** = median plane of the ovuliferous scale; **e** = embryo; **meg** = megagametophyte ("endosperm"). **A, B, D,** and **E** indicate individual resin vesicles located on the adaxial (**ad**) or abaxial (**ab**) surfaces, and medial (**med**) and marginal (**marg**) edges of the seed (after Cermak 1987).

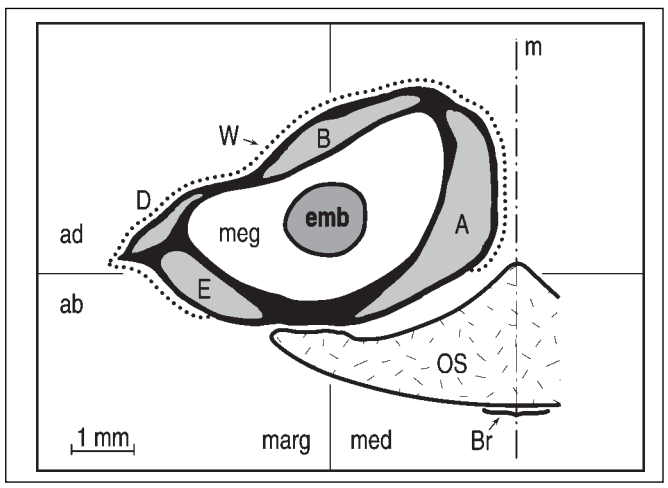

Figure 9—*Abies alba* European silver fir: digrammatic view of the abaxial surface of 1 seed. **W** = wing; **m** = median plane of the ovuliferous scale. Resin vesicles appear on the medial (**A**) or marginal (**E**) sides of the seeds, and at both ends (**C** and **F**) (after Cermak 1987).

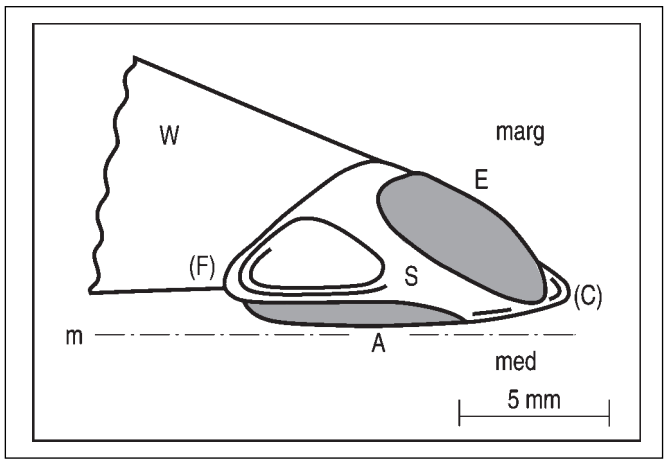
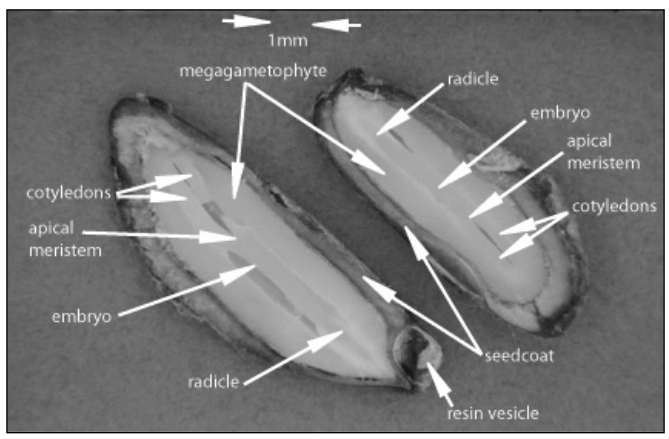


vals may vary considerably due to numerous factors. Strobilus production in balsam (Powell 1977) and Spanish firs (Arista and Talavera 1995) occurs in alternate years. This was previously thought to be due to an endogenous rhythm unrelated to environmental factors (Greenbank 1963), but it has been shown that good cone crops in grand fir require both a cool, moist summer the year before seed maturation and a warm, dry summer the year of seed matu-

Figure 10—*Abies grandis*, grand fir: longitudinally sectioned mature seeds showing embryos (**e**) occupying 90+% of the corrosion cavity in the megagmetophytes (meg) ("endosperm." **C** = cotyledons; **AP** = apical meristem; **R** = radicle; **H**= hypocotyl/shoot axis: **V** = resin vesicle; **SC** = seedcoat. Scale bar is in millimeters (courtesy of D. Pigott).



ration (Eis 1973). Thus, large crops are unlikely in consecutive years. Other environmental requirements must be met also, which is why lapses of several years between heavy crops is more the rule. For example, the interval between heavy crops of white fir in California is commonly 5 years (McDonald 1992) but may vary from 3 to 9 years (Fowells and Schubert 1956). Henderson (1982) found that for subalpine fir, only 1 year over a 28-year period produced a "bumper" crop, whereas 4 other years were "good." Several true firs in Oregon and Washington produce good crops on a 3-year cycle (Franklin 1968), with noble fir averaging medium or better crops 50% of the time over its range, although some sites may go as long as 6 years without significant cone production (Franklin 1982b). Crop year can have a large effect on seed weight and cotyledon number in noble fir (Sorensen and Franklin 1977); cotyledon number in Sakhalin fir was weakly correlated with provenance (Okada 1966).

Several methods for forecasting cone crops have been devised. One, for Maries fir, is based on bud counts the previous year (Matsuura 1963); another uses visual estimates of the number of cones on individual Sierra white fir trees and the proportion of trees bearing cones (McDonald 1992); a photographic method is more accurate than visual rating for red fir (Gordon 1962). Crop production in grand fir can be estimated using a regression equation that employs the number of cones on the top 2 whorls of the crown, and the num-

ber on the south side of the tree (Kulhavy and Schenk 1976).

Cone length and seed yield are significantly correlated in grand fir (Ching 1960), and cone length and seed weight are correlated with mean temperature during maturation in Sakhalin fir (Okada 1983). The fertile length, or "effective size," of balsam fir cones ranges from 60% in small cones to 83% in large cones and, because larger cones are borne higher in the crown, the upper branches bear a greater proportion of the potential seed yield than they bear of the cone crop (Powell 1979). The fertile length of a European silver fir cone represents 74% of the total cone length, and the average yield of potentially fertile seeds varies from 122 (small cones) to 272 (large cones) (Nanu 1979a).

Total seed set (including damaged seeds) can be estimated for subalpine fir (Kulhavy and others 1976) and other firs (Douglass 1969) from the number of exposed seeds—sound and insect-damaged—when cones are cut in half lengthwise. The number of filled seeds exposed when cones are cut in half longitudinally is used in British Columbia to judge whether the crop is worth collecting; for Pacific silver fir at least 8 to 12, for grand fir at least 12 to 14, and for subalpine fir at least 4 to 6 filled seeds must be exposed on one cut face of the cone (Edwards 1986a; Eremko and others 1989). These numbers apply just prior to collection, because insects or disease may decrease counts if there is a significant time lag between cone examination and cone collection.

Tree age and size affect seed quality, sometimes in contradictory ways. Best seeds were obtained from younger (40- to 50-year-old) trees of the rare Sicilian fir in Italy (Arena 1960) and balsam fir in Michigan (Benzie 1960), than from trees more than 150 years old. European silver fir trees between 40 and 100 years old were judged best (Magini 1953), but Bosnian sources of this species showed no decrease in fertility with age (Panov 1949). West Himalayan fir at 200 years in Pakistan still produced enough seeds for adequate natural regeneration (Haq 1992), although viable seeds did not exceed 15% of the crop.

Almost 90% of white fir cones are borne on dominant trees, 12% on codominants, and almost none on intermediate and suppressed trees (Fowells and Schubert 1956). In white fir, cone production peaks in trees with 75 cm dbh, then gradually decreases as diameter increases (Fowells 1965). Seed-bearing white fir trees over 60 cm dbh are targets for the fir engraver beetle (*Scolytus ventralis* LeConte), which weakens and damages tops and thus may seriously impair cone production in old-growth stands (Hopkins 1982). Most cones occur on branches of the second and third nodes from the apex of balsam fir trees (Powell 1979). Similarly, cones occur at the very top of dominant Siberian fir trees over 28 cm dbh (Kolomiec 1950). In Siberian fir, the frequency of fruiting is correlated also with height, diameter, and trunk volume (Nekrasova and Ryabinikov 1978): all trees with a dbh of 24 cm or larger bear cones (Atimetov 1968). For European silver fir, seed numbers per tree generally increase with dbh, whereas the 1,000-seed weight peaks at dbh 40 to 50 cm, then decreases. Nursery seedlings surviving into their second growing season increased with parent-tree dbh up to 50 to 60 cm, so cones should be collected from trees 35 to 50 cm dbh (Souleres 1965). Germination in Himalayan fir seeds is optimal from trees in the 1.3- to 2-m dbh class (Puri and Gupta 1968). Cone diameter, 1,000-seed weight, and germination varied significantly with dbh of west Himalayan fir trees (Arya and others 1994).

Proper form and timing of nitrogen fertilizer has increased the frequency and size of balsam fir seedcrops—producing bigger and heavier cones and better quality seeds—in both natural stands and seed orchards (Arnold and others 1992; Edwards IK 1986; Sheedy 1974, 1978). Similar effects have been reported for European silver fir (Huchler 1956). Foliar levels of phosphorus and magnesium were identified as the nutritional elements most limiting cone yields in a Fraser fir seed orchard; the relative nitrogen status of high-yielding trees was superior to that of low-yielding trees. However, increasing the level of the most limiting nutrient may not increase cone production because other internal and external factors play a more decisive role (Arnold and others 1992).

Causes of reduced seed production. Despite producing abundant amounts of pollen, firs typically are poor seed producers, the reasons (in decreasing order of importance) being infrequent cone initiation, insect infestation, frost damage to cones and ovules, inadequate pollination, and several other minor causes (Owens and Morris 1998). The main factor affecting the number of cones produced is the proportion of initiated female strobili that develop into fully mature cones (Eis 1970; Nekrasova 1974; Owens and Molder 1974, 1977a&b; Owens and Morris 1998; Powell 1973; Shea 1989a&b). In a good crop year, an average grand fir tree produces over 40 cones (Foiles and others 1990). Cool wet weather may interfere with pollen dispersal (Franklin 1974a). Lack of pollination, incomplete development, and abortion, in balsam fir may cause more empty seeds than insect damage (Fye and Wylie 1968). Self-pollination in noble fir may reduce seed yield by 31%; although seed weight, germination, and seedling survival are not affected, seedlings of selfed parents show a 24%

inbreeding depression of 3-year height growth (Sorensen and others 1976). Late frosts up to 6 to 8 weeks after bud burst, that is, late May and early June (Fowells and Schubert 1956; Franklin and Ritchie 1970) may cause total abortion of female strobili in several species. Additionally, some primordia may become latent or differentiate as vegetative structures, depending on environmental and physiological factors during their development. Aerial contaminants may reduce seed yields also (Loffler 1988; Sidhu and Staniforth 1986).

High percentages of empty seeds have been observed in collections of numerous fir species (Franklin 1974b; Keen 1968; Khutortsov 1987; Nanu 1979b). The proportion of empty seeds increases in poor seed years, up to 90% in Siberian fir (Nekrasova 1978b) and to 63% plus 36% insect damaged in noble fir (Scurlock and others 1982). Cone crops of noble fir must be medium size or larger for sound seed to exceed 10% (Franklin 1982b).

The proportion of high-quality germinable seeds is often reduced by frequent infestations of insects that damage both cones and seeds (Hedlin 1974; Hedlin and others 1980). Insect predators appear wherever firs grow worldwide and about 50 insect species have been identified as damaging agents to fir cone and seedcrops (table 4). Tortrix moths are a major pest in China (Zhang 1982). Damage caused by cone midges, moths, maggots, and seed chalcids (*Megastigmus* spp.) usually is extensive, but cone moths (*Barbara* spp. and *Dioryctria* spp.) (figure 11) and cone maggots (*Earomyia* spp. and *Hylemya* spp.) that mine through the cones, injuring more than 1 seed (Hedlin 1966; Hedlin and Ruth 1974; Keen 1968; Pfister and Woolwine 1963) cause the most conspicuous destruction. The insect complex colonizing white fir cones comprises 3 feeding guilds—cone and seed miners, seed miners, and scale and bract feeders (Shea 1989a&b). These include at least 11 different insects (Shea 1989a&b):

- cone and seed miners—*Dioryctria abietivorella* Grote, *Eucosma* probably *siskiyouana* (Kearfoot), *Cydia* probably *bracteatana* (Fernald), and *Barbara* spp.
- seed miners—*Megastigmus pinus* Parfitt, *M. rafni* Hoffmeyer, and *Earomyia abietum* McAlpine
- scale and bract feeders—*Asynapta hopkinsi* (Felt), *Dasineura* probably *abiesemia* Foote, *Resseliella conicola* (Foote), and *Lasiomma* (*Strobilomyia*) *abietis* (Huckett)

Seed-mining guild insects cause the major seed damage in most years and, as cone crop size decreases, the proportion of cones with more than 1 insect species increases, together with an increase in co-occurrence of members of different guilds (Shea 1989a&b). In contrast, the larvae of seed chalcids (figure 12), which are the most common insects destroying coniferous seeds across the North American continent (Speers 1974a), destroy 1 seed each (Nanu 1980; Speers 1967). By means of seed x-radiography, not only can the degree of damage be estimated readily (Kulhavy and others 1976; Overhulser and Tanaka 1983; Speers 1967; Tanaka 1982), but larvae of *Megastigmus* spp. can be distinguished from those of *Resseliella* spp. (Gagov 1976).

In poor seed years, insects may totally destroy seedcrops of white fir in the western United States (Keen 1968), Fraser fir in the eastern United States (Speers 1968), and Siberian fir in western Siberia (Kolomiec 1950). Damage generally is

* Insect names, in alphabetical order, are listed as cited by sources. No attempt has been made to rationalize synonyms, because sources rely on different nomenclature authorities.
† For simplicity and conciseness, where several species in a single genus have been identified, insects are grouped by genus, for example, *Asynapta* spp.

higher in poor crop years (Speers 1967), because adult female insects have fewer cones on which to concentrate (Lanz 1943). Even in good cone crop years, the number of emerging adult insects may be positively correlated with the flowering intensity of the food plants, with the most important factor influencing the size of the insect population being the amount of seeds produced (Annila 1982). Little in-depth research on the biology, ecology, and effective control of fir seed and cone insects has been done (Gara 1982).

Although cone and scale midges cause no significant loss, seed or gall midges may reduce seed yields (up to 72%) (Skrzypczynska 1985) by fusing seeds to the scales, although germinability of galled noble fir seeds was not reduced (Franklin 1974b). Likewise, larvae of *Spermatolonchaea viridana* L. (table 4) cause deformations on the cone scales and seed wings of Cilician fir in Turkey but do not affect the seeds (Kayacik 1964).

Most insects damage seeds directly, but the spruce budworm—*Choristoneura fumiferana* (Clemens), a defoliating insect—also attacks balsam fir by feeding on pollen in

developing male strobili (Bess 1946; Blais 1952; Greenbank 1963). Also, the budworm girdles the basal parts of developing female strobili (Powell 1973), thereby reducing the formation of female buds and hence the cone crop for the following season (Powell 1973; Woodwell 1961). Severe defoliation decreases tree vigor, food reserves, and cone production (Hall 1981; Schooley 1975, 1976, 1978), and the trees become susceptible to secondary attacks (by root rot and beetles), a condition referred to as Stillwell syndrome (Moody 1988).

In some localities, Douglas squirrels (*Tamiasciurus douglassi*) and red squirrels (*T. hudsonicus richardsoni*) cut and cache large quantities of cones of Pacific silver, grand, and subalpine firs. They may sever the twigs that support the current cones, and also those that bear the female buds for the next year's crop (Franklin 1964; McKeever 1964; Smith 1968). In the Northeast, voles and mice (*Clethrionomys gapperi*, *Peromyscus maniculatus, P. leucopus*, and *Microtus pennsylvannicus*) prefer spruce (*Picea glauca, P. rubens*) and pine (*Pinus strobus, P. resinosa*) seeds to balsam fir seeds, even in extreme hunger (Abbott 1962; Abbott and Hart 1960). However, a titmouse (*Parus ater*) is known to eat European silver fir seeds, causing many problems in Slovakian nurseries (Bauer and Tichy 1960). Titmice, voles (*Clethrionomys rutilus*), mice (*Apodemus* spp.), and shrews (*Sorex* spp.) can destroy 60 to 80% of the Siberian fir seedcrop in Siberia (Vladyshevskii and Shtarker 1982).

Several fungi associated with fir seeds usually make their presence apparent during stratification and germination (table 5), but it has not been shown if the cones become infected before harvest or during harvest, handling, transporting, or processing. The fungal pathogen *Caloscypha fulgens* (Pers.) Boud. was found in 25% of stored grand fir seedlots, but not in Pacific silver fir (Sutherland 1979). Dwarfmistletoes (*Arceuthobium* spp.) attack firs, especially red and white firs, to such an extent that stand control measures can be required (Hawksworth and Wiens 1965; Parmete and Scharpf 1963). Infected trees show less growth and

vigor (Laacke 1990a&b) and produce fewer seeds with lower viability (Hawksworth 1978).

Collection of cones. Fir seeds ripen in 2 recognizable phases, the first being the accumulation of organic materials, and the second involving metabolic changes within the seeds, so that germinative capacity continuously increases up to (or almost up to) seed dispersal (Edwards 1969; Franklin 1974b; Pfister 1967; Speers 1962; Weyerhaeuser 1958; Yanagisawa 1965). In noble fir, germination increases to a peak, accompanied by an increase in seed dormancy (Edwards 1969, 1982a), then levels off before seed dispersal (Edwards 1969; Franklin 1965; Rediske and Nicholson 1965); a similar trend occurs in Turkey fir (Beskok 1970). In contrast, in grand (Pfister 1966; Snyder 1976) and Fraser firs (Speers 1962) germination continues to increase right up to seed dispersal. For this reason, seeds should not be removed from fir cones—particularly cones collected early—immediately after collection, because low seed viability may result (Edwards 1969; Rediske and Nicholson 1965; Speers 1962) due to curtailment of the second phase of ripening.

The period for cone collection, from the time organic accumulation ends until seed dispersal begins, typically ranges from 4 to 6 weeks, depending on location. Calendar dates are unreliable and vary with locality—especially elevation—and weather patterns, but if cone storage facilities are available, collections in the West may begin by mid- to late-August. Knowledge of local ripening conditions (degree-day summations are useful) and the use of the few known ripeness indices (table 6) can aid the decision to begin collecting (Edwards 1982a).

Judging when to start cone collection can be a major difficulty. In many tree genera, not all fruits mature simultaneously, maturation date varying among cones on the same tree (cones on the southern aspect of the crown generally ripening earlier), among trees within the same stand, from stand to stand in the same year, and from one year to the next (Edwards 1980a; Franklin 1965). The extent to which collections can be made in advance of seed dispersal is largely governed by the fact that fir seed development ceases if the cones are detached from the parent tree too soon, especially if the primary organic-accumulation phase is incomplete. Early-collected cones are more sensitive to handling method, but this sensitivity declines in later collections (Edwards 1980a). Cone maturity indices are very important for firs, therefore.

In firs, cone and seed color (common maturity indices in many conifers) may be more closely related to seed source and to individual parent tree than to ripeness. For example, mature cones of white fir may be either green or purple, with green cones having (on average) 25% fewer viable seeds, and the seeds weighing 15% less, than seeds from purple cones, although there were significant interactions with elevation of the seed source (Farris and Mitton 1985). Similarly, in the former Yugoslavia, mature seeds of white fir from violet cones germinate better than those from yellow cones (Stilinovic and Tucovic 1971). Quality of Siberian fir seeds is better from trees with light-green cones than that of trees with dark-green cones (Kirgizov and Mosin 1980). Progressively southern sources of European silver fir in Bulgaria have darker colored and more germinable seeds (Gagov 1973).

Nevertheless, workable indices of fir maturation have been devised for some species based on changes in cone color, seedcoat color, or the development of color in the seed wing (table 6), although this remains subjective and depends on the experience of the collector (Rudolf 1940). When cones of noble fir in Denmark begin to change from green to yellowish brown and bend down the branches because of their weight, natural seedfall is 2 to 3 weeks ahead; thus at the first signs of cone scale separation, the cones are collectable (Dalskov 1960).

Two interrelated parameters—cone moisture content and cone specific gravity—are more objective and reliable indices (Rediske 1961). There is some general agreement (table 6) that maturity is reached when specific gravity of cones has fallen below 0.9, indicating a moisture content below 50%. Either of these 2 parameters must be measured only on freshly picked cones, and because cone moisture content is not easily determined in the field, specific gravity is usually the measurement of choice. Thus, if cones of white and red firs (and of other conifers) float in kerosene, a 50:50 mixture of kerosene and linseed oil, or any mineral/lubricating oil of specific gravity 0.85 to 0.80, the crop is ready to be picked (Lanquist 1946). However, cone specific gravity is of little use in judging maturity in Japanese fir (Yanagisawa 1965).

Although no documented use of the following attribute has been found outside British Columbia, one criterion for judging when to begin fir cone collections is to allow a sample of longitudinally cut seeds to dry out overnight at room temperature. Then, if the megagametophyte tissue shows very little or no shrinkage away from the testa in most (if not all) of the seeds, they are sufficiently well developed for cone collections to begin (Dobbs and others 1976; Edwards 1980a, 1982a; Eremko and others 1989). Shrinkage of the megagametophyte indicates that the seeds are still high in moisture content and that collection should be delayed.

Table 6—*Abies*, fir: cone and seed maturity indices identifying earliest collection date

Species	Cones	Seeds
A. amabilis	Green with yellow tinge, turning gray or purple	Seedcoat cream or tan; wing light brown/pale purple, with brown margin; megagametophyte opaque & firm; embryo yellow/yellow-green, 90% extended; rudimentary cotyledons well developed*
A. balsamea	Turning purple; moisture content < 60%	—
A. concolor	Specific gravity 0.85–0.96	Wing uniform brown, deep magenta edge; seed detached/loosely attached to cone scale; embryo pale yellow-green, 9 of 10 fully elongated
A. firma	Turning yellow-brown, losing luster	—
A. fraseri	Blue-green turning brown	Distinct seedcoat color visible
A. grandis	Light brown; specific gravity <0.90 In BC: turning gray or purple.	Wing purple-brown (green-colored cones only); seed detached from cone scales In BC: seedcoat cream or tan; wing light brown/pale purple, with brown margin; megagametophyte opaque & firm; embryo yellow/yellow-green, 90% extended; rudimentary cotyledons well developed
A. guatemalensis	Turning dark green or purple; resin droplets visible on exterior	Wings yellow
A. homolepis	Turning yellow-brown & losing luster	—
A. lasiocarpa	Green with yellow tinge, turning gray or purple	Seedcoat cream or tan; wing light brown/ pale purple, brown margin; megagameto-phyte opaque & firm; embryo yellow/ yellow-green, 90% extended; rudimentary cotyledons well developed
A. magnifica	Specific gravity < 0.75.	Wing uniform brown, deep magenta edge; detached/loosely attached to cone scale; embryo pale yellow-green, 8 of 10 fully elongated
A. mariesii	Turning brown & losing luster.	—
A. procera	Light brown; specific gravity < 0.90	Wing uniform brown; detached from cone scale; embryo 90% extended & firm; crude fat content 25 mg/g dry weight †
A. sachalinensis	Turning brown & losing luster	—
A. veitchii	Turning brown & losing luster	—

* Using 10 × lens.

† Rediske and Nicholson (1965).

The ratio of embryo length to the length of the cavity in the megagametophyte (figure 10) is also widely employed in British Columbia for judging when to collect (Eremko and others 1989). Embryos do not have to be fully elongated to be germinable, but seeds with embryos less than 50% extended germinate less vigorously and predictably. This extension can be determined readily by field personnel equipped with a sharp knife, a 10 × lens and a little training (Dobbs and others 1976; Eremko and others 1989), and it can be recorded easily on x-ray film. Thus, when a majority of the embryos—94% in white fir seeds (usually some 3.5 weeks before seedfall) and 84% in red fir (2 weeks before seed dispersal)—are fully elongated, provided other criteria are satisfactory (table 6) the cones are ripe enough to collect (Oliver 1974).

Because megagametophyte tissues do not mature as quickly as the embryos, collections should be delayed until these tissues have achieved a firm consistency (similar to the meat of a coconut), that is, they have lost their earlier watery, translucent appearance. Megagametophyte tissues will then exhibit little or no shrinkage or curling and retain a relatively firm, fresh appearance when longitudinally sliced seeds are left uncovered overnight at room temperature. The current prescription is to delay collections until embryos are at least 90% extended (figure 10), by which time the megagametophyte tissue has matured sufficiently also (Edwards 1982a; Eremko and others 1989) (table 6). As previously mentioned, another useful criterion of seed maturation is the degree to which the seeds have abscised/detached from the ovuliferous scales on which they developed. Seed

detachment indicates that they have ceased, or have greatly reduced, the accumulation of organic materials and that the seedcoats are undergoing the final stages of their development and becoming impermeable, usually signaled by the attainment of a distinct seedcoat (and seedwing) color.

Chemical indices of maturity have been explored. The crude fats and lipids that—together with protein bodies—are the main storage structures in fir seeds (Kovac and Wrischer 1989) reach high levels in mature seeds of several fir species (Bennett 1966). At a seed crude-fat content of 250 mg/g (dry weight), noble fir cones were judged to be ripe enough to collect, but that some artificial ripening (the "after-ripening" phase) prior to seed extraction was required to achieve maximum seed quality (Rediske and Nicholson 1965). A later study on maturing noble fir seeds was unable to substantiate the pattern of crude fat accumulation (Edwards 1969). Metabolism of fir seed lipids during germination has been linked to the glyoxalate cycle (Firenzuoli and others 1968).

As a general recommendation, no single criterion should be relied on when judging maturity of fir seeds. Rather, several characteristics such as seedcoat and wing color, seed detachment from cone scale, and embryo color and extension should be assessed before large-scale cone collections are undertaken (Oliver 1974; Snyder 1976).

Because fir cones disintegrate and seeds disperse at maturity, then making cone collection impossible, it is necessary to collect in advance of full seed ripeness. Collections may be by hand from standing (Seal and others 1965) or recently felled trees, or from squirrel-cut cones on the ground or from squirrel caches. Extensive collections in the western United States used to be made by climbing open-grown trees in 40- to 70-year-old stands, and some cones are still collected this way, but caution is required because fir stems are relatively brittle and tops may break out (Franklin 1974b). Cones collected by climbing should not be thrown to the ground, even in sacks, because of the danger of resin vesicle damage discussed earlier. Collections made close to the time of natural seed dispersal—when the cones are lighter (drier), the seeds are riper, and the seedcoats tougher—still require care to avoid resin vesicle injury (Dalskov 1960).

Synchronizing cone collections with felling operations, so that cones can be collected from newly felled trees reduces this danger, but the cones may disintegrate upon impact with the ground (making gathering time consuming) and may be difficult to separate from the branch debris (Pigott 1994). Squirrel-cut or -cached cones are easier to collect and the seeds are more likely to be ripe for 2 reasons: squirrels in the Pacific Northwest (at least) do not begin to cut in quantity until cones are approaching maturity, so that full seed development can be achieved because the cones are typically cached in cool, moist microsites (Franklin 1974b; Halvorson 1986; Pedro White and White 1986). However, red squirrels in the Rocky Mountains and Douglas squirrels in the southern Cascades have been seen to cut and begin caching white fir cones before they were fully mature (Fowells and Schubert 1956; Lanner 1983); red squirrels also cut immature subalpine fir cones (Lanner 1983). The high crude-fat content of conifer seeds, especially that of fir seeds, probably resists spoilage in the caches (Halvorson 1986). Although there is no direct evidence that seeds collected in this way are inferior, some squirrel-cut fir cones may have been bruised, and the seeds damaged, on impact with the ground. Also, the parent trees from which they were cut will not be known. Because squirrels collect far more cones than they can eat, they later fail to find all the cones they have cached. Thus only a portion of the caches are found by human collectors and there is no danger of depriving the animals of their winter food supply (Pedro White and White 1986).

Shooting-out cone-laden tops of fir trees with a rifle has been used with some degree of success, with smaller crews collecting many (if not more) cones than by climbing. However, there are inherent dangers in this technique, especially in the vicinity of other work crews, and/or near urban areas (Dobbs and others 1976). Cone harvesting by mechanically shaking the trees was unsuccessful on both noble and grand firs (Anon. 1970).

One technique developed in the past 2 decades is the aerial cone-rake, a device designed to be lifted by helicopter and lowered over the crowns of cone-bearing trees (figure 13). In the process of retrieving the device, cones and cone-laden branches are raked from the tree by a circle of tines and collected in a basket (figure 14. When the basket is full, the device is lowered to a cone-dump site and the cones and slash sorted by hand (Wallinger 1986) (figure 15). By this means, larger volumes of cones per day—up to 10 hl (28 bu) of Pacific silver fir, 10 hl or more of grand fir, but only 2 to 5 hl (5 to 15 bu) of subalpine fir—can be collected in a much shorter time than by traditional methods (Eremko and others 1989; Portlock 1996), making the technique economically viable. There are additional advantages in that cone collection can begin closer to seed dispersal, that is, full maturity, and cones can be collected from areas that have no road access. The technique works best on tree species (such as fir) that bear cones in the upper third of the crown. Cone rakes have been used to collect over 90% of all fir cones collected in British Columbia (Wallinger 1986). All aspects

Figure 13—*Abies procera*, noble fir: aerial collection using a cone rake (courtesy of D. Pigott).

Figure 14—*Abies procera*, noble fir: cones collected by aerial cone rake (courtesy of D. Pigott).

of the application of the technique, as well as aerial clipping/sawing, and aerial topping for cone collection, have been comprehensively reviewed (Camenzind 1990).

Cone and seed processing. Seed germinability of a number of species, including white (Oliver 1974), grand (Pfister 1966), Nordmann (Muller 1971), and noble firs (Edwards 1969; Franklin 1965; Rediske and Nicholson 1965) can be improved by storing the cones under cool, moist conditions for several weeks after collection. In contrast, cones of red fir need to be collected as close as possible to seed fall (Oliver 1974). Artificial ripening of early-collected seeds allows cone collections to be started sooner, thus extending the collection period, so that immature cones from logging operations can be used (Edwards 1982a). The maximum period of collection prior to the onset of natural seed dispersal appears to be around 6 weeks, but it is safer to think in terms of only 4 weeks. Warmer, drier summers (after pollination) may allow earlier starts to cone collection than cool, wet summers. In most years, the beginning of August is probably the earliest any cones should be collected, and only then if storage facilities can provide the cool, slow-drying conditions required. Because water loss is an intrinsic part of the maturation process (Pollock and Roos 1972) in orthodox seeds (see chapter 1), the cones need to be dried, preferably slowly, so that mold build-up and heating are avoided.

The period of cone storage is governed by the natural disintegration of the cones; once they have fallen apart they can be regarded as fully mature (Edwards 1969; Muller 1971). Well-spaced (not stacked) sacks of cones should be stored for periods of several weeks or months in drying sheds with good air circulation, for cones mature best in cool (<10 °C), shaded conditions (Edwards 1969; Franklin 1965; Rediske and Nicholson 1965). Storing grand fir cones with their bases in water or nutrient solutions gave higher seed weights and increased germination (Pfister 1966), but storing grand and noble firs cones in damp peatmoss was deleterious (Franklin 1965; Pfister 1966). For immature cones that are high in moisture, rebagging the cones as they arrive at the storage station and reducing by half the amount of cones in each sack will promote good curing. Periodic inspection for deterioration and turning the material within the sacks are good cone storage practices. Spreading balsam fir cones on mesh-bottomed trays is advantageous also; cones should not be more than 6 cm deep and they may

Figure 15—*Abies grandis*, grand fir: bagging aerially collected cones at a dump site; note the wooden box by picker's knee, this is a cone-volume measuring device (courtesy of D. Pigott).

need turning at least once each day, especially if they settle onto the trays in a compact mass (Carman 1953). No deterioration in seed quality was found when Pacific silver fir cones were stored for 6 months (October to March), either in a covered shed exposed to ambient external temperatures or in a refrigerated compartment at 2 °C prior to seed extraction, provided the cones had been properly handled in the field (Leadem 1982). Therefore, fir cones may be among the last to be scheduled for seed extraction, December or even later, by which time full seed maturity has been achieved and the cones have completely disintegrated, making seed extraction simpler. It cannot be over emphasized that fir seeds should not be extracted from the cones immediately after collection, especially from early-collected cones, otherwise viability is likely to be low.

Cones should be placed in proper storage facilities as soon as possible after harvesting and on no account should they be left untended at the collection site or in a vehicle for more than a few hours. Especially for premature collections, interim collection facilities in the field are essential to allow for continuing maturation (Dobbs and others 1976; Eremko and others 1989; Stein and others 1974; see also chapter 3). Incompletely ripened fir seeds store poorly, with serious losses in germinative capacity (Muller 1971; Yanagisawa 1965). Even when collected close to full maturity, fir cones that are not placed in suitable interim storage which will permit continued loss of moisture, the heat of respiration is liable to cause an increase of the surrounding temperature and non-dormant seeds may sprout before the cones can be processed. Such viviparous germination has been observed in subalpine fir (figure 16 and 17) and in other conifer species (Edwards 1980a). Although interim storage is a minor component of seed collection costs, it is important and yet is often poorly addressed (Pigott 1994). Cones should be moved to a more permanent storage location as soon as other operations permit, but for reasons similar to the above, long-distance transportation should be avoided. Turpin (1963) recommended field extraction using an inexpensive, easily erected structure so that only the extracted seeds of European silver, white, grand, and Sierra white firs are shipped.

Processing fir cones (table 7) is similar to processing cones of other conifers, except that if the fir cones have been stored for 2 to 3 months, they will have disintegrated naturally, the seeds will have separated from the scales, and the kiln-drying and tumbling steps can be dispensed with. In British Columbia, storage of the cones of Pacific silver, grand, and subalpine firs not only conditions the cones, but also, if the cones are dried to a target-moisture content of 15%, damage through seedcoat abrasion is reduced and makes the seed wings become more brittle and easier to break off (Rooke 1997).

Figure 16—*Abies lasiocarpa*, subalpine fir: viviparous germination, with seeds germinating in the cone before they could be extracted (courtesy of D. Pigott).

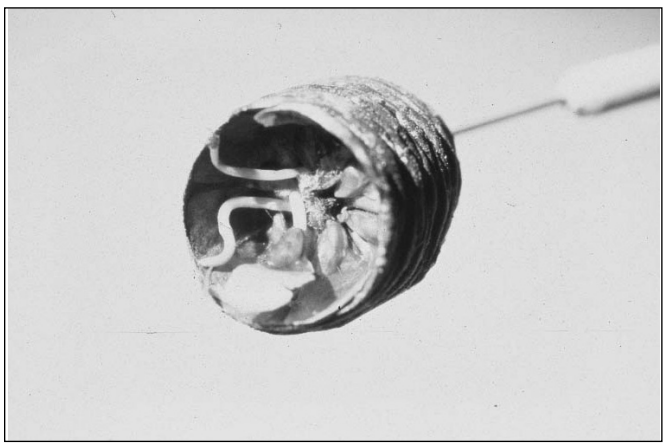

Figure 17—*Abies lasiocarpa*, subalpine fir: viviparous germination, with seeds germinating while still attached to the ovuliferous scales (courtesy of D. Pigott).

When additional drying is required, cones should be air-dried for 3 weeks or more at 20 to 30 °C (Franklin 1974b) where ambient conditions permit. If kiln drying is absolutely necessary, temperatures between 30 and 38 °C for up to 14 hours are used (table 7), but care must be taken to avoid damage through too rapid or prolonged drying. When possible, kiln-drying should be avoided so that any possibility of heat damage to the seeds is eliminated.

Partially or wholly disintegrated cones are tumbled or passed over vibrating screens (Carman 1953; Rooke 1994) to separate the seeds from the cone axes, scales, and bracts.

Table 7—*Abies*, fir: cone drying schedules

† If air-drying not possible, but cones should not be processed immediately after harvest.

‡ In a rotary kiln; seeds removed from heat as soon as they fall through the tumbler mesh.

§ In the shade.

Screening is more gentle and less damaging to seedcoat resin vesicles. Nordmann fir seeds can be extracted by passing the cones between series of rotating and fixed teeth, the spacing of which gradually decreases (Saralidze and Homeriki 1964). The separated seeds are then de-winged, a step during which fir seeds can be easily damaged (Allen 1958; Franklin 1974b; Roe 1948b; Weyerhaeuser 1957), thereby exacerbating losses of viability during storage (Rediske 1967). Small lots are best de-winged by hand (Roe 1948b), but even this can rupture some vesicles in noble fir (Edwards 1982a). Grand fir seeds de-winged by hand germinated significantly better than those commercially processed (Wang 1960). When mechanical processes must be used on large lots, one common technique for true firs is to break the wing at or near the point that it extends beyond the seedcoat, relying on friction in a mass of seeds agitated by gentle rolling of the seed mass (Rooke 1994). Using a spiral screw or auger, or drawing the seeds through tubing connected to a vacuum cleaner, may achieve the same goal. Some machines employ rotary screens that permit the wing, but not the seed, to protrude and to be broken by a brush. Some wings may be removed during the initial vibratory-screening to separate seeds from other cone parts (Carman 1953). Special processing and sowing machinery designed for European silver fir in Poland are based on morphological measurements of the seeds (Czernik 1993).

All these methods, which are performed on dry seeds and can be quite effective in breaking the seedwing, provide for impact damage to the resin vesicles and to the seedcoat itself. Prolonged de-winging, or de-winging fir seeds in a mixture that includes a considerable amount of hard, sharp debris such as cone scales, can cause considerable injury. When subalpine fir seeds were run through a brush de-winger 3 times, 50% of their original viability was lost (Allen 1958). A simple, efficient 2-step process using a scalper treatment followed by pneumatic separation was recommended for white and red fir seeds by Kitzmiller and others (1975). The scalper did less damage than hand de-winging, and although the pneumatic separator inflicted some injury, it eliminated most of the impurities remaining after the scalper treatment.

As described earlier, the fir seedwing forms on the adaxial (upper) surface of the developing seed and is attached to the seed by an integument. Two narrow flaps wrap around the long margins of the seedcoat toward the abaxial surface, thereby gripping the seed (figure 6). Most integuments remain attached to dry seeds after normal de-winging but often loosen and separate from the seedcoats when they become wet during a germination test. This suggests that the seeds might be de-winged when wet, but no documented use of the method is known for fir seeds.

Gravity table cleaning can be very efficient and gentle (Rooke 1994). An aspirator sorter works well for cleaning and for separating filled and empty seeds of Pacific silver, grand, and subalpine firs (and other conifer seeds), although small-filled seeds generally accumulate in the empty seed fraction, whereas large-empty seeds separate out with the filled seeds (Edwards 1979). Prior seed sizing improves the efficiency of this technique.

The IDS (incubating-drying-separating) method (see chapter 3) works well on seeds of other Pinaceae (Bergsten 1993; Karrfalt 1997; Simak 1984) and has been used to remove seeds infested with *Megastigmus spermotrophus* Wachtl. (Sweeney and others 1991). A variant of the IDS method known as density separation processing (DSP) is used to upgrade seed quality of Pacific silver and subalpine firs in British Columbia. In 12 seedlots of Pacific silver fir, an average gain in germination of 24% and an increase in potential seedlings of 48% was obtained, but gains in seedlots of subalpine fir were smaller (Kolotelo 1993). The method does not work on all seedlots, especially those with a high proportion of immature seeds, and seedlots from sources above 1,000 m elevation (Kolotelo 1994); the reasons for this are not known. Another approach to flotation sorting has been described (Edwards 1978). Separation in other liquids, such as petroleum ether (Lebrun 1967) or absolute alcohol (Simak 1973) cannot be recommended because the ether is highly flammable and alcohol is phytotoxic to true fir seeds (Edwards 1980b).

Another advantage of processing fir cones late in the year during cold weather is that low temperatures solidify any resin that has leaked from the vesicles in the seedcoat or may be present as an impurity from other sources. This makes the resin less likely to gum-up processing machinery as well as making it easier to separate from the seeds. Resin/pitch is relatively dense, so it sinks and seeds float in a water separator. Seeds may be chilled as a first step in cleaning to reduce resin problems, but additional chilling may be required as the seeds warm up (Rooke 1994). When de-winging and cleaning to the desired level of purity are complete, seed moisture contents should be checked, adjusted as required, prior to cold storage. In the past, recommended processing standards of 20 to 35% viability used to be common for commercial lots of North American fir species (WFTSC 1966), and fir seed quality traditionally was low, rarely exceeding 50% germination (Franklin 1974b). This was often the result not only of poor (by present standards) seed processing methods that failed to remove many unfilled or partially filled seeds, but also of inadequate methods for overcoming dormancy.

Typical cone and seed yields and numbers of fir seeds per unit weight are listed in table 8.

Seed storage. Fir seed storage has been intensively researched (Barton 1961; Holmes and Buszewicz 1958, 1962; Magini 1962; Wang 1974) and is summarized in table 9. Fir seeds are orthodox in storage behavior, meaning that they store well at low temperatures and moisture contents. Most experts agree, however, that the seeds lose viability quickly unless special precautions are taken, possibly because of the high oil and resin contents that (when oxidized) may be toxic to the embryo (Bouvarel and Lemoine 1958). Guatemalan fir seeds have been found to lose their viability in a few weeks; one report states that they cannot be dried below 12% moisture content and are considered recalcitrant (Anon. 1998). However, other workers recommend drying them to 6 to 8% moisture, which permits storage for nearly a year (Donahue and others 1985) (table 9). The embryonic radicle usually dies first in stored European silver fir seeds (Gogala and Vardjan 1989).

One decision that must be made is whether the seeds are to be stored for a few months or for a year or more, because lower temperatures will be required for longer periods (Tocci 1966). For example, it may be pointless to store large volumes of seeds for periods longer than the interval between good cone crops (Edwards 1982a). Although the superiority of sub-freezing conditions as low as –17 °C has been amply demonstrated (they are commonly used for long-term storage of fir and other orthodox seeds), higher temperatures (never above 4 °C) can suffice for short-term storage. Fir seeds store well for 3 to 10+ years in sealed containers (Allen 1957; Gradi 1966), but such containers are not a panacea if the seeds have not been properly prepared (Gradi 1966; Tumbarello 1960). Experiences with fir-seed storage durations and conditions have been amply reported (Allen 1957; Carrillo and others 1980; Isaac 1930a, 1934; Issleib 1956; Larsen 1922; Roe 1948b; Rohmeder 1953; Rudolf 1952; Schubert 1954; Vilmorin 1944; Vlase 1960), and cryopreservation of fir seeds also has had some success (Jorgensen 1990; Neuhoferova 1994; Stanwood and Bass 1978).

In principle, storage temperature is of greater significance when seed moisture content is high and, conversely, has less effect when moisture content is low (Barton 1953; Magini and Cappelli 1964a&b). At low moisture contents, seed storage becomes almost independent of temperature, an inverse relationship demonstrated by Danielson and Grabe (1973) in a 2-year trial with noble fir seeds that (a) deteriorated rapidly when moisture content was above 12%, irrespective of storage temperature; (b) maintained viability at 12% moisture when stored at –18 °C, but not at +5 or +20 °C; (c) maintained viability at 6 to 9% moisture when stored at –18 and +5 °C; and (d) maintained viability at 4% moisture when stored at –18, +5, and +20 °C. For firs in general, the critical safe moisture level appears to lie between 5 and 8% of seed fresh weight (Wang 1974).

Sources: Allen (1957), Edwards (1982a), Franklin (1974b), Gradi (1966), Heit (1941, 1968b), Hofman and Vackova (1966), Holmes and Buszewicz (1962), Issleib (1956), Jones (1962), Loffler (1985), Machanicek (1965), Mormann (1956), Radulescu (1968), Speers (1974b), Tillisch (1952), Tokarz (1974).

Pregermination treatments. Dormancy in fir may be both physical and physiological, but it apparently does not reside in the embryo, because embryos excised from unstratified noble fir seeds grow just as well as those from stratified seeds (Edwards 1969). Reasons for fir seed dormancy may be poor oxygen exchange or an inhibitor, because chipping the seedcoat to expose and remove a sliver of megagametophyte was as effective as (or more so than) stratification in stimulating germination of seeds of noble, Pacific silver, and grand firs (Edwards 1969) and European silver fir (Gogala and Vardjan 1989). Stratification also probably overcomes dormancy by reducing the mechanical restraint of the tissues surrounding the embryo (Edwards 1962, 1969; Jones and others 1991; Speers 1962; Wang 1960). Length of treatment is usually 21 to 28 days for laboratory tests (AOSA 1998; ISTA 1993), but other reported periods range from 14 to 120 days, and longer periods are the rule for nursery sowing (table 10). Longer treatments should be approached with care because they may result in more fungal/bacterial damage and premature germination (Edwards 1982a; Grittanuguya 1962; MacGillivray 1955; Zentsch 1960) and are best at lower seed moisture levels, as demonstrated for various hybrid firs (Wright 1950) (see also stratification–redry method below).

As with many tree seeds, dormancy among the firs is quite variable. Although stratification is routinely prescribed for European silver and Fraser firs, there are reports (Speers 1967; Zentsch and Jahnel 1960) that some seedlots of both species show little or no dormancy. The only way to determine whether or not a lot is dormant is to perform 2 germination tests—one with stratified seeds and one with unstratified seeds (Edwards 1962). The response to stratification may be regarded as an indicator of the degree of dormancy in the lot; after stratification, more-dormant seedlots germinate more rapidly than less dormant lots. In some instances, stratification has increased total germination as well as germination rate (Jones and others 1991; Pfister 1966; Speers 1968), although this may have been due partially to the seeds' germinating before development of the

a Depth of mulch: peat moss, 0.5–1.5 cm (_–_ in); pine needles, 3–4.5 cm (1_–1_ in); sawdust, 0.5 cm (_ in); straw, 5 cm (2 in).

b Containers are all PSB type; Styro = Styroblocks, PCT = copper treated. The various containers listed have the following volumes: 313A, 52 ml (3.6 in^3); 313B, 65 ml (3.9 in^3); 410A & PCT 410, 80 ml (4.9 in^3); 415B, 93 ml (6.3 in^3); 412A, 126 ml (7.7 in^3); 415D, 172 ml (10.5 in^3); 615A, 336 ml (20.0 in^3); Styro 2, 39 ml (2.3 in^3); Styro 5, 77 ml (4.7in^3); Stryo 7, 121 ml (7.4in^3); Leach 1, 50 ml (3 in^3), Leach 2, 164 ml (10 in^3).

c Seeds covered with 1 cm nursery soil plus 1 cm sand.

d For 28–30 days only if intending to strat-redry.

e Some container transplants grown as P+2, P+3, P+4.

f Stratified in wet vermiculite, wet sand, or 1.5- to 2-day running-water soak and naked stratification.

g Used overwinter on first-year seedlings.

h Some free moisture left in plastic bag for long stratification.

i Light may be beneficial to germination.

j When not stratified, soaked 2 days before sowing.

k Alternatively, bury the seeds in snow for 50 days.

extensive fungal and bacterial molding common to more-slowly-germinating unstratified seeds (Edwards 1969). In noble fir, an increasing response to stratification as the seeds matured suggested that dormancy increased also, and that dormancy and maturity are interrelated (Edwards 1969). Whereas much of the variability in dormancy among seedlots may be attributable to seed origin, crop year, and time of collection, it may also be due to methods of cone processing, seed cleaning, and seed storage (Franklin 1974b; Wang 1960).

Laboratory and nursery stratification is often performed by refrigerating previously hydrated seeds in plastic bags or other containers—the "naked stratification" method (Allen and Bientjes 1954) favored in many nurseries for its ease of seed handling. More traditionally, dry seeds (at storage moisture contents) are placed on a moist medium (filter paper, vermiculite, or wet sand) and refrigerated. The moist filter paper method produced higher germination in noble fir because it was believed that the preliminary water soak that is the first step in the naked stratification procedure damaged the seeds by too-rapid tissue hydration, a phenomenon well-documented in legumes (Jones and others 1991). Soaking temperature in this noble fir study was 4 °C. However, no direct evidence for the damage, particularly its location, was provided. It is unlikely that any damage occurred in the tissues of the embryo. When noble fir seeds were soaked in water at 25 °C, after 48 hours most of the water was still in the seedcoat: the outer region of the megagametophyte had become moist, but the embryo was still dry (Edwards 1969). It was found that noble fir embryos require hydration of between 48 and 72 hours, even at room temperature, before they absorb enough moisture to be safely excised (Edwards 1969). Furthermore, when dry noble fir seeds are placed on a moist medium and refrigerated, they absorb water slowly during the entire chilling period and achieve a higher moisture content than seeds soaked in water at room temperature for the same length of time (Edwards 1971). Thus, in the above comparison, the moisture content of soaked seeds averaged 36%, whereas that of seeds chilled on moist filter papr averaged 43% (Jones and others 1991). This difference, small as it may appear, may have been significant due to the moisture content in soaked seeds possibly being less than adequate for optimal stratification to occur. In the development of the stratification/redry method (see below), it was found that if fir seeds were initially hydrated only to 35% moisture content (the same moisture content achieved after redrying), subsequent stratification was far less effective (Edwards 1986). If noble fir seeds are sensitive to imbibitional damage as claimed (Jones and others 1991), then the stratification/redry method—which involves a preliminary soak at room temperature—must repair such damage since germination is greatly increased. However, no evidence for this repair, or the initial imbibitional-damage phenomenon, has been documented.

In any event, crop year, seed source, seed vigor (as distinct from seed quality), as well as chilling method and germination temperature played roles in the response of different seedlots of Pacific silver fir to stratification (Leadem 1986). Stratification response of Nordmann fir was also believed to be strongly seedlot dependent (Poulsen 1996). For balsam fir seeds, prolonged soaking in cold water containing a fungicide was deleterious (Kozlowski 1960), but changing the water weekly produced germination similar to that after stratification (Rudolf 1950). Best results with Manchurian fir occurred when soaked seeds were stored in snow for 1 to 2 months (Pavlenko 1972).

Stratification temperature range is often specified as 1 to 5 °C (Franklin 1974b), although testing laboratories typically use a narrower window of 3 to 5 °C. Stratifying grand and subalpine fir seeds at 2 °C was optimal (compared to –2, 5, and 7 °C), especially during extended chilling (Edwards 1982a). Fir seeds will germinate during stratification if left for a sufficient length of time (Allen 1960; Edwards 1969; Blazich and Hinseley 1984; Roe 1948b; Vabre-Durrieu 1956). Such observations reinforce the idea that stratification is incipient germination. In this regard, it should be remembered that late-dispersed seeds of numerous high-elevation firs (plus some other conifers) germinate in snow banks (Anon. 1951; Franklin and Krueger 1968; Gordon 1970; Hetherington 1965; Irmak 1961; Roe 1946; Stein 1951). Snow absorbs 99% of the infra-red (IR) radiation from sunlight, and dark-colored seeds embedded in snow may reach several degrees above freezing by absorbing these IR rays. However, these germinants seldom establish as seedlings when the snow melts (Gordon 1970; Stein 1951).

Despite the fact that lower than normal levels of seed moisture were known to benefit extended treatments of hybrid fir seeds (Wright 1950), fir seed research continued to focus on stratification temperature and duration and not on moisture level during treatment. Since the 1980s it has been demonstrated conclusively that seeds of Pacific silver, grand, subalpine, and noble firs stratified at 2 to 5 °C in plastic bags for 4 weeks (moisture content 45% or higher), then air-dried to moisture contents between 25 and 35%, can be returned to the same refrigerator for (a) another 12 months (at 25%) without significant decreases in subsequent germination or (b) a further 3 to 6 months (at 35%) with greatly enhanced germination rate and germination capacity (Edwards 1980b, 1981, 1982a,b, &c, 1986b, 1997; Leadem 1986, 1988b, 1989; Tanaka and Edwards 1986). When air-

dried to 35% and refrigerated for a further 3 months, all viable grand fir seeds germinated within 2 weeks (Edwards 1980b). This is the result of achieving a synchronicity in germination achieved by the reduced moisture content that places the embryos under a moisture stress. This stress prevents less-dormant seeds in the mixture from germinating, while allowing more-dormant seeds to achieve a ready-to-germinate state when the extended chilling ends. Subsequently, sowing the seeds on a non-moisture-limiting medium permits all the viable seeds to germinate at the same time (Edwards 1981, 1982b, 1986b). In addition, the reduced moisture content "protects" the energy supplies of the megagametophyte from being respired as rapidly as in seeds undergoing traditional stratification at high moisture content (Leadem 1993).

This process, which has become known as the stratification-redry method, differs from traditional stratification as shown diagrammatically in figure 18. During routine stratification (upper), seeds are soaked for 24 to 48 hours at room temperature, drained, chilled at 2 °C for 4 to 8 weeks in their "fully imbibed" state (moisture content around 45% or higher) until they are sown in the nursery. In the new process (lower), seeds are soaked for 24 to 48 hours at room temperature, drained, and chilled for 4 weeks while fully-imbibed (as in the old method). Then, the stratified seeds are removed from the refrigerator and air-dried to 30 to 35% moisture content. Next, they were returned to the refrigerator for an additional 1 to 3 months of chilling for the most rapid and complete germination. Alternatively, when dried to 25% moisture content and returned to the refrigerator, they can be kept for up to an additional 12 months until they are sown. The procedure has been described in detail (Edwards 1982b, c, 1986, 1997) and is now used operationally in British Columbia (Leadem and others 1990). An almost identical procedure has been described for Nordmann fir seeds (Jensen 1997; Poulsen 1996), and control of moisture level during stratification has been recommended for Guatemalan fir (Donahue and others 1985).

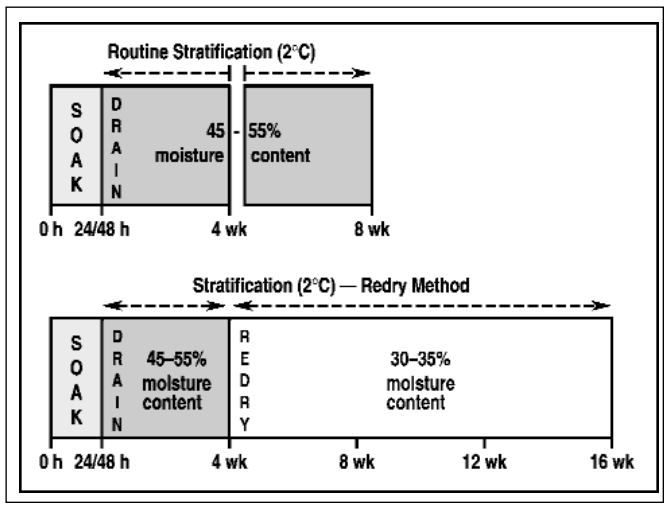
As described above, seeds air-dried to 25% moisture content can be "stored" in the refrigerator for up to a year without losing the beneficial effect of the initial stratification, that is, they remain in a ready-to-germinate state. Stratified seeds of noble and Pacific silver firs have been dried to 5 to 9% moisture content and stored for 1 year, after which they germinated significantly better than the original controls (Hall and Olson 1986). For the seedling grower, these methods allow stratification to begin well in advance of nursery sowing date and/or make the sowing date more flexible (Edwards 1980b, 1981, 1982a, 1986b). Two additional beneficial effects of redrying (to either 35 or 25%) observed in the laboratory were that fungal and bacterial molding of seeds was greatly reduced and that emerging radicles were more positively geotropic than in germinants from routinely stratified seeds. This latter is important in that germination in firs is epigeal (figure 19) and a vigorous healthy radicle is essential for successful seedling establishment.

There is little reported evidence of the use of gibberellins increasing fir seed germination, but a combination of stratification for 40 to 60 days and treatment with 200 ppm GA_3 worked well for Guatemalan fir seeds (Salazar 1991). Use of gibberellin GA_{4+7} improved dark-germination of Fraser fir at 30/20 °C over a 42-day test but was ineffective (light or dark) at 20/15 °C unless the seeds were first hydrated for 20 hours (Henry and Blazich 1988). The beneficial effect of an auxin has been reported in Sakhalin fir (Yoshida 1960).

Germination tests. Stratification treatments for 10 fir species regarded as consistently dormant are prescribed in seed testing rules (AOSA 1998; Edwards 1987; ISTA 1993), whereas double (paired) tests (with and without stratification) are recommended for 8 other species in which dormancy varies among seedlots. West Himalayan fir might be added to the list of species requiring double tests (Khattak and Ahmad 1980), but Korean fir is consistently dormant (Jakimova 1965). The officially prescribed stratification period for all fir species is either 21 or 28 days, the longer period being favored by the AOSA rules for 6 species.

Alternating temperatures of 30 °C with light for 8 hours and 20 °C for 16 hours without light are standard for most fir species, with 3 notable exceptions. For Pacific silver fir, the current AOSA prescription is for 25 °C (light) for 8 hours and 15 °C (dark) for 16 hours. However, seeds of this species germinate more slowly but more completely at 15 °C (light) for 8 hours and 10 °C (dark) for 16 hours (Leadem 1986). Similarly, subalpine fir seeds stratified for 8 weeks germinate well under a 25/15 °C regime (Hansen and Leivsson 1990; Leadem 1989), whereas Fraser fir seeds stratified for 12 weeks germinate well at 20 °C for 8 hours with light for 1 hour (only) during the latter part of this warm period, followed by 10 °C (dark). If stratified for 8 weeks only, Fraser fir seeds should be tested at the standard 8/16 hours 30/20 °C, with a 1-hour light treatment during the higher temperature (Adkins 1984; Adkins and others 1984; Henry and Blazich 1990). The involvement of phytochrome has been demonstrated in the germination responses of Fraser fir (Henry and Blazich 1990) and is suspected in several other firs (Li and others 1994; Nagao and Asakawa 1963; Messeri and Salvi 1964), making it essential to use fluorescent-only lighting for laboratory tests (Asakawa 1959; Blazich and Hinseley 1984; Nagao and Asakawa 1963).

Figure 18—*Abies*, fir: schematic comparison between traditional stratification (**upper**) and the newer stratification–redry method (**lower**).



The germination substrate is usually kept at its maximum moisture-holding capacity so the test samples are not under any moisture stress but without excess free water present. Full germination of Pacific silver and grand fir seeds was unaffected unless the medium was moistened to below 40% of maximum holding capacity (Edwards unpublished data). However, completeness of germination, and germination rate of west Himalayan fir seeds was highly sensitive to moistening the filter paper with PEG (polyethylene glycol) solution (Singh and others 1986). Many laboratories use a paper/blotter substrate as this allows easy evaluation of the radicles (figure 20), but porous mineral substrates such as perlite, vermiculite, and Sponge Rok® may be employed also. Tests conducted according to standard laboratory prescriptions usually terminate after 21 or 28 days, although those on unstratified seeds may continue for 35 or 42 days. As a means of predicting operational sowing requirements in nurseries, some agencies test stratified true fir seeds in fumigated soils at temperatures of around 24 °C during the day and 18 °C at night (Johnson 1984).

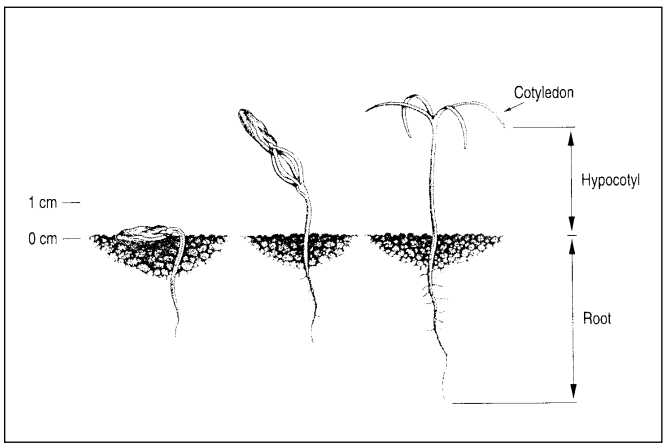
By the time newly harvested fir seeds have been processed, there is often insufficient time to complete standard germination tests that require a minimum of 3 weeks for completion, and more than twice this duration if the seeds must be stratified, before they are required for sowing the following spring. To provide more rapid estimates of seed quality, several so-called quick tests have been developed. The simplest is the cutting test, but it is also the least reliable because it fails to detect seeds damaged during handling and processing or that have died during storage. The cutting test invariably overestimates seed quality in grand (Rohmeder 1960b) and European silver fir seeds (Enescu 1968; Ducci and Paci 1986).

Where equipment is available, x-radiography quickly determines percentages of filled seeds of several fir species (Edwards 1982a,b&c; Speers 1967) and provides indirect indications of seed viability (Allison 1980) that are more accurate in fresh than in stored seeds of white fir (Eden 1965). When barium chloride was used as an contrast agent, x-radiography tended to over-estimate the viability of poor-quality seeds and under-estimate that of high-quality seeds of Siberian fir (Scerbakova 1964). When chloroform was used as the contrast agent, there was fairly good agreement with standard tests for seedlots of Pacific silver fir below 30% germination, but in general the germination capacity was over-estimated (Edwards 1982a; Leadem 1984).

Hydrogen peroxide has been used *in lieu* of stratification to stimulate germination in subalpine (Shearer and Tackle 1960), European silver (Simak 1970), and grand firs (Gyimah 1977), but not in Pacific silver fir (Edwards 1982a; Edwards and Sutherland 1979). For a rapid viability test, hydrogen peroxide gives results in 5 to 9 days with viable seeds producing visible radicles. The results correlate well with the standard germination test for noble, grand, and white fir lots between 24 and 64% germination (Ching and Parker 1958), but the method under-estimates germination capacity in lots below 30% (Edwards 1982a; Leadem 1984). As with other rapid viability assessments, the hydrogen peroxide test does not provide any information about the speed of germination, or the requirement for stratification (Johnson 1984).

Official prescriptions for tetrazolium chloride (TZ) staining tests of fir have been developed (AOSA 1998; Buszewicz and Holmes 1957; ISTA 1993; Knierim and Leist

Figure 19—*Abies amabilis*, Pacific silver fir: germinant and seedling development at 3, 5, and 7 days after germination.



1988). Tetrazolium test results often correlate with seedling emergence experienced in nursery sowings (Franklin 1974b). Tetrazolium agreement with standard germination tests can vary among lots of many species (Ducci and Paci 1986; Flemion and Poole 1948; Leadem 1984; Rohmeder 1960b), and a "best estimate" of 2 methods (for example, hydrogen peroxide and TZ) has been proposed for rapid tests (Edwards 1982a). An excised embryo method that requires about 1 week for assessment of European silver fir has been described (Nyholm 1956), but no official prescriptions for fir have been developed. Although "quick tests" may be completed in a matter of hours, or days, compared to weeks required for standard germination tests, not only do they over-estimate (Franklin 1974b; Rohmeder 1960b; Stein 1967) or underestimate (Edwards 1982a; Leadem 1984) viability of fir seeds, they are more time (and labor) consuming, and a single skilled analyst can complete fewer quick tests per month than standard germination tests. They also require a high degree of skill and experience to perform them consistently and well. Their technology was described as unreliable for firs (Edwards 1982a), and it remains so.

Although a number of vigor tests have been devised for agricultural and vegetable seeds (AOSA 1983; ISTA 1995), no tests have been adapted, or are widely used, for firs. However, it is known that stratification broadens the temperature range for optimal germination of Pacific silver (Davidson and others 1984) and grand firs (Wang 1960), and that the stratification/redry method (described earlier) broadens the range even further (Davidson and others 1984). This temperature-range broadening is a sure sign of increased vigor (Grabe 1976). One distinction between seed vigor and seed germination can be seen in the effects of long-term seed storage, which causes a reduction in plant percentage in the nursery before it affects germination percentage (Giannini and Murazio 1972; Muller 1977, 1980). Seed vigor was related to germination rate, seed protein levels, and seed respiration, all of which were thought to have potential for development as quantifiable indices of this variable in subalpine fir (Leadem 1988a&b, 1989).

Figure 20—*Abies lasiocarpa*, subalpine fir: stages in seed germination, from an ungerminated seed (**lower left**) to a 3-day-old germinant (**upper right**) (courtesy of D. Pigott).

Nursery practice. Fir seedlings are grown as both bareroot and container stock. A 1997 survey found 20 nurseries growing almost 21 million seedlings of 16 (including 6 non-native) fir species for reforestation purposes. Several other exotic firs are grown, especially in the northeastern United States, for Christmas trees (Girardin 1997a&b). For bareroot sowing in the past, most Pacific Northwest and California nurseries stratified for 1 to 2 months (table 10) at 0 to 3 °C, and sowed between mid-April to mid-May (exceptionally as late as June), favoring a seedling density of 270 to 330 seedlings/m^2 (25 to 30/ft^2) (Lavender 1979) (table 10). Bareroot sowing rates for Pacific silver, grand, subalpine, and noble firs in British Columbian nurseries usually were lower—220 to 240/m^2 or 260 to 300/linear m of seed bed (20 to 23/ft^2 or 79 to 91/linear ft of seed bed)—to produce more open-grown plants (Arnott and Matthews 1982).

Although seeds of European silver, balsam, and Fraser firs normally may be fall-sown in bareroot beds without stratification (table 10) as are seeds of noble and white firs raised in European nurseries (Franklin 1974b)—spring-sowing of stratified seeds has been recommended for balsam (Roe 1948b), and European silver firs (Neubacher 1959; Paiero and Piussi 1964; Vlase and Iesan 1959). Fall-sowing of freshly collected fir seeds may not be possible because seed processing is incomplete, so sowing the following spring provides the earliest opportunity. Spring-sowing of stratified seeds is the traditional standard for most western North American species (table 10), which minimizes losses from birds, rodents, and adverse weather (Lanquist 1946). Merely soaking grand fir seeds can be beneficial (Hofman 1966). Sowing unstratified seeds of grand and noble firs in January to March or stratified seeds in April gave satisfactory results in the United Kingdom (Faulkner and Aldhous 1959). Most bareroot nurseries use a seedling caliper between 2.5 and 5 mm (metric measure only) for culling purposes.

Fir seedling production in Canadian nurseries is now entirely from container systems (figure 21), a method widely used in the United States also. In container nurseries, sowing usually occurs in the spring, as early as January or as late as June (for stock being grown for $1^1/_2$ seasons) (table 10). Nearly all container-grown firs are started in greenhouses to provide warm temperatures for germination and early growth and then moved to cooler shadehouses during the hotter part of the summer; alternatively, the greenhouse covers (or sides) may be removed. January-sown seedlings maybe ready for mid-October planting, but more optimal dormancy and frost-hardiness is achieved by delaying planting until mid-November. However, high-elevation sites then may be inaccessible, so cold storage is required to keep stock dormant until spring planting. If noble fir seedlings are to be fall-planted, it is important to switch to cool conditions by mid-summer to achieve adequate cold-hardiness (Owston and Kozlowski 1981). Although stock quality varies widely according to planting site requirements, 1+0 seedlings 7.5 to 10 cm tall with 2.5-mm caliper are acceptable provided the root plugs remain intact on extraction from the containers (Owston 1979).

Many container nurseries stratify fir seeds by soaking them in cold water, then draining them and placing them in large plastic bags. Water temperature is normally uncontrolled and is ambient for the local supply. Seeds to water ratio (by volume) should be at least 1:3. Running water soaks, or water changes during longer soaking periods, are quite common and are used especially to help clean seeds of pathogens (Campbell and Landis 1990). One nursery follows the initial soak with a brief dip in 1% hydrogen peroxide to control fungal infections, but the efficacy of this has not been verified. After draining, no more than 2 to 2.5 kg (5 lb) of seeds are placed in plastic bags that are either loosely tied (Jones and others 1991) or have a breather tube inserted (before the tops of the bags are tied) to ensure gas exchange with the outside air (Johnson 1984). Hanging the bags from a bar in the chilling facility assures that free water will continue to drain to the bottom, and several pin pricks in the bag will allow any excess moisture to drain away. At least once weekly (several times being preferred by some operators) the seeds are rolled within the bags to bring those from the center or bottom of the mass near the top. This provides maximum exposure to the air and ensures that moisture remains evenly distributed and all seeds achieve the chilling temperature. Water is added if the seeds appear to be drying. Several nurseries now use the stratification/redry method (see the section entitled Pregermination Treatments), or a variation thereof, for improving germination in 12 species (table 10). Not every user succeeds with this technique, possibly due to differences in seedlot dormancy, because—as with routine stratification—the stratification/redry method has a greater effect on more-dormant fir seeds, less-dormant lots not benefiting as well.

Container seedlings of grand and noble firs grow quickly and evenly, so that 10- to 15-cm-tall plants can be obtained about 20 weeks after sowing without using extended photoperiods. By artificially increasing daylengths to 18 hours, similarly sized Pacific silver fir seedlings (figure 21) can be produced, but subalpine fir plants generally set bud early and achieve no more than 6 cm of height (Arnott and Matthews 1982; Gates 1994). When 5-month-old container-grown Fraser fir seedlings were naturally chilled outdoors through mid-November (fluctuating temperatures and natural photoperiods), then returned to a greenhouse, at 15 months they were taller than conventionally grown 3+1 and artificially chilled plants (Seiler and Kreh 1987).

Most containers are made of Styrofoam® blocks with cavities (Sjoberg 1974) or trays of individual plastic cells; cavity and cell volumes vary widely (table 10). In general, smaller containers are used for early sowing if the stock is to be transplanted. Later sowings use bigger containers to produce bigger plants, some of which may be transplanted also (table 10). The principles of container nursery technology are well established (Landis and others 1989, 1990a&b, 1992, 1995), and the concept is now widely accepted.

Herbicides are not used at most container nurseries, whereas bareroot facilities employ a range of chemicals; recommendations for some of these (and for damping-off control) have been published (Imai and others 1955; Roe 1948b; Sanftleben 1989; Sato 1962; Singh and Bhagat

Figure 21—*Abies amabilis*, Pacific silver fir: seeds germinating in a container nursery; wooden toothpicks (left-rear of cavities) were used to mark the progression of germination for a research trial (courtesy of C. L. Leadem).

1989). Pesticide use changes over time, so nursery operators should seek the advice of local extension agents for current recommendations.

In bareroot beds, irrigation control may be combined with wrenching, side pruning, and undercutting to assist in achieving seedling dormancy. Undercutting is often repeated, for example at 2-week intervals beginning in late July/early August for 1+0 bareroot stock. For 2+0 seedlings, a combination of sidepruning, wrenching, and undercutting before new growth gets underway (late February/early March), and at other times during the second growth season, is practiced. In contrast, irrigation control is seldom used to regulate the growth cycle in container nurseries because seedlings of many fir species are drought-intolerant. Some nurseries recommend a moist growing regime, as if growing spruce stock, whereas others may reduce irrigation late in the growing season when target heights are assured. Induction of seedling dormancy and better height control are achieved by the use of black-out control (short photoperiods) in several nurseries. Black-out followed by a 4-week rest period and then 1 to several weeks of 23-hour photoperiods may give a slight increase in height growth. Several cycles of black-out and extended photoperiod can induce multiple flushes in 1+0 seedlings of Pacific silver and subalpine firs to ensure that they reach target height as 2+0 crops. However, the second year reflush (in late March as the greenhouse temperature is raised) is sensitive to molding because the emerging new foliage tends to collect a large drop of water.

Extended photoperiods (16- to 23-hour days) during the accelerated growth phase, beginning 4 weeks after sowing for early-sown stock and continuing almost the entire season, are used in many container facilities. Except where high sunlight is encountered, shading usually is not employed. Greenhouse roofs may be removed during the summer to increase light levels and improve cooling. Shading bareroot seedbeds for 2 months after germination and hoeing or hand pulling to control weeds is advised for European silver fir (Vlase and Iesan 1959), but open beds receiving full light are best for noble fir (Schwenke 1956, 1961).

Lifting dates for 1+0 container stock vary from August for “hot” (that is, immediate) planting or transplanting, to mid-November/December for planting the following spring. Depending on weather conditions (such as snowmelt), lifting from bareroot beds may extend from December through March.

Fir seedlings are shippable as 1+0 plugs (85% of total container production), 2+0 plugs, and P+1 (transplanted from containers to outside beds); in addition, some container transplants may be shipped as P+2, P+3, or even older stock (table 10) depending on the species and customer requirements. Plug stock may be transplanted both spring and fall (August), fall transplantation giving larger seedlings but at the risk of damage during the first winter. Bareroot 2+1 seedlings are reported to perform better when transplanted in the fall.

Shippable heights for container seedlings vary between 13 cm (5 in) for 1+0, and 15 cm (6 in) to 26+ cm (10+ in) in 2+0. Transplants from containers may be between 20 cm (8 in) to 46 cm (18 in), averaging 30 to 36 cm (12 to 14 in). Root caliper generally varies from 2.5 to 3.5 mm for 1+0 stock of all fir species and up to 6 mm for 2+0. Sizes of shippable bareroot stock are not well defined, depending largely on contract requirements.

To overwinter stock in bareroot beds, some nurseries find mulches such as peat moss, pine needles, sawdust, and straw beneficial, especially during the first winter (table 10). Protection of 1+0 seedlings can be accomplished also by sowing seeds between rows of transplants (Anon. 1977). Germination and seedling survival of west Himalayan fir was improved by sowing the seeds 15 to 20 mm ($^1/_2$ to $^3/_4$ in) deep (Singh and Singh 1984), then covering the beds with 10 to 15 cm (4 to 6 in) of humus (Singh and Singh 1990); other aspects of nursery culture of this species have been reviewed (Sharma and others 1987).

Vegetative propagation of Fraser fir, which is easy to graft and air-layer and readily produces roots on stem cuttings, is transforming the production of this species for the all-important (4 to 5 million trees annually) eastern North America Christmas tree market (Blazich and Hinesley 1994, 1995). A genetically improved balsam fir Christmas tree, with increased foliage density and higher frost resistance, has been field tested (Girardin 1997b).

Micropropagation techniques have been applied to selected firs, and regeneration of somatic embryos using seed explants of European silver fir (Gebhart 1990; Hartmann and others 1992), and Pacific silver fir (Kulchetscki and others 1995) have been obtained. However, the problems encountered with Fraser and balsam firs make cloning of these 2 species by micropropagation a future development (Blazich and Hinesley 1994).

Fabaceae—Pea family

Acacia L.

acacia

John K. Francis and Craig D. Whitesell

Dr. Francis retired from the USDA Forest Service's International Institute of Tropical Forestry;
Dr. Whitesell retired from the USDA Forest Service's Pacific Southwest
Forest and Range Experiment Station

Growth habit, occurrence, and use. The acacias include about 1,200 species of deciduous or evergreen trees and shrubs widely distributed in the tropics and warmer temperate areas (Guinet and Vassal 1978). Nearly 300 species are found in Australia and about 70 in the United States. Some 75 species are of known economic value, and about 50 of these are cultivated. Certain species of acacias—Cootamundra wattle (*A. baileyana* F. Muell.), Karoo thorn (*A. karroo* Hayne), golden wattle (*A. pycnantha* Benth.), and others—rank among the most beautiful of all flowering trees, and many have been planted in the warmer regions of the United States (LHBH 1976; Menninger 1962, 1964; Neal 1965). Acacias produce many benefits: collectively they yield lumber, face veneer, furniture wood, fuelwood, and tannin; and such products as gum arabic, resins, medicine, fibers, perfumes, and dyes; some are useful for reclamation of sand dunes and mine spoils, and for shelterbelts, agroforestry hedgerows, and forage; and some serve as a host for the valuable lac insect (ACTI 1980; Prasad and Dhuria 1989; Turnbull 1986). They are valuable not only to the forest but also to pastures and agricultural crops for the nitrogen that is fixed in their root nodules (Hansen and others 1988).

Green wattle, introduced to Hawaii about 1890, has been declared noxious for state land leases (Haselwood and Motter 1966). A fast-growing tree of no local value, it spreads rapidly by seeds and root suckers, crowding out other plants. More than 90 years ago, Maiden (1908) commented on the pestiferous nature of several varieties of this species in Australia. Only acacia species that do not spread by suckering should be selected for planting. Also to be avoided under most circumstances are the thorny acacias—such as sweet acacia and gum arabic tree—which are widely dispersed rangeland pests. These 2 species are know to exert allelopathic effects on plants growing near them (Hampton and Singh 1979; Singh and Lakshminarayana 1992). Reliable seed data are available on 8 species (table 1), all of which grow naturally or are widely planted in the United States or associated territories.

Flowering and fruiting. Acacia flowers are perfect or polygamous; most of them are yellow, some are white. They usually appear in the spring or summer. The fruit is a 2-valved or indehiscent legume (pod) that opens in the late summer. The 1 or more kidney-shaped seeds (figure 1) that develop per fruit are usually released by the splitting of the legume. The seeds contain no endosperm (figure 2). Acacias begin bearing seeds between 2 to 4 years of age (Atchison 1948; Turnbull 1986). There are good seedcrops nearly every year and seed production can be quite high. Individual trees in a mangium plantation were reported to produce 1 kg (2.2 lbs) of seeds (about 100,000 seeds) annually (ACTI 1983). Seeding habits of 8 acacias are listed in table 2.

Collection, cleaning, and storage. Ripe acacia legumes are usually brown. They can be picked from the trees, or fallen legumes and seeds can be collected from underneath the trees. Collections from the ground may include legumes more than a year old. Seeds can be extracted by hammermilling, trampling, or placing the

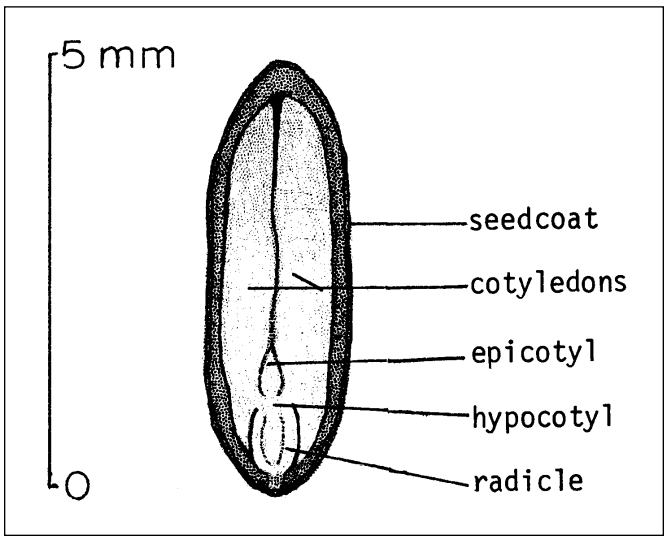
Figure 2—*Acacia melanoxylon*, blackwood: longitudinal section through a seed.



legumes in a cloth bag and flailing it against the floor. Seeds are sometimes separated by feeding the legumes to cattle and collecting the seeds from the manure (NFTA 1992). Blowers and shakers will remove legume fragments and debris satisfactorily for most species. The weights of cleaned seeds for 8 species are listed in table 3 (Goor and Barney 1968; Letourneux 1957; Mangini and Tulstrup 1955; Salazar 1989; Turnbull 1986; Whitesell 1964, 1974). Seeds of blackwood collected and cleaned in Uruguay had a purity of 93% (Whitesell 1974).

Acacia seeds are among the most durable of forest seeds and need not be kept in sealed containers, although it is still advisable to do so. If kept in a cool, dry place, the seeds of most acacia species will germinate after many years of storage. For example, 63% of green wattle seeds germinated after 17 years in storage (Atchinson 1948). Seeds of blackwood, which were air-dried to a constant weight and then stored in sealed containers, retained viability unimpaired for at least 3 months; seeds stored in the open still retained 12% viability after 51 years (Whitesell 1974). Koa seeds lying on the ground are known to have retained their ability to germinate for as long as 25 years (Judd 1920).

Pre-germination treatments. The seeds of most species have hard coats that cause poor germination unless they are first scarified by briefly treating them with sulfuric acid or soaking in hot water (Gunn 1990; Kumar and Purkayastha 1972; Natarajan and Rai 1988; Rana and Nautiyal 1989). Hot water treatment is the most practical. The seeds are placed in hot or boiling water, the source of heat removed, and the seeds allowed to soak for 3 minutes to 24 hours (Clemens and others 1977). Blackwood seeds subjected to 90 to 100 °C water for 3 minutes and than stratified at 4 °C for 4 to 6 weeks germinated at a rate of

Sources: ACTI (1983), Fagg (1992), Goor (1968), Letourneux (1957), Magini and Tulstrup (1955), NFTA (1987a,b), Salazar (1989), Turnbull (1986), Whitesell (1974).

over 98% and grew 25% faster than control seedlings in the first 3 months (De Zwaan 1978). Some species also appear to require 2 to 4 months of "after-ripening" in dry storage before good germination may be obtained (Whitesell 1974). Germination is epigeal.

Germination testing. Prescriptions for official testing for acacias call for clipping, nicking, or filing through the seedcoats and soaking in water for 3 hours, or soaking seeds in concentrated sulfuric acid for 1 hour, then rinsing thoroughly (ISTA 1993). Germination should then be tested on moist blotter paper at alternating 20/30 °C or constant 20 °C for 21 days. Germination tests of acacias can also be made in flats with sand or soil. Results of tests for 8 species of acacias are given in table 4**.**

Nursery and field practice. After proper pretreatment, the small-seeded acacias should be covered with 6 to 12 mm (1/4 to 1/2 in) of soil. Optimum sowing depth for sweet acacia seeds was found to be 2 cm (3/4 in) (Scifres 1974). A 2:1 mixture of soil and sand proved to be a better germination medium for gum arabic tree than other mixtures of soil, sand, and manure (Bahuguna and Pyare 1990). The use of sawdust in germination mixtures was found to inhibit the germination of mangium (Newman 1989b). Sowing is done in spring in the warm temperate zone of the United States mainland and year-round in tropical areas, except during dry periods. Earleaf acacia can be grown from cuttings treated with indole acetic acid (IAA) with a high degree of success (Huang 1989). Seedlings of mangium and earleaf acacia inoculated with Bradyrhizobium and Rhizobium bacterial strains nodulated, but only the Bradyrhizobium strains fixed nitrogen (Galiana and others 1990). Blackwood is preferably outplanted as small 1.25-cm ($^{6}/_{10}$-in) stumps lifted from a seedbed 1 year after planting (Parry 1956) or as transplanted seedling 20 to 25 cm (7.8 to 9.8 in) high (Streets 1962). The best survival for koa planted in Hawaii is obtained with potted seedlings. Mangium is usually planted as potted (plastic nursery bags, or polybags) seedlings but may be planted bareroot (Webb and others 1984). Container seedlings 20 cm (7.8 in) high were recommended for earleaf acacia (Wiersum and Ramlan 1982).

Plantable seedlings of gum arabic tree were produced in India by planting pretreated seeds in May in polybags containing a nursery mixture in full sun and fertilizing them twice (Kumar and Gupta 1990). The use of straw mulch increased the emergence of direct-seeded sweet acacia in old fields (Vora and others 1988).

A

Aceraceae—Maple family

Acer L.

maple

John C. Zasada and Terry F. Strong

Dr. Zasada retired from the USDA Forest Service's North Central Research Station; Mr. Strong is a research silviculturalist at the USDA Forest Service's North Central Research Station, Rhinelander, Wisconsin

Growth habit, occurrence, and use. Maples—members of the genus *Acer*—are deciduous (rarely evergreen) trees; there are 148 species (de Jong 1976; Van Gelderen and others 1994). The majority of species originate in central and eastern Asia, China, and Japan (de Jong 1976; Van Gelderen and others 1994; Vertrees 1987). There are several taxonomic treatments available for the genus. Vertrees (1987) and Van Gelderen and others (1994) should be consulted for a discussion and comparison of the different classifications. Van Gelderen and others (1994) recognize 16 sections, some of which are further divided into 2 to 3 series. The publications by De Jong (1976), Van Gelderen and others (1994), and Vertrees (1987) are filled with interesting information and are wonderful reference books for the genus *Acer*.

Based on the classification of Van Gelderen and others (1994), there are 9 species in the United States and Canada (tables 1 and 2). In addition, there are 8 taxa closely related to sugar maple—these include black maple, Florida maple, bigtooth maple, and whitebark maple—as well as a number of subspecies for others. Van Gelderen and others (1994)

Table 1—*Acer,* maple: nomenclature, occurrence, and uses

Scientific name & synonym(s)	Common name(s)	Occurrence
***A. circinatum* Pursh**	**vine maple,** mountain maple	SW British Columbia to N California E side of Cascades W to Pacific Coast
***A. ginnala* Maxim.**	**Amur maple,** Siberian maple	NE Asia; introduced to N & central Great Plains

Note: *A. rubrum, A. negundo, A. pensylvanicum,* and *A. saccharinum* are dioecious to varying degrees. The other species are monoecious, but male and female flowers may occur in different parts of the tree.

actually classify the 4 species mentioned above as subspecies of sugar maple. Eight of the 16 sections of the genus are represented in North America (Van Gelderen 1994). Additionally, a number of species (table 1) have been introduced for use as ornamentals (Burns and Honkala 1990; Dirr 1990; Dirr and Heuser 1987; Fischer 1990; Van Gelderen and others 1994; Vertrees 1987). The native species range in size from trees that dominate forest canopies to medium to tall understory shrubs or small trees (table 2). Boxelder has been introduced into Alaska, where it survives and reproduces; however, it does dieback periodically under extreme winter temperatures (Viereck 1997).

The native maples all regenerate vegetatively by basal sprouting, but the ability to do so varies among species and with plant age (Burns and Honkala 1990; Fischer 1990). Vine, Rocky Mountain, striped, and mountain maples frequently layer, giving them the potential to develop relatively complex clones of varying size and morphology (Hibbs and Fischer 1979; O'Dea and others 1995; Post 1969; Zasada and others 1992).

Some species of maple are important sources of firewood, pulpwood, high-quality lumber, and veneer (Alden 1995; Burns and Honkala 1990). Four species have been used to produce maple sugar and syrup—sugar, black, red (Jones 1832; USDA FS 1982), and bigleaf maple. Sugar maple is the most important of these species because it has the highest sugar content. In the western United States, bigleaf maple produces adequate quantities of sap, but its sugar content is low compared to the sap of sugar and red maples, and the flow is erratic (Burns and Honkala 1990).

Maples are very important for wildlife, providing browse and cover for a variety of mammals, important sites for cavity-nesting birds, and food for seed-eating mammals and birds (Burns and Honkala 1990). Maples are also important substrates for various lichens and mosses. Their occurrence on mountain slopes makes them useful in the protection of watersheds. Boxelder is an important species for shelterbelt planting.

Many of the maples have ornamental value because of their attractive foliage or interesting crown shape, flowers, or fruit; native and introduced maple varieties with desirable features such as a particular foliage color or attractive bark have been propagated specifically for ornamental use (Dirr 1990). For an interesting discussion of variation in form and leaf morphology in Japanese maples, see the wonderfully written and illustrated book by Vertrees (1987).

Flowering and fruiting. There is substantial variation within the genus in terms of gender of trees. Some species—for example sugar, black, and bigleaf maples—are monoecious with flowers that appear perfect but are functionally either male or female. In the monoecious species, the functionally male and female flowers often occur in different parts of the crown (Burns and Honkala 1990; De Jong 1976).

Other species—for example boxelder and red, striped, silver, and bigtooth maples—are primarily dioecious, but some individual trees are monoecious to varying degrees. In natural populations of red maple, the sex ratio tends to be male-biased. The ratio may vary somewhat between geographic areas within the species range. Sex ratio was also

found to be highly skewed to males in red maples just beginning to flower. Change of sexual expression does occur in these dioecious species but only in a small percentage of the population. Variation in sex expression was related to site conditions in boxelder (Freeman and others 1976), but the relationship of gender to site has not been well-established for all species. There do not appear to be consistent differences in growth rate between males and females. Sakai and Oden (1983) reported that monoecious silver maples were larger than dioecious trees and exhibited a different size distribution pattern. Male boxelder trees showed no growth advantage over females despite the increased amount of carbon needed for fruit production (Willson 1986). However, it was observed that female trees that were previously male had a higher mortality rate than trees that were consistently male or trees that were previously female (Barker and others 1982; De Jong 1976; Hibbs and Fischer 1979; Primack and McCall 1986; Sakai 1990b; Sakai and Oden 1983; Townsend and others 1982).

Flowering and pollination occur in spring and early summer (table 3). Dichogamy (male and female parts in the same flower or different flowers on the same tree mature at different times) is common in maples and has been described for sugar maple and other species (De Jong 1976; Gabriel 1968). Insect and wind pollination both occur, but the relative importance of each differs among species (De Jong 1976; Gabriel 1968; Gabriel and Garrett 1984).

The fruit is composed of 2 fused samaras (a term used interchangeably with seeds here), which eventually separate on shedding, leaving a small, persistent pedicel on the tree. The fused samaras may be roughly identical in appearance or differ in physical size; both samaras may or may not contain viable embryos (Abbott 1974; Greene and Johnson 1992). Parthenocarpic development occurs but differs in the strength of expression among species; this phenomena may explain size differences in paired samaras (De Jong 1976). Samara pairs may occur singly or in clusters of 10 or more. The fruits of the maples vary widely in shape, length of wings, and angle of divergence of the fused samaras (figure 1) (Carl and Snow 1971; De Jong 1976; Greene and

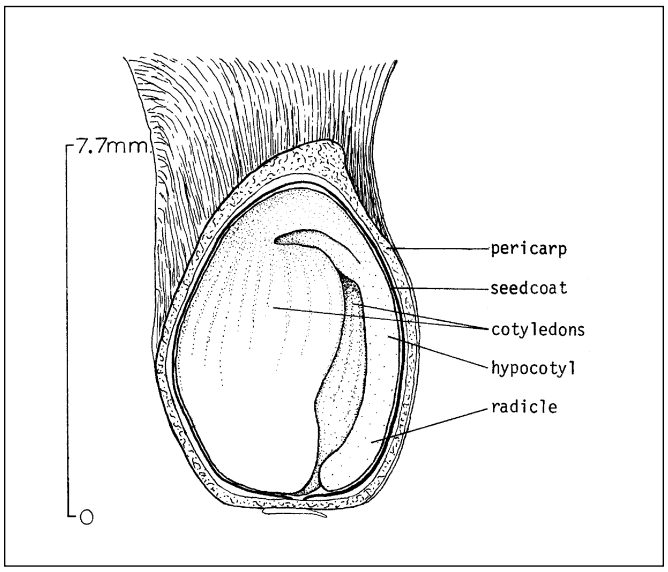
Sources: Dirr (1990), Burns and Honkala (1990), Olson and Gabriel (1974).

Johnson 1992; Sipe and Linnerooth 1995). Each filled samara typically contains a single seed without endosperm (figure 2). However, polyembryony has been observed in sugar and bigleaf maples (Carl and Yawney 1972; Zasada 1996). Maple seeds turn from green or rose to yellowish or reddish brown when ripe; the color of mature samaras can vary among species. Pericarps have a dry, wrinkled appearance when fully mature (Al'benskii and Nikitin 1956; Anon. 1960; Carl and Snow 1971; Harris 1976; Rehder 1940; Sargent 1965; Vertrees 1987).

The embryo with associated seedcoats is contained within the pericarp (figure 2). The surface of the pericarp is usually glabrous (except that of bigleaf maple, which has dense, reddish brown pubescence). The pericarp can be extremely hard (particularly when it has dried out) and difficult to cut open. Development of the samara in black maple has been described in detail by Peck and Lersten (1991). Both the pericarp and seedcoat have been identified as causes of dormancy. The cavity (locule) in which the embryo occurs may have concave or convex walls. There are 2 types of embryo folding: (a) incumbent folding, in which the hypocotyl is against the back of one cotyledon, and (b) accumbent folding, in which the hypocotyl is against the edges of the folded cotyledons. Of the native maples, vine and sugar maples are classified as incumbent and the others (except bigtooth maple, which was not classified) are accumbent. The cotyledons may be green while still in the pericarp (Carl and Yawney 1972; De Jong 1976; Dirr and Heuser 1987; Olson and Gabriel 1974; Peck and Lersten 1991; Vertrees 1987).

Figure 2—*Acer circinatum*, vine maple: longitudinal section of a seed showing bent embryo. On drying the seed shrinks, leaving space between the seedcoat and the pericarp.



During the maturation process, the pericarp and wing change color as seed biochemistry, anatomy, and moisture content change (Carl and Yawney 1966; Peck and Lersten 1991; Vertrees 1987). Both anatomical and physiological studies indicate that green samaras photosynthesize, thus contributing to the carbon balance and growth of the fruit (Bazzaz and others 1979; Peck and Lersten 1991).

The native species can be divided into 2 groups based on timing of seed dispersal (table 3) (Burns and Honkala 1990). Silver and red maples release samaras in late spring and early summer, whereas the other species disperse theirs in late summer and fall. The summer-dispersing species appear to release seeds over a period of about 1 month (Bjorkbom 1979). The fall-dispersing species release samaras in a more protracted manner, usually over 2 months or more (Bjorkbom 1979; Garrett and Graber 1995; Graber and Leak 1992). In sugar maples, seedfall has been observed in every month of the year, but seeds dispersed during the summer months are usually empty (Garrett and Graber 1995). Bigleaf maples in western Oregon and Washington may retain seeds through March.

The mechanics of samara flight following release from the tree have been studied in considerable detail (Green 1980; Greene and Johnson 1990, 1992; Guries and Nordheim 1984; Matlack 1987; McCutchen 1977; Norberg 1973; Peroni 1994; Sipe and Linnerooth 1995). The remainder of this paragraph briefly summarizes the main points of these papers. Maple seeds spin when they fall. There are 2 components to flight—the initial free-fall before spinning and the spinning itself. Depending on species, the initial phase covers a distance of 0.4 to 0.8 m. The terminal velocity attained during spinning varies from 0.8 to 1.3 m/sec and is related to the size of the seeds. Within an individual species, descent rate of individual samaras varied from 0.6 to 1.7 m/sec, depending on seed size and shape. These are the main factors determining how far seeds will fly during primary dispersal under different wind conditions. In relatively strong winds, the free-fall phase may not occur. Wind conditions for early summer dispersal of red and silver maples may differ substantially from those of fall dispersal of seeds because the fully developed canopy can affect within-stand wind conditions. Secondary dispersal after flying may occur over a fairly long distance if seeds fall into moving water or a short distance if seeds are cached by rodents or moved by rainwater or snowmelt.

The maximum dispersal distance for maple seeds is reported to be at least 100 m under open conditions as might occur in a large gap or clearcut (Burns and Honkala 1990). Dispersal distance and patterns of seed rain will vary within

stands due to tree distribution and stand microclimate. For example, seed rain around an individual red maple within a hemlock–hardwood forest dropped from 340 seeds/m^2 (range, 200 to 450/m^2) at the base of the tree to about 50/m^2 (range, 0 to 100/m^2) at 10 m from the base (Ferrari 1993). The large variation in seed rain at each distance indicates that microclimate, location of seeds within the tree crown, and other factors create a relatively heterogeneous pattern of seed deposition.

The weight of maple seeds varies substantially among species (table 4) (Green 1980; Guries and Nordheim 1984). Some examples of within-species variation in seed weight are given below. The average dry weight of sugar maple seeds varied from 0.09 to 0.03 g in a collection from across the eastern United States; the heaviest seeds were from New England area and the lightest from the southern part of the range (Gabriel 1978). In the central Oregon coastal range, the dry weight of bigleaf maple samaras varied from 0.25 to 0.65 g; embryo dry weight accounted for 30 to 40% of total samara weight (Zasada 1996). Sipe and Linnerooth (1995) found that average weight of silver maple seeds varied from 0.10 to 0.16 g. Peroni (1994) found that the dry weight of red maple samaras from 10 North Carolina seed sources varied from 0.013 to 0.016 g. Townsend (1972) reported a 2- to 3-fold variation in red maple fruit weight for seeds collected throughout the species' range.

Seed production can vary significantly among years for a single stand or between stands in a given year in quantity, quality, biomass, and seed weight as a percentage of total litterfall (Bjorkbom 1979; Bjorkbom and others 1979; Burns and Honkala 1990; Chandler 1938; Curtis 1959; Garrett and Graber 1995; Godman and Mattson 1976; Graber and Leak 1992; Grisez 1975; Pregitzer and Burton 1991; Sakai 1990). Although separated geographically and conducted in stands differing in composition, seed production studies over 11 to 12 years in Wisconsin and New Hampshire reported similar results. In Wisconsin, the quantity of sugar maple seedfall in a pure stand of sugar maple varied from 0.1 to 13 million seeds/ha and percentage of filled seeds from 3 to 50% during a 12-year period. Seed production exceeded 2.5 million seeds/ha in 5 of 12 years (Curtis 1959). In a mixed hardwood stand in New Hampshire in which sugar maple made up 69% of the basal area, production varied from 0.2 to 11.9 million seeds/ha; viability was generally related to size of the seed crop and ranged from 0 to 48%. Seed production exceeded 2.5 million seeds/ha in 6 of 11 years (Graber and Leak 1992). In northern Wisconsin, good or better seed years occurred every other year in red maples over a 21-year period and every third year for sugar maples over a 26-year period (Godman and Mattson 1976). In a gradient study of sugar maple stands from southern Michigan to the Upper Peninsula, production of reproductive litter (seeds and flower parts) varied by a factor of 2 and 4 for 2 seed years. The southern stands were more productive one year, whereas the northern stands were more productive the other year (Pregitzer and Burton 1991). Flower and seedcrops in red and sugar maples were related and the former could be used to predict seedcrops (Bjorkbom 1979; Grisez 1975). Fertilization has been shown to alter seed production in maples (Bjorkbom 1979; Chandler 1938). Long and others (1997) reported that liming affected seedcrop size but not periodicity in sugar maple in Allegheny hardwood forests. They also reported that good sugar maple seedcrops occurred the year after a June–July period with a relatively severe drought index (that is, when plants were subjected to a high level of moisture stress).

Table 4—*Acer*, maple: seed yield data

	Cleaned seeds/weight			
	Range		Average

Most studies of seed production are conducted in pure stands or those with a majority of the stems of the desired species. However the availability of seeds when species make up only a minor component of the stand is of interest when estimating seeds available for further colonization. An example of this is provided for a New Hampshire sugar maple–yellow birch–beech stand (Graber and Leak 1992). In this study covering 11 years, the total production of red and striped maples, both minor components, was 0.6 (0% viability) and 0.5 million seeds/ha (40% viability), respectively (Graber and Leak 1992). Seed quality of species present in low number may be limited by pollination. Ferrari (1993) provided information on production and dispersal of seeds from an isolated red maple in a hemlock–hardwood forest in upper Michigan.

Abbott (1974) and Grisez (1975) found that seed production in red and sugar maples was related to dbh. The following listing provides some indication of this relationship for red maple (Abbott 1974):

Tree dbh (cm)	Seeds/tree (thousands)
5	11.9
12	54.3
20	91.4
31	955.8

Reductions in the potential seedcrop can result from biotic and abiotic factors. The strong summer winds and rain associated with thunderstorms in the northern hardwood forests often litter the forest floor with immature seeds and flower parts. Post-zygotic abortion occurring soon after fertilization was the primary cause of empty seeds; in addition, insects affected the quality of more than 10% of seedfall (Graber and Leak 1992). Furuta (1990) found that aphid infestations had an adverse effect on seed production in the Japanese maple *A. palmatum* subsp. *amoenum* (Carr.) H. Hara. Carl and Snow (1971) suggest that heavy aphid infestations affect seed production in sugar maple. Experimental defoliation reduced seed production in striped maples during the year of defoliation but not in the following year (Marquis 1988). Once seeds have been dispersed, seed predation by small mammals can greatly reduce the seed pool before germination (Fried and others 1988; Graber and Leak 1992; Myster and Pickett 1993; Tappeiner and Zasada 1993; Von Althen 1974).

Collection of fruits. Minimum seed-bearing age differs among species. Intervals between mast years vary by species, but some seeds are usually produced every year (table 3) (Burns and Honkala 1990). Seeds may be picked from standing trees or collected by shaking or whipping the trees and collecting the samaras on sheets of canvas or plastic spread on the ground. Samaras may also be collected from trees recently felled in logging operations. Samaras from species such as boxelder and vine, sugar, bigleaf, silver, and Norway maples can be gathered from lawns and pavements and from the surface of water in pools and streams. After collection, leaves and other debris can be removed by hand, screening, or fanning. The following weights were reported (Olson and Gabriel 1974) for samaras:

	Weight/volume of samaras	
Species	kg/hl	lb/bu
vine maple	15.3	11.9
bigleaf maple	5.9	4.6
sugar maple	13.1	10.2

Seed collection for most species occurs when the samaras are fully ripened and the wing and pericarp have turned tan or brown in color (Carl 1982a; Carl and Yawney 1966). However, for maples that are difficult to germinate—such as vine maple, striped maple, and the Japanese maples—it is recommended that seeds be collected before they have dried completely, when the wing has turned brown but the pericarp is still green (Dirr and Heuser 1987; Vertrees 1975, 1987).

Although the seeds of most maples are glabrous, those of bigleaf maple are often densely pubescent. The pubescence may irritate the skin and cause some respiratory tract congestion when airborne. Individuals who might be sensitive to this material should use rubber gloves and a face mask.

Extraction and storage of seeds. Maple seeds are generally not extracted from the fruits (samaras) after collection, except when seeds are used in research on seed dormancy or lots of particularly valuable seeds that are difficult to germinate. De-winging reduces weight—wings account for about 15 to 20% of samara weight (Greene and Johnson 1992; Sipe and Linnerooth 1995)—and bulk for storage. The separation of filled and empty samaras for sugar maple can be accomplished on small lots by floating the samaras in n-pentane (filled seeds sink). This practice had no apparent effect on long-term seed viability (Carl 1976, 1982a; Carl and Yawney 1966). Removal of empty samaras, which can be done readily on a gravity table, improves seed handling, storage, sowing, and control of seedbed density.

After dispersal, maple seeds (with the exception of silver maple seeds and some red maple seeds) lie dormant in

the forest floor for at least 3 to 5 months before germinating (Fried and others 1988; Houle and Payette 1991; Marquis 1975; Sakai 1990b; Tappeiner and Zasada 1993; Wilson and others 1979). Sugar and bigleaf maples usually germinate fully in the spring and summer after dispersal. Seeds of vine, striped, red, and mountain maples and the Japanese maples may lie dormant for 1 to 2 or more growing seasons before germinating (Marquis 1975; Peroni 1995; Sakai 1990b; Tappeiner and Zasada 1993; Vertrees 1987; Wilson and others 1979). In the southern United States, however, one test has indicated that seeds of red maple will maintain viability only for a few months when buried in the litter (Bonner 1996). Thus, with the exception of silver maple and possibly red maple seeds in some areas, seeds of all maples are "stored" naturally in the forest floor for varying lengths of time.

The critical factors in seed storage are temperature and seed moisture content. The moisture content of samaras depends on the stage of seed development and species. Beginning in late August, the moisture content of sugar maple seeds declined from about 160% (dry weight basis) to between 30 to 40% at dispersal (Carl and Snow 1971). The moisture content of sycamore maple seeds decreased from 750% (100 days after flowering) to 125% (200 days after flowering). Moisture content at dispersal for other species has been reported to be 7 to 50% for bigleaf maples (Zasada and others 1990); 80 to 100% for silver maples (Becwar and others 1983; Pukacka 1989), 30 to 35% for Norway maples (Hong and Ellis 1990), and 125 to 130% for sycamore maple (Hong and Ellis 1990).

Moisture content for seed storage defines into 2 groups—seeds that can be stored at relatively low moisture contents (orthodox seeds) and those that must be stored at relatively high moisture contents (recalcitrant seeds). Silver and sycamore maple are clearly recalcitrant (Becwar and others 1982, 1983; Bonner 1996; Dickie and others 1991; Hong and Ellis 1990; Pukacka 1989). Seeds of these species can be stored for about a year (Bonner 1996), and seed moisture content should be maintained at about 80% (dry weight) (Dickie and others 1991; Pukacka 1989).

Orthodox seeds can be stored for longer times and at lower moisture contents than recalcitrant seeds. Viability of sugar maple seeds did not decrease over a 54-month storage period when seeds were stored in sealed containers at a moisture content of 10% (dry weight) and a temperature range of –10 to 7 °C. Similarly, viability did not decrease significantly at 17% moisture content and –10 °C. Seeds stored in open containers at the same temperature lost viability more rapidly than those in sealed containers (Yawney and Carl 1974). Sugar maple seed moisture content can be reduced slowly from 100% (dry weight basis) at the time of collection to 20% with little effect on viability (Carl and Yawney 1966). Under stress conditions (seeds maintained at 52 °C), longevity of Norway maple seeds increased linearly as seed moisture content declined from 23 to 7% (fresh weight); seeds died when dried to moisture contents of 4 and 2.5% (Dickie and others 1991). Viability of bigleaf maple seeds declined from 73 to 62% when they were stored for 1 year in sealed containers at 1 °C and at a moisture content of 16% (dry weight); viability was reduced from 73 to 12% when seeds were stored at –10 °C (Zasada and others 1990).

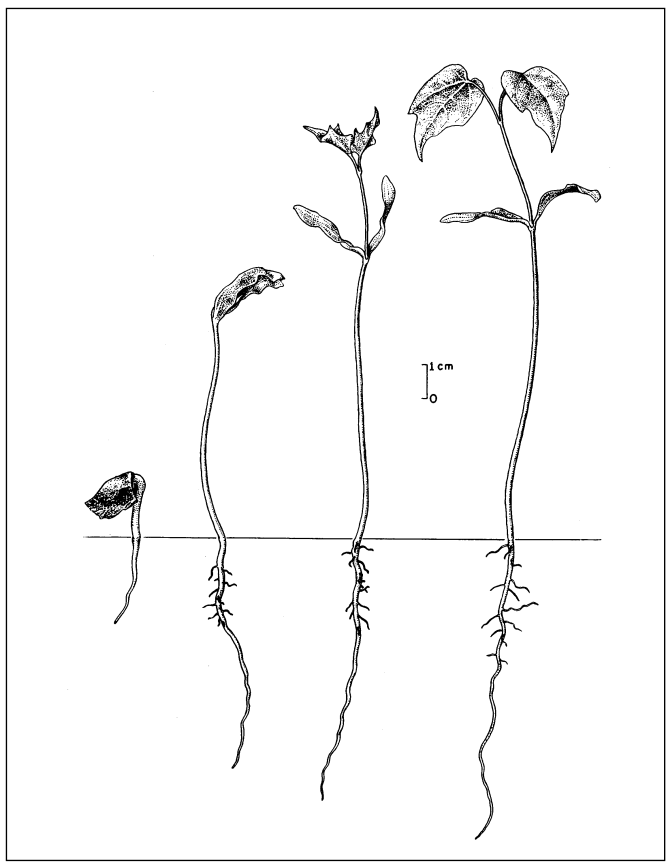
It was previously believed that bigleaf maple seeds could not be stored for even short periods (Olson and Gabriel 1974). Based on recent work by Zasada and coworkers (Zasada 1992, 1996; Zasada and others 1990) in the central Oregon coastal range, an important consideration in storing these seeds seems to be collecting them before autumn rains begin, when the seeds are at their lowest water content. When collected at this time, some seedlots have moisture contents of 7 to 15% (dry weight basis), whereas seeds collected at other times have moisture contents of 25 to 35%. Once autumn rains begin, seeds attached to the tree increase in moisture content and, if they stay on the tree, can germinate under the right conditions. Although more work is required to determine the optimum storage conditions, the limited data suggest that seeds collected at the lowest moisture content behave more like orthodox seeds whereas those collected after autumn rains have increased moisture contents and some characteristics similar to recalcitrant seeds. The pubescent pericarp may play an important role in the moisture content of samaras.

For the other native maples, the fact that they remain viable for 1 year or more in the forest floor or nursery bed suggests that they could be stored for extended periods. Temperatures of 1 to 3 °C and seed moisture contents when dispersed should retain viability for several years.

Pregermination treatment and germination. Germination is epigeal for most species (figure 3), but silver maple and *A. tataricum* L. exhibit hypogeal germination (Burns and Honkala 1990; De Jong 1976; Harris 1976).

Under field conditions, maple germination falls into 3 general types, with red maple exhibiting a combination of 2 types. The first general pattern includes the 2 late spring/early summer seed dispersers (table 3)—red and silver maples—which is the best example. All seeds of this species must germinate before they dry below a moisture content of about 30% (fresh weight) or they die (Pukacka 1989). In red

Figure 3—*Acer platanoides*, Norway maple: seedling development at 1, 3, 7, and 19 days after germination.



maples, the percentage of non-dormant seeds varies with the seed source and among trees in a given geographic area; indeed, this species shares some characteristics with the second type of germination (Abbott 1974; Farmer and Cunningham 1981; Farmer and Goelz 1984; Marquis 1975; Peroni 1995; Wang and Haddon 1978).

The second pattern is typified by sugar and bigleaf maples. Seeds are dispersed in the fall and early winter, stratify during winter and spring, and germinate as soon as temperature thresholds are reached. Both can germinate at constant temperatures just above freezing. In the relatively mild climate of western Oregon, bigleaf maple germinants begin to appear in late January. Bigleaf maple seeds that remain on the tree until late February or March can germinate on the tree (Zasada 1992; Zasada and others 1990). Sugar maple seeds have been observed to germinate under the snow in the spring (Godman and others 1990).

The third pattern has been observed in vine and striped maples (Tappeiner and Zasada 1993; Wilson and others 1979) and may occur in Rocky Mountain and mountain maples. Japanese and paperbark maples and other maples from Asia also exhibit this pattern (Dirr and Heuser 1987; Vertrees 1987). Seeds are dispersed as in the second pattern, but germination occurs over several years. In Massachusetts, less than 1 and 25% of striped maple seeds germinated, respectively, in the first and second years after sowing at the time of natural seedfall (Wilson and others 1979); in coastal Oregon 70 to 80% of vine maple seeds germinated in the second growing season after fall-sowing, with the remainder germinating in the first and third growing seasons (Tappeiner and Zasada 1993). Delayed germination of vine maple has also been observed in nursery beds (Vertrees 1975; Zasada 1996). Vertrees (1987) observed that Japanese maple germinants appeared over a 5-year period after a single sowing.

Methods for testing germination and pre-sowing treatments in nurseries are related in general to the germination patterns described above (tables 5 and 6). Silver maple seeds are not dormant (Pukacka 1989). Some red maple seeds may germinate without stratification, but stratification is necessary for seeds from some populations (Abbott 1974; Farmer and Cunningham 1981; Farmer and Goelz 1984; Peroni 1995; Wang and Haddon 1978). The group represented by sugar and bigleaf maples requires 30 to 90 days of stratification. Germination paper, sand, perlite, and sphagnum moss were all suitable stratification media for sugar maple seeds (Carl and Yawney 1966). Seeds will germinate completely at stratification temperatures. To assure that seeds have been stratified long enough, it may be advisable to wait until the first germinants appear before moving them to warmer temperatures to increase germination rate or sowing in the nursery. The optimum temperature for stratification in general is 0 to 3 °C, but some species will germinate well after stratification at temperatures up to 10 °C (Nikolaeva 1967).

The species that exhibit delayed germination are, under field conditions, exposed to warm and cold conditions and thus a warm period of incubation followed by cold stratification may stimulate germination. These species may also germinate better after a treatment that physically breaks the seed pericarp and testae (tables 5 and 6). Soaking seeds in warm water for 1 to 2 days is often recommended when they are completely dried out and the seedcoat has become very hard (Browse 1990; Dirr and Heuser 1987; Vertrees 1987). Seed testing rules recommend tetrazolium testing and excised embryo tests for the more difficult to germinate species (ISTA 1993).

Note: Even after standard pretreatment, seedlots of *A. griseum* may require 2 to 3 years for complete germination.

* Mechanical rupture of the pericarp may improve germination. This is necessary in *A. negundo* when seeds are very dry; a warm soak as for *A. palmatum* may suffice.

† The benefit of warm incubation prior to stratification is not well-documented. Seeds may go through at least 1 warm/cold cycle before germinating under field conditions.

‡ Water temperature at start of incubation is 40 to 50 °C and allowed to cool gradually. Some recommend a 21 °C incubation period following warm water treatment and a 90-day stratification period.

§ Requirement for stratification is highly variable. In all seedlots, some seeds will germinate without stratification.

Optimum temperatures for germination are not clearly defined. Although most species have their best germination at higher temperatures within the optimum range (table 6), this is not always the case. Studies with red and striped maples have shown that, for seeds from some sources, germination is faster at lower than at higher temperatures (Farmer and Cunningham 1981; Farmer and Goelz 1984; Wilson and others 1979).

Germination occurs on a wide variety of substrates and a full range of light conditions (Burns and Honkala 1990; Fischer 1990; Olson and Gabriel 1974). Under field conditions, germination often occurs in association with leaf litter and other organic substrates on relatively undisturbed seedbeds. Germination paper, sand, perlite, and sphagnum moss support good germination in controlled environments. Red maple was shown to be more sensitive to the acidity of a substrate than sugar maple (Raynal and others 1982).

The morphological and physiological basis for seed dormancy in maples varies among species and includes pericarp-and-seed-coat-imposed dormancy and embryo dormancy (Farmer 1996; Young and Young 1992). The type of dormancy may change as seeds mature. There may be little relationship between dormancy of the mature seed and that of a seed with a fully developed embryo that is not yet mature in a biochemical sense (Thomas and others 1973). Thus for some species it may be best to collect and sow immature seeds as suggested by Vertrees (1975, 1987) for vine and Japanese maples and more generally by Dirr and Heuser (1987) for species with the third germination pattern mentioned above. The type of dormancy imposed by the pericarp and seedcoat (such as that in vine and striped maples) may be released by removing the pericarp and all or part of the testae (figure 2) or by physically breaking the pericarp without actually removing the embryo (table 5) (Wilson and others 1979). Some of the delayed field germination described above is caused by the impenetrability of the seedcoat after embryo dormancy has been released (Dirr and Heuser 1987; Wilson and others 1979).

Nursery practice. Maple seedlings can be produced as container stock or as bareroot seedlings. Bareroot seedlings seem to be the most common when all species of maples are considered. Pre-sowing treatment and sowing time are based on the characteristics of the seeds being sown, convenience, and experience. Cutting tests or x-radiography to determine the presence of embryos are advised for some of the introduced species because poor seed quality is common (Dirr and Heuser 1987; Hutchinson 1971; Vertrees 1987). The information reviewed above on dormancy and germination pattern suggest a number of options for sowing. The least amount of seed handling is required when seeds are sown immediately after collection and allowed to stratify "naturally" before germination. Silver and red maple

Notes: Germination rate indicates the number of seeds germinating in the time specified and total germination all of the seeds germinating in the test. The length of germination tests are not same for all species.

Seeds of *A. griseum* and *A. palmatum* are very difficult to germinate and seed quality is usually poor. Cutting tests are recommended to determine potential viability. Tetrazolium tests could be used to determine if seeds are alive; knowing this one can sow and wait several years for seeds to germinate. Because the delay in germination appears related to a very hard pericarp, removing the pericarp can improve germination.

* Seed sources from central Oregon coastal range. Germination rate greatly increased when seeds moved to 20 to 25 °C when germination in stratification begins (Zasada 1996).

† Germination of seeds with testa removed over radicles. Seeds with testae did not germinate at 23 °C even after 5 months of stratification, whereas seeds kept at 5 °C germinated completely after 6 months (Wilson and others 1979).

‡ Seed sources from Tennessee, total germination at higher temperatures was lower than shown here (Farmer and Cunningham 1981). Similar trends were observed with red maple from Ontario (Farmer and Goelz 1984). U = stratified seeds, S = unstratified seeds.

seeds are sown after collection in late spring, whereas seeds of other maples are sown in the fall when they are mature and the nursery beds mulched (Harris 1976; Olson and Gabriel 1974; Yawney 1968). If stratification requirements are not satisfied with this method or if secondary dormancy is imposed, there may be a substantial number of seeds that do not germinate in the first growing season. Treatment of seeds may result in more uniform germination. For example, Webb (1974) proposed soaking sugar maple seeds for 24 hours before stratification to promote more uniform germination.

For difficult species such as vine and striped maples, which germinate over a several-year period, it has been recommended that seedcoats be either physically broken to promote more uniform germination or soaked in warm water, or given both treatments to reduce the number of seeds not germinating during the first growing season (Browse 1990; Olson and Gabriel 1974; Vertrees 1975, 1987). Vertrees (1987) describes several sowing methods for Japanese maples. The choice of a method depends on degree of maturity, length of time seeds have been stored, and the time desired for sowing. It is also recommended that nurserybeds in which these seeds are sown be maintained for several years so that late-germinating seeds are not destroyed; this is particularly true when seed supplies are limited.

Maple seeds are usually sown 0.6 to 2.5 cm ($^1/_4$ to 1 in) deep, either broadcast or using drills. Seedbed densities from 158 to 1,520/m^2 (15 to 144/ft^2) have been recommended (Carl 1982b; Olson and Gabriel 1974; Vertrees 1987; Yawney 1968). Densities in the range of 158 to 320/m^2 (15 to 30/ft^2) appear most satisfactory for the production of vigorous seedlings. In some instances, seedbeds require treatment with repellents against birds and mice and treatment with fungicides to prevent damping off (Olson and Gabriel 1974; Vertrees 1987). Shade is recommended during the period of seedling establishment (Olson and Gabriel 1974).

Sometimes maple seedlings are large enough to plant as 1+0 stock, but frequently 2+0 or even 2+2 stock is needed to ensure satisfactory results. In general, the larger the planting stock, the better the survival.

Container seedling production is less common than bareroot production, but is used by some producers (Tinus 1978). Container seedlings grown in a greenhouse will usually be larger than those grown outdoors in containers or in a nursery bed (Wood and Hancock 1981). Container production would probably be best achieved with stratified seeds that are just beginning to germinate; this can be easily achieved for species like bigleaf and sugar maples that germinate during stratification. Various sizes and types of containers can be used. One grower uses a container that is 4 cm (1.6 in) in diameter and 15 cm (6 in) deep to produce 30- to 40-cm-high (12- to 16-in-high) stock in 1 growing cycle. These seedlings can be outplanted or transplanted to nursery beds or larger containers for production of larger stock for ornamental purposes.

Artificial sowing in field situations is an alternative to planting seedlings. Successful germination and early growth have been demonstrated for bigleaf maple and vine maple under a variety of forest conditions (Fried and others 1988; Tappeiner and Zasada 1993) and red maple (Brown and others 1983). One drawback to sowing under forested conditions is heavy seed predation by various small mammals.

Desirable maple genotypes can also be propagated vegetatively by rooting stem cuttings and various types of layering (Dirr 1990; Dirr and Heuser 1987; O'Dea and others 1995; Post 1969; Vertrees 1987; Yawney 1984; Yawney and Donnelly 1981, 1982). Methods for rooting and overwintering cuttings before outplanting are available for sugar maple (Yawney and Donnelly 1982) and Japanese maples (Dirr and Heuser 1987; Vertrees 1987).

Fabaceae—Pea family

Adenanthera pavonina L.

peronías

J.A. Vozzo

Dr. Vozzo retired from the USDA Forest Service's Southern Research Station

Other common names. jumbie-bead

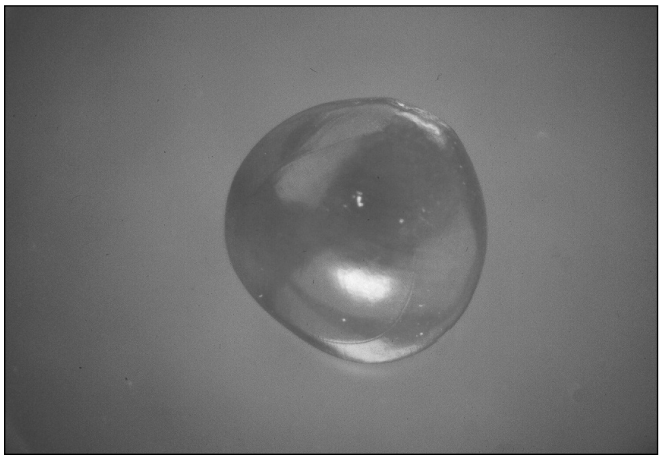
Occurrence and growth habit. Originally from tropical Asia, this genus has spread to parts of tropical Africa and America that have 1,300 to 2,100 mm of rainfall, soil pH 5.0 to 7.5, and nutrient-rich soils with moist but well-drained profiles. It maintains a common abundance relative to other competitors (Francis and Liogier 1991). *Peronıas—Adenanthera pavonina* L.—has large bipinnate leaves, 30 to 60 cm in length, and narrow, erect flower clusters with shiny scarlet seeds. The medium-sized deciduous tree can be 13 m tall and 45 cm in trunk diameter, with brown, smooth bark (Little and Wadsworth 1964). Two other species—*A. microsperma* Teysm. & Binn. and *A. bicolor* Moon —are similar but smaller (Neal 1965). Only a small number of species are included in the genus. Gunn (1984) recognizes only the following 5 species—*A. abrosperma* F. v. *Mueller, A. bicolor, A. intermedia* Merrill, *A. pavonina* L. var. *microsperma,* and *A. pavonina* L. var. *pavonina*. Only *A. pavonina* var. *pavonina* is commonly found in the American tropics, where it has naturalized in Puerto Rico (Francis and Liogier 1991).

Use. The mature trees are good shade trees but not particularly ornamental (Neal 1965), although they are valued for their attractive feathery foliage and bright red seeds in Nyasaland (Streets 1962). Peronıas is also planted as a hedge in Asia, where it is called peacock flower fence (Bailey 1941). Its sapwood is light brown and hard, and its heartwood is hard and red. The heavy, hard wood (specific gravity 0.6 to 0.8) makes durable, strong furniture. It is used locally for poles and firewood as well as a source of red dye (Little and Wadsworth 1964). It gets its Asian common name—red sandalwood—from its use as a substitute for sandalwood. The red seeds are known as "Circassian seeds" and used for bead work. An interesting (but questionable) use is as commercial weights for goldsmiths and silversmiths, who claim each seed weighs a uniform 4 grains (Neal 1965).

Flowering and fruiting. Flowers are borne on racemes (either lateral or terminal) on short stalks 3 mm long and may be pale yellow to white. The small, inconspicuous flowers have a sweet smell and form axillary clusters during the hot, humid season. The fruits mature in the dry season and remain on the tree several months as dark brown legumes (pods) that measure 10 to 20 mm wide and 15 to 20 cm long and are twisted. They readily split and show seeds (figures 1 and 2) attached to the smooth, yellow interior. There are about 3,500 seeds/kg (~1,580/lb) (Bailey 1941; Little and Wadsworth 1964; Neal 1965; Troup 1921). Seeds store well with no special techniques required (Francis 1994).

Germination. Although presoaking is helpful, seeds will germinate with no pre-germination treatment. Several reports do, however, suggest that germination is enhanced by hot-wire scarification (Sandiford 1988) and sulfuric acid exposure (Ahmed and others 1983; Xu and Gu 1985). Francis and Rodriguez (1993) report 86% germination of mechanically scarified seeds held for 6 days on blotter paper at ambient temperature (24 to 30 °C). Germination is epigeal (figure 3).

Figure 1—*Adenanthera pavonia*, peronías: seed.



A

Nursery practice. Although there are no printed reports of nursery practices, seeds readily germinate along moist roadsides. Peronıas will readily propagate from cuttings planted during rainy periods (Troup 1921).

Figure 2—*Adenanthera pavonia,* peronías: cross section of a seed.

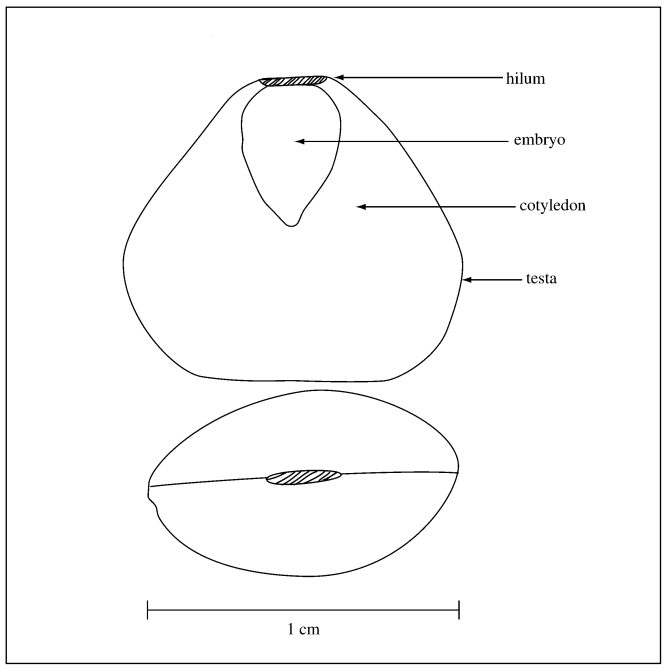


Figure 3—*Adenanthera pavonia*, peronías: seedling, 15 days.

Hippocastanaceae—Horsechestnut family

Aesculus L.

buckeye

Paul O. Rudolf and Jill R. Barbour

Dr. Rudolph (deceased) retired from the USDA Forest Service's North Central Forest Experiment Station; Ms. Barbour is a germination specialist at the USDA Forest Service's National Seed Laboratory Dry Branch, Georgia

Growth habit, occurrence, and use. The buckeyes—which occur in North America, southeastern Europe, and eastern and southeastern Asia—include about 25 species of deciduous trees and shrubs (Rehder 1940). They are cultivated for their dense shade or ornamental flowers, and the wood of some species is occasionally used for lumber and paper pulp. They also provide wildlife habitat. The shoots and seeds of some buckeyes are poisonous to livestock (Bailey 1939). Seven of the 9 species described (table 1) are native to the United States. The horsechestnut was introduced into this country from southern Europe, and the Himalayan horsechestnut occurs naturally in the Himalayas.

Seven of these 8 species are not used much in reforestation, but all are used for environmental forestry planting. Himalayan horsechestnut is used extensively for reforestation and the nuts are fed to sheep and goats (Maithani and others 1990). This is also true of horsechestnut, which has been widely planted as a shade tree in Europe and also in the eastern United States, where it sometimes escapes from cultivation (Bailey 1939). Ohio and yellow buckeyes are sometimes planted in Europe and the eastern United States, the former having been successfully introduced into Minnesota, western Kansas, and eastern Massachusetts. California buckeye is also occasionally planted in Europe and to a somewhat greater extent in the Pacific Coast states. A natural hybrid—*A.* × *bushii Schneid. (A. glabra* × *pavia),* called Arkansas buckeye—occurs in Mississippi and Arkansas (Little 1953). At least 5 other hybrids are known in cultivation (Little 1953).

Flowering and fruiting. Buckeye flowers are irregular in shape and white, red, or pale yellow in color; they are borne in terminal panicles that appear after the leaves. The

Table 1—*Aesculus,* buckeye: nomenclature and occurrence

Scientific name & synonym(s)	Common name(s)	Occurrence
***A. californica* (Spach) Nutt.** *A. octandra* Marsh	**California buckeye**	Dry gravelly soils; lower slopes of coastal range & Sierra Nevada in California

Source: Rudolph (1974).

flower spikes are 15 to 20 cm tall by 5 to 7.5 cm wide (Browse and Leiser 1982). The flowers are polygamo-monoecious, bearing both bisexual and male flowers. Only those flowers near the base of the branches of the cluster are perfect and fertile; the others are staminate (Bailey 1939; Rehder 1940).

The fruit is a somewhat spiny or smooth, leathery, round or pear-shaped capsule with 3 cells (figure 1), each of which may bear a single seed. Sometimes only 1 cell develops and the remnants of the abortive cells and seeds are plainly visible at maturity. When only 1 cell develops, the large seed is round to flat in shape. The ripe seeds (figure 1) are dark chocolate to chestnut brown in color, with a smooth and shining surface and have a large, light-colored hilum resembling the pupil of an eye. They contain no endosperm, the cotyledons being very thick and fleshy (figure 2). When ripe in the fall, the capsules split and release the seeds. The times of flowering and fruiting for 7 species of buckeyes are given in table 2. Other fruiting characteristics are listed in table 3.

Normally, horsechestnut and Ohio buckeye will set viable seeds almost every year. Bottlebrush buckeye rarely sets seed except in very hot, dry, late summers (Browse 1982).

Collection of fruits; extraction and storage of seeds. The fruits may be collected by picking or shaking them from the trees as soon as the capsules turn yellowish and begin to split open or by gathering them from the ground soon after they have fallen. The fruits may be dried for a short time at room temperature to free the seeds from any parts of the capsules that may still adhere to them, but great care must be taken not to dry them too long. When this occurs, the seedcoats become dull and wrinkled and the seeds lose their viability. There is ample evidence that buckeyes are recalcitrant in nature (Bonner 1969; Pence 1992; Tompsett and Pritchard 1993). Moisture contents at the time of shedding have been reported as 49% for horsechestnut (Suszka 1966) and 56% for red buckeye (Bonner 1969). The seeds of this genus should be sown at once in the fall or stratified promptly for spring-sowing.

Figure 1—*Aesculus,* buckeye: capsules and seeds of *A. glabra*, Ohio buckeye (**topleft**); *A. pavia*, red buckeye (**top right**); *A.hippocastanum*, painted buckeye (**middle left**); *A. sylvatica*, horsechesnut (**middle right**); *A. california*, yellow buckeye (bottom).

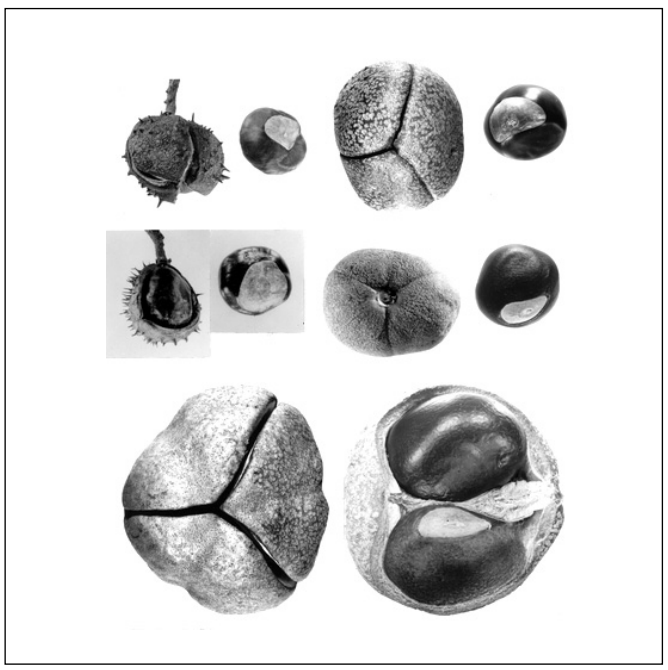

Figure 2—*Aesculus glabra*, Ohio buckeye: longitudinal section through a seed.

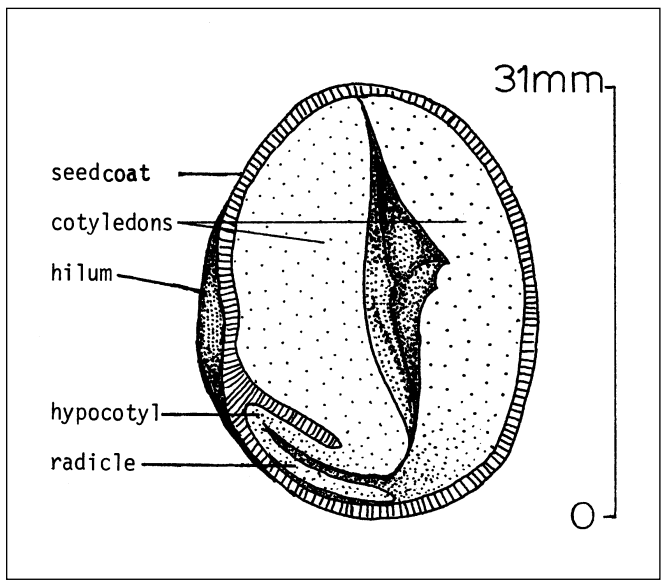

Buckeye seeds must be stored with moisture contents close to what they are shed with, but even then their viability cannot be maintained very long. Initial viability of fresh seeds of horsechestnut was maintained for 6 months when they were stored in polyethylene bags at 1 °C. This storage condition is the same as cold moist stratification because of the high moisture content of fresh seeds (Suszka 1966). When seeds were stored at –1 °C in sealed packages without added moisture for 13 months, germination dropped from 85% to 60%; after 15 months, however, germination was only 25% (Widmoyer and Moore 1968). Data on number of cleaned seeds per weight are listed for 7 species in table 4. Purity and soundness usually are close to 100% (Rudolf 1974). Nonviable seeds will float in water and can be discarded (Browse 1982).

Pregermination treatments. Seeds of Ohio, yellow, and painted buckeyes and horsechestnut require stratification or prechilling to induce prompt germination (Rudolf 1974). Stratification has been done in moist sand or sand-peat mix-

Sources: Browse (1982), NBV (1946), Rudolf (1974).
* This value varies not only with seed size but also with moisture content, which is initially rather high in *Aesculus* seeds. One sample of *A. flava* seeds showed a moisture content of 95% (dry-weight basis) after it had been kept at room temperature for 36 days after collection.

tures at 5 °C for about 120 days, and by storage in sealed containers at 1 °C for 100 days or longer (May 1963; Rudolf 1974; Suszka 1966). In contrast, fresh seeds of California and red buckeyes can germinate satisfactorily without pretreatment (Rudolf 1974). Red buckeye seeds requires no stratification even though germination is delayed until spring. Cool winter temperatures suppress the germination, thus preventing autumn emergence (Browse 1982).

Bottlebrush buckeye seeds exhibit a type of epicotyl dormancy in so far as the root system continues to develop, but the shoot becomes dormant after it has emerged (Browse 1982). Further development of the shoot system does not occur until the spring (Browse 1982).

Presowing treatments of horsechestnut seeds increased germination 3 to 15% over the control. The treatments yielded the following germination rates: exposure to 50 °C, 92% germination; soaking with slight drying, 92%; exposure to 35 °C, 87%; exposure to high pressure, 87%; soaking in cobalt nitrate, 85%; soaking in chlorocholine chloride, 80%; and control, 77% (Tarabrin and Teteneva 1980).

Stratification benefits Himalayan horsechestnut. There was a 5-fold increase in germination at 30 °C from 12% for the control to 60% following stratification for 15 days (Maithani and others 1990). Prolonging the stratification period to 30 days resulted in 79% germination (Maithani and others 1990).

Germination tests. Stratified buckeye seeds have been germinated in sand or on wet paper at diurnally alternating temperatures of 30 and 20 °C. Results are summarized in table 5. Official testing rules for red buckeye (AOSA 1998) call for germinating unstratified seeds for 28 days on the top of wet paper at the 30/20 °C regime. A recommendation for germinating seeds of horsechestnut without stratification is to soak them in water for 48 hours and cut off one-third of the seed at the scar end without removing the seedcoat. The portion with the scar should then be germinated in sand flats for for 21 days at the same 30/20 °C regime (ISTA 1993).

Nursery practice. Under natural conditions, seeds of most buckeye species germinate in the early spring. California buckeye, however, germinates just after winter rains have begun, usually in November. In the nursery, buckeye seeds usually are sown in the fall as soon after collection as possible to prevent drying and loss of viability. If desired, however, the seeds of species having embryo dormancy can be stratified or placed in cold, moist storage promptly and then sown in the spring (Rudolf 1974; Suszka 1966). Himalayan horsechestnut seeds without any treatment showed 80% germination after 133 days (Maithini and others 1990). Seeds sown after 30 days of cold stratification showed 68% germination in 78 days (Maithini and others 1990). The seeds should be sown about 5 cm (2 in) apart in rows 15 cm (6 in) apart (NBV 1946) and covered with 2.5 to 5 cm (1 to 2 in) of soil. The seeds should be sown with the scar underneath so that the radicle emerges in the correct position to produce a normal seedling (Browse and Leiser 1982). If the seeds are variable in size, it is better to grade them so that small sizes are discarded or sown separately, as these rarely make large 1-year seedlings (Browse 1982).

Germination is hypogeal (figure 3) and usually is complete 3 to 4 weeks after spring sowing (NBV 1946). A tree percentage of 70 has been obtained (Rudolf 1974). The beds should not be over-watered because the seeds rot rather easily (Rudolf 1974). Ordinarily, 1+0 stock is large enough for field planting.

Table 5—*Aesculus,* buckeye: cold stratification periods, germination test conditions, and results

Species	Cold stratification* (days)	Daily light (hrs)	Germination test conditions				Germinative energy		Germinative (%)
			Medium	Temp (°C) Day	Temp (°C) Night	Days	Amount (%)	Time (days)

A

Simaroubaceae—Quassia family

Ailanthus altissima (P. Mill.) Swingle

ailanthus

John C. Zasada and Silas P. Little

Dr. Zasada retired from the USDA Forest Service's North Central Research Station; Dr. Silas Little (deceased) retired from the USDA Forest Service's Northeastern Forest Experiment Station

Synonyms. *Toxicodendron altissimum* Mill., *Ailanthus glandulosa* Desf.

Other common names. Tree-of-heaven ailanthus, tree-of-heaven, copaltree.

Growth habit, occurrence, and use. Native to China, this 12.5- to 25-m-tall deciduous tree is described as "the most adaptable and pollution tolerant tree available" (Dirr 1990). Although it was originally considered a desirable ornamental tree, its desirability and usefulness are now questioned (Dirr 1990; Feret 1985) and many consider it an "invasive alien pest." It is sometimes planted for shelterbelts, for game food and cover, and, rarely, for timber as in New Zealand. Ailanthus was introduced into cultivation in England in 1751 (Feret 1985; Illick and Brouse 1926) and brought to America in 1784 (Little 1974). It has become naturalized in many parts of the United States—from Massachusetts to southern Ontario, Iowa, and Kansas, and south to Texas and Florida, as well as from the southern Rocky Mountains to the Pacific Coast (Feret and Bryant1974; Feret and others 1974; Little 1979). In some localities, ailanthus is so well-established that it appears to be a part of the native flora. Wood properties are summarized by Alden (1995) and silvics by Miller (1990). There are a number of other *Ailanthus* species grown in other parts of the world for various purposes (Alam and Anis 1987; Beniwal and Singh 1990; Feret 1985; Rai 1985; Ramikrishnan and others 1990).

Ailanthus is an aggressive, intolerant pioneer species with rapid juvenile growth of 1 to 1.5 m/year. It invades severely disturbed sites, harsh environments, and poor soils. It suckers from roots and can form dense stands, making it difficult for native species to colonize. Stands may be maintained by root suckering but it does not regenerate from seed under its own canopy (Bordeau and Laverick 1958; Miller 1990). One or more potent inhibitors of seed germination and seedling growth are produced in the bark, leaves, and seeds (Heisey 1990; Lawrence and others 1991). Heisey (1990) concluded that allelochemicals in ailanthus may have potential as naturally produced herbicides.

Flowering and Fruiting. The tree is mainly dioecious, with some monoecious individuals (Dirr 1990; Miller 1990). Flowers are usually unisexual, but perfect flowers do occur in some individuals (Feret 1973). Flowering has been observed in seedlings 6 weeks after germination (Feret 1973).

Commercial "seed" consists of the 1-celled, 1-seeded, oblong, thin, spirally twisted samaras. These samaras, with seeds near the middle, are 8 to 12 mm wide and 33 to 48 mm long (Feret and others 1974) and light reddish brown in color (figure 1). Flowering occurs from mid-April to July (Little 1974). Seeds ripen in large panicles in September to October of the same season and are dispersed from October to the following spring (Illick and Brouse 1926). Ailanthus is a prolific seeder: 15- to 20-year-old trees bear considerable quantities. Seeds have no endosperm (figure 2).

Collection of fruits; extraction and storage of seeds. Ailanthus seeds have been found in soil seedbanks in stands with no individuals present in the overstory. This suggests that seeds may be stored in the soil for some period of time after parent trees have disappeared from a site (Dobberpuhl 1980).

Figure 1—*Ailanthus altissima*, ailanthus: samara.

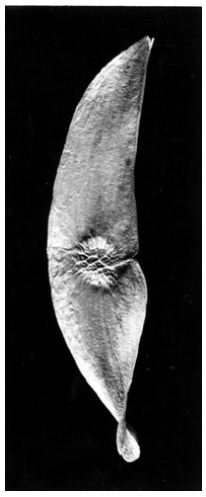

Figure 2—*Ailanthus altissima*, ailanthus: longitudinal section through a seed.

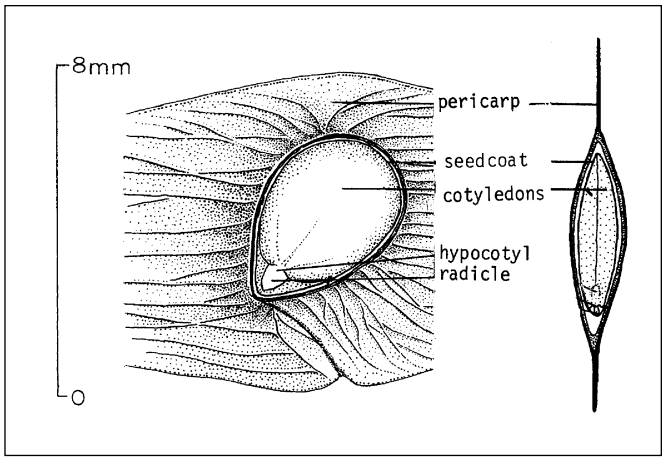

Ailanthus fruits are picked from standing trees by hand or flailed or stripped onto canvas at any time during the late fall and early winter. After collection, the fruits should be spread out to dry (to lose superficial moisture). They may then be run through a macerator and fanned to remove impurities, or they may be flailed or trampled in a burlap bag and run through a fanning mill (Little 1974).

Forty-five kilograms (100 lb) of fruit yields 13.6 to 40.9 kg (30 to 90 lb) of cleaned seeds (Little 1974). Seeds with wings attached weigh from 22,700 to 75,500/kg (10,300 to 34,300/lb), with an average of about 38,700/kg (17,500/lb) (Feret and others 1974; Little 1974). Cleaned seeds (without wings) weigh from 29,000 to 43,000/kg (13,200 to 19,500) with a mean of 37,200/kg (16,900/lb) (Al'benskii and Nikitin 1956). Germination capacity of seedlots is normally in the 75 to 96% range (Al'benskii and Nikitin 1956; Graves 1990; Little 1974).

Seeds should be stored with low moisture contents at temperatures of 1 to 3 °C, and in sealed containers (Heit 1967). However, seedlots stored in sacks for over a year at temperatures ranging from –6 to 40 °C still had germination of 75% (Little 1974). In Russia, seeds are stored in boxes at 0 to 4 °C, layers about 2.5 cm (about 1 in) thick being separated and topped by layers of dry sand half as thick (Shumiliana 1949). Although sensitive to moisture and fluctuating temperatures, seeds can be successfully stored for long periods in sealed containers at low moisture contents in a refrigerator (Heit 1967).

Germination. Stratification appears to improve germination in most cases, although varying amounts of germination occur in unstratified seeds (Bordeau and Laverick 1958; Dirr 1990; Graves 1990; Little 1974; Shumilina 1949). Graves (1990) found that although total germination was not affected by stratification, germination rate was greater in stratified seeds. Thirty to 60 days of stratification at 1 to 5 °C is usually recommended (Dirr 1990; Little 1974; Shumilina 1949); however, Graves reported 70, 77, and 96% germination after stratification at 5 °C for 0, 4, and 12 days, respectively. Seed testing rules recommend temperatures of 20 to 30 °C with no stratification (pericarp removal may increase germination rate); first evaluation at 7 days and a test duration of 21 days (ISTA 1993). Ailanthus seed germination was little affected by salt concentrations representative of roadside environments where salt is applied in winter; seeds of native oaks and birch were more sensitive (Bicknell and Smith 1975). Other *Ailanthus* spp. are more difficult to germinate than tree-of-heaven (Ramakrishnan and others 1990).

Nursery practice. Seeds can be sown immediately after collection if conditions permit or they can be stratified and sown in the spring with drills. Broadcast seeds should be covered with 1.3 cm ($^1/_2$ in) of soil. Fifteen to 25% of the viable seeds sown produce usable 1+0 seedlings (Little 1974). Thus, 0.45 kg (1 lb) of seeds may yield 3,000 usable plants (Van Dersal 1938). Greenhouse studies indicate that ailanthus could be grown in containers (Feret and Bryant 1974; Feret and others 1974; Heninger and White 1974). Maximum seedling growth occurs at a soil temperature of 19 °C (Heninger and White 1974). Ailanthus can be produced vegetatively from root cuttings (Dirr and Heuser 1987).

Fabaceae—Pea family

Albizia Durazz.

albizia

John A. Parrotta, Herbert L. Wick, and Gerald A. Walters

Dr. Parrotta is a research program leader at the USDA Forest Service's Research and Development National Office, Arlington, Virginia; Drs. Wick and Walters retired from the USDA Forest Service's Pacific Southwest Forest and Range Experiment Station

Growth habit, occurrence, and use. The albizias include about 50 species of medium- to large-sized deciduous trees and climbers distributed throughout tropical and subtropical Asia, Africa, and Australia (Rock 1920). Many species have been introduced into the United States, and the 4 listed in table 1 are important. Silktree was introduced into the southern United States in 1745 and planted widely for ornamental purposes. Currently it is considered invasive. The species is also valuable for wildlife cover and browse (Wick and Walters 1974). Siris is planted in Hawaii for shade and ornament (Neal 1965) and was introduced into Puerto Rico during the Spanish colonial era. Its yellowish brown heartwood is moderately hard, coarse-grained, strong, and fairly durable and is used for a variety of purposes, including furniture-making, in its native Asian range (Parrotta 1987a). White siris is planted in Hawaii (Neal 1965) and was introduced into Puerto Rico in 1927 as an ornamental and fuelwood species. In Puerto Rico, white siris has become naturalized and is now common on severely disturbed sites and old fields. The light brown heartwood is moderately hard, straight-grained, strong, and durable and is used in the species' native range as an all-purpose timber (Parrotta 1987b). Raintree (formerly known as *Pithecellobium saman)* is valued for timber and wildlife habitat and as an ornamental. The wood is used for paneling, furniture, and specialty items. The tree was introduced into Florida and Hawaii (Little and Wadsworth 1964; Magini and Tulstrup 1955) and is now considered invasive.

Flowering and fruiting. The flowering and seeding dates of *Albizia* species are listed in table 2. Flowers of siris are greenish-yellow to whitish, those of silktree are light pink, and those of white siris are whitish (Little and Wadsworth 1964; Wick and Walters 1974). All species bear their flowers in clusters near the tips of branches. The fruits of all species are flat, linear, 6- to 12-seeded legumes (pods) (figure 1) and ripen within a year after the trees flower (Little and Wadsworth 1964; Rock 1920; Wick and Walters 1974). Silktree legumes are about 15 cm long; siris and white siris legumes are up to 20 cm long. When mature, the legumes of tall albizia are reddish brown, whereas those of

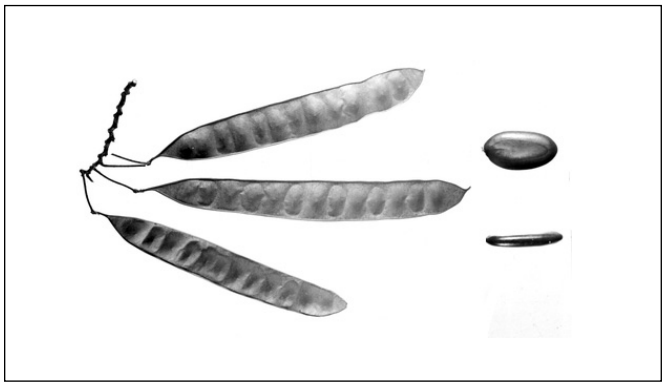
Figure 1—*Albizia julibrissin*, silktree: legumes and seeds.



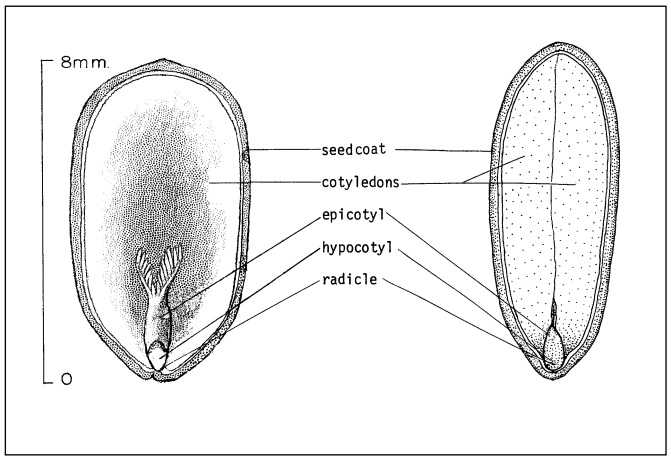
the other 2 species are straw-colored. The light brown seeds of all species are released from the dehiscent legumes from legumes that are still attached to the tree or from fallen legumes, which may travel considerable distances in high winds (Parrotta 1987a; Rock 1920; Wick and Walters 1974).

Collection, extraction, and storage. Collection of albizia seeds should begin as soon as the legumes mature. Siris seeds are particularly prone to predation by insect larvae, especially those of bruchid beetles (Parrotta 1987a). The legumes may be picked or shaken from the trees and collected on canvas. Seeds are readily extracted from the legumes by flailing or threshing. A seed cleaner or a fanning mill can be used to separate seeds from the remaining debris. Silktrees average about 24,000 clean seeds/kg (11,000/lb) (Wick and Walters 1974); siris, 7,000 to 11,000 seeds/kg (3,000 to 5,000/lb) (Parrotta 1987a); white siris, 17,000 to 25,000 seeds/kg (8,000 to 11,000/lb) (Francis and Rodrıguez 1993; Parrotta 1987b); and raintrees, 4,400 to 7,720 seeds/kg (2,000 to 3,500/lb) (Walters and others 1974). Albizia seeds are orthodox in nature. Air-dried seeds of siris and white siris generally retain high germination rates for at least 1 to 2 years in storage at room temperature or under refrigeration (Parrotta 1987a). No definitive information is available on how long silktree seeds can be stored, although a small sample of seeds kept in loosely corked bottles in a laboratory for almost 5 years had a germination rate of almost 90% (Wick and Walters 1974).

Germination. Germination of albizia seeds is slow because of their impermeable seedcoats (figure 2). Dormancy can be broken either by mechanical scarification, sulfuric acid scarification, or soaking in water (Francis and Rodrıguez 1993; Parrotta 1987a). The easiest, safest, and usually most effective means for breaking dormancy in siris and white siris is immersion of the seeds in boiling water for 1 to 3 minutes, soaking them in water at room temperature for 24 hours, then sowing the seeds immediately (Parrotta 1987a). Germination rates for scarified seeds range from 50 to 99% and germination begins within 2 to 4 days after sowing (Francis and Rodrıguez 1993; Parrotta 1987a&b). Raintree seeds will often germinate without pretreatment, but a 10-minute soak in sulfuric acid will increase the percentage and rate of germination (Walters and others 1974). Germination as high as 92% has been reported for this species (Neal 1965; Rock 1920). Germination in albizias is epigeal (figure 3).

Nursery practice. Germination and seedling growth of albizia is favored by shallow sowing, up to 2.5 cm (1 in)

Figure 2—*Albizia julibrissin*, silktree: longitudinal section through a seed.



depth, in loose, moist soil under full sun (figure 3). Seedling growth is rapid; siris and white siris seedlings reach plantable size (20 cm in height) usually within 2 to 3 months after sowing under nursery conditions in Puerto Rico (Parrotta 1987a). Raintree seeds are sown in March in Hawaii for outplanting as $^{3}/_{4} + 0$ stock the following winter. A sowing depth of 2.5 cm (1 in) and density of 160 to 215 seedlings/m^2 (15 to 20/ft^2) are recommended, with 75 to 85% shading of the beds (Walters and others 1974). Plantations can be established by direct sowing (for siris and white siris) or by using container seedlings (for all species). Stumped seedlings or stem, branch, and root cuttings can also be used to propagate siris and white siris (Parrotta 1987a).

Euphorbiaceae—Spurge family

Aleurites moluccana (L.) Willd.

Indian-walnut

Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Synonyms. *Aleurites javanica* Gand., *A. triloba* Forster & Forster f.

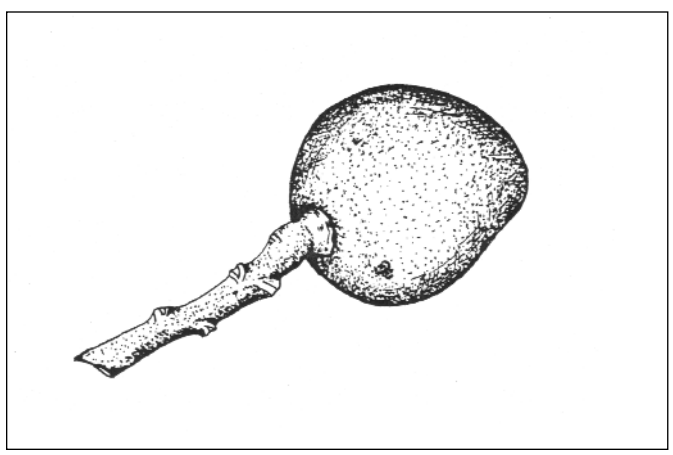
Other common names. Kukui, candlenut-tree, *tutui, nuez, nuez de India, lumbang, sakan, lama*.

Growth habit, occurrence, and uses. Indian-walnut is well-known as kukui, the state tree of Hawaii. On the Islands, it is a large, evergreen, spreading tree of moist lowland mountains up to an elevation of 671 m. It may grow to a height of 24 m and a bole diameter of 0.9 m (Little and Skolmen 1989). This species is a probable native of Malaysia, as its name suggests that it came from the Moluccan Islands. It can be found on islands throughout the Pacific region, and it has been introduced to other tropical areas, including Puerto Rico and the Virgin Islands (Little and Skolmen 1989).

The tree was introduced by early Hawaiians for its oily, nutlike seeds. Oil pressed from these seeds was once widely used for fuel in stone lamps, for paints and varnishes, and for medicines. In past years, as much as 37,850 liters (10,000 gal) of the oil was exported annually, but the industry has become unprofitable in Hawaii (Little and Skolmen 1989). The trees are still grown for production of the oil in the Philippines and other parts of the Pacific region (Eakle and Garcia 1977). In addition, the leftover oil cake can be used as fertilizer or cattle food. Local uses also included folk medicine and dyes, and a waterproofing substance can be made from the tree's sap and green fruits (Little and Skolmen 1989). Indian-walnuts have been utilized in shade, ornamental, and protection plantings in Hawaii (Little and Skolmen 1989).

Flowering and fruiting. Indian-walnut's flowers are borne in terminal cymes 9 to 15 cm long. The white individual flowers are about 10 mm long. Flowering is monoecious, with many more male flowers than female on the cymes (Little and Skolmen 1989). Fruits are round to ellipsoidal in shape, 5 to 6 cm long, and 5 to 7 cm wide, with fleshy to leathery husks (figure 1). There are 1 or 2 elliptical seeds per fruit. The seeds are 2.5 to 3.5 cm long, and the shells are hard, rough, and black (Dayan and Reaviles 1995; Little and Skolmen 1989). Flowering and fruiting occurs intermittently in Puerto Rico (Little and others 1974).

Figure 1—*Aleurites moluccana*, Indian-walnut: fruit (drawing from Little and others 1974).



Collection, extraction, and storage. Fruits may be collected from the ground after shedding or picked from the trees. In the Philippines, it is common practice to let the fruits decay for 3 to 5 days after collection and then remove the husks by hand under running water. The seeds are then dried in the sun for 3 or 4 days to a low moisture content; there are about 116/kg (53/lb) (Dayan and Reaviles 1995). Empty or deteriorated seeds can be removed by water flotation (Tamesis 1958; Eakle and Garcia 1977). There are no long-term storage data on Indian-walnut, but the seeds are apparently orthodox in storage characteristics. Dayan and Reaviles (1995) reported that seeds dried to 10 to 12% moisture can be successfully stored at room temperature for 7 months.

Germination. Indian-walnut germinates slowly, apparently due to dormancy imposed by the hard seedcoat (Eakle and Garcia 1977). Several pretreatments have been

used to speed germination. In early tests in the Philippines, seeds were heated by burning grass over a layer of seeds or by planting imbibed seeds in drums of moist soil exposed to the sun (Tabat 1925; Tamesis 1958). The heat and moisture were thought to cause the seedcoats to crack. Sometimes, very good germination could be obtained by planting untreated nuts and keeping the seedbeds very moist; this method produced 86% germination 5 months after planting (Tabat 1925). Eakle and Garcia (1977) tested numerous acid scarification treatments with sulfuric, nitric, and hydrochloric acids, but none were successful. Dayan and Reaviles (1995) recommend manual cracking of the nuts, followed by an overnight soak in tap water.

Nursery practice. Seedborne fungi may be a problem for Indian-walnut, so treatment with a good fungicide prior to planting is recommended. For container production, a 1:1:1 ratio of sand, top soil, and dried organic matter should be used as a medium (Dayan and Reavile 1995). Direct seeding has also been successful in the Philippines. Seeds are allowed to start germination in a drum of moist soil heated by the sun, then removed for direct planting in the field when they start to crack open (Tamesis 1958).

Betulaceae—Birch family

Alnus P. Mill.

alder

Constance A. Harrington, Leslie Chandler Brodie, Dean S. DeBell, and C. S. Schopmeyer

Dr. Harrington and Ms. Brodie are foresters on the silviculture research team at the USDA Forest Service's Pacific Northwest Research Station, Olympia, Washington; Dr. DeBell retired from the USDA Forest Service's Pacific Northwest Research Station; Dr. Schopmeyer (deceased) was the technical coordinator of the previous manual

Growth habit and occurrence. Alder—the genus *Alnus*—includes about 30 species of deciduous trees and shrubs occurring in North America, Europe, and Asia and in the Andes Mountains of Peru and Bolivia. Most alders are tolerant of moist sites and thus are commonly found along streams, rivers, and lakes and on poorly drained soils; in addition, some species occur on steep slopes and at high elevations. The principal species found in North America are listed in table 1. Many changes in the taxonomy of alder have been made over the years; in this summary, species are referred to by their currently accepted names although in many cases the information was published originally under the synonyms (and alternative common names) listed in table 1.

Although some cultivated European alder is used commercially in the eastern United States, red alder is the largest native species. It is also the most extensively utilized of the native species. Management interest and research activity on red alders have increased dramatically during the past 2 decades, and the resulting information accounts for the majority of new information added to the previous summary on alder seeds prepared by Schopmeyer (1974).

Alders are pioneer species favored by high light levels and exposed mineral soils; in addition, their ability to fix atmospheric nitrogen facilitates establishment on geologically young or disturbed sites with low levels of soil nitrogen (Harrington and others 1994). Dense stands of naturally regenerated red alders established quickly on mudflows associated with the eruption of Mount St. Helens. The trees grew rapidly and soon overtopped other pioneer species such as poplars in the nitrogen-deficient soils (Heilman 1990). Sitka alder plays a similar role in primary succession following deglaciation in Alaska.

Use. Seedlings have been planted successfully for reforestation of coal mining spoil banks (Lowry and others 1962). Soil fertility is improved through fixation of atmospheric nitrogen by microorganisms in the root nodules (Tarrant and Trappe 1971). Alders also have been planted for wildlife food and cover (Liscinsky 1965) and for ornamental use. European and red alders have been considered for use in biomass plantings for energy (Gillespie and Pope 1994) and are considered excellent firewood. In recent years, harvest and utilization of red alder has expanded greatly on the Pacific Coast of North America, where the species is used for paper products, pallets, plywood, paneling, furniture, veneer, and cabinetry (Harrington 1984; Plank and Willits 1994). Red alder is also used as a fuel for smoking or curing salmon and other seafood and its bark is used to make a red or orange dye (Pojar and MacKinnon 1994). The soft, even-grained wood lacks odor or taste and has been traditionally been used by native peoples, and more recently other woodworkers, to make bowls, eating utensils, and other items (Pojar and MacKinnon 1994). In addition, alder exports have grown from almost nothing in 1990 to more than 153,000 m^3 (or 65 million board feet) of lumber annually (Tarrant and others 1994). Several options exist for managing alder in both mixed (Miller and Murray 1978) and pure stands (Tarrant and others 1983), and a summary of management principles and alternative strategies are available for red alder (Hibbs and DeBell 1994).

Geographic races and hybrids. Considerable geographic variation exists among populations of red (Ager and others 1993; Ager and Stettler 1994; Dang and others 1994; Hamann and others 1988; Lester and DeBell 1989), speckled (Bosquet and others 1988), American green (Bosquet and others 1987), and European alders (Funk 1990; Hall and Maynard 1979). Disjunct populations of red alder have been located in Idaho (Johnson 1968), and growth of such populations and those at the extremes of species' range differs markedly from that of most populations (Lester and DeBell 1989). Natural hybridization is common in alder, and zones of introgression between some species can occur where ranges overlap (Ager and Stettler 1994). Artificial hybridization has been conducted with numerous species, including

hybrids of red alder with European or mountain alders (Chiba 1966; Hall and Maynard 1979; Ljunger 1959).

Flowering and fruiting. Species in the genus are typically monoecious, with clusters of separate male and female flowers in close proximity. Flower initiation probably occurs during late June or July for both red and European alders (Ager and others 1994; Brown 1986; McVean 1955). The male and female flowers develop into catkins that elongate in late winter or early spring and mature on the previous year's twigs (table 2). For red alders, peak pollen shedding precedes peak female receptivity by only 2 to 4 days (Stettler 1978). For a specific description of staminate and pistillate catkins, see Brayshaw (1976). The strobiles of most species are 10 to 15 mm long when mature (figure 1), but those of Nepal, red, and Sitka alders are larger, having lengths of 12 to 24 mm (Carlson and Bryan 1959; Funk 1990; Harrington 1990; Krstinic 1994; Townsend and Douglass 1994). They are produced in abundance before trees reach 10 years of age in at least 2 species. European alders can produce flowers by their second growing season, and individual red alder trees are sexually mature at 3 or 4 years. Most dominant trees in a red alder stand will produce seeds by age 6 to 8 years (Harrington and DeBell 1995; Stettler 1978). Although the majority of seeds produced are probably the result of outcrossing, both selfing and apomixis occur in red alder (Stettler 1978). Seed production resulting from selfing has been reported for European and mountain alders; however, in many cases self-fertilization results in

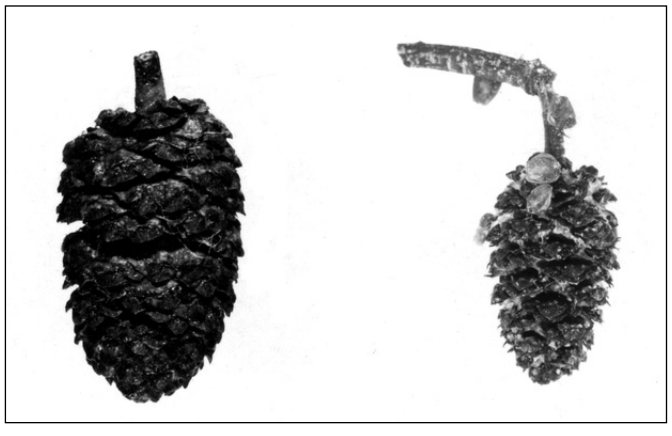
* In western North America, Siberian alder (*A. viridis* ssp. *fruticosa*) has long been mistaken for American green alder (*A. v.* ssp. *crispa*), which it closely resembles, or for Sitka alder (*A. v.* ssp. *sinuata*) (FNASEC 1997).

Figure 1—*Alnus*, alder: mature female catkins (strobiles) of *A. rhombifolia*, white alder (**left**); *A. serrulata*, hazel alder (**right**).



aborted ovules (Krstinic 1994). Information on the effects of management practices on reproductive processes is limited. In young red alder plantings in western Washington, flowering varied by half-sib family but overall was reduced in close spacings and by summer irrigation (Harrington and DeBell 1995). However, dry weather in spring reduced germination rates of European alder seeds, making irrigation early in the year desirable when precipitation is below normal (Hall and Nyong 1987).

Seed production varies from year to year, site to site, and tree to tree (Ager and others 1994; Brown 1985, 1986; Lewis 1985; Koski and Tallquist 1978; Krstinic 1994; McGee 1993), but good crops are borne at least once every 4 years (table 3). LaBastide and van Vredenburch (1970) reported that seed crops for European alder follow an annually alternating pattern. McVean (1955) concluded that seed crops of European alder could vary substantially from year to year, but that "boom-and-bust" patterns of seed production were not typical. Complete failure of a seedcrop is rare, but after a severe freeze in November 1955, almost no red alder seeds were produced in 1956 (Worthington 1965).

Seeds are small nuts ("nutlets") borne in pairs on the bracts of the strobiles. The nuts of red, Siberian, and Sitka alders have broad wings about as wide as or wider than the body of the nut. In the other species included here, the wings are reduced to a narrow border (figure 2) (Fernald 1950; Sargent 1965). Seeds are without endosperm and contain only small cotyledons (figure 3). For additional information on reproductive biology of red alders, see Ager and others (1994).

The factors regulating the timing of seed dispersal in alders have not been investigated, but they are probably similar to those regulating the release of seeds from the cones of conifers; that is, once strobiles are mature, disper-

sal is determined by the occurrence of weather that dries them, thus opening scales and allowing the seeds to be released (Harrington and others 1994). In general, wet weather following dry weather closes the strobiles, thus terminating a dispersal event. Nonetheless, heavy seedfall can occur during wet weather under certain conditions (Lewis 1985), but dispersal will not occur if ice freezes the seeds in the strobile. Although most seed dispersal occurs from September or October through February to April (table 2), some red alder seedfall has been observed in all months (Lewis 1985). American green alder strobiles do not release many seeds if the weather is wet during the autumn; substantial seed dispersal onto snow can occur throughout the winter (Densmore 1979). Alder seeds are very light, and when released they are dispersed long distances by wind, and in some species by water. Seeds of European alder have remained viable after floating for 12 months in still water (McVean 1955). In Alaska, seeds of thinleaf alder have corky, thick wings and float for long periods of time, whereas seeds of American green alder have thinner wings and sink rapidly (Densmore 1979). Birds or other animals also act as dispersal agents when moving through alder crowns and when extracting seeds from the strobiles (Harrington and others 1994).

Information on damaging agents is limited. Fungal diseases of alder catkins—caused by *Taphrina occidentalis* Ray and *T. alni* (Berk. & Broome) Gjaerum—cause enlargements of the bracts of female catkins (Mix 1949) and thus prevent or hinder normal fertilization and seed development. Jumping plant lice—*Psylla alni* (L.)—lay eggs in alder catkins in western North America (Furniss and Carolin 1977). Alder seeds are an important source of food for some

bird species (White and West 1977), and presumably seed predation by birds could have significant impacts when seedcrops are small.

Collection of fruits, extraction and cleaning, and storage of seeds. Seedcrops can be assessed in mid-summer by obtaining a count of mature strobiles and filled seeds (Ager and others 1994). Filled seed count should be determined from the upper third of the crown where viability is highest (Brown 1985). Seed quality can be assessed by cutting the strobile longitudinally and counting the filled seeds on one of the cut faces. Although the number of filled seeds on a cut face can vary from 0 to 20 or more in red alders, less than 3 or 4 seeds per cut face indicate a marginal crop (Ager and others 1994). Strobiles may be collected from standing or recently felled trees when the bracts (scales) start to separate on the most mature strobiles. In red alders, ripeness can be judged by twisting the cone along the long axis; if it twists easily and the scales part slightly, the seeds are sufficiently mature for collection (Hibbs and Ager 1989). Color is also a good indicator of maturity; immature cones are green whereas mature cones are mottled shades of green, yellow, gray, or brown (Hibbs and Ager 1989). Strobiles should be collected as soon as they are ripe, for the largest seeds with the best germinability are usually released first. Thus, both seed quality and seed yield are higher if collections are made in the fall rather than in the winter or spring (Lewis 1985; Krstinic 1994). Alder cones will open after being dried on screens or in fine mesh bags in a well-ventilated room for several weeks at ambient air temperature. They can be opened in a shorter time (2 to 7 days) by drying them in a kiln at 16 to 27 °C. Higher temperatures should not be used, as the strobiles will dry too quickly, harden and not open completely. Most of the seeds fall out of the strobiles during the drying process. The remainder, if needed, may be extracted by shaking or tumbling. Overall seed yields can be improved by either wetting cones again, placing them in a cooler for 24 hours, or spraying them with a fine water mist and then redrying (Ager and others 1994). Seeds may be cleaned by screening to remove large trash and further processing with an air column to remove small extraneous material.

Purity as high as 90% has been attained with European alder by fanning and screening seedlots. Quality, however, may be low because the light weight of alder seeds makes it difficult to separate and remove empty seeds (Ager and others 1994). Soundness in most cleaned seedlots has been between 30 and 70% (table 4). Number of seeds per weight ranges from 660,000 to 2,816,000/kg (or 300,000 to 1,277,000/lb) in lots of average quality (table 4). Except for seeds of American green alder, higher numbers may indicate a low percentage of filled seeds. Numbers ranging from 1,800,000 to 4,400,000 seeds/kg (800,000 to 2,000,000/lb) have been found in samples of Nepal, red, and thinleaf alders, but less than 5% of the seeds in these samples were full (Schopmeyer 1974). One red alder seedlot, however, was 70% sound and had 2,700,000 seeds/kg (1,224,000/lb). In a trial with red alder, the percentage of filled seeds determined by x-radiography was highly correlated ($r^2 = 0.91$)

* Yield data were determined on clusters of strobiles including stems.

with the actual germination percentage (Ager and others 1994).

Air-dried seeds have been stored in sealed containers at < – 2 °C. Under these conditions, viability has been maintained for 2 years in seeds of European alder (Holmes and Buszewicz 1958) and for 10 years in speckled alder (Heit 1967). For long-term storage, however, further drying of seeds to moisture content of less than 10% has been recommended for red alder (Ager and others 1994). This can be accomplished by kiln-drying or placing seeds in a room at 27 °C with less than 25% relative humidity. Red alder seeds can then be placed in moisture-proof containers and stored at < –12 °C for 10 to 20 years without substantial losses in viability (Ager and others 1994).

Pregermination treatments and germination tests. The degree of dormancy appears to vary among alder species and among provenances (geographic origins) within species. Thus, percentage germination of fresh seeds of white and thinleaf alders was equally good for stratified and nonstratified seed (Schopmeyer 1974). Fresh seeds of European and mountain alders also germinated promptly without stratification; but dried seeds, at a moisture of content of 8 to 9%, were dormant (table 5) (Schalin 1967). Germination capacity of the dried seeds, after stratification for 180 days at 5 °C was higher than that of fresh seeds. Maximum germination capacity, however, was obtained only when the stratification period was followed by 3 days at –20 °C (table 5) (Schalin 1967). A more recent study found that fresh mountain alder seeds initially exhibited some dormancy (that is, only about half of the filled seeds germinated in the incubator), but no dormancy was observed after one winter in the soil (Granstrom 1987). Dormancy also has been encountered in occasional seedlots of speckled (Heit 1968) and American green alders (Schopmeyer 1974). Stratification for 30 to 60 days at 1 to 5 °C has been recommended for these dormant lots (Schopmeyer 1974). Stratification for 30 to 90 days also has been recommended for Sitka alder (Emery 1988).

Although physiological seed dormancy is not widespread in red alder, it can exist (Elliot and Taylor 1981). Stratification at low temperature (0 to 5 °C) has little or no effect on the rate or completeness of germination of red alder seeds when tested at warm germination temperatures (Elliot and Taylor 1981; Radwan and DeBell 1981; Tanaka and others 1991).

† 180 days at 5 °C, plus 3 days at 20 °C,
‡ No difference for 0, 30, or 60 days of stratification.
§ Light period was 10 housr/day at this temperature.
|| Seeds were stratified for an unspecified period.

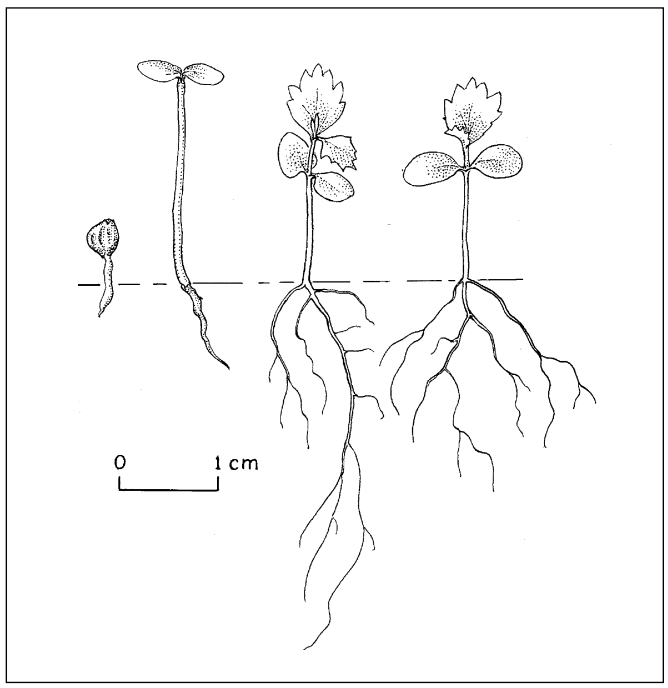
Under cool temperatures similar to those likely to prevail during outdoor sowings in early spring, however, 2 to 4 weeks of stratification substantially enhanced rate of germination and total germination (Tanaka and others 1991) and such a period is therefore recommended (Ager and others 1994). Thinleaf and American green alder seedlots collected near Fairbanks, Alaska, also germinated well without stratification at 25 °C but only germinated well at lower temperatures (10 to 15 °C) when combined with 72 days of stratification (Densmore 1979). Studies have also indicated the potential of 3 quick pregermination treatments for red alder seeds: gibberellin (Berry and Torrey 1985), 1% captan (Berry and Torrey 1985), and 30% hydrogen peroxide (Neal and others 1967). The results from these pregermination treatments, however, were obtained under warm germination conditions and need to be tested under the cooler conditions encountered in spring sowings. The captan and peroxide treatments may have a beneficial effect by reducing the amount of disease organisms present on seedcoats. Pretreatment with gibberellic acid improved greenhouse germination (21 °C day/13 °C night) of thinleaf alder seeds from 2 sources but did not affect germination of Arizona alder seeds from a single source (Dreesen and Harrington 1997).

For germination testing, both constant temperatures and diurnally alternating temperatures have been used (table 5). Official tests of the International Seed Testing Association (ISTA 1993) call for a 21-day test at alternating temperatures of 20/30 °C, with light during the 8 hours at 30 °C. Although seeds of European alder germinated as well in continuous darkness as under normal day length (McVean 1955), recent work indicates that seed germination of many alder species is markedly affected by light regime (Berry and Torrey 1985; Boojh and Ramakrishnan 1981; Bormann 1983; Densmore 1979; Khan and Tripathi 1989). Such effects in red alder are mediated by phytochrome: red light stimulates seed germination, far-red light inhibits it, and the effect of each light treatment can be reversed by the alternative treatment (Bormann 1983). Seeds of red alder are also sensitive to amount and quality of light under field conditions, and these factors—along with soil moisture—control germination success on disturbed sites (Haeussler and Tappeiner 1993; Haeussler and others 1995).

Nursery practice. Alder seedlings have been produced by bareroot nursery (open field or bedhouse) and container methods, as well as combinations thereof (Ahrens 1994; Ahrens and others 1992; Funk 1990; Radwan and others 1992). Successful stock types for red alder are grown in 1 year and include 1+0 open-bed bareroot, 1+0 bedhouse bareroot, 1+0 plug, and +0.5 (plug+transplant). Most nurseries sow in the spring when growing alder species (Ahrens and others 1992; Schopmeyer 1974), but fall-sowing is mentioned by Heit (1968). Spring-sowing is sometimes delayed until late spring to reduce seedling size. Sowing depths of 2 to 5 mm (.1 to .2 in) have been used for seeds of European alder and red alder (Schopmeyer 1974). In California, seeds of red alder have been mixed with 10 parts of vermiculite and drilled 1 cm (.4 in) deep (Schopmeyer 1974). In Oregon, seeds of red alder have also been sown on the soil surface and covered with peat. Seeds of Nepal alder have been mixed with sand and spread over the nursery beds. The number of plantable seedlings obtained from 1 kg (2.2 lb) of seed was 22,000 (10,000/lb) for European alder and 88,000 (40,000/lb) for hazel alder (Van Dersal 1938). Germination is epigeal (figure 4).

Alder seedlings, particularly those of red alder, grow rapidly and seedling densities should be lower than those used for conifers. Seedlings grown at open-bed densities of 60 to 180 seedlings/m^2 (5 to 15/ft^2) or in large containers result in much better outplanting performance than those grown at greater densities or in small Styroblocks® (Ahrens 1994). Inoculation of beds or container media with the nodulating actinomycete *Frankia* can improve establishment

Figure 4—*Alnus glutinosa*, European alder: seedling development at 1 and 7 days after germination (**left**); *Alnus incana* ssp. *tenuifolia*, thinleaf alder: 2 older seedlings (**right**).



and early growth in the nursery (Berry and Torrey 1985; Hilger and others 1991) and may enhance outplanting performance (McNeill and others 1990). Diluted suspensions of pure Frankia cultures and homogenates of crushed, fresh root nodules have been used for inoculation (Ahrens and others 1992; Perinet and others 1985). Detailed methods of preparation and application are available (Martin and others 1991; Molina and others 1994; Zasada and others 1991).

Development of nitrogen-fixing nodules is promoted by fertilization with low to moderate applications of nitrogen; phosphorus and lime are likely to be necessary for production of high-quality stock (Hughes and others 1968; Radwan 1987; Radwan and DeBell 1994). Although alder seedlings are produced operationally, optimum combinations of fertilizer source, amount, and timing of application have not been completely worked out; some combinations have had detrimental effects on alder seedlings or their root associates. Frequent irrigation may be necessary to prevent desiccation and heat damage of surface-sown seeds or germinants during germination and early establishment (Ahrens 1994).

Direct seeding in the field has been done successfully with 2 species. Speckled alder has been established in Pennsylvania by broadcast sowing on disked areas and on sod. Seeds collected in the fall were broadcast during the following February and March. Seeding rates were 0.28 liter/10 m^2 (or 0.5 pint/100 ft^2) on bare soil and 0.38 liter (0.7 pint) for the same area of sod (Liscinsky 1965). In England, better stocking was obtained on a shallow blanket bog with spot sowing of European alder than with broadcast sowing. About 15 viable seeds were sown in each spot and fertilized with about 60 g of rock phosphate (McVean 1959).

Seedling care. Information to guide lifting dates is very limited, even for red alder (Ahrens 1994; Ahrens and others 1992); current recommendations based on experience in southwest Washington are to lift seedlings in January. They are then stored at either +2 °C or –2 °C; the lower temperature is recommended because it prevents budbreak during storage (and possible *Botrytis* infection associated with budbreak during storage) and reduces the tendency for planted alders to break bud too soon after planting. Storage in sealed bags will prevent desiccation. Because alder stems are brittle and sensitive, seedlings must be handled carefully during storage, transport, and outplanting to avoid damage to stems, branches, and buds. At low elevations (< 300 m) in western Washington, it has been recommended that seedlings be planted between mid-March and mid-April. The spring planting period should begin when the probability of severe frost is low and end before there is appreciable soil drying (Dobkowski and others 1994).

Asteraceae—Aster family

Ambrosia dumosa (Gray) Payne

bursage

Jane E. Rodgers and Carol Miller

Ms. Rodgers is at the Point Reyes National Seashore, Point Reyes Station, California; and Ms. Miller is former propagationist at USDI National Park Service's Joshua Tree National Park, Center for Arid Lands Restoration and Native Plants Nursery, Twentynine Palms, California

Synonyms. *Franseria dumosa* Gray

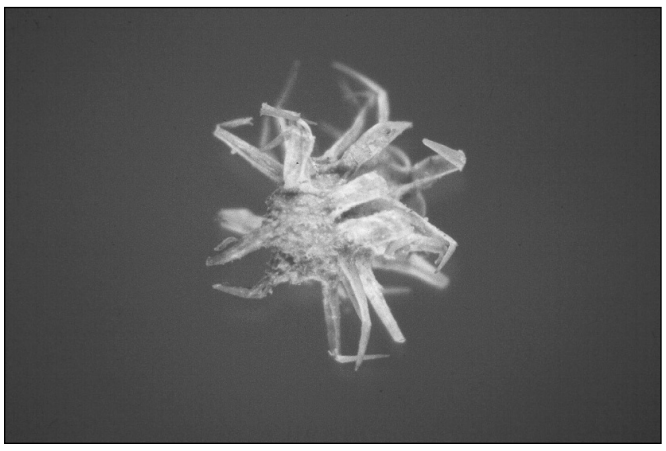
Other common names. white bursage, white burrobush, burrobush, burroweed, sandbur

Growth habit, occurrence, and use. Bursage is a low, intricately branched, rounded shrub abundant on well-drained soils through much of the Southwest. It is significant component in creosote bush scrub and Joshua tree woodland communities of the Mojave and Colorado Deserts of California, south and east to Utah, Arizona, Mexico, and lower California (Kay 1977). Bursage, like creosote, has a rhizomatous growth habit and is thus an extremely long-lived shrub (Muller 1953).

Flowering and fruiting. Bursage flowers are inconspicuous, with staminate and pistillate heads intermixed in the terminal and lateral spikes of the panicle (Bainbridge and Virginia 1989). Blooming occurs primarily from February to June, and occasionally during the fall or after rain (Kay 1977). Seeds resemble cockleburs (figure 1) and mature 3 to 4 months after flowering.

Collection, extraction, and storage. Seeds can be hand-stripped from the plants; collecting burs from the ground beneath the plants is impractical because the light burs are rapidly blown away (Bainbridge and Virginia 1989). Seed cleaning is difficult and rarely done due to the spiny burs. In long-term storage trials by Kay and others (1988), seeds were stored at room temperature, 4 °C, – 15 °C, and in warehouse conditions, with germination rates tested annually over a 14-year period. The results indicated that seed quality had been poor, even though seeds were collected numerous times. The sporadic germination under a variety of conditions reflected this. Kay recommended that seeding guidelines should specify seeding rates in seed weight of pure live seeds required for sowing an area (that is, kilograms per hectare or pounds per acre), and providing that extra seeds are planted to compensate for the low quality.

Figure 1—*Ambrosia dumosa*, bursage: mature seed.



Pregermination treatments. After overnight leaching/soaking, seeds begin germinating during the first and second weeks in moist paper towels or directly in a 50% vermiculite–50% soil mixture (CALR 1995). Optimal germination temperatures appear to be between 15 to 25 °C (table 1), as colder temperatures tend to inhibit germination (Kay 1975).

Germination tests. Tests using activated carbon and scarification both resulted in a slightly improved early germination rate (Graves and others 1975). Germination conditions tested at Joshua Tree National Park (JTNP) Native Plants Nursery include: (1) direct sowing to blotter paper, (2) overnight cold water soaking, and (3) initial cold water soaking followed by overnight leaching. All of these methods had moderate success, indicating that no treatment is necessary when sowing directly to moist toweling; average gemination ranges from 30 to 50% (CALR 1995). Other tri-

Source: Kay and others (1988).

als by Kay and others (1988) refer to initial germination of seeds using 4 replications of 100 seeds in damp paper toweling placed in a growth chamber at 15 °C. Test conditions were maintained for 28 days, with germination percentages recorded every 7 days; initial germination rate for bursage was 5%. Germination tests, conducted annually to test the effects of storage, were then averaged to a "best germination" of 9%. These annual tests consisted of 4 replications of 50 seeds using the same initial testing methods. Also tested were the effects of temperature on germination rates (table 1).

Nursery practice. Mature specimens have been transplanted with greater than 90% survival (Ruffner and others 1985). Graves (1976) transplanted 2-month-old stock in February 1973, with a survival rate 2 years later of 44 and 48% for 2 separate sites. Flowering occurred in 25% of the plants during first year's growth at one site, with no flowering or seed at other site. Initial mortality was due to cold transplanting temperatures. Spot-seeding, in comparison, was poor, with 18 burs/spot resulting in 16% germination and 0 to 4% stocking at the same sites. A one-time irrigation treatment did not improve results of either transplanting or spot-seeding. Seed germination may be induced from September–October rains (Went 1979).

At JTNP, 12-month-old plants grown from seed have been successfully outplanted using a 76-cm (30-in) tube "tall pot" with a 15-cm (6-in) diameter (CALR 1995). Other outplantings of bursage in the park include a restoration project at an abandoned surface mine. Three types of containers were used: 3.8-, 6.8-, and 9.2-liter (1-, 1.8-, and 2.6-gal) pots with an elongated design 35 to 43 cm (14 to 17 in) in height. Latest monitoring noted an overall survival rate of 80% (CALR 1995). Prior to outplanting, plants in smaller containers were between 4 and 5 months old and those in larger containers, between 6 and 7 months.

Seedling care. Seedlings grow quickly in greenhouse conditions, and new growth can be pruned back frequently to strengthen the sensitive root collar (CALR 1995). Both Graves (1976) and the JTNP Native Plants Nursery have noted seedling sensitivity to hardening-off in sub-freezing temperatures. Using plant bands, Graves (1976) recorded 80% mortality at 10 to –7 °C, with better survival after restarting and hardening-off at day-night temperatures of 14 and 4 °C. Stem pieces root easily from the field or greenhouse by dipping in rooting hormone powder and placing cuttings in vermiculite in a mist house until rooted (Wieland and others 1971).

Rosaceae—Rose family

Amelanchier Medik.

serviceberry

Kenneth A. Brinkman and Terry F. Strong

Dr. Brinkman retired from the USDA Forest Service's North Central Forest Experiment Station; Mr. Strong is a research forester at the USDA Forest Service's North Central Research Station, Rhinelander, Wisconsin

Growth habit, occurrence, and use. The serviceberries—the genus *Amelanchier*—include about 25 species of small deciduous trees and shrubs native to North America, Europe, and Asia. The distribution and chief uses of 6 species are listed in table 1. Most species provide browse and edible fruits for wildlife and many have attractive flowers. Saskatoon and common serviceberries have been used to a limited extent for shelterbelt and wildlife plantings and as a minor fruit crop, but other species also should be considered for these and other environmental uses. Native Americans have traditionally used most species of serviceberry for food and medicine (Meeker and others 1993; Moerman 1986). Common and Saskatoon serviceberries are tolerant of temperatures to –60 °C (Junttila and others 1983; Kaurin and others 1984; Lindstrom and Dirr 1989). Common serviceberry regenerates vegetatively and by seed after clearcutting and burning (Scheiner and others 1988). Geographic races of *Amelanchier* have not been identified, but they could occur in widely distributed species such as the Saskatoon and common serviceberries. Several natural hybrids are known (Campbell and others 1991; Cruise 1964; Flessner and others 1992).

Flowering and fruiting. The perfect white flowers of serviceberries appear in terminal and lateral clusters early in spring, before the leaves in some species (table 2). Fruits are berrylike pomes (figure 1) that turn dark purple or black when they ripen (table 3). Each fruit contains from 4 to 10 small seeds weighing from 1.1 to 6.9 mg, although some of these are usually abortive (St. Pierre and Steeves 1990). Gorchov (1985) reported that fruits containing more seeds develop quicker, suggesting asynchronous fruit development of the genus. Fertile seeds are dark brown with a leathery seedcoat (figure 2) and with the embryo filling the seed cavity (figure 3). Seeds are dispersed almost entirely by birds and animals; however, Turcek (1961) reported that seeds of some species are distributed by insects. Fruits usually are

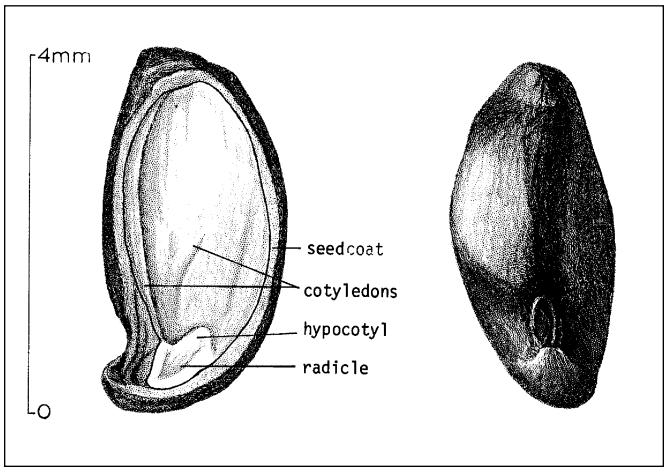
eaten by birds or animals as soon as they ripen. Fruit loss of Saskatoon serviceberry can be significant (up to 81% of the potential). These losses occurred because of insects and disease (54%) and frost (27%), with the remaining losses (19%) undetermined (St. Pierre 1989). Fruit loss can exceed 95% in some years and some locations (St. Pierre 1996).

Collection of fruits. To minimize losses to wildlife, fruits must be picked from the shrubs as soon as possible after ripening (table 2). Fruit color is the best way to judge maturity (table 3). Unless the seeds are to be extracted promptly, the fruits should be spread out in thin layers to dry. Loss of viability will result if the fruits are allowed to overheat.

Figure 3—*Amelachier sanguinea*, roundleaf serviceberry: longitudinal section through a seed (**left**) and exterior view (**right**).



Extraction and storage of seeds. Serviceberry seeds are usually extracted by macerating the fruits in water and washing them over screens (Heit 1967; Munson 1986; Peterson 1953), which removes most of the pulp. After this remainder is dried and rubbed through the screens, the seeds and remaining debris are run through a fanning mill to remove small, aborted seeds and bits of fruit (Brinkman 1974). Seed yield and weight data are listed in table 4. Few storage tests have been made of serviceberry seeds, but dry storage in sealed containers at 5 °C is usually recommended (Brinkman 1974; Crocker and Barton 1931). However, excessive drying of seeds may induce a deeper dormancy with consequential decrease in germination rate (St. Pierre 1996).

Pregermination treatments. Embryos of all species show dormancy that can be at least partially overcome by cold stratification (Crocker and Barton 1931), however, control of fungi during this period is critical (McTavish 1986). The seedcoat of some species also may retard germination. Scarification of Allegheny serviceberry in concentrated H_2SO_4 followed by stratification improved germination (Hilton and others 1965). Addition of a mixture of benzyladenine and thiourea enhanced seed germination of Saskatoon serviceberry (Weber and others 1982). The necessary time period of cold stratification varies, but most species require 2 to 6 months (Heit 1968) (table 5). Robinson (1986) reports improved germination from seeds of fruits consumed by cedar waxwings (*Bombycilla cedrorum*).

Germination tests. Germination of Saskatoon serviceberry appears to be genetically controlled and, to a limited extent, can be influenced by environmental fluctua-

tions (Acharya and others 1989). Germination of stratified seeds can be tested in sand or a sand–peat mixture. Constant temperatures of 21 °C or alternating day/night temperatures of 30 and 20 °C have been equally successful. Light does not appear to be necessary during tests (table 5).

Germination is epigeal (figure 4). Germination of Saskatoon serviceberry seeds often occurs during stratification (St. Pierre 1996). Previously stratified seeds of Saskatoon serviceberry showed 84 to 99% germination at 2 to 5 °C (McKeever 1938; McLean 1967). Under natural conditions, germination could begin in the early spring under snow or shortly after snowmelt.

Nursery practice. Serviceberry seeds may be either sown in the fall or stratified and sown in the spring (Bailey 1935). Many seeds do not germinate until the second spring. It is suggested that the seeds be sown as soon as possible after collection and that the beds be kept mulched until germination begins the following spring (Brinkman 1974). Seeds should be sown in drills at the rate of 80 sound seeds/m (25 seeds/ft) and covered with 6 mm ($^1/_4$ in) of soil. At least for Saskatoon serviceberry, half-shade during the first year apparently is beneficial.

Fabaceae—Pea family

Amorpha L.

amorpha, indigobush

John C. Zasada and David Martineau

Dr. Zasada retired from the USDA Forest Service's North Central Research Station; Mr. Martineau is the plant division manager at the Prairie Nursery, Westfield, Wisconsin

Growth habit, occurrence, and use. In North America, the amorphas include about 15 species of deciduous shrubs or subshrubs (Wilbur 1975). Wilbur (1975) provides a thorough description of all species with range maps showing distribution. Four of the more common species and their ranges are listed in table 1. Leadplant and indigobush are the 2 most widely distributed and used species in the genus.

Leadplant is common in dry to wet–mesic prairie communities; in Wisconsin, its highest presence values are in the dry to dry–mesic communities (Curtis 1959; Henderson 1995; Johnson and Anderson 1985; Voigt and Mohlenbrock nd). Kotar and others (1988) list leadplant as a diagnostic species for the white oak–pin oak–leadplant habitat type that is transitional between prairie and forest in Wisconsin. Indigobush has a large range and within that range occurs on sites with fairly wet to dry moisture regimes and is relatively more common in riparian areas (Curtis 1959; Glad and Halse 1993). It can be an aggressive invader, as demonstrated by its spread along the Columbia and Snake Rivers in Oregon and Washington (Glad and Hulse 1993). Wilbur (1975) reported that indigobush is highly variable and that it is best described as a complex with variation due to both environmental and genetic factors. In North Dakota, plants from more southern seed sources grow more rapidly and are taller than those from North Dakota sources, but they are also more susceptible to winter damage (Lincoln Oakes Nurseries 1996).

Leadplant and indigobush are reported to hybridize, although hybrids are believed rare (Wilbur 1975). The hybrid has the greatest affinity with leadplant and differs in having a taller growth form as well as in several morphological traits (Wilbur 1975).

The growth form and stature of leadplant results from its tendency to die-back to varying degrees each year. Regrowth from basal stem and root collar buds maintains the above ground stems. Under some conditions, stems will be relatively longer-lived and attain heights of 1.5 to 2 m (table 2). Indigobush is taller than leadplant and its stem longevity is like that of a true shrub.

Leadplant is palatable to domestic livestock and under heavy grazing tends to disappear (Voigt and Mohlenbrock nd); however its palatability for whitetail deer (*Odocoileus virginiana*) was rated as low in a study in the Black Hills (Rosario 1988). A primary use, at present, is for landscaping, where low-maintenance, drought-resistant plants are desirable, and in restoration and reclamation projects (Brown and others 1983; Cox and Klett 1984; Dirr 1990;

Salac and others 1978). Indigobush is used in reclamation of strip-mined areas (Brown and others 1983; Weber and Wiesner 1980). Leadplant is an important prairie plant and is included in restoration projects (Salac and others 1978). All amorpha species are nitrogen-fixers and thus have the potential for improving soil nutrient status. In the traditional medicine of the Great Lakes Ojibwa, a decoction of the root of leadplant was used to treat stomach pain (Meeker and others 1993); leaves were used as a tobacco and for making tea (Niering and Olmstead 1979).

Flowering and fruiting. The irregular, perfect flowers of amorphas are blue to violet purple in color and are borne in the spring or summer (table 3). The inflorescence is a raceme; leadplant can have 200 to 300 flowers/raceme. The fruit is short, indehiscent, somewhat curved and often gland-dotted legume (pod) containing 1 (or sometimes 2) small glossy seed (figures 1 and 2). When ripe in mid to late summer, the legumes are light brown in color. Commercial seed usually consists of the dried legumes.

Good seedcrops of mock locust are borne every 2 years (Brinkman 1974), and similar frequencies probably are typical of the other species. Flowering in leadplant was stimulated by spring burning; periodic burning appears to stimulate both vegetative and reproductive growth (Richards and Landers 1973; Rosario 1988). Periodic, not annual, mowing may also improve seed production (Rosario 1988). Indigobush seed availability may be lowered significantly by seed beetles (Rogers and Garrison 1975). The majority of

Figure 1—*Amorpha*, amorpha: legume and seed of *A. fruticosa*, indigobush.

leadplant seeds are dispersed in September and October, but a few may may remain on the plant during winter.

Collection of fruits; extraction and storage of seeds. The ripe legumes can be stripped from the inflorescences and spread out in thin layers for a few days to permit drying.

Extraction of seeds is not essential for germination. The legumes are usually 1-seeded, thin walled, and soft enough so that germination does not appear to be reduced significantly if seeds are not removed from the legumes. However, the seeds may be extracted by gently beating or rubbing the legumes. Available data on seed and fruit weights are listed in table 4. Little is known about optimum storage conditions, but all evidence suggests that the seeds are orthodox in storage behavior. Seeds of leadplant stored for 22 months at 41 °C followed by 16 months at room temperature showed little loss in germination; sealed storage at continuous low temperature probably would prolong viability (Brinkman 1974). Seeds of indigobush have retained viabili-

Table 3—*Amorpha,* amorpha: phenology of flowering and fruiting

ty for 3 to 5 years at room temperature (Brinkman 1974); more recent experience indicates that seeds can be stored at 2 °C for at least several years with little loss in viability (Lincoln Oakes Nurseries 1996). The presence of leadplant in prairie soil seed banks also suggests that seeds may have relatively long lives without cold storage (Johnson and Anderson 1985).

Pregermination treatments and germination. The degree and type of dormancy appear to differ among species. As with many woody species, drying of seeds may induce seedcoat dormancy in seeds that would normally germinate without pretreatment (Dirr and Heuser 1987). Both mock locust and leadplant will germinate completely without treatment (Martineau 1996; Mirov and Kraebel 1939). Leadplant seeds obtained from commercial dealers following an unknown period of storage germinated without treatment, but stratification at 3 to 4 °C for 2 and 8 weeks increased the rate of germination; 30 minutes of scarification in sulfuric acid reduced germination by 50% (Cox and Klett 1984). Germination of some seed lots has been improved by soaking the seed in hot water for about 10 minutes. Cold stratification has been used in preparation for spring sowing in a nursery bed (Brinkman 1974). This cold treatment may reduce seedcoat impermeability. Dirr and Heuser (1987) indicate that fresh leadplant seeds germinate without pretreatment but that stored seeds may benefit from acid treatment.

Indigobush and dwarf indigobush appear to have seed coat dormancy. Light scarification of indigobush seeds and soaking seed of both this species and dwarf indigobush in sulfuric acid for 5 to 8 minutes have been used to stimulate germination (Brinkman 1974; Dirr and Heuser 1987). However, fall sowing with no pretreatment results in some, but not complete, germination (Brown and others 1983). Simulated acid rain with pH of less than 5 tended to reduce germination in indigobush, but significant germination occurred at pH 3 and 4 (Lee and Kim 1986). Total seedling dry weight of indigobush increased with decreasing pH of simulated acid rain (Lee and Kim 1986). Germination test conditions and results on pretreated seeds are in table 5. Germination is epigeal (figure 3).

Indigobush is the only species of amorpha that is listed in official seed testing rules. International Seed Testing Association (ISTA 1993) prescriptions call for a 28-day test at alternating temperatures of 20/30 °C on the top of moist

* One hundred pounds of dried fruit will produce about 60 pounds of clean seeds (Swingle 1939).

germination paper. Light is required during the 8 hours at 30 °C, but no pretreatments are called for.

A procedure for tetrazolium testing of depodded seeds of indigobush has been developed (Weber and Wiesner 1980). Seeds are chipped at the distal end to avoid injury to the embryonic axis (the more rounded end in figure 1) and stained for 18 hours. Lactophenol clears the seed coat, making it possible to interpret seed viability without removing the seedcoat. The method distinguishes living from dead seeds (Weber and Wiesner 1980).

Nursery practice. Seedlings can be produced in containers or as bareroot stock. The need for pretreatment of seeds will be determined by species and condition of the seeds, for example, seeds may germinate faster if they are removed from the legume. Timing of sowing in container production is more flexible than in outdoor beds. Seed use may be more efficient in containers than in outdoor beds because temperature and water availability are more easily controlled in the greenhouse environment. Rock (1981) recommends inoculating seeds of leadplant with nitrogen-fixing bacteria before sowing. This recommendation is probably applicable to all amorpha species.

For container production of leadplant in a greenhouse, cleaned seeds (removed from the legumes, inoculated, and unstratified) may be sown at any time during the summer. Initial sowing is in small cells (about 2 to 3 cm^3); germination is completed in about 15 days. When seedlings are at the 3- to 5-leaf stage, they are transplanted to larger containers. Seedlings are kept in the greenhouse until established in the new containers and then moved outside. If seeds are sown in spring, seedlings can be transplanted to ~1 liter containers (~1 qt) in early to midsummer; seedlings will be ready for outplanting by fall (Martineau 1996).

For bareroot production of leadplant, cleaned, inoculated, unstratified seeds are sown in the spring, covered with a few millimeters of soil followed by a layer of sawdust. Seedbeds are lightly compacted and the beds are watered as needed. Germination will occur mostly in the first year with a small amount of carryover to the second growing season. Juvenile leaves (simple, round as in figure 3) are produced part way through the growing season with a transition to the characteristic pinnately compound leaves in mid to late summer. Seedlings will be about 30 to 50 cm (12 to 20 in) tall, with a taproot of equivalent length, after 2 growing seasons. Seedlings are lifted and sold after the second growing season or in the following spring while still dormant. Care should

Note: Temperature is day/night regimen, photoperiod is 8 hours, based on Brinkman (1974).
* Germination of leadplant (*Amorpha canescens*) takes about 2 weeks when sown in nurserybeds in the spring (Lincoln Oakes Nurseries 1996; Martineau 1996).

A

be taken when lifting, as the roots are split easily (Martineau 1996). Similar procedures are used for leadplant in North Dakota (Lincoln Oakes Nurseries 1996).

The following schedule for growing bareroot indigobush seedlings is reported by the Lincoln Oakes Nurseries (1996):

1. Legumes are hand-stripped from the plants in late September–late October.
2. Stem parts and impurities are removed, but the legumes are not removed.
3. Seeds are cold-stratified for 60 to 90 days in sand before sowing in the spring.
4. Seeds are sown in a single row of 80 to 100 seeds/m (25 to 35 seeds/ft) at a depth of 0.8 cm ($^1/_3$ in). Seedlings grow to heights of 25 to 35 cm (8 to 14 in) the first year and 0.6 to 1.2 m (2 to 4 ft) the second year.
5. Plants are harvested as 2+0 seedlings.

Seeds can also be sown in the fall to allow natural stratification to occur; this appears to partially eliminate the need for acid treatment in those species where it is recommended (Brown and others 1983; Dirr and Heuser 1987). For leadplant, 0.45 kg (1 lb) of commercial seed has produced about 22,000 usable plants; for indigobush, 1,000 to 5,600 plants (Brinkman 1974).

Amorpha species can be propagated from softwood and semi-hardwood cuttings. Untreated softwood cuttings root readily, but later-season cuttings may require treatment with a rooting compound (Bailey 1939; Dirr 1990; Dirr and Heuser 1987).

Aralia L.

aralia

John C. Zasada and Barton M. Blum

Dr. Zasada retired from the USDA Forest Service's North Central Research Station; Dr. Blum retired from the USDA Forest Service's Northeastern Forest Experiment Station

Growth habit, occurrence, and uses. The genus *Aralia* comprises about 20 species of deciduous trees, shrubs, and herbs found in North America, Asia, Malayasia, and Australia (Blum 1974; Fernald 1950). The main species in North America include 3 subshrubs and a small tree (table 1)—the devil's-walkingstick—that is planted as an ornamental, as is the exotic Japanese angelica-tree—*A. elata* (Miq.) Seem. Animals utilize the vegetative growth and fruits to varying degrees. Two species were used for medicinal purposes by Native Americans. Underground parts are known for their aromatic qualities (Blum 1974; Braun 1961; Dirr 1990; Fernald 1950; Kenfield 1966; Krochmal and others 1969; MacKinnon and others 1992; Meeker and others 1993; Moore 1993; Stupka 1964; Tehon 1951; Voss 1985).

Within their respective ranges, the species occupy different types of sites. Devil's-walkingstick is intolerant of shade, occurring mostly on disturbed sites with no or light forest canopy. It develops best on rich, mesic soils but also occurs on a range of site conditions. Dense stands are formed by shoot production from rhizomes. The stem has prominent spines, hence the species' common name of devil's-walkingstick (Sullivan 1992).

Of the herbaceous perennials, wild sarsaparilla is the most widely distributed. It is a common understory species in a variety of forest types. In Wisconsin, for example, it occurs throughout the state but is most common in northern forests with dry-mesic to wet-mesic moisture regimes (Curtis 1959); it occupies similar sites in Newfoundland, Michigan, and British Columbia (MacKinnon and others 1992; Meades and Moores 1994; Voss 1985). Compound leaves develop annually from a well-developed rhizome system. Clones may be 10 m or more in diameter (Bawa and others 1982; Edwards 1984). The age of the perennial shoot-bearing portion of the rhizome can be determined from leaf scars and frequency of flowering from inflorescence scars (Bawa and others 1982).

Spikenard and bristly aralia are less widespread than wild sarsaparilla. Spikenard occurs on relatively richer sites and is described as one of the largest herbaceous plants in the flora of Michigan (Voss 1985).

Bristly aralia occurs on drier sites. Small clones are formed by development of the rhizome system and consist of vegetative and reproductive ramets (Thomson and Barrett

1981). A distinguishing characteristic is the presence of spines on the stem (Curtis 1959; Voss 1985).

Flowering and fruiting. The flowers of *Aralia* are polygamous, white or green, and occur in umbels or panicles (Fernald 1950; Harrar and George 1962). Wild sarsaparilla has 3 to 4 umbels/inflorescence (figure 1) and bristly aralia has approximately 9 umbels/ramet. Flowering occurs from May to September depending on species; fruits mature in late summer or fall (figure 2) (Blum 1974; Fernald 1950). Flowers of wild sarsaparilla develop on a separate stalk that is overtopped by the associated vegetative stalk. In the other species, flowers are terminal and axillary or a combination of the two (Fernald 1950). Fruits are light green when immature, changing to bluish or purplish black when mature (Dirr 1990; Mackinnon and others 1992; Meades and Moores 1994; Soper and Heimberger 1982; Voss 1985). Male flowers retained in bristly aralia umbels with both male and hermaphrodite flowers turn red, making the fruit more conspicuous than if only the fruits were present (Thomson and Barrett 1981).

In bristly aralia, umbels contain male-only and hermaphrodite flowers. During the early stages of flowering, all flowers function as males; the female portion of the hermaphrodite flowers is receptive after the male parts have ceased to function. The number of flowers per umbel ranges from 30 to 40. Twenty-seven to 35% of the flowers are

Figure 1—*Aralia nudicaulis*, wild sarsaparilla: male inflorescence with 3 umbels, stamens just beginning to appear; the larger vertical stem in the background is the leaf-bearing vegetative shoot.

Figure 2—*Aralia nudicaulis*, wild sarsaparilla: developing fruits with stigmas still attached; additional blurred umbels are part of the same inflorescence.

hermaphrodites and more than 90% of these produced fruits (Thomson and Barrett 1981).

Wild sarsaparilla is dioecious with complete flowers uncommon (Bawa and others 1982). The sex ratio tends to be male-dominated but varies among sites and with time during the period of flowering, as male and female ramets do not flower synchronously (Barrett and Helenrum 1981). Infloresences on female plants contain on average 55 to 125 flowers. About 68% of the flowers produced fruits. Controlled pollinations produced 90 to 100% fruit set; flowers remain receptive for about 6 days. Some of the main differences between male and female clones are that males have more flowers per inflorescence, greater frequency of flowering, and occur in higher densities and greater numbers of ramets than do females (Barrett and Helenrum 1981; Barrett and Thomson 1982; Bawa and others 1982).

Insects are the major means of pollination in the genus (Bawa and others 1982; Barrett and Helenrum 1981; Thaler and Plowright 1980; Thomson and Barrett 1981; Thomson and others 1982). In areas treated to control spruce budworm, 71% of flowers produced fruits in sprayed and 49% in unsprayed sites, respectively (Thaler and Plowright 1980).

The fruit is a small, berry-like drupe containing 2 to 5 compressed, crustaceous, light reddish brown nutlets that are round, oblong, or egg-shaped. Each nutlet contains 1 compressed, light brown seed with a thin coat that adheres closely to the fleshy endosperm (Sargent 1965; Thomson and Barrett 1981) (figures 2 and 3).

Collection, extraction, and storage. Aralia fruits may be collected when they begin to fall from the plants in autumn (table 2). The seeds are ripe when the endocarps of the nutlets become hard and brittle, and this ripening may occur somewhat later than the ripening of pulp. The fruits should be run through a macerator, with water, immediately after collection. This will prevent fermentation and enable

the pulp and empty seeds to float off or be screened out. Small samples can be pulped by rubbing, with water, between 6.35-mm (#16) screens. Purity of seeds cleaned by the macerator technique was 98% (Blum 1974), but soundness in some lots has been only 30 to 60% (Heit 1968). Seed size and weight of cleaned seeds is indicated in figures 3 and 4 and table 3. Refrigerated storage of cleaned seed in sealed containers is recommended (Dirr and Heuser 1987; Heit 1967a), but the duration of viability under these conditions is not known.

Seeds of early successional aralia species from temperate and tropical regions elsewhere in the world have been found in soil seedbanks (Cheke and others 1979; Hirabuki 1988). Seedbanks in beech–birch–maple forests in New England had a minor amount of spikenard, bristly aralia, and wild sarsaparilla (Graber and Thompson 1978). No information was found on buried seeds of devil's-walkingstick, a plant that better fits the ecological characteristics—that is, early successional, intolerant species—of the aralia species found to occupy seedbanks in other parts of the world (Cheke and others 1979; Hirabuki 1988). The longevity of aralia seeds in the forest floor environment is not known.

Germination. Aralia seeds have dormant embryos, and some species, notably bristly aralia, appear to have impermeable endocarps (hardseededness) (Heit 1967b). There may be a combination of both hardseededness and embryo dormancy, requiring either mechanical or chemical scarification of the seedcoat in addition to a prechilling treatment (Heit 1967b). Seed dormancy in devil's-walkingstick can be overcome satisfactorily by 3 months of stratification at low temperatures (Blum 1974; Dirr and Heuser 1987). Hartmann and others (1990) also suggest that 30 minutes of soaking in sulfuric acid in addition to stratification improves germination. Dirr and Heuser (1987) reported 1% germination without stratification and 55% following 3 months of cold treatment. Although pretreatment with sulfuric acid and stratification at low temperatures will partially overcome hardseededness and embryo dormancy, other complications such as immature embryos further hinder germination (Heit 1968). In a study by Nichols (1934), seeds of wild sarsaparilla had 34% germination in 21 to 35 days after pretreating for 71 days at low winter temperatures in a cold frame. However, in this same study, seeds of bristly aralia had only 8% germination after exposure to low temperatures for 83 days. Seeds not exposed to low temperatures, on the other hand, had only 3% germination. Seeds of bristly aralia

were shown to benefit from after-ripening at temperatures ranging between 1 to 10 °C; optimum 5 °C for 90 to 120 days before planting in a greenhouse (Crocker 1948).

Japanese angelica-tree may benefit from 3 months of warm followed by 3 months of cold treatment; however, 70% germination has been reported following cold treatment only (Dirr and Heuser 1987).

Warm plus cold stratification of wild sarsaparilla brought about germination of 24% (with a potential germination of 66 to 92%). The seeds were stratified for 60 days at 20 °C (night) to 30 °C (day), plus 60 days at 5 °C, plus 60 more days at 20 to 30 °C, plus 60 more days at 5 °C. Similar treatment brought about only 0.5% germination of bristly aralia (Blum 1974). Obviously, this species still needs further study before fully satisfactory seed treatments can be developed (Heit 1967a).

Nursery practice. Heit (1968) recommends treating small lots of aralia seeds with sulfuric acid for 30 to 40 minutes and broadcast sowing in September. The aralias also may be propagated vegetatively. Root and rhizome cuttings offer the best method of vegetative propagation (Dirr and Heuser 1987).

Araucariaceae—Araucaria family

Araucaria Juss.

araucaria

Gerald A. Walters and John K. Francis

Dr. Walters retired from the USDA Forest Service's Pacific Southwest Forest and Range Experiment Station; Dr. Francis retired from the USDA Forest Service's International Institute of Tropical Forestry

Growth habit, occurrence, and use. The araucarias are 15 species of evergreen coniferous trees that are generally confined to the Southern Hemisphere. They are found in South America, Australia, New Guinea, New Caledonia, the New Hebrides Islands, and Norfolk Island under tropical, subtropical, and temperate climates (Dallimore and Jackson 1954; Howcroft 1978a&b; Ntima 1968; Record and Hess 1943; Veblen and Delmastro 1976; Webb and others 1984). They are noted for their long, straight, clear boles and symmetrical crowns; many are useful for timber and some are cultivated as ornamental trees and houseplants (Streets 1962).

Several species have been introduced to California, Oregon, Washington, Florida, Hawaii, Puerto Rico, the U.S. Virgin Islands, Guam, American Samoa, and other U.S. territories in the South Pacific region (table 1) (Francis 1988; Walters 1974). Araucaria species are generally found on sites at elevations from sea level to 2,100 m, with 1,200 to 2,400 mm of rainfall and well-drained soils. Cook-pine and Norfolk-Island-pine have been widely planted in Hawaii (Menninger 1964; Walters 1974). The botanical identities of these 2 species are often confused, and no one (not even visiting foresters from Australia) is absolutely sure which species is which! Recipients of araucaria seeds shipped out of Hawaii should be made aware of this confusion. All data on phenology and methods reported here are based on information obtained from the areas of natural occurrence. Norfolk-Island-pine is also a very common ornamental tree in Florida, California, Puerto Rico, and the U.S. Virgin Islands.

Flowering and fruiting. Araucarias generally begin to flower and set seeds between the age of 15 to 20 years. Most hoop-pine trees begin producing female flowers and fruits when they are between 10 and 12 years old and 6 to 10 m tall. Flowering and fruiting is very intermittent from year to year, and pollen production begins when trees are 22

Sources: Dallimore and Jackson (1954), LHBH (1976), Walters (1974).

to 27 years old and are about 20 m tall (Haines and Nikles 1987). Male and female flowers are generally found on different parts of the same tree. Male flowers usually appear at the base of the crown in young trees and the female flowers at the top. As the tree grows older, the male and female flowers come closer to each other. Bisexual flowers are also found. After pollination, the female flowers develop slowly, with the cones maturing in about 2 years (Ntima 1968). The mature cones are ovoid or almost spherical, ranging in size from 10 by 5 cm for hoop-pine to 30 by 20 cm for bunya-pine (Ntima 1968). In natural stands, seedlots collected from hoop-pines are rarely more than 65% viable (Haines and Nikles 1987).

Upon maturing, cones turn from green to brown (Ntima 1968; Walters 1974). Cones disintegrate on the tree or fall to the ground and disintegrate. The brown seeds are kite-shaped and have papery wings on either side (figures 1 and 2) or are thick and heavy with much endosperm. Araucaria seeds may be carried a short distance from the mother tree by wind, but generally the seeds fall within the periphery of the crown (Ntima 1968). Animals and birds that prey on the seeds are the most effective natural dispersers of the heavy seeds. The time of flowering, seed development, and seed dispersal, as well as seedcrop intervals are listed for 5 species in table 2.

Collection, cleaning, and storage. Most of the seeds of hoop-pine collected for planting are grown in seed orchards (Haines and Nikles 1987). Collection of cones should begin when the first trace of brownness is observed on the cone. In natural stands, the second-year cones are generally picked by climbing or felling trees (Howcroft 1978; Ntima 1968; Walters 1974). Cone collection must be timed correctly to get the highest proportion of mature and fertile seeds. A method for timing cone matureness is to pick a cone and measure the time it takes to disintegrate; ripe cones spontaneously disintegrate within 7 days. Collected cones should be spread on shelves in single layers for drying and turned daily. The cones normally will begin to disintegrate within a few days. Cones that fail to disintegrate within 10 days should be discarded, as they are considered too immature (Ntima 1968; Walters 1974). The average number of seeds per weight ranges from 77/kg (35/lb) for bunya-pine to 4,400/kg (1,995/lb) for hoop-pine (table 3) (Howcroft 1986; Walters 1974).

Most araucaria are recalcitrant (that is, intolerant of desiccation). Their seeds have short viability under atmospheric conditions and normally should be sown within a month of collection (Ntima 1968). If the seeds cannot be sown immediately, they should be stored under cold, moist, and airtight conditions at a temperature of 3 °C (Ntima 1968; Walters 1974). Klinki-pine seeds can be stored for at least 6 months with 32% moisture at a temperature of 3.5 °C (Willan 1991). Damp storage at 4 to 7 °C was best for monkey-puzzle-tree seeds. After 3 months of storage, these seeds began to germinate after 21 days at 25 to 30 °C and reached 70 to 90% germination after 7 days (Swindells 1980). Hoop-pine seeds appear to be orthodox (that is, tolerant of dessication); air-dried seeds stored at temperatures ranging from 1.7 to –15 °C showed little reduction in germination percentage for 17 months of storage (46 to 50% germination), but

Sources: Howcroft (1986b), Walters (1974).

decreased significantly between 17 and 100 months of storage. However, after 100 months of storage, germination still ranged from 25 to 44% (Shea and Armstrong 1978). Tompsett (1984) found that seeds of monkey-puzzle-tree, parana-pine, klinki-pine, and bunya-pine could not be safely dried below 25 to 40% moisture content; seeds of cook-pine and 2 other araucarias (*A. nemorosa* de Laubenfels and *A. scopulorum* de Laubenfels) cannot be dried below 12%; and seeds of hoop-pine could be dried to 2% without damage. Seeds in the second 2 groups dried to moisture contents just above the critical levels can be stored at –18 °C and thus appear to be orthodox. Parana-pine, monkey-puzzle-tree, and bunya-pine seeds are classified as recalcitrant (Farrant and others 1989; Ramos and others 1988). Plastic bags are good containers (Ntima 1968). Seeds of hoop-pine can be stored up to 8 years (Shea and Armstrong 1978).

Germination. No pregermination treatments are needed for araucaria seed (Ntima 1968; Walters 1974). Under suitable moisture and temperature (21 to 30 °C) conditions, germination (which is cryptogeal in this genus) may begin about 10 days after sowing. Germination is delayed by cooler temperatures, sometimes taking 50 days or more (Ntima 1968). Seed quality varies from year to year; if sufficient pollen is available to the parent trees, seed quality is generally good (Walters 1974).

Twenty-nine and 45% of a large number of hoop-pine and klinki-pine seeds germinated within 9 weeks in a germination test (Thong 1974). Klinki-pine seeds are pregerminated (incubated until the radicle begins to show) before sowing into containers. In a test with 3 replications of 1,200 seeds each, germination averaged 85% in 22 days. Of those seeds not germinating, 54% were dead, 30% were rotten, and 16% had not germinated yet. Survival of seedlings in containers to outplanting size was 88%. Broadcasting seeds on the surface of wet sawdust with a second shadecloth a few centimeters above the bed gave better germination than covering seeds with sawdust or germinating them without the second shadecloth covering (Howcroft 1974). Tompsett (1984) obtained 80 to 100% germination of 6 species tested when seed moisture contents were optimal.

Nursery practice. Araucarias can be grown under high shade or low shade. For both types of shade, seeds are sown during spring. Norfolk-Island-pine seeds are placed on a bed of sand–soil–peat mix to germinate with the pointed end of the seed slightly embedded. About 70% of fresh seedlots germinate in 4 to 12 days (Logsdon 1973). Seeds

should be treated with a fungicide to prevent damping-off. Fungi pathogenic to seedlings can be isolated from seed collected from the ground and even from seeds extracted from cones collected from trees (El-Lakany and others 1981). *Rhizoctonia solani* Kühn—the fungal species causing most of the cases of pre- and post-emergence damping-off—was one of the most commonly isolated fungi from *Araucaria* seeds (Kamara and others 1981). Control of seedborne and soilborne fungi should be undertaken before planting. With high shade, the seeds of all species except bunya-pine are sown in flat-bottomed drills about 1.25 cm ($^1/_2$ in) deep and then covered with the same amount of softwood sawdust (fungicide-treated hardwood sawdust may also be suitable).

Bunya-pine seeds are sown in drills 7 to 10 cm (3 to 4 in) deep or on shaded, moist media. A few months after sowing, fusiform radicles, called "tubers," are formed. The seedbeds are re-dug, and these tubers are collected and then either planted directly into containers or stored at room temperature until required for planting. Exposure of the tubers to sunlight before re-planting breaks their dormancy, and the plants begin to grow. Almost every seed produces a tuber and all of these develop into plants (Walters 1974).

With low shade, the seeds are broadcast on well-prepared nursery beds and covered with about 2 cm ($^3/_4$ in) of sawdust. The aim in both types of sowing is to have a stocking of 130 to 180 plants/m^2 (12 to 17/ft^2) (Ntima 1968; Walters 1974).

Newly sown beds should be given full overhead shade within several days of sowing. Best shoot development occurs when the seedbeds are given 75% shade for the first few months and 5% shade for the next 3 months (except for hoop-pine). Shading should be removed in 2 steps after this shading treatment to give full exposure 2 weeks before transplanting to containers. Full light is not admitted until nearly 1 year after sowing hoop-pine. When 75% of the seedlings are 15 to 22 cm (6 to 9 in) tall, the seedlings should be transplanted. Lifting and planting need to be done carefully to minimize damage to the roots. Transplanting should be done about 5 months before field planting. The seedlings should be spaced 5 by 20 cm (2 to 8 in) apart (stem to stem) and given full shade. The shade should be gradually removed to give full sunlight to the seedlings for at least a month before transferring them to the planting site (Ntima 1968). About 50 to 60% of the seeds will develop into plantable seedlings. Seedlings are generally outplanted when 2 years old (Ntima 1968). Norfolk-Island-pine seedlings grown in nursery beds or containers will be 15 to 20 cm (6 to 8 in) tall in 1 year and 60 to 76 cm (24 to 30 in) tall in 2 years (Logsdon 1973).

Ericaceae—Heath family

Arbutus menziesii Pursh

Pacific madrone

Philip M. McDonald

Dr. McDonald is a research silviculturist at the USDA Forest Service's Pacific Southwest Research Station, Redding, California

Other common names. madrone, arbutus, madroño.

Occurrence and growth habit. Pacific madrone—*Arbutus menziesii* Pursh—is 1 of 3 species of *Arbutus* native to the western United States (Little 1979). It is an evergreen tree that occurs in coastal mountains from southwestern British Columbia to southern California, and also in the Sierra Nevada of north central California. It often is found as a single tree or in groves, only rarely occupying extensive areas (McDonald and Tappeiner 1990; McDonald and others 1983). Seldom does Pacific madrone form pure stands; usually it is found in mixture with several conifer and hardwood species. It also competes successfully in both overstory and understory canopies (Sawyer and others 1977). Although some trees originate from seed, most begin life as root crown sprouts. Tree height and form vary widely: height from 8 to 38 m, and form from straight to crooked (Sudworth 1908). Stand density is a prime determinant of form and also affects tree height. In general, the more dense the stand, the better the form and the greater the height. On good sites with well-stocked stands, plentiful moisture, and some shade, the tree grows straight and tall with a narrow crown. On poorer sites with lower stocking and inadequate soil moisture, the tree becomes short and crooked, with a relatively wide crown. Clumps of trees are prevalent and increase as stands become more open. The species seems to be phototropic and trees are often observed leaning into gaps in the canopy. Asymmetric bole development is common. Over the entire range, the majority of Pacific madrone trees have some lean and some crook. Forking also is common.

Use. The strong, smooth, fine-grained wood has been utilized for many purposes, ranging from lumber, veneer, and fuelwood to furniture, flooring, interior trim, and paneling (EDA 1968; Overholser 1968). In the past, the wood of Pacific madrone was prized for making charcoal for gunpowder (Koch 1973) and was found to be without peer when made into bobbins and spools. This species was first cultivated in 1827 and has been planted occasionally as an ornamental tree in Europe and the United States (McMinn and Maino 1959).

Flowering and fruiting. Flowers, which bloom from March to June, are formed on a panicle 12 to 15 cm long. The 8-mm flowers consist of 5 sepals fused at the base with 5 fused urn-shaped petals and 10 stamens. The anthers split open when ripe, the awns are elongate, and the superior ovary is rough and bumpy with 5 chambers (Hickman 1993). The fruit is a berry, also rough and bumpy, less than 12 mm in diameter (figure 1). The generic name derives from *arboise*, a Celtic word for "rough fruit" (Roy 1974). The thin-skinned berry has rather dry, mealy flesh and generally is 5-celled (figures 1 and 2). McDonald (1978) found that, in northern California, the number of seeds per berry ranged from 2 to 37, with an average of 20. The berries ripen in September through November but often remain on the trees through December. Fully ripe berries are bright red

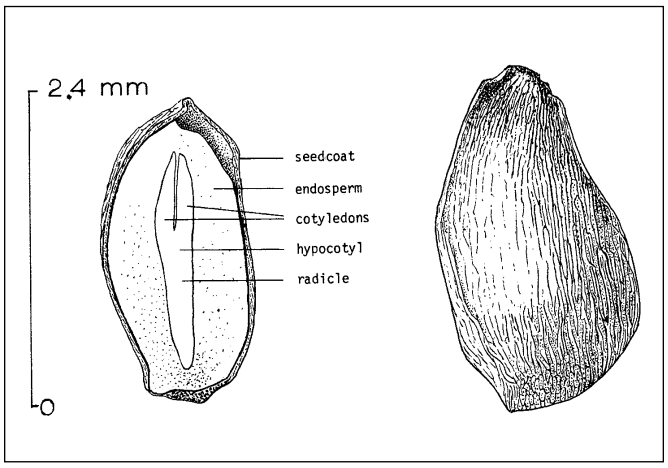
A

Figure 2—*Arbutus menziesii*, Pacific madrone: longitudinal section through a seed (**left**) and exterior view of a seed (**right**).



or bright reddish orange (Peattie 1953). However, the smaller numbers of yellowish orange or yellowish green berries that are usually present at the same time also furnish viable seeds (McDonald 1978).

The minimum seed-bearing age (from root crown sprouts) is 4 years but more commonly at least 8 years. Older trees have tremendous capability to produce seeds. On a good site in northern California, the number of berries produced during a light seed year for 3 representative trees that were 23, 36, and 41 cm in dbh ranged from 13,320 to more than 107,000/tree and related best to amount of living crown (McDonald 1978). On this same site, annual records showed that during a 24-year period (1958–1981), Pacific madrone produced 2 medium to heavy and 10 very light to light seedcrops (McDonald 1992). In years when the overall seedcrop is poor or nonexistent, madrone trees may be stimulated to produce heavy crops by logging and thinning. Apparently, the reduced stand density provides additional water and nutrients that become manifest in reproductive material.

A recent phenomenon that has greatly reduced seed production (Thornburgh 1994) is dieback and death of Pacific madrone trees infected by the madrone canker—*Botryosphaeria dothidea Moug.:Fr.*) Ces. & De Not.—which is virulent in northern California (McDonald and Tappeiner 1990).

Collection, extraction, and storage. Berries of Pacific madrone can be collected during the ripening period, dried thoroughly, and stored at room temperature for 1 or 2 years (Mirov and Kraebel 1939). Separating the seeds from the pulp after soaking and maceration of the berries probably is best (McDonald 1978). Only dry seeds should be stored, probably in sealed containers at temperatures just above freezing (Roy 1974). Fresh berries picked in the northern Sierra Nevada numbered 1,390 to 2,490/kg (630 to 1,130/lb), and the yield of cleaned seeds was 1.6 to 2.0 kg/45 kg (3.6 to 4.4 lb/100 lb) of fruit. The number of seeds ranged from 434,310 to 705,470/kg or 197,000 to 320,000/lb (McDonald 1978). Dried berries from an unknown source numbered 900/kg (2,000/lb) (Mirov and Kraebel 1939).

Pregermination treatments. Because the seeds exhibit strong embryo dormancy, stratification is critical. McDonald (1978) found that only 1 of 400 sound seeds germinated without stratification. For stratification, much evidence shows that storage in a plastic bag containing a small amount of moist paper or peat moss at temperatures just above freezing for 35 to 45 days is all that is needed to break dormancy (McDonald 1978; Roy 1974). With this treatment, 78 to 90% of a seedlot will have germinated in 10 days.

Germination tests. Only sound seeds should be used in germination trials. For red berries, darker color and slight rounding at the pointed end proved diagnostic for separating sound from unsound seeds; for yellowish berries, only seed size was a worthwhile indicator—larger seeds were more likely to be sound than small ones (McDonald 1978). Extensive trials in laboratory and field have shown the perils of germinating seeds in berries. If berries were present, so were virulent fungi and consumers. Indeed, in a field trial, snaptraps baited with a single red madrone berry caught more white-footed deer mice (*Peromyscus maniculatus*) than those baited with peanut butter and wheatflakes.

Nursery practice. Pacific madrone can be propagated by germinating seeds in flats and transplanting the seedlings to individual containers. Losses from damping-off fungi, however, can be huge. Hundreds of seedlings die overnight and the number available for planting often is small. Van Dersal (1938) noted that a yield of about 450 usable plants/kg of seeds (1,000/lb) was the best that could be expected. Although this species has been propagated vegetatively by grafting, layering, and rooting of cuttings (Roy 1974), no operational application of these techniques is known.

Seedling care. The problem of fungi does not end after the germinants become seedlings. Even after transfer to peat pots or other containers, the seedlings need to be protected from fungi. And even after great care, survival and growth in a conventional (sunlit) plantation is poor. In a trial on a high site in the northern Sierra Nevada, survival of seedlings in large containers (plugs) on competition-free ground was 33% after 6 years (McDonald 1978). All

seedlings died back at least once, developed multiple stems of poor form, and grew poorly. Natural seedlings developing in the wild also have a dismal establishment record, with first-year survival rates of 0 to 6%. Damping-off fungi, drought, predation by invertebrates, and litterfall, often interacting together, seriously limit the reproductive efforts of Pacific madrone (McDonald 1978; Pelton 1962; Tappeiner and others 1986). Based on this evidence, the best environment for establishment of both natural and planted seedlings is bare mineral soil and moderate shade (McDonald and Tappeiner 1990). However, the rate of seedling growth and its consistency in this environment is unknown.

Ericaceae—Heath family

Arctostaphylos Adans.

manzanita

Susan E. Meyer

Dr. Meyer is a research ecologist at the USDA Forest Service's Rocky Mountain Station, Shrub Sciences Laboratory, Provo, Utah

Growth habit, occurrence, and uses. The shrub genus *Arctostaphylos,* or manzanita, comprises about 50 species, 90% of which are endemic to California and adjacent areas (Munz and Keck 1959). Three species—greenleaf manzanita, Mexican manzanita, and rosybract manzanita—are widely distributed in the southwestern United States and Mexico. One species—bearberry or kinnickinnick—is circumboreal in distribution (table 1). The manzanita habit varies from mat-forming (bearberry) to nearly arborescent (bigberry manzanita). About a quarter of the species have subterranean burls that generate new sprouts both after fire and throughout the long life of the plant (Keeley 1992; Wells 1969). The leaves of manzanitas are leathery, entire, and evergreen. They are major components of chaparral and are also common understory species in montane coniferous forest types, especially ponderosa (*Pinus ponderosa* Dougl. ex Laws.) and Jeffrey (*P. jeffreyi* Grev. & Balf.) pines. They are most abundant in the fire-prone vegetation of regions with dry summers.

The manzanitas are moderately important as winter browse plants for wild ungulates but are less important for domestic livestock (Berg 1974). They are used principally after fire, when new shoots or seedlings are produced in abundance. The fruits are eaten by bears (*Ursus* spp.), grouse (*Dendragapus* spp.), and coyotes (*Canis latrans*) (Belcher 1985; Kauffmann and Martin 1991) and the seeds by various rodents (Keeley and Hays 1976). The sprouting species are particularly important for watershed protection after fire, and many species could be used in revegetation for erosion control. Manzanitas also have great potential for use as ornamentals. Their smooth red bark; interesting, twisted growth forms; and bright evergreen leaves make them attractive year-round. Bearberry has found wide

acceptance as a versatile groundcover (Dirr 1983) and has also been used medicinally (Belcher 1985).

Flowering and fruiting. Small urn-shaped white to pink perfect flowers appear on the plants from early winter through spring. The bud primordia are formed the previous year, and flowering and fruiting intensity is positively correlated with the previous year's precipitation (Keeley 1977). The flowers are pollinated by insects, principally bees and flies (Fulton and Carpenter 1979). Obligately seeding species (that is, those unable to sprout after fire) may have a higher investment in pollinator attraction than sprouting species, as evidenced as higher flower density and nectar production (Fulton and Carpenter 1979). They may also be more likely to be self-fertile and to have higher seed-set overall as measured by the incidence of inviable or unfilled seeds (Keeley and Zedler 1978). Many of the sprouting species are tetraploids, and Kelly and Parker (1991) report that lower seed set may be associated with polyploidy rather than the sprouting habit per se.

Fruits ripen about 2 months after full-flowering, generally from June to September, depending on elevation. The fruits are drupe-like, with a hard, bony endocarp enclosing multiple seeds, a mealy mesocarp, and a thin exocarp (figure 1). Each seed is borne in a nutlet-like section. Ripe fruits may persist on the plant for several months but eventually fall. They may be dispersed by birds or mammals, especially coyotes (*Canis latrans)* (Kauffman and Martin 1991). The nutlets themselves may be dispersed by scatter-hoarding rodents, but rodents most often consume the seeds *in situ* and thus act solely as seed predators (Keeley 1977).

The nutlets may break apart at maturity or remain variously fused. In some species (for example, bigberry manzanita) the nutlets are completely coalesced, whereas in most species, including Eastwood and greenleaf manzanitas, the stone breaks irregularly into 1- to several-seeded-segments. The endocarp wall surrounding each seed is usually thick, hard, resinous, and impervious (figure 2). The wall has a channel (periole) at the basal or micropylar end. This channel is plugged with tissue that is not as hard as the endocarp itself. When the seed germinates, the radicle and hypocotyl are forced out through this periole (Berg 1974). The endocarp wall is thought to have a protective function, especially with regard to heat damage during fire. Seeds surrounded by very thick endocarps or contained within fused nutlets are apparently more likely to survive fire than those borne singly or with thinner endocarps (Keeley 1977). The testa itself is thin and membranous, and the well-developed straight or curved embryo is embedded in abundant endosperm (Berg 1974).

Seed collection, cleaning and storage. Good seed crops are produced on average every 2 to 3 years, usually the year following a year of high precipitation (Keeley 1977). The fruits range from pink or red to black when ripe, depending on species. They may be hand-stripped or picked up off the ground. Seed fill is often low, and considerable insect damage may be evident (Keeley and Hays 1976). Fill

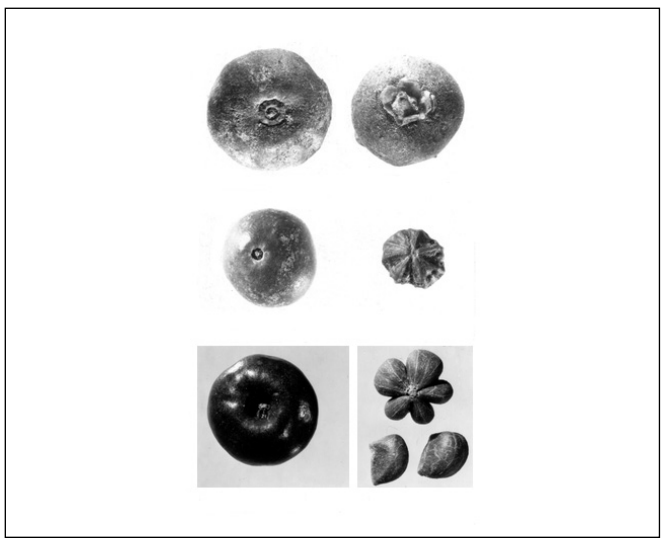

Figure 2—*Arctostaphylos uva-ursi*, bearberry: longitudinal section through a nutlet.

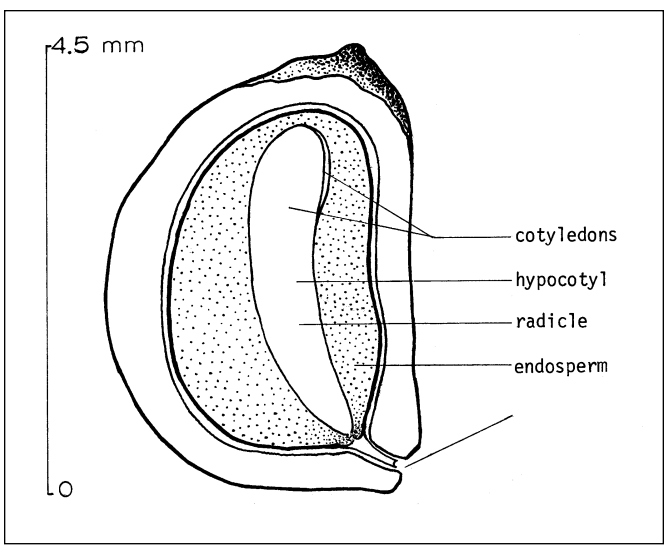

may be checked in the field by cutting the fruits transversely, preferably before the endocarp hardens (Berg 1974). Kelly and Parker (1991) reported a mean set (percentage of ovules forming seeds) of 62% for 14 California species, with a range from 50 to 80%.

To clean manzanita seeds, the fruits should be soaked in water, then macerated by hand or in a macerator to separate the pulp from the stones. The pulp may be removed by flotation, or the material may be dried, after which nutlets may be separated from the dried pulp using screens or a fanning mill (Berg 1974). Seedlots may be cleaned to high purity (Belcher 1985). Representative seed unit weights are given in table 2. Seed unit weights are highly variable even within a seedlot because a seed unit may be single or multiple-seeded, depending on the degree of coalescence of the nutlets.

Manzanita seeds form persistent seed banks and are apparently long-lived under field conditions (Kelly and Parker 1990). There is little information on longevity in warehouse storage, but it is probable that seedlots would maintain viability over periods of 10 years or more.

Germination and seed testing. In natural stands, new seedlings (figure 3) of most species of manzanita grow only after fire, and the seeds of these species are considered to be refractory, that is, germinating only in response to fire-related environmental cues (Keeley 1991, 1995). But unlike the refractory seeds of most chaparral shrubs, manzanita seeds apparently do not become germinable through heat shock (Kauffman and Martin 1991; Keeley 1987a). There is evidence that charate leached from incompletely burned wood can trigger germination in manzanita seeds, but the maximum percentages attained using recently collected seeds were not high (13% for Eastwood manzanita and 19% for greenleaf manzanita (Keeley 1987a, 1991). It is probable that, under field conditions, the seeds change in some way following dispersal (perhaps through dry after-ripening at the embryo level) that renders them more responsive to the charate stimulus. Parker and Kelly (1989) report that hoary manzanita seeds retrieved from the soil seedbank germinated readily in response to charate, whereas hand-harvested seeds less than 1 year old did not. In spite of the massive endocarp, manzanita nutlets are permeable to water, and the enclosed seeds are capable of imbibition without any pretreatment, at least in greenleaf manzanita (Meyer 1997). This explains how charate rather than heat shock could trigger germination. Presumably the charate stimulus enters the seed through the periole.

Even though manzanitas form persistent seedbanks, there is evidence that these seedbanks turn over fairly quickly, as there was no net gain in size of the seedbank in the absence of fire over 10 years for 2 chaparral species (bigberry and Eastwood manzanitas), even in the face of massive inputs (Keeley 1987b). Most of the seed loss appears to be due to rodent predation rather than germination or loss of

A. patula	1-seeded	44,100	20,000	85	1
A. uva-ursi	1-seeded	59,535–90,405	27,000–41,000	—	3+

Sources: Belcher (1985), Berg (1974), Keeley (1977, 1991), Keeley and Hayes (1976), Meyer (1997).

viability (Keeley and Hays 1976). This suggests that the seeds available for seedling recruitment after fire probably belong mostly to recently produced cohorts.

Even though manzanita nutlets are water-permeable, most reports on germination describe the seeds as hard-seeded, and the traditional pretreatment is sulfuric acid scarification for 3 to 15 hours (Belcher 1985; Berg 1974; Carlson and Sharp 1975; Emery 1988). Because the periole is much weaker than the endocarp wall, acid can enter there and damage the embryo long before the endocarp wall is stripped away, so care must be taken to remove the seeds before this damage occurs (Belcher 1985; Berg 1974). Coalesced nutlets generally require more time in acid than solitary nutlets, perhaps because the perioles, which are on the inner face of each nutlet, are better-protected when the nutlets are coalesced. Chaparral species such as bigberry and Eastwood manzanitas may be rendered immediately germinable by acid scarification, although reported percentages are low—3 to 8% (Berg 1974). Populations of greenleaf manzanita required both acid scarification (2 to 4 hours) and subsequent chilling for 60 days (Berg 1974) and 90 days (Carlson and Sharp 1975). Final germination percentages were 20 to 50%. Bearberry has been reported to respond to warm plus cold stratification following a 3- to 6-hour acid treatment—60 to 120 days at 25 °C, followed by 60 to 90 days at 5 °C (Berg 1974). Final germination percentages ranged from 30 to 60%. Belcher (1985) reported that warm plus cold stratification of bearberry resulted in 40 to 60% germination without acid scarification, but that acid scarification for 3 hours could be substituted for warm stratification. In bearberry, even excised embryos were dormant prior to chilling (Giersbach 1937).

Emery (1988) reported that a fire treatment (burning 3 to 4 inches of pine straw or excelsior over the planted seeds) in fall resulted in some emergence the following spring for many species of manzanitas, but the mechanism of dormancy loss under these conditions was not further explored. Charate could have been the stimulus responsible for this effect. It would be worth experimenting with charate as a germination stimulant in a nursery propagation setting.

Formal seed quality evaluation in manzanita is rendered difficult by the lack of reliable germination tests and by the thick endocarp. Tetrazolium staining requires excision of the seed from the endocarp by twisting it open along the suture or by cutting the nutlet off-center longitudinally, procedures difficult to carry out without damage (Belcher 1985). A seed unit may contain multiple seeds, only 1 of which has to be viable for the seed unit to be considered viable. For seedlots that have not been incorrectly handled (for example, stored at high moisture content) or stored for long periods, a cut test to determine fill is probably the best way to get a quick idea of total viability.

Field seeding and nursery practice. It will probably continue to be very difficult to obtain manzanita from direct seeding until there is a much better understanding of factors controlling release from dormancy. The absence of manzanita seedlings in unburned chaparral (Keeley 1992) coupled with the regular appearance of thousands of manzanita seedlings per hectare following fire, as reported by Keeley (1977), strongly suggests that a successful seeding prescription would include a seed pretreatment simulating fire-related germination cues. The sulfuric acid–stratification treatments described above and the fire treatment of Emery (1988) are currently the only published procedures for nursery seed propagation. The mazanitas are much more easily propagated from cuttings than from seeds, and in practice most nursery propagation is probably accomplished in this way (Berg 1974; Emery 1988).

Rosaceae—Rose family

Aronia Medik
chokeberry

John D. Gill, Franz L. Pogge, and Franklin T. Bonner

Dr. Gill and Mr. Pogge retired from the USDA Forest Service's Northeastern Forest Experiment Station; Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Growth habit, occurrence, and uses. The chokeberries—genus *Aronia*—discussed here are 2 closely related species (red and black chokeberries) and 1 hybrid deciduous shrub (purple chokeberry) (table 1). Black chokeberry is small, only 0.5 to 1 m tall. Red chokeberry and purple chokeberry are medium sized, 3 to 4 m tall. Red and black chokeberries hybridize readily and may be difficult to distinguish. Red and purple chokeberries are practically identical ecologically (Van Dersal 1938), and the only satisfactory way to distinguish between them is by the color of their ripe fruit. Both have pubescence on younger branches, leaf stems, and lower leaf surfaces. In contrast, black chokeberry is smooth or has only a few scattered hairs on these parts (Gleason 1963). The combined ranges of these 3 include most of the eastern United States and southern parts of adjacent Canadian provinces (table 1). All are moderately tolerant of shading and prefer moist soils, which usually are acidic. The most likely habitats are bogs and swamps, low woods, clearings, and damp pine barrens. However, each species will tolerate drier conditions, and black chokeberry is better adapted than the others to growth in drier thickets or clearings on bluffs or cliffs (Fernald 1950; Gleason 1963). All are valuable as food sources for wildlife in fall and winter (Hosely 1938). Their handsome foliage, flowers, and fruits also make them attractive as ornamentals, but none has been cultivated extensively. Red and black chokeberries were first cultivated about 270 years ago (Rehder 1940).

Flowering and fruiting. The white, bisexual flowers bloom for 2 to 3 months during March to July, the local flowering period depending on latitude and elevation. Fruit ripening dates are similarly dependent and range from August to November (table 2). Fruits drop from the plants shortly after ripening and may continue through the winter and spring. The fruits are rather dry, berrylike pomes (figure 1) containing 1 to 5 seeds (figure 2), some of which may be empty (aborted). Natural seed dispersal is chiefly by animals. Black chokeberry fruits shrivel soon after ripening,

Figure 1—*Aronia arbutifolia*, red chokeberry: leaf and cluster of fruits (pomes).

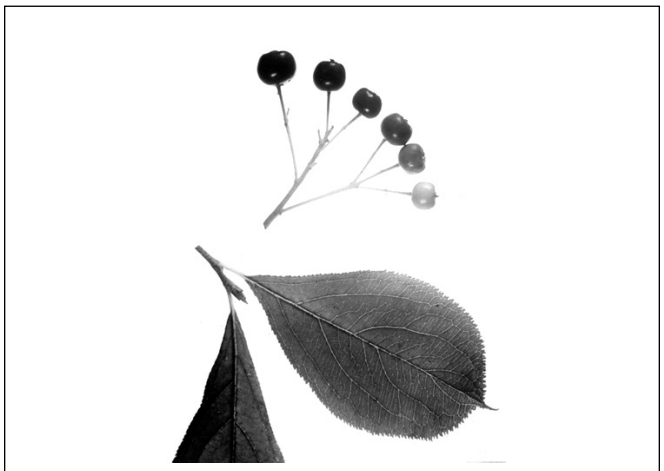

Figure 2—*Aronia melanocarpa*, black chokeberry: exterior views of seed, as well as longitudinal and transverse

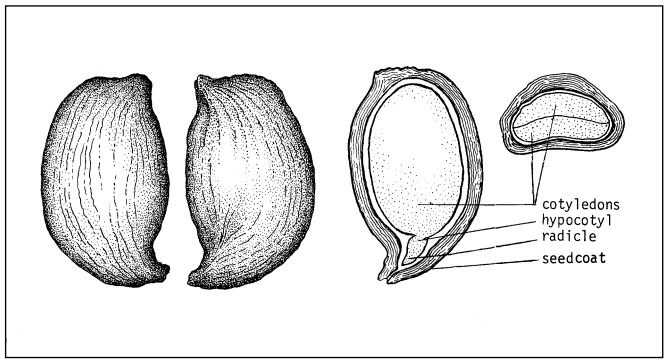

and most of them drop. Purple chokeberry fruits shrivel at the beginning of winter, whereas fruits of red chokeberry remain plump and bright into the winter. Red chokeberry may yield fruit first at 2 years of age (Spinner and Ostrum 1945) and produces good seedcrops almost every year. Black chokeberry yields a good crop about every second year (Gill and Pogge 1974).

Collection of fruits; extraction and storage of seeds. If loss to birds is a hazard, fruits should be handpicked as soon as they ripen. Otherwise, they should be picked within a month or so. The delay should be least with black chokeberries and can be longest with red chokeberry. Fruits of the latter species collected in January and cleaned and sown right away will germinate in 2 weeks (Dirr and Heuser 1987). Commercial seeds usually consist of the dried pomes or "dried berries" as usually listed in seed catalogs. There are about 16,220 dried pomes/kg (7,355/lb) of red choke berry (Swingle 1939). Although seed extraction and cleaning may be impractical on a large scale, small lots of seeds can be extracted by rubbing fresh fruits over screens and floating off the debris. If the fruits have dried, they can be soaked in water until the pulp is soft enough to come off (Mahlstede and Maber 1957). A kitchen blender can be useful for extracting seeds from small lots of several kinds of small berries and other soft fruits, including chokeberries (Morrow and others 1954; Munson 1986). Cleaned seeds per weight average about 564,480/kg (256,000/lb) for red chokeberry and 608,580/kg (276,000/lb) for black chokeberry (Gill and Pogge 1974; Swingle 1939). No data were found on longevity of seeds, but drying before storage is recommended (Chadwick 1935), so they are undoubtedly orthodox in storage behavior.

Pregermination treatments and germination tests. Chokeberry seeds have an internal dormancy that can be overcome by stratification in a moist medium at temperatures of 1 to 5 °C. A higher stratification temperature 10 °C also was effective on seeds of purple chokeberry (Crocker and Barton 1931). Optimum duration of stratification may be 60 to 120 days and varies with the species (table 3).

Table 3—*Aronia,* chokeberry: cold stratification periods, germination test conditions and results

Species	Cold stratification period (days)	Germination test conditions: Temp (°C) Day	Germination test conditions: Temp (°C) Night	Germination test conditions: Days	Germinative capacity: Amount (%)	Germinative capacity: Samples
A. arbutifolia	90	20	20	30	94	4
A. melanocarpa	90–120	30	20	30	22	4
A. x prunifolia	60	20	20	30	96	2

Sources: Crocker and Barton (1931), Gill and Pogge (1974).

There are no official test prescriptions for chokeberries, but tests of stratified seeds can be done on paper or in soil, sand, or peat for 28 days, at diurnally alternating temperatures of 30 (day) and 20 °C (night) or at a constant 20 °C. Gemination starts after about 8 days and may be virtually complete in 20 to 30 days (Crocker and Barton 1931). Germination of seeds stratified as recommended here was mostly in the 90 to 100% range (table 3). Germination of unstratified seed was quite low, 0 to 15%, in tests that extended into a second year (Adams 1927). Germination is epigeal.

Nursery practice. In some nurseries, the dried fruits are soaked in water for a few days and mashed and then the whole mass is stratified until spring. Limiting the stratification period to 60 days for purple, 90 days for red, and 120 days for black chokeberry may increase germination in the nursery. Fall planting is done by some growers (Dirr and Heuser 1987). The recommended sowing depth is about 10 mm ($^1/_3$ in) (Sheat 1948). Germination mostly takes place within a few days after sowing. As a rule of thumb, 0.45 kg (1 lb) of cleaned seed may yield about 10,000 usable plants (Van Dersal 1938). Outplanting may be done with 2-year-old seedlings (Sheat 1948).

Vegetative propagation is possible with red chokeberry (and perhaps the others). Softwood cuttings taken in July and treated with 4,000 ppm of indole-butyric acid solution root very well. Cuttings taken in December or January will root also (Dirr and Heuser 1987). Irrigation of the mother plant a few days before the cuttings are taken will help rooting (Dehgan and others 1989).

A

Asteraceae—Aster family

Artemisia L.

sagebrush

Susan E. Meyer

Dr. Meyer is a research ecologist at the USDA Forest Service's Rocky Mountain Research Station, Shrub Sciences Laboratory, Provo, Utah

Growth habit, occurrence, and use. Sagebrush—*Artemisia* L.—species are probably the most common shrubs in western North America. Big sagebrush alone occupies an estimated 60 million ha as a landscape dominant or codominant in the semiarid interior, and related species of the subgenus Tridentatae are estimated to occupy an additional 50 million ha (Beetle 1960; McArthur and Stevens in press). Sagebrush-dominated vegetation occurs mostly under semiarid climatic regimes characterized by cold winters and predominantly winter precipitation. The genus is circumboreal in distribution and consists of about 400 species of mostly evergreen shrubs, subshrubs, and herbaceous perennials.

The 20 or so shrubby sagebrush species in the United States differ widely in their growth form, ecology, distribution, and abundance (table 1). Big, black, silver, and low sagebrushes are widely distributed, polymorphic species of relatively broad ecological amplitude, whereas most of the remaining species are either more geographically restricted or more specialized in their habitat requirements. The subshrub fringed sagebrush, common and widespread in both the Old and New Worlds, may be the most widely distributed sagebrush taxon. Sand sagebrush is an important species on sandy soils on the Great Plains and in the Southwest, whereas the summer-deciduous subshrub budsage is the principal sagebrush species of salt desert shrub vegetation in the Great Basin.

Because of their status as regional dominants, sagebrush species—especially those of the subgenus *Tridentatae*—have been the object of a great deal of study (McArthur and Welch 1986). Many have long been regarded as undesirable plants by the ranching industry because of their perceived low palatability to livestock and propensity for increase under conditions of abusive grazing. However, they provide a principal source of browse on winter ranges for both wild and domestic ungulates, and undoubtedly are central to the habitat requirements of many other wildlife species.

Most sagebrush species rely on seeds for regeneration and have neither the ability to resprout following burning—with notable exceptions (McArthur and others 2004)—nor a long-lived soil seedbank (Young and Evans 1975, 1989; Meyer 1990). Invasion by exotic annual grasses and the associated increase in fire frequency has resulted in loss of big sagebrush over vast acreages of its former area of dominance (Billings 1990; D'Antonio and Vitousek 1992). This loss has led to a realization of the importance of the shrub overstory for maintaining the integrity of the ecosystem and also to a renewed interest in seed propagation of sagebrush species (Meyer 1994). Sagebrush has been seeded as part of big-game winter-range rehabilitation and mined-land reclamation efforts for over 30 years, so there is a considerable fount of knowledge to draw upon (Plummer and others 1968).

Subspecies and ecotypes. The more complex sagebrush species are made up of series of subspecies that are morphologically and ecologically distinct. In addition, many sagebrush taxa have been shown through common garden studies to be made up of numerous ecotypes that result from adaptation to local conditions through the process of natural selection (McArthur and others 1979). Such site-specific adaptation may be reflected in traits such as frost or drought hardiness, growth rate, competitive ability, flowering time, and seed germination regulation (McArthur and Welch 1982; Meyer and Monsen 1990). This means that the use of seed from locally adapted or at least habitat-matched populations is important to successful long-term restoration of these species.

An alternative to using adaptedness as the principal criterion for ecotype selection has been to identify native germplasms with desirable traits such as high winter-forage-quality for wild ungulates (for example, Welch and others 1986). Their use is recommended in artificial seedings with specific management objectives on sites that fall within their range of adaptation.

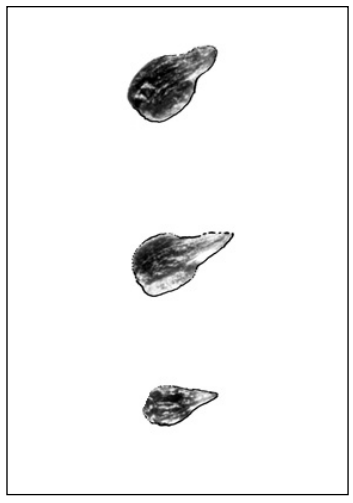
***A. tripartita* Rydb.**	**threetip sagebrush**	Columbia Plateau E into Wyoming	Deep to shallow mostly volcanic soils at low elevations
OTHER SUBGENERA			
***A. filifolia* Torr.**	**sand sagebrush,** old man sagebrush	W Great Plains & SW deserts	Sandy soils at low to middle elevations
***A. frigida* Willd.**	**fringed sagebrush**	W North America to central Asia	Very wide ecological amplitude
***A. spinescens* D.C. Eat.** *Picrothamnus desertorum* Nutt.	**budsage**	Widely distributed, mostly N intermountain region	Semiarid bottoms, benches, & foothills, salt desert shrublands

Flowering and fruiting. Most North American sagebrush species flower in late summer or autumn and ripen fruit from September through December. Seeds of high-elevation populations generally ripen earlier than those of low-elevation populations. Budsage, which flowers in March or April and sets seed in May or June before entering summer dormancy, is a major exception. The tiny yellowish or brownish flowers are wind-pollinated and are borne in groups of about 2 to 70 (depending on species) in small heads enclosed in overlapping bracts with thin, dry margins. The numerous heads are arranged in spikelike or open panicles that occur terminally on the branches of current-season growth. Each fertile floret within a head may develop into a small, 1-seeded fruit (achene) that lacks any special appendages for dispersal (figure 1). The pericarp of the achene is papery and membranous, whereas the seedcoat of the enclosed seed is firmer and somewhat shiny. The endosperm is reduced to a membrane fused to the inner wall of the seedcoat, whereas the embryo is well-developed and fills the interior of the seed. Mucilaginous nerves on

Figure 1—*Artemisia*, sagebrush: achenes (cleaned seeds) of *A. arbuscula*, low sagebrush (**top**); *A. nova*, black sagebrush (**middle**); and *A. tridentata*, big sagebrush (**bottom**).



the exterior of the pericarp may aid in adhesion to the soil surface during radicle penetration (Walton and others 1986). The hypocotyl hairs that develop as a first manifestation of germination have been shown to have a similar function (Young and Martens 1991).

The fruits fall or are shaken from the plant by wind within a few weeks of maturation. The potential yearly seed production of a single plant of big sagebrush is prodigious, on the order of hundreds of thousands of seeds (Welch and others 1990). However, many factors operate to restrict seed production in wildland stands, including excessive browsing (Fairchild 1991; Wagstaff and Welch 1991), intraspecific competition (Fairchild 1991; Young and others 1989), insect and disease attack (Welch and Nelson 1995), and cycles of dry years (Young and others 1989). Sagebrush in field cultivation for seed production yields harvestable crops within 2 years of establishment and generally produces high yields yearly (Welch and others 1990). Wildland stands vary in the consistency and quality of their seedcrops, depending on the factors listed above and also on the taxon under consideration and on site quality factors. An alternative to field cultivation for needed ecotypes that produce minimal numbers of seeds in the wild is management of wildland stands through thinning or protection from browsing to maximize seed production.

Seed collection, cleaning, and storage. Sagebrush seeds (actually, the 1-seeded achenes) are collected by beating or stripping them into shoulder hoppers, baskets, or bags. They are much more easily harvested by beating when dry than wet. Usually there is considerable among-bush variation in ripening date within a population. Harvesting too late may result in a high proportion of half-filled and aborted fruits.

Purity on a dry-weight basis before cleaning is often 10% or less. Passage through a barley de-bearder serves to break up the inflorescences to release the seeds; hammermilling is less desirable, as it tends to make the material ball-up and may damage the seeds (McArthur and others 2004). Screening and fanning can then be used to remove sticks and other debris, resulting in lot purities of 50% or more. This cleaning procedure may strip many of the seeds of their membranous pericarps, but this has no effect on viability or storage life, although it may reduce seed dormancy or light requirement somewhat (Meyer and others 1990; Welch 1995). Sagebrush seeds are not easily damaged in cleaning equipment because of their small size (Welch 1995). Advantages to cleaning to relatively high purities include improved accuracy in quality evaluation; reduced shipping, handling, and storage costs; better regulation of moisture content during storage; and better metered flow through seeding devices (Welch 1995). On the other hand, sagebrush seeds are so small that lots at high purity must be diluted with a carrier in order to achieve realistic seeding rates. Seed size varies substantially among species and also among populations within species (table 2). Seeding rates should take seed size and therefore seed number per unit weight into account.

Sagebrush seeds are not long-lived in warehouse storage. Seedlots commonly hold full viability for 2 or 3 years (Stevens and others 1981). Seedlots of initial low quality lose viability more quickly than high-quality lots. Careful attention to moisture content (6 to 8% is optimal) and storage at relatively low temperatures (<10 °C) can extend storage life to 5 years and possibly longer. Because of late ripening dates, almost all sagebrush seed is held at least 1 year (until the following autumn) before planting.

Germination. We have good information on seed germination patterns for only a few species of sagebrush, but evidence indicates that this information may be broadly applicable to other species (Meyer and Monsen 1991, 1992; Meyer and others 1990). Variation in germination response is generally related to climatic variation at collection sitse rather than to specific or subspecific identity. Timing mechanisms are keyed to a pattern of winter or early spring germination and early spring emergence for all species examined so far. Sagebrush seeds are characterized by relatively low levels of dormancy at dispersal but may be more or less strongly light-requiring or slow to germinate. Both dormancy and light requirement are removed through moist chilling (stratification), so that most seeds become germinable during winter. After-ripening in storage also tends to reduce dormancy or light requirement. In the studies of big sagebrush germination ecophysiology cited above, patterns of variation in dormancy, light requirement, and germination rate were shown to be linked to collection site habitat. Seeds of populations from montane habitats with long, snowy winters tend to be dormant, light-requiring, or slow to germinate at autumn temperatures. These traits protect them from autumn germination, a risk for seeds dispersed in early autumn into relatively mesic environments. Seeds of populations from habitats with short, mild winters and hot, dry springs are dispersed later. They tend to be nondormant, not light-requiring, and quick to germinate, which facilitates germination during winter, when conditions are most favorable on warm desert fringe sites.

Germination under winter snowcover conditions is also keyed to habitat. Seeds of montane populations may take 20 weeks or more to germinate under conditions simulating

snowcover in the field, whereas those of warm desert fringe populations may do so in as little as 1 week. Seeds of montane populations can also sense and respond with increased germination rates to the shift from dark to light in the cold that results from thinning snow cover in the early spring. These habitat-correlated patterns apparently hold for black, silver, and low sagebrushes as well as for big sagebrush, based on preliminary data (table 3). Germination under snowcover seems to be a common pattern for sagebrush, ensuring emergence in very early spring just as the snow is melting (Meyer 1990; Meyer and Monsen 1990; Monsen and Meyer 1990).

Most big sagebrush seeds germinate during the winter and spring following the autumn of their production. They have no apparent mechanisms for seed bank carryover from year to year, and studies on *in situ* seed banks have failed to detect any substantial carryover (Young and Evans 1975, 1989). The tiny fraction of seeds that sometimes carries over (Hassan and West 1986) is probably made up of buried seeds whose light requirement has not yet been overcome because of inadequate chilling (Meyer and others 1990).

The observation that sagebrush seeds germinate over a broad range of temperatures (see for example, Bai and Romo 1994; McDonough and Harniss 1974; Weldon and

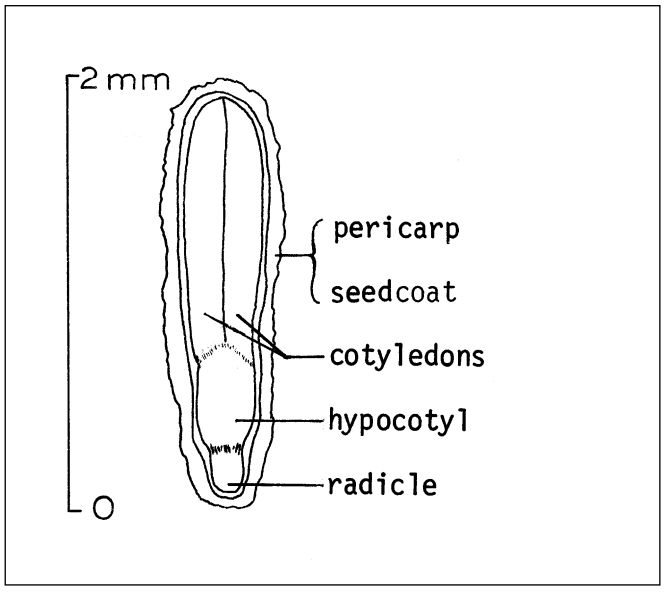
others 1959; Wilson 1982) probably stems from the fact that sagebrush seeds have no need for protection from germination at summer temperature, as they almost never encounter summer regimes. Budsage, a species with seeds that ripen in early summer but do not germinate until the following early spring, shows strong germination suppression at summer temperatures (Meyer and Kitchen 1997).

Germination testing for sagebrush species is a relatively straightforward process. We recommend a 21-day test at 15 or 20 °C with light as the standard for big sagebrush and black sagebrush, with a 2-week chill (stratification) for more dormant lots (AOSA 1993; Meyer and others 1988a, 1988b). Because many dormant sagebrush seeds will not germinate in response to a short chilling, the viability of ungerminated seeds should be evaluated with tetrazolium.

Tetrazolium staining also represents an alternative to the germination test for evaluating the viability of sagebrush seeds. The fruits are pierced with a needle through the center of the cotyledon region of the embryo (figure 2) and immersed in buffered 1% tetrazolium chloride solution for 6 hours at 25 °C. The pericarp and seedcoat are then slit with a needle at the cotyledon end, and the embryos are squeezed out. Embryos stained a uniform bright red may be classed as viable.

The principal source of inconsistent results in sagebrush seed testing comes from decisions made during the purity evaluation. The inclusion of non-viable half-filled and aborted fruits in the pure seed fraction has little effect on the value for percentage purity but can affect the viability percentage considerably. In research, we routinely exclude such fruits and only occasionally encounter recently collected or properly stored lots whose viability is less than 90%. The seed analyst has a more difficult problem and we hope that the advent of better cleaning procedures for sagebrush seeds will help to make these difficulties unnecessary.

Figure 2—*Artemisia nova*, black sagebrush: longitudinal section through an achene.



Nursery and field practice. Many species of sagebrush have been successfully grown both as container and as bareroot stock (Long 1986; McArthur and others 2004; Welch and others 1986). In addition, the practice of transplanting wildlings has been particularly successful with sagebrush (McArthur and others 2004). Planting is best carried out in early spring, when moisture conditions are favorable. Container stock requires careful hardening (Long 1986).

Sagebrush species are among the few native shrubs that can be reliably established by direct seeding. Seedling recruitment is regularly observed on small-scale disturbances in wildland stands where competition from adult plants and from weedy understory species is not too severe. Artificial seeding should mimic natural processes of dispersal. Seeding in late fall or onto snow in winter is most successful; spring-seeding is not recommended. Seeding rates that result in an average of 50 to 100 seeds/m^2 (5 to 9/ft^2) usually result in adequate stands. This corresponds to a rate of 0.1 to 0.2 kg/ha (1.5 to 3 oz/ac) on a pure live seed (PLS) basis for a lot that averages 4 million seeds/kg (113,400/oz). The seeds should be planted at or near the surface of a firm but not compacted seedbed. Because of their small size, drilling or broadcasting seeds into a loose, sloughing seedbed may bury them too deeply for successful emergence (Jacobsen and Welch 1987; Monsen and Meyer 1990).

Sagebrush plants are generally quite long-lived, and successful recruitment from seeds every year is not necessary for perpetuation of the stand. On drier sites, winter snowfall may be inadequate for successful emergence and establishment in a typical year, especially on the bare, windswept surfaces of artificial seedings. Small-scale use of snow-fencing has been shown to enhance sagebrush stand establishment under such marginal conditions (Monsen and others 1992). Once nuclear stands are established, the shrubs themselves may act as both seed sources and living snow entrapment structures. It is common to see newly establishing seedlings spread out on the leeward side of an adult plant, where drifting snow accumulates.

Sagebrush species have been successfully seeded onto drastic disturbance sites such as mine- waste rock dumps, but adding topsoil (even minimally) often greatly enhances

success, perhaps through re-inoculation with essential symbionts such as mycorrhizae (Monsen and Richardson 1984). Fertilization per se usually favors herbaceous competitors over the shrub seedlings and is not generally recommended.

Reports on seedling competitiveness in sagebrush are somewhat contradictory. In the era of sagebrush control on rangelands, managers often remarked on the ability of sagebrush to reestablish in perennial forage grass plantings (Pechanec and others 1944). Follow-up moisture in the summer appears to facilitate shrub seedling survival in competition with perennial grasses. Success in mixed seedings may be enhanced by separating the seeds spatially, for example, in separate drop boxes on the seeding implement, or by interseeding into scalps (McArthur and others 2004).

Sagebrush seedings in the presence of strong exotic annual grass competition have almost universally been failures (Monsen 1995). It may be that, in order to restore big sagebrush–bunchgrass communities on many sites now dominated by exotic annuals like cheatgrass (*Bromus tectorum* L.) and medusahead (*Taeniatherum caput-medusae* (L.) Nevski), seeding and establishment of the native perennial understory is a necessary prerequisite to successful establishment of sagebrush. More-expensive weed-control measures are often not an option on the large acreages involved.

Annonaceae—Custard-apple family

Asimina Adans.

pawpaw

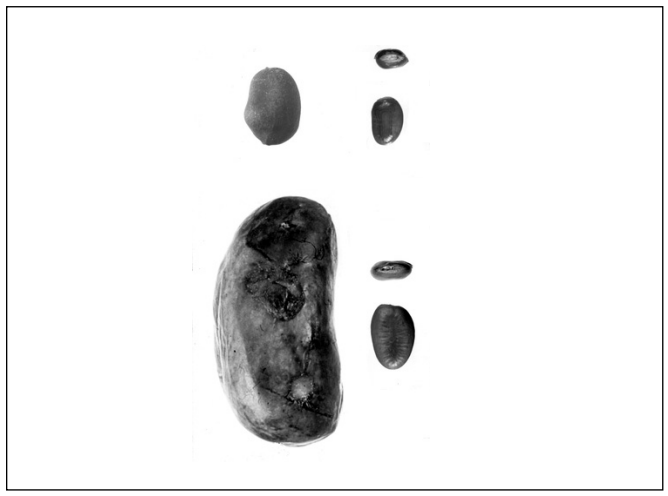
Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Growth habit and use. Of the 9 species of the genus *Asimina*, seed data are available only for small-flower pawpaw and pawpaw (table 1). Both form shrubs or small deciduous trees (Vines 1960). Their fruits provide food for wildlife and are also eaten by humans. There is some interest in commercial fruit production of pawpaw, and cultivar selections have been made since the early part of the century (Peterson 1990).

Flowering and fruiting. Flowers of the pawpaw genus are solitary, perfect, and greenish purple. They appear in the spring during March to May, about the same time as the leaves. In natural stands of pawpaw, pollination and seed set are very poor (Norman and others 1992; Willson and Schemske 1980), conditions that discourage commercial productions. In central Illinois, pawpaw averaged 3.5 to 10.5 seeds/fruit (Willson and Schemeske 1980). Pawpaw fruits are 5 to 17 cm long, whereas those of small-flower pawpaw are 5 to 12 cm long (Halls 1973). Pawpaw fruits are greenish yellow before maturity and turn brown to black as they ripen in July to August and fall to the ground in August and September. Seeds of small-flower pawpaw mature while the fruit coat is still green (Norman and others 1992). The fruits are fleshy berries that contain several dark brown, shiny seeds (figure 1). The fleshy part of the fruit is considered edible, but there appear to be 2 different fruit types. Those with white flesh are barely edible, whereas others are larger and have a yellowish or orange flesh with a much better taste (Bonner and Halls 1974). The seeds themselves are oblong, rounded, flat, and bony (figures 1 and 2).

Figure 1— *Asimina*, pawpaw: fruits and seeds of *A. parviflora*, small-flower pawpaw (**top**) and *A. triloba*, pawpaw (**bottom**).



Collection and extraction. Pawpaw fruits should be picked or shaken from the trees as soon as the flesh is soft. The seeds may be extracted by macerating the fruits in water and floating off the pulp, but the entire fruit may be sown (Bonner and Halls 1974). Seed yield, purity, and

Table 1— *Asmina,* pawpaw: nomenclature, occurrence, and size

***A. triloba* (L.) Dunal**	**pawpaw,** custard-apple common pawpaw	Texas & Arkansas E to Florida; N to New York, Michigan, & Nebraska	12

Source: Vines (1960).

soundness are as follows (Bonner and Halls 1974; Vines 1960):

	small-flower pawpaw	pawpaw
Cleaned seeds/wt	2,860/kg (1,300/lb)	1,540/kg per (700/lb)
Purity (%)	98	100
Sound seeds (%)	94	96

There is no storage information available on these species.

Germination. Germination is usually very slow because seeds have dormant embryos, and seedcoats are slowly permeable. Moist stratification for 60 days at 5 °C resulted in germination of 50, 62, and 82% for 3 samples of pawpaw seeds (Bonner and Halls 1974). Stratification for 100 days has been recommended, but germination still may be slow and irregular. Fall-sowing of untreated seeds does not improve results (Bonner and Halls 1974). No specific test conditions have been reported, but alternating temperatures of 20 °C during the day and 30 °C at night on a moist medium have been satisfactory for most species of the northern temperate zone.

Nursery practice. Pawpaw seeds may be sown in the fall without pretreatment, or stratified and sown in the spring. Seeds should be covered about 20 mm ($^3/_4$ in) deep. Some shade is helpful to germinating seedlings (figure 3). Another method is to plant fresh seeds, before they dry, in pots of sand and then to keep them in a cool cellar or similar place. As the seeds sprout, they can be picked out and transplanted into nursery beds. Pawpaws can also be propagated by layering and root cuttings (Bonner and Halls 1974) but apparently not by stem cuttings (Dirr and Heuser 1987).

Figure 2—*Asimina parviflora*, small-flower pawpaw: longitudinal section through a seed.

Chenopodiaceae—Goosefoot family

Atriplex L.

saltbush

Susan E. Meyer

Dr. Meyer is a research plant ecologist at the USDA Forest Service's Rocky Mountain Research Station, Shrub Sciences Laboratory, Provo, Utah

Growth habit, occurrence, and use. The genus *Atriplex* L.—saltbush—is cosmopolitan in distribution and comprises about 250 species of annual and perennial herbs, subshrubs, and shrubs (McArthur and Sanderson 1984). Most species are halophytic (at least to some degree) and occupy salt desert, coastal strand, or saltmarsh habitats. Shrubby species are important in arid and semiarid regions throughout the world, with centers of diversity in south central Asia, Australia, temperate South America, and western North America. Western North America is an area of particularly high genetic diversity, with more than 20 principal species of shrubs and subshrubs as well as countless hybrids and variants; 12 of these species are described here (table 1). The genus is in a state of active evolution in the Intermountain region (Stutz 1978, 1984). The drying up of Pleistocene lakes 10,000 or so years ago opened up vast areas of unexploited salt-desert habitat. Shrubby saltbush species migrated in rapidly from several directions and hybridized freely, giving rise to the rich complex of forms in the region today.

In terms of areal extent, the most important species are probably shadscale and Gardner saltbushes (Blauer and others 1976). These species are regional dominants over millions of hectares in the Intermountain and northwestern Great Plains regions, respectively. Shadscale saltbush mostly occurs with winterfat (*Krascheninnikovia lanata* (Pursh) Guldenstaedt.); budsage (*Artemesia spinescens* D.C. Eaton); and other salt-desert shrubs, whereas Gardner saltbush is able to maintain codominance with perennial grasses (Stutz 1978). In the Mojave Desert, desert-holly is an upland landscape dominant, particularly in the Death Valley region, whereas allscale saltbush is a dominant species on playa fringes. Fourwing saltbush is the most widely distributed shrubby saltbush in North America and is often an important component of grassland communities, especially in the Chihuahuan Desert and western Great Plains. Sickle and basin saltbushes are inconspicuous but common components of northern Intermountain salt-desert vegetation.

Shrubby saltbush species are extremely important as forage plants for livestock and wildlife in arid and semiarid regions worldwide (Goodall 1982). They provide palatable and nutritious feed on a year-round basis and are especially important on winter ranges. As a consequence, they have been studied and used in range rehabilitation far more extensively than most other shrubs (Jones 1970; McArthur and Monsen in press; Osmond and others 1980; Tiedemann and others 1984). There is also considerable interest in utilizing saltbush species as irrigated forage crops on marginal, salinized agricultural land (Glenn and others 1992; Watson and O'Leary 1993). Some shrubby saltbush species are also used extensively for the stabilization of drastically disturbed land because of their ability to establish and grow on harsh sites.

Geographic races and hybrids. An important feature of infraspecific variation in many saltbush species is the presence of series of races at different ploidy levels (Sanderson and others 1990; Stutz 1978; Stutz and Sanderson 1979). Polyploid races often show dwarfing and adaptation to extremely harsh environments. The tendency to evolve polyploid races has also been important in facilitating the formation and stabilization of interspecific hybrids. Saltbush species possess a wealth of genetic variability, both within and among ploidy levels for numerous traits that may be important for survival both of local populations in nature and of the products of artificial seedings. Hybrid forms, even those that have not yet formed stabilized populations in nature, may possess attributes that make them useful in specific disturbed land rehabilitation applications (Stutz 1995).

Common garden studies with fourwing saltbush have demonstrated ecotypic variation in growth form, growth rate, winter-greenness, drought and cold hardiness, palatability, nutrient status, seed size, and seed germination and establishment traits (McArthur and others 1983; Springfield 1970; Van Epps 1975; Welch and Monsen 1981, 1984). It is

Scientific name	Common name(s)	Geographic distribution	Ecology
***A. canescens* (Pursh) Nutt.**	**fourwing saltbush,** chamisa	Widely distributed in W North America	Wide ecological amplitude; mostly in sandy uplands & gravelly washes
***A. confertifolia* (Torr. & Frem.) S. Wats.**	**shadscale saltbush,** spiny saltbush, sheepfat	Widely distributed in W North America	Wide ecological amplitude; mostly on silt or clay soils of low to moderate salinity
***A. corrugata* S. Wats.**	**mat saltbush**	Colorado Plateau N to Red Desert of Wyoming	Restricted to heavy saline clays on shale outcrops
***A. cuneata* A. Nels.**	**Castle Valley saltbush**	Colorado Plateau	Restricted to heavy saline clays on shale outcrops
***A. falcata* (M.E. Jones) Standl.**	**sickle saltbush,** falcate saltbush, Nuttall saltbush	N Great Basin	Subsaline soils of benches & alluvial fans
***A. gardneri* (Moq.) D. Dietr.**	**Gardner saltbush**	NW Great Plains, Wyoming, & Montana	Mostly on saline or subsaline clay soils
***A. hymenelytra* (Torr.) S. Wats.**	**desert-holly**	Mojave Desert	Clay flats & gravelly fans under extreme aridity
***A. lentiformis* (Torr.) S. Wats.**	**big saltbush,** quailbush, lensscale	Mojave Desert; cismontane & coastal California	Mostly around saline springs & seeps
***A. obovata* Moq.**	**mound saltbush,** broadscale saltbush	Chihuahuan Desert	Saline flats
***A. polycarpa* (Torr.) S. Wats.**	**allscale saltbush,** cattle saltbush, desert saltbush	Mojave Desert; Central Valley of California	Saline & subsaline slopes & flats
***A. semibaccata* R. Br.**	**Australian saltbush,** trailing saltbush	Introduced from Australia	Along roadsides & in saline disturbances
***A. tridentata* Kuntze**	**basin saltbush,** trident saltbush	NE Great Basin, & Uinta Basin of Utah	Saline flats

likely that other widely distributed saltbush species possess similar ecotypic differentiation. Many researchers who have studied saltbush establishment from artificial seedings emphasize the importance of using not just adapted species, but locally adapted ecotypes of these species (Bleak and others 1965; McArthur and others 2004; Nord and others 1971; Plummer and others 1968; Springfield 1970).

Cultivar development for saltbush has also emphasized ecotypic adaptation. The 3 released cultivars of fourwing saltbush were developed for warm winter ('Marana'), intermountain cold desert ('Rincon'), and northwestern Great Plains ('Wytana') planting applications (Carlson 1984). 'Wytana' was developed from a fourwing saltbush × Gardner saltbush hybrid entity known as *Atriplex aptera* A. Nels.

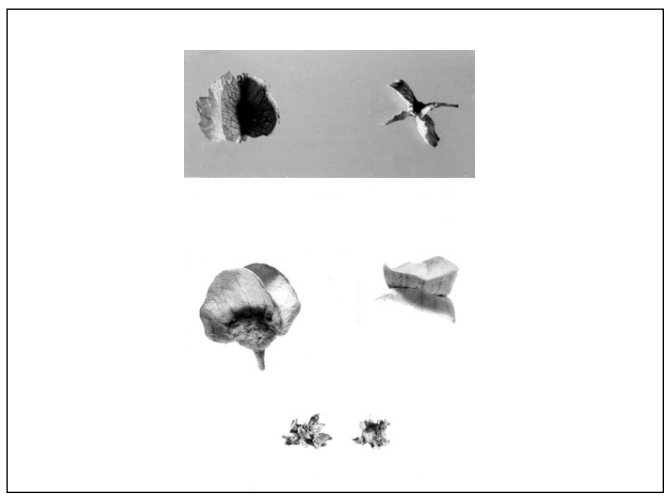
Flowering and fruiting. The flowers of saltbush are yellowish or brownish, inconspicuous, and unisexual, and are borne in the axils of the upper leaves or in terminal spikes. The male flowers consist of groups of stamens within a shallow 5-toothed calyx; petals are absent. Both petals and calyx are absent in the female flowers. The naked 1-seeded ovary is borne instead between 2 leaflike bracteoles.

Most native shrubby saltbush species are dioecious, that is, the sexes are borne on separate plants. Fourwing saltbush possesses a unique gender system known as trioecy, with genetically male plants, genetically female plants, and a third category that can switch sexes depending on environmental conditions (McArthur and others 1992). Australian saltbush is monoecious, that is, the flowers are unisexual and both sexes are present on the same plant.

Saltbush species flower in early to late summer, and fruits ripen from early fall to winter. The flowers are wind-pollinated. The leaflike bracteoles stay green and photosynthetically active until quite late in the ripening process and probably provide resources directly to the ripening ovule within. The fruits often persist on the bushes at least until spring, and it is not uncommon to find 2 generations of fruits on a plant simultaneously. Harvestable seedcrops of fourwing saltbush are produced on average 3 of every 5 years, whereas some of the more xerophytic species, such as mat saltbush, produce good seedcrops only occasionally.

The terminology describing the fruits of saltbush has been a source of confusion. The family Chenopodiaceae as a whole is characterized by a fruit type known as a utricle, which is defined as a small, bladdery 1-seeded fruit with a thin, membranous pericarp (Munz 1974). The utricle in saltbush is contained within the bracteoles, which enlarge in size and become more or less sealed, forming a false-fruit, which will hereafter be referred to simply as "the fruit"

Figure 1—*Atriplex*, saltbush: bract-enclosed utricles ("fruits") of; *A. canescens*, fourwing saltbush (**top**), *A. confertifolia*, shadscale saltbush (**middle**); and *A. falcata*, sickle saltbush (**bottom**).



(figure 1). The bracteoles are not fused to the utricle, but in native species they usually enclose it so completely that threshing is not possible. In Australian saltbush, the bracteoles are not fused across the top and the utricles may be threshed free (figure 2) (Foiles 1974).

The saltbush seed itself is contained within the utricle and is generally not separable from it (figure 3). The disk-shaped seed has a curved embryo on its outer perimeter and a scanty provision of storage tissue (in this case perisperm) in the center. In most native species, the ovule (and thus the seed) is inverted within the fruit, meaning that the radicle end points upward. This facilitates radicle emergence from between the bracteoles, which often have their only opening or weakest point at the tip. The degree of woody thickening of the bracteole walls varies among and within species and may be linked to the persistent seed dormancy often encountered.

Seed collection, cleaning and storage. Saltbush seeds are harvested by stripping or beating the ripe fruits into shoulder hoppers, boxes, or bags, or onto tarps spread under the bushes. Vacuum or reel-type harvesters may also be used (McArthur and others 2004). In field cultivation, 'Wytana' fourwing and Gardner saltbushes have been cut and windrowed with a hay-swather and then combine-harvested. Seeds shattered during combining were salvaged using a vacuum harvester (Carlson and others 1984).

Seed collections of fourwing and shadscale saltbushes are commonly hammermilled to remove the bracteole wings (McArthur and others 2004). This reduces bulk by half and facilitates cleaning, handling, and seeding through conventional drills. Hammermilling has little effect on dormancy of

A

Figure 2—*Atriplex semibaccata*, Australian saltbush: bract-enclosed utricle

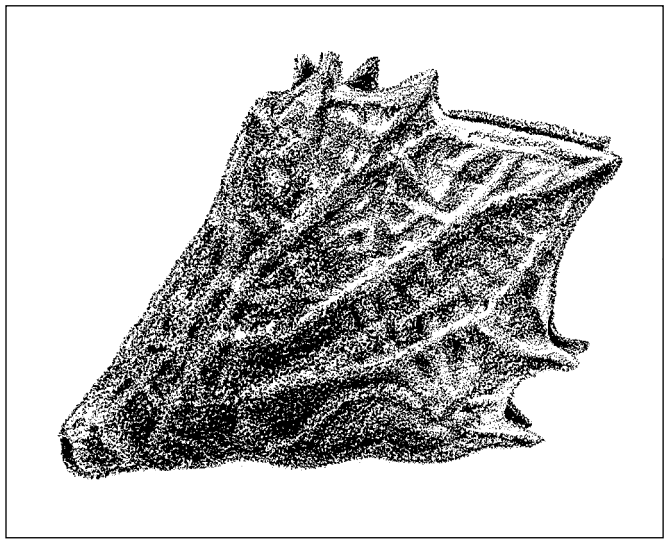


Figure 3—*Atriplex semibaccata*, Australian saltbush: exterior views in 2 planes of utricles removed from their bracts and a longitudinal section through a utricle.

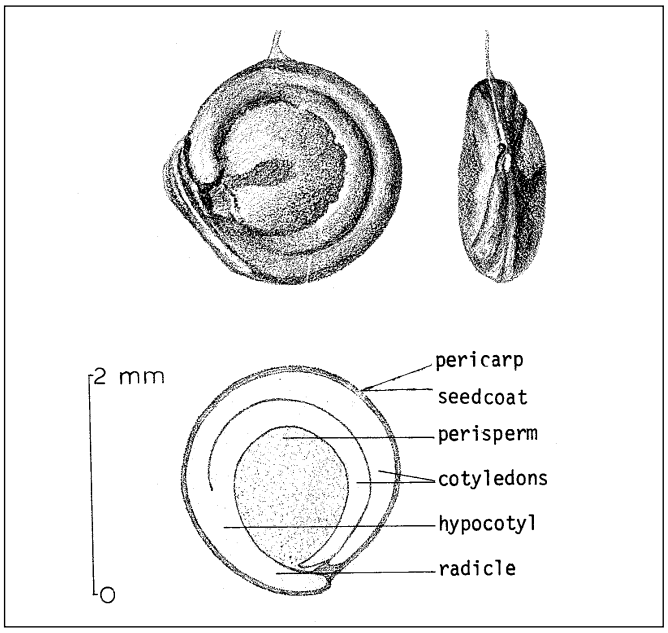

fourwing saltbush but may speed the germination of nondormant seeds somewhat (Gerard 1978; Springfield 1970). Collections of wingless small-fruited species such as Gardner, sickle, and mat saltbushes do not require hammermilling. Seed collections of all species may be cleaned by screening and blowing in a fanning mill (McArthur and others 2004).

Even relatively high-quality seedlots of saltbush may average only 50% fill. A cut test to determine fill is often carried out before harvest. Fills of 40% or less are usually considered substandard. Such a seedlot would not normally be worth the expense of harvesting, cleaning, and transporting. Field-grown saltbush seedlots often have higher fill than wild-collected lots (Briggs 1984; Carlson and others 1984; McArthur and others 1978; Stroh and Thornberg 1969). Most of the weight of a saltbush fruit is in the bracteole walls, even after de-winging. Filled and unfilled fruits thus have similar density, making it impossible to remove unfilled fruits by fanning. Also, the variation in fruit size within a lot is not highly correlated with fill, so that screening to improve fill is not feasible.

Fruit size varies considerably among and within lots, especially for fourwing and shadscale saltbushes (table 2). Polyploid races often have smaller fruits. This variation in fruit size makes it essential to explicitly consider number of fruits per unit weight as well as fill percentage when planning seeding rates.

Seeds of most saltbush species are long-lived in dry storage and can be stored in an open warehouse for at least 5 to 10 years with little or no loss of viability (Springfield 1970; Stevens and others 1981). Controlled storage presents little advantage over open warehouse storage for these species. Attack by seed-destroying insects such as dermestid beetles (*Dermestes* spp.) during storage has been reported (Haws and others 1984)

Germination. Seeds of saltbush species as a group are characterized by high levels of dormancy and complex multiple dormancy mechanisms. The most universal characteristic seems to be the tendency to lose dormancy, or after-ripen, under dry conditions. For less-dormant species and lots this is manifested as an increase through time in the fraction of seeds germinable without pretreatment, or in the fraction of seeds able to germinate under non-optimum conditions, for example, osmotic stress. For more dormant species, after-ripening is manifested as an increase through time in storage in the response to dormancy-breaking treatments such as chilling (table 3).

In general, species and populations from warm desert and California cis-montane habitats produce seeds that are relatively nondormant, after-ripen quickly, and do not require chilling (Cornelius and Hylton 1969; Edgar and Springfield 1977; Kay and others 1977a&b; Mikhiel and others 1992; Springfield 1970; Warren and Kay 1984; Young and others 1980) (tables 1 and 3). Seeds of species and populations from cold desert, foothill, and northern plains habitats often require chilling for germination even after an after-ripening period (Ansley and Abernethy 1985; Meyer and others 1998) (tables 1 and 3). Shadscale saltbush seeds

Note: Germination period is 28 days and germination is expressed as percentage of filled fruits, except for *A. gardneri* data, where germination is 14 days, and for *A. lentiformis* and *A. semibaccata* data, where germination is expressed as percentage of total fruits.

rarely become germinable without chilling, regardless of their habitat of origin (Mikhiel and others 1992) (table 3).

Other treatments that have sometimes been found to remove dormancy include scarification and leaching (Ansley and Abernethy 1985; Graves and others 1975; Nord and Whitacre 1957; Sabo and others 1979; Twitchell 1955; Young and others 1980). Scarification apparently acts by weakening the bracteole walls. Actual rupture of the membranous utricle wall is usually damaging to the seed (Sabo and others 1979). After-ripening may also act on the bracteole walls, as evidenced by work with a seedlot of the South American species *A. repanda* Phil., for which optimum time for sulfuric acid scarification decreased from 7 to 2 hours during 5 years in dry storage (Fernandez 1978). The bracte-

ole walls may also be weakened by the action of saprophytic fungi under field conditions (Vest 1952). Hand-removal of the bracteoles promotes increased germination in many species but does not necessarily remove dormancy completely, suggesting that either the utricle wall or the testa interacts with the embryo to impose dormancy even in excised fruits. The failure of excised fruits to germinate suggests a chilling requirement. Sanderson and others (1990) found that excised fruits of warm-winter populations of shadscale saltbush were more likely to germinate without chilling than those of cold winter populations.

Leaching probably promotes germination by removing some inhibitor from the fruit, either inorganic salts such as sodium chloride (Beadle 1952) or an organic inhibitor such as saponin (Nord and Van Atta 1960). It is important to remove excess water after soaking, as germination can be inhibited by inadequate aeration (Beadle 1952; Young and others 1980). Rates of leaching under field conditions are probably controlled by the osmotic potential of the seedbed. In the highly saline litter underneath bushes of many species, the salts in the bracteole walls would make only a minor contribution.

The complex dormancy mechanisms shown by many saltbush species function both to time germination appropriately within a given year and to ensure carryover of a persistent seedbank between years (Garvin and others 1996). Seed pretreatments to circumvent these mechanisms have limited application in field plantings but may be useful in seed quality evaluation and in nursery propagation.

Seed quality evaluation in saltbush is complicated by dormancy problems. Seedlots are usually cleaned to high purity, making the purity analysis quite simple. For fourwing saltbush, we proposed a 21-day germination test at 15 °C, a recommendation that was subsequently accepted as the official testing procedure (Meyer and others 1986). The most important determinant of viability is the fill percentage, that is, the proportion of fruits that contain an undamaged seed with a well-developed embryo. Post-test viability determination is essential in fourwing saltbush. Germination percentage may vary as a function of after-ripening status, or the test temperature may not be optimum for a particular lot. Post-test evaluation is even more essential for species of saltbush with less-known germination requirements.

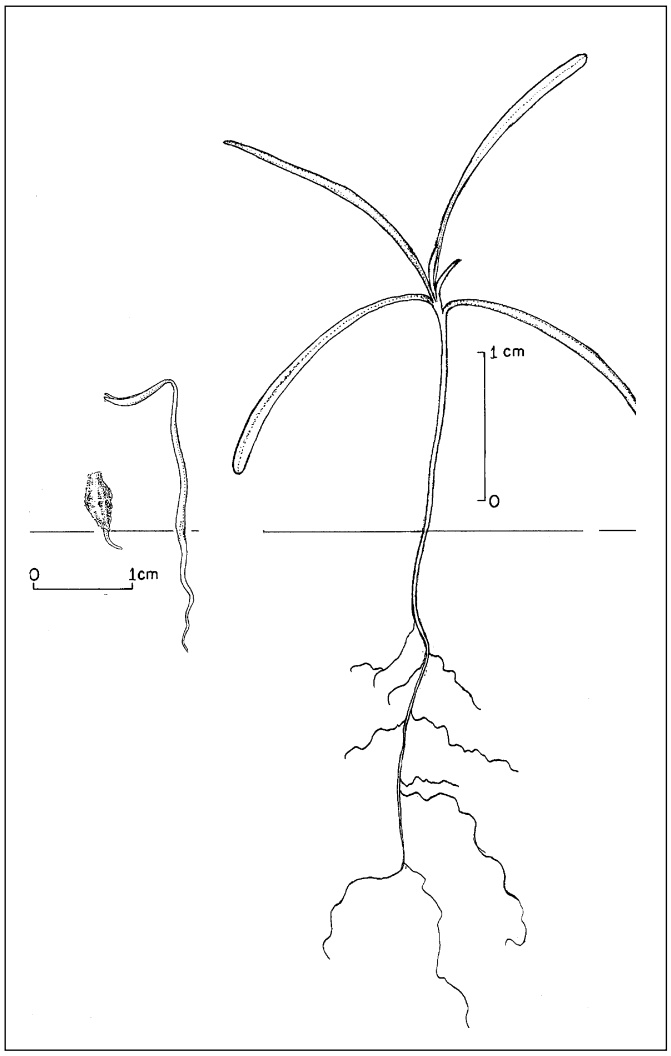
In practice, few seedlots of saltbush are evaluated using a germination test. Because of dormancy problems, the tetrazolium test has become the standard method. The general method is to soak the intact (bracteoled) fruit for several hours or overnight and extract the utricle by either prying open the bracts, clipping at the stem end, or off-center longitudinal bisection (Belcher 1985). The utricles are then pierced in the center and placed in 1% tetrazolium solution for several hours, and the staining patterns on the linear embryos are evaluated. Saltbush seed quality is somewhat difficult to evaluate using tetrazolium. Staining is often weak and incomplete for embryos that are germinable, resulting in viability estimates that tend to be low (Ansley and Abernethy 1984; Springfield 1970).

Nursery and field practice. Saltbush species have been successfully propagated in the nursery, both as container stock (Ferguson 1980) and as bareroot stock (Shaw and Monsen 1984). Most of the information available is for fourwing saltbush, but it is probably broadly applicable to other species. Propagation may be from seeds or from stem cuttings (McArthur and others 1984; Richardson and others 1979). The latter are advantageous for obtaining clonal material of known sex for the establishment of seed orchards with optimal sex ratios (McArthur and others 1978). When high-quality seedlings of an adapted ecotype are outplanted during periods of optimal moisture, survival can be high (Foiles 1974; McArthur and others 2004). Wildlings of fourwing saltbush have also been used as transplant stock.

Saltbush species may also be direct-seeded successfully, although results have been inconsistent (McArthur and others 2004). Pitfalls include poor choice of species or ecotypes; using poor-quality seeds (low fill); planting too deep; planting at the wrong season; excessive competition from weeds or seeded grasses; interactions with pathogenic fungi such as damping-off diseases; and seedling predation by grasshoppers, rabbits, or other animals. Fourwing saltbush fruits are apparently not particularly attractive to granivorous rodents (Everett and others 1978), possibly because of the saponin content of the bracts (Sanderson and others 1986), so pre-emergence seeds predation is rarely a problem. Seeding rates of 4 to 8 kg/ha (3.5 to 7 lb/ac) have been recommended for de-winged lots of fourwing saltbush. This corresponds to about 200 to 530 live seeds/m^2 (25 to 50/ft^2) for a seedlot of average fruit size (122,000/kg) and fill (50%). In regions of low and unpredictable precipitation, saltbush seedlings may fail to emerge or survive in dry years even when all planting guidelines are followed. As annual recruitment is not necessary for the perpetuation of natural stands, this poses a problem only in artificial revegetation. Once seedlings establish, however, young plants grow rapidly (figure 4) and may become reproductively mature in their second growing season.

The large fruits may create the impression that saltbush should be drill-seeded at considerable depth, but seed reserves are small, as bracteole tissue is not nutritive. Most

Figure 4—*Atriplex canescens*, fourwing saltbush: seedling development at 1 and 2 days after germination, and at a later time.



authors recommend drilling at depths of 0.5 to 1 cm. Broadcast seeding followed by chaining has produced good stands of fourwing saltbush (Plummer and others 1966). Most species probably need shallow coverage. Young and others (1980) reported that surface seeding prevented emergence of quailbush and reduced that of Australian saltbush by half, even under conditions of unlimited moisture.

Optimal season for planting varies according to precipitation patterns. In winter precipitation zones such as the Intermountain area and the Mojave Desert, fall or early winter planting has been most successful (Kay and others 1977a&b; McArthur and others 2004; Plummer and others 1968). In summer precipitation zones such as the southern Great Plains and Chihuahuan Desert, spring and midsummer plantings are more likely to succeed (Springfield 1970). Northern Great Plains species with a chill requirement, such as Gardner saltbush, are probably best fall-seeded, whereas fourwing saltbush could be fall- or spring-seeded in the northern Great Plains area.

The expectation that highly dormant seedlots will emerge during the first year after planting is possibly the major source of disappointment in saltbush seedings. Knowledge of after-ripening patterns in the genus suggests that the best way to circumvent this problem is to use seedlots that have been given ample opportunity to after-ripen in dry storage prior to planting.

Asteraceae—Aster family

Baccharis L.
baccharis

Robert P. Karrfalt and David F. Olson, Jr.

Mr. Karrfalt is director of the USDA Forest Service's National Seed Laboratory, Dry Branch, Georgia; Dr. Olson retired from the USDA Forest Service's Southeastern Forest Experiment Station

Growth habit, occurrence, and use. The genus *Baccharis* is composed of more than 400 species native to tropical and subtropical America (Barkley 1986; Correl and Johnson 1970). Some species are used as ornamentals, some for erosion control, and some for medicinal purposes (Olson 1974). There are 21 species native to the United States (table 1); 14 of which are found in the far western United States. Baccharis plants are of poor forage value and some are poisonous to livestock and can cause contact dermatitis in humans. On the positive side, baccharis species have metabolites that have antitumor, antimicrobial, and insecticidal properties (Kuti and others 1990). Coyotebrush has a special use in southern California as a fire protection plant (Olson 1974). Desertbroom has been found suitable for copper mine reclamation in Arizona (Day and Ludeke 1980). Eastern baccharis is reported to be an important flower for beekeepers in Queensland, Australia (Westman and others 1975). Many species have good salt tolerance, and saltwater falsewillow and eastern baccharis are known for good growth in soil conditions that range from pure sand to pure clay (Dirr and Heuser 1987).

Growth habit varies considerably among the different species; a few examples follow. Saltwater falsewillow is a small evergreen shrub to 2.4 m high; eastern baccharis is deciduous to 3.6 m in height; Rooseveltweed is also deciduous, growing to 2.7 m or more; coyotebrush is a low evergreen shrub, 15 to 30 cm high, spreading out as much as 3 m; mulefat baccharis is an evergreen shrub to 3.6 m (LHBH 1976). Desertbroom is a shrub to 3.6 m (Sundberg 1993).

Flowering and fruiting. The white or yellowish male and female flowers, borne separately on different plants, are in heads that occur in clusters. In eastern baccharis, the male flowers are yellow and the female are white (Westman and others 1975). The female flowers develop into compressed, usually 10-ribbed achenes, tipped by a pappus of bristly hairs 13 mm long or less (figures 1 and 2). Achenes are dispersed by wind soon after ripening (table 2). Seedcrops are borne annually.

Quantities of seeds produced on an individual plant can be very high in full sunlight. A single plant of eastern baccharis has been estimated to produce over 1 million seeds (Westman and others 1975). Dense shade (3% of full sunlight) reduced seed production dramatically but did not totally eliminate it (Westman and others 1975).

Collection of fruits; extraction and storage of seeds. The ripe fruits of baccharis are either collected by hand or brushed onto cloth or plastic sheets spread beneath the shrubs. The fruits should be spread out to dry in a warm well-ventilated room or in the sun, protected from the wind. When dried, the fruits may be rubbed between the hands or treated in bulk to remove the pappus. Alternatively, full inflorescences can be fed into a brush machine, where the fruit is threshed from the stems and the pappus removed. The seeds can then be cleaned with air, screens, or other equipment described in the seed handling chapter. Sometimes the entire fruits are used without removing the pappus. The number of fruits per weight for coyotebrush is about 180,800/kg (82,000/lb) (1 sample); for mulefat baccharis, about 110,250/kg (50,000/lb) (1 sample) (Olson 1974). Cleaned seeds of baccharis species can be stored dry at 1.7 to 4.5 °C in airtight containers (McBride 1964). Data published by Westman and others (1975) indicate that seeds of eastern baccharis could be stored for 1 to 4 months at room temperature. After 4 months of room temperature storage, the final germination was actually slightly higher than with seeds stored for only 1 month. Panetta (1979) found that seeds stored in an atmosphere of 33% relative humidity maintained their germination of 98% for 12 months at 20 °C but that their percentage germination had dropped to 67% by 24 months. For seeds stored in the laboratory in a constant 70% relative humidity, germination began to drop at 6

Sources: BONAP (1996), Olson (1974).

months. By contrast, seeds buried in the soil in the field at a depth of 5 cm maintained their germination rate at 99% for 2 years. Numbers of cleaned seeds per weight (determined from 1 sample, except for coyotobrush, which was determined from 2) for 4 species are as follows (McBride 1964; Mirov and Kraebel 1939; Olson 1974; Panetta 1979):

Species	seeds/kg	seeds/lb
saltwater falsewillow	4,989,600	2,268,000
eastern baccharis	10,000,000	4,500,000
coyotebrush	8,316,000	3,780,000
mulefat baccharis	11,000,000	5,000,000

Germination tests. Tests have been completed in 15 to 30 days at diurnally alternating temperatures of 30/20 °C (table 3). When comparing germination at constant 10, 15, 20, 25, 30, and 35 °C, Westman and others (1975) found that eastern baccharis germinated most quickly above 20 °C but germinated at higher numbers between 15 and 20 °C. Light was necessary for germination of eastern baccharis and mulefat baccharis. Without light, no or minimal germination was obtained. In another experiment with eastern baccharis (Panetta 1979), alternating temperatures of 19/22 °C partially compensated for the lack of light. However, in this same experiment, it was shown that an 8-hour photoperiod produced twice as much germination as constant light. Alternating temperatures were used and the effective range was from 19/22 °C to 19/24 °C. The ratio of red to far red light was also examined by Panetta (1979), but it was found to be important only when constant light was used. Therefore, either incandescent or fluorescent light for 8 hours each day would give good germination results for eastern baccharis. No pregermination treatments are needed (Emery 1964; McBride 1964; Mirov and Kraebel 1939), although prechilling at 5 °C for 1 week gave higher germi-

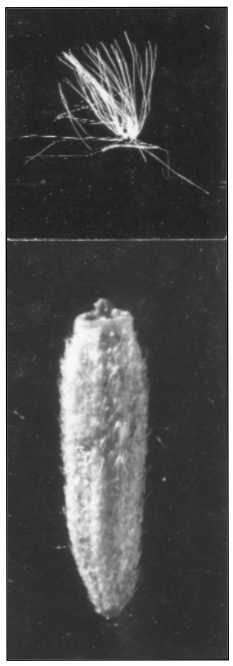

Figure 2—*Baccharis viminea,* mulefat baccharis: achene with pappus (**left**) and longitudinal section through an achene (**right**).

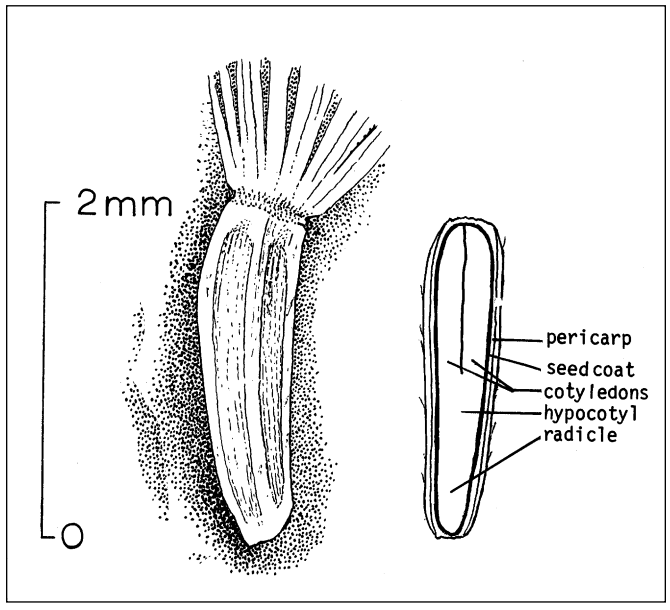

nation than no prechilling or prechilling at 0 °C when eastern baccharis was germinated at 10, 15, or 20 °C with continuous light. In a greenhouse test of eastern baccharis, there was no apparent reduction in germination under 56.7, 23.6, or 17.4% of full sunlight (Panetta 1990). Embryo excision was found to speed embryo germination in both Encinitis falsewillow and eastern baccharis (Kuti and others 1990), demonstrating that there is some inhibitory effect from the seedcoat.

Nursery practice. Seeds may be sown in the fall or early spring in flats or seedbeds using a sandy soil mixture, or one of the vermiculite, perlite, or sphagnum moss seeding media (Everett 1957). Seeds usually germinate within 7 to 15 days. Plants large enough for 10-cm (4-in) pots can be taken from outside seedbeds within 4 months (Everett 1957) (figure 3). Rooseveltweed seeds sown in 15-cm-deep (6-in-deep) pots germinated slowly, requiring 1 month to establish seedlings (Van Auken and Bush 1990).

Fabaceae—Pea family

Bauhinia L.

bauhinia

Kristina F. Connor

Dr. Connor is a plant physiologist at the USDA Forest Service's Southern Research Station, Auburn University, Alabama

Growth habit, occurrence, and use. There are about 600 species of the bauhinia genus found in the tropical regions of the world (Larson 1974). The genus includes trees, vines, and shrubs that are frequently planted for their showy flowers and ornamental foliage (Bailey 1941; Neal 1965). Practical usage of the bark of orchidtree as an astringent in tanning and dyeing and of the leaves and flower buds as a vegetable has been reported (Bailey 1941). Seeds of some bauhinia species have served as a human food source (malucreeper, *B. vahlii* Wight & Arn.) (Ramasastri and Shenolikar 1974); a source of vitamin A (butterfly bauhinia) (Essien and Fetuga 1989); and as a possible pest control agent (malucreeper) (Freedman and others 1979). Butterfly bauhinia is used for fuelwood on Puerto Rico and for fences on Jamaica (Little and Wadsworth 1964), but it is considered a weed on Guam (McConnell and Muniappan 1991). Four species, all small evergreen or deciduous trees, have been planted in the continental United States (table 1). Hawaii has 13 species of introduced bauhinias (Neal 1965), whereas Puerto Rico has at least 5 (Francis and Liogier 1991).

Flowering and fruiting. The large 5-petaled orchid-like flowers of bauhinias occur in racemes and range in color from white to deep purple and yellow. The fruits (figure 1) are flat and dark, and dehiscent or indehiscent legumes (pods) varying in length from 8 to 60 cm (Bailey 1941). Flowers of butterfly bauhinias have only 1 fertile

Figure 1—*Bauhinia variegata,* orchidtree: flowers and legumes (from Little and others 1974).

Table 1—*Bauhinia,* bauhinia: nomenclature, occurrence, and uses

Scientific name & synonym(s)	Common name(s)	Occurrence
***B. megalandra* Griseb.** *B. multinervia* (Kunth) DC.	**bauhinia** petite flambouyant	Carribean basin
***B. monandra* Kurz** *B. kappleri* Sagot *Caspareopsis monandra* (Kurz) Britt. & Rose	**butterfly bauhinia,** pink bauhinia, pink orchidtree	Native of SE Asia; planted in Hawaii, escaped & naturalized in Puerto Rico & throughout the West Indies

Table 2—*Bauhinia,* bauhinia: flower and fruit morphology

Species	Flowering time	Petal color	Fertile stamens/flower	Legume
B. monandra	All year	Pink with red dots	1	15–30 cm long, pointed at apex, twists as opens
B. purpurea	Autumn & winter	Deep pink to purple	3–4	15–30 cm long, black, thin, twists as opens
B. variegata	Autumn to spring	Purple variegated with red & yellow	5–6	13–30 cm long, thin, pointed on both ends

stamen per flower and a calyx splitting along one side (Little and Wadsworth 1964; table 2). Flowers of purple bauhinias have 3 to 4 fertile stamens and a 2-parted calyx, whereas those of orchidtrees have 5 to 6 fertile stamens/flower and a calyx that splits on one side (Little and others 1974; Neal 1965). Information on pollinators is scarce, but Heithaus and others (1982) report that *B. ungulata* L. is pollinated by bats and that 59.4% of flowers examined show evidence of herbivory.

Butterfly bauhinia seeds are elliptic, flat, and 1 cm long; fruits are present throughout the year (Little and Wadsworth 1964). Purple bauhinia seeds are shiny-brown, rounded, flat, and range in length from 1.3 to 1.6 cm; flowering and fruiting occur in autumn and winter months (Little and others 1974). Orchidtree seeds are fairly large, about 1.3 cm in diameter, and the fruits mature in late spring or early summer. *Bauhinia megalandra* seeds are shown in figure 2 and 3. Rugenstein and Lersten (1981) report the presence of stomata on the seeds and pods of purple bauhinias and orchidtrees. In general, bauhinia seeds contain high amounts of linoleic and oleic fatty acids and low amounts of myristic and linolenic fatty acids (Balogun and Fetuga 1985; Ramasastri and Shenolikar 1974; Sherwani and others 1982; Zaka and others 1983).

Collection, storage, and germination. Seeds may be stripped from unopened legumes (pods). Some and others (1990) reported satisfactory germination after 52 weeks when seeds of *Bauhinia rufescens* Lam. were scarified using 97% sulfuric acid (H_2SO_4), washed, dried, sealed into containers, and stored at 4 °C. Another study determined that seeds of orchidtree had a higher germination percentage when stored after cleaning; however, viability was lost within 3 years (Athaya 1985). Because *Bauhinia* is a hard-seeded Fabaceae, dry seeds should store well for many years. Loss of viability after 3 years could be attributable to high moisture content or mechanical damage. Germination studies of orchidtree using excised embryos produced results comparable to experiments using intact seeds (Babeley and Kandya 1986). Francis and Rodrıguez (1993) reported excellent germination of bauhinia without scarification (table 3).

Nursery practices. Bauhinias species grow easily from seeds and bloom within 3 to 4 years (Bailey 1941). Some species can be propagated from suckers but rarely from cuttings.

Figure 2—*Bauhinia megalandra,* bauhinia: seed.

B

Berberidaceae—Barberry family

Berberis L.

barberry

Don Minore and Paul O. Rudolf

Dr. Minore retired from USDA Forest Service's Pacific Northwest Research Station;
Dr. Rudolf (deceased) retired from the USDA Forest Service's North Central Forest Experiment Station

Growth habit, occurrence, and use. The barberries include about 500 species of spiny or unarmed, evergreen or deciduous shrubs (rarely small trees) native to Asia, Europe, North Africa, and to North, Central, and South America (Ahrendt 1961). Some authorities consider that the genus *Mahonia*, consisting of about 100 species that closely resemble the barberries, should be a section of *Berberis* (Hitchcock and others 1964), whereas others consider *Mahonia* to be a separate genus (Ahrendt 1961). The USDA plant nomenclature system (USDA NRCS 1999) separates them into 2 separate genera, and that is the authority used for this manual (table 1). Thus, *Mahonia* is treated separately in a later chapter. The barberry genus is essentially diploid, with 2n = 28 (Cadic 1992). Many interspecific hybrids are known, such as those between Japanese and common barberries (*B.* × *ottawensis* Scheid.), and Japanese barberry and Julian berberis (Rehder 1940). There are more than 60 crosses within *Berberis*, 6 in *Mahonia,* and 4 "mahoberberis" hybrids (Ahrendt 1961).

Several barberry species are grown as ornamentals because of their handsome foliage and often attractive flowers or fruits (Bailey 1939; Rehder 1940; Schlosser and others 1992). Barberries also are of value for wildlife food (Decker and others 1991), cover, and erosion-control planting. However, Japanese and common barberries, as "invasive aliens," are considered by many to be noxious weeds (Mack 1991). The names, heights, habits, and ripe fruit colors of some common species are listed in table 1.

A yellow dye can be extracted from barberry roots, and the plants contain many alkaloids (Hussain and others 1984;

Table 1—*Berberis,* barberry: nomenclature, height, growth habit, and color of ripe fruit

Sources: Ahrendt (1961), Dirr (1990), Dirr and Heuser (1987), Garrett (1969), Hitchcock and others (1964), McMinn (1951), Rehder (1940), Rudolf (1974), Vines (1960).

Ikram 1975; Kostalova and others 1986; Pitea and others 1972). Some of those alkaloids (for example, berberine and jatrorrhizine) are used for medicinal purposes (Ikram 1975; Liu and others 1991). Other barberry extracts may significantly reduce infection with fireblight—*Erwinia amylovora* (Burrill) Winslow et al.—infection when applied as bactericides (Mosch and Zeller 1989). Three species that have been used for conservation planting but are now often considered invasive are listed in table 2. Many of the barberries are alternate hosts for the black stem rust—*Puccinia graminis* Pers:Pers.—of grains, but common barberry is the most susceptible species (LHBH 1976). Some species (for example, Korean barberry and Japanese barberry) are resistant (Rehder 1940).

Flowering and fruiting. Perfect yellow flowers are borne in the spring in racemes, panicles, umbels, fascicles, or individually, depending on the species (Ahrendt 1961). Stamens are contact-sensitive, and they respond to a tactile stimulus by snapping toward the stigma (Fleurat-Lessard and Millet 1984; Lebuhn and Anderson 1994; Millet 1976, 1977). Fruit set and fruit weight are improved by spraying with 200 ppm gibberellic acid (GA_3) at full bloom and again 15 and 30 days later (Malasi and others 1989). The fruit is a berry with one to several seeds (figure 1). Late-fruiting plants often contain more seeds per berry than early-fruiting plants in common barberry; and late-fruiting, large-berried plants may disperse seeds more efficiently than early-fruiting plants with smaller berries (Obeso 1989). Predation by fly larvae (diptera: Tripetidae) tends to increase with increasing number of seeds in the fruit, however, and individual developing seeds have a greater average probability of escaping predation when they occur singly in fruits (Herrera 1984). Fruits having the least number of seeds contain the highest amounts of edible pericarp (Malasi and Paliwal 1984). Starch is not present, but polyfructans are characteristic of barberry fruits (Srepel and Mijatovic 1975). Soluble sugar and anthocyan levels increase while those of chlorophyll and berberine decrease during the ripening of those fruits (Chandra and Todaria 1983).

Good fruit crops are borne almost annually. They ripen in the summer and autumn (table 2). In New Zealand, the proportion of mature flowers that survive to produce ripe fruit and the proportion of ripe fruit taken by birds may be higher in introduced, naturalized barberry species than in most other species with similar reproductive ecology that are growing within their natural range (Allen and Wilson 1992). As a result, establishment of seedlings of Darwin barberry may exceed that of native shrub and tree species in New Zealand (Allen 1991). The presence of a waxy bloom does

not increase fruit attractiveness, but physical alteration of the fruit surface reduces fruit selection by birds (Allen and Lee 1992). Seed dispersal by both birds and mammals is widespread (Rudolf 1974; Vines 1960).

Collection of fruit; extraction and storage of seeds. Ripe barberry fruits may be picked by using protective gloves, or they may be flailed onto cloths or receptacles spread beneath the bushes. The ripe fruits may be run through a macerator or blender with water and the pulp then screened out or floated off. The seeds should then be dried superficially and either sown immediately or stored in sealed containers at temperatures slightly above freezing (Heit 1967a; NBV 1946; Rudolf 1974). Seed purity and soundness for the species included here have been as high as 90 to 99% (Davis 1927; Rafn and Son nd; Rudolf 1974). Seeds of Japanese and common barberries remained viable for at least 4 years when held at 1 to 3 °C in sealed containers (Heit 1967b), which indicates that these species are orthodox in storage behavior. Fruit yields, seed yields, and numbers of seeds per weight for 3 species are listed in table 3.

Pregermination treatments. Seeds of some barberry species have embryo dormancy that requires cold stratification to provide prompt germination. Dirr and Heuser (1987) recommend 1 to 2 months for wildfire and Japanese barberries, and 2 to 3 months for boxleaf, paleleaf, cutleaf, Darwin, Julian, and Korean barberries. Germination data for 3 species are found in table 4. However, a simple cold stratification is not always successful. Immature or improperly developed embryos may be present in some barberry seeds, and maximum germination may require warm incubation, followed by cold stratification as in the closely related *Mahonia* genus (Dirr and Heuser 1987; McLean 1967). Under natural conditions, barberry seeds germinate in the spring following seed dispersal (Kern 1921).

Germination tests. Germination of seeds from several barberry species has been tested in sand-filled flats, in petri dishes, on paper or blotters, or in standard germinators. Day temperatures of 16 to 30 °C, night temperatures of 13 to 21 °C, and germination periods of 20 to 95 days have been used. Results are summarized in table 4. For Japanese and common barberries, the Association of Official Seed Analysts (AOSA 1993) recommends germination of excised embryos in covered petri dishes at temperatures of 18 to 22 °C for 10 to 14 days. This method may be satisfactory for other barberry species.

Nursery practice. Whole berries or (preferably) cleaned seeds may be sown in the fall, or stratified seeds may be sown in the spring. Injury from molds is more likely if whole berries are used (Chadwick 1936). Fall-sown beds should be mulched until germination begins (NBV 1946). The seeds should be covered with 0.3 to 1.3 cm ($^1/_8$ to $^1/_2$ in) of soil plus 0.6 cm ($^1/_4$ in) of sand (Rudolf 1974). Germination is epigeal (Terabayashi 1987), and seedlings develop rapidly (figure 2). In a sowing of common barberry, 22% of the seeds survived to produce shrubs (Swingle 1939). Barberries may be field-planted as 2+0 stock (Rudolf 1974).

The barberries can be propagated from rooted stem cuttings. Several deciduous species are best rooted when propagated from softwood cuttings collected in the summer, but many of the evergreen species root better when hardwood cuttings are collected in the autumn or winter (Dirr and Heuser 1987). Both should be treated with indole butyric acid (IBA) rooting hormone in talc or in solution.

Betulaceae—Birch family

Betula L.

birch

Robert P. Karrfalt

Mr. Karrfalt is director of the USDA Forest Service's National Seed Laboratory, Dry Branch, Georgia

Growth habit, occurrence, and use. The birch-genus—*Betula*—consists of about 40 to 50 species of deciduous trees and shrubs occurring in the cooler parts of the Northern Hemisphere (Weaver 1978). Several species produce valuable lumber. Other species are useful for ornamental plantings because of their attractive growth habit, foliage, and bark. Nearly all species provide food and cover for wildlife, and some are valuable because they seed-in promptly on harvested or burned lands. The 14 species native to the Unites States are listed in table 1, along with several species that are introduced or are referenced in the seed literature.

Flowering and fruiting. The flowers are monoecious and borne in catkins. Staminate catkins are formed in late summer or autumn, remain naked during winter, and open after considerable elongation in the spring (table 2). The pistillate catkins, which are cone-like with closely overlapping scales, are born terminally on short, spur-like lateral branches and appear with the leaves (table 2). When the female catkins (strobiles) ripen in late summer or autumn (table 2), they become brown and woody and are either erect or pendulous (figure 1). Each scale may bear a single small, winged nut (seed) (figures 2 and 3) that is oval, with 2 persistent stigmas at the apex. The seeds turn from greenish tan to light brown or tan when mature (Brinkman 1974). Seeds disperse from late fall until the following spring (Houle and Payette 1990; Matlack 1989). Although seeds can begin to disperse in late summer, these early-shed seeds may be of poor quality. Seeds of yellow birch shed in August were found to not be viable. Viable seeds were not released in meaningful amounts until September, with the maximum of good seeds being released in October (Houle and Payette 1990). After seedfall, the strobiles slowly disintegrate on the trees, with the axes persisting on the branchlets.

Seed production. Birch tends to flower at the relatively young age of 10 to 15 years (Lepisto 1973) (table 3). Some individuals are precocious in flowering and this appears to be under genetic control (Huhtinen and Yahyaoglu 1974). Clausen (1980) reported on a progeny test of 147 open-pollinated yellow birch families from 21 stands. He found that some female-flowering began at 6 years from seed, but this occurred in only 1% of the trees. By age 9, 14% of the trees were producing seeds. Male-flowering commenced 1 year later than female-flowering. Seedlings from northern sources tended to flower earlier than those from southern sources. In greenhouse conditions with irrigation, fertilization, and CO_2-enriched air, European white birch seedlings have produced male catkins as early as 9 months and commercial quantities of seed at 5 years (Lepisto 1973).

Birches are known to hybridize readily. These hybrids appear to be at least partially fertile, allowing for the production of second generation hybrids and backcrossing to the parent species (Barnes and others 1974).

The holartic lygaeid—*Kleidocerys resedae* (Panzer)—feeds on the seeds of European white birch and cause premature drop of catkins and seed failure. The feeding does not affect the vigor of the parent plant, even though the insects can be quite numerous and visible (Wheeler 1976).

Seed production is usually regular and abundant. Bjorkbom and others (1965) reported that paper birch produced a higher proportion of viable seeds in good seed years than it did during poor seed years. The percentage of viable birch seeds can be estimated by examining the seeds on a light table (Patterson and Bruce 1931). The seeds are primarily dispersed by wind as they are shed from the catkins. Wind can also blow seeds along the surface of the snow up to 80 m from the mother tree. This secondary dispersal may be the more effective method; it has been predicted to increase sweet birch seed dispersal by a factor of 3.3 over that of aerial dispersal alone (Matlack 1989). Ford and others (1983) trapped about 5% of the total seed-fall from round-leaf birch at nearly 100 m from the parent tree.

Sources: Ahlgren (1957), Brinkman (1974), Damberg (1915), Fernald (1950), NBV (1946), Sarvas (1952), Van Dersal (1938), Wappes (1932).

Although an abundance of seeds can be found in the forest soil, these seeds are short-lived. Most seeds are nonviable after the second or third year (Granstrom 1987; Granstrom and Fries 1985; Johnson 1975; Moore and Wein 1977; Perala and Alm 1989; Steijlen and Zackrisson 1986). The abundance of seeds in the forest soil is, therefore, likely supported by regular replenishment from new crops (Komarova 1986). A rare case of excessive seed production has been observed to lead to crown deterioration and reduced growth of the parent trees (Gross 1972).

Seed collection. Birch seeds are collected by picking or stripping the strobiles from standing trees or shrubs or from trees recently felled in logging operations. This is best done while strobiles are still green enough to hold together. Because ripe strobiles shatter readily, they are usually put directly into bags rather than allowed to fall onto the ground or tarps, which can result in loss of the seeds. However, seeds can also be collected from paved surfaces in urban areas.

Seed extraction. Freshly collected strobiles can be subject to heating because they usually are at least somewhat green. They should be spread out to dry for several weeks until they begin to disintegrate. Low relative humidity is the most important factor in drying the strobiles. Matlack (1989) found that sweet birch strobiles released their seeds at low humidity anywhere in the temperature range of –14 to 16 °C. Once the strobiles begin to fall apart, they can be shattered by rubbing or shaking, and the seeds can be separated from most of the scales and debris by screening and fanning. Round-hole screens of the following sizes have

Figure 1—*Betula*, birch: ripe female strobiles; *B. pendula*, European white birch (**top right**); *B. populifolia*, gray birch (**bottom left**); *B. papyrifera*, paper birch (**bottom middle**); and *B. lenta*, sweet birch (**bottom right**).

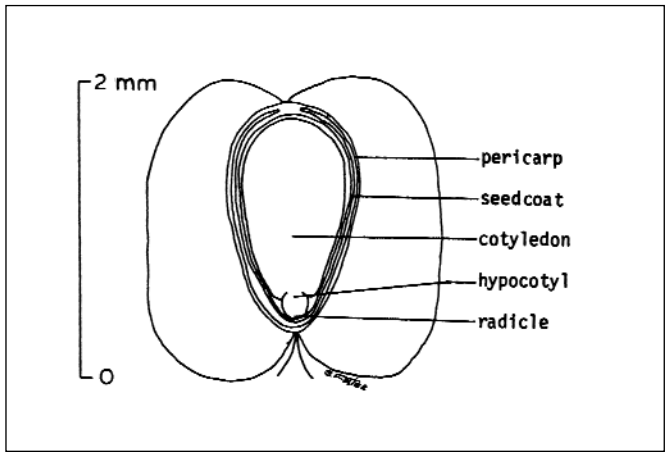
proved satisfactory for the following species: glandulose birch, 2.38 mm (#6); yellow birch, 3.2 mm (#8); river birch, 4 mm (#10); paper birch, 3.2 mm (#8); European white and downy birches, 2.6 mm (~#7). The remaining scales can be removed by fanning (Brinkman 1974). Any stems can be removed with an indent cylinder. Very careful adjustment

Figure 3—*Betula nigra*, river birch: longitudinal section through a nut (seed).



with a column blower or a specific gravity table can upgrade the seedlot. Birch seeds are very small and light, with the number per weight and yield per volume varying considerably among species (table 4).

Seed storage. Heit (1967) reported that birch seeds apparently stored best at 1 to 3% moisture content and temperatures of 2.2 to 3.3 °C. Other tests with sweet, paper, and gray birches are in basic agreement with this position, thus indicating that birch seeds are orthodox in storage behavior. Seeds of these 3 species were found to keep for 1 $^1/_2$ to 2 years at room temperature if the moisture content was between 1 and 5%. If the moisture content was much higher, germination dropped even though the seeds were stored at 1.7 to 4.4 °C (Brinkman 1974). Slightly higher moisture content seems possible if freezer storage is used. One lot each of yellow, sweet, and paper birch seeds was successfully stored in the USDA Forest Service's National Tree Seed Laboratory seed bank for about 15 years with moisture contents between 5 to 9% at –8 °C (table 5). A lower moisture content would probably have been better, because the paper birch seeds began to deteriorate at 15 years and were discarded at 17 years. Liquid nitrogen storage also appears to be an option for the birch seeds (Iriondo and others 1992).

Pregermination treatment. It has been known for over 50 years that prechilling (that is, stratification) improved germination of birch seeds (Brinkman 1974). Several sources (Brinkman 1974; Heit 1967; ISTA 1996) state that light during germination is able to reduce or replace the need for prechilling to obtain complete germination. The barriers to germination in European white birch are removed by light or stratification (Black 1956; Black and Wareing 1954, 1955). However, prechilling can still be an important procedure. For example, Vanhatalo and others

* De-winged seeds.

(1996) found that not only did prechilling result in faster and higher germination, but it also improved the ability to germinate at temperatures below the optimum.

Furthermore, the birch genus is divided into 2 groups in regards to prechilling: those that will germinate in the dark with adequate prechilling and those that require light. For example, European white birch (Black and Wareing 1955, Vaartaja 1956) and paper birch (Bevinton and Hoyle 1981) can germinate in the dark, whereas monarch and Japanese white birches and Erman birch require light regardless of prechilling (Nagata and Black 1977; Nagata and Tsuda 1975; Odani and Anma 1986). Giberellic acid (GA_3) in concentrations of 50 to 100 ppm could substitute for the light with Erman birch (Odani and Anma 1986). However, in the light-obligatory group, the sensitivity to light is markedly increased by providing prechilling (Nagada and Black 1977). Therefore, prechilling can reduce the requirement for light when growing plants under artificial conditions. This might provide some cost savings during the germination phase by reducing lighting expense. Reducing the light requirement might also allow birch to be germinated in a greenhouse with other plants that had low light requirements. On the other hand, if there is not time for pregermination chilling, then light sufficient to keep dark periods less than about 6 hours may fully replace the need for prechilling.

It is important to know a seedlot's characteristics well when making the refined manipulations of light and prechilling suggested above, for prechilling beyond 3 weeks can lead to increased dormancy and obligatory use of light

in some sources of paper birch (Bevington 1986; Bevington and Hoyle 1981). Although light use was obligatory in these sources of paper birch, the seeds were well sensitized to the light and germination was prompt and complete. Bevington (1986) further found that seeds from different sources varied in the range of temperatures at which they would germinate. Seeds from northern sources were able to germinate over a wider range of temperatures than those from southern sources, mostly because they could germinate at cooler temperatures. Sensitivity to light did not seem to be related to geographic source but was universally enhanced in proportion to the length of prechilling, at least up to 6 weeks as demonstrated by faster and higher germination (Bevington 1986).

Prechilling temperatures need to be close to 2 or 3 °C. A rise in temperature to even 5 °C can increase the time needed to effectively overcome the dormancy (Bevington and Hoyle 1981; Vanhatalo and others 1996).

Germination tests. The use of light during the test can reduce or eliminate the need for prechilling. However, because some seedlots may benefit from prechilling, a test with and a test without prechilling are frequently recommended (AOSA 1998; ISTA 1996). Tests should be made on germination paper or sand at alternating temperatures of 30 °C for 8 hours and 20 °C for 16 hours with light supplied during the 30 °C period. Testing by AOSA rules requires planting 4 dishes of 100 seeds each. Should the seedlot be less than 98% pure, then a partial purity analysis must be done to acquire the needed pure seeds for the germination test. Because catkin bracts are not removed from many seedlots, the seedlots have low purity and ISTA prescribes testing by weighed replicate. In the weighed replicate test, 0.10 g of seed are planted in each of the 4 replicates. The number of normal seedlings per weight of seeds is then reported instead of a germination percentage. The results of some published test data are presented in table 6.

Nursery practice. Birch seeds can be sown after collection in the late summer or fall, or in the spring after prechilling for 4 to 8 weeks. Seeds are broadcast and covered as lightly as possible, with about 3 mm ($^1/_{16}$ to $^3/_{16}$ in) of soil. The seeds can be sown without covering (Brinkman 1974) if adequate irrigation can be supplied, which provides more light to the seed. Germination is epigeal (figure 4) and usually complete in 4 to 6 weeks after spring-sowing. Birch seedlings require light shade for 2 to 3 months during the first summer. Tree percent is low; only 15 to 20% of European white birch and downy birch seeds will produce 1+0 seedlings (Deasy 1954; Wappes 1932). A seedling density of 278 to 500/m^2 (25 to 45/ft^2) is desirable (Heit 1964). Stock usually is field planted as 1+0 or 2+0 seedlings. Birch seeds have shown marked sensitivity to herbicides and insecticides (Weinberger and others 1978; Weinberger and Vladut 1981).

In a study of open-pollinated families of yellow birch (Wearstler and Barnes 1977), heavier seeds produced taller seedlings immediately after germination. Seeds from mountain and more northern sources germinated earlier, but the seedlings tended to be shorter. The shorter seedlings and faster germination were generally associated with shorter growing season.

Cherry leaf roll virus is known to be transmitted through seeds. Transmission of this pathogen is highly variable and not generally strong. Two generations were estimated to be enough for the disease to be lost from a population of European white birch (Cooper and others 1984).

Germination on adverse sites. Environmental disturbances caused by mining operations and air pollution create conditions that have been suspected of interferring with normal seed germination for birch. The germination of European white and downy birches was found to be inhibited by high zinc concentrations (Brown and Wilkins 1986). Such heavy metal concentrations were thought to be a major reason for lack of colonization of these 2 species on mine

spoil in Wales. On the other hand, Scherbatskoy and others (1987) found that heavy metals and low pH did not reduce germination of yellow or paper birch seed samples taken in Vermont. Reduced regeneration of these 2 species had been associated with low soil pH and increasing concentrations of heavy metals believed to be caused by air pollution. In fact, pH of 3 produced germinations higher than controls or pH values of 4 or 5. Growth of gray birch on coal mine spoils in Pennsylvania is likely to be inhibited by the high temperatures of the soil surface(Pratt 1986).

Verbenaceae—Verbena family

Callicarpa americana L.

American beautyberry

Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Other common names. French-mulberry, Spanish-mulberry, sour-bush, sow-berry.

Growth habit, occurrence, and uses. American beautyberry—*Callicarpa americana* L.—is a small, woody shrub of the pine forests in the southern coastal plain. It seldom grows taller than 2 or 3 m. The shrub is common underneath the pine overstory and along roads and forest edges, where it grows best. It is found from Virginia to Florida and west to Texas and Oklahoma; it also occurs in the West Indies (Vines 1960). American beautyberry is an important food plant for wildlife, especially birds and eastern white-tailed deer *(Odocoileus virginianus)* (Blair and Epps 1969; Grelen and Duvall 1966; Halls 1973). The shrub's well-branched root system and drought resistance make it desired for erosion control in some areas (Brown 1945), and it is frequently grown as an ornamental because of the colorful fruits (Dirr and Heuser 1987).

Flowering and fruiting. The small, inconspicuous flowers are borne in axillary, dichotomous cymes about 8 to 36 mm long. Flowering starts in early June and may continue into the fall months, even as the fruits mature in August to November (Dirr and Heuser 1987; Vines 1960). The fruit is a berrylike, globose drupe, about 3 to 6 mm in diameter, that is borne in conspicuous axillary clusters on the current season's growth. The rose to purple, or sometimes white (Brown 1945), fruit color gives this plant its ornamental value. A single fruit cluster may contain as many as 300 fruits, although about 100 is typical. Each fruit usually contains 4 small flattened seeds that are light brown in color and about 1 to 1.5 mm in length (Grelen and Duvall 1966; Vines 1960) (figures 1 and 2). Plants begin to bear fruit as early as 2 years of age, and mature plants may yield over $^1/_2$ kg (about 1 lb) annually (Halls 1973).

Collection of fruits; extraction and storage of seeds. Fruits can be easily collected by hand in autumn, when their rose to purple color indicates maturity. The soft fruits quickly disintegrate when they are macerated with water. Filled

Figure 1—*Callicarpa americana*, American beautyberry: seeds.

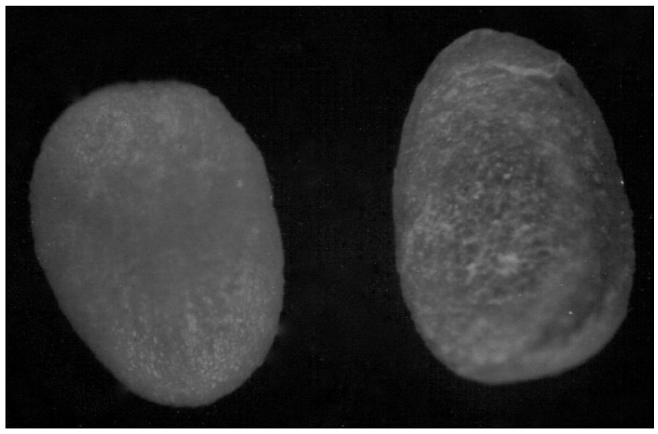

Figure 2—*Callicarpa americana*, American beautyberry: longitudinal section through a seed.

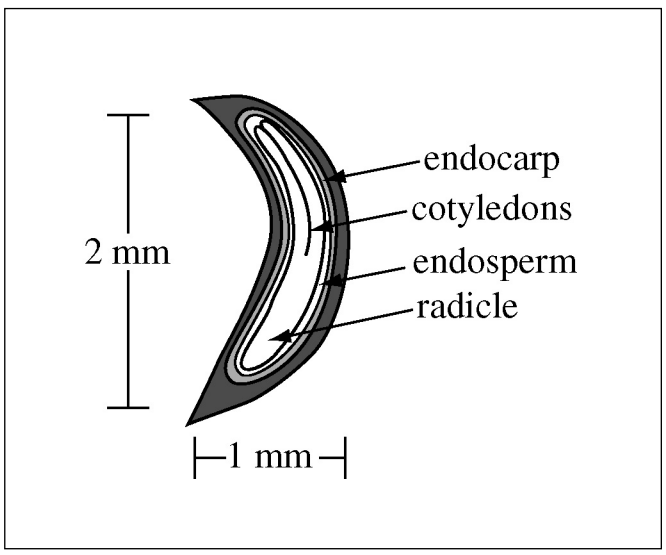

seeds sink in water, and the pulp can be floated off. Any type of macerator should work, even laboratory or kitchen blenders for small lots. There are about 600 seeds/g (17,000/oz), and good cleaning should yield a purity of practically 100%. There are no known storage data for this species, but soil seed bank studies show that the seeds will survive for at least 1 year buried in the soil. This fact, plus the hard seedcoat, suggest that these seeds are orthodox in storage behavior. Long-term storage at temperatures near or below freezing should be successful with seeds that are dried to below 10% moisture content.

Pregermination treatments and germination tests. The seeds have a hard seedcoat, and germination is relatively slow. One sample stratified for 30 days yielded only 22% germination in 90 days when tested at an alternating temperature of 20 °C at night and 30 °C in the light. Untreated seeds sown in the fall, however, were reported to give excellent germination in the spring (Dirr and Heuser 1987). There are no official test prescriptions for American beautyberry.

Nursery practice. No details of nursery practices for American beautyberry are available, except the successful fall-sowing mentioned above. The small seed size suggests that soil or mulch covers after sowing must be very light. Vegetative propagation is not difficult with this species. Softwood cuttings taken anytime from June to September root well if treated with IBA (1,000 ppm) and placed in a mist bed (Dirr and Heuser 1987).

Cupressaceae—Cypress family

Calocedrus decurrens (Torr.) Florin

incense-cedar

William I. Stein

Dr. Stein is a forest ecologist emeritus at the USDA Forest Service's Pacific Northwest Research Station, Corvallis, Oregon

Synonyms. *Libocedrus decurrens* Torr., *Heyderia decurrens* (Torr.) K. Koch.

Other common names. California incense-cedar, pencil cedar, pecky cedar.

Growth habit, occurrence, and uses. Incense-cedar was once classified as the only species in the genus *Libocedrus* native to the United States (Harlow and others 1979; Little 1979), but recent taxonomic changes have included it as 1 of 3 species in the genus *Calocedrus* Kurz. Regional genetic variation within incense-cedar is small, but 12-year growth of trees from southern California was less than that of trees from more northerly regions (Rogers and others 1994). Recognized cultivars under the former classification include *L. decurrens* cv. *aureovariegata* Beissner, *L. decurrens* cv. *columnaris* Beissner, *L. decurrens* cv. *compacta* Beissner, and *L. decurrens* cv. *glauca* Beissner (Harrison and Dallimore 1966; Rehder 1940).

Mature trees of this evergreen conifer vary in height from 15 to 46 m and from 0.3 to 2.13 m in diameter (Jepson 1910; Sargent 1961; Sudworth 1908). A maximum circumference of 12.9 m (van Pelt 2001) and a maximum height of 68.6 m have been reported (Stein 1974). Young trees generally have dense pyramidal to columnar crowns; older trees are characterized by more open, irregular crowns; rapidly tapering trunks with buttressed bases; and deeply furrowed and ridged bark.

The range of incense-cedar spans about 15 degrees of latitude, from the southeastern slopes of Mount Hood in Oregon southward within and adjacent to the Cascade, Siskiyou, coastal, and Sierra Nevada ranges to the Sierra de San Pedro Martír in northwestern Mexico (Griffin and Critchfield 1976; Sudworth 1908). It extends eastward from the coastal fog belt to arid inland parts of central Oregon, northern California, and westernmost Nevada. In elevation, incense-cedar is found from 50 to 2,010 m in the north and from 910 to 2,960 m in the south (Peattie 1953; Powers and Oliver 1990; Sudworth 1908). Incense-cedar grows on many kinds of soil and is one of the most prominent conifers on serpentine soils. Typically, it is a component of mixed conifer forest and may make up as much as 50% of the total stand (Powers and Oliver 1990).

Trees are harvested primarily for lumber and for round or split wood products. The wood is variable in color, durable, light, moderately soft, uniformly textured, easy to split and whittle, and finishes well. Incense-cedar is also used as a pulp additive and for making a variety of specialty items, the best known being the wooden pencil (Betts 1955; Panshin and others 1964). Boughs, particularly those bearing staminate cones, are harvested commercially for decorations (Schlosser and others 1991), and young trees are a minor component of the Christmas tree trade.

First cultivated in 1853, ornamental specimens with shapely crowns have grown well in many places outside of their native range in the Pacific Northwest—in New England and in the mid-Atlantic region of the United States and western, central, and southern Europe (Edlin 1968; Harrison and Dallimore 1966; Jelaska and Libby 1987; Sargent 1961). Within its native range, incense-cedar is commonly planted for highway landscaping, screenings, and home-site improvement.

Young incense-cedars are sometimes browsed extensively (Stark 1965), but in general, the species rates low to moderate in value as wildlife browse (Longhurst and others 1952; Sampson and Jespersen 1963; Van Dersal 1938). Its seeds are eaten by small mammals (Martin and others 1951) but are not a preferred food of chipmunks (Tevis 1953). Dense understory incense-cedars provide an important source of cover and food for overwintering birds in the western Sierra Nevada (Morrison and others 1989).

Flowering and fruiting. Yellowish green staminate flowers develop terminally on twigs as early as September even before the current year's cones on the same twigs have opened (Stein 1974). These flowers, 5 to 7 mm long, are prominently present "...tingeing the tree with gold during

the winter and early spring..." (Sargent 1961). The inconspicuous pale yellow ovulate flowers also develop singly at tips of twigs. Flowering has been reported to occur as early as December and as late as May (Britton 1908; Hitchcock and others 1969; Mitchell 1918; Peattie 1953; Sargent 1961; Sudworth 1908), but it is not clear how well observers distinguished between flower appearance and actual pollen dissemination. Unopened staminate flowers and open or nearly open ovulate flowers were present on branches collected in the first week of April west of Klamath Falls, Oregon (Stein 1974).

Individual cones (figure 1), each containing up to 4 seeds, are scattered throughout the crown, and mature in a single growing season. As they ripen, their color changes from a medium green to a yellowish green or yellow tinged with various amounts and shades of brown. During opening, the cone becomes reddish brown and acquires a purplish cast. Insect-attacked cones are among the first to change color. Generally, cones of many color shades are found on a tree as opening commences.

Seed dispersal may extend over a lengthy period, from late August through November or later (Fowells and Schubert 1956; McDonald 1992; Mitchell 1918; Powers and Oliver 1990; Sudworth 1908). For example, in 1937 and 1940, respectively, 11 and 32% of the seed had fallen by early October at 1 or 2 California locations, yet 47 and 66% of the total fell after November 11 (Fowells and Schubert 1956). Cutting tests have shown that 14 to 65% of the naturally dispersed seeds appear sound, with higher values coincident with heavy crops (Fowells and Schubert 1956).

The oft-repeated generalization that incense-cedars bear some seeds every year and abundant crops frequently (Betts 1955; Mitchell 1918; Sudworth 1908; Van Dersal 1938) has not been confirmed by systematic observations made in 3 locations. During a 35-year period on the Stanislaus National Forest in California, incense-cedars bore a heavy or very heavy crop in 7 of those years, a medium crop in 11 years, and a light crop in 17 years (Schubert and Adams 1971). On the Challenge Experimental Forest in central northern California, there were 1 medium to heavy and 9 light to very light crops in 24 years (McDonald 1992). During 15 years on the South Umpqua Experimental Forest in southwest Oregon, there were 2 abundant crops, 1 medium crop, and 12 years with light or no crops (Stein 1974). Generalized statewide reports for California and Oregon show that incense-cedar cone crops are often light and that there is wide geographic variability in crop abundance (Schubert and Adams 1971). During years when crops are reported as light or a failure, scattered cones, even an occasional heavily loaded tree, may be found somewhere.

Figure 1—*Calocedrus decurrens*, incense-cedar: cones hang singly from branch tips well-dispersed over the crown and contain up to 4 seeds each.

Flowers and young cones may be damaged or killed occasionally by adverse climatic factors, and squirrels cut some mature cones (Fowells and Schubert 1956). Losses are also caused by sawflies (*Augomonoctenus libocedrii* Rohw.), juniper scale (*Carulaspis juniperi* Bouche*)*, and leaf-footed bugs (*Leptoglossus occidentalis* Heidemann) that feed on developing cones and seeds (Furniss and Carolin 1977; Koerber 1963).

Collection of cones. Cones are generally hand-picked from standing or felled trees. Stripping cones or using a cone rake will expedite collection because cones hang dispersed over the crown. The ideal time for collection is the short period when cleavages appear between the scales of many cones on a tree. If large quantities of seeds are needed, both collecting them from plastic sheets spread beneath or enclosing the tree and vacuum-harvesting seeds from the ground merit consideration. Dispersed seeds should be collected promptly to minimize heat damage. To facilitate later seed cleaning, foliage intermixed with cones or seeds should be removed during collection or shortly afterward, before it dries and crumbles.

Cones are normally handled and transported in partly filled open-mesh sacks that facilitate cone expansion and air exchange. Good aeration should be provided around each sack to keep the cones from overheating during storage.

Extraction and storage of seeds. To maintain high seed viability, cones should not be exposed to high temperatures. Under warm, dry conditions, cones will air-dry outdoors or indoors in 3 to 7 days if layered thinly in trays or on sheeting or tarps. Turning or stirring layered cones will

facilitate drying and opening. They may also be kiln-dried at 27 °C or lower (Lippitt 1995).

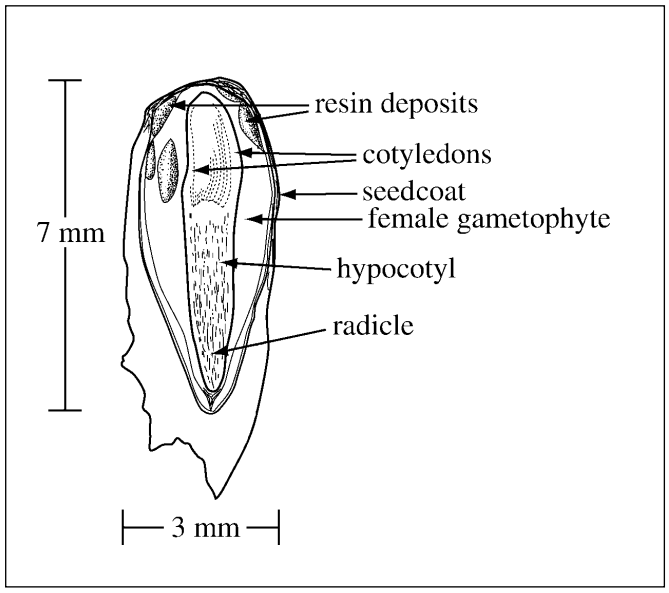
Seeds separate readily from well-opened cones; moderate tumbling or shaking is helpful. Whether done by improvised methods or in commercial machines, tumbling or shaking should be done gently, preferably at less than 27 °C, because seedcoats of incense-cedar are thin and easily broken.

The winged seeds are about 2.5 cm long and nearly one-third as wide (figure 2). Although appearing to have only 1 wing, each seed actually has 2 wings—a long, wide wing extending lengthwise beyond the seed on one side and a narrow, much shorter wing barely merging alongside the first from the opposite side. The wings are persistent and project past the narrow radicle end of the seed rather than from the cotyledon end as in many other conifers (figure 3).

The persistent wings should be left intact. When seeds are run through mechanical de-wingers, the narrow radicle ends may break off along with the wings. This type of damage was the probable cause of the very low viability observed in some lots of de-winged seeds. Damaging effects should be evaluated before using any proposed hand or mechanical de-winging technique.

Figure 2—*Calocedrus decurrens*, incense-cedar: each seed has 2 wings, a long, wide wing on one side (**right**) and a narrow, much shorter one on the other side (**left**).

Figure 3—*Calocedrus decurrens*, incense-cedar: longitudinal section showing the radicle located at the narrow end of the seed.



Small particles of debris can be removed from among winged seeds by screening. Sensitive adjustment of an air stream or gravity separator will permit further cleaning and adequate separation of empty from full seeds with wings intact. Purities of 85 to 98% or more have been obtained (Lanquist 1946; Lippitt 1995; Rafn 1915; Toumey and Korstian 1942).

Thirty-five liters (1 bu) of cones weigh 18 to 23 kg (40 to 50 lbs) and yield from 0.45 to 1.36 kg (1 to 3 lb) of seeds (CDF 1969; Tillotson 1925; Toumey and Korstian 1942). A minimum of 14,110 and a maximum of 63,930 seeds/kg (6,400 and 29,000 seeds/lb) were found among 55 samples from northern California weighed by Show in 1918. More recent collections indicate that seeds per weight values differ by seed zone (Lippitt 1995):

	Average		Range		
Region & seed zone series no.	**/kg**	**/lb**	**/kg**	**/lb**	**Samples**
Siskiyou Mtns. & inland north coastal range (SZ #300)	27,270	12,368	24,820–29,960	11,260–13,588	41
Sierra Nevada (SZ #500)	31,820	14,433	21,540–45,330	9,768–20,562	36
Southern California & Central Valley (SZ #900)	33,420	15,160	24,120–38,760	10,940–17,583	5

Reported averages representing collections made largely in northern and central parts of the species' range vary from 27,270 to 44,450 seeds/kg (12,368 to 20,160 seeds/lb) (CDF 1969; Lanquist 1946; Lippitt 1995; Mitchell 1918; Rafn 1915; Show 1918; Stein 1963; Sudworth 1900; Tillotson 1925; Toumey and Korstian 1942). The smaller averages are probably the most realistic, for samples weighed by several investigators contained only 60 to 67% full seeds either winged or wingless (Lanquist 1946; Show 1918).

Incense-cedar seeds do not keep well in dry storage at room temperature (Shaw 1918), but high viability can be maintained for several years in cool storage. In limited tests, 2 seedlots retained 98% and 74% viability after storage in closed metal containers at 5 °C for 2 and 3 years, respectively, but lost all viability after 8 years (Schubert 1954). It is now common practice to store incense-cedar seeds dried to low moisture content near –18 °C in cloth or plastic bags or in plastic-lined fiberboard containers. Mature, undamaged seedlots have retained viability in cold storage for 10 years at 5 to 9% moisture content (Lippitt 1995); maximum duration before such lots begin losing viability has not been determined.

Pregermination treatments and germination tests. Standard procedures prescribed by the Association of Official Seed Analysts (1999) for testing incense-cedar seeds include chilling them for 30 days at 2 to 5 °C before germination. Comparison tests showed that prechilling markedly improved total germination and rate of germination of some but not all lots (Stein 1974). Short of making a paired test, there is no way to identify which lots benefit from prechilling and which ones do not. To prepare them for prechilling, seed samples are either (1) placed on a moist substratum in a closed dish; (2) placed in a loosely woven bag or screen surrounded by moist peat, sand, or vermiculite; or (3) allowed to soak for 24 hours in tap water at room temperature, drained, and then placed in a glass or plastic container.

Following prechilling, germination of incense-cedar is determined by subjecting seeds for 28 days to alternating temperatures—16 hours at 20 °C and 8 hours at 30 °C with 750 to 1250 lux (75 to 125 foot-candles) exposure to cool-white fluorescent illumination at least during the high-temperature period (AOSA 1999). Tests should be carried out on cellulose paper wadding or blotters in closed germination boxes. Germination for 85 lots now in storage at one nursery has averaged 72% following 8 weeks of naked stratification (Lippitt 1995).

The viability of incense-cedar seeds can also be determined by a tetrazolium test (AOSA 2000). The preparation sequence involves removal of wings from dry seeds followed by soaking in water at room temperature for 6 to 18 hours (overnight). Shallow longitudinal cuts are then made on both ends of the seed to expose the embryo. Cut seeds are immersed in a 1% tetrazolium solution and kept in darkness for 6 to 18 hours at 30 to 35 °C. Seeds having a completely stained embryo and a completely stained endosperm are considered viable. Viability determined by the tetrazolium test reveals the seeds' maximum potential and generally is somewhat higher than indicated by a germination test.

Nursery practice and seedling development. Soil fumigation of outdoor beds to combat damping-off and other diseases may or may not be necessary before sowing incense-cedar seeds. Maintenance or replacement of endomycorrhizal fungi is of concern if beds are fumigated. Spring-sowing is now most common even though fall-sown seeds germinated earlier and more uniformly than those sown in the spring and resulting seedlings grew larger in the first season if they escaped damage by late spring frosts (Show 1930). An intermediate approach is to prepare seedbeds in the fall to facilitate early sowing in February or March. Before sowing, seeds are usually stratified naked or in a moist medium at 2 to 5 °C for 30 to 60 days (Lippitt 1995). Well-timed spring-sowings of unstratified seeds have produced satisfactory crops (Show 1930; Stein 1974), but results are less certain. Some spring-sown seeds may hold over to produce seedlings the following spring (Show 1930).

The winged seeds are usually hand-sown in rows. They should be covered about 6 to 12 mm ($^1/_4$ to $^1/_2$ in) deep (Show 1930). Burlap mulch proved satisfactory to keep seedbeds moist (Show 1930); sawdust or other mulch material and frequent sprinkler irrigation are currently used.

Incense-cedar can readily be grown in containers to plantable size in one season. Containers about 15 cm (6 in) deep with a volume of 165 to 215 cm^3 (10 to 13 in^3) are recommended. The seedlings may be started about February in a greenhouse and moved outdoors after 4 to 8 weeks or they may be germinated and grown entirely outdoors.

Germination is epigeal and the radical emerges from the narrow winged end of the seed (figure 4). Young seeds usually have 2, rarely 3, cotyledons (Harlow and others 1979). Leaves about 1.2 cm (0.5 in) long develop along the epicotyl (figure 5). On the first branches, awl-shaped transitional leaves grade into the normal scalelike leaves (Jepson 1910). Seedlings grow 5 to 20 cm (2 to 8 in) tall in the first season and develop a well-branched root system. Young seedlings are fairly resistant to frost and drought (Fowells and Stark 1965; Pharis 1966; Stone 1957). They are preferentially attacked by cutworms, however, and need protection from damping-off (Fowells 1940; Fowells and Stark 1965; Show

Figure 4—*Calocedrus decurrens*, incense-cedar: germinating seed with radicle and hypocotyl emerging from the winged end.

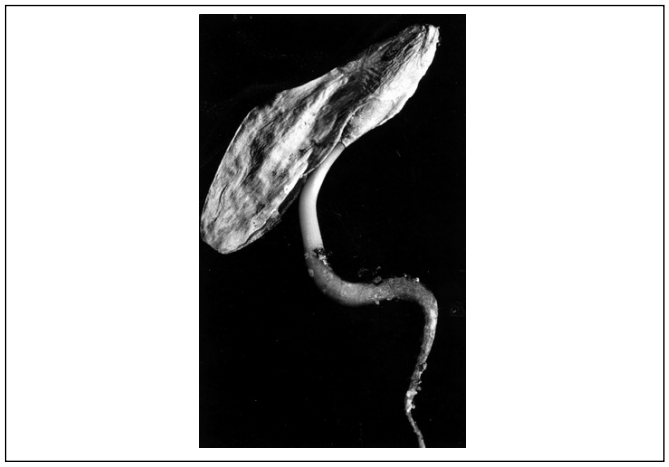


Figure 5—*Calocedrus decurrens*, incense-cedar: seedling development 4, 7, 10, and 17 days after germination.

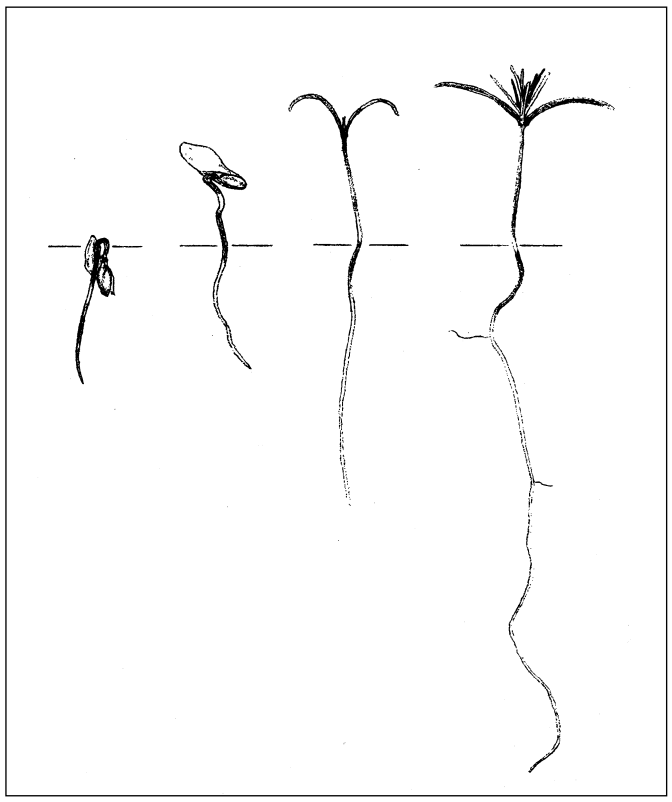

1930; Stein 1963). In the north-central Sierra of California, they grew about as well unshaded as with one-fourth shade (Show 1930). In current practice, both bareroot and container seedlings are grown without shade. They should be watered regularly but not to excess. Beds may be weeded entirely by hand or with mechanical and chemical assistance.

Seedbed densities of 270 to 325 seedlings/m^2 (25 to 30/ft^2) are satisfactory for producing 1+0 stock. Densities of 160 to 215 seedlings/m^2 (15 to 20/ft^2) are used for 2+0 stock. Tree percents range from 20 to 75 (Show 1930; Stein 1974). Generally, 2+0 bareroot seedling stock is used for outplanting, but 1+0, 1+1, 2+1, and 1+2 transplants have also been used. Some of the target sizes now used for producing stock include 1+0 (stem caliper 3 mm and top length 13 cm), 2+0 (stem caliper 3.5 cm and top length 20 cm), and 1+1 (stem caliper 4 mm and top length 25 cm). Outplanting in the spring proved best in long-ago tests (Show 1930) and continues to be favored.

Incense-cedar also can be reproduced from cuttings started in November (Nicholson 1984), and responds better than most conifers to cell and tissue culture (Jelaska and Libby 1987).

Bignoniaceae—Trumpet-creeper family

Campsis radicans (L.) Seem. ex Bureau

common trumpet-creeper

Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Synonyms. *Bignonia radicans* L., *Tecoma radicans* (L.) Juss.

Other common names. trumpetvine, cowitch vine, trumpet-flower.

Growth habit, occurrence, and uses. Common trumpet-creeper—*Campsis radicans* (L.) Seem. ex Bureau, a deciduous vine—is native from Texas to Florida and north to Missouri, Pennsylvania, and New Jersey (Vines 1960). It has also been introduced into New England (Bonner 1974). The vine is sometimes used in erosion control and as an ornamental, but its greatest value is for wildlife food. Hummingbirds are common visitors to trumpet-creeper flowers.

Flowering and fruiting. The large, orange-to-scarlet, perfect flowers are 5 to 9 cm long and appear from May through September (Bonner 1974; Vines 1960). This species is largely self-sterile, but pollinates well when self and cross pollen are mixed (Bertin and Sullivan 1988). The fruit is a 2-celled, flattened capsule about 5 to 15 cm long (figure 1) that matures from September to November (Vines 1960). The capsules turn from green to gray brown as they mature, and the small, flat, winged seeds (figures 1 and 2) are dispersed chiefly by wind as the mature capsules split open on the vine from October through December (Bonner 1974; Vines 1960). Good seed crops are borne annually.

Collection and extraction. Ripe capsules should be gathered when they turn grayish brown in the fall before splitting open. Seeds can be extracted by hand-flailing. There are approximately 300,000 cleaned seeds/kg (136,000/lb) (Bertin 1990; Bonner 1974). One sample had a purity of 98%, with 52% sound seeds (Bonner 1974). The longevity of common trumpet-creeper seeds in storage is not known, but if the seeds are dried to about 10% moisture content, they should store as well as other orthodox seeds.

Germination and nursery practice. The seeds exhibit some embryo dormancy. Pretreatment is not necessary for germination, but cold, moist stratification for 60 days at 5 to

Figure 1—*Campsis radicans*, common trumpet-creeper: fruit (**top**) and seed (**bottom**).

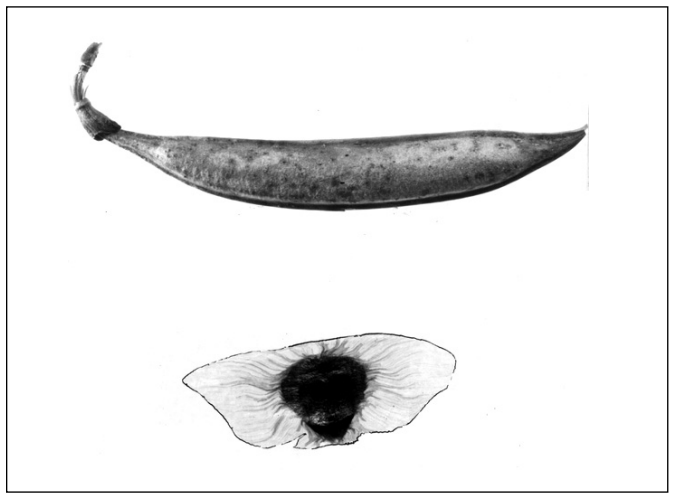

Figure 2—*Campsis radicans*, common trumpet-creeper: longitudinal section through a seed.

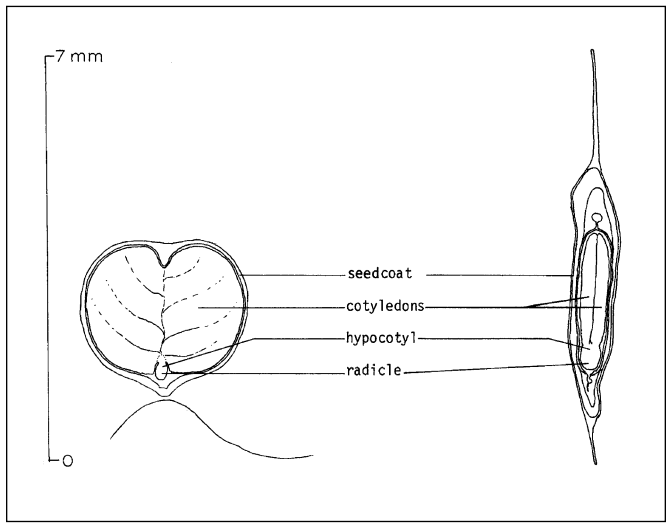

10 °C is recommended for quick and uniform germination (Bonner 1974; Dirr and Heuser 1987). Germination tests in sand have been run for 30 days at 20 °C night and 30 °C day temperatures. Four tests with stratified seeds averaged 66% germination, and germination rate was 51% in 19 days (Vines 1960). Germination is epigeal (figure 3). Seedlings can be grown in nurserybeds from either untreated seeds sown in the fall or from stratified seeds sown in the spring. Some horticultural cultivars are propagated by stem and root cuttings and layering. Softwood cuttings taken in June to September are easily rooted without hormone treatments (Dirr and Heuser 1987).

Fabaceae—Pea family

Caragana arborescens Lam.

Siberian peashrub

Donald R. Dietz, Paul E. Slabaugh, and Franklin T. Bonner

Drs. Dietz and Slabaugh (deceased) retired from the USDA Forest Service's Rocky Mountain Forest and Range Experiment Station; Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Synonym. *Caragana caragana* Karst.

Other common names. caragana, pea-tree.

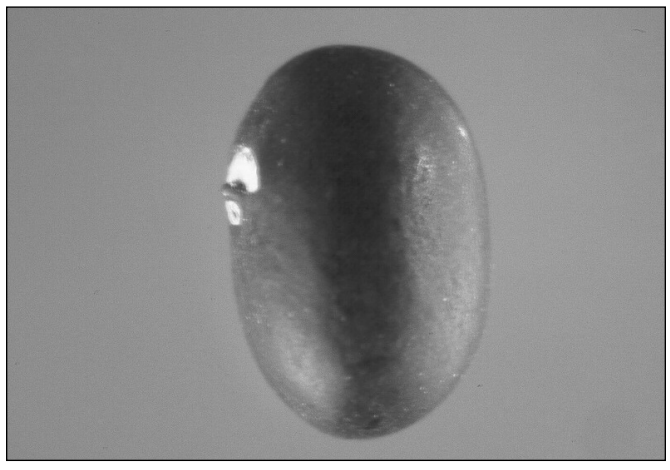
Growth habit, occurrence, and use. Siberian peashrub—*Caragana arborescens* Lam.—is one of the most hardy small deciduous trees or shrubs planted on the northern Great Plains (George 1953; Rehder 1940). Introduced into North America in 1752 (Rehder 1940), Siberian peashrub is native to Siberia and Manchuria and occurs from southern Russia to China *(Graham 1941)*. Varieties include the dwarf (*C. a. nana* Jaeg.) and Lorberg (*C. a. pendula* Carr.) peashrubs (Kelsey and Dayton 1942). The species readily adapts to sandy, alkaline soil and open, unshaded sites on the northern Great Plains, where it grows to heights of 7 m. It has been planted extensively for shrub buffer strips and windbreaks on farmlands and for hedges and outdoor screening in many towns and cities of the upper mid-West (Dietz and Slabaugh 1974; George 1953). It was also planted for wildlife and erosion control in the Great Lakes region (Graham 1941) and for deer-range revegetation programs in the Black Hills of South Dakota (Dietz and Slabaugh 1974). It is now considered invasive.

Flowering and fruiting. The yellow bisexual flowers appear from April to June. The fruit is a legume (pod) that measures 2.5 to 5 cm (figure 1) and contains about 6 reddish-brown, oblong to spherical seeds 2.5 to 4.0 mm in diameter (Lindquist and Cram 1967; Ross 1931) (figures 2 and 3). Fruits change in color to amber or brown as they ripen from June to July (Rehder 1940). Seed dispersal is usually completed by mid-August in most areas on the Great Plains. Shrubs take about 3 to 5 years to reach commercial seed-bearing age, and good crops occur nearly every year (Dietz and Slabaugh 1974).

Collection of fruits. The optimum seed collection period for Siberian peashrub is less than 2 weeks—usually in July or early August. Because the fruits begin to split open and disperse the seeds as soon as they are ripe, the legumes should be gathered from the shrubs by hand as soon as the first ones begin to open (Dietz and Slabaugh 1974).

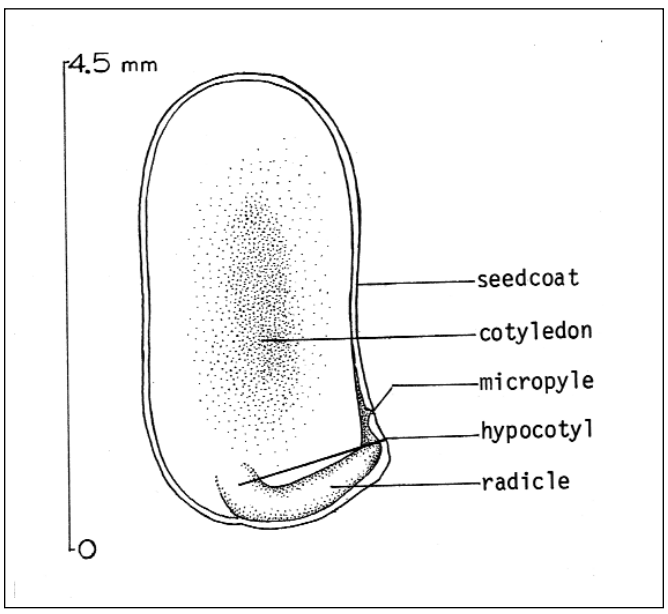
Figure 1—*Caragana arborsecens*, Siberian peashrub: legume.

Figure 2—*Caragana arborsecens*, Siberian peashrub: seed.



Extraction and storage of seeds. The legumes should be spread out to dry in a protected area until they pop open. The seeds can then be extracted easily by light maceration or beating. Legume fragments and other trash can be removed with aspirators, air-screen cleaners, or fanning mills. The average number of cleaned seeds per weight ranges from 28,700 to 48,500/kg (13,000 to 22,000/lb), with a purity of 97 to 100% (Dietz and Slabaugh 1974). A yield

Figure 3—*Caragana arborsecens*, Siberian peashrub: longitudinal section through a seed.



of 13 to 20 kg of seeds/100 kg (13 to 220 lb/100 lb) of fresh legumes has also been reported.

Seeds of Siberian peashrub, like those of other legumes, are orthodox in storage behavior. Studies in Canada have shown that the seeds remain viable for at least 5 years when stored dry at room temperatures. Germination of seedlots stored this way was 94% after 1 and 2 years and 93% after 5 years (Cram 1956). For the best long-term storage, seeds should be stored dry in polyethylene bags (or other sealed containers) at –18 to 4 °C, with a moisture content between 9.6 and 13.5% (Lindquist and Cram 1967).

Pregermination treatments and germination testing. For a leguminous species, Siberian peashrub does not have a very impermeable seedcoat. Untreated seeds will germinate in 15 days after sowing, but the best germination (87 to 100% in 5 days) can be obtained by soaking seeds for 24 hours in cold or hot (85 °C) water (Dirr and Heuser 1987). Successful germination has also been reported after acid scarification, cold stratification for 2 weeks, or fall planting (Dietz and Slabaugh 1974; Dirr and Heuser 1987; Hamm and Lindquist 1968; Lindquist 1960). Certain pesticides, such as captan and thiram, can apparently increase germination, possibly by inhibiting seed-borne disease (Cram 1969). The official testing prescription for Siberian peashrub seeds calls for clipping or filing through the seedcoat on the cotyledon end, soaking these seeds in water for 3 hours, then germinating them for 21 days at alternating temperatures of 20/30 °C (ISTA 1993). Germination tests have also been carried out in flats of sand or perlite and in Jacobsen germinators for 14 to 60 days at the same alternating temperatures (Dietz and Slabaugh 1974; Hamm and Lindquist 1968). Germination after 25 to 41 days averaged 45 to 72%, and 55 to 100% after 60 days (Dietz and Slabaugh 1974).

Nursery practice. Seeds of Siberian peashrub may be drilled or broadcast in late summer or spring. In a North Dakota nursery, Siberian peashrub is seeded during the last week in July or the first week in August. A cover crop of oats is seeded between the tree rows early enough to give winter protection. The shrubs are large enough to dig the following fall (Dietz and Slabaugh 1974). Many nurseries recommend drilling 80 to 160 seeds/m (25 to 50/ft) at 6, 9, or 12 mm ($^1/_4$ to $^1/_2$ in) depth; percentages of seeds growing into seedlings have varied from 35 to 50 (Dietz and Slabaugh 1974; Lindquist and Cram 1964).

Grading seeds for size has greatly increased the percentage of plantable seedlings. To be plantable, seedlings should be 30 cm (12 in) or more in height at the time of lifting. Only 87% of the seedlings grown from seeds measuring 2.5 mm in diameter were plantable, whereas 77% of seeds measuring 4.0 mm in diameter were plantable (Lindquist and Cram 1967). Inoculation of seeds with *Rhizobium* ssp. before sowing has been recommended (Wright 1947), but other workers report no significant effect on 1+0 seedlings (Cram and others 1964). Commercial nurseries have recommended anywhere from 1+0 to 3+0 stock for outplanting (Dietz and Slabaugh 1974).

Spraying to control insects in the nursery may be necessary. Grasshoppers are especially destructive to Siberian peashrub, sometimes completely defoliating the plants (Kennedy 1968). Plants have also been extensively damaged by deer browsing.

Vegetative propagation of Siberian peashrub is also possible. Untreated cuttings taken in late July rooted 80% in sand, whereas cuttings taken earlier (May to June) responded well to indole-butyric acid (IBA) in talc (Dirr and Heuser 1987).

C

Cactaceae Cactus family

Carnegiea gigantea (Engelm.) Britton & Rose

saguaro or giant cactus

Susan E. Meyer

Dr. Meyer is a research ecologist at the USDA Forest Service's Rocky Mountain Research Station, Shrub Sciences Laboratory, Provo, Utah

Growth habit, occurrence, and use. Saguaro—*Carnegiea gigantea* (Engelm.) Britton & Rose—has the northernmost distribution of any of the large, columnar cacti of the tropical and subtropical Americas. Formerly regarded as a member of the genus *Cereus,* it is now considered the single species of its own genus, *Carnegiea*. It is a principal indicator species of the Sonoran Desert and is found at elevations below 1,200 m from extreme southeastern California east to south central Arizona and south into northern Sonora (Kearney and Peebles 1960; Munz 1964). Saguaro is an arborescent, sometimes branched, stem succulent that reaches 10 m in height. It is found primarily in desert upland communities with coarse, gravelly, well-drained soils.

Saguaro is an important component of the communities where it occurs, providing food and shelter to a host of desert animals. Its wood has been used for fence and hogan construction by indigenous people of the area, and its fruits provided one of their most reliable wild food sources. The sweet, fleshy fruit pulp can be eaten raw or used to make confections or jams. The nectar is reported to be a source of excellent honey (Alcorn and Martin 1974). In addition, saguaro is one of the most well-known and beloved plants in the country, recognizable at a glance by most Americans.

Flowering and fruiting. Saguaro plants normally produce fruit on a yearly basis, even if the winter has been dry (Steenbergh and Lowe 1977). They have sufficient water and energy reserves in their succulent stems to buffer fruit production from the yearly vagaries of water availability. Even plants that have been severed at the base are capable of fruit production for 2 subsequent years. Plants in the wild reach reproductive maturity at a height of about 2 m and an age of about 40 years (Steenbergh and Lowe 1983). Flowering occurs from March through May, depending on latitude and elevation, with later flowering on cooler sites. The fruit crop may be damaged or destroyed by frost during flowering. The large, fragrant, epigynous flowers are borne at the stem apices. They open in the evening, and each lasts only until midday the following day. The flowers produce copious pollen and nectar and are pollinated primarily by nectar-feeding bats, although many other visitors take advantage of the rich resource (Hevly 1979; Steenbergh and Lowe 1977).

Fruits ripen from June through August. A single fruit contains 2,000 to 2,500 seeds. The succulent fruits usually split open while still attached to the plant, exposing the tiny seeds (figures 1 and 2) to removal by rain, but the fruits eventually fall to the ground. Many animals utilize the fruits and seeds. Larger mammals such as coyotes (*Canis latrans*) may act as dispersers, but most users, especially harvester ants (*Pogonomyrmex* spp.) and doves (*Zenaida* spp.), are consumers only. Most of the seeds are consumed before the beginning of summer rains, especially in years when fruits ripen early or initiation of the summer rainy season is delayed (Steenbergh and Lowe 1977).

Figure 1—*Carnegiea giganteus*, saguaro: seeds.

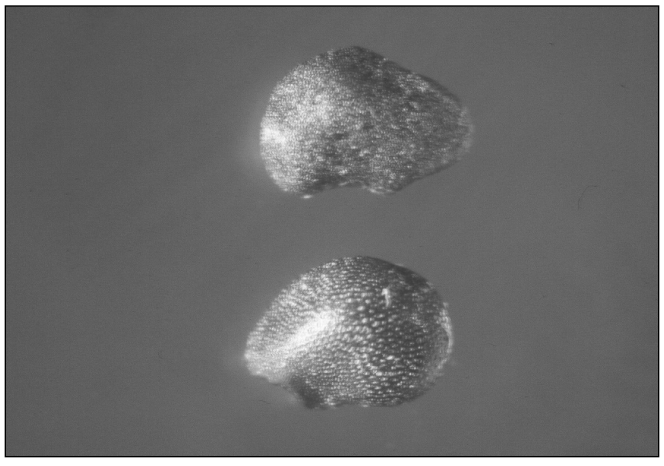

Figure 2—*Carnegiea giganteus*, saguaro: longitudinal section through a seed.

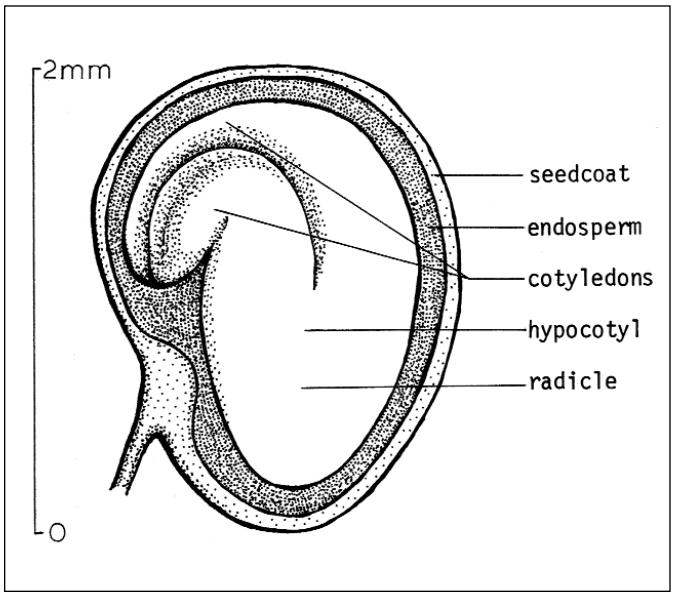

Seed collection, cleaning and storage. Ripe fruits turn from green to purple and can be collected by cutting with long-handled knives prior to dehiscence on the plant. The seeds can be removed from the fruits using standard procedures for fleshy fruited species, such as maceration in a macerator; forcing the fruits through an appropriately sized sieve; removing the pulp by flotation; drying the seeds and cleaning them in a fanning mill or aspirator. Extra care must be taken because of the small size of the seeds. The average number of seeds per weight is 990/g (450,000/lb) (Alcorn and Martin 1974). The seeds are usually of high quality (>95% germination of seedlots). Seeds apparently may be stored at room temperature for several years without much loss of viability, and germination values as high as 51% have been recorded, even after 10 years (Alcorn and Martin 1974).

Germination. Saguaro seeds are readily germinable when the fruits are ripe. Their germination is suppressed by the fruit pulp, but once they are washed free of the pulp they germinate freely, as long as temperatures are high (25 °C is optimum) and the seeds are exposed to light (Alcorn and Martin 1974; Steenburgh and Lowe 1977). Official testing calls for germination on moist blotter paper for 20 days at alternating temperatures of 20/30 °C, with light during the 8 hours at the higher temperature; no pretreatment is needed (AOSA 1993). In the field, seeds germinate soon after dispersal in response to adequate summer storms. Time to 50% germination of initially air-dried seeds is about 72 hours. If seedlots are first exposed to high-humidity air (without condensation) for 24 hours, they can reach 50% germination in 48 hours, an apparent adaptation for speeding germination during closely spaced summer storms (Steenbergh and Lowe 1977). Saguaro seeds do not form persistent seed banks; all viable seeds germinate soon after dispersal.

Because of apparently poor recruitment in natural stands, factors affecting survival of saguaro seedlings and young plants have been studied in some detail (Despain 1974; Nobel 1980; Steenbergh and Lowe 1969, 1976, 1977, 1983). New seedlings are highly susceptible to drought and herbivore damage, and young plants are at risk both of overheating in summer and freezing in winter. Nurse plants and other sheltering objects such as rocks greatly decrease these risks.

Nursery practice. Cleaned saguaro seeds may be surface-sown on coarse potting medium. The seedlings are highly susceptible to fungal pathogens, and care must be taken to provide good drainage and avoid overwatering (Alcorn and Martin 1974). They must be protected from freezing and also from full sunlight. Shade is probably beneficial for plants up to a meter (39 in) in height. The seedlings grow very slowly at first—only a few millimeters a year for the first several years.

C

Hydrangeaceae—Hydrangea family

Carpenteria californica Torr.

carpenteria

Donald L. Neal

Dr. Neal retired from the USDA Forest Service's Pacific Southwest Forest and Range Experiment Station

Growth habit. Carpenteria (bush-anemone or tree-anemone)—*Carpenteria californica* Torr.—is an erect evergreen shrub that is 1 to 3 (sometimes 4 m) tall with large showy white flowers. Plants are usually multi-stemmed and about as wide as tall. The leaves are oblong–lanceolate on short petioles and placed opposite. The leaves are leathery and in response to moisture stress, they turn yellow and twist and their edges roll under. They return to normal appearance and color when moisture is available (Kottcamp 1983; Sanwo 1997).

Occurrence. The range of carpenteria is extremely limited, occurring only between 300 and 1,500 m on the west slope of the Sierra Nevada, between the San Joaquin and Kings Rivers in eastern Fresno County, California. The shrub is found in scattered stands over an area 20 by 30 km or about 60,000 ha. The total number of plants has been estimated to less than 5,000 (Clines 1995).

Most stands are in small drainages on dry rocky slopes, mixed with Digger pine (*Pinus sabiniana* Dougl. ex Dougl.), interior live oak (*Quercus wislizeni A*. DC.), chaparral whitethorn (*Ceanothus leucodermis* Greene), and other representatives of the foothill woodlands at the lower elevational limits of its range. At their upper elevational limit, carpenteria plants can be found growing with ponderosa pine (*Pinus ponderosa* P. & C. Lawson), interior live oak, and other species of the lower yellow pine zone.

About two-thirds of the existing plants occur on lands of the USDA Forest Service's Sierra National Forest, and carpenteria is classified as a sensitive plant by the Forest Service. It receives some protection on 2 areas set aside by the Sierra National Forest and 1 owned by The Nature Conservancy. Carpenteria is a threatened species under the California Endangered Species Act, and in October of 1994 it was proposed for listing as endangered under the Federal Endangered Species Act (Federal Register 1994).

Natural reproduction. Until recently, all observed natural reproduction was by stump-sprouting after fire (Stebbins 1988; Wickenheiser 1989). However, after a large wildfire in 1989, an abundance of naturally occurring seedlings were found where mineral soil was exposed (Clines 1994) and many of them later had become established plants. In one study, hand-seeding in mineral soil after a fire produced abundant seedlings (Clines 1994). Stem layering and adventitious rooting have also been observed (Clines 1994).

Use. Carpenteria was first collected by the John C. Fremont expedition of 1845. It drew the attention of horticulturalists early and was found in gardens in the United States, England, and Europe by the early 1880s (Cheatham 1974). It is raised commercially for the garden in several California nurseries (Laclergue 1995).

Flowering and fruiting. Flowers are large (3 to 7 cm in diameter) and appear in May and June in a terminal cyme. The calyx is 5 (or 6) parted and there are 5 to 8 large white petals. The ovary is incompletely 5 (2 to 8)–celled. Up to 1,500 (2,000) ovules are attached to axile placentas that protrude into the locule (Clines 1994). The style has 5 to 7 closely grouped branches topped with numerous spreading yellow stamens. Pollination seems to be mostly outcrossing by insects but geitonogamy also produces viable seeds (Clines 1994).

Extraction and cleaning. Capsules (figure 1) can be collected by hand in July and August from native or commercially grown stands. The capsules are hard and must be cut open when collected intact. They can be found partially open on the shrubs later in the season. Each capsule may contain over 1,000 viable seeds (figure 2). Germination occurs easily without treatment and ranges from 70 to 100% (Mirov and Kraebel 1939; Clines 1994). There are 33 to 47.2 million seeds/kg (15.0 to 21.5 million/lb) (Mirov and Kraebel 1939).

Nursery practice. Carpenteria is grown in commercial nurseries both from seeds and cuttings. One common practice involves direct seeding into flats of well-drained soil. Damping-off is a problem and top dressing with perlite reduces but does not eliminate this problem. Cuttings root readily, especially those taken from the terminal few inches of the branches and treated with rooting compound.

C

Betulaceae—Birch family

Carpinus L.

hornbeam or ironwood

Paula M. Pijut

Dr. Pijut is a plant physiologist at the USDA Forest Service's North Central Research Station, Hardwood Tree Improvement and Regeneration Center, West Lafayette, Indiana

Growth habit, occurrence, and use. The hornbeam genus—*Carpinus* L.—includes about 35 species of deciduous, monoecious, small to large trees, that are native to the Northern Hemisphere from Europe to eastern Asia, south to the Himalayas, and in North and Central America (Furlow 1990; Hillier 1991; Krüssmann 1984; LHBH 1976; Suszka and others 1996). Five species are considered here (table 1). Hornbeams occur mainly as understory trees in rich, moist soils on bottomlands and on protected slopes (Metzger 1990; Rudolf and Phipps 1974). European hornbeam is an important forest tree species throughout Europe (Furlow 1990). In Mexico and Central America, *Carpinus tropicalis* (J.D. Sm.) Lundell forms a dominant canopy component (Furlow 1990). American hornbeams, which are native to the eastern United States and Canada, are smaller trees that grow in the mixed hardwood forest understory (Furlow 1990; Metzger 1990). Several geographic races of American hornbeam exist in North America (Fernald 1935; Furlow 1990). The races are morphologically variable and difficult to distinguish on the basis of independent characters. Furlow (1987a), using multivariate analysis, analyzed this geographical variation. The northern American hornbeam species is divided into the subsp. *caroliniana* from along the Atlantic and Gulf Coastal Plains of the southeastern United States and the subsp. *virginiana* of the Appalachian Mountains and northern interior regions to the West (Furlow 1987b). The Latin American *C. tropicalis* is divided into subsp. *tropicalis* of the highlands of southern Mexico and north Central America and subsp. *mexicana* of the mountains in northeastern Mexico and the trans-Mexican volcanic belt (Furlow 1987b).

The wood of hornbeams is extremely hard—hence the common name "ironwood"—and is used for making tool handles and mallet heads. It is also used to produce the high-quality charcoal used in gunpowder manufacture (Bugala 1993; Furlow 1990). Species of ornamental interest in the United States are listed in table 1. Most of the information presented in this chapter deals with European and American hornbeams, unless noted otherwise.

European hornbeam is a slow-growing tree (about 3 m over 10 years) that is pyramidal in youth but oval-rounded to rounded at maturity (Dirr 1990; Suszka and others 1996). This species is planted in the landscape as single specimen trees or as screens or hedges. It tolerates a wide range of soil and light conditions but grows and develops best in full sun on rich, moist sites with good drainage (Dirr 1990; Metzger 1990). Several cultivars produce excellent color, form, and texture. The cultivar 'Fastigiata' is the most common one in cultivation, with foliage more uniformly distributed along the branches than on other cultivars (Dirr 1990; Hillier

Table 1—*Carpinus,* hornbeam: nomenclature, occurrence, height at maturity, and date of first cultivation

Sources: Dirr (1990), Hillier (1991), Krüssmann (1984), LHBH (1976), Metzger (1990).

1991; Krüssmann 1984). This cultivar is used primarily as a screen hedge because of its dense, compact, ascending branches (Dirr 1990). The bark on older trees is gray and beautifully fluted.

American hornbeam is a small, multi-stemmed, bushy shrub or single-stemmed tree with a wide-spreading, flat or round-topped crown, that grows slowly; averaging 2.5 to 3 m over a 10-year period (Dirr 1990; Metzger 1990). This species has considerable fall color variation, from yellow to orange-red, and is planted in the landscape in groups or as an understory tree (Beckett 1994; Dirr 1990). The bark on older trees is slate gray, smooth, and irregularly fluted; the overall appearance is comparable to the flexed bicep and forearm muscles—hence another common name, "musclewood" (Dirr 1990).

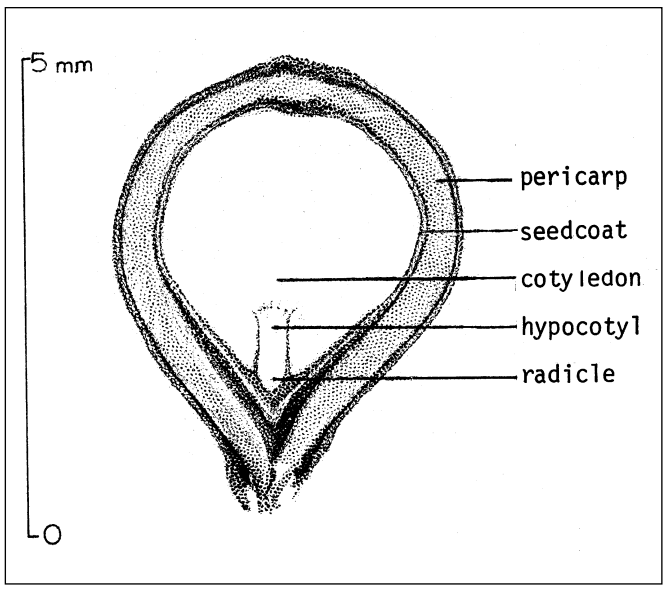
Heartleaf hornbeam is a small tree of rounded habit with leaves that are large with deeply heart-shaped bases, and with large, rich brown winter buds (Dirr 1990; Hillier 1991; Krüssmann 1984). The bark is slightly furrowed and scaly (Dirr 1990). The fruits are borne in cigar-shaped catkins (Dirr 1990). Japanese hornbeam is a wide-spreading small tree or large shrub with prominently corrugated leaves and with branches that radiate like the ribs on a fan (Dirr 1990; Hillier 1991). Oriental hornbeam grows as a large shrub or small tree with an overall U-shaped branching pattern (Dirr 1990). The bracts of this species are unlobed, differentiating it from European and American hornbeams (Dirr 1990). The main branches and stems are twisted, giving this species an interesting winter appearance (Dirr 1990).

Flowering and fruiting. In most species, the staminate and pistillate catkins appear in the spring concurrently as the trees are leafing out (Dirr 1990; Furlow 1990; Metzger 1990; Suszka and others 1996). The fruits are ovoid, ribbed, single-seeded nutlets (figures 1 and 2), each borne at the base of a distinctive 3-lobed involucre (bract) (Metzger 1990; Rudolf and Phipps 1974). The fruits ripen from late summer to fall. They are dispersed from fall to spring and are carried only a short distance by the wind or may be dispersed farther by birds (Rudolf and Phipps 1974). Details of flowering and seeding habits for European and American hornbeams are described in tables 2 and 3.

Collection of fruits; extraction, cleaning, and storage of seeds. Fruits harvested while they are still green (when the wings are turning yellow and are still soft and pliable) can be fall-sown for germination the following spring (Bugala 1993; Dirr 1990; Hartmann and others 1990). These seeds should not be allowed to dry out, as a hard seedcoat will develop, and they should be checked before sowing for the presence of well-developed embryos (Bugala 1993;

Figure 1—*Carpinus caroliniana*, American hornbeam: nutlet with involucre removed

Figure 2—*Carpinus caroliniana*, American hornbeam: longitudinal section through a nutlet.



Leiss 1985). Green seeds can also be stratified for 3 to 4 months over winter and sown the following spring (Hartmann and others 1990).

Mature seeds (with hardened seedcoats) should be collected, spread out in thin layers in a cool, well-aerated room or shed, and allowed to dry superficially (Macdonald 1986; Rudolf and Phipps 1974; Suszka and others 1996). The bracts do not need to be removed if the seeds are to be broadcast (Macdonald 1986). They should be removed, however, from large quantities of seeds (to aid in mechanical sowing) by placing the seeds in a de-winging machine or beating the seeds in bags (Rudolf and Phipps 1974; Suszka

Table 2—*Carpinus,* carpinus: phenology of flowering and fruiting

and others 1966). The debris can be removed from seedlots by screening and fanning (Macdonald 1986). European hornbeam seeds with bracts weigh 15 to 18 kg/0.35 hl (33 to 40 lb/bu). Fruits weighing 45 kg (100 lb) yield about 23 kg (50 lb) of cleaned seed (Rudolf and Phipps 1974). The average numbers of cleaned seeds per weight of European and American hornbeam are listed in table 3.

Hornbeam seeds stratified immediately after extraction can be stored up to 2 years (Rudolf and Phipps 1974). European hornbeam seeds in nuts partially dried to 8 to 10% moisture content can be stored in sealed containers at a temperature of –3 °C for at least 5 years (Bugala 1993). Seeds of this species stored at 10% moisture content in sealed containers at 3 °C lost no viability after 14 months (Suszka and others 1969).

Pregermination treatments. Hornbeam seeds that are allowed to mature and become dry will develop a hard seedcoat. Dormancy, caused by conditions in the embryo and endosperm, may be overcome by stratification treatments (a warm period followed by a cold period). In general, 1 to 2 months of warm stratification followed by 2 to 3 months of cold stratification are necessary to break dormancy of the European hornbeam. The International Seed Testing Association (1993) prescribes 1 month of moist incubation at 20 °C, followed by 4 months at 3 to 5 °C, for laboratory testing of European hornbeam. Results of stratification treatments vary for different species of hornbeam, so several are presented in table 4. Bretzloff and Pellet (1979) reported that gibberellic acid treatment at 0.025, 0.1, and 0.5 g/liter (25, 100, and 500 ppm) generally increased germination of American hornbeam seeds stratified at 4 °C for 6, 12, or 18 weeks, compared to stratification alone. Scarification of the seedcoat plus gibberellic acid also improved germination (Bretzloff and Pellet 1979). Gordon and others (1991) and Suszka and others (1996) provide extensive information on the sampling, seed pretreatment, purity, viability, and germination testing, seedling evaluation, and storage of forest tree and shrub seeds. Specific procedures are presented for a number of species.

Germination tests. Germination percentage of stratified seeds is low, usually less than 60% and occasionally as low as 1 to 5% (Metzger 1990). Germination tests may be made on pretreated seeds in germinators, or in flats of sand, or sand plus peat (Rudolf and Phipps 1974). Viability of European and American hornbeams is best determined by using the tetrazolium test for viability (Chavagnat 1978; Gordon and others 1991; ISTA 1993; Suszka and others 1996). Details of germination test results are shown in table 5. Germination of hornbeam seeds is epigeal.

Nursery practice and seedling care. The optimum seedbed is continuously moist, rich loamy soil protected from extreme atmospheric changes (Rudolf and Phipps 1974; Suszka and others 1966). Germination of many naturally disseminated seeds is delayed until the second spring after seed dispersal (Rudolf and Phipps 1974). If germination is expected the first spring, seeds should be collected while they are still green (the wings turning yellow and still soft and pliable) and sown in the fall, or stratified immediately and sown the following spring (Bugala 1993; Dirr 1990; Hartmann and others 1990; Rudolf and Phipps 1974). Macdonald (1986) suggested collecting European hornbeam seeds in the fall, followed by extraction, stratification for 8

Table 4—*Carpinus,* hornbeam: stratification treatments for breaking embryo dormancy

* Tests were made in sand or soil.

weeks at 18 to 21 °C and then for 8 to 12 weeks at 0.5 to 1 °C, and then spring-sowing. Seeds collected later should be partially dried, stratified, and sown the next fall or the following spring to avoid having seedbeds with germination spread out over 2 years (Rudolf and Phipps 1974). Seeds should be sown in well-prepared beds at a rate of 323 to 431/m^2 (30 to 40/ft^2) and covered with 0.6 to 1.3 cm ($^1/_8$ to $^1/_4$ in) of soil (Rudolf and Phipps 1974). Macdonald (1986) suggested sowing seeds at a rate of 250/m^2 (23/ft^2) for lining-out stock and 150 to 250/m^2 (14 to 23/ft^2) for rootstocks. Fall-sown beds should be mulched with burlap, pine straw, or other material until after the last frost in spring (Rudolf and Phipps 1974). The soil surface should be kept moist until after germination, and beds should shaded lightly for the first year (Rudolf and Phipps 1974). Davies (1987, 1988) demonstrated that growth of European hornbeam transplants was greatly increased by using a chemical for weed control and various synthetic sheet mulches. Black polythene sheets (125 m thick) gave the best results for controlling weeds and aiding in tree establishment (Davies 1988).

Cultivars of hornbeam may be grafted (side whip or basal whip) or budded onto seedlings of the same species (Hartmann and others 1990; Macdonald 1986; MacMillan-Browse 1974). Hornbeam can also be propagated by cuttings, but with variable success. Stem cuttings of European hornbeam 'Fastigiata' rooted when treated with 2% (20,000 ppm) indole-3-butyric acid (IBA); American hornbeam 'Pyramidalis' with 1 and 1.6% IBA; heartleaf hornbeam (var. *chinensis*) with 1.6 and 3% IBA–talc; and Japanese hornbeam with 3 g/liter (3,000 ppm) IBA–talc plus thiram (Cesarini 1971; Dirr 1990; Dirr and Heuser 1987; Obdrzalek 1987). After rooting, the cuttings require a dormancy period (Dirr 1990). Placing cuttings at a temperature of 0 °C during the winter months satisfies the dormancy requirements (Dirr 1990). Stock plant etiolation and stem banding have been shown to improve the rooting of hornbeam (Bassuk and others 1985; Maynard and Bassuk 1987, 1991, 1992, 1996). Chalupa (1990) reported the successful micropropagation of European hornbeam by using nodal segments and shoot tips as initial explants. Oriental hornbeam has been established in bonsai culture (Vrgoc 1994).

Juglandaceae—Walnut family

Carya Nutt.

hickory

Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Growth habit, occurrence, and use. Of the dozen or so species of hickories native to the United States, 9 are valuable for timber and the food they provide for wildlife (table 1). All are deciduous trees. Pecan and its many horticultural varieties and hybrids are widely cultivated for nuts in large plantations in the southern and southwestern United States, as well as in many other countries. The first known selections were made in 1846, and many cultivars were available by the late 19th century (Madden and Malstrom 1975). Budding and grafting have been the primary means of improvement, but new provenance studies (Grauke and others 1990) and advanced research on the reproductive biology and genetics of pecan (Graves and others 1989; McCarthy and Quinn 1990; Yates and Reilly 1990; Yates and Sparks 1990) demonstrate the promise for future improvements in nut production and disease resistance. Shellbark and shagbark hickories have also been planted for nut production.

Flowering and Fruiting. Hickories are monoecious and flower in the spring (table 2). The staminate catkins develop from axils of leaves of the previous season or from inner scales of the terminal buds at the base of the current

growth. The pistillate flowers appear in short spikes on peduncles terminating in shoots of the current year. Hickory fruits are ovoid, globose, or pear-shaped nuts enclosed in husks developed from the floral involucre (figure 1). Husks are green prior to maturity and then turn brown to brownish black as they ripen (Bonner and Maisenhelder 1974). The husks become dry at maturity in the fall (table 2) and split away from the nut into 4 valves along sutures. Husks of mockernut, nutmeg, shagbark, and shellbark hickories, as well as those of pecan, split to the base at maturity, usually releasing the nuts. Husks of pignut, bitternut, sand, and water hickories split only to the middle or slightly beyond and generally cling to the nuts. The nut is 4-celled at the base and 2-celled at the apex. The edible portion of the embryonic plant is mainly cotyledonary tissue (figure 2) and has a very high lipid content (Bonner 1971; Bonner 1974; Short and Epps 1976).

Figure 1—*Carya*, hickory: nuts with husks attached and removed (the size and shape of individual nuts varies greatly within a species and may differ from the examples shown here); *C. aquatica*, water hickory (**first row left**) and *C. cordiformis*, bitternut hickory (**first row right**); *C. glabra*, pignut hickory (**second row left**) and *C. myristiciformis*, nutmeg hickory (**second row right**); *C. illinoensis*, pecan (**third row left**) and *C. laciniosa*, shellbark hickory (**third row right**); *C. ovata*, shagbark hickory (**fourth row left**) and *C. alba*, mockernut hickory (**fourth row right**).

Collection, extraction, and storage. Hickory nuts can be collected from the ground after natural seedfall or after shaking the trees or flailing the limbs. Persistent husks may be removed by hand, by trampling, or by running the fruits through a macerator or a corn sheller. Several studies have shown that the larger nuts of pecan make larger seedlings (Adams and Thielges 1977; Herrera and Martinez 1983), so sizing of nuts may be beneficial. Shagbark and shellbark hickory trees have been known to produce 0.5 to 0.75 hl ($1^1/_2$ to 2 bu) and 0.75 to 1.1 hl (2 to 3 bu) of nuts, respectively (Bonner and Maisenhelder 1974). Good crops of all species are produced at intervals of 1 to 3 years (table 3). Some typical yield data are presented in table 4.

Storage tests with pecan and shagbark hickory have demonstrated that the hickories are orthodox in storage behavior, that is, they should be dried to low moisture contents and refrigerated. Seedlots of nuts of both species dried to below 10% moisture and stored at 3 °C in sealed containers retained viability well for 2 years before losing half to two-thirds of their initial viability after 4 years (Bonner 1976b). The poor results after 4 years are probably due to the high lipid levels in these seeds, which places them in the sub-orthodox storage category (Bonner 1990). There are no storage data for other species of hickory, but it is reasonable to think that they can be stored in a similar fashion.

Pregermination treatments. Hickories are generally considered to exhibit embryo dormancy, although work with pecan suggests that mechanical restriction by the shell is the reason for delayed germination in that species (van Staden and Dimalla 1976). Other research with pecan has shown that there is a clinal gradient in stratification requirement. Seedlots from southern sources are practically nondormant, whereas those from northern sources require treatment for prompt germination (Madden and Malstrom 1975). The common treatment is to stratify the nuts in a moist medium at 1 to 4 °C for 30 to 150 days (table 5). Stratification of

imbibed nuts in plastic bags without medium is suitable for most species (Bonner and Maisenhelder 1974), and good results have been reported for pecans from southern sources by soaking the nuts at 20 °C for 64 hours (Goff and others 1992). There are indications that stratification should be shortened for stored nuts; this was the case in one storage test on pecan and shagbark hickory (Bonner 1976b). If cold storage facilities are not available, stratification in a pit with a covering of about 0.5 m of compost, leaves, or soil to prevent freezing will suffice. Prior to any cold stratification, nuts should be soaked in water at room temperature for 2 to 4 days with 1 or 2 water changes each day to ensure full imbibition (Eliason 1965). There is evidence that germination of pecan can be increased by treatment with gibberellins (Bonner 1976a; Dimalla and van Staden 1977), but practical applications have not been developed.

Germination tests. Official testing rules for North America (AOSA 1993) prescribe testing pecan and shagbark hickory at alternating temperatures of 20 °C (dark) for 16 hours and 30 °C (light) for 8 hours on thick creped paper for 28 days. Stratification for 60 days as described above is also recommended. Adequate germination tests can also be made on stratified nuts in flats of sand, peat, or soil at the same temperature regime (table 5). Quick tests with tetrazolium salts can also be used with hickories (Eliason 1965).

Nursery practice. Either fall-sowing with untreated seed or spring-sowing with stratified seed may be used. Excellent results with fall-sowing have been reported for shagbark hickory, but good mulching is necessary (Heit 1942). Drilling in rows 20 to 30 cm (8 to 12 in) apart and 2 to 4 cm ($^3/_4$ to 1 $^1/_2$ in) deep with 20 to 26 nuts/m (6 to 8/ft) is recommended; about 100 seedlings/m^2 (10/ft^2) is a good density (Williams and Hanks 1976). Mulch should remain until germination is complete. Shading is generally not necessary, but shellbark hickory may profit from shade. Protection from rodents may be required for fall-sowings.

C

Fagaceae—Beech family

Castanea P. Mill.

chestnut

Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Growth habit, occurrence, and use. The genus *Castanea*—the chestnuts—comprises 11 species of small to medium-sized deciduous trees found in southwestern and eastern Asia, southern Europe, northern Africa, and the eastern United States. Five species are covered in this chapter; only 2 are native to the United States (table 1). American chestnut formerly ranked as one of the most valuable timber species in the Appalachian region, and the nuts were an important wildlife food as well as being extensively marketed for human consumption. In the years since the chestnut blight—*Cryphonectria parasitica* (Murr.) Barr—was discovered in New York in 1904, the disease has spread throughout the range of the American chestnut and completely destroyed it as a commercial species. Many rootstocks still survive and send up multiple sprouts that grow to the size of a small tree (table 2) before dying. Some of these sprouts occasionally produce a few seeds, but they usually do not live long enough for significant production (Sander 1974).

Japanese, Chinese, and European chestnuts (table 1) were introduced into the United States in the 18th and 19th centuries (Anagnostakis 1990; Sander 1974). The Asian species demonstrated good resistance to the chestnut blight, and breeding programs were started as early as the 1890s to transfer the resistance to American chestnut (Jaynes 1975). Chinese chestnut, the most promising of these introductions, has been widely planted throughout the eastern United States, mostly in orchards for nut production. Allegheny chinkapin is somewhat resistant to the blight and might be useful as a rootstock in grafting; its other good features are small size, precocity of fruiting, and heavy seedcrops (Payne and others 1994). Breeding for resistance has not been highly successful, but advances in tissue culture offer new promise (Dirr and Heuser 1987).

Flowering and fruiting. Chestnuts are monoecious, but some trees produce bisexual catkins also (Sander 1974). Unisexual male catkins, 15 to 20 cm long, appear near the base of the flowering branches. The pistillate flowers occur singly or in clusters of 2 to 3, near the end of the branches (Brown and Kirkman 1990; Sander 1974), with the female catkins at the base of the shoot (Payne and others 1994). Flowering begins in April or May in the Southeast (Hardy 1948) and in June in the Northeast (Sander 1974).

Chestnut fruits are spiny, globose burs, from 2.5 to 7.5 cm in diameter, borne singly or in spikelike clusters (Sander 1974; Vines 1960). The fruits each contain from 1 to 3 seeds (nuts); Allegheny chinkapins have 1 seed and American chestnuts (figure 1) have 3 seeds/fruit (Brown and Kirkman 1990; Sander 1974). The nuts are flattened on one side and range from light to dark brown or black in color (Brown and Kirkman 1990; Rehder 1940). Nuts of American chestnut are 12 to 25 mm wide and about 25 mm long. The exotic chestnuts bear larger nuts that are 19 to 38

Table 1—*Castanea,* chestnut: nomenclature and occurrence

Scientific name	Common name(s)	Occurrence

Table 2—*Castanea,* chestnut: height, year first cultivated, and seed weights

Species	Height at maturity (m)	Year first cultivated in US	Cleaned seeds/weight /kg	Cleaned seeds/weight /lb
C. crenata	10	1876	33	15
C. dentata	20–25*	1800	220–360	100–162
C. mollissima†	21	1853	50–220	23–100
C. pumilla	15	—	300	136
C. sativa	21	Pre 1880	33	15

Sources: Payne and others (1994), Sander (1974).
* Height refers to sprouts from living rootstocks of trees killed by the blight; before the blight this species obtained heights of 21 to 30 m.
† Bears large crops annually in orchards beginning at about 8 years of age.

Figure 1—*Castanea dentata*, American chestnut: fruit (bur) and nut.

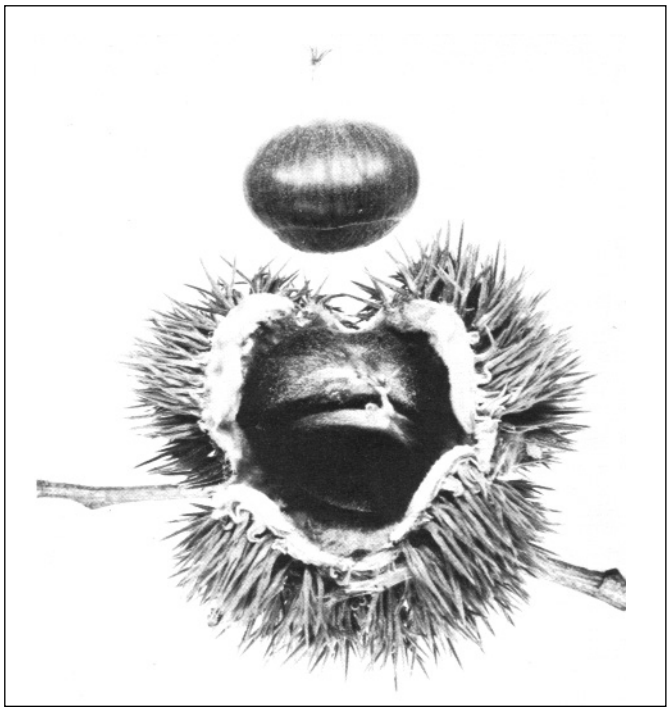

Figure 2—*Castanea dentata,* American chestnut: longitudinal section through a nut.

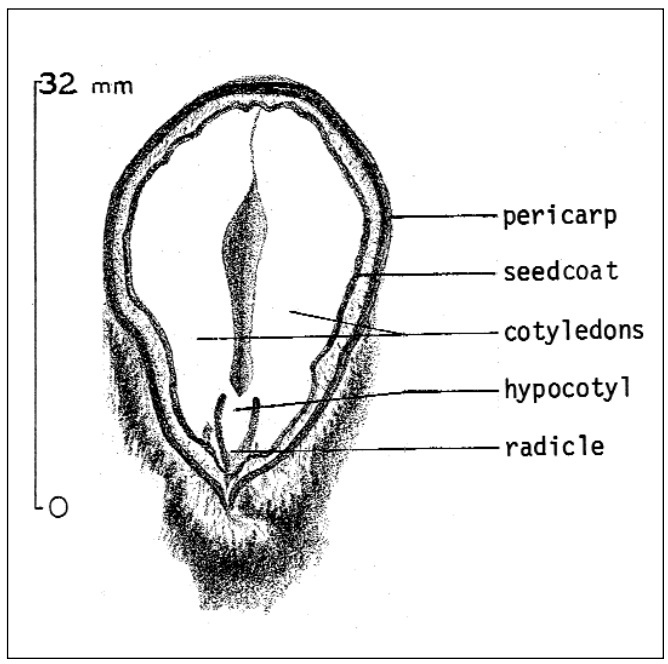

mm wide (Sander 1974). Food reserves, primarily starch, are stored in the large cotyledons (figure 2). Fresh nuts are 40 to 45% starch by weight, with very little lipid content (Jaynes 1975; Payne and others 1994; Wainio and Forbes 1941). Seeds ripen in August to October, depending on species and location (Hardy 1948; Sander 1974). Seed weights are listed in table 2.

Superior strains and hybrids. There are no identified superior strains of native chestnuts, but many cultivars and hybrids have been developed with the exotic chestnuts, primarily in Europe. The search for blight-resistant American chestnuts continues, however, with breeding, tissue culture, and innovative budding and grafting techniques (Ackerman and Jayne 1980; ACF 2002).

Collection of fruits. Chestnuts can be picked from the trees, collected from the ground by hand, or shaken from the trees onto ground cloths. Burs of Allegheny chinkapin do not open widely, and the seeds are difficult to shake out. Some remain on the trees throughout winter (Payne and others 1994). Harvesting should begin as soon as the burs begin to split open. The nuts are intolerant of desiccation (recalcitrant) (Aldous 1972; Pritchard and Manger 1990), so collections from the ground should be done very soon after dissemination to prevent excessive drying. Frequent collection

is especially important if the weather is hot and dry, as nuts can lose viability within a week on the ground (USDA 1951). If the weather is wet, Allegheny chinkapin nuts will sometimes germinate on the trees (Payne and others 1994).

Storage of seeds. Because of their recalcitrant nature, chestnuts are normally stored no longer than 6 months (overwinter). With good care, however, storage for 18 months is not difficult, and some have been successfully stored for 3.5 years (Jaynes 1975). Immediately after collection, the nuts should be floated in water to remove trash and immature and damaged nuts. If collected from the ground in a dry condition, they should be left in water overnight to restore their naturally high moisture content. Upon removal from water, the nuts should be spread to dry in a cool, well-ventilated place to remove all surface moisture. The nuts should be placed in containers that inhibit drying, such as polyethylene bags, and stored at 1 to 3 °C; however, the containers should not be airtight so that some gas exchange between nuts and the storage atmosphere is possible. Moisture content of the nuts should be about 40 to 45% during storage (Sander 1974). Too much moisture can result in loss of seeds to microorganisms (Woodruff 1963).

Pregermination treatments. Chestnut seeds are dormant and require a period of cold, moist stratification for prompt germination. In normal nursery practice, overwinter storage of fully imbibed nuts at 1 to 3 °C will satisfy the chilling requirement to overcome dormancy. For nuts that have not been stored moist, or if a deeper dormancy than usual is suspected, then stratification should be used; 1 to 3 months is the recommended period for American and Chinese chestnuts (Dirr and Heuser 1987; Jaynes 1975). If nuts are planted in the fall, stratification is not necessary, but the nuts should be kept in cold storage until planted (Sander 1974).

Chestnuts are commonly infested with the larvae of the seed weevils *Curculio sayi* Gyllenhall and *C. caryatrypes* Bohemon (Gibson 1985). A simple method to kill the larvae is to submerge the nuts for 20 to 40 minutes in water at 49 °C (Payne and Wells 1978).

Germination tests. The standard laboratory testing procedure for European chestnut is to (1) soak the seeds in water for 24 hours; (2) cut off a third of the seed at the cup-scar end; (3) remove the testa; and (4) germinate the seeds for 21 days in or on top of sand at the standard test regime of alternating 20 and 30 °C (ISTA 1993). If only constant temperatures are available, 28 °C is recommended for this species, which also has no specific light requirement of germination (Pritchard and Manger 1990). Data are lacking on other chestnut species with this procedure, but it quite likely will work for any of them. There are alternate procedures for whole nuts. Stratified nuts of Chinese chestnut have been germinated in a moist medium at 15 to 21 °C; germination reached 100% in 42 days (Berry 1960).

Nursery practice. Chestnuts may be planted in autumn or spring. Nuts that have been kept in cold storage from the time they are harvested should be planted in September or October (Sander 1974). Fall-sown beds should be mulched and protected as much as possible against rodents (Williams and Hanks 1976). Nuts for spring-planting should be stratified for 2 to 3 months.

In both fall- and spring-plantings, nuts should be sown 2 to 4 cm ($^3/_4$ to 1 $^1/_2$ in) deep and spaced 7.5 to 10 cm (3 to 4 in) apart in rows 7.5 to 15 cm (3 to 6 in) apart in the nursery beds. Nuts can be either sown or drilled by hand, or broadcast mechanically (Sander 1974; Williams and Hanks 1976). Some growers recommend planting by hand so that the nuts can be placed on their sides to promote better seedling form (Jaynes 1975). European chestnuts are normally broadcast at a density of 100 nuts/m^2 (9 to 10/ft^2) (Aldous 1972). One should expect 75 to 80% germination in beds with good seeds (Aldous 1972; Sander 1974). A study with Chinese chestnuts found that grading nuts by size had no influence on time of emergence, although larger seeds did tend to produce larger seedlings (Shepard and others 1989).

C

Casuarinaceae—Casuarina family

Casuarina Rumph. ex L.

casuarina

David F. Olson, Jr., E. Q. P. Petteys, and John A. Parrotta

Dr. Olson retired from the USDA Forest Service; Dr. Petteys is the district forester of Kauai, Hawaii Department of Lands and Natural Resources, Division of Forestry and Wildlife; Dr. Parrotta is a research program leader at the USDA Forest Service's Research and Development National Office, Arlington, Virginia

Growth habit, occurrence, and use. The genus *Casuarina*—the only genus in the Casuarina family—comprises about 50 species, chiefly Australian, with a few having native ranges extending from Bangladesh to Polynesia. Casuarina trees are evergreen angiosperms, resembling conifers, with thin crowns of drooping branches and leaves reduced to scales (Little 1949; Little and Wadsworth 1964). Three species of this genus have been introduced successfully into continental United States, Hawaii, and Puerto Rico (table 1) (Bailey 1949; Rockwood and others 1990). Beach she-oak, especially, is planted as a windbreak throughout its native and introduced ranges and as an ornamental in parks and gardens (Parrotta 1993; Rockwood and others 1990). It was first introduced into Hawaii in 1882 (Neal 1965). The bark has been used in tanning, in medicine, and for the extraction of dye (Parrotta 1993). The fruits are made into novelties and Christmas decorations (Little and Wadsworth 1964). The wood is hard and heavy and is difficult to work, hence the common name "ironwood." It was once heavily used for building poles and firewood but now is seldom used commercially in the United States (Parrotta 1993). Beach and gray she-oaks are considered invasive pests in southern Florida and gray she-oak in Hawaii.

Flowering and fruiting. Casuarinas are monoecious or dioecious. Minute male flowers are crowded in rings among grayish scales. Female flowers lack sepals but have pistils with small ovaries and threadlike dark red styles (Little and Wadsworth 1964). The multiple fruit is conelike, about 8 to 20 mm in diameter (figure 1), and composed of numerous individual fruits. Each fruit is surrounded by 2 bracteoles and a bract that splits apart at maturity and releases a 1-winged light brown samara (figures 2 and 3). The immature fruits of the genus are green to gray-green, becoming brown to reddish brown when ripe (Neal 1965). In warm climates, flowering and fruiting occur throughout the year. Consequently, time of seed collection varies from place to place (Little and Wadsworth 1964; Olson and Petteys 1974). In Hawaii, Florida, and Puerto Rico, the peak of the flowering period appears to be April through June, with fruiting from September through December (Magini and Tulstrup 1955; Neal 1965; Olson and Petteys 1974; Rockwood and others 1990). Minimum seed-bearing age is 2 to 5 years, and good seedcrops occur annually (Magini and Tulstrup 1955; Olson and Petteys 1974; Parrotta 1993).

Collection, extraction, and storage. The multiple fruits may be picked from the trees or shaken onto canvas or

Table 1—*Casuarina,* casuarina: nomenclature, occurrence, and uses

Scientific name(s) & synonym	Common name(s)	Occurrence (native & introduced)

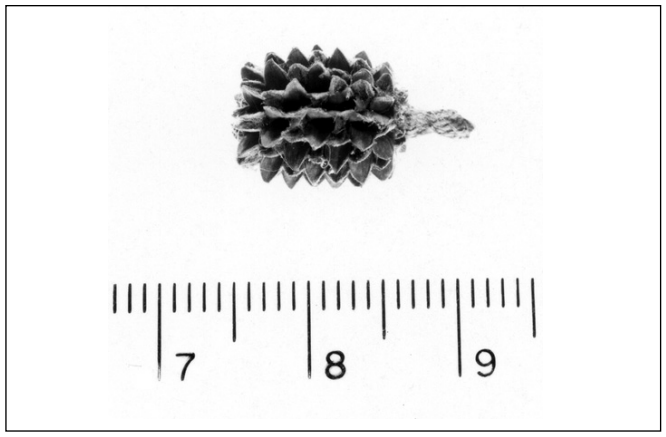

Figure 2—*Casuarina cunninghamiana*, river she-oak: longitudinal section through a seed.

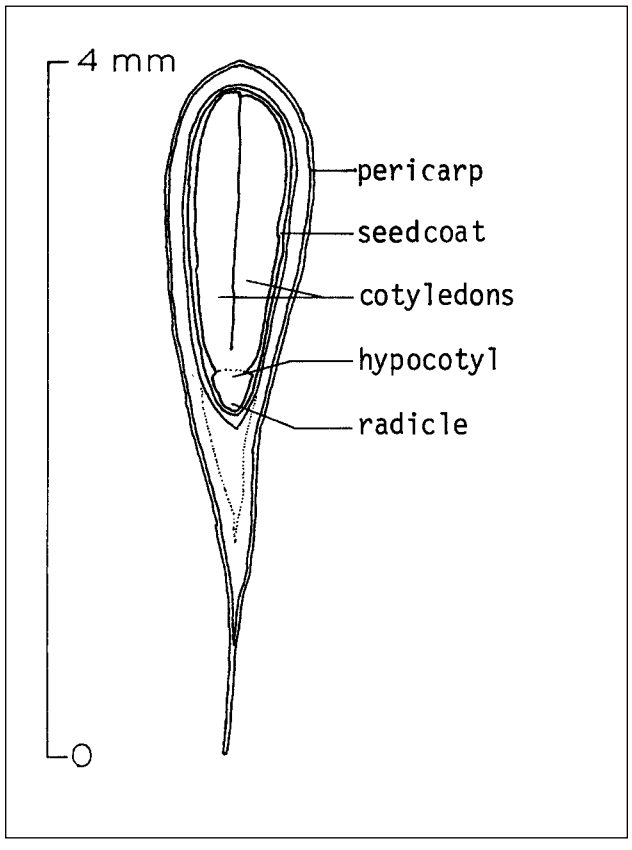
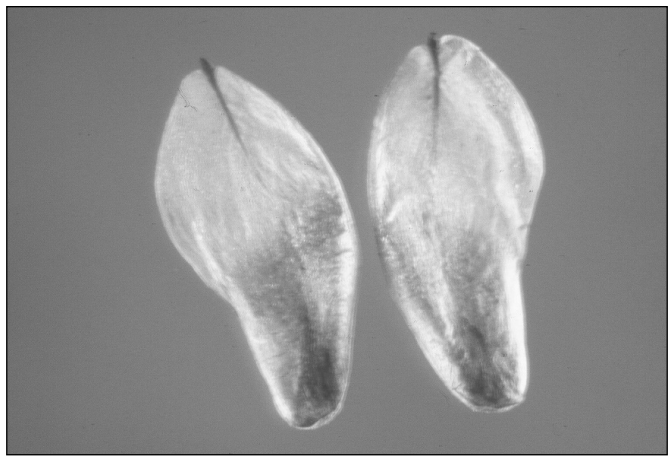


plastic sheets. Seeds reach maximum weight and germinability 18 weeks after anthesis, or when cones change in color from green to brown (Rai 1990). The samaras, which are used as seeds, may be separated from the fruits by shaking and screening (Olson and Petteys 1974). Cones placed in trays, covered by a thin cloth, and dried under full sunlight will soon begin to release their seeds, usually within 3

Figure 3—*Casuarina cunninghamiana*, river she-oak: winged seeds.



days (Kondas 1990). A kilogram of fruits (about 250 cones) yields between 20 and 60 g of seeds (1 lb of cones yields 1.5 to 2.4 oz of seeds). There are about 650 to 760 seeds/g (300,000 to 350,000 seeds/lb) (Kondas 1990; Turnbull and Markensz 1990). The application of an insect repellant effective against ant predation is advisable during the drying process (Kondas 1990). Seeds do not retain their viability for more than 3 months at ambient temperatures (Kondas 1990), but appear to be orthodox in storage behavior (Jones 1967). Seeds stored at subfreezing (–7 °C) or close to freezing (3 °C) temperatures, with moisture contents ranging from 6 to 16%, retain viability for up to 2 years (Turnbull and Markensz 1990). In Hawaii, seeds have been successfully stored in sealed polyethylene bags at 1 °C (Olson and Petteys 1974).

Germination. Germination in beach she-oak is epigeal; it takes place 4 to 22 days after sowing and is optimal at 30 °C under well-lighted conditions (Parrotta 1993). Casuarina seeds are usually sown without pretreatment (Magini and Tulstrup 1955; Olson and Petteys 1974), although soaking seeds for 36 hours in a 1.5% solution of potassium nitrate reportedly enhances germination (Rai 1990). Germination ranges from 40 to 90% for fresh seeds and from 5 to 25% for seeds stored in airtight containers at 4 °C for 1 year (Parrotta 1993). Official test prescriptions for casuarina species call for a 14-day test at alternating temperatures of 20/30 °C on the top of moist blotter paper (AOSA 1993). In the Philippines, germination of seedlots collected from different trees within a single plantation ranged from 33 to 75% for fresh seeds (Halos 1983). A significant positive relationship between cone size and seed germination rate was also noted in this study.

Nursery practice. In the nursery, seeds are generally germinated in trays under full sunlight at an optimal density of 1,000 to 7,500 seeds (weighing 2 to 10 g) /m^2 (93 to 700 seeds/ft^2), covered with about 0.5 cm of soil (Olson and Petteys 1974; Parrotta 1993). In South Africa, seedling yield averages are 18,000 plants/kg (8,200/lb) of river she-oak seeds (Magini and Tulstrup 1955). Nursery soils should be light textured, optimally sandy loams or a mixture of sand and peat moss. Seedlings are transferred from germination trays to containers when they reach a height of 10 to 15 cm (4 to 6 in), usually within 6 to 10 weeks after germination. Seedling containers measuring about 15 cm (6 in) in diameter and 20 cm (8 in) in depth are recommended. Seedlings may also be transplanted to new beds at densities of 100 to 400 seedlings/m^2 (9 to 37/ft^2) to obtain bareroot planting stock. Seedlings should be kept under partial shade until shortly before outplanting. Seedlings reach plantable size of 20 to 50 cm (8 to 20 in) in height in 4 to 8 months (Parrotta 1993). It is recommended that seedlings be inoculated in the nursery with pure cultures of effective strains of *Frankia* (a nitrogen-fixing actinomycete) or an inoculum from a nodule suspension prepared from fresh, healthy nodules collected in the field. Roots can be inoculated by dipping them into the suspension or by directly applying the suspension to the soil. Alternatively, crushed, fresh nodules, leaf litter, or soils from the vicinity of effectively inoculated trees may be incorporated directly into the nursery potting mix (Parrotta 1993).

Bignoniaceae—Trumpet-creeper family

Catalpa Scop.

catalpa

Franklin T. Bonner and David L. Graney

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi; Dr. Graney is a research forester at the USDA Forest Service's Southern Research Station, Fayetteville, Arkansas

Growth habit, occurrence, and use. The catalpas include about 10 species of deciduous or rarely evergreen trees native to North America, the West Indies, and eastern Asia (Rehder 1940). Two deciduous species, southern catalpa and northern catalpa (table 1), are native to the continental United States and have been planted quite widely outside their native range, especially northern catalpa. Mature trees of both species attain heights of 9 to 18 m (Little and Delisle 1962; Sargent 1965). Both have been grown to some extent in Europe. Catalpas are used in shelterbelts and ornamental planting and have minor value as timber trees, mainly for posts and small poles. Haitian catalpa, or yokewood, a native of the West Indies, has also been widely planted for forestry and ornamental purposes (table 1).

Flowering and fruiting. Attractive clusters of showy, white perfect flowers with purplish and orange blotches and stripes in the throat are borne in May and June on southern and northern catalpas (Brown and Kirkman 1990; Sargent 1965). Fruits of these species ripen in October, and good crops are borne every 2 to 3 years beginning at about age 20 (Bonner and Graney 1974; Sargent 1965; Vines 1960). Haitian catalpa flowers, which vary from white to solid rose in color, appear irregularly throughout the year. Even 6-month-old seedlings flower, and abundant seed crops are borne by the age of 18 months (Francis 1993). Mature fruits are round, brown, 2-celled capsules, 15 to 75 cm long (figure 1). In late winter or early spring, the capsules of northern and southern catalpas split into halves to disperse the seeds (Sargent 1965). Each capsule contains numerous oblong, thin, papery, winged seeds 1 to 5 cm long and about 1 to 6 mm wide (figure 2). Removal of the papery outer seedcoat reveals an embryo with flat, round cotyledons (figure 3). Southern and northern catalpas are separate from each other. The most consistent identification feature is the relative thickness of the fruit walls. Northern catalpa fruit walls are considerably thicker than those of southern catalpa (Brown and Kirkman 1990).

Collection, extraction, and storage. Fruits should be collected only after they have become brown and dry. When dry enough, the seeds can be separated by light beating and shaking. Pods of northern catalpa collected in February and March had seeds of higher quality than those collected in

Table 1—*Catalpa,* catalpa: nomenclature and occurence

Scientific name & synonym(s)	Common name(s)	Occurrence	Year first cultivated
***C. bignonioides* Walt.** *C. catalpa* (L.) Karst.	**southern catalpa,** common catalpa, Indian-bean, catawba, cigar-tree	SW Georgia & Florida to Louisiana; naturalized to New England, Ohio, Michigan, & Texas	1726
***C. longissima* (Jacq.) Dum.-Cours.**	**Haitian catalpa,** yokewood, *roble de olor, chenn*	Hispaniola & Jamaica; naturalized in Martinique, Guadeloupe, & the Grenadines; planted in Florida, Hawaii, & the West Indies	—
***C. speciosa* (Warder) Warder ex Engelm.**	**northern catalpa,** hardy catalpa, western catalpa, western Catawba-tree, Indian-bean, catawba	SW Indiana & Illinois to NE Arkansas & W Tennessee; widely naturalized in NE & SE US	1754

Sources: Bonner and Graney (1974), Francis (1990), Little (1979).

Figure 2—*Catalpa speciosa,* northern catalpa: seed.

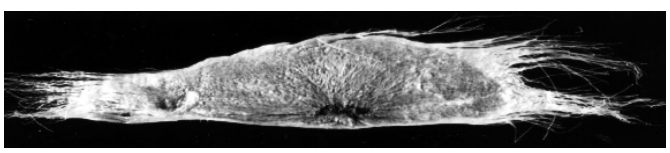

Figure 3—*Catalpa speciosa*, northern catalpa: longitudinal section through a seed.

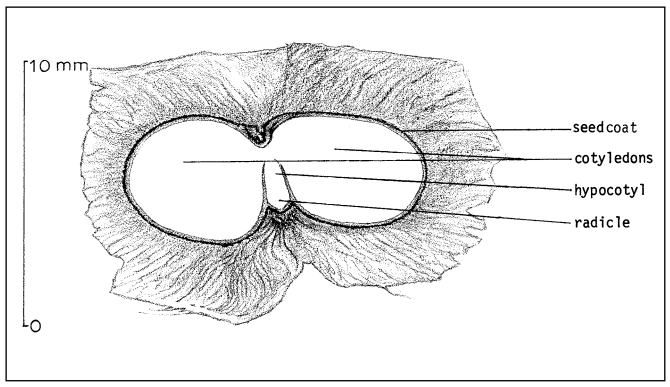

the fall (Bonner and Graney 1974). In terms of size, seeds of northern catalpa are slightly smaller than seeds of southern catalpa, and seeds of Haitian catalpa are by far the smallest of these three (table 2). Seeds of all 3 species dried to about 10% moisture content can be stored under refrigerated conditions. Successful storage for 2 years has been reported for southern catalpa (Bonner and Graney 1974) and 1 year for Haitian catalpa (Francis 1990). Long-term storage has not been studied, but this genus appears to be orthodox in storage behavior and capable of extended storage at low moisture contents and temperatures.

Germination tests. Seeds of all 3 species germinate promptly without pretreatment. Tests should be made on wet germination paper for 21 days with 20 °C night and 30 °C day temperatures. Other moist media also are satisfactory. Although northern catalpa is known to be photosensitive (Fosket and Briggs 1970), light is not necessary for germination tests (AOSA 1993). Germination in excess of 90% (25+ samples) has been obtained in about 12 days with good quality seeds of southern and northern catalpas (Bonner and Graney 1974). Francis (1993) has reported 40% germination of Haitian catalpa in 8 days on potting mix. Germination is epigeal, and the emerging 2-lobed cotyledons look like 4 leaves (figure 4).

Nursery practice. Catalpa seeds should be sown in late spring in drills at the rate of about 100/linear m (30/ft), and covered lightly with 4 mm ($^1/_8$ in) of soil or sown on the surface. A target bed density of 108 to 215 seedlings/m^2 (10 to 20/ft^2) is recommended (Williams and Hanks 1990). Stratification or other pretreatment is not needed. A pine needle mulch has been recommended for southern catalpa (Bonner and Graney 1974). In Louisiana, this species starts germination about 12 days after March sowing and germination is about 80%. In Puerto Rico, Haitian catalpa seeds can be spread thinly on a shaded bed of moist, sterile soil or

sand and covered lightly with sand (Francis 1990). This species can also be sown directly into containers; germination begins in about 10 days. Nematodes, powdery mildews, and the catalpa sphinx—*Ceratonia catalpae* (Boisduval)—may give trouble in the nursery. Southern and northern catalpas are normally planted as 1+0 stock (Bonner and Graney 1974). Haitian catalpa seedlings should be ready for planting 10 to 14 weeks after sowing in containers. Untreated woody cuttings can also be used for vegetative propagation of Haitian catalpa (Francis 1990).

C

Rhamnaceae—Buckthorn family

Ceanothus L.

ceanothus

Susan G. Conard and Merton J. Reed

Dr. Conard is a program leader at the USDA Forest Service's Research and Development National Office, Arlington, Virginia; Dr. Reed retired from the USDA Forest Service's Southwestern Forest and Range Experiment Station

Growth habit, occurrence, and use. Van Rensslaer and McMinn (1942) recognized 55 species of ceanothus, 25 varieties, and 11 named natural hybrids, all restricted to the North American continent. Most of them are found along the Pacific Coast of the United States, and only 2 are found east of the Mississippi River (Hitchcock and others 1961; Kearney and Peebles 1951; Munz and Keck 1968; Rowntree 1948; Sampson and Jesperson 1963; Schmidt 1993; Van Rensslaer and McMinn 1942). Forty-three species and 21 varieties are described in the most recent flora of California, which does not recognize hybrid forms (Schmidt 1993). Although hybridization appears to be common in nature, there are few named hybrids (Lentz and Dourley 1981; Schmidt 1993). Ceanothus species are mainly evergreen or deciduous shrubs, some of which may attain the height of small trees. In the West, they occur in a diversity of habitats, ranging from interior desert chaparral to moist redwood forest along the Pacific Coast (table 1). Ceanothus species are important as wildlife food and shelter, for erosion control, as hedges and shelterbelts, and in soil development and soil nitrogen regimes (Conard and others 1985; Graham and Wood 1991). Deerbrush ceanothus is rated as one of the most important summer browse species in California for deer and cattle (Sampson and Jesperson 1963), and redstem ceanothus is a key winter browse plant for deer (*Odocoileu* spp.) and elk (*Cervus cervus*) in parts of Idaho, Washington, and Oregon (Hickey and Leege 1970). All species that have been investigated bear root nodules containing a nitrogen-fixing *Frankia* symbiont (for example, Delwiche and others 1965); species from both forest and chaparral systems have been associated with accretion of soil nitrogen over time (Binkley and Husted 1983; Binkley and others 1982; Conard and others 1985; Hellmers and Kelleher 1959; Youngberg and Wollum 1976; Youngberg and others 1979; Zavitkovski and Newton 1968; Zinke 1969).

On forest sites, ceanothus species have alternately been considered a problem because they compete with commercial conifers and a benefit because of their nitrogen-fixing ability and their wildlife value (Conard and others 1985). Although there was early experimentation with planting ceanothus species for erosion control on chaparral sites (DFFW 1985) and there has been some interest in ceanothus establishment for browse or general site improvement in forest sites (Hickey and Leege 1970; Radwan and Crouch 1977), the dominant horticultural uses have continued to be for domestic, commercial, and right-of-way landscaping—particularly in California and the Pacific Northwest. Ceanothus species are valued particularly for their showy flowers (they are sometimes called "California lilacs"), relatively rapid early growth, drought adaptation, and ability to tolerate landscape watering. Some species have been cultivated for many years (table 2), and the potential for hybridization has led to the development of numerous cultivars, many of which are available from commercial native plant nurseries (for example, Lentz and Dourley 1981; Perry 1992). Distribution and uses of some of the more common species are described in table 1.

Flowering and fruiting. Flowers are small, bisexual, and regular, and are borne in racemes, panicles, or umbels. The 5 sepals are somewhat petal-like, united at the base with a glandular disk in which the ovary is immersed. The 5 petals are distinct, hooded, and clawed; the 5 stamens are opposite the petals, with elongated filaments. Petals and sepals can be blue, white purple, lavender, or pink. The ovary is 3-celled and 3-lobed, with a short 3-cleft style. Fruits are drupaceous or viscid at first but soon dry up into 3-lobed capsules (figure 1) that separate when ripe into 3 parts. Seeds are smooth, varied in size among species (figures 2 and 3; table 3), and convex on one side.

Flowering and fruiting dates for several species are listed in table 2. Feltleaf ceanothus is reported to begin bearing seeds at 1 year (Van Rensslaer and McMinn 1942), deerbrush ceanothus at 3 years (McDonald and others 1998),

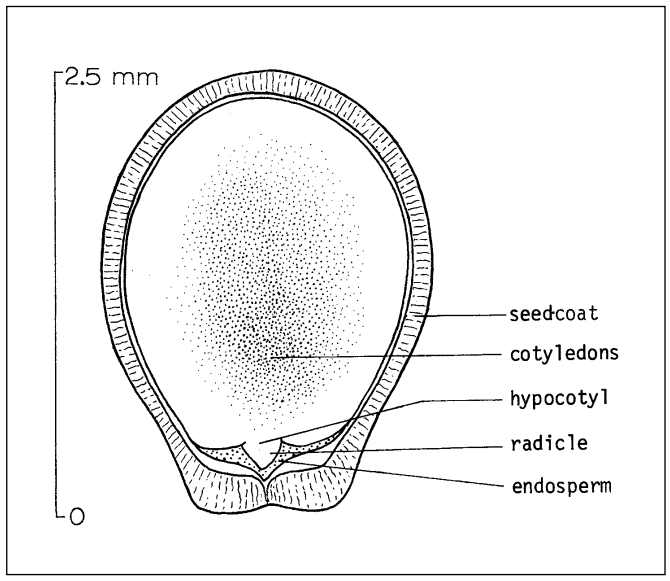
hoaryleaf ceanothus at 5 years (Everett 1957), desert ceanothus at 6 to 8 years (Zammit and Zedler 1992), and snowbrush ceanothus at 6 to 10 years (McDonald and others 1998). Thus it appears that most species can be expected to begin producing seeds by about 5 to 10 years of age. Fendler ceanothus has been reported to bear good seedcrops annually (Reed 1974). However, in hoaryleaf ceanothus, desert ceanothus, chaparral whitethorn, and other species,

Figure 3—*Ceanothus americanus*, New-Jersey-tea: longitudinal section through a seed.



both annual seed production and the amount of seeds stored in the soil may be quite variable (Conard and others 1985; Keeley 1977, 1987b; Zammit and Zedler 1988).

Collection, extraction, and storage. Several useful points on collecting ceanothus seeds have been described (Van Rensslaer and McMinn 1942; Emery 1988). Seeds should be collected only from vigorous plants, as weak, diseased plants do not produce sound seeds. To obtain plants similar to mature specimens, seeds should be collected in single-species stands in the wild or from isolated garden plants. Because many species hybridize freely, asexual propagation is the only certain way of maintaining species or varieties free from hybridization (Lenz and Dourley 1981). As the capsules split, ripe seeds are ejected with considerable force, such that about two-thirds of the seeds fall outside the shrub canopy, to distances up to 9 m (Evans and others 1987). Therefore, a common method of seed collection is to tie cloth bags—preferred to paper—securely over clusters of green seedpods. It is also possible to cut seedpod clusters before capsules have split, but the degree of maturity of the seeds is critical, as few prematurely collected seeds will germinate. Seeds that contain milky or gelatinous substances are not mature enough to harvest (Emery 1988). Green seeds should be air-dried at 29 to 38 °C.

If necessary, the seeds can be separated from capsule fragments by screening and blowing (Reed 1974), or seeds can be passed through a mill and floated (Plummer and others 1968). Average number of cleaned seeds per weight ranges from 90,000 to over 350,000/kg (41,000 to

178,000/lb), depending on the species (table 3). Adequate information on long-term storage is not available, but the seeds are apparently orthodox in storage behavior. Dry storage at around 4.5 °C should be satisfactory. Quick and Quick (1961) reported good germination in seeds of a dozen ceanothus species that had been stored for 9 to 24 years, with no apparent effect of seed age on viability. Seeds are apparently long-lived in litter; viable seeds of snowbrush ceanothus have been found in the surface soil of forest stands that were between 200 to 300 years old (Gratkowski 1962).

Germination. The long-term viability of seeds of ceanothus species apparently results from a strong seed coat dormancy, which in nature is typically broken by fire but may occasionally be broken by solar heating or mechanical scarification, such as from forest site preparation activities (Conard and others 1985). Germination of ceanothus seeds generally increases with increasing fire intensity (Conard and others 1985; Moreno and Oechel 1991), although at very high intensities, soil temperatures may be high enough to kill substantial numbers of seeds, resulting in decreased germination (Lanini and Radosevich 1986). In varnish-leaf ceanothus, Gratkowski (1962) observed that when seeds were exposed to drying conditions at normal air temperature, the hilum (the attachment scar on the seed, through which the radicle would normally emerge) functioned as a one-way hygroscopic valve that allowed moisture to pass out but prevented moisture uptake by the seeds. Heat caused a permanent, irreversible opening of the hilar fissure, which rendered the seed permeable to water. However, the seedcoat itself remained impermeable to moisture even after heating. This mechanism likely accounts for the abundant germination of ceanothus species that often occurs after fire on both chaparral and forest sites (Conard and others 1985).

In the laboratory, germination has been induced by soaking in hot water or heating in an oven, with or without a subsequent period of cold stratification (table 4). The typical pattern is that germination increases with the temperature of heat treatments up to a maximum, at which point seed mortality begins to occur. Seed germination and mortality are a function of both temperature and length of exposure, but for most species these optima are poorly defined. For hoaryleaf ceanothus, for example, maximum germination was obtained after heat treatments of 10 minutes to 1 hour at

Sources: Emery (1964), Hubbard (1958), Mirov and Kraebel (1939), Plummer and others (1968), Quick (1935), Quick and Quick (1961), Reed (1974), Swingle (1939).

70 to 80 °C. At higher temperatures, germination dropped off increasingly rapidly with duration of treatment, until at 100 °C there was a linear decrease in germination with times over 5 minutes (Poth and Barro 1986). In the wild, this range of time and temperature optima gives the advantage of allowing dormancy to be broken at a range of soil depths as a function of fire temperature and residence times. Quick and Quick (1961) reported that germination of mountain whitethorn and, to a lesser extent, deerbrush ceanothus began to drop off rapidly after a few seconds to several minutes in boiling water. Although "steeping" treatments at cooler temperatures (for example, 70 to 95 °C) were also found effective on several species (Quick 1935; Quick and Quick 1961), many investigators have continued to use treatments of boiling water (table 4). Dry heat treatments may be less damaging at higher temperatures than wet heat (table 4), although careful comparisons have not been made. In place of hot water treatments, seeds can also be immersed in sulfuric acid for 1 hour (Reed 1974).

Seeds of species found at high elevations also require cold stratification for good germination (Quick 1935; Van Rensslaer and McMinn 1942). Although some lower-elevation species from chaparral sites can germinate reasonably well without this cold treatment, their germination rates generally increase with stratification (table 4). Cold stratification is accomplished by storing seeds in a moist medium for periods of 30 to 90 days at temperatures of 1 to 5 °C. In general, longer periods of cold stratification are more effective than short ones. For example, Radwan and Crouch (1977) observed increasing germination of redstem ceanothus as cold stratification was increased from 1 to 3 or 4 months; no germination occurred without stratification. Similar patterns were observed by Quick and Quick (1961) for deerbrush ceanothus (increased germination up to 2 months of stratification) and Bullock (1982) for mountain whitethorn (increased germination up to 3 months). In lieu of cold stratification, a chemical treatment with gibberellin and thiourea was used to induce germination of buckbrush ceanothus (Adams and others 1961). Treatment with potassium salts of gibberellin also sucessfully replaced cold stratification in germination tests on redstem ceanothus seeds (Radwan and Crouch 1977). Following chemical treatments, seeds may then be germinated or dried again and stored (Adams and others 1961). Although emphasis has been on more natural methods of stimulating germination, seeds of snowbrush ceanothus and other species can be germinated quite successfully with acid scarification followed by a gibberellin treatment (Conard 1996).

Specific germination test conditions have not been well defined for most species of ceanothus. Sand or a mixture of sand and soil has been used as the moisture-supplying medium in most of the reported germination tests (Emery 1964; Quick 1935; Reed 1974), but filter paper has also been used successfully (Keeley 1987a). Diurnally alternating tempera-

Sources: Emery (1964), Keeley (1987a), Mirov and Kraebel (1939), Quick (1935), Quick and Quick (1961), Radwan and Crouch (1977), Reed (1974), Van Dersal (1938).

* ttc = "time to cool" (to room temperature) varied from several hours to overnight.

† Results reported here are for dry heat treatments, with germination in the dark; see Keeley (1987) for data on light germination.

tures of 30 °C in light and 20 °C in darkness have been effective, but constant temperatures of 10 °C (Reed 1974) and 24.5 °C (Emery 1988) also have been suitable for germination. A need for light has not been reported (Keeley 1991), and at least 1 species (deerbrush ceanothus) appears to germinate significantly better in the dark (Keeley 1987a). Germination rates resulting from selected pregermination treatments are listed in table 4 for 19 species.

The genus includes both species that sprout vegetatively following fire (sprouters) and species that are killed by fire and reproduce only from seeds (obligate seeders). Obligate seeders appear to have overall higher germination following heat treatment and to tolerate higher temperatures and longer periods at high temperature without damage to seed viability (Barro and Poth 1987). Germination test results suggest that eastern species may not be dependent on fire to

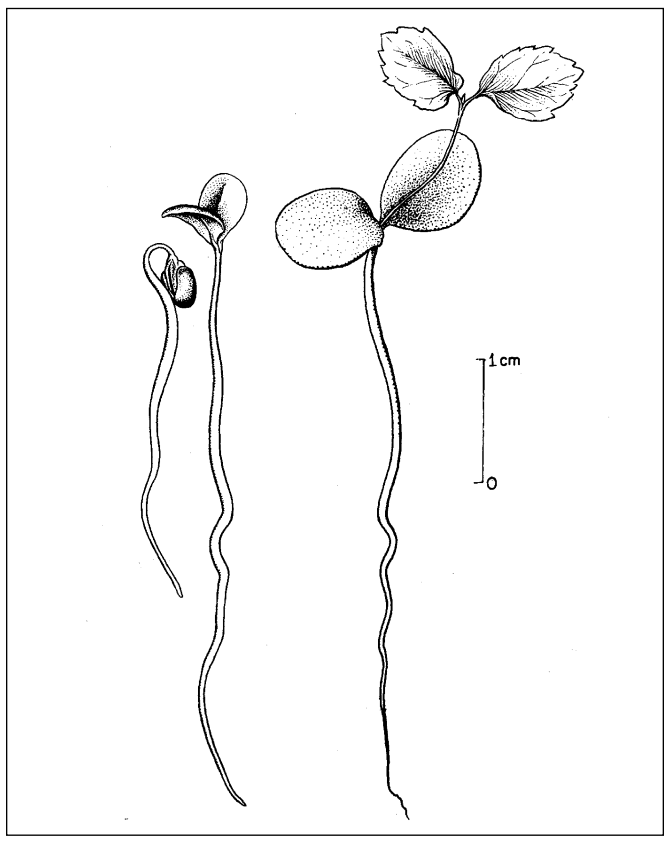
stimulate germination. For western species, however, some level of heat treatment, followed by stratification, will typically enhance germination. Although there has certainly been considerable variability in test results (table 4), a 5- to 10-minute dry heat treatment at 100 °C or a steeping treatment starting with 85 °C water, followed by several months of cold stratification, should effectively stimulate germination in most species.

Nursery practice. Seeding has been done in flats containing a medium of 5 parts loam, 4 parts peat, and 3 parts sand (Van Rensslaer and McMinn 1942). Leaf-mold may be substituted for the peat, but the peat is preferred because it is comparatively free of fungi. Sand is needed for drainage, a higher proportion being used in the seeding than in the potting medium. Seedlings are sensitive to sowing depth. In a trial by Adams (1962), deerbrush and buckbrush ceanothuses emerged best when sown at depths of 12 to 25 mm ($^1/_2$ to 1 in), and shading favored emergence of the first 2 species. However, some germination and emergence occurred at sowing depths ranging from 6 to 64 mm ($^1/_4$ to $2^1/_2$ in). Many species are sensitive to damping off, so for safety soil should be sterilized (Van Rensslaer and McMinn 1942). In California, seeding is usually done in November to January. Germination is epigeal (figure 4). Although all species of *Ceanothus* apparently fix nitrogen symbiotically, there has apparently been little or no research into the efficacy of or need for seed inoculation with *Frankia* to ensure nodulation of seedlings after outplanting. This is not likely to be a problem on soils where *Ceanothus* species are present, as nodulation appears to occur readily (Conard 1996) but may be of concern for horticultural uses of the genus.

Seedling care. When several sets of leaves have formed, the seedlings can be carefully planted into 2- or 3-inch (5- or 7.6-cm) pots. A good potting medium is 5 parts loam, 3 parts peat or leaf mold, and 1 part sand (Van Rensslaer and McMinn 1942). Care must be taken not to place the seedlings too deep in the soil, with root crowns should be just below the soil surface. Seedlings are susceptible to stem rot, and the loss will be greater if young plants are kept in moist soil that covers the root crown. The root development should be examined from time to time. When a loose root system has formed on the outside of the ball, the plant is ready for shifting to a larger pot or gallon can. It is best to discard potbound plants rather than to carry them along.

Planting stock of most common western ceanothus species is now available from commercial nurseries or botanic gardens, and numerous hybrids and cultivars have been developed for the nursery trade. Cultural notes on some of the commonly available species (table 1) and cultivars (Brickell and Zuk 1997) follow:

Figure 4—*Ceanothus americanus*, New-Jersey- tea: seedling development at 1, 5, and 15 days after germination.



- feltleaf ceanothus—*C. arboreus*—which can attain a height of 5 to 8 m and has pale blue flowers, grows best in coastal areas or with partial shade in areas with hot, dry summers.
- Fendler ceanothus—*C. fendleri*—up to 2 m tall with pale, bluish-white flowers, has been propagated from seeds sown in the spring and from cuttings in autumn. It grows best in light, well-drained soils and can tolerate cold.
- Carmel ceanothus—*C. griseus* var. *horizontalis* McMinn—a spreading, low-growing (to 1 m) variety, is used as ground cover and for slope stabilization. It performs best in mild coastal regions but will do well in partial shade in drier areas with adequate watering. Several named varieties are available.
- prostrate ceanothus—*C. prostratus*—a spreading, prostrate groundcover with small blue flower clusters, usually is propagated by layering. It is best if grown within its native range (for example, ponderosa pine zone of Sierra Nevada) and does not grow well at low elevations.

- Monterey ceanothus—*C. cuneatus* (Nutt.) Hoover var. *rigidus* cv. Snowball—a white-flowered cultivar, 1 to 1.5 m tall, recommended for coastal areas from southern California to the Pacific Northwest. Summer water should be restricted. It is a good bank and background plant.
- Sierra blue—*C. cyaneus* Eastw.—a medium to large shrub (to 6 m) with showy blue flowers, is a relatively fast grower that will tolerate hot, dry environments with some supplemental summer water.
- blueblossom—*C. thyrsiflorus*—a large shrub (2 to 7 m tall) with showy deep blue flowers, is a native of coastal forests. It grows well in its native range (Pacific coastal mountains) and needs shade from afternoon sun on dry inland sites, but requires little summer water once established.

There are many more ceanothus varieties that are excellent candidates for a range of domestic, commercial, or right-of-way landscaping situations. Although they are typically not widely available at retail nurseries, many native plant nurseries within the native range of ceanothus have wide selections. Additional information can be found in Kruckeberg (1982), Lenz and Dourley (1981), Perry (1992), Schmidt (1980), and the Sunset Western (1995) and National (1997) Garden Books, among others.

Pinaceae—Pine family

Cedrus Trew

cedar

Paula M. Pijut

Dr. Pijut is a plant physiologist at the USDA Forest Service's North Central Research Station, Hardwood Tree Improvement and Regeneration Center, West Lafayette, Indiana

Growth habit, occurrence, and use. The genus of true cedars—*Cedrus*—consists of 4 (or fewer) closely related species of tall, oleoresin-rich, monoecious, coniferous, evergreen trees, with geographically separated distributions (Arbez and others 1978; Bariteau and Ferrandes 1992; Farjon 1990; Hillier 1991; LHBH 1976; Maheshwari and Biswas 1970; Tewari 1994; Vidakovié 1991). The cedars are restricted to the montane or high montane zones of mountains situated roughly between 15°W and 80°E and 30 to 40°N (Farjon 1990). This discontinuous range is composed of 3 widely separated regions in North Africa and Asia (Farjon 1990): the Atlas Mountains of North Africa in northern Morocco and northern Algeria; Turkey, the mountains on Cyprus, and along the eastern border of the Mediterranean Sea in Syria and Lebanon; the Hindu Kush, Karakoram, and Indian Himalayas. The 4 species of cedars (table 1) are so closely related that habitual characteristics help differentiate the species (Farjon 1990). Isozyme analysis of cedar diploid tissue raises questions about the separation of Atlas cedar and cedar of Lebanon into 2 distinct species, because no distinguishing gene marker was detected (Panetsos and others 1992). There is disagreement as to the exact taxonomic status of the various cedars, with some authors suggesting that they be reduced to only 2 species: deodar cedar and cedar of Lebanon. In this writing, we will examine all 4 species.

The cedars are both valuable timber trees and quite striking specimen plants in the landscape. The wood of cedar of Lebanon is fragrant, durable, and decay resistant; and on a historical note, the ancient Egyptians employed cedar sawdust (cedar resin) in mummification (Chaney 1993; Demetci 1986; Maheshwari and Biswas 1970). Upon distillation of cedar wood, an aromatic oil is obtained that is used for a variety of purposes, from scenting soap to medicinal practices (Adams 1991; Chalchat and others 1994; Maheshwari and Biswas 1970; Tewari 1994).

Atlas cedar is a large tree that grows rapidly when young and is closely related to cedar of Lebanon. The Atlas cedar is distinguished by a taller crown, less densely arranged branchlets, bluish green leaves (needles) that vary from light green to silvery blue, smaller cones, and smaller

Table 1—*Cedrus,* cedar: nomenclature, occurrence, height at maturity, and date first cultivated

Scientific name	Common name	Occurrence	Height at maturity (m)	Year first cultivated
***C. atlantica* (Endl.) G. Manetti ex Carriere**	**Atlas cedar**	In Algeria on Mts. Babor & Tababort & in Hodna Mtns; in Morocco in Rif Mtns (at 1,370–2,200 m); planted in US	9–40	Before 1840
***C. breviifolia* (Hook. f.) A. Henry**	**Cyprian cedar**	Two separate locations on Mt Paphos in western Cyprus (at 900–1,525 m)	8–24	1879
***C. deodara* (Roxb. ex D. Don) G. Don F.**	**deodar cedar**	E Afghanistan (Hindu Kush), NW Pakistan (Karakoram), NW India (Kashmir & Gharwal Himalaya), rare in Nepal (1,700–3,000 m in western range & 1,300–3,300 m in eastern range); planted in US	15–50	1831
***C. libani* A. Rich.**	**cedar of Lebanon**	In S Turkey (Taurus Mtns), also Syria (Djebel el Ansiriya) & Lebanon (Djebel Loubnan); disjunct relict population in N Turkey near Black Sea (at 1,300–3,000 m); planted in US	15–40	Pre-1650

Sources: Dirr (1990), Farjon (1990), Hillier (1991).

seeds (table 2) (Dirr 1990; Farjon 1990; Hillier 1991; Loureiro 1990, 1994). Young trees appear stiff, with an erect leader and a pyramidal overall shape; with maturity this species assumes a flat-topped habit with horizontally spreading branches (Dirr 1990). Atlas cedar is hardy in USDA zones 6 to 9, with several beautiful cultivars that differ in color and characteristic habit (Dirr 1990; Hillier 1991; Vidakovié 1991). Of special note is '*Glauca*' (f. *glauca*), with very blue to silvery blue leaves, which is a spectacular specimen tree (Dirr 1990; Hillier 1991).

Cyprian cedar is a rare species that grows slowly but eventually develops into a medium-sized tree. This species is distinguished from cedar of Lebanon only by its habitual form and shorter leaves (table 2) and the broad and umbrella-shaped crown on older specimens (Farjon 1990; Hillier 1991; Vidakovié 1991).

Deodar cedar is an excellent specimen tree. The deodar cedar is broadly pyramidal when young, with gracefully pendulous branches (Dirr 1990; Tewari 1994). It is distinguished from the other species by its drooping leader and longer leaves (table 2) (Hillier 1991). Multi-stemmed crowns occasionally evolve from the higher branches turned erect, but the crown seldom becomes flat-topped, remaining conical or pyramidal (Farjon 1990). Deodar cedar is hardy in USDA zones 7 to 8, but young trees are prone to injury from frosts and cold wind (Dirr 1990). There are many cultivars of deodar cedar, but 2 worth mentioning are 'Kashmir' and 'Shalimar'. The former is winter-hardy—it tolerates cold winters to –30 °C—with silvery blue-green foliage (Dirr 1990; Vidakovié1991). The latter displays good blue-green leaf color and is the hardiest cultivar planted in the United States (Dirr 1990; Koller 1982).

Cedar of Lebanon is a majestic tree with innumerable historical and biblical references. It has a thick, massive trunk and wide-spreading branches; it is pyramidal when young but develops a flat-topped crown and horizontally tiered branches when mature (Chaney 1993; Dirr 1990; Farjon 1990; Hillier 1991). The dark green foliage, stiff habit, and rigidly upright cones (table 2) give this tree its splendor for landscape specimen planting. The morphological differences between cedar of Lebanon and Atlas cedar are small and not entirely constant (Farjon 1990; Maheshwari and Biswas 1970). Cedar of Lebanon is hardy in USDA Zones 5 to 7 (Dirr 1990; Dirr and others 1993). A geographical form—*C. libani* ssp. *stenocoma* (Schwarz) Davis—differs from the typical Lebanon cedar in having a broadly columnar habit and needle and cone characteristics that are intermediate between Atlas cedar and cedar of Lebanon; it is also more cold-hardy (Hillier 1991; Vidakovié 1991). There are also several dwarf cultivars of cedar of Lebanon that are of interest for use in the landscape (Hillier 1991; Vidakovié 1991).

Flowering and fruiting. The male flowers of cedar are erect catkins, up to 5 cm in length, whereas the female flowers are erect, cone-like inflorescences, 1 to 1.5 cm long, surrounded by needles at the base (Vidakovié 1991). Male and female strobili of the true cedars are borne (usually) on the same tree, but on separate branches (Farjon 1990; Maheshwari and Biswas 1970; Rudolf 1974). The male cones are solitary, grow more or less erect from the short shoots, and bear abundant yellow pollen (Farjon 1990; Maheshwari and Biswas 1970). Depending upon the altitude, locality, and weather, the pollen is shed late in the year (September through November), relating to the late development of the female strobilus (Farjon 1990; Maheshwari and Biswas 1970). The female cones are borne singly at the tips of the dwarf shoots, stand erect, and are less abundant than the male cones (Farjon 1990; Maheshwari and Biswas 1970). Although pollination takes place in the fall, the cones do not mature until the second year, requiring about 17 to 18 months for full development (Farjon 1990; Maheshwari and Biswas 1970; Rudolf 1974).

The mature, barrel-shaped cones (figure 1) are resinous and characterized by numerous closely appressed, very broad scales, each containing 2 seeds (table 2) (Rudolf 1974). The scales are attached to the persistent rachis with a narrowed, petiolate base and dismember from it by abscission at maturity, as in fir (*Abies*) (Farjon 1990; Rudolf 1974). The irregularly triangular mature seed is rather soft and oily, with resin vesicles present on each side of the seed,

Table 2—*Cedrus,* cedar: cone, seed, and leaf (needle) characteristics

	Cone characteristics			Seed size		Leaf characteristics	
Species	Ripe color	Length (cm)	Width (cm)	Length (mm)	Width (mm)	Length (cm)	No. in whorls
C. atlantica	Light brown	5–8	3–5	8–13	4–6	1–2.5	20–45
C. brevifolia	Light brown	5–10	3–6	8–14	5–6	0.5–1.6	15–20
C. deodara	Reddish brown	7–13	5–9	10–15	5–7	2–6.0	20–30
C. libani	Grayish brown	8–12	3–6	10–14	4–6	1–3.5	20–40

Sources: Farjon (1990), Rudolf (1974), Vidakovie (1991).

and it has a membranous, broad wing that is several times larger than the seed (figures 2 and 3) (Farjon 1990; Rudolf 1974). Seeding habits of the various species are given in table 3. Commercial seed bearing of deodar cedar begins from 30 to 45 years of age, and good seedcrops are borne every 3 years, with light crops in the intervening years (Doty 1982; Maheshwari and Biswas 1970; Rudolf 1974; Tewari 1994; Toth 1979).

Collection of fruits; extraction, cleaning, and storage of seeds. Cones should be collected directly from the trees, before the cones turn brown, or cone-bearing twigs may be cut from standing or felled trees just before ripening is complete (Dirr and Heuser 1987; Rudolf 1974; Singh and others 1992). One cubic meter (28.38 bu) of cones weighs from 12.2 to 15.9 kg (27 to 35 lb) and yields about 1.4 kg (3 lb) of cleaned seeds (Rudolf 1974). Cones should be allowed to dry until the scales loosen and the seeds can be removed (Dirr and Heuser 1987; Macdonald 1986; Toth 1980a). It is important to avoid any more drying than is absolutely necessary, because the seeds may be killed. Cones of cedar may be soaked in warm water for 48 hours to encourage them to disintegrate (Rudolf 1974; Macdonald 1986). Freezing moist cones (as a last resort) will also force the scales to open up (Macdonald 1986). After the cone scales are dry, they can be placed in a cone shaker to remove the seeds (Rudolf 1974), and seeds can be separated from the debris by fanning or sieving (Macdonald 1986). Seeds are de-winged by simply rubbing them in a dry cloth (Macdonald 1986), for resin from the resin pockets in the wings can make de-winging with bare hands difficult (Macdonald 1986). Purity of commercially cleaned seed has been 85 to 90% (table 4).

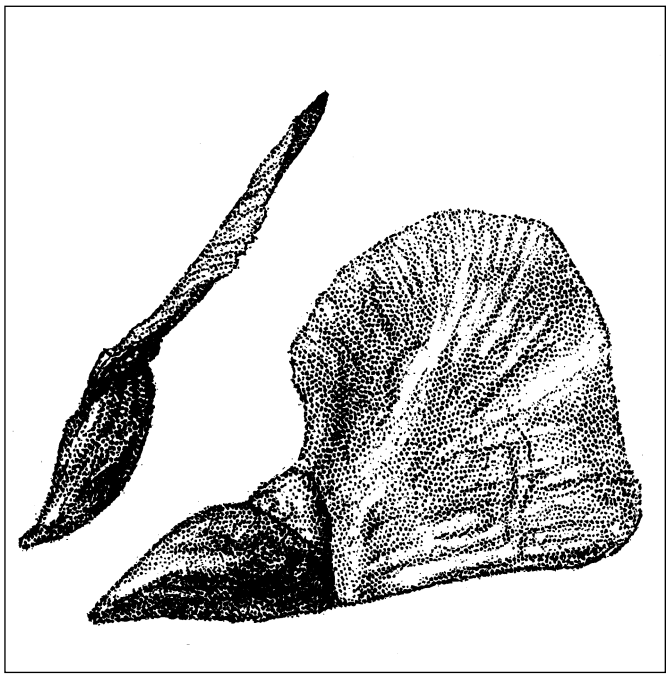
Even though cedar seeds are orthodox in storage behavior, they are very oily and do not keep well under many storage conditions (Allen 1995; Rudolf 1974). If cedar seeds are dried below a critical level, they will not imbibe water in a way that will allow the food reserves to be used by the embryo (Macdonald 1986). Cedar seeds have retained viability for 3 to 6 years when dried to a moisture content of less than 10%, placed in sealed containers, and held at temperatures of –1 to –5 °C (Erkuloglu 1995; Rudolf 1974).

Pregermination treatments. Cedar seeds exhibit little or no dormancy and will germinate without pretreatment. However, variable degrees of dormancy may be observed within a single lot of seeds (Dirr and Heuser 1987). Seeds should be stratified at 3 to 5 °C for 2 weeks (6.5 weeks for Cyprian cedar) to give more uniform germination (Allen 1995; Rudolf 1974). Thapliyal and Gupta (1980) found that 9 °C was a better temperature for stratification than 3 °C. Deodar cedar and cedar of Lebanon seeds are prone to damping-off disease and thus should be treated with an appropriate fungicide (Mittal 1983).

Germination tests. The AOSA (1993) prescribes germination tests of stratified seeds (14 days) on top of blotters for 3 weeks at 20 °C for all cedars (see also Toth 1980a). ISTA (1993) rules, however, specify diurnally alternating

Figure 1—*Cedrus libani*, cedar of Lebanon: mature cone.

Figure 2—*Cedrus libani*, cedar of Lebanon: seeds with membranous wing attached.



temperatures of 20 °C (night) and 30 °C (day) for a period of 4 weeks. Tests may also be made in sand flats (Rudolf 1974). Deodar cedar seeds stratified at 4 °C in moist sand for 30 days showed 45% germination versus 11% without stratification (Dirr and Heuser 1987). Thapliyal and Gupta (1980) also found that the percentage of germination without stratification to vary from 16 to 69%. Singh and others (1992) found that seeds from larger cones exhibited higher germination (66%) in Himalayan cedar. Singh and others (1997) also found that there were significant differences between tree-diameter classes in fresh and dry weight of seeds and also in germination in the laboratory and in the nursery. Germination of cedar seed is epigeal (figure 4).

Nursery practice and seedling care. Deodar cedar seeds should be sown in the fall (or in spring) at a rate of 200 to 250 seeds/m^2 (19 to 23/ft^2), in drills 10 to 15 cm (4 to 6 in) apart for lining-out stock and for root stocks (Macdonald 1986; Rudolf 1974). Chandra and Ram (1980) recommend sowing deodar seeds at a depth of 1 cm (0.4 in); further increase in depth results in decreased germination. Al-Ashoo and Al-Khaffaf (1997) reported that the best treatment for germination of cedar of Lebanon seeds was a 1.5-cm (0.6-in) sowing depth, with a covering medium of clay or alluvial soil. In northern areas, fall-sown beds should be mulched over winter, the mulch removed early in the spring, and the bed racks covered with burlap on critical spring nights to prevent freezing (Heit 1968). Cedar seeds can be sown in containers in the fall, transplanted into other containers during the winter, and kept in shaded beds in the summer to produce $^1/_2$- to 1 $^1/_2$-year-old planting stock (Rudolf 1974). The size of the propagation container, growth media, transplanting date, and handling of seedlings is important in container or field grown stock (Appleton and Whitcomb 1983; Burger and others 1992; Doty 1982; Guehl and others 1989; Puxeddu and Alias 1991; Toth 1980b).

Deodar cedar 'Shalimar' can be propagated by collecting cuttings in late fall to early winter; 67% of such cuttings given a quick dip in 5 g/liter (5,000 ppm) indole-3-butyric acid (IBA) solution and placed in a sand–perlite medium with bottom heat (Nicholson 1984) rooted. Shamet and Bhardwaj (1995) reported 69% rooting of deodar cedar cut-

tings treated with 0.5% indole-3-acetic acid–talc or 1% naphthaleneacetic acid–activated charcoal, both supplemented with 10% captan and 10% sucrose. However, cuttings taken from Atlas cedar and cedar of Lebanon are difficult to root, although some rooting may occur on cuttings taken in late winter and treated with 8 g/liter (8,000 ppm) IBA–talc (Dirr and Heuser 1987). Cultivars of cedar species are more routinely propagated by grafting (Blomme and Vanwezer 1986; Dirr and Heuser 1987; Hartmann and others 1990; Lyon 1984; Macdonald 1986; Richards 1972). Two reports have been published on the *in vitro* culture of deodar cedar (Bhatnagar and others 1983; Liu 1990). A method for *in vitro* propagation of cedar of Lebanon through axillary bud production, a study of bed dormancy *in vitro*, and detection of genetic variation of *in vitro*–propagated clones has also been described (Piola and Rohr 1996; Piola and others 1998, 1999).

Celastrus scandens L.

American bittersweet

G.W. Wendel, Jill R. Barbour, and Robert P. Karrfalt

Dr. Wendel retired from the USDA Forest Service's Northeastern Forest Experiment Station; Ms. Barbour is a germination specialist at and Mr. Karrfalt is director of the USDA Forest Service's National Seed Laboratory, Dry Branch, Georgia

Other common names. climbing bittersweet, shrubby bittersweet.

Growth habit, occurrence, and use. American bittersweet is a deciduous climbing or twining shrub of eastern North America (Brizicky 1964; Fernald 1950) that occurs in thickets, in stands of young trees, along fence rows, and along streams, usually in rich soil. It occurs naturally from southern Quebec; west to southern Manitoba; and south to Oklahoma and central Texas, Arkansas, Tennessee, northern Alabama, and western North Carolina (Brizicky 1964). Some authors (Fernald 1950; USDA FS 1948) reported it in Louisiana, New Mexico, Georgia, and Mississippi, but its occurrence has not been verified in Georgia, Louisiana, or Mississippi (Brizicky 1964).

The plant is valuable for ornamental purposes and game food and cover; the bark has been used for medicinal purposes (USDA FS 1948). Among the animals and birds feeding on American bittersweet are the bobwhite quail (*Colinus virginianus*), ruffed grouse (*Bonasa umbellus*), ringneck pheasant (*Phasianus colchicus*), eastern cottontail (*Silvilagus floridanus*), fox squirrel (*Sciurus niger*), and various songbirds (Van Dersal 1938). It was introduced into cultivation in 1736 (USDA FS 1948).

By 1970, oriental or Asiatic bittersweet—*C. orbiculatus* Thunb.—had become naturalized on at least 84 sites from Georgia to Maine and west to Iowa (McNab and Meeker 1987), occupying many of the same sites as American bittersweet. It is listed as an invasive plant by the United States Government (USDA NRCS 1999). In some locales, the species is found mainly along fence lines, resulting from the germination of seeds contained in the droppings from frugivorous birds (McNab and Meeker 1987). The stem, leaves, and berries of oriental bittersweet are reported to be toxic for human consumption (McNab and Meeker 1987).

Flowering and fruiting. The small greenish, polygamo-dioecious or dioecious flowers open from May to June and are borne in raceme-like clusters at the end of branches (Brizicky 1964; Fernald 1950). Hymenopterous insects, especially bees, seem to be the main pollinators, although wind may also be involved (Brizicky 1964). Seeds are about 6.3 mm long and are borne in bright orange to red, fleshy arils, 2 of which are usually found in each of the 2 to 4 cells composing the fruit, a dehiscent capsule (figure 1). The yellow to orange capsules ripen from late August to October. They split open soon thereafter, exposing the seeds covered with showy red arils (figures 2 and 3). Good seedcrops are borne annually and may persist on the bushes throughout much of the winter (USDA Forest Service 1948). In Pennsylvania, only 1 seedcrop failure was reported in a 14-year period (Musser 1970). Sunlight is reported necessary for abundant fruiting to occur (Musser 1970).

Collection of fruit. The ripe fruits should be collected as soon as the capsules separate and expose the arils, or from about mid-September as long as they hang on the vines (USDA FS 1948), but rarely later than December (Van Dersal 1938). In Pennsylvania, the fruits are collected from late October through November (Musser 1970).

Figure 1—*Celastrus scandens*, American bittersweet: fruiting branch.

Extraction and storage of seeds. Collected fruits should be spread out in shallow layers and allowed to dry for 2 or 3 weeks (USDA FS 1948). In Pennsylvania, the fruits are allowed to air-dry for 1 week in shallow trays (Musser 1979). The seeds are then removed from the capsules by flailing or running the fruits through a hammermill or macerator with water (Musser 1970; USDA FS 1948). Then the seeds are allowed to dry for another week and the chaff is separated by windmilling (Musser 1979). The dried arils are left on the seeds (USDA FS 1948) except when seeds are to be stored.

American bittersweet has 4 to 8 seeds/fruit. On the basis of 10 samples, the number of seeds per weight ranged from 26,000 to 88,000/kg (12,000 to 40,000/lb) with an average of 57,000/kg (26,000/lb). Average purity was 98% and average soundness 85% (USDA FS 1948).

In Pennsylvania, the seeds usually are sown in the fall soon after collection and extraction or stored in cloth bags until used (Musser 1970). For longer storage periods, viability has been retained for 4 to 8 years by cleaning the fleshy material from the seeds, air-drying the seeds at low humidity, and then storing them in sealed containers at a temperature between 1 and 3 °C (Heit 1967).

Pregermination treatments. Seeds of American bittersweet have a dormant embryo and thus require afterripening for germination. There is also some evidence that the seedcoat may have an inhibiting effect on germination (Hart 1928; USDA FS 1948). Good germination is obtained by fall-sowing or by stratification in moist sand or peat for 2 to 6 months at 5 °C (Heit 1968; Musser 1970; USDA FS 1948). Three months of cold stratification has resulted in good germination for American bittersweet (Dirr and Heuser 1987). It seems to make little difference whether cleaned seeds or dried fruits are sown; however, it appears that both cleaned seeds and fruits should be dried at room temperature for 2 to 3 weeks before they are sown (USDA FS 1948).

Figure 2—*Celastrus scandens*, American bittersweet: seeds with aril removed.

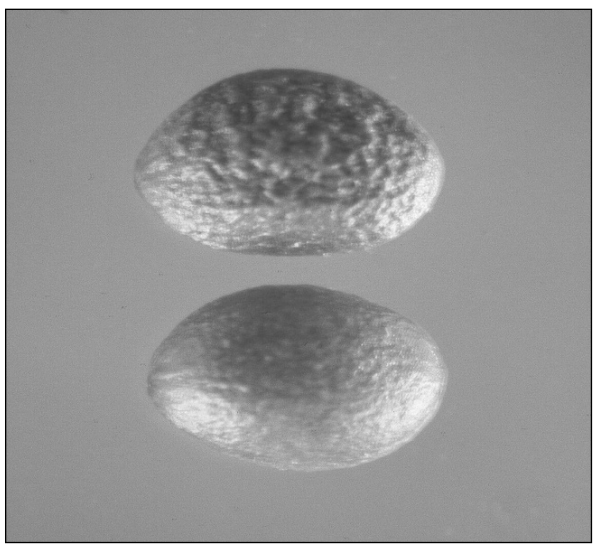

Figure 3—*Celastrus scandens*, American bittersweet: longitudinal section through a seed.

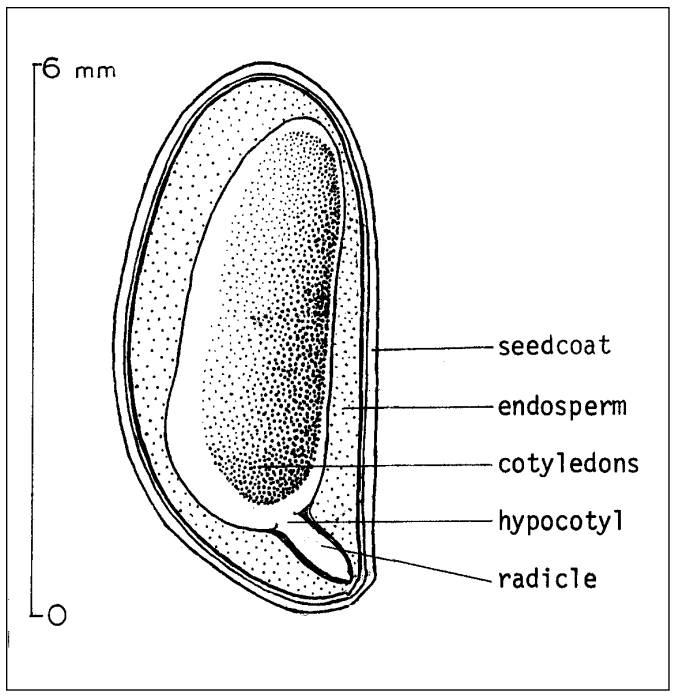
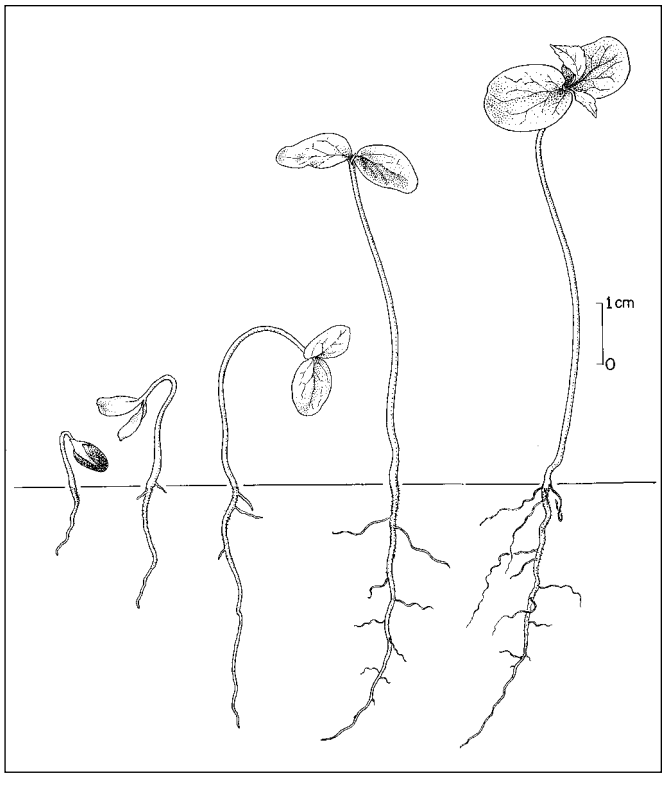


Germination tests. On the basis of 6 tests, using stratified seedlots in sand flats, at temperatures alternating from 10 to 25 °C, germinative capacity was found to range from a low of 9 to a high of 80% in 30 days, with an average of 47%. Potential germination varied from 9 to 93% (USDA FS 1948). Seedlots of oriental bittersweet showed 100% germination after 3 months of cold stratification (Dirr and Heuser 1987). Germination of American bittersweet is epigeal (figure 4).

A good estimate of germination can be obtained by the excised embryo method (Heit and Nelson 1941). The seeds are soaked until plump; seedcoats are removed and the embryos excised. The excised embryos are placed on moistened filter paper in covered petri dishes. A room temperature of 21 to 22 °C appears to be most satisfactory. Viable embryos will either show greening of the cotyledons, remain perfectly white in color but grow larger, or exhibit radicle elongation. Embryos exhibiting such characteristics can be counted as being from healthy seeds, capable of germinating

Figure 4—*Celastrus scandens,* American bittersweet: seedling development at 1, 2, 5, 10, and 30 days after germination.



with proper afterripening treatment. Five to 20 days are required to secure approximate germination by the excised embryo method.

Nursery practice. In Pennsylvania, good results have been obtained by sowing cleaned seeds in the first fall after collection and extraction. The seeds are broadcast on seedbeds and firmed in with a roller; then covered with a mixture of 1 part of sand to 2 parts of sawdust. The beds are covered with shade until germination occurs. Germination usually begins about 20 days after conditions become favorable (Musser 1970).

Another practice is to stratify cleaned or dried seeds in the pulp in January, and then sow them in the early spring. Young seedlings are somewhat susceptible to damping-off (USDA FS 1948). About 6,600 usable plants can be produced per kilogram of seeds (3,000/lb) (Van Dersal 1938). Propagation by root cuttings, layers, or stem cuttings is also sometimes practiced (Sheat 1948).

C

Ulmaceae—Elm family

Celtis L.

hackberry

Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Growth habit, occurrence, and use. The genus *Celtis*—hackberry—is a large, widespread genus that includes about 70 species of shrubs and trees in the Northern Hemisphere. The 3 species listed in table 1 are all medium to large deciduous trees.

Flowering and fruiting. The small, greenish flowers of all 3 species appear in the spring as the new leaves emerge (table 2). These species are polygamo-monoecious (Krajicek and Williams 1990; Kennedy 1990; Vines 1960). Hackberry fruits are spherical drupes 6 to 13 mm in diameter with a thin pulp enclosing a single bony nutlet (figures 1–3). Good seedcrops are borne practically every year, and the fruits persist on the branches into winter (Bonner 1974; Krajicek and Williams 1990; Kennedy 1990). Other fruit and seed data (Little 1950; Preston 1947; Rehder 1940; Swingle 1939) are presented in tables 2 and 3.

Collection of fruits. Mature fruits can be picked by hand from trees as late as midwinter. Collection is much easier after all leaves have fallen (Bonner 1974). Limbs of sugarberry can be flailed to knock the fruits onto sheets spread under the trees. Fruits collected early in the season should be spread to dry to avoid overheating and molding (Williams and Hanks 1976). Fruits collected later in the season, unless the collection is done in wet, rainy weather, usually do not require additional drying (Bonner 1974).

Extraction and storage. Twigs and trash can be removed by screening or fanning, and the fruits can be depulped by wet or dry maceration. If wet maceration is used, the seeds will have to be dried for storage. If they are to be planted immediately, drying is not necessary. The pulp on dried fruits can be crushed and the resulting debris removed by washing on a screen under water pressure (Williams and Hanks 1976).

Table 1—*Celtis*, hackberry: nomenclature and occurrence

Scientific name & synonym	Common name(s)	Occurrence
***C. laevigata* Willd.** *C. mississippiensis* Spach	**sugarberry,** sugar hackberry, hackberry, sugarberry, *palo blanco*	Maryland & Virginia to Florida & Texas; N to Kansas, Texas, Illinois, & Kentucky

Figure 1—*Celtis*, hackberry: fruits (**left**) and seeds (**right**) of *C. laevigat*a, sugarberry (**top**) and *C. laevigata* var. *reticulata,* netleaf hackberry (**bottom).**

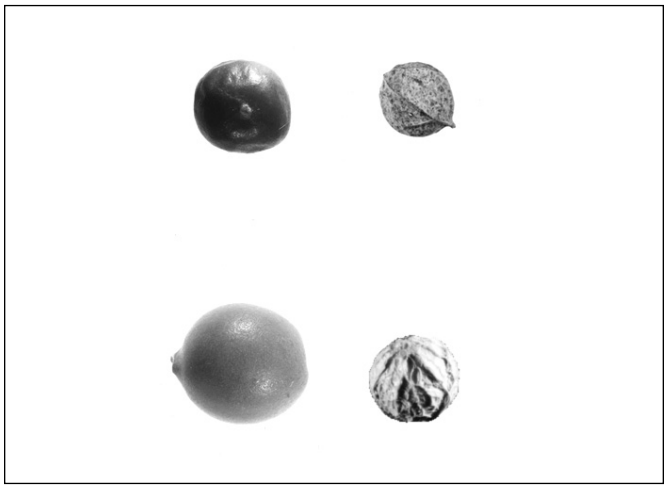

Figure 2—*Celtis occidentalis*, common hackberry: exterior view of seed (**top left**) and transverse section (**top right**) and cross section (**bottom**) of a seed.

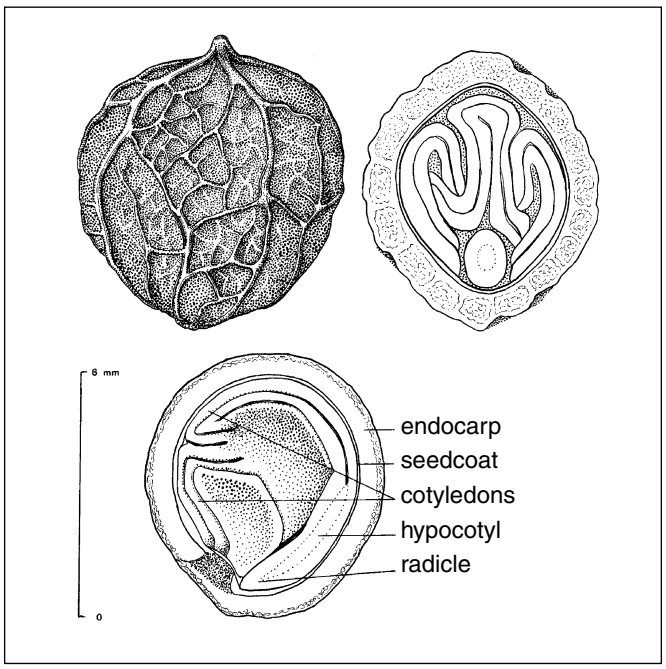
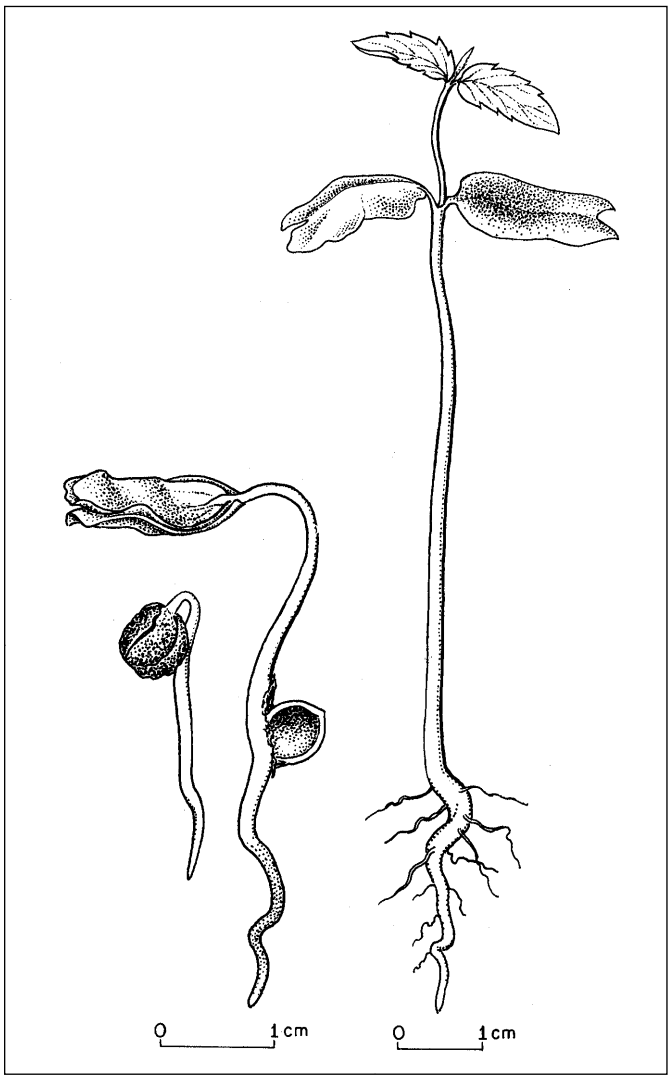


Removal of the pulp may not be absolutely necessary, but it has been reported to aid germination of all 3 species (Bonner 1974; Vines 1960). Seed yield data are listed in table 4. Dry fruits or cleaned seeds store equally well in sealed containers at 5 °C. Dried fruits of hackberry were stored in this manner for 5 $^{1}/_{2}$ years without loss of viability (Bonner 1974), proving that they are orthodox in storage behavior.

Figure 3—*Celtis laevigata*, sugarberry: seedling development at 1, 2, and 5 days after germination.



Pregermination treatments. Hackberry seeds exhibit dormancy that can be overcome with stratification at 5 °C in moist media. Sugarberry, common hackberry, and netleaf hackberry all should be stratified for 90 to 120 days (Bonner 1974, 1984). In the southernmost part of sugarberry's range, no pretreatment was required for timely germination, but depulping prior to sowing was very beneficial (Vora 1989). Fermenting the fruits for 3 days at room temperature and then depulping before stratifying gave excellent results for common hackberry (Bonner 1974).

Germination tests. Germination test recommendations for treated seeds are the same for all 3 species (table 5). Untreated seeds should be tested for 90 days (Bonner 1974). Because of the long periods necessary for germination tests, rapid estimates of viability are very useful in this genus. Tetrazolium chloride staining works well with sugarberry. Incubation of clipped and imbibed seeds in a 1% solution for 24 hours at 26 °C has given good results (Bonner 1984).

Table 3—*Celtis,* hackberry: height, seed-bearing age, and fruit color

Species	Height at maturity (m)	Year first cultivated	Minimum seed-bearing age (yrs)	Fruit color	
				Preripe	Ripe
C. laevigata	18–24	1811	15	Green	Dark orange to red
C. laevigata var. *reticulata*	9–14	1890	—	—	Orange-red or yellow
C. occidentalis	9–40	1656	—	Orange-red	Dark reddish purple

Source: Bonner (1974).

Table 4—*Celtis,* hackberry: seed yield data

Species	Fruits/weight		Cleaned seeds/weight			
			Range		Average	
	/kg	/lb	/kg	/lb	/kg	/lb
C. laevigata	4,850	2,200	8,150–15,600	3,700–7,080	13,200	6,000
C. laevigata var. *reticulata*	—	—	5,150–14,500	2,340–6,600	10,500	4,870

Table 5—*Celtis,* hackberry: germination test conditions and results

Species	Germinative test conditions *			Germination rate		Germination %	
	Temp (°C)			Amount			
	Day	Night	Days	(%)	Days	Avg	Samples
C. laevigata	30	20	60	30–50	25–30	55	6+
C. laevigata var. *reticulata*	30	20	60	—	—	37	7
C. occidentalis	30	20	60	39	37	47	7

Source: Bonner (1974).

* Media used: sand, a sand–peat mixture, or a sandy loam soil.

Nursery practice. Both fall-sowing of untreated seeds and spring-sowing of stratified seeds are satisfactory. Seeds may be broadcast or drilled in rows 20 to 25 cm (8 to 10 in) apart and covered with 13 mm ($^1/_2$ in) of firmed soil. Beds should be mulched with straw or leaves held in place with bird screens until germination starts. Germination is epigeal (figure 4). These species can be propagated by cuttings (Bonner 1974), and grafting and budding success has been reported for common hackberry and sugarberry (Williams and Hanks 1976).

Rubiaceae—Madder family

Cephalanthus occidentalis L.

buttonbush

Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station
Mississippi State, Mississippi

Other common names. common buttonbush, honeyballs, globe-flowers.

Growth habit, occurrence, and use. Buttonbush is a deciduous shrub or small tree that grows on wet sites from New Brunswick to Florida, west to southern Minnesota, Kansas, southern New Mexico, Arizona, and central California. It also occurs in Cuba, Mexico, and Central America (Little 1979). In the southern part of its range, buttonbush reaches heights of 4.5 to 6 m at maturity (Maisenhelder 1958), but it is shrubby in other areas. The seeds are eaten by many birds, and the tree has some value as a honey plant (Van Dersal 1938). Cultivation as early as 1735 has been reported (Vines 1960).

Flowering and fruiting. The perfect, creamy white flowers are borne in clusters of globular heads and open from June to September (Vines 1960). There is good evidence that buttonbush is largely self-incompatible (Imbert and Richards 1993). The fruiting heads (figure 1) become reddish brown as they ripen in September and October. Single fruits are 6 to 8 mm long (figure 2). Each fruit is composed of 2 or occasionally 3 or 4 single-seeded nutlets (figure 3) that separate eventually from the base (Bonner 1974b).

Collection and extraction. Collection can begin as soon as the fruiting heads turn reddish brown. Many heads disintegrate after they become ripe, but some persistent through the winter months. When the heads are dry, a light flailing will break them into separate fruits. Data from 4 samples of scattered origin showed 295,000 fruits/kg (134,000/lb), with a range of 260,000 to 353,000 (118,000 to 160,000). Purity in these seed lots was 96% (Bonner 1974b). The number of seeds per weight is about twice the number of fruits. Longevity of buttonbush seeds in storage is not known, but they appear to be orthodox in nature and thus easy to store. The principal storage food in the seeds is carbohydrate (Bonner 1974a).

Figure 1—*Cephalanthus occidentalis*, common buttonbush: fruiting heads.

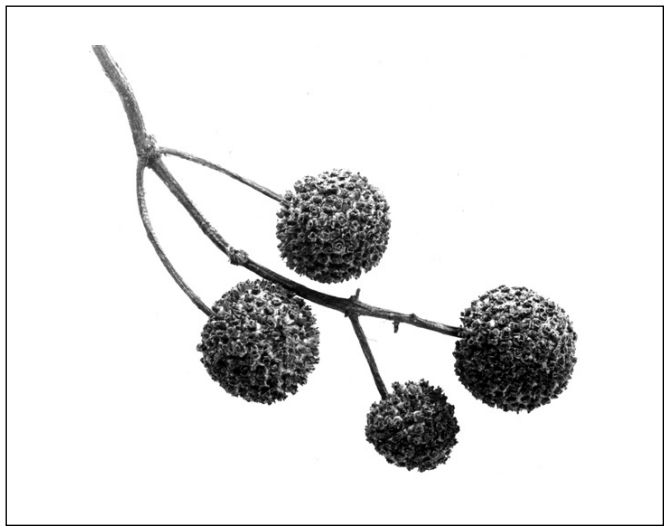

Figure 2—*Cephalanthus occidentalis*, common buttonbush: single fruits.

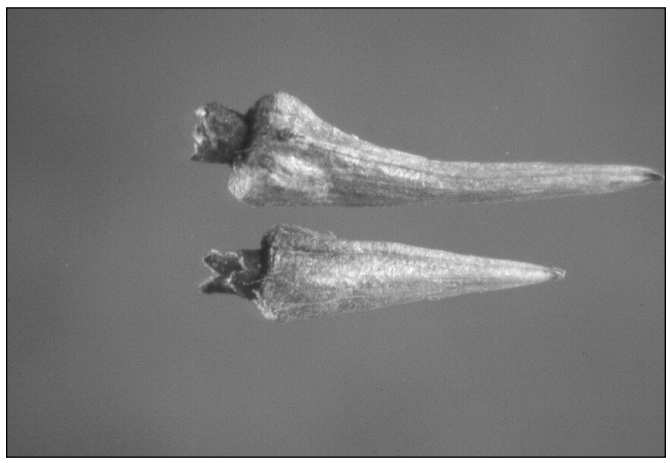

C

Germination tests. Buttonbush seeds germinate promptly without pretreatment. Germination is epigeal (figure 4). Results with 2 test methods on seed from Louisiana (DuBarry 1963) and Mississippi (Bonner 1974b) were as follows:

	Louisiana	Mississippi
Medium	Water	Blotter paper
Temperature (°C)	24–34	30
Light	Yes	No
Test duration (days)	30	10
Germination (%)	86	78
No. of samples	4	4

Figure 3—*Cephalanthus occidentalis*, common buttonbush: longitudinal section through the 2 nutlets of a single fruit.

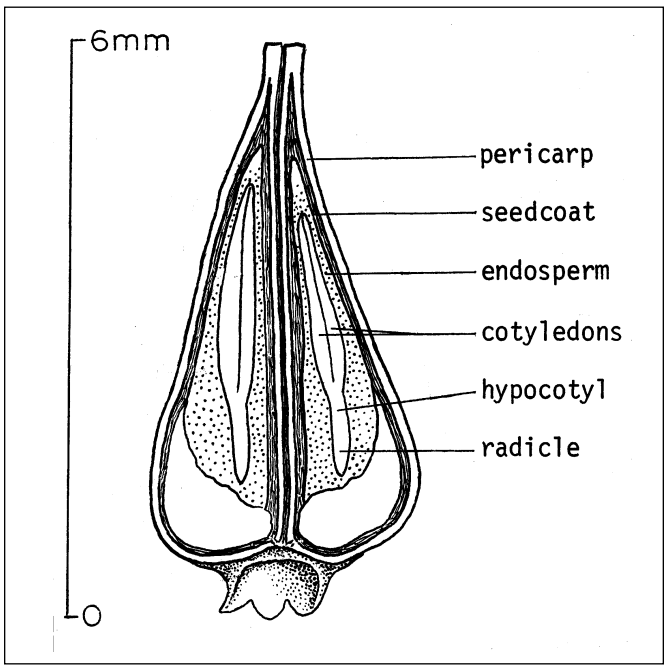

Figure 4—*Cephalanthus occidentalis,* common buttonbush: seedling development at 1, 23, and 40 days after germination.

Fabaceae—Pea family

Ceratonia siliqua L.

carob

Wayne D. Shepperd

Dr. Shepperd is a principal silviculturist at the USDA Forest Service's Rocky Mountain Research Station, Fort Collins, Colorado

Growth habit. *Ceratonia siliqua* L.—carob, St. John's bread, or locust—is a small to medium-sized broadleaf, evergreen tree that may grow to 20 m in height under ideal climatic conditions (Catarino 1993) but usually reaches heights of 8 to 15 m (Goor and Barney 1968). Carob is thought to be a tropical plant that has adapted well to Mediterranean climates by utilizing its deep rooting habit and xerophilous leaves to avoid water stress (Catarino 1993). The deep taproot's penetration into moist regions of the soil profile effectively lengthens the active growth period for carob leaves during the Mediterranean dry season (Rhizopoulou and Davies 1991).

Occurrence. Carob is native to the eastern Mediterranean from the southern coast of Asia Minor to Syria (Goor and Barney 1968; Griffiths 1952; Karschon 1960). It has been cultivated for thousands of years as a forage crop on a wide variety of soils in Asian, European, and North African countries along the coast of the Mediterranean Sea (Bailey 1947; Catarino 1993). Carob's sensitivity to low temperatures limits its area of distribution (Catarino 1993). Since its introduction to the United States in 1854, carob has done well only in the warm subtropical climates (southern Florida, the Gulf States, New Mexico, Arizona, and southern California) where annual rainfall is not below 30 to 35 cm (Bailey 1947; Coit 1951, 1962).

Use. Carob legumes (pods) are commonly used as animal feed or ground into flour and mixed with other cereals for human consumption. The legumes are rich in protein and sugar and are a highly nutritious livestock feed, comparable to barley and superior to oats (Bailey 1947; Coit 1962). However, the high sugar content (< 50%) is offset by a high tannin content (16 to 20%) that inhibits protein assimilation (Catarino 1993). Techniques are currently being developed to enzymatically separate and extract the phenolic tannin compounds to increase utilization (Catarino 1993). Legumes are also used in making health foods (as a chocolate "substitute"), carob syrup, and medicines such as laxatives and diuretics (Binder and others 1959; Coit 1951, 1962). In addition, they can be used as a cheap carbohydrate source for ethanol production, yielding 160 g of ethanol/kg of dry legumes (Roukas 1994). The annual production of carob legumes is 340,000 to 400,000 metric tons (374,800 to 441,000 tons), with Greece, Spain, Italy, and Portugal being primary producers (Roukas 1994; Catarino 1993).

Carob seeds are extremely hard, but the endosperm contains 30 to 40% by weight of galactomanane polysaccharides collectively known as carob-, or locust-bean gum (Catarino 1993). The compound is a valuable stabilizing and thickening additive used in the food processing, pharmaceutical, textile, paper, and petroleum industries.

The adaptability, ease of cultivation, and aesthetic appeal of carob also make it a desirable landscape plant (Catarino 1993). It is chiefly valuable in the United States as an ornamental evergreen but has been used to some extent in environmental plantings (Toth 1965).

Flowering and fruiting. The flowers, borne in small, lateral, red racemes, are polygamo-trioecious (Loock 1940). Nearly all cultivated species are dioecious, although flowers of both sexes may possess vestigial components of the other sex. Rarely, plants will possess both male and female flowers on the same stalk or completely hermaphroditic flowers (Catarino 1993). Flowers bloom from September to December in California, depending on the variety and the weather (Bailey 1947; Coit 1951).

The fruit is a coriaceous, indehiscent legume 10 to 30 cm long, 6 to 20 mm thick, filled with a sweet, pulpy substance bearing 5 to 15 obovate, transverse, brown, bony seeds about 6 mm wide (figures 1 and 2) (Bailey 1947; Coit 1951). Legumes ripen, turn dark brown, and begin to fall from September to November (California), depending on the variety and the weather (Bailey 1947; Coit 1951, 1962). Natural seedlings appear in Greece in November, even though temperatures do not favor shoot growth (Rhizopoulou and Davies 1991). Plants begin to bear fruit when 6 to 8 years old, and crops are abundant every second year (Bailey 1947). Average annual yield per tree at maturity

C

Figure 1—*Ceratonia siliqua*, carob: seed.

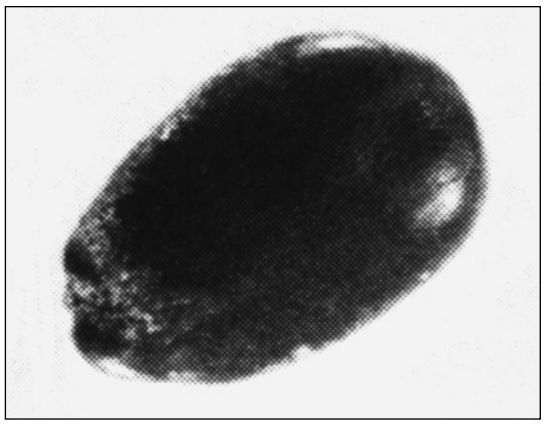

Figure 2—*Ceratonia siliqua*, carob: longitudinal sections through a seed.

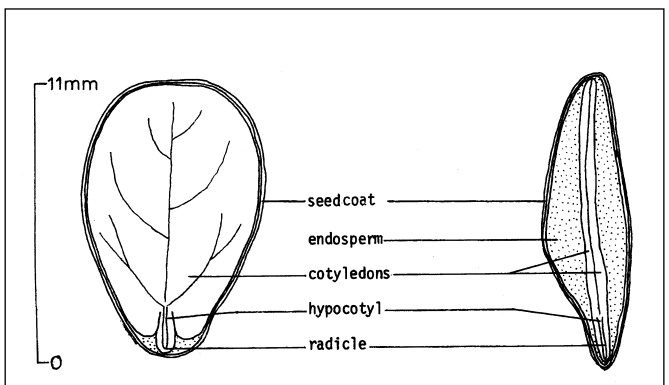

is about 90 to 113 kg (200 to 250 lbs) of fruit (Coit 1951, 1962).

Collection of fruits. Fruits may be collected on the ground, or the ripe legumes may be shaken from the trees onto canvas sheets (Coit 1951). Legumes shaken from the tree should be allowed to remain on the ground for 2 to 3 days until completely dry (Coit 1962). Because of their high sugar content, legumes are likely to become moldy and quickly infested with a small scavenger worm—*Paramycelios transitella* Walker—if wet weather occurs during the harvesting season (Coit 1951, 1961, 1962). Because the worms infect the legumes while they are still attached to the tree, it is advisable to limit collections to dry years.

Extraction and storage of seed. Seeds are easily extracted after the legumes have been air-dried for a few days (Coit 1951; Goor and Barney 1968). If the legumes are to be stored for a time before extracting the seeds, they should be fumigated with an acceptable substitute for methyl bromide, which was recommended by Coit (1962) but is scheduled to be removed from use in the future. One kilogram (2.2 lb) of legumes yields about 50 to 140 g (1.8 to 4.9 oz) of cleaned seeds (Binder and others 1959). Cleaned seeds average 4,400 to 5,500 seeds/kg (2,000 to 2,500 seeds/lb) (Alexander and Shepperd 1974; Goor and Barney 1968). Soundness appears to be relatively high (<80% for 2 samples) (Alexander and Shepperd 1974). Seeds have remained viable for as long as 5 years when stored dry at low temperatures in sealed containers (Goor and Barney 1968).

Pregermination treatments. Seeds sown from recently ripened legumes germinate well without pretreatment (Rhizopoulou and Davies 1991), but if the seeds dry out they become very hard and do not readily imbibe water (Coit 1951). The best treatments to overcome seedcoat impermeability are soaking in concentrated sulfuric acid (H_2SO_4) for 1 hour and then in water for 24 hours, or alternatively, soaking for 24 hours in water that has first been brought to a boil and then allowed to cool (Goor and Barney 1968; Karschon 1960). Mechanical scarification is also effective in increasing the rate of water absorption with small lots of seeds (Coit 1951).

Germination tests. Germination tests have been run in moist vermiculite for 34 days at 21 °C. The germination rate was 66% for 16 days and the percentage germination was 80% (Alexander and Shepperd 1974).

Nursery practice. Seeds should be scarified by acid or hot water treatment and sown immediately afterwards in sterile soil or vermiculite under partial shade (Coit 1962; Karschon 1960). Seeds can be sown in either the spring or fall (Goor and Barney 1968). Seedlings have also been grown at 14 to 17 °C greenhouse temperatures with a 12-hour photoperiod of natural light supplemented with 250-W metal halide lamps (Rhizopoulou and Davies 1991). Seedlings develop a single deep taproot with a few small lateral roots less than 1.0 cm in length (Rhizopoulou and Davies 1991). Because the long taproot is easily injured, seeds should be sown in flats, pots, or containers so that seedlings can be outplanted with the original rooting medium intact (Coit 1951; Loock 1940). An alternate practice is to soak the legumes in water for 2 to 3 days and then plant without removing the seeds, but the germination rate is usually low (Coit 1951).

Fabaceae—Pea family

Cercis L.

redbud

Valerie A. Banner and William I. Stein

Ms. Banner is a general biologist and Dr. Stein is a forest ecologist emeritus at the USDA Forest Service's Pacific Northwest Research Station, Corvallis, Oregon

Growth habit, occurrence, and uses. The genus *Cercis L.*—redbud—includes 8 species of trees and shrubs; 2 are indigenous to North America, 5 to China, and 1 to an area from southern Europe eastward to Afghanistan (Little 1979; Robertson and Lee 1976). Eastern redbud is widely distributed from southernmost Canada to central Mexico, spans about 24 degrees of longitude and 23 degrees of latitude, and has at least 1 well-defined variety, Texas redbud (table 1). This species shows clinal variation and substantial differences in morphological, dormancy, and hardiness characteristics associated with climatic and geographic conditions (Donselman 1976; Donselman and Flint 1982; Raulston 1990). California redbud also has variable characteristics (Smith 1986) within its much more restricted range in the southwestern United States. About 15 cultivars of eastern redbud have been developed and cultivars of other redbuds also are propagated (Raulston 1990).

Redbuds are deciduous, small- to medium-sized trees or shrubs with unarmed slender branchlets that lack terminal buds. Eastern redbud typically is a straight-trunked tree up to 12 m tall (table 2); the tallest on record reaches 13.4 m (AFA 1996). Although they also reach tree size, California and Texas redbuds are more commonly described as multiple-stemmed shrubs. California redbud grows from 2 to 6 m tall; the tallest one on record is 8.8 m and the tallest Texas redbud is about the same (AFA 1996). Eastern redbud occurs on many soils in moist open woodlands, flood plains, river thickets, and borders of small streams, whereas the variety, Texas redbud, often inhabits drier locations, primarily paleozoic limestone formations such as xeric pastures, hills, outcrops, and bluffs (Hopkins 1942). California redbud is unevenly distributed at elevations of 70 to 1,524 m along foothill streams, flats, draws, low slopes and canyons and on dry gravelly and rocky soils (Chamlee 1983; Jepson 1936; Sudworth 1908).

Redbuds are valued particularly for their showy buds and flowers that appear before the leaves (Clark and Bachtell 1992; McMinn and Maino 1937). They exhibit cauliflory—flowering directly along older branches and trunks—which is rare among temperate species (Owens and Ewers 1991) and contributes greatly to flowering showiness. Flowers typically are a deep reddish purple (magenta) but vary among localities (Coe 1993; Smith 1986) and species (table 3). Some white ones occur naturally, and cultivars have been developed for particular flower and leaf colors (Raulston 1990). Ornamental uses are extensive within each species' indigenous range and several species have proven hardy more extensively (McMinn and Maino 1937;

Robertson 1976). Where redbuds are numerous, they provide valued bee pasture in early spring (Magers 1970). The buds, flowers, and legumes (pods) of redbuds are edible and have been used in salads or batter (Coe 1993). Native Californians used the roots and bark of California redbud in basketry (Coe 1993; Jepson 1936); remedies for diarrhea and dysentery were also made from the astringent bark (Balls 1962).

Redbuds also are used for borders, erosion control, windbreaks, and wildlife plantings. Eastern redbud is browsed by white-tail deer (*Odocoileus virginiana*) and the seeds are eaten by birds, including bobwhite (*Colinus virginianus*) (Van Dersal 1938). California redbud is moderately important as fall and spring browse for deer but has been rated only fair to poor for goats and poor or useless for other livestock (Sampson and Jespersen 1963).

Two fungal diseases affect the flowering and attractiveness of eastern redbud—verticillium wilt (*Verticillium* sp.) and botryosphaeria canker (*Botryosphaeria dothidea* (Moug.:Fr.) Ces. & De Not.)—by causing die-back of branches. The canker has become more common and destructive in the eastern United States, appearing to attack trees that are under stress (Geneve 1991a; Raulston 1990; Vining 1986).

Flowering and fruiting. Flowering occurs from February to May, varying somewhat by species and location (table 3). The bisexual redbud flowers are brilliant pink to reddish purple and develop on older wood from dormant axillary buds laid down 1 to several years earlier (Owens and Ewers 1991). The flowers are borne sessile or on short, thin pedicels in umbel-like clusters densely covering the branches and trunk. Flowers of California redbud are somewhat larger than those of eastern redbud (Hopkins 1942; Robertson 1976). Eastern redbud begins flowering in 3 to 4 years from seed when trees are 1.5 to 2 m tall, and trees in open or semi-open locations flower most abundantly (Clark and Bachtell 1992; Raulston 1990). Pollination is usually done by long- and short-tongued bees (Robertson 1976). Crops of legumes are produced abundantly by both eastern and California redbud but seed set is more variable (Hopkins 1942; Jepson 1936).

Redbud fruits are pendulous, flattened legumes (figure 1) 4 to 10 cm long (table 2). The generic name *Cercis* (Greek *kerkis*, weaver's shuttle) apparently alludes to the shape of the legume (Robertson and Lee 1976). The legumes of California redbud are somewhat wider and shorter than those of eastern redbud. Legumes of eastern redbud contain 4 to 10 seeds each; those of California redbud only a few (Hopkins 1942; Robertson 1976). Legume color varies from lustrous reddish brown to dull red and turns tan or brown as the fruits mature and dry in July or later. Some legumes open and release their seeds in autumn, but many remain closed for most of the winter. Seeds are released from legumes on the tree or on the ground when the legume

Figure 1—*Cercis canadensis*, eastern redbud: 4 to 10 seeds (**left**) are in each legume (**right**).

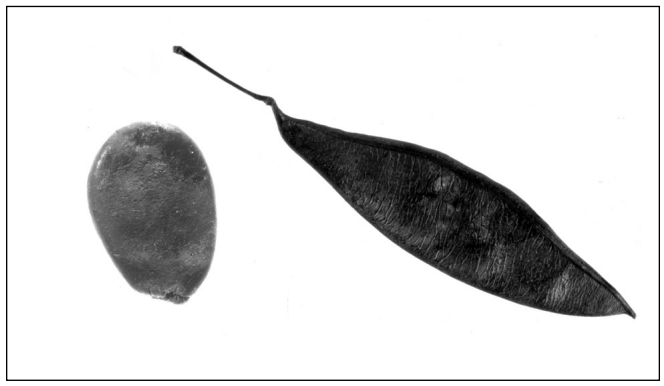

Figure 2—*Cercis canadensis*, eastern redbud: the flattened seed in transverse section (**above**) and longitudinal section (**below**).

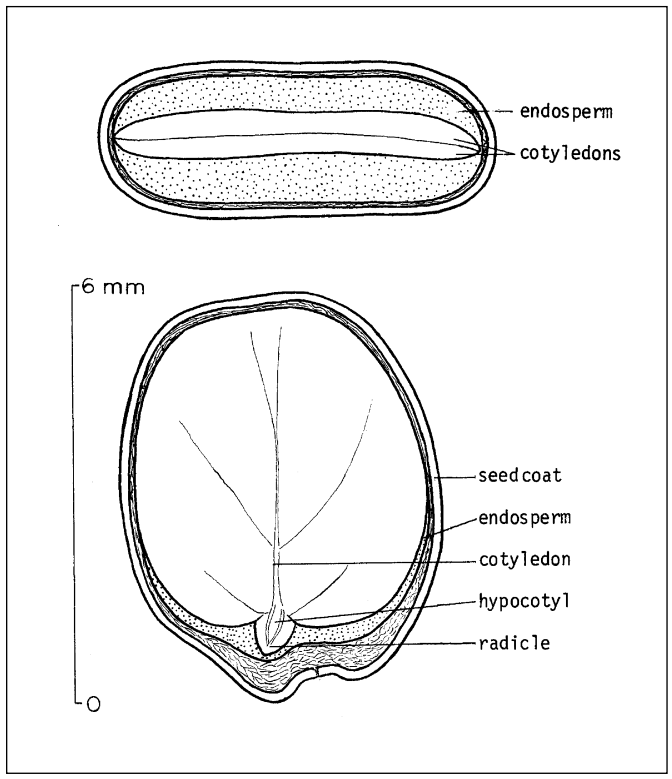

sutures open or the walls decay (Robertson 1976). The seeds are dispersed by wind, birds, and animals, with the proportions carried by each varying by location.

Redbud seeds are somewhat flattened, oval to rounded, and hard (figures 1 and 2). Those of eastern redbud are 4 to 5 mm in diameter; those of California redbud are slightly smaller (table 2). The light tan to dark brown seedcoats are thin but made up of thick-walled cells impermeable to water (Afanasiev 1944). At maturity the embryo is straight, well-developed, and surrounded by endosperm (figure 2).

Collection, extraction, and storage. Legumes can be collected any time after they turn tan or brown. Although legumes remain closed on trees for lengthy periods, prompt collection is prudent to minimize the substantial seed losses that might occur from insects or other factors (Afanasiev 1944). Legumes can be picked by hand or loosened by flailing or shaking the branches and caught on ground cloths. Collected legumes should be temporarily stored and transported in loosely woven sacks.

If legumes are not fully dry when collected, they should be spread thinly and dried until brittle in the sun, under shelter, or in a kiln at 38 to 41 °C. The legumes can be threshed manually or in a variable speed, modified seed separator, hammermill, or grinder. Seeds are separated from the chaff by screening and fanning. Nearly 100% purity is readily obtainable in cleaning the smooth redbud seeds (Lippitt 1996).

After thorough air-drying, seeds can be stored in cloth bags or in closed glass, metal, or fiberboard containers. Because of their impermeable seedcoats, redbud seeds should store dry reasonably well at room temperature or in cool or cold storage, but little storage experience has been reported. Zins (1978) obtained substantial germination from an eastern redbud seedlot stored for 13 years in a glass jar at –25 °C. Seeds of California redbud have been stored satisfactorily for 12 years or more under the same conditions as many conifers at a moisture content of 5 to 9% and temperature of –18 °C (Lippitt 1996).

Seeds of California redbud average about half again as heavy as those of eastern redbud but seed weight varies widely among lots for both species (table 4).

Pregermination treatments and germination tests. Redbud seeds generally require pregermination treatment to overcome dormancy attributable both to a hard, impermeable seedcoat and to some demonstrated, but not fully identified, embryo dormancy (Afanasiev 1944; Geneve 1991b; Hamilton and Carpenter 1975; Heit 1967a7b; Jones and Geneve 1995; Profumo and others 1979; Rascio and others 1998; Riggio-Bevilacqua and others 1985; Tipton 1992; Zins 1978). Test results indicate that the level of dormancy varies by species, seed source, seedlot, age of seeds, and perhaps other factors. Given such variable dormancy, pretreatment might involve using the one demonstrated to be most broadly applicable, or determining sufficiently the nature of dormancy in local lots and applying a customized pretreatment.

Three pretreatments have proven satisfactory for overcoming redbud's seedcoat impermeability—mechanical scarification, immersion in sulfuric acid, or in hot water (table 5). In comparison tests, the acid treatment has generally produced more consistent or slightly better results (Afanasiev 1944; Liu and others 1981), but good imbibition of water has resulted after all 3 treatments. Acid treatment involves immersing redbud seeds in concentrated sulfuric acid for 15 to 90 minutes at room temperature followed by thorough washing in water (Afanasiev 1944; Frett and Dirr 1979; Liu and others 1981). Length of treatment required can be determined on a small sample; if immersion is too short, seedcoats remain impermeable, if too long, the seeds are damaged. Well-rinsed, acid-scarified seeds can be placed immediately in stratification or surface-dried and stored several months until sown by hand or seeder (Heit 1967a).

Abrading, clipping, or piercing the seedcoat to expose the endosperm and allow ready entry of water (Hamilton and Carpenter 1975; Riggio-Bevilacqua and others 1985; Zins 1978) can be done easily for small test lots but not as readily in quantity. Immersing small or large quantities of seeds in hot or boiling water can be done easily, but results have been more variable than for acid treatment—sometimes reasonably good (Fordham 1967; Mirov and Kraebel 1939), other times poor to mediocre (Afanasiev 1944; Liu and others 1981). Hot water treatment clearly makes redbud seedcoats permeable but may cause internal damage. Better calibration of time–temperature effects appears needed—

whether to dip the seeds for 15 or more seconds in boiling water or immerse them overnight in 60 to 88 °C water that cools gradually. Application of dry heat also appears to have promise (Williams 1949).

After scarification, cold stratification is generally required to overcome some degree of internal dormancy and maximize seed germination. Germination differences between unstratified and cold-stratified seeds range from none (Hamilton and Carpenter 1975), to fractional differences in the response of excised embryos (Geneve 1991b), up to major differences for intact seeds (Afanasiev 1944; Fordham 1967; Frett and Dirr 1979; Geneve 1991b). Stratification of eastern redbud for 28 to 60 days at 1 to 7 °C has proven satisfactory (table 5) and 90 days for California redbud (Heit 1967a; Van Dersal 1938). Up to a point, seed response improves with longer stratification, and extended stratification generally does no harm. Seeds should be sown promptly after stratification; drying out for more than 6 days at room temperature reduced germination of eastern redbud seeds (Afanasiev 1944).

A pretreatment and germination test protocol has not yet been specified for redbud seeds due perhaps to extensive variability in seedlot characteristics, length of time required, and low demand for a standard test. Pretreated seeds of eastern redbud will germinate at temperatures of 1 to 38 °C; Afanasiev (1944) concluded 8 days at 21 °C was most satisfactory. Texas redbud seeds germinate at 24 to 31 °C and 28 °C was optimum (Tipton 1992). Germination test methods currently used for many species—14 to 28 days at alternating temperatures of 20 and 30 °C—seem to nicely bracket conditions that yielded high germination from pretreated redbud seeds (table 5).

Viability of redbud seeds is most easily and rapidly determined by a tetrazolium (TZ) test or a growth test of excised embryos. The TZ test is the only method prescribed by the International Seed Testing Association; preparation and evaluation procedures to use are listed in a published handbook (Moore 1985). In brief, the seeds are cut at the distal end of the cotyledons either dry or after overnight soaking in water at room temperature. Soaking in a 1% TZ solution follows for 6 to 24 hours at 35 °C. The embryos are then cut longitudinally, and the staining pattern of cotyledons, hypocotyl, and radicle evaluated. A growth test of excised embryos requires making the seedcoats permeable with acid, hot water, or mechanical scarification; soaking the seeds overnight, excising the embryos, and incubating them for 4 to 6 days on moist filter paper at 20 °C (Flemion 1941; Geneve 1991b). Viability determined by tetrazolium or excised embryo test reveals that the seeds' maximum potential and generally is higher than indicated by a germination test (Flemion 1941; Hamilton and Carpenter 1975; USDA FS 1996).

Nursery practice. Redbuds are propagated most readily from seeds sown either in the fall or spring. Fall-sown seeds may or may not be scarified, and stratification occurs naturally in the seedbeds (Lippitt 1996; Raulston 1990). In one reported instance, immature seeds of eastern redbud collected, extracted, and sown before the seedcoats hardened yielded 90% germination the following spring (Titus 1940). When seeds need to be scarified for either fall- or spring-sowing—acid treatment for 15 to 60 minutes, rinsing, and a 24-hour soak in water; a boiling water dip for 15 seconds or more followed by a 24-hour soak in cooler water; or immersion overnight in 88 °C hot water that gradually cools—can be generally used to overcome seedcoat dormancy (Frett and Dirr 1979; Heit 1967b; Lippitt 1996; Raulston 1990; Robertson 1976; Smith 1986). After scarified seeds have imbibed water, they may need to be sorted to separate those not swollen and still impermeable for further treatment. When necessary, seeds are stratified at 1 to 5 °C for 30 to 90 days. Stratification requirements are uncertain for 2 reasons: variability among seedlots and the unknown stratification effect produced by low temperature storage of the seeds.

Surface-dried seeds are drill- or broadcast-sown and covered 0.6 to 2.5 cm (0.2 to 1 in) deep with soil, sand, sawdust, or bark. Some nurseries fumigate, then reinoculate before sowing seedbeds. Presence of an endomycorrhizal fungus is important; inoculation with *Glomus fasciculatum* (Thaxter) Gerdemann and Trappe has increased first-season growth of eastern redbud as much as 72% (Maronek and Hendrix 1978). Mulching of fall-sown beds can be beneficial but the mulch must be removed when germination starts. Germination is epigeal (figure 3).

Seedling return from nursery sowings is very variable. For eastern redbud, an average of 2,425 usable seedlings (range 617 to 7,055) were produced per kilogram of seeds (1,100 usable seedlings/lb, range 280 to 3,200/lb) (Roy 1974). Germination is fairly consistent year to year for California redbud, averaging 54 to 60% (Lippitt 1996). Under favorable conditions, seedling height growth of eastern redbud can be rapid: about 0.5 m (20 in) in reinoculated soil (Maronek and Hendrix 1978), 1 m (40 in) or more under an intensive nitrogen fertilizer schedule, and about 2 m (80 in) if started in January in a greenhouse under long-day conditions and transplanted outdoors after the danger from frost is over (Raulston 1990).

Redbud seedlings are also produced in pots and tube containers in both greenhouses and shadehouses where production practices and growth conditions can be closely controlled. To gain the benefits of natural stratification, containers may be sown in the fall and overwintered in shadehouses. Treatments to prevent botrytis are necessary soon after late February germination of California redbud (Lippitt 1996). Seedlings suitable for outplanting—15 to 30 cm (6 to 12 in)—can be produced readily in one season (Clark and Bachtell 1992; Lippitt 1996).

Redbuds are relatively difficult to propagate vegetatively, but that must be done to produce the desired cultivars. Redbud cultivars are generally budded or grafted. Field-grown stock is easier to bud then container-grown stock, and summer budding is much more successful then winter budding (Raulston 1990). Much effort and some progress has been reported on reproducing redbud from stem cuttings (Tipton 1990) and tissue cultures (Bennett 1987; Geneve 1991a; Mackay and others 1995).

Rosaceae—Rose family

Cercocarpus Kunth

mountain-mahogany

Stanley G. Kitchen

Mr. Kitchen is a botanist at the USDA Forest Service's Rocky Mountain Research Station, Shrub Sciences Laboratory, Provo, Utah

Growth habit, occurrence, and use. The mountain-mahoganies—genus *Cercocarpus*—are 8 to 10 species of moderately to intricately branched shrubs or small trees that are endemic to dry coastal and interior mountains of the western United States and Mexico (Stutz 1990). Leaves are generally persistent and stems are unarmed. Two of the most widely distributed and utilized species are described here (table 1).

Curlleaf mountain-mahogany populations demonstrate considerable variability in height (Davis 1990; Stutz 1990). In some areas, the species occurs as a medium-statured shrub of 1 to 2 m. More commonly, it is a small tree of 4 to 10 m at maturity. Trunk diameter of mature trees measures 30 to 100 cm (Johnson 1970). Schultz and others (1990) estimated the mean age of trees in central and western Nevada stands to be 352 years. Mean plant age in Utah stands (85 years) is less than that in Nevada stands but greater than that in Oregon and Montana stands (Davis 1990).

True mountain-mahogany is a deciduous shrub of 1 to 5 m. Both species occur as components of mixed communities and as dominants in extensive stands and are important cover and browse species for wildlife, especially big game (Davis 1990). When burned, true mountain-mahogany resprouts from the crown, resulting in relatively rapid stand recovery following fire. Recovery of curlleaf mountain-mahogany stands following fire is from seed only and can be extremely slow. Because they are long-lived, produce an extensive root system, and survive well on dry steep slopes, mountain-mahogany plants play an important role in erosion control. Nitrogen fixation in root nodules has been described for both curlleaf (Lepper and Fleschner 1977) and true mountain-mahoganies (Hoeppel and Wollum 1971), suggesting a significant role by these species in improving fertility in otherwise infertile soils. The wood of curlleaf mountain-mahogany is extremely dense and heavy and has had limited use, primarily as fuel wood (Johnson 1970).

Geographic races and hybrids. Two distinct subspecies or varieties of curlleaf mountain-mahogany occur in the western United States (Stutz 1990). Although considerable overlap in distribution exists, *C. ledifolius* ssp. *ledifolius* (formerly ssp. *intercedens)* has a more northeastern distribution, whereas the distribution of ssp. *intermontanus* is centered to the west of its sister taxon. In northern Idaho, northern Wyoming, and southern Montana, ssp. *ledifolius* is the only mountain- mahogany taxon present (Stutz 1990). The leaves of ssp. *ledifolius* plants differ from those of ssp. *intermontanus* in being narrower, more strongly involute, and densely pubescent ventrally. The leaves of ssp. *intermontanus* are broadly elliptic and glabrous. Habit of ssp.

Table 1—*Cercocarpus*, mountain-mahogany: nomenclature and occurrence

Scientific name(s)	Common name(s)	Occurrence
***C. ledifolius* Nutt.**	**curlleaf mountain-mahogany**, curlleaf cercocarpus, curlleaf mahogany, desert mahogany	Washington & Oregon E to Montana & Wyoming, S to Arizona, California, & Mexico (Baja)
***C. montanus* Raf.** *C. betuloides* Nutt. *C. parvifolius* Nutt. *C. flabellifolius* Rydb.	**true mountain-mahogany,** mountain cercocarpus, birchleaf cercocarpus, birchleaf mountain-mahogany, alderleaf mountain-mahogany, blackbrush, deerbrush, tallowbrush	Oregon E to South Dakota S to Mexico, incl. parts of Wyoming, Colorado, Nebraska, Kansas, Texas, New Mexico, Arizona, Utah, & California

ledifolius is more shrubby (or less tree-like) than that of ssp. *intermontanus,* especially in its northern distribution. Although it is treated as a separate species, littleleaf mountain-mahogany—*C. intricatus* Wats.—is taxonomically and phenotypically close to curlleaf mountain-mahogany spp. ledifolius. It is distinguished by its smaller leaves and stature, fewer stamens, and shorter style on mature fruits (Stutz 1990). The evolutionary processes that produced littleleaf mountain-mahogany are still proceeding and intermediates between the 2 taxa are common.

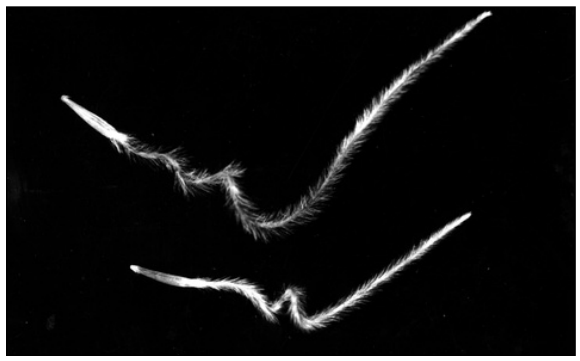
As reflected in its taxonomy, true mountain-mahogany is also quite variable across its range. *C. montanus* ssp. *montanus* has the most widespread distribution (Stutz 1990). Separate taxa have been described for parts of the Pacific Coast (ssp. *betuloide*s Nutt.) and in the Southwest (ssp. *paucidentatus* S. Wats and *argenteus* Rydb). *Cercocarpus mexicanus* Hendrickson, *C. rzedowski* Hendrickson, and *C. fothergilloides* Kunth. are closely related Mexican species.

Inter-specific hybrids are common between curlleaf and true mountain-mahoganies (Stutz 1990). Fertility in hybrids of true mountain-mahogany and curlleaf mountain-mahogany ssp. *ledifolius* is good in contrast to the low fertility encountered in hybrids of true mountain-mahogany × curlleaf mountain-mahogany spp. *intermontanus* (Stutz 1990). Hybrids between true and littleleaf mountain-mahoganies are rare.

Flowering and fruiting. Small perfect flowers bearing no petals are borne individually or in small clusters. Flowering for these wind-pollinated shrubs occurs some time between late March and early July depending on latitude, elevation, and aspect. Fruits are cylindrical achenes bearing a single seed and are distinguished by a 3- to 10-cm plumose style that facilitates wind dispersal (figure 1). Ripened fruits disperse from July through October. Abundant fruit production occurs at 1- to 10-year intervals (Plummer and others 1968); however, a high percentage of nonviable (empty) fruits is not uncommon. Plants may reach reproductive maturity in 10 to 15 years (Deitschman and others 1974).

Fruit collection. Fruit maturation within a stand is generally somewhat asynchronous. Because of this and because fruits will not dislodge before they are fully ripe, harvests are most productive when delayed until the fruits on a majority of plants ripen. Optimal timing for harvest varies between July and September. Delays may result in diminished or lost harvests due to wind dispersal. Fruits of several plants must be examined for fill and insect damage before starting collection. Ripe, dry mountain-mahogany fruits are easily shaken from branches onto tarps or hand-held hoppers using a beating stick. During harvest and handling, short hairs dislodge from the fruits. These hairs cause considerable discomfort to eyes and skin, thus the cowboy epithet of "hell feathers" (Plummer and others 1968). Fruits may collect in harvestable depths on the ground during years of superior production. However, collections from ground accumulations are often of poor quality due to the removal of viable seeds by rodents.

Figure 1—*Cercocarpus*, mountain-mahogany: achenes with feathery style; the size of the achene varies greatly within each species.

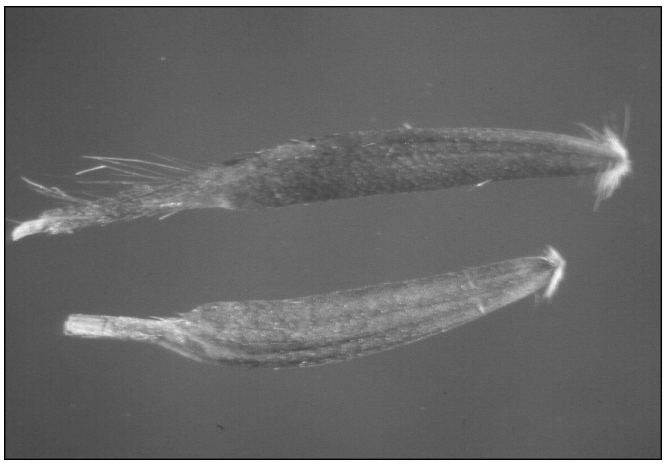


Cleaning and storage. Highest purity values are obtained by removing most broken branches from fruits during collection. For large collections, empty fruits, styles, and fine hairs are best removed using a variable-speed debearder and a 9.5-mm (#2) screen fanning mill (figure 2). Hammermilling causes excessive breakage and should not be used. Minimum standards accepted by the Utah Division of Wildlife Resources for both species are purity values of 95%, and viability values of 85% (Jorgensen 1995).

Cleaned-fruit sizes differ by species, ecotype, and year of collection. In one study, average number of fruits per weight for curlleaf (8 collections) and true mountain-mahoganies (10 collections) was 106,000 and 88,000/kg (48,000 and 40,000/lb), respectively (Kitchen and others 1989a&b). These fruit weights were either equivalent to or somewhat heavier than those previously reported (Deitschman 1974). Curlleaf and true mountain-mahogany fruits stored under warehouse conditions experienced no significant loss of viability during 15 and 7 years, respectively (Stevens and others 1981).

Germination. Reported germination responses to moist chilling for curlleaf mountain-mahogany range from no response after 12 weeks (Young and others 1978), to good germination with 4 weeks (Heit 1970). In most of these studies, interpretation of results is difficult because fruit fill percentage was not determined. Dealy (1975) reported 20% germination in response to 60 days of moist

Figure 2—*Cercocarpus montanus*, true mountain-mahogany: achenes with styles removed (cleaned seeds).



chilling (4 °C) followed by 30 days at 20 °C for a 2-year old Oregon source that had tested 78% viable. He also observed germination during extended chilling (75 to 270 days). Kitchen and Meyer (1990) found the length of wet chilling (1 to 2 °C) required to make 90% of viable seeds germinable at 15 °C ranged from 6 to 10 weeks for 6 fresh collections from Utah, Idaho, and Nevada. They observed that cold-temperature germination began at about 8 weeks. Chemical treatments that have provided limited success in breaking dormancy with curlleaf mountain-mahogany seeds include: gibberellins (GA_3), thiourea, hydrogen peroxide, and sulfuric acid (Dealy 1975; Stidham and others 1980; Young and others 1978).

Some collections of true mountain-mahogany seeds have tested largely nondormant (Deitschman and others 1974). More typically, 2 to 12 weeks of moist chilling are required to break dormancy (Kitchen and Meyer 1990). Kitchen and Meyer (1990) found that cold-temperature germination (1 to 2 °C) for 9 Colorado and Utah collections began after 7 to 10 weeks of moist chilling.

Consistent estimations of embryo viability using standard TZ (tetrazolium) staining procedures are difficult to obtain for both species (Kitchen and others 1989a, 1989b). This is because the embryo is held tightly in the cylindrical pericarp and is difficult to extract for staining and examination (figure 3). Technical experience with mountain-mahogany TZ evaluations appears to be a major factor in accuracy of test results.

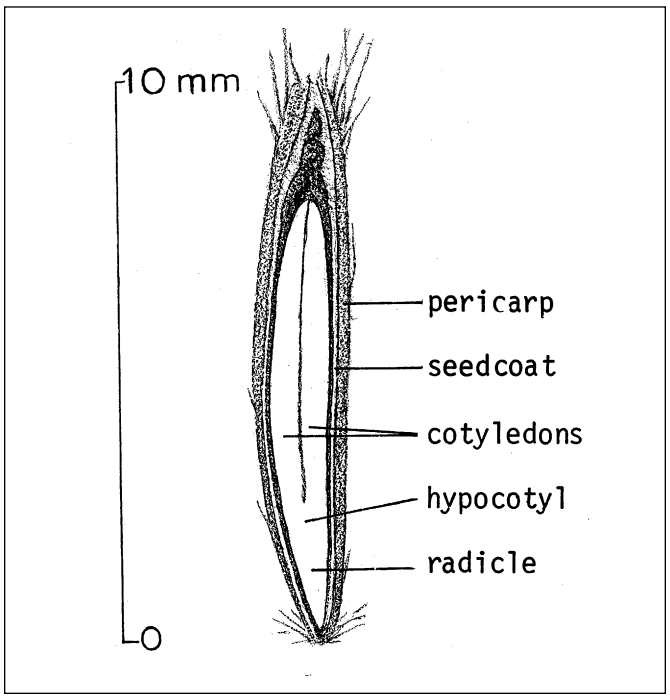

Figure 4— *Cercocarpus montanus*, true mountain-mahogany: seedling with primary leaves and well-developed secondary leaves.

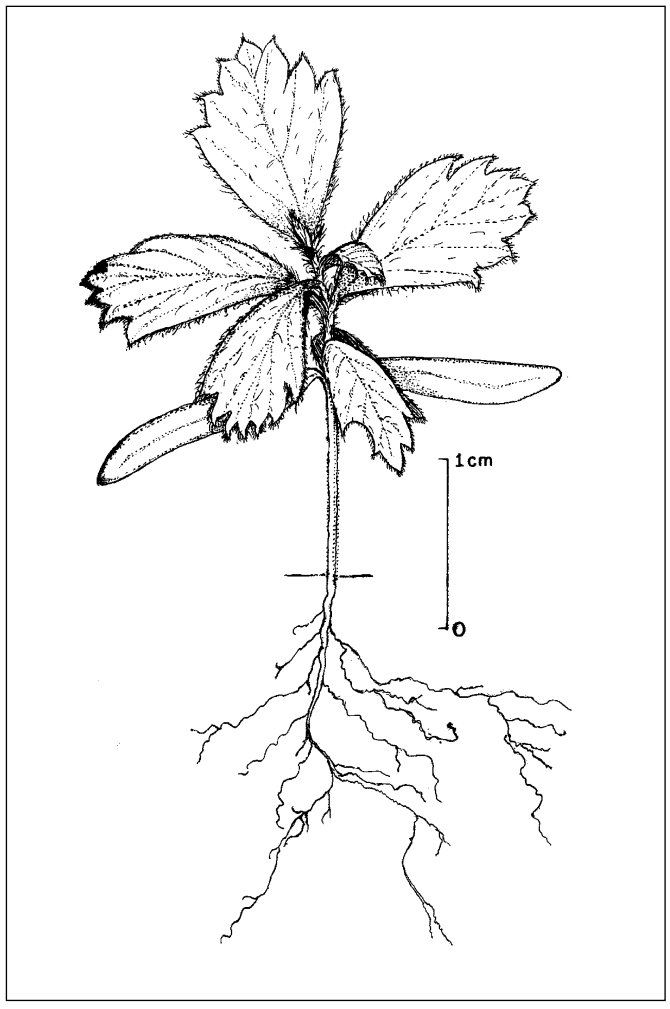

C

Nursery and field practice. Curlleaf and true mountain-mahoganies were first cultivated in 1879 and 1872, respectively (Deitschman and others 1974). Bareroot and container nursery stock are commercially available for both species, generally as 1- or 2-year-old stock. Unless nondormant collections are used, cleaned fruits are either prechilled or fall-sown. Seedbeds should be kept moist until seeds have germinated (Deitschman and others 1974). Deep-rooting containers filled with a minimum of 0.2 liter (13 in^3) standard potting mix is recommended for container stock production (Landis and Simonich 1984). With optimum rearing conditions a minimum of 4 to 6 months is required to develop an adequate root system. Figure 4 illustrates a seedling with well-developed secondary leaves. Direct seeding of mountain-mahogany should be carried out in fall or early winter in conjunction with seedbed preparations that minimize competition to first-year seedlings (Plummer and others 1968).

Rosaceae—Rose family

Chamaebatia foliolosa Benth.

bearmat

Arthur W. Magill and Susan E. Meyer

Dr. Magill retired from USDA Forest Service's Pacific Southwest Forest and Range Experiment Station;
Dr. Meyer is a research ecologist with the USDA Forest Service's Rocky Mountain Research Station,
Shrub Sciences Laboratory, Provo, Utah

Other common names. southern bearmat, mountain-misery, Sierra mountain-misery, San Diego mountain-misery, bearclover, tarweed, and running-oak.

Growth habit, occurrence, and use. Two varieties of this species—*Chamaebatia foliolosa* Benth.—are recognized. The typical variety, bearmat, is an evergreen shrub, 15 to 60 cm tall, that grows between 600 and 2,100 m elevation on the western slopes of the Sierra Nevada in California. It occurs in open ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) and in California red fir *(Abies magnifica* A. Murr.) forests (Munz and Keck 1963). Southern bearmat—*C. foliolosa* var. *australis* Brandg.—grows to a height of nearly 2 m on dry slopes in the chaparral type from San Diego County to Baja California.

The typical variety is normally regarded as a pest because it inhibits the establishment and growth of trees (Adams 1969; Dayton 1931). From an aesthetic viewpoint, the plants can provide attractive ground cover, but their glutinous leaves are highly aromatic (Bailey 1928; McMinn 1959). It is useful for watershed stabilization and is a potential landscape plant (Magill 1974).

Flowering, seed production, and seed use. Bearmat produces perfect flowers throughout its range from May through July; southern bearmat flowers from November through May (McMinn 1959). The fruits are brown achenes about 5 mm in length (figures 1 and 2). Seeds require from 1 to 3 months of moist stratification at temperatures ranging from 1 to 5 °C before they will germinate (Emery 1964; Magill 1974). In the nursery, seeds should be sown in spring (Bailey 1928).

Rosaceae—Rose family

Chamaebatiaria millefolium (Torr.) Maxim.

fernbush

Nancy L. Shaw and Emerenciana G. Hurd

Dr. Shaw is a research botanist at the USDA Forest Service's Rocky Mountain Research Station, Boise, Idaho; Dr. Hurd retired from the USDA Forest Service's Rocky Mountain Research Station

Other common names. desert sweet, fern-bush, desert-sweet.

Synonyms. *Spiraea millefolium* Torr., *Sorbaria millefolium* Focke, *Basilima millefolium* Greene, *Chamaebatiaria glutinosa* Rydb., and *Spiraea glutinosa* Fedde (Davis 1952; Hitchcock and others 1961; Peck 1961; Young and Young 1986).

Growth habit, occurence and use. Fernbush—*Chamaebatiaria millefolium* (Torr.) Maxim.—the only species in its genus, is endemic to the Great Basin, Colorado Plateau, and adjacent areas of the western United States. It is an upright, generally multistemmed, sweetly aromatic shrub 0.3 to 2 m tall. Bark of young branches is brown and becomes smooth and gray with age. Leaves are leathery, alternate, simple, bipinnatisect, stipulate, and more or less clustered near the ends of the branches. Foliage and young branches are viscid and pubescent, with simple and stellate hairs that are sharp-pointed or glandular-capitate. Southern populations are more or less evergreen (Phillips 1949), whereas northern populations are largely deciduous, retaining a few leaves near the branch tips through winter and initiating leaf development in early spring (Hitchcock and others 1961; Kirkwood 1930).

Fernbush is distributed east of the Cascade and Sierra Nevada Mountains from Deschutes Co., Oregon, to southern California and eastward across southern Oregon and Idaho, Nevada, Utah, northern Arizona, and New Mexico (Hitchcock and others 1961; Phillips 1949; Welsh and others 1987; Young and Young 1992). Fernbush is often present as an early successional species on cinder cones and basalt lava flows but is also found on soils derived from limestone and granite (Eggler 1941; Everett 1957; Merkle 1952). It occurs in cracks and fissures of rock outcrops and on well-drained soils of dry, rocky, gravelly canyons and mountain slopes at elevations ranging from 900 to 3,400 m (Albee and others 1988; Hickman 1993). Fernbush grows in isolated populations or as an associated species in sagebrush scrub (*Artemisia* spp.), sagebrush, northern juniper, mountain brush, aspen, limber pine, ponderosa pine, spruce–fir, and western bristlecone pine communities (Hickman 1993; Munz and Keck 1959; Welsh and others 1987).

Fernbush is occasionally browsed by mule deer (*Odocoileus hemionus*), sheep, and goats, but only rarely by cattle (Mozingo 1987; van Dersal 1938). Native Americans used a tea made from its leaves for treatment of stomach aches (Mozingo 1987).

Unlike its namesake genus—*Chamaebatia* Benth., bear-mat or mountain misery—fernbush is not nodulated by nitrogen-fixing actinomycetes (McArthur and Sanderson 1985). Plants are cyanogenic (Fikenscher and others 1981). The species is a very rare host of juniper mistletoe—*Phoradendron juniperinum* Engelm. (Hawksworth and Mathiasen 1978).

First cultivated in 1878 (Rehder 1940), fernbush has long been recognized as an attractive ornamental because of its profuse and conspicuous inflorescences of white- to cream-colored flowers, long flowering season, and aromatic, fernlike foliage (Bailey 1902; Hitchcock and others 1961; Phillips 1949; Young and Young 1986). It is used effectively in mass plantings, xeriscapes, screens, and hedges when planted in full sun. Specimen plants provide color and texture accents (Phillips 1949).

Genetic variation, hybridization, and origin. McArthur (1984) and McArthur and others (1983) described *Chamaebatiaria* and other monotypic western North American genera of the Rosaceae as showing little variation compared to larger genera such as *Rosa* (rose) or *Cercocarpus* (mountain-mahogany). Typical of shrubby western North American members of subfamily Spiraeoideae, fernbush has x = n = 9 chromosomes (McArthur and Sanderson 1985). Hybridization of fernbush with other species has not been reported.

Chamaebatiaria (subfamily Spiraeoideae) was named for its morphologic resemblance to *Chamaebatia* (subfamily

Rosoideae). McArthur and Sanderson (1985) suggest that shrubby Spiraeoideae and Rosoideae of western North America may be rather closely related based on similarities in morphologic and other characteristics of the 2 groups. Wolfe and Schorn (1989) and Wolfe and Wehr (1988) discuss evidence from Paleogene montane floras of the Rocky Mountains indicating the possible divergence of *Chamaebatiaria* and *Chamaebatia* from a common Eocene ancestor. They suggest both lines adapted to progressively drier post-Eocene conditions than the mesic coniferous forest environment inhabited by the ancestor.

Flowering and fruiting. The showy, white, insect-pollinated flowers develop in profuse, terminal, leafy-bracteate panicles up to 20 cm in length. Flowers are complete, regular, and about 0.8 to 1.5 cm in diameter. The calyx consists of 5 persistent green sepals. A glandular disk lining the hypanthium bears 5 petals and numerous stamens. Pistils are 5 (rarely 4), ovaries superior, and styles free. The ovaries are more or less connate below in flower, but separate in fruit. The pubescent, coriaceous, few-seeded follicles dehisce along the ventral suture and upper half of the dorsal suture (figure 1). Seeds are erect, yellowish to brownish, linear to narrowly fusiform, and somewhat flattened at each end (figure 2). The outer layer of the soft thin seedcoat is ridged, giving the body of the seed a 3-angled appearance; the inner layer is thin and translucent. A fleshy endosperm layer adheres to the seedcoat. The embryo is linear-oblong with 2 flat cotyledons and occupies the central portion of the seed (figure 3). Germination is epigeal (Hickman 1993; Hitchcock and others 1961; Hurd 1995; Kirkwood 1930; Welch and others 1987).

Figure 1—*Chamaebatiaria millefolium,* fernbush: follicle.

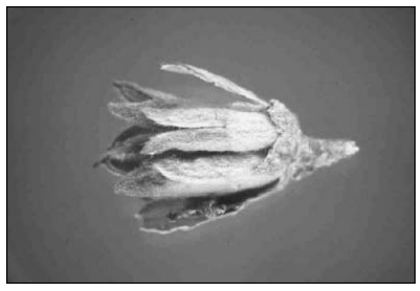

Figure 2—*Chamaebatiaria millefolium*, fernbush: seeds.

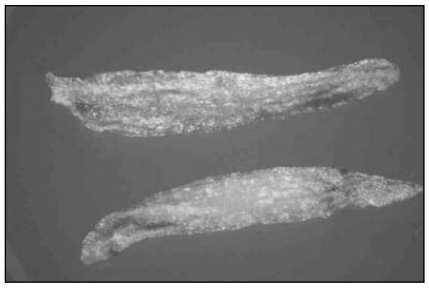

Figure 3—*Chamaebatiaria millefolium*, fernbush: longitudinal section through a seed.

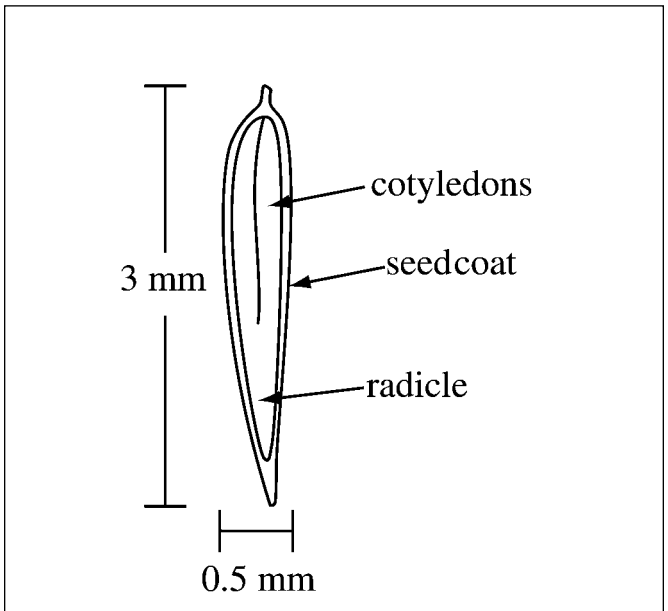

Irrigated plants may begin flowering during the second growing season (Shaw 1995). Plants flower from June to September (Hitchcock and others 1961; Phillips 1949) with irrigation prolonging the flowering season (Shaw 1995). Fruits ripen from August to October.

Collection of fruits, seed extraction, cleaning, and storage. Fruits are harvested by clipping or stripping inflorescences when they are dry and brown, but before follicles open. Seeds can also be collected by briskly shaking or beating the inflorescences once the follicles begin dehiscing. Most follicles open during air-drying, releasing the seeds. Debris may then be removed with screens or a seed blower. Larger collections may be cleaned using air-screen machines. For 2 Idaho seedlots produced with irrigation, the number of seeds per seed weight averaged 3,700,000/kg (1,700,000/lb) (Hurd 1995). Storage requirements and seed longevity have not been determined, but the seeds are probably orthodox in storage behavior.

Pregermination treatments and germination and viability tests. Fresh seeds are nondormant, whereas stored seeds require 1 to 3 months of chilling to relieve dormancy (McDorman 1994; Phillips 1949; Young and Young 1986, 1992). The optimum temperature range for germination of southwestern populations is 18 to 26 °C (Phillips 1949).

Fernbush germination has received little study. Shaw (1995) examined the germination of 3 seed collections. Nampa, ID, and Sun Valley, ID, collections were harvested from irrigated plantings of seeds from a single unknown source. The third collection was from an irrigated Sante Fe, NM, planting of seeds from a western New Mexico source. All 3 collections were cleaned and held in dry storage for 4 to 5 months before testing. Total germination percentage of the Sante Fe, NM, and Sun Valley, ID, seed collections (but not the Nampa, ID, seed collection) was greater when untreated seeds were incubated at 20/10 °C (8 hours/16 hours) than at 15 °C for 28 days. A 28-day wet chilling at 3 to 5 °C (table 1) improved the total germination percentage of all seed collections when they were subsequently incubated at either 15 °C or 20/10 °C for 28 days.

Viability of fernbush seeds may be tested as follows: first, the seeds are soaked in water at room temperature for 1 hour, then the water is drained away. A horizontal slit should be made across the center of each seed without cutting it in half. Seeds are then submerged in a 1% solution of 2,3,5-triphenyl tetrazolium chloride for 6 hours at room temperature. Evaluate as described by Peters (2000) for Rosaceae III. The embryos may be read in place. The endosperm of viable seeds is living and will stain red (Hurd 1995).

Nursery practice. Nursery plantings should be made in late fall or early winter. As an alternative, artificially wet-chilled seeds may be planted in early spring. Fernbush seeds are small and must be sown on the soil surface or with a very light covering of sand or soil. Seedlings develop rapidly with irrigation and reach an adequate size for lifting after 1 growing season (Shaw 1995).

Seeds for production of container stock should be wet-chilled before planting. Survival of germinants moved from seeding flats to production containers is low (Everett 1957). Better establishment is obtained by sowing seeds directly into containers and thinning to 1 seedling per container. Developing seedlings are easily moved from small to larger containers (Phillips 1949). Seedlings should be grown in a well-drained medium.

Direct seeding. Seeds should be planted in fall or early winter. Seedlings emerge in spring from seeds naturally dispersed in late summer on rough or mulched soil surfaces (Mackie 1995; McDorman 1994; Shaw 1995). Naturally occurring seedlings generally establish where vegetative competition is limited (Shaw 1995).

Table 1—*Chamaebatiaria millefolium*, fernbush: germination test conditions and results

Source	Elevation (m)	Origin	Cold, wet chill (days)*	% Germination‡ 15 °C Incub†	% Germination‡ 20/10 °C Incub†	Seed fill (%)	Seed viability (%)
Nampa, ID	831	Unknown§	0	3	1	100	96
			28	72	65	100	96
Sun Valley, ID	1,773	Unknown§	0	12	20	100	86
			28	33	44	100	86
Santa Fe, NM	2,134	W New Mexico	0	9	22	100	85
			28	58	60	100	85

* Chilling temperature = 3 to 5 °C.

† Incub = incubation time = 28 days; seeds were exposed to 8 hours of light (PAR = 350 M m/sec) each day with temperatures of either constant 15 °C or 8 hours of 20 °C and 16 hours of 10 °C. In the alternating temperature regime, plants were exposed to light during the high-temperature period.

‡ Based on the percentage of viable seeds to germinate normally.

§ The Nampa and Sun Valley, ID, plants were grown from the same unknown seed source.

Cupressaceae—Cypress family

Chamaecyparis Spach

white-cedar

Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Growth habit, occurrence, and use. The genus *Chamaecyparis* occurs naturally on the Atlantic and Pacific Coasts of North America and in Japan and Taiwan. Three species are native to North America, 2 to Japan, and 1 to Taiwan (Sargent 1965). The North American species (table 1) are long-lived evergreens that attain large size. Port-Orford-cedar, the largest, has reached diameters of more than 1 m and heights of near 70 m in old-growth stands (Zobel 1990a). Branching is distinctive, with many-branched twigs and small paired scalelike leaves arranged in fernlike sprays. Another common name is "false cypress" (Little 1979); they are not true cedars (*Cedrus* spp.). Because of their somber beauty and variety of form, white-cedars are often used for ornamental plantings, hedges, and windbreaks (Rehder 1940). They produce valuable timber, the wood being sought for poles, posts, construction timbers, specialty items, and other uses where durability is desired. Atlantic white-cedar wood is especially popular for boats, outdoor furniture, posts, and utility poles (Kuser and Zimmerman 1995).

Geographic races and hybrids. Two geographic races of Atlantic white-cedar have been proposed: var. *henryae* (Li) Little in Georgia, Florida, Alabama, and Mississippi and var. *thyoides* in the area from South Carolina to Maine (Little 1966). Great variation exists within the genus, and numerous horticultural selections have been made of the 3 North America species as well as the Asian ones (Dirr and Heuser 1987; Harris 1990; Little and Garrett 1990; Zobel 1990a). Both interspecific and intergeneric crosses have been successful with certain of the cedars. Alaska-cedar and 2 of the Asian species have been crossed (Yamamoto 1981), and Alaska-cedar has also been crossed with several species of Cupressus (Harris 1990). The most well-known of these crosses is with Monterey cypress (*Cupressus macrocarpa* Hartw. ex Gord.) to produce the widely planted Leyland cypress (*Cupressocyparis* × *leylandii*).

Flowering and fruiting. White-cedars are monoecious. Their tiny inconspicuous yellow or reddish male pollen-bearing flowers and greenish female flowers are borne on the tips of branchlets (Harris 1974). Staminate flowers of Atlantic white-cedar, for example, are about 3 mm long, and the pistillate flowers are approximately 3 mm in diameter (Little and Garrett 1990). Pollination occurs generally from March to May, and cones ripen in September to October. Cones are slow to open fully, and seed dispersal occurs from fall into the following spring (table 2). Cones of Port-Orford-cedar and Atlantic white-

Sources: Harris (1974), Little (1940).
* Cones require 2 years to reach maturity in the northern part of the range.

cedar mature the same year that they are pollinated, whereas cones of Alaska-cedar, in most of the species' range, take a second year to complete maturation (Harris 1974, 1990). In the extreme southern portion of the range of Alaska-cedar, cones may mature in only 1 year (Owens and Molder 1975). This condition even occurs on trees from more northern origins or from higher elevations when established in seed orchards in warm, southern, coastal sites (El-Kassaby and others 1991). The seeds from these 1-year cones are of size and germination quality equal to seeds from 2-year cones.

The white-cedars bear cones at an early age—5 to 20 years for Port-Orford-cedar (Zobel 1990a) and 3 to 5 years for Atlantic white-cedar (Little and Garrett 1990). Sprays of gibberellin (primarily GA_3) will induce flowering in even younger seedlings of Port-Orford-cedar and Alaska-cedar (Owens and Molder 1977; Pharis and Kuo 1977). The use of GA_3 and supplemental pollination on container-grown Port-Ordford-cedar trees 4 to 6 years from rooting or grafting has shown good potential to produce a large amount of seeds in a short period (Elliott and Sniezko 2000). Mature cones are 6 to 12 mm in diameter, spherical, and are borne erect on branchlets (figure 1). Cones have from 6 to 12 scales, each bearing from 1 to 5 seeds with thin marginal wings (figures 2 and 3) (Harris 1974). The average number of seeds per cone is 7 for Alaska-cedar (Harris 1990) and 8 for Atlantic white-cedar, but less than a third of these seeds may be filled. With controlled crosses in a seed orchard, Port-Orford-cedar averaged as high as 8.6 filled seeds per cone (Elliott and Sniezko 2000). Cone ripeness is normally determined by their exterior color (table 3).

Seedcrops of both western white-cedars can be damaged by larvae of the seedworm *Laspeyresia cupressana* (Kearfott) feeding on seeds in the cones. Larvae of the incense-cedar tip moth—*Argyresthia libocedrella* Busck—mine the cones and seeds of Port-Orford-cedar and can destroy practically the entire seedcrop (Hedlin and others 1980).

Collection of cones. Cones may be collected by hand or raked from the branchlets of standing or felled trees. As with many species, cone production is usually less in dense stands, although local conditions cause much variation (Zobel 1979), and open stands should be favored in collections from natural stands. In a North Carolina study,

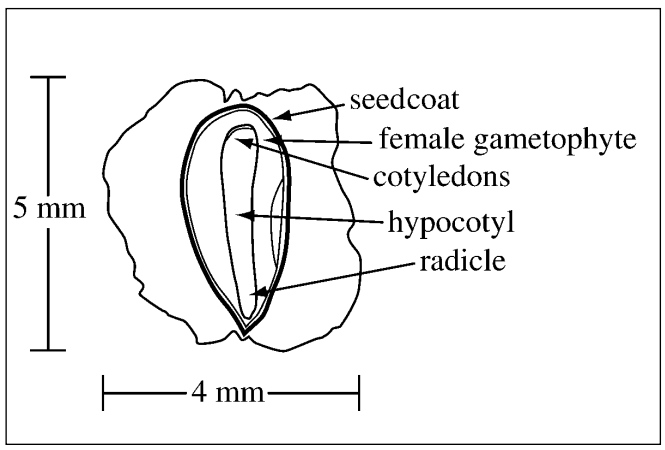
Table 3—*Chamaecyparis,* white-cedar: height, seed-bearing age, seed crop frequency, and color of ripe cones

Species	Height at maturity (m)	Year first cultivated	Minimum seed-bearing age (yrs)	Years between large seedcrops	Color of ripe cones
C. lawsoniana	to 73	1854	5–20	3–5	Greenish yellow to red brown
C. nootkatensis	to 53	1851	—	4 or more	Yellow brown to red brown
C. thyoides	12–27	1727	3–20	1 or more	Greenish with glaucous bloom to bluish-purple & glaucous, finally red brown

Sources: Little (1950), Korstian and Brush (1931), Ouden (1965), Rehder (1940), Sargent (1965).

Figure 3—*Chamaecyparis lawsoniana*, Port-Orford cedar: longitudinal section through a seed.



8- to 10-year-old plantations of Atlantic white-cedar produced good seedcrops that were easy to collect (Bonner and Summerville 1999). When collecting cones of Alaska-cedar in the northern part of the range, precautions are needed to limit the collection to mature, second-year cones. The smaller, greenish-blue, immature, first-year cones are often present on the same branches with the yellow-brown mature cones (Harris 1974).

Extraction, cleaning, and storage of seeds. Cones of white-cedars may be dried by spreading them in the sun or in a warm room, or they may be kiln-dried at temperatures below 43 °C (Harris 1974). Over 90% of the seeds can be recovered from cones of Atlantic white-cedar dried at 35 to 40 °C if 2 or 3 cycles of drying, interspersed with re-wetting of the cones, are used (Bonner and Summerville 1999). Each time the cones are redried, they open a little more. Mature cones of all white-cedars open when dried properly, and their seeds may be extracted by gentle shaking or tumbling. The thin-coated seeds of all species are easily injured and de-winging should not be attempted (Harris 1974).

Cleaning seeds of white-cedars to high purity values is difficult because the small, scalelike leaves are similar to the seeds in size and weight. For seedlots of Atlantic white-cedar, large trash can be removed with round-hole screens, and small trash can be blown off with any number of pneumatic cleaners or seed blowers. These same blowers can be used to upgrade Atlantic white-cedar seedlots by removing many of the empty seeds that occur naturally in this species. Separation is not absolute, of course, and many smaller filled seeds will be lost. With care, however, purities above 90% and filled seed percentages close to 90% can be obtained (Bonner and Summerville 1999). Similar data on the other 2 species are not available. Numbers of cleaned seeds per weight are listed in table 4.

Seeds of the white-cedars are orthodox in storage behavior. They should be stored at or below freezing at a seed moisture content of 10% or below (Allen 1957; Harris 1974). Seeds of Port-Orford-cedar from several origins stored at –15 °C lost no germination capacity over an 11-year period (Zobel 1990b). There are no comparable storage data for Alaska-cedar or Atlantic white-cedar, but the latter species is known to survive at least 2 years of similar storage without loss of viability (Bonner and Summerville 1999). Atlantic white-cedar seeds will also survive for at least 2 growing seasons in natural seedbeds (Little 1950).

Pregermination treatments and germination tests. Germination of white-cedar species is reported to be extremely variable and usually low, but this is due primarily to the naturally low percentages of filled seeds and the failure of seed managers to remove these empty seeds from the seedlots. Port-Orford-cedar germinates readily in the laboratory without pretreatment, and cold stratification does not appear to even improve germination rate (Zobel 1990b). Alaska-cedar exhibits a dormancy that can be somewhat overcome by warm incubation followed by cold stratification, but optimum schedules have not been determined (Harris 1990). In laboratory testing of germination, stratifi-

* 1.64 kg (3.46 lb) of seeds were obtained from 1 bushel of cones (Van Dersal 1938).

cation of 21 days at 3 to 5 °C has been recommended (ISTA 1993). In nursery sowing, however, environmental conditions are seldom as favorable as those in the laboratory, so longer pretreatments are usually beneficial. One promising pretreatment schedule is moist stratification for 30 days at alternating temperatures of 20 and 30 °C, followed by 30 days at 5 °C (Harris 1974). The beneficial effect of warm incubation suggests that many of the seeds are not quite fully matured, and the incubation period enhances maturation in the same manner as warmer temperatures were shown to speed up cone ripening (Owens and Molder 1975).

Atlantic white-cedar has a variable dormancy also, although probably not as deep as that of Alaska-cedar. Some lots will germinate completely in the laboratory without any pretreatment (table 5). Recent tests with samples from North Carolina indicate that maximum germination in 28 days at good rates requires 4 weeks of moist stratification at 3 °C. Official test prescriptions (ISTA 1993) call for 90 days of stratification at 3 °C for germination within the same time period. Extremely slow germination has been reported in nursery beds in New Jersey (Little 1950), so some stratification would certainly be recommended. Germination is epigeal.

Nursery practice. For all 3 species of North American white-cedars, spring-sowing of stratified seeds is recommended. Port-Orford-cedar has the least dormancy and may only require 30 days of cold stratification. In England this species is normally not stratified at all (Aldous 1972). Alaska-cedar and Atlantic white-cedar have deeper levels of dormancy, and more extended pretreatments are necessary. Warm incubation at alternating temperatures, followed by cold stratification (as described in the previous section), has been recommended for both of these species (Dirr and Heuser 1987). Seeds from the more southern sources of Atlantic white-cedar seem to be not so dormant, and 30 to 60 days of cold stratification alone may be sufficient. Experience with Port-Orford-cedar in western nurseries suggests covering the sown seeds with 3 to 6 mm ($^1/_{10}$ to $^1/_4$ in) of soil and calculating sowing rates to produce 320 to 530 seedlings/m^2 (30 to 50/ft^2). One kilogram (2.2 lb) of Port-Orford-cedar seeds should produce about 284,000 plantable seedlings (Harris 1974). Shading the seedbeds until midseason of the first year may also be beneficial. For field planting, 2+0 stock is commonly used in the western United States, although 2+1 transplants are favored for Port-Orford-cedar in England (Harris 1974). For Atlantic white-cedar, 2+0 seedlings are used in New Jersey and 1+0 seedlings in North Carlina (Kuser and Zimmerman 1995).

All white-cedars can be propagated vegetatively and are commonly produced this way for the ornamental market. Port-Orford-cedar cuttings should be taken between September and April, treated with indole butyric acid (IBA) powder (3,000 to 8,000 ppm), and placed in peat or perlite with mist and bottom heat (Dirr and Heuser 1987). Zobel (1990a) suggests taking cuttings from tips of major branches from lower branches of young trees. Alaska-cedar cuttings need 8,000 or more ppm of IBA, and cuttings should be taken in late winter to early spring (Dirr and Heuser 1987). After 4 years, growth of outplanted rooted cuttings was equal to that of seedlings in British Columbia (Karlsson 1982). Atlantic white-cedar cuttings taken in mid-November and treated with auxins also root very well (Dirr and Heuser 1987). With auxins and bottom heat in mistbeds, 90% rooting can be expected. Early comparisons show that growth of seedlings and stecklings (rooted cuttings) to be about the same (Kuser and Zimmerman 1995).

C

Bignoniaceae—Trumpet-creeper family

Chilopsis linearis (Cav.) Sweet

desert-willow

Arthur W. Magill, Carol Miller, and Jane E. Rodgers

Dr. Magill retired from USDA Forest Service's Pacific Southwest Forest and Range Experimental Station; Ms. Miller was a propagationist at the USDI National Park Service Joshua Tree National Park Center for Arid Lands Restoration and Native Plant Nursery, Twentynine Palms, California; Ms. Rodgers, is a restoration ecologist at the Point Reyes National Seashore Point Reyes Station, California

Synonyms. *C. saligna* D. Don, C. *linearis* var. *originaria* Fosberg, *C. linearis* var. *glutinosa* (Engelm.) Fosberg, C. *linearis* var. *arcuata* Fosberg.

Other common names. false-willow, *jano,* flowering-willow, desert catalpa, catalpa-willow.

Growth habit, occurrence, and use. Desert-willow grows along dry washes and streams in the desert between 450 and 1,500 m of elevation from southern California through southern Utah to western Texas and southward into Mexico and Lower California. It is a deciduous shrub or small tree that attains heights of 3 to 7.5 m or occasionally more. Growth can be rapid, up to 1 m annually (Munz 1979). The plant is useful for wildlife cover, erosion control, restoration, stream stabilization, and ornamental plantings in arid regions (McMinn 1959; Bainbridge and Virginia 1989; Munz 1959). Seed pods and flowers are edible, but the major use for Native American people was the wood (for house frames, granaries, and bows) and the fibrous bark (for weaving nets, shirts, and breechclouts) (Bainbridge and Virginia 1989).

Flowering and fruiting. Desert-willow produces perfect flowers between April and August throughout its range (Magill 1974; McMinn 1959). The fruit is a 2-celled capsule about 6 mm in diameter and from 10 to 30 cm long. It ripens from late summer to late fall (Afanasiev 1942) and persists through winter (Little 1950). The numerous light-brown oval seeds are about 8 mm long and have a fringe of soft white hairs on each end (figures 1 and 2).

Collection, extraction, and storage. Seedpods can be hand-picked after late September and through the winter months. Care must be taken not to pick unripened fruits—the fruits on a tree may mature unevenly because of their long flowering period (Engstrom and Stoeckeler 1941). Seed extraction simply requires that the pods be spread out, dried, beaten lightly, and shaken, and then the seeds screened out. Each 45 kg (100 lb) of dried pods should produce 14 to 23 kg (30 to 50 lb) of clean seeds, which number from 88,200 to 282,240/kg (40,000 to 128,000/lb) and average 189,130/kg (86,000/lb) (Magill 1974). Commercial seedlots have averaged 92% in purity and 87% in soundness (Magill 1974). These seeds are orthodox in storage behavior, so cold, dry storage conditions are recommended for storage. Seeds have been successfully propagated after 4 years of refrigerated storage at 7 °C (CALR 1993).

Germination. Desert-willow seeds are not dormant, but storage for several days in wet sand or between wet blotter paper will speed germination. In germination tests 1,000 seeds were placed in a sand or water medium for 21 to 60 days with a night temperature of 20 °C and a day temperature of 30 °C (Engstrom and Stoeckeler 1941; Magill 1974). Germination averaged 14 to 60% in 9 to 30 days and germinative capacity ranged from 26 to 100% (Magill 1974). Average germination using blotter paper is 80% (CALR 1993).

Figure 1—*Chilopsis linearis*, desert-willow: seed.

Nursery field practice and seedling care. Desert-willow seeds may decay unless sown in spring soon after the soil warms up. Sowing depth should be 6 mm ($^1/_4$ in). A ratio of seven times as many viable seeds as the desired number of usable seedlings is required to grow nursery stock (Magill 1974). Damping-off can be a problem.

Desert-willow may also be propagated from cuttings (Magill 1974); cuttings should be handled carefully and allowed to produce an extensive rootball before transplanting. Mature plants grown in ~57-liter (15-gal) pots and 0.8-m (30-in) tubes have been successfully outplanted as windbreaks and for desert restoration at Joshua Tree National Park (CALR 1993).

Figure 2—*Chilopsis linearis*, desert-willow: longitudinal section through a seed.

C

Pyrolaceae—Shinleaf family

Chimaphila Pursh

chimaphila

Don Minore

Dr. Minore retired from the USDA Forest Service's Pacific Northwest Research Station

Growth habit, occurrence, and use. Taxonomists sometimes differ when classifying plants in the genus *Chimaphila* (Blake 1914; Camp 1939; Hitchcock and others 1959; Stapf 1930; Takahashi 1987; Traulau 1981; Wordsdell and Hill 1941), but there are at least 4 clearly defined species (table 1). All have a chromosome number (2n) of 28 (Haber and Cruise 1974), and all occur in the Northern Hemisphere (table 1). Pipsissewa, the most widespread species, has been divided into 5 geographically delimited subspecies: *C. umbellata* ssp. *occidentalis* (Rydb.) Hult. in western North America; ssp. *acuta* (Rydb.) Hult. in Arizona and New Mexico; ssp. *mexicana* (DC) Hult. in Mexico; ssp. *cisatlantica* (Blake) Hult. in eastern North America; and ssp. *umbellata* in Europe and Asia (Takahashi 1987).

The chimaphilas are low, usually creeping, evergreen subshrubs (Krüssmann 1984) with alternate leaves that are crowded near the summit of each year's annual growth, giving the appearance of being whorled on the short shoots ("pseudo-whorls"). Those shoots produce annual growth rings (Copeland 1947) and are connected by elongate rhizomes that are as much as 2.5 m long. The rhizomes are slender (not more than a few millimeters in diameter) and yellow or brown. They bear distant buds that are subtended by small scales and associated with single roots. The leaves may persist as long as 7 years in pipsissewa and 8 years in little pipsissewa (Copeland 1947).

Chimaphila leaves are purported to have antibacterial properties. They contain taraxerol, beta-sitosterol, ursolic acid, nonacosane, hentriacontane, isohomoarbutin, renifolin, arbutin, avicularin, hyperoside, several flavonoids, and a compound called chimaphilin (Lucia 1991; Sheth and others 1967; Trubachev and Batyuk 1968; Walewska 1971). Chimaphilin has a quinone structure similar to that of 1,4-naphthoquinone (DiModica and others 1953), and it may be responsible for the medicinal properties attributed to the chimaphilas. The boiled leaves are taken as a liver remedy (Altschul 1973). The plants also have been used as diuretics and to treat rheumatism and fever (Krüssmann 1984). Large quantities of pipsissewa are now being harvested for use as flavoring in a popular beverage.

Flowering and fruiting. Striped pipsissewa usually flowers in its third growing season, but flowering may be delayed in pipsissewa and little pipsissewa until 7 or 8 annual pseudo-whorls of leaves have been produced (Copeland 1947). Flowers are choripetalous, pentacyclic, pentamerous, actinomorphic, and protogynous (Holm 1927; Pyykko

Table 1—*Chimaphila*: nomenclature and occurrence

Scientific name	Common name(s)	Distribution
***C. japonica* Miq.**	**Japanese chimaphila**	Japan, Korea, China, & Taiwan

***C. umbellata* (L.) W. Bart.**	**pipsissewa,** prince's-pine	North America from Alaska to Mexico & from Ontario & New Brunswick to Georgia; Europe (incl. Scandinavia), Eurasia, Japan, & West Indies

Sources: Barrett and Helenurm (1987), Blake (1914), Camp (1939), Fernald (1950), Hill (1962), Nordal and Wischmann (1989), Ohwi (1965), Prain (1960), Traulau (1981).

1968). They have 5-parted calyxes, 5 petals, 10 stamens, 5-chambered ovaries, and short thick styles with wide, 5-pointed stigmas (Krüssmann 1984). The ovary is superior, and there is a well-developed, collar-like disk at the base of the pistil that secretes nectar. Placentation is central-axile, with a massive, 2-lobed placenta intruding into each locule (Pyykko 1968). Those placentae are beset with numerous minute ovules (Copeland 1947). The 1 to 3 (little pipsissewa and Japanese chimaphila) or 2 to 6 (striped pipsissewa and pipsissewa) flowers are borne in pendulous, terminal inflorescences (Krüssmann 1984; Ohwi 1965). In pipsissewa those inflorescences are corymbs; in striped and little pipsissewas, they are cyme-like clusters (Copeland 1947). Flowers are pink or white and slightly fragrant.

Chimaphila pollen grains are packed into polyads composed of indefinite numbers of tetrads (Knudsen and Olesen 1993; Takahashi 1986). Pollination is by insects. In pipsissewa, bumble bees are the most important pollinators but the flowers also are visited by staphylinid beetles (Barrett and Helenurm 1987; Knudsen and Olesen 1993), and there is a small amount of self-pollination (Barrett and Helenurm 1987). Differences in the flower preferences of the bumble bee species involved may help to prevent interbreeding between pipsissewa and striped pipsissewa during a short overlap in flowering periods where these inter-fertile species grow together (Standley and others 1988).

An average pipsissewa flower produces 308,800 pollen grains and 5,587 ovules—a pollen to ovule ratio of 58 (Barrett and Helenurm 1987). In central New Brunswick, Canada, anthesis occurs over a 30-day period in July (Helenurm and Barrett 1987). In the Pacific Northwest, pipsissewa flowers may be found from June until August (Hitchcock and others 1959). The fruits matured in about 70 days in New Brunswick, where an average fruit weighed 23 mg, and fruit set was 75% for both self-pollinated and cross-pollinated flowers (Barrett and Helenurm 1987).

The chimaphila fruit is a 5-celled, loculicidally dehiscent capsule that contains very large numbers of tiny seeds (Barrett and Helenurm 1987; Copeland 1947; Pyykko 1968) that sift out of the capsule openings to be borne away by the wind. The embryos of those seeds develop no distinct parts during seed development, but they eventually absorb all of the endosperm except a single layer of cells. The inner integumental cells die and remain in existence as more or less shriveled empty spaces at the ends of the seeds (Copeland 1947). The seedcoat consists only of the outer cell layer of the integument, which loses protoplasm and tannin to become transparent (Pyykko 1968). Although the inner periclinal walls of those transparent testa cells are smooth or slightly pitted in all species, intraspecific differences occur in pipsissewa (Takahashi 1993).

Chimaphila seeds are characterized by very small size, few cells, and little differentiation (figure 1). Each contains a central ellipsoidal mass consisting of an embryo covered by a single layer of endosperm cells, surrounded by a transparent seedcoat that is hollow and shriveled at each end. Ripe seeds are 0.6 to 0.9 mm long and 0.1 mm wide. There are about 1,500,000 seeds/g (42,524,250/oz) (Minore 1994).

Collection and storage of seeds. Seeds can be collected in the field by tapping recently dehisced capsules to dislodge the tiny seeds, which can then be captured in a jar or plastic bag as they drift downward. Recently dehisced capsules may be difficult to find, however, because mature capsules often are not open or have already lost their seeds. Mature closed capsules can be collected, dried, and macerated to recover the seeds. Unfortunately, this latter procedure creates debris that is difficult to separate from the seeds, and seed maturity is not assured. Optimal storage conditions and seed longevity are unknown.

Figure 1—*Chimaphila umbellata*, pipsissewa: seeds (0.1 mm wide and ~ 0.7 mm long, at center) with central embryo and elongate, transparent seedcoat.

Pregermination treatments; germination tests; and nursery practice. Chimaphila seeds have not been sown and germinated successfully. Forest soil that had been sifted to remove debris and rhizome material and then stored outdoors all winter produced pipsissewa seedlings in the spring, however, indicating that there are viable seeds in the soil seed bank and that extensive stratification may be necessary (Wilson 1994). No formal pregermination treatments or germination tests are known. Chimaphila seedlings are seldom found in nature (Holm 1927). Therefore, most natural regeneration may be accomplished by the spread of rhi-

zomes. Cultivation attempts often fail (Kruckeberg 1982), but division of the rhizome has been recommended as a suitable method of propagation (Bailey and Bailey 1976). The chimaphilas may be partial root parasites (Kruckeberg 1982). If they are, special practices that include an unknown host may be needed to achieve successful large-scale nursery production.

Oleaceae—Olive family

Chionanthus virginicus L.

white fringetree

John D. Gill, Franz L. Pogge, and Franklin T. Bonner

Dr. Gill and Mr. Pogge retired from the USDA Forest Service's Northeastern Forest Experiment Station; Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Forest Experiment Station, Mississippi State, Mississippi

Other common names. old-man's-beard, flowering-ash, grandfather-graybeard.

Growth habit, occurrence, and uses. White fringetree—*Chionanthus virginicus* L.—occurs on rich, well-drained soils of streambanks, coves, and lower slopes but is most abundant in the understory of pine–hardwood forests, especially on moist, acid, sandy loam soils (Goodrum and Halls 1961). It develops best in semi-open situations but is moderately shade-tolerant, being found occasionally in dense understories. Though widely distributed, it usually is a minor part of the total vegetation. White fringetree is a relatively short-lived shrub or small tree and may attain 11 m in height (Rehder 1940). Its range is from southern Pennsylvania and Ohio south to central Florida and westward through the Gulf Coast region to the Brazos River in Texas and to northern Arkansas (Brown and Kirkman 1990).

Fringetrees are planted as ornamentals throughout the South and elsewhere beyond their natural range. The bark is used as a tonic, diuretic, and astringent; it is also used to reduce fever. In Appalachia, a liquid of boiled root bark is applied to skin irritations (Krochmal and others 1969). Twigs and foliage are preferred browse for deer (*Odocoileus* spp.) in the Gulf Coastal Plain but are less preferred in the Piedmont and mountains. Browsing is least in winter. The species is only moderately resistant to browsing, and plants may die when more than a third of the annual growth is removed. The date-like fruits are eaten by many animals, including deer, turkey (*Meleagris gallopovo*), and quail (*Callipepla* spp.). Cattle may eat the foliage (Goodrum and Halls 1961). The date of earliest known cultivation is 1736 (Rehder 1940).

Flowering and fruiting. White fringetree's flowering habit is polygamo-dioecious, although it is functionally dioecious (Brown and Kirkman 1990; Gleason 1963). The white, fragrant flowers are borne in pendant axillary panicles 10 to 25 cm long that appear from March to June, depending on latitude (Brown and Kirkman 1990; Gill and Pogge 1974). The fruit is a dark blue to purple ovoid drupe about 2 cm long (figure 1). It is usually single-seeded (figures 1 and 2); rarely 2- or 3-seeded. Fruits ripen and drop from the trees in July in eastern Texas and as late as October in the northern part of the range (Lay 1961; Van Dersal 1938). Seeds are dispersed beyond the immediate vicinity of the tree by birds and rodents. Plants first produce seeds at 5 to 8 years of age. In eastern Texas, they produced some fruit each year; no seedcrop failure occurred (Lay 1961).

Collection, extraction, and storage. The fruits should be collected from the branches after they have turned purple and before birds remove them, which should be August in the South and September and October in the North (Dirr and Heuser 1987). The pulpy pericarp should be removed by maceration with either mechanical macerators for large lots or kitchen blenders for small lots, or by rubbing the fruits over hardware cloth fine enough to retain the seeds. The pulp may then be washed away. The seeds contain about 40% moisture when they are shed and must be dried to at least 22% if they are to be stored at low temperatures (Carpenter and others 1992). There have been no long-term storage tests of white fringetree seeds reported,

Figure 1—*Chionanthus virginicus*, white fringetree: fruit (drupe, **left**) and seed (**right**).

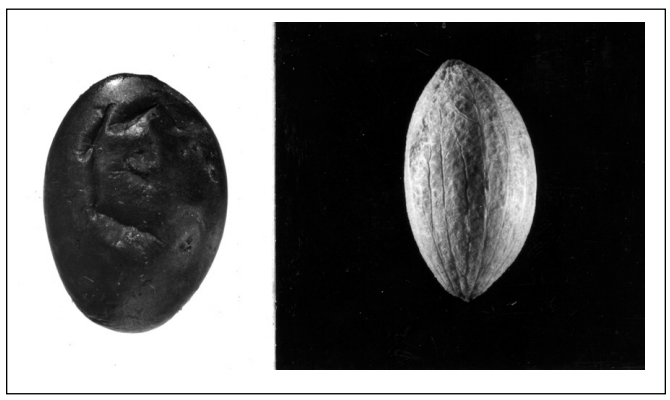

Figure 2—*Chionanthus virginicus*, white fringetree: longitudinal section through a seed.

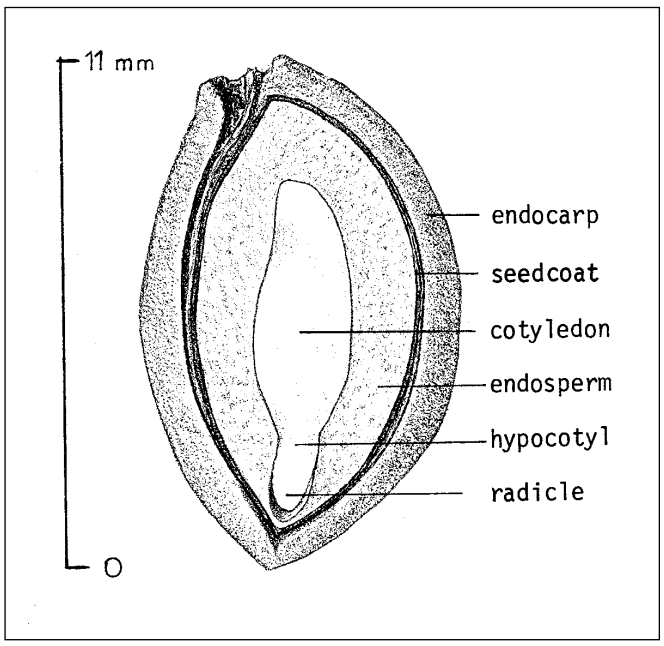

although seeds have remained viable in cold stratification for 1 to 2 years (Gill and Pogge 1974). It is not known if these seeds are orthodox or recalcitrant. There are about 1,400 fruits/kg (630/lb); 1 kg of fruits yielded 330 g of seeds and 1 lb yields 5 1/4 oz. The average number of seeds per weight is 4,000/kg (1,800/lb) with a range of 2,420/kg to 4,410 (1,100 to 2,000/lb) (Gill and Pogge 1974; Swingle 1939; VanDersal 1938).

Germination. Natural germination usually occurs in the second spring after seedfall, the results of an apparent double dormancy or combined dormancy in the seeds. Fringetree seeds first need a period of warm temperatures, commonly 3 to 5 months, during which the radicle develops while the shoot remains dormant. Subsequently, cold exposure during winter overcomes the shoot dormancy (Flemion 1941; Schumacher 1962). In the wild, these temperature exposures occur during the first summer and second winter after seedfall. In a test with 2 seedlots, seeds were held at 20 °C for 1 or more months; stratified at 5 °C for 1 month or more; then sown in flats and held at 20 to 30 °C for 1 year. Germination was about 40% (Gill and Pogge 1974). Good germination (80%) can also be obtained with removal of the hard endocarp; soaking in 1,000 ppm solution of gibberellin (GA_3) for 6 hours; then germinating at 25 °C (Carpenter and others 1992). No official test methods have been prescribed, and the embryo excision method has been recommended for quick viability estimates (Barton 1961; Flemion 1941; Heit 1955). Germination is hypogeal (figure 3).

Nursery practice. Seeds may be sown in either fall or spring. Seeds can be sown soon after they are cleaned, but no later than mid-October in the northern part of the range (Heit 1967). Drills should be set 20 to 30 cm (8 to 12 in) apart and the seeds covered with 6 to 12 mm ($^1/_4$ to $^1/_2$ in) of firmed soil. Beds should be covered with burlap or mulched with straw or leaf mulch until after the last frost the following spring. If spring-sowing is desired, then seeds should be given 3 months of warm storage, then 3 months of cold stratification (Dirr and Heuser 1987). As an alternative for the amateur gardener, seeds can be sown under glass, in boxes with standard compost, during February–March (Sheat 1948). Propagation by layering, grafting, or budding onto ash seedlings is sometimes practiced, but the species is almost impossible to root (Dirr and Heuser 1987).

C

Fagaceae—Beech family

Chrysolepis Hjelmqvist

chinquapin

Philip M. McDonald

Dr. McDonald is a research silviculturist at the USDA Forest Service's Pacific Southwest Research Station, Redding, California

Synonyms. The 2 species of *Chrysolepis* found in the United States are distinct from their Asian relatives in the genus *Castanopsis* and were placed by Hjelmqvist (1948) in their current genus. This genus was accepted in Hickman's extensive and long-researched flora of California (1993). These American species, which have a floral morphology that is intermediate between *Castanopsis* and *Lithocarpus*, represent the ancient condition of the family Fagaceae (McKee 1990). The common name also has changed throughout the years. Early workers called the species "chinquapin." Later, it became "chinkapin" but more recently it was changed back to "chinquapin" (Hickman 1993; Keeler-Wolf 1988).

Occurrence and growth habit. In North America, the genus *Chrysolepis* consists of 2 species and 1 variety (Hickman 1993), all located in the Pacific Coast region. Giant chinquapin—*Chrysolepis chrysophylla* var. *chrysophylla* (Dougl. ex. Hook) Hjelmqvist —is a tree that ranges from southwestern Washington southward to San Luis Obispo County in the Cascade, Klamath, and Coastal Mountains of California. A remnant stand also exists in El Dorado County in the north central Sierra Nevada. This species achieves its best form from Marin County, California, northward (Griffin and Critchfield 1972) to Lane County, Oregon. Giant chinquapin also has a shrub form—*C. chrysophylla* var. *minor* (Benth.) Munz, often called "golden chinquapin"—that is found throughout the range of its taller brethren.

The second species—*C. sempervirens* (Kellogg) Hjelmqvist—which is always a shrub, has the common name "bush chinquapin." This species is found from the Cascade Mountains of southern Oregon westward in the Siskiyou Mountains of northern California, and southward along the east-facing slopes of the north Coast Range and the west-facing slopes of the Sierra Nevada, San Jacinto, and San Bernardino Mountains (McMinn 1939). Throughout its range, the habitat is characterized as being of low quality with shallow, rocky, and often droughty soils. In western Siskiyou County, California, and in other places where the ranges of the 2 shrub forms overlap, hybridization probably occurs (Griffin and Critchfield 1972).

Giant chinquapin is often found as a single tree or in groves; it rarely occupies extensive areas. This shade-tolerant tree is rarely found in a dominant position; it is more often found in intermediate and codominant crown positions. Pure stands are uncommon and rarely exceed 10 ha (McKee 1990). In the Klamath Mountains of northern California, giant chinquapin shows a distinct preference for mesic conditions, with highest basal areas occurring on north-facing slopes or in mesic canyon bottoms (Keeler-Wolf 1988). In general, best growth is achieved in moist environments with deep and infertile soils (Zobel and others 1976). The shrub forms occupy a plethora of topographic/edaphic sites over an elevational range that varies from 300 to 3,000 m. The shrub forms can be quite extensive and achieve greatest coverage in the extreme environments of xeric sites at higher elevations. Here they dominate, with their area corresponding to the extent of past disturbance. The amount of time that they dominate also can be lengthy, given a lack of seed source for inherently taller competitors. Over a long time span, however, disturbance is necessary for the continued presence of chinquapin. Because of its wide ecological amplitude, chinquapin is part of many associations that include most of the forest-zone conifers and hardwoods on the Pacific Coast. A general pattern for all the species and varieties is that they are at their competitive best on infertile soils (McKee 1990).

Chinquapins are vigorous sprouters and most trees originate as root crown sprouts. The sprouts grow rapidly and outstrip natural conifer seedlings for several years. Mature trees tend to have straight boles and narrow crowns. The largest trees may reach over 33 m in height and 1 to 1.2 m in girth (Sudworth 1908). For shrubs, var. *minor* tends to be stiff and upright in exposed areas and semiprostrate in shaded environments. Bush chinquapin is stiff and upright in all environments.

Use. The light, fairly hard, and strong wood of chinquapin has been used for veneer, paneling, cabinets, furniture, turned products, pallets, and fuel (EDA 1968).

Flowering and fruiting. The flowers of giant chinquapin, which bloom from June through midwinter, and the flowers of the shrubs, which bloom throughout the summer, are unisexual, with staminate and pistillate flowers being borne on the same plant. The staminate flowers are borne in groups of 3 in the axils of bracts, forming densely flowered, erect cylindrical catkins 2.5 to 7.6 cm long; 1 to 3 pistillate flowers are borne in an involucre, usually at the base of the staminate catkins or borne in short separate catkins. At the time of peak blooming in June, each tree is covered with erect creamy white blossoms, which provide a pleasing contrast to the more somber foliage (Peattie 1953).

The fruit consists of 1 to 3 nuts (figures 1 and 2) enclosed in a spiny golden brown bur. The nuts mature in fall of the second year (Hickman 1993). The minimum seed-bearing age (from root crown sprouts) is 6 years (McKee 1990). Giant chinquapin trees have been reported as producing seeds at 40 to 50 years of age but probably do so before this age (McKee 1990). Controversy exists over seed productivity. Sudworth (1908) reported that the tree form is an abundant seeder, but Peattie (1953) noted that although flowering is abundant, fruiting is "strangely shy." Insects, squirrels, and birds often consume most of a given crop. Indeed, Powell (1994) observed tree squirrels (*Sciurus* spp.) cutting burs of large chinquapins during a bumper seed year. By late fall, the ground beneath the trees was covered with burs.

Collection, extraction, and storage. Because of heavy predation by many animals, collectors should hand-pick the burs in late summer or early fall, after they ripen but before they open (Hubbard 1974). The collected burs should be spread out to dry in the sun or in a warm room. After drying, the nuts can be separated from the burs mechanically. The following number of nuts per weight have been recorded (Hubbard 1974; McMinn 1939):

	Nuts/kg	Nuts/lb
giant chinquapin (*C. chrysophylla* var. *chrysophylla*)	1,826–2,420	830–1,100
golden chinquapin (*C. chrysophylla* var. *minor*)	1,540	700
bush chinquapin (*C. sempervirens*)	—	2,640 1,200

Figure 1—*Chrysolepsis chrysophila* var. *chrysophila*, giant chinquapin: nut.

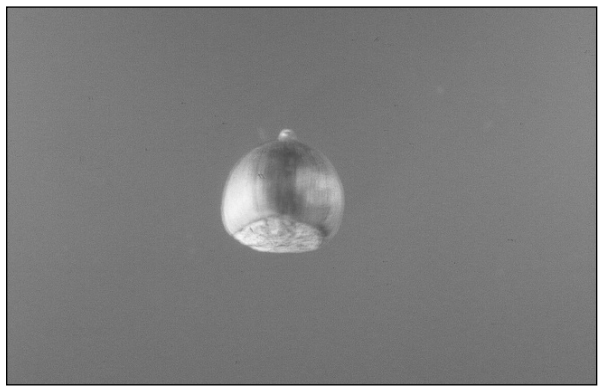

Figure 2—*Chrysolepsis*, chinquapin: longitudinal section through a seed.

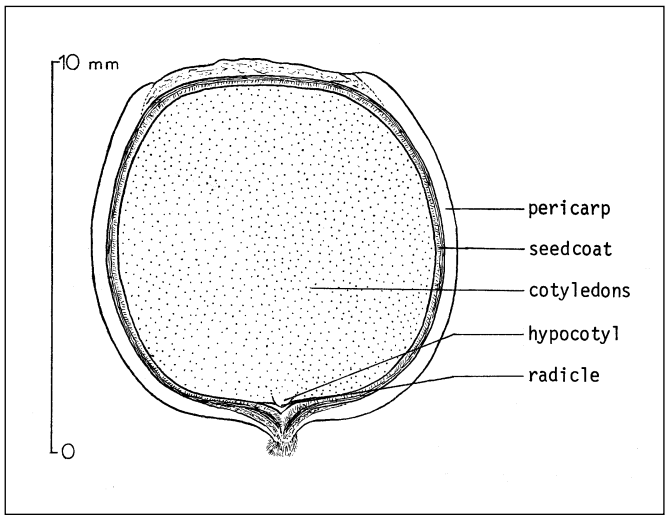
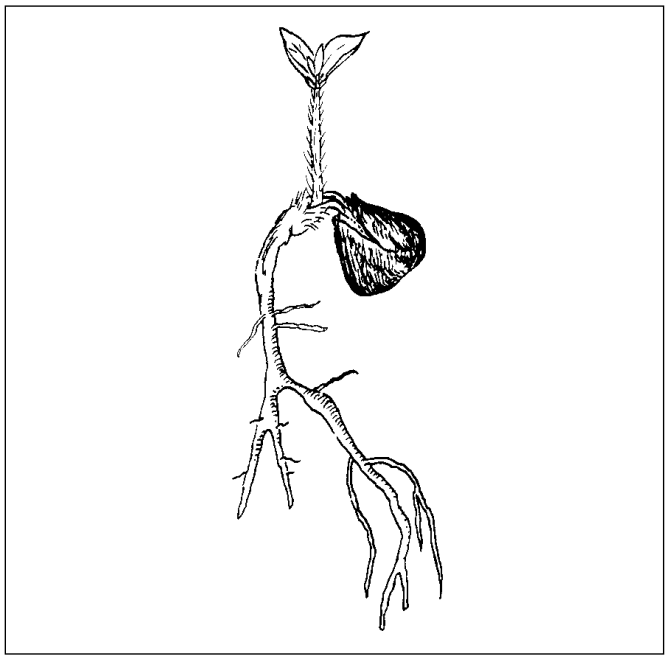


When stored in sealed containers at 6 °C, chinquapin seeds retain their viability well for at least 2 years and probably longer. Viability of 1 sample of giant chinquapin seeds stored in this manner dropped only from 50 to 44% in 5 years (Hubbard 1974).

Pregermination treatments. Mirov and Kraebel (1937) found that no stratification was needed.

Germination. Germination of untreated seeds of giant chinquapin in 3 tests ranged from 14 to 53% (Hubbard 1974)—the poorest of all hardwoods in the Klamath Mountains provenance of southwestern Oregon and northern California (McDonald and others 1983). Mirov and Kraebel (1937) found highest germination values for giant chinquapin to be 50% in 24 days and for bush chinquapin was 30% in 16 days. Germination is hypogeal (figure 3) and best in peat.

Figure 3—*Chrysolepsis,* chinquapin: seedling at 1 month after germination



Nursery practice. Little is known about raising chinquapins in nurseries. In a study at the Rancho Santa Ana Botanic Gardens in California, the 3 native species were raised in pots. Some survived through 1 or more potting stages, but none survived after outplantings (Hubbard 1974). Propagation by layering, grafting, or budding is feasible (Hubbard 1974).

Seedling care. Natural regeneration of giant chinquapin usually is sparse or totally lacking. Powell (1994) noted that not a single seedling was present on ground covered with burs beneath large seed trees. McKee (1990) also inferred that regeneration was lacking in environments of deep litter and dense understory vegetation. Sudworth (1908) noted that regeneration was best if seeds were covered, apparently by eroded soil. Keeler-Wolf (1988) found sexually reproduced seedlings and saplings to average about 19/ha (7/ac) in the Klamath Mountains but only in shaded mesic environments. In the Oregon Cascade Mountains, McKee (1990) noted that chinquapin reproduction occurred in light leaf mulch in partial shade, with plantlets that were 15 to 45 cm tall at ages 4 to 12. For bush chinquapin in the northern Sierra Nevada on 10 study areas over a 10-year period, not 1 seedling was found. Although tiny plants looked like seedlings, a gentle tug showed that they were connected to parent-plant root systems. The number of new sprouts averaged over 39,000/ha (16,000/ac) 6 years after site preparation by bulldozer bared the ground (McDonald and others 1994).

Altogether, this evidence suggests that for both natural and artificial regeneration, best seedling care will be achieved with covered seeds in partially shaded, moist conditions. Seedling growth in this environment, however, is unknown.

Asteraceae–Aster family

Chrysothamnus Nutt.
rabbitbrush

Susan E. Meyer

Dr. Meyer is a research ecologist at the USDA Forest Service's Intermountain Research Station, Shrub Sciences Laboratory, Provo, Utah

Growth habit, occurrence, and use. Members of the rabbitbrush genus—*Chrysothamnus* spp.—are among the best-known of western shrubs (Johnson 1987; McArthur and Welch 1986; McArthur and others 2004, 1979). The genus is endemic to western North America and is made up of 16 species (Anderson 1986; McArthur and Meyer 1987). It has recently been partially subsumed under the new genus *Ericameria*, formerly an infraspecific taxon within the related genus *Haplopappus* (Anderson 1995; USDA NRCS 2001). Because the durability of this nomenclatural change has yet to be demonstrated, the decision here is to follow the traditional nomenclature (table 1).

Rabbitbrush commonly occurs on sites of natural or human disturbances such as washes, drainage-ways, and quarries; they may also occur as subdominants in later seral vegetation. Their conspicuous golden flowers are a familiar sight in autumn along roadsides throughout the West. Three of the species—rubber rabbitbrush, Parry rabbitbrush, and green rabbitbrush—are widespread, polymorphic taxa made up of multiple subspecies, whereas the remainder are taxonomically simpler and more restricted in distribution. Rubber rabbitbrush is made up of 22 subspecies, many of which are ecologically distinctive. Its more ecologically specialized subspecies are restricted to dunes, rock outcrops, shale badlands, alkaline bottomlands, or montane riparian communities. Most of the widely distributed subspecies are also broad in their ecological requirements but tend to be commonest on disturbed ground. Common garden studies have shown that marked ecotypic differentiation occurs within subspecies for such traits as growth form, growth rate, cold and drought hardiness, competitive ability, flowering time, achene weight, and germination patterns (McArthur and others 1979; Meyer 1997; Meyer and others 1989). Such ecotypic variation is to be expected in other widely distributed species as well. It is therefore important to consider ecotype as well as species and subspecies when selecting seed sources for artificial seeding projects.

Species, subspecies, and populations of rabbitbrush also vary widely in their palatability to livestock and wildlife. Certain unpalatable taxa such as threadleaf rubber rabbitbrush tend to increase on abused rangeland, and considerable energy has been invested in control methods (Whisenant 1987). A tendency to resprout after herbicide spraying, chopping, or burning, combined with an ability to reestablish from seeds, can make rabbitbrush difficult to eradicate (Young and Evans 1974).

Basin and mountain whitestem rubber rabbitbrush races are highly palatable as winter forage for deer (*Odocoileus* spp.), sheep, and cattle, and have been included in seeding mixes for the rehabilitation of big game winter range for over 30 years (Monsen and Stevens 1987). Other species and subspecies also provide winter forage for wildlife and livestock (McArthur and others 2004). Rabbitbrushes are extensively used for mined-land rehabilitation in the West (Romo and Eddleman 1988). Thousands of pounds of wildland-collected seed are bought and sold annually (McArthur and others 2004; Monsen and others 2004, 1987). Rabbitbrushes may be seeded as pioneer species on harsh mine disturbances for erosion control and site amelioration and often invade such sites on their own (Monsen and Meyer 1990). They can act as nurse plants to facilitate establishment of later seral species, as they generally offer little competition to perennial grasses or later seral shrubs (Frischknecht 1963).

Rabbitbrushes have potential uses in landscape plantings, especially with the recent emphasis on xeriscaping. Rubber rabbitbrush has also been examined as a commercial source of natural rubber and other plant secondary metabolites such as resins (Weber and others 1987).

Flowering and fruiting. The perfect yellow disk flowers of rabbitbrushes usually occur in groups of 5 in narrowly cylindrical heads subtended by elongate, often keeled bracts. The heads are numerous and are clustered in often flat-topped terminal or lateral inflorescences that can be

quite showy. Flowering occurs from late July through October, with higher elevation populations flowering earlier. The fruits ripen in September in the mountains but may not be ripe until December in warm desert populations. There may be considerable variation in flowering and fruiting phenology within populations and even on individual plants (Meyer 1997). Each flower has the potential of producing a single narrowly cylindrical achene that is completely filled by the elongate embryo (figures 1 and 2). The achene is topped with a ring of pappus hairs that aid in dispersal by wind. The pappus may also be involved in orienting and anchoring the achene during seedling establishment (Stevens and others 1986). Fully ripened fruits are easily detached from the plant by wind under dry conditions. Abundant flowering occurs most years, but fill is variable. Sometimes there is considerable damage by noctuid moth larvae during seed development. The damaged fruits remain attached to the plant, creating the appearance of an abundant harvest after all the sound fruits have dispersed.

Seed collection, cleaning, and storage. Dry, calm conditions are best for the harvest of rabbitbrush seeds. Fully ripe fruits are fluffy and easily detachable, and they may be stripped or beaten into shoulder hoppers, bags, or boxes. Seed fill must average 30 to 50% in order to attain purities high enough for commercially profitable harvest. On favorable upland sites, harvestable crops occur in 4 of 5 years (Monsen and Stevens 1987). The purity of the bulk-harvested material is usually near 10%. Seeds are often moist at harvest and must be dried before cleaning.

Rabbitbrush seeds are difficult to clean. The elongate achenes are brittle and easily damaged in most mechanical cleaning equipment. Using flail-type cleaners such as barley debearders results in less damage than using hammermills. After initial cleaning, the material can be fanned and screened in a fanning mill to achieve the desired purity. Cleaning removes sticks and large debris, separates the achenes from the inflorescences, detaches the pappus from the achenes, and removes unfilled fruits and other fine debris.

Figure 1—*Chrysothamnus*, rabbitbrush: achenes with pappi intact of *C. viscidiflorus*, Douglas rabbitbrush (**left**) and *C. nauseosus*, rubber rabbitbrush (**right**).

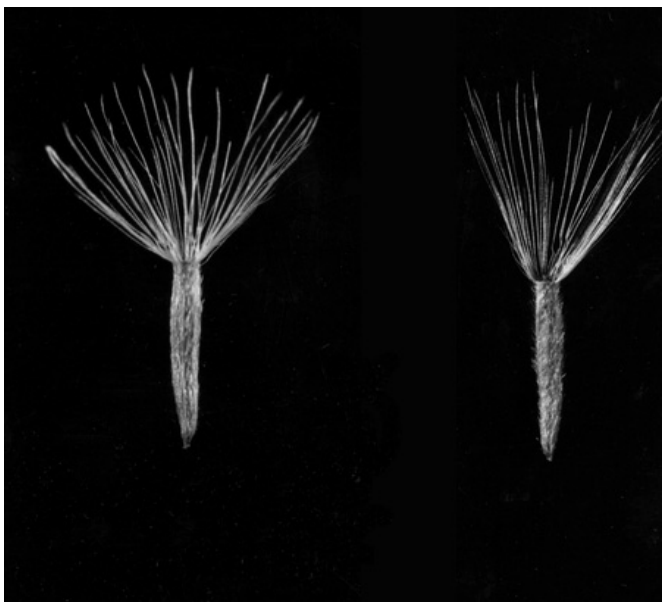

Figure 2—*Chrysothamnus viscidiflorus* spp. *lancedatus*, Douglas rabbitbrush: longitudinal section through an achene.

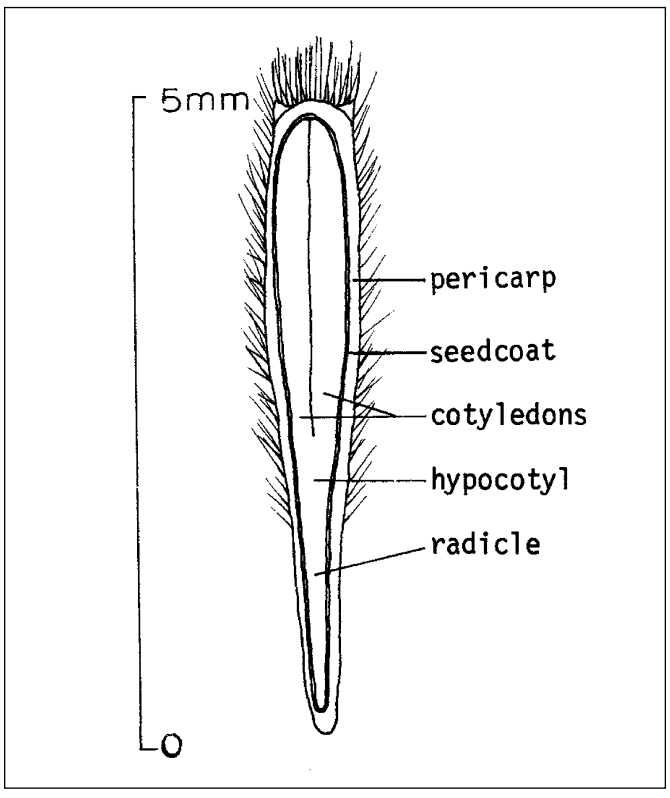

These steps are necessary to raise purities to 20% or higher and to make it possible to use conventional seeders (Monsen and Stevens 1987).

Achene weight varies substantially among species, subspecies, and populations of rabbitbrush (table 2). In rubber rabbitbrush, weight is correlated with habitat; the largest achenes come from plants that are specialized for growing on dune and badland habitats, and the smallest come from populations on temporarily open saline bottoms (Meyer 1997). There is a ninefold difference in achene weight among populations of rubber rabbitbrush, and other species also show achene weight variation (table 2). This makes it important to consider achene number per unit weight explicitly when calculating seeding rates.

Rabbitbrush seeds are not long-lived in warehouse storage. Substantial loss of viability may occur within 3 years, and storage beyond 3 years is not recommended (Monsen and Stevens 1987; Stevens and others 1981). Seeds should be retested immediately before planting so that seeding rates can be based on current values for pure live seed. Rabbitbrush seedlots with initially low vigor and viability values tend to lose their remaining viability more quickly in storage (Meyer and McArthur 1987). Because of late ripening dates, rabbitbrush seeds are usually held for a year (until the following autumn) before planting. Careful attention to moisture content (7 to 8% is probably near optimum) and storage at low temperature may prolong storage life, but data to substantiate this are lacking.

Germination. Germination requirements for rabbitbrush vary both among and within species. Rubber rabbitbrush germination is best understood (Khan and others 1987; McArthur and others 1987; Meyer and McArthur 1987; Meyer and Monsen 1990; Meyer and others 1989; Romo and Eddleman 1988). Seeds are usually nondormant at high incubation temperatures (30 °C) even when recently harvested, but display variable levels of dormancy at the intermediate temperatures characteristic of autumn seedbeds. Seeds of early-ripening high-elevation collections are most likely to be dormant or slow to germinate at autumn temperatures, whereas seeds of late-ripening warm-desert collections germinate completely and rapidly over a wide temperature range. The conditional dormancy of recently dispersed seeds is removed through moist chilling, so that all seeds are nondormant in the field by late winter. Germination rate at near-freezing temperature is even more closely tied to habitat. Collections from montane sites may

* 100% purity.

require more than 100 days to germinate to 50% at 3 °C, whereas warm desert collections may reach 50% germination in as few as 5 days. These germination features act in concert with seasonal patterns of temperature and precipitation in each habitat to ensure complete germination in mid to late winter. Germination is often completed just before the snow melts, with little or no carryover of seed between years. The ecotypic variation in germination phenology results in reduced emergence and survival when seed-source habitat is not matched to planting site habitat (Meyer 1990; Meyer and Monsen 1990).

Preliminary data for Intermountain and Mojave Desert populations of other species of rabbitbrush suggest that they share the same basic habitat-correlated germination patterns. Information on germination response to temperature for 6 collections of green rabbitbrush indicates that it differs from rubber rabbitbrush in having 25 °C rather than 30 °C as an optimum germination temperature and in showing some dormancy even at this optimal temperature (table 3) (Meyer 1997). Habitat-correlated germination responses at autumn and winter temperatures were similar for the 2 species and also for collections of Parry, spearleaf, and Mojave rabbitbrushes.

Evaluation of the seed quality for rabbitbrush is not without pitfalls. Reasonably repeatable purity values are obtained when only filled achenes are included as pure seed (Meyer and others 1989). Germination tests for rubber rabbitbrush should be carried out at alternating temperatures of 20 to 30 °C or a constant 25 °C for 28 days (Meyer and others 1989). This procedure is the only one listed in the official testing rules for this genus (AOSA 1993). Seedlots from low and middle elevations should complete germination within 14 days, whereas seedlots from high elevations may still show some dormancy even after 28 days, making post-test viability evaluation essential. Tests at 30 °C are not recommended, even though relative germination percentage (that is, percentage of viable seeds germinating) may be higher because there are indications that 30 °C is more stressful to marginally viable seeds.

Tetrazolium viability testing of rabbitbrush seeds is also somewhat problematical. The embryos must be removed from the achene prior to immersion in the stain because of poor penetration of the stain, even with piercing or cutting of the achene wall. The process of removal often damages the embryo, making the staining patterns hard to interpret. We frequently obtained higher viability estimates from germination tests than from tetrazolium evaluation for these species (Meyer 1997).

Nursery and field practice. Rabbitbrush species are easily propagated as container stock (Deitschman and others 1974). Seeds are sown directly into containers that provide depth for root development, sometimes after a short wet chill to ensure uniform emergence (Long 1986). The seedlings grow rapidly and are ready for outplanting in 3 to 4 months, after a hardening period. They may be outplanted in fall or spring, whenever moisture conditions are optimal. Bareroot propagation of rabbitbrush has also been successful. In spite of considerable among-lot and among-plant variation in seedling size, transplants survive quite well. Fall-seeding in nursery beds is recommended. Plants require less water than most other shrubs and should not be overwatered or fertilized excessively (Monsen 1966).

Rabbitbrushes are among the easiest shrubs to establish from direct seeding, and most plantings on wildland sites use this method. Minimal seedbed preparation is required. Surface planting onto a firm but roughened seedbed in late fall usually results in adequate stands. This planting may be accomplished through aerial seeding; hand-broadcasting; or seeding with a thimble seeder, seed dribbler, browse seeder, or a drill with the drop tubes pulled so that the seed is placed on the disturbed surface behind the disk furrow openers (McArthur and others 2004). Seeds should not be planted too deeply. One millimeter of soil coverage is sufficient. Seeding rates of about 20 to 30 live seeds/m^2 (2 to 3/ft^2) are usually adequate. This is equivalent to about 200 g/ha (ca 3 oz/ac) on a pure live seed basis for a seedlot that averages 1.5 million seeds/kg (680,400/lb). If the seedlot is cleaned to high purity, it may be necessary to dilute it with a carrier such as rice hulls in order to achieve uniform seeding rates. Seedlings emerge in early spring, and young plants grow rapidly, often producing seeds in their second growing season.

Fabaceae—Pea family

Cladrastis kentukea (Dum.-Cours.) Rudd

yellowwood

David F. Olson, Jr., R. L. Barnes, and Jill R. Barbour

Drs. Olson and Barnes retired from the USDA Forest Service's Southeastern Forest Experiment Station; Ms. Barbour is a germination specialist at the USDA Forest Service's National Tree Laboratory, Dry Branch, Georgia

Synonym. *Cladrastis lutea* (Michx. f.) K. Koch

Other common names. Kentucky yellowwood, virgilia, American yellowwood.

Growth habit, occurrence, and use. Yellowwood—*Cladrastis kentukea* (Dum.-Cours.) Rudd—is a small deciduous tree that attains a height of 12 to 18 m at maturity (Sargent 1965). The native range of yellowwood is restricted; it extends from western North Carolina into eastern and central Tennessee, northern Alabama, Kentucky, southern Illinois, and Indiana; it also occurs in the glades country of southwestern Missouri and in central and northern Arkansas. Locally, it grows on limestone cliffs in rich soils, and its greatest abundance is in Missouri and in the vicinity of Nashville, Tennessee. The wood is hard, close-grained, and bright yellow, turning to light brown on exposure to light; commercially, it is a substitute for walnut in gunstocks and a source of clear yellow dye. Yellowwood is hardy as far north as New England and is often planted for its ornamental value. It was introduced into cultivation in 1812 (Olson and Barnes 1974).

Flowering and fruiting. The fragrant, perfect, white, showy flowers bloom in June, usually in alternate years, and the fruit ripens in August or September of the same year (Bailey 1949; Radford and others 1964; Sargent 1965). The fruit is a legume (pod), 7.5 to 10 cm long (figure 1) (Fernald 1950), that falls and splits open soon after maturing. The seeds are dispersed by birds and rodents. Each legume contains 4 to 6 short, oblong, compressed seeds with thin, dark brown seedcoats and without endosperm (figure 2). Weights of seeds in legumes containing 2 to 4 seeds decreased from the base of the legume to the style (Harris 1917). Good seedcrops are produced generally in alternate years.

Collection of fruits. The legumes may be collected soon after maturity by handpicking them from trees or by shaking or whipping them onto outspread canvas or plastic sheets. Legumes turn brown and split open easily at maturity.

Extraction and storage of seeds. After the legumes are allowed to dry, they can be opened by beating them in sacks or running them through a macerator. The seeds may be separated from the legume remnants with screens or air separators.

Cleaned seeds average about 24,900 to 32,200/kg (11,300 to 14,600/lb). Average purity and soundness of seeds from commercial sources have been, respectively, 82 and 67% (Olson and Barnes 1974). Seeds of yellowwood are orthodox in storage behavior and may be stored dry in sealed containers at 5 °C (Olson and Barnes 1974). For overwinter storage, seeds may be stratified in sand or a mixture of sand and peat (Olson and Barnes 1974), or they may be dried and sown the following spring (Wyman 1953).

Pregermination treatments. Natural germination of yellowwood is epigeal (figure 3) and takes place in the spring following seedfall. Dormancy is chiefly caused by an impermeable seedcoat and to a lesser degree by conditions in the embryo (Burton 1947). Burton (1947) found that shaking yellowwood seeds for 20 minutes at 400 strokes per minute made 82% of the seed permeable to water. A successful dormancy-breaking treatment is sulfuric acid scarification for 30 to 60 minutes (Heit 1967). Dormancy may be overcome also by stratification in sand or sand and peat for 90 days at 5 °C or by scarification and storage for 30 days (Olson and Barnes 1974).

An early method of overcoming dormancy includes soaking the seeds in water that is nearly at the boiling point (Jenkins 1936). The water should be preheated to 71 to 100 °C at the time the seeds are immersed; the heating element is then removed and the seeds are allowed to soak and cool for 12 to 24 hours in water (Heit 1967).

Germination tests. There are no official test prescriptions for yellowwood. Germination has been tested on pretreated seeds in sand or sand and peat flats in 30 to 42 days at 20 to 30 °C (Olson and Barnes 1974) and on moist filter paper medium for 24 days at 0, 25, and 50 °C (Rivera and others 1937). Acid-treated seeds germinated from 51 to 67% in 11 days; final germination ranged from 56 to 67% (Olson and Barnes 1974). Acid treatment for 0, 30, 60, and 120 minutes produced 5, 41, 92, and 96% germination, respectively (Frett and Dirr 1979).

Figure 1—*Cladrastis kentukea*, yellowwood: legumes.

Figure 2—*Cladrastis kentukea*, yellowwood: longitudinal section (**left**) and exterior view of a seed (**right**).

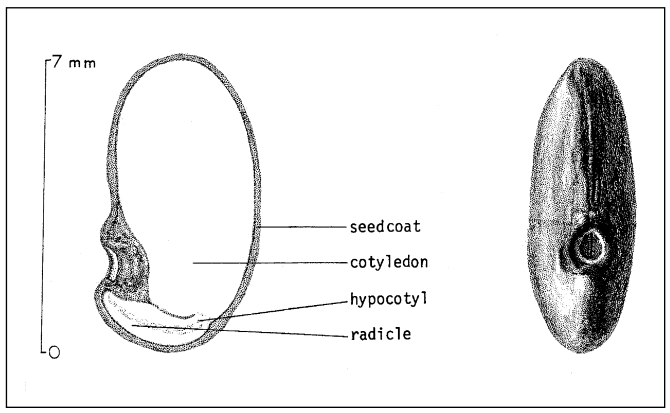

Figure 3—*Cladrastis kentukea*, yellowwood: seedling development at 1, 6, 10, 16, and 20 days after germination.

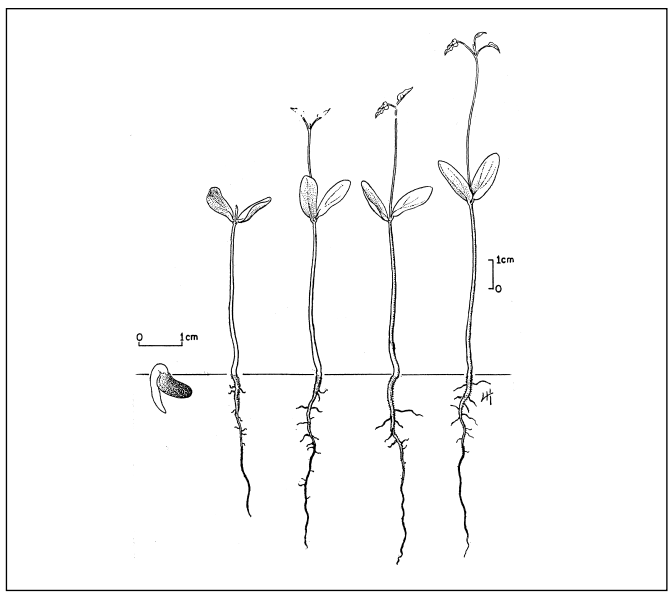

Applying hydrostatic pressure to yellowwood seeds increased their permeability in the region of the hilum and greatly increased the speed of germination (Rivera and others 1937). Pressures of 68,950 kN/m^2 (10,000 lb/in^2) applied for 10 minutes at 0 °C, 1 minute at 25 °C, and 1 minute at 50 °C resulted in 100% germination within 24 days (Rivera and others 1937). At 206,850 kN/m^2 (30,000 lb/in^2) of pressure for 1 minute or 5 minutes at 25 °C, 100% of the seeds germinated by the 12th day. However, a 20-minute exposure to a pressure of 68,950 kN/m^2 (10,000 lb/in^2) at 50 °C proved injurious to the seeds, with 15.5% of the seeds appearing soft and dead (Rivera and others 1937).

Nursery practice. Seeds may be sown in autumn or spring. Beds should be well prepared and drilled with rows 20 to 30 cm (8 to 12 in) apart, and the seeds covered with about 6 mm ($^1/_4$ in) of firmed soil. Untreated seeds may be sown in autumn and the seedbeds should be mulched and protected with bird or shade screens until after late frosts in spring. Side boards simplify mulching and screening. Stratified seeds or dry-stored seeds that have been treated to break dormancy are used for spring-sowing. If seeds were soaked in hot water at 49 °C for 24 to 36 hours until swollen and then surface-dried and planted in the nursery, they germinated readily in the spring (Dirr and Heuser 1987). Shading of seedlings is unnecessary.

Growth habit, occurrence, and use. The genus *Clematis* includes more than 200 species of climbing vines, and erect or ascending perennial herbs (sometimes woody) widely that are distributed through the temperate regions, chiefly in the Northern Hemisphere (Rehder 1940). *Clematis* is subdivided into 3 sections—Flammula (western and eastern virgin's-bowers), Atragene (western blue clematis and *C. occidentalis* (C.L. Hitchc.) Pringle), and Viorna (traveler's-joy). The taxonomy and distribution of section Atragene are described by Pringle (1971). Many horticultural varieties are grown for ornamental purposes (Dirr 1990; Lloyd 1977; Markham 1935). The 8 species included here (table 1) are also useful for erosion control, ground cover, and wildlife food (Bailey 1939; Dirr 1990; Fernald 1950; Rehder 1940; Van Dersal 1938).

Species occupy different site types within their range. In Wisconsin, for example, eastern virgin's-bower was found in 13 community types but was most abundant in the wet alder thicket community. Rock clematis is present in 2 communities and most abundant in northern dry mesic forests (Curtis 1959). Western species seem to be more common on drier well-drained sites than species native east of the Mississippi (table 1).

Geographic races. Two varieties of western virgin's-bower—*C. ligusticifolia* var. *californica* Wats. and var. *brevifolia* Nutt.—are separated geographically within the species' range (Vines 1960). These and a variety of eastern virgin's-bower—*C. virginiana* var. *missouriensis* (Rydb.) Palmer & Steyrm.—may be geographic races. Wild plants intermediate between Drummond clematis and western virgin's-bower may be of hybrid origin (Vines 1960). Several hybrids of Italian clematis are known (Rehder 1940).

Flowering and fruiting. There are both monoecious and dioecious species. Eastern virgin's-bower and western virgin's-bower (section Flammula) are dioecious, but their female flowers have non-functional stamens. Species in the sections Atragene and Viorna are monoecious (Fernald 1950). Flower size differs significantly among species, for example, eastern virgin's-bower flowers occur in clusters (panicles) containing several flowers, and their sepals are about 0.5 cm in diameter, whereas rock clematis flowers are borne singly, and their sepals are about 4 cm. Fruits are borne in heads of 1-seeded achenes with persistent feathery styles. Achenes (figures 1 and 2) are produced annually (Rudolf 1974) and are dispersed by wind in late summer or fall. Some species have been shown to produce viable seeds the first year after sowing (neoteny) (Beskaravainya 1977).

Table 1—*Clematis*, clematis: nomenclature and occurrence

Scientific name & synonym(s)	Common name(s)	Occurrence
***C. columbiana* (Nutt.) Torr. & Gray** *C. verticillaris* var. *columbiana* (Nutt.) Gray	**rock clematis,** mountain clematis, purple clematis	Quebec to Manitoba, S to New England, West Virginia, Ohio, Wisconsin, &

C

Dates of flowering and fruiting are listed in table 2. Effects of day length and temperature on flowering and flowerbud development were reported by Goi and others (1975). Other characteristics of 8 common species are presented in table 3.

Collection of fruits and extraction and storage of seeds. Fruits are brown when ripe and may be gathered from the plants by hand, dried, and shaken to remove the seeds from the heads. Other characteristics of ripeness are when the styles have become feathery (figure 1) and the achene appears shrunken and separates easily from the head (Stribling 1986). Large quantities of fruits may be collected by means of a vacuum seed harvester, run dry through a hammermill to break up the heads, and fanned to remove debris (Plummer and others 1968).

Numbers of cleaned seeds per unit weight are listed for 7 species in table 4. Limited data for eastern virgin's-bower, traveler's-joy, and Italian clematis indicate that, in seeds not freed from the styles, purity runs from 90 to 95% and soundness about 85% (Rafn and Son 1928; Rudolf 1974). For hammermilled seeds of western virgin's-bower, a purity of 20% is acceptable in Utah (Plummer and others 1968) because separation of the broken styles from the seed is difficult and expensive. Viability of dry seeds of this species has been maintained for 2 years without refrigeration (Plummer and others 1968).

Germination. Clematis seeds have dormant or immature embryos (Dirr 1990; Dirr and Heuser 1987). Some species and hybrids may germinate over a period of from months to years (Lloyd 1977). Dirr (1990) and Dirr and Heuser (1987) also indicate that requirements for germination vary among the taxa.

Prechilling at 1 to 5 °C in moist sand, peat, or a mixture of the two for 60 to 180 days has been used to promote germination in some species (Dirr and Heuser 1987; Fordham 1960; Hartmann and others 1990; Heit 1968). Field-sowing responses of traveler's-joy and Italian clematis (Blair 1959) indicate that warm plus cold stratification may be needed. The presence of an immature embryo in Italian clematis suggests that the warm stratification allows the embryo to mature, which allows germination to occur (Clark and others 1989). Germination of seeds of *Clematis microphylla* F. Muell. ex Benth. was improved by removing the pericarp or by exposing them to a cycle of wetting and drying (Lush and others 1984). Germination of seeds of traveler's-joy collected and sown in November was lower and germination rate lower than that of seeds collected and sown in February (Czekalski 1987).

Germination tests can be run on pretreated seed in sand flats or germinators for 40 to 60 days at 20 °C (night) to 30 °C (day) (Rudolf 1974). Test results available for 4 species are shown in table 5.

Nursery practice. Only a few species are propagated from seeds because of unacceptable variation in form and flowering that detracts from their value as ornamentals (Evison 1977; Lloyd 1977). The most appropriate sowing schedule is based on species and winter conditions and will vary with geographic location. General recommendations

are to sow untreated seeds in the fall soon after collection or to sow in the spring using seeds stratified over winter (Bailey 1939). Untreated fall-sown seeds of traveler's-joy and Italian clematis have germinated the following fall (Blair 1959). Stribling (1986) recommends the following schedule for propagating Armand clematis—*C. armandii* Franch—in central California: store seeds collected in late May in a refrigerator until September; soak in cold water for

Table 5—*Clematis,* clematis: germination test results for stratified seeds

24 hours and treat with a fungicide; stratify for up to 180 days at 1 to 5 °C in sealed plastic trays; and sow in March or April.

Vegetative propagation is a common practice and used exclusively to propagate most of the popular species and varieties. Procedures for vegetative propagation from cuttings, grafting, and division are discussed by Dirr and Heuser (1987), Evison (1977), Lloyd (1977), and Markham (1935).

Clethraceae—White alder family

Clethra L.

sweet pepperbush, summersweet

Jason J. Griffin and Frank A. Blazich

Dr. Griffin is assistant professor at Kansas State University's Department of Horticulture, Forestry, and Recreation Resources, Manhattan, Kansas; Dr. Blazich is alumni: distinquished graduate professor of plant propagation and tissue culture at North Carolina State University's Department of Horticultural Science, Raleigh, North Carolina

Growth habit, occurrence, and uses. The genus *Clethra* L. comprises about 30 species native to eastern Asia, eastern North America, and Madeira (Huxley 1992; LHBH 1976). Of those, cinnamon-bark clethra and sweet pepperbush are native to eastern North America, occurring from southern Maine to Florida and west to Texas (LHBH 1976). Some taxonomists consider woolly summersweet to be a separate species in this same range, but others consider it to be a variety of sweet pepperbush (Huxley 1992; Kartesz 1994; Radford and others 1968). Japanese clethra, a native of Japan, is commonly cultivated in North America (Koller 1974). Specific geographic regions of occurrence differ among these species (table 1).

North American species of *Clethra* are deciduous shrubs or small trees with heights ranging from 3 to 10 m in their natural settings (Krüssmann 1984). Species generally grow as rounded, multi-stemmed plants that can be shaped easily into attractive small trees (Bir 1992b).

Valued for fragrant, late summer blooms and exfoliating, cinnamon-colored bark, cinnamon-bark clethra can be useful in the landscape as a specimen plant (Bir 1992b; Koller 1974) or as a hedge (Huxley 1992). Plants also fit nicely into shrub borders and are effective particularly along the edge of water (Dirr 1994). Adaptability to unfavorable environments make summersweets ideal selections for adverse planting sites. The species discussed herein perform well in both full sun and dense shade, while tolerating soil conditions ranging from drought-prone (once established) to saturated (Bir 1992b). Sweet pepperbush also has been cultivated successfully in coastal regions where it tolerates salt mist (but not salt spray), which frequently damages other plants (Bir 1993).

Geographic races and hybrids. Naturally occurring summersweets are quite variable. Although the exfoliating bark of cinnamon-bark clethra is typically cinnamon-red in color, variations of pink, chartreuse, gold, and mahogany

Table 1—*Clethra*, sweet pepperbush: nomenclature and occurrence of species cultivated in North America

Scientific name & synonym(s)	Common name (s)	Occurrence

Sources: Huxley (1992), Ohwi (1984), Sleumer (1967), Small (1933).

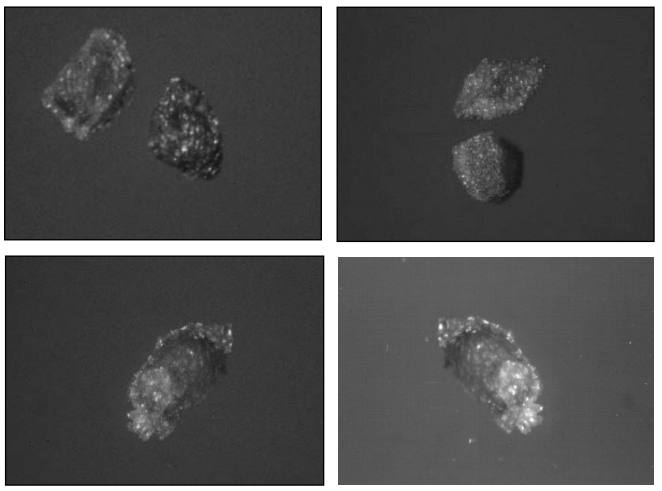
have been observed (Bir 1992b). The majority of named selections have originated from sweet pepperbush. Inflorescences of this species normally form erect racemes (LHBH 1976). However, inflorescences occur occasionally as branched panicles (Everett 1981), in which case the plants are often classified as C. *alnifolia* var. *paniculata* (Ait.) Rehd. or *C. paniculata* Ait. (Everett 1981; Huxley 1992; LHBH 1976). Dirr (1994) cited many cultivars in detail. Some of the more outstanding selections include *C. alnifolia* 'Compacta', a compact, 1.0- to 1.2-m-tall selection with lustrous, dark green foliage; 'Creel's Calico', the only variegated selection; 'Fern Valley Late Sweet', a late-flowering, almost columnar selection; and 'Hummingbird', unquestionably the most popular selection, which grows to a height of 0.8 to 1.0 m, with lustrous, dark green foliage that is covered by fragrant white flowers in mid to late summer. Of the pink-flowering forms, 'Pink Spires' and 'Rosea' are most common (Dirr 1994). These cultivars frequently are indistinguishable and may in fact be the same clone. 'Ruby Spice' occurred as a bud sport on 'Rosea' and is distinguished by deeper pink flowers that do not fade in late season. Another pink selection, 'Fern Valley Pink', produces inflorescences that can reach lengths of 20 to 25 cm for a spectacular floral display.

Flowering and fruiting. Fragrant white flowers, about 1 cm in diameter, are borne on upright or horizontally held terminal racemes or panicles, to 15 cm long (Huxley 1992), arising from the axils of leaves (Everett 1981). Flowering begins in July (with the exception of woolly summersweet, which flowers in August) and lasts to September (Krüssmann 1984), making summersweets excellent selections for late summer color. Pollination of perfect flowers most likely occurs by bees, which can be a nuisance if plants are located near walks or sitting areas (Bir 1992b; Dirr 1994; Koller 1974). Fruits are subglobose, 3-valved capsules, ranging from 2.5 to 5.0 mm in length with a persisting style and calyx (figure 1) (Huxley 1992). Upon maturation, capsules split to release many seeds. Seeds are quite small and irregularly angled, and dispersal is presumably by wind (figures 2 and 3) (Sleumer 1967). Sweet pepperbush in New Jersey averaged 6 to 17 seeds per capsule from 3 collection sites, with total seed production per plant ranging from 1,348 to 7,920 (Jordan and Hartman 1995).

Collection of fruits, seed extraction, cleaning, and storage. It appears that seeds do not mature until long after leaf abscission, November in North Carolina (Bir 1992a). Thus, collecting and sowing seeds before maturation may result in poor or no germination. Once seeds have matured, capsules can be collected before they open and

Figure 1—*Clethra*, sweet pepperbush: fruits (capsules) of *C. acuminata*, cinnamon-bark clethra (**top**); *C. alnifolia*, sweet pepperbush (**bottom**).

Figure 2—*Clethra*, sweet pepperbush: seeds of *C. acuminata*, cinnamon-bark clethra (**top left**); *C. alnifolia*, sweet pepperbush (**top right**); *C. barbinervis*, Japanese clethra (**bottom left**); and *C. tomentosa*, woolly summersweet (**bottom right**).



allowed to dry until they split. Seeds can then be shaken from the capsules and cleaned (Dirr 1994; Dirr and Heuser 1987). There are no reports of long-term storage, but seeds can be stored successfully for short periods at low temperatures (5 °C) and moisture contents (Bir 1992a; Dirr and Heuser 1987). The seeds are therefore apparently orthodox in storage behavior.

Pregermination treatments and germination testing. Jordan and Hartman (1995) reported up to 58% germination with New Jersey sources of sweet pepperbush after 5 months of stratification at 0 to 2 °C in the dark. Their germination regime was 16 hours of light at 30 °C and 8 hours in the dark at 15 °C. Other reports, however, suggest that no pretreatments are required and that germination occurs readily if seeds are sown immediately following collection (Bir 1992a; Dirr and Heuser 1987).

For successful germination seeds should be treated similar to those of azalea (*Rhododendron* L.) (Bir 1992a&b; Dirr and Heuser 1987). In general, when mature seeds are sown on the surface of a germinating medium and placed under mist at 24 °C, germination occurs within 2 weeks and is complete within 1 month (Bir 1992b).

Nursery practice. When seedlings are grown in a typical azalea growing medium of 3 parts pine bark to 1 part peat (vol/vol)—amended with 4.2 kg/m^3 (7.0 lb/yd^3) dolomitic limestone and fertilized following recommendations for azaleas—seedlings grow well, filling a 3.8-liter (1-gal) pot by the end of a growing season (Bir 1992b). Although naturally occurring as an understory species, seedlings of cinnamon-bark clethra show no symptoms of stress when grown in full sun and are visually no different than seedlings maintained under 50% shade (Bir 1992b). The species is well adapted to dry soils once established. However, if seedlings are exposed to drought conditions before a sufficient root system has developed, high mortality can be expected (Bir 1992b).

Asexual propagation of species of summer-sweet is very easy and is widely used for propagation of particular cultivars. Species listed in table 1 are propagated readily by stem cuttings taken during the summer, as well as by root cuttings taken during December and January (Dirr and Heuser 1987).

Rosaceae—Rose family

Coleogyne ramosissima Torr.

blackbrush

Burton K. Pendleton

Dr. Pendleton is a research plant ecologist at the USDA Forest Service's Rocky Mountain Research Station, Forestry Sciences Laboratory, Albuquerque, New Mexico

Growth habit, occurrence, and use. Blackbrush—*Coleogyne ramosissima* Torr.—grows in the transition zone between warm and cold deserts of southern California, southern Nevada, southern Utah, northern Arizona, and southwestern Colorado. It is found at elevations of 760 to 1,980 m. Ranging from 0.3 to 1.2 m in height, blackbrush forms almost monotypic stands in the lower Mojave–Great Basin ecotone, bounded by creosote bush (*Larrea tridentata* (Sesse & Moc.) ex DC. Coville.) communities at low elevations and by juniper–big sagebrush (*Artemesia tridentata* Nutt.) communities at higher elevations. In the eastern part of its range, blackbrush is bordered by Sonoran communities on the south and by big sagebrush, juniper, and mixed shrub communities of the Colorado Plateau in the north. Distribution of blackbrush is limited by soil depth, temperature extremes, and moisture availability.

Blackbrush occurs as a landscape dominant over much of its range and forms a major vegetational component of national and state parks in Utah, Nevada, and California. Blackbrush provides significant year-round forage for desert bighorn sheep (*Ovis canadensis*) and is eaten by mule deer (*Odocoileus hemionus*) in winter. Foliage may be grazed by domestic goats and sheep in spring, but receives minimal use by cattle. Blackbrush provides habitat to many small mammals, and its seeds are eaten by both rodents and birds.

Blackbrush, although a monotypic genus, occurs over a wide geographic and elevational range. Differences in plant size and germination characteristics suggest ecotypic variability. Use of locally adapted seed collection sites should improve chances for successful propagation and establishment.

Flowering and fruiting. Flowers are perfect, apetalous, with yellow sepals 4.5 to 6.5 mm in length; however, rare individuals with 1 to 4 yellow petals can be found in most populations (Welsh and others 1987). Flowering occurs from late March through early May, each population flowering for 2 to 3 weeks (Bowns and West 1976), with individual plants lasting some 7 to 10 days. Flowering is induced by fall and winter rains, and the timing and degree of flowering varies significantly from year to year (Beatley 1974). Ripe achenes are reddish brown in color (figure 1). The fruit is an ovate glabrous achene, somewhat curved in shape, and 4 to 8 mm long (figure 2). Blackbrush is wind-pollinated (Pendleton and Pendleton 1998).

Blackbrush is mast-fruiting: the size of the seedcrop is related to plant resource reserves. The mast crop comprises almost all of the seed production at low-elevation sites, whereas some seeds are produced in the more mesic higher-elevation sites in all but the driest intermast years. Periods between mast seedcrops often exceed 5 years. Late frosts can reduce or eliminate flowering and fruit production.

Seed collection, cleaning, and storage. The ripe seeds readily separate from the floral cup. Natural seed-fall is correlated with rain showers, which dislodge the achenes from the floral cup. The fruit ripens between late May and the third week of July, depending upon elevation and year-to-year variation. Harvesting is accomplished by beating the branches with a stick or board. Fruits can be collected onto a tarp spread under the shrub or into a basket or hopper (Nord

Figure 1—*Coleogyne ramosissima*, blackbrush: fruits with and without pubescence.

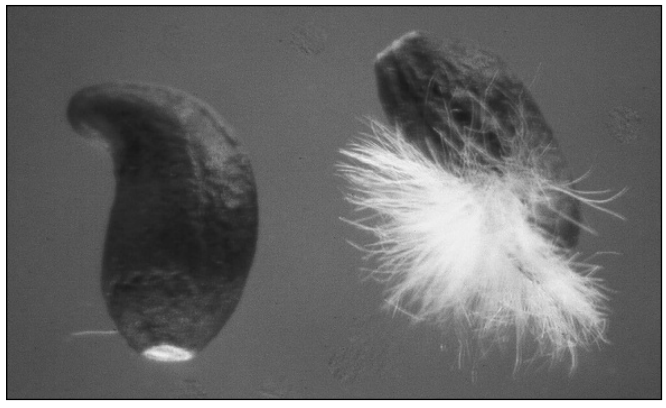

Figure 2—*Coleogyne ramosissima*, blackbrush: longitudinal section of achene with seed (drawing courtesy of Dr. Emerencia Hurd, retired, USDA Forest Service, Boise, ID).

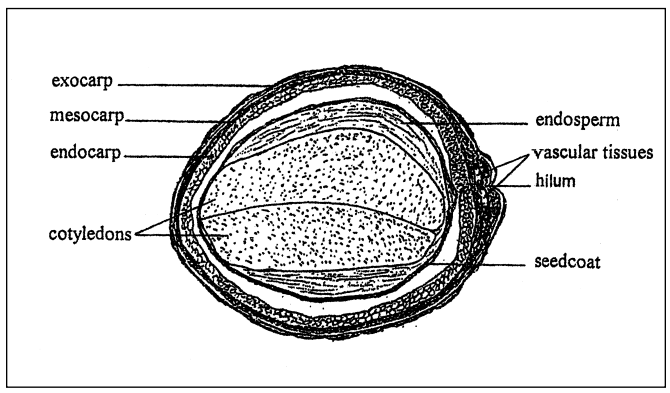

1962). Seed collections contain a significant amount of debris and cleaning is required. Seeds can be cleaned in a fanning mill or with a gravity separator (Monsen 2004). A portion of the achenes are retained within the floral cup. These can be removed with a barley de-bearder or through use of a rubbing board.

Viability of cleaned seeds is generally high, and the incidence of insect damage is extremely low. Twenty-four collections from Utah and Nevada populations ranged in viability from 74 to 98%. Nineteen collections had viability percentages greater than 85%. The number of cleaned seeds per weight averages 60,000/kg (27,000/lb), with a range of 47,500 to 68,000/kg (21,500 to 31,000/lb).

Seeds of blackbrush are long-lived and orthodox in storage behavior; they can be stored in a cool dry location for long periods without loss of viability (table 1). Germination tests on seeds collected in Washington County, Utah, showed no loss in viability after 10 and 15 years. Plants were produced from this seedlot 12 years after collection. However, the vigor of older seeds (10+ years) in field plantings has not been determined.

Germination. Fresh blackbrush seedlots are 68 to 95% dormant and remain dormant in laboratory storage for the first year after collection (table 1). Seed dormancy increases with increasing elevation of the seed source. Five-year-old seeds are essentially nondormant and will readily germinate at cool temperatures (–15 °C) (Pendleton and others 1995). Stratification of fresh seeds for 4 to 6 weeks at 1 °C will produce rapid maximum germination of all collections when seeds are removed from chill and placed at temperatures between 5 and 25 °C. Under field conditions, seeds are nondormant by October, and germination can occur at this time given proper moisture conditions and cool soil temperatures. Field germination typically occurs during the winter and early spring (figure 3) (Meyer and Pendleton 2002).

Nursery and field practice. Container stock can readily be produced from seeds. However, both stratified and unstratified seeds will germinate and emerge over a long period of time (up to 1 year). The most efficient method to synchronize germination and produce uniform-aged plants is to plant germinated seeds. Fresh seeds should be stratified between moist blotter paper for 6 weeks at 1 °C. When seedlots are removed from 1 °C and kept at room temperature, more than 75% will germinate in 24 to 48 hours. Seed collections 3 years old or older, stratified for 3 to 4 weeks, produce similar results. Germinated seeds, with radicals 2 to 10 mm (0.1 to 0.4 in) long, should be planted about 2 cm (0.8 in) deep in a well-draining soil mix. However, using a soil medium that retains moisture often leads to problems with damping-off diseases. Under experimental greenhouse conditions, blackbrush responds positively to inoculation with arbuscular mycorrhizal fungi (Pendleton and Warren

Table 1—*Coleogyne*, blackbrush: germination of nonstratified and stratified* seeds

Seed age	Percent germination†		Collections
	Range	Mean	
Fresh			
Stratified	5–32	17.6	10
Nonstratified	84–98	91.8	10
1 year			
Stratified	0–13	6.5	10
Nonstratified	85–95	92.0	10
5 years			
Nonstratified	82–96	90	6

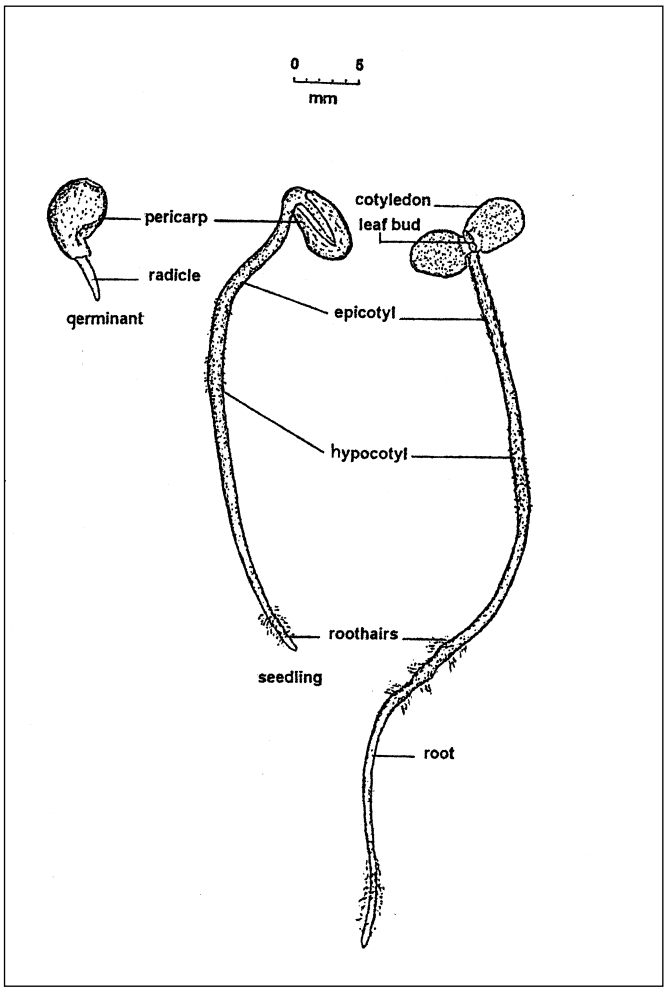
* Stratification was a moist chilling for 4 weeks at 1 °C.
† Germination tests done on wet blotter paper with a 12-hour alternating temperature regime of 5 and 15 °C; mean percent viability of these collections > 90%.

Figure 3—*Coleogyne ramosissima*, blackbrush: germination and seedling development (courtesy of Dr. Emerencia Hurd, retired, USDA Forest Service, Boise, ID).



1996). Addition of mycorrhizal inoculum to the planting medium should be considered. Optimal growing temperature for seedling growth is about 20 °C (Wallace and others 1970; Wallace and Romney 1972). Warmer conditions result in slow growth and plants that enter dormancy. Greenhouse-grown plants are susceptible to aphid infestation, but blackbrush is tolerant of standard control methods.

When seeds are not available, plants can be produced from stem cuttings. About half of the cuttings taken from current-year growth (June or September) and treated with 0.8% indole butyric acid (IBA) or commercial rooting hormone produced roots (Hughes and Weglinski 1991).

Outplanted container stock, whether produced from seeds or cuttings, should be protected from herbivory by tree tubes or diamond netting. Container stock has successfully been outplanted at Joshua Tree National Monument in California (Holden 1994) and on a natural-gas pipeline right-of-way in Arches National Park in Utah.

A limited number of attempts to establish blackbrush through seeding have been reported. In general, these attempts have had poor success (Monsen 2004). Factors that may have been responsible include low moisture levels during the germination season, lack of sufficient seeds, seeding at a less than optimal time, weed competition, herbivory, and seed theft by rodents. Seed availability is a major limiting factor in blackbrush reestablishment. Mast crops of seeds occur infrequently (5- to 10-year periods) and should be collected and stored for future use. Blackbrush seeds maintain good viability when stored for these time periods.

Insufficient work has been done to firmly determine the seeding rates and seedbed conditions necessary to establish blackbrush stands from seeds, but experimental work and reported successful seedings do offer some guidelines. Rodent-cached seeds are found at depths of 1 to 3 cm (0.4 to 1.2 in), suggesting that conventional seeders should be set to this planting depth. Because blackbrush does exhibit ecotypic variation, locally collected seeds should be used. Seeding should be done in the late summer or fall. Germination and emergence occurs as early as November (Graham 1991) and, more typically, January to March (Bowns and West 1976; Meyer and Pendleton 2002).

Spring seedings have also been attempted. Blackbrush was included in seed mixes used in experimental restoration plantings at the Nevada Test Site in southern Nevada. The seedings were conducted during March 1993. Although no blackbrush seedlings emerged that spring, some seedlings were observed during subsequent springs (USDoE 1994). An experimental spring-seeding conducted in southeastern Utah in March 1992 included stratified and unstratified seeds from 4 populations. Of the stratified seedlots, 12.5% emerged during spring 1992; of the unstratified seedlots, <1%. During spring 1993, an additional 16% of the stratified and 62% of the unstratified seedlots emerged. Lots of stratified seeds produced half as many seedlings as unstratified seeds from March 1992 through May 1993 (Pendleton and Meyer 2002). Blackbrush will form a short-term seedbank during drought conditions, but most, if not all, seeds will germinate when moisture is adequate for winter germination.

As with all dryland and desert species, successful establishment from seeds depends on the availability of moisture during the germination and establishment periods. Spring and early summer precipitation is not the norm for Mojave and Sonoran blackbrush communities, a fact that makes blackbrush seeding establishment in these areas difficult, especially in lower-elevation sites.

Fabaceae—Pea family

Colutea L.

bladder-senna

Paula M. Pijut

Dr. Pijut is a research plant physiologist at the USDA Forest Service, North Central Research Station's Hardwood Tree Improvement and Regeneration Center, West Lafayette, Indiana

Growth habit, occurrence, and use. The genus *Colutea*—the bladder-sennas—includes about 26 species of deciduous shrubs or small trees, with a distribution ranging from the Mediterranean region and southeastern Europe to northwest Africa and the western Himalayas (Browicz 1963, 1967; Hillier 1991; Krüssmann 1984; LHBH 1976). The 3 taxa of interest in the United States are common bladder-senna (*C. arborescens* L.), *C. orientalis* Mill., and *C.* × *media* Willd. (table 1). Bladder-senna species are cultivated in temperate climates primarily for ornamental purposes but may also be used for erosion control (Krüssmann 1984). In Spain, the potential use of common bladder-senna as a forage crop has been investigated because of its ligneous nature and summer utility (Allue Andrade 1983a). Antifungal compounds have been isolated from root bark of common bladder-senna (Grosvenor and Gray 1998). The bladder-sennas are very distinct shrubs, and the common name is derived from their large, inflated legumes (pods).

Common bladder-senna is a vigorous shrub of bushy habit, with medium to fast growth. It prefers a sunny location (Dirr 1990) but is easily grown in almost any soil type (except waterlogged). The cultivar 'Bullata' is a dwarf form with dense habit (about $^1/_3$ to $^1/_2$ the size of the species at maturity) whose 5 to 7 leaflets are small, rounded, and somewhat bullate (Dirr 1990; Krüssmann 1984). The cultivar 'Crisp' is a low-growing form with leaflets that are sinuate (Dirr 1990; Krüssmann 1984). *Colutea orientalis* is a rounded shrub with attractive glaucous leaflets (Hillier 1991; Krüssmann 1984). *Colutea* × *media* is a recognized as a hybrid (*C. arborescens* × *C. orientalis*), with bluish green foliage, that originated before 1790 (Dirr 1990; Krüssmann 1984).

Flowering and fruiting. The papillionaceous flowers are about 2 cm in length, bloom from May to July (with scattered blossoms into September), and occur in axillary, long-stalked racemes (Dirr 1990; Krüssmann 1984; LHBH 1976). The pea-shaped flowers of common bladder-senna are yellow, the standard petal having red markings; the flowers of *C. orientalis* are a reddish brown or copper color; and those of *C. media* range in color from the typical yellow to those which blend through markings or tints of copper, pink, or reddish brown (Krüssmann 1984; LHBH 1976). The fruit is a inflated, bladder-like legume, 6 to 7.6 cm long and 2.5 to 3.8 cm wide, that varies in color from lime green to tints of pink or bronze and is very ornamental (Dirr 1990; Krüssmann 1984). Fruits mature from July to September (Dirr 1990) and each legume contains several small seeds (figure 1) (Rudolf 1974). The legumes of *C. orientalis* dehisce at the tip.

Collection of fruits; extraction, cleaning, and storage of seeds. Ripe legumes can be harvested from the shrubs in late summer or fall and then spread in a shed (with good air circulation) to dry (Rudolf 1974). The legumes are threshed to remove the seeds and the debris is fanned out (Rudolf 1974). Bladder-sennas average 74,956 seeds/kg (34,000/lb) (Allen 1995). Dry seeds stored at 5 °C in glass

Table 1—*Colutea*, bladder-senna: morphological characteristics, height at maturity, and date first cultivated

Scientific name	Leaflets	Flowers/ raceme	Height at maturity (m)	Year first cultivated
C. arborescens	9–13	6–8	1.8–4.5	1570
C. orientalis	7–11	2–5	2	1710
C. x media	11–13	Varies	1.8–3.0	1809

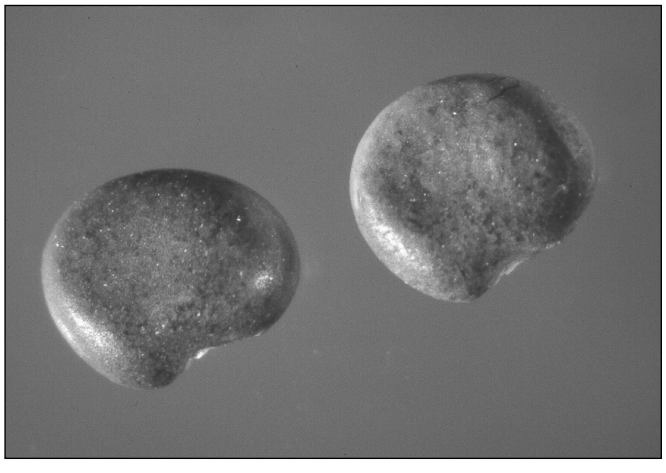
Figure 1—*Colutea* arborescens, common bladder-senna: seeds.



containers will be viable for 1 to 3 years, depending upon the species. Like most genera in Fabaceae, this genus is orthodox in storage behavior. Seeds can be stored in liquid nitrogen without a significant loss in germination percentage (Gonzalez-Benito and others 1994; Iriondo and others 1992).

Pregermination treatments. Bladder-senna seeds do not germinate readily unless the impermeable seedcoat is ruptured by mechanical or chemical scarification. Soaking the seeds in concentrated sulfuric acid for 30 to 60 minutes, before sowing in nursery beds, results in good germination (Dirr 1990; Dirr and Heuser 1987). Steeping seeds in water that was initially brought to 88 °C and then allowed to cool 24 hours also results in good seed germination (Allue Andrade 1983b; Dirr 1990; Dirr and Heuser 1987).

Germination tests. Pretreated bladder-senna seeds can be tested in germinators at 20 °C night and 30 °C day for 30 days (Rudolf 1974).

Nursery practice and seedling care. Untreated seeds may be sown in the fall, but scarified seeds are required for spring-sowing (Allen 1995; Dirr and Heuser 1987). Seedlings germinate within 1 to 2 weeks and grow rapidly. Bladder-senna species may also be propagated by cuttings. In England, 29% of half-ripened cuttings taken in early November rooted without treatment; the cuttings failed to respond to naphthaleneacetic acid (NAA); and 73% rooted after treatment with 0.1 g/liter (100 ppm) indole-3-butyric acid (IBA) solution for 18 hours (Dirr 1990; Dirr and Hesuer 1987). Summer softwood cuttings should be treated with about 1 to 3 g/liter IBA solution (1,000 to 3,000 ppm) or talc formulation (Dirr and Heuser 1987). Bladder-senna plants develop a thin, rangy root system that makes transplanting difficult. Growing plants in containers is the preferred production method.

C

Cornaceae—Dogwood family

Cornus L.

dogwood

Kenneth A. Brinkman and Victor Vankus

Dr. Brinkman retired from the USDA Forest Service's North Central Experiment Station;
Mr. Vankus is a botanist at the USDA Forest Service's, National Seed Laboratory, Dry Branch, Georgia

Growth habit, occurrence, and use. About 40 species of dogwood—*Cornus* L.—are native to the temperate regions of the Northern Hemisphere, and 1 is found in Peru. Most species are deciduous trees or shrubs (2 are herbs) useful chiefly for their ornamental qualities—flowers, fruit, foliage, or color of twigs. Many varieties have been developed for a number of the species for their landscape or horticultural value. The wood of flowering dogwood, the most commercially important species in the United States, is hard and heavy and was used extensively by the textile industry earlier in the 20th century for shuttle blocks. Today the species is widely known due to its popular use as an ornamental landscape tree. Some species produce edible fruits (Edminster 1950; Edminster and May 1951), and the bark of others contains a substitute for quinine. Roots and bark of several species have long been known to have medicinal properties that can be used to fight fevers. Distribution data and chief uses of 17 species of present or potential importance in the United States are listed in table 1.

Flowering and fruiting. The small, perfect flowers—white, greenish white, or yellow in color—are borne in terminal clusters in the spring. In flowering and Pacific dogwoods, the clusters are surrounded by a conspicuous enlarged involucre of 4 to 6 white or pinkish petal-like, enlarged bracts. Fruits are globular or ovoid drupes 3 to 6 mm in diameter, with a thin succulent or mealy flesh containing a single 2-celled and a 2-seeded bony stone (figures 1 and 2). However, in many stones, only 1 seed is fully developed, but larger stones generally have 2 developed seeds. The fruits ripen in the late summer or fall (table 2). Data on minimum seed-bearing age and fruiting frequency are limited (table 3). Stones are dispersed largely by birds and animals.

Collection of fruits. Dogwood fruits should be collected when the fruit can be squeezed and the stone will pop out. To reduce losses to birds, fruits should be collected as soon as they are ripe by stripping or shaking them from the branches. Short ladders may be useful for collecting fruits from the taller species, but ordinarily this can be done from the ground. Fruits of flowering dogwood should not be collected from isolated trees because these seem to be self-ster-

ile, and a high percentage of the stones will be empty (Mugford 1969).

Extraction and storage of seeds. The stones can be readily extracted by macerating the fruits in water and allowing the pulp and empty stones to float away (see chapter 3 on seed processing) (Brinkman 1974; Mugford 1969). Stone yields and weights are summarized in table 4. If the fruits cannot be extracted immediately after fruits are collected, they should be spread out in shallow layers to prevent excessive heating; however, slight fermentation facilitates removal of the fruit pulp (Brinkman 1974; NBV 1946). Clean air-dried stones may be stored in sealed containers at 3 to 5 °C (Heit 1967; Mugford 1969; Sus 1925; Swingle 1939). Stones of flowering dogwood have been successfully stored at 4% moisture content at –7 °C for 7 years by the Georgia Forestry Commission with only a 1% decrease in viability (Brock 1997), thus demonstrating the orthodox nature of seeds of this genus. Brinkman (1974) wrote that dogwood stones could be sown without extracting them from the fruit and that stones were cleaned when storage was required and that commercial seedlots may or may not have the dried fruit attached. Presently, however, all commercial lots of dogwood seeds now are cleaned (table 4) and some nursery managers report that if the stones are not cleaned, the fruits may inhibit germination (Brock 1997). After the fruits are collected and cleaned, the stones may be sown immediately or stratified for spring-planting.

Pregermination treatments. Natural germination of most species occurs in the spring following seedfall, but some seeds do not germinate until the second spring. Germination is epigeal (figure 3). Seeds of all species show delayed germination due to dormant embryos; in most species, hard pericarps also are present. Where both types of dormancy exist warm stratification for at least 60 days in a

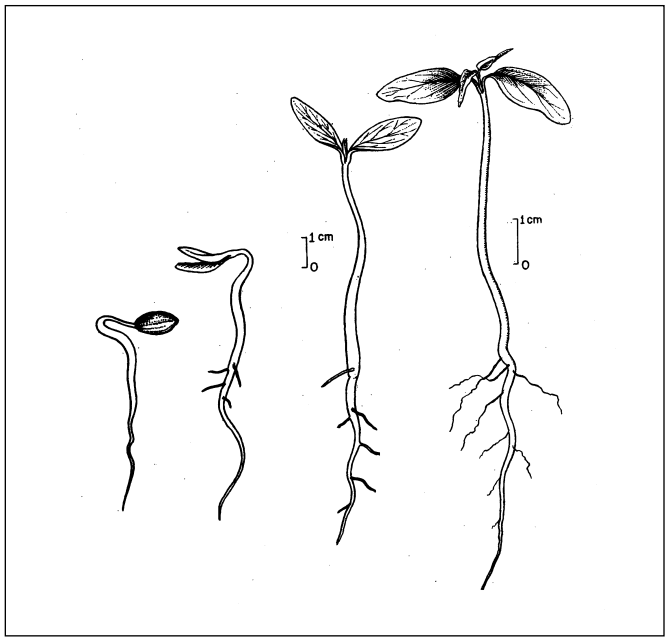
moist environment followed by a longer period at a much lower temperature is required (table 5). A more complicated procedure has been recommended for cornelian-cherry by Tylkowski (1992). The warm phase of treatment is at alternating temperatures (15/25 °C) on 24-hour cycles for 18 weeks, then a cold phase at 3 °C for 15 to 18 weeks or until the first germination is observed. Immersion in concentrated sulfuric acid for 1 to 4 hours or mechanical scarification can be used in place of warm stratification for most species. Soaking stones in gibberellic acid for 24 hours also has been successful for roughleaf (Furuta 1960) and flowering dogwoods (Litvinenko 1959). In species having only embryo dormancy, this can be broken by low-temperature stratification.

Germination tests. Official testing rules for dogwoods call for germination tests for some species, but rapid tests, such as tetrazolium (TZ) staining or excised embryos, are also recommended (AOSA 1993; ISTA 1993). Flowering and western dogwoods can be tested on the top of moist blotters or creped paper for 28 days at alternating temperatures of 30 °C (day) and 20 °C (night). Excised embryo testing is an alternate method for flowering dogwood, and TZ is an alternate method for western dogwood (AOSA 1993). TZ

Figure 3—*Cornus florida*, flowering dogwood: seedling development at 2, 4, 8, and 31 days after germination.



staining is recommended for the European species Cornelian-cherry and bloodtwig dogwood (ISTA 1993). The seeds must be soaked in water for 48 hours, then cut transversely on the ends and soaked for another 6 hours. The TZ incubation should be for 48 hours in a 1% solution; presence of any unstained tissues is cause to consider the seeds non-viable (ISTA 1993).

Germination tests using 400 properly pretreated seeds per test can be performed using sand, soil, paper, or blotters, but long stratification periods of 3 to 5 months are usually required. The same diurnally alternated temperatures of 30/20 °C appear to be satisfactory for all species (table 6), although Heit (1968a) recommended 30 and 10 °C for silky dogwood. Estimating the viability of dogwood seed lots by TZ staining is the common practice at the USDA Forest Service's National Seed Laboratory and at other seed testing facilities. In many cases, this is the preferred testing method of seed collectors and dealers, nursery managers, and seed testing laboratories. TZ tests performed by trained personnel will provide accurate, reliable data that are comparable to field germination. A TZ test only takes a few days to conduct as compared to a germination test, which requires several months of stratification before the germination period. The quicker TZ test will provide nursery managers with more time to secure different seedlot for either fall-sowing or stratification if the first seedlot is substandard or dead. Excised embryos also have been used (Flemion 1948; Heit 1955).

Nursery practices. Best results for most species are obtained when freshly collected stones are sown in the fall as soon after cleaning as possible (Heit 1968a; Stevenson 1969). Seeds of most species will germinate the following spring. Seeds of species that require a warm-cold pretreatment (table 6) can be planted in the summer but should be left in the ground until the second spring because many will not germinate the spring following planting (Murphy 1997). Dry-stored stones probably should be soaked in water and sown before October (Heit 1968a). Fruits collected too late for fall-sowing should be cleaned, stored over winter and spring, stratified in summer and sown in the fall (NBV 1946; Shumilina 1949). An alternate procedure is to stratify the seeds at about 4 °C for 3 to 4 months during the winter

Betulaceae—Birch family

Corylus L.

hazel

Jill Barbour and Kenneth A. Brinkman

Ms. Barbour is a germination specialist at USDA Forest Service's National Seed Laboratory, Dry Branch, Georgia; Dr. Brinkman retired from the USDA Forest Service's North Central Forest Experiment Station

Other common names. Filbert, hazelnut.

Growth habit, occurrence, and use. The hazels—*Corylus* L.—include about 15 species of large, deciduous shrubs (rarely small trees) that occur in the temperate parts of North America, Europe, and Asia. Some species are grown for their nuts or for ornament, and most species provide food for wildlife. In this country, 4 species have present or potential value for wildlife, shelterbelt, or environmental plantings (table 1). For many years, European hazel has been cultivated for the commercial production of its edible nutmeats, known as hazelnuts or filberts, mostly in Europe but to some extent in the United States, especially in the Willamette Valley of Oregon. Years of first cultivation for other species are as follows: American hazel (1798), beaked hazel (1745), and California hazel (1910).

Flowering and fruiting. Male and female flowers are borne separately on 1-year-old lateral twigs of the same plant. They are formed late in the summer and open the following spring before the leaves appear (table 2). The male flowers are borne in clusters of 2 to 5 pendulous catkins, consisting only of stamens. The female flower is budlike, each flower has a single ovary with 2 styles that are strikingly red at pollination (Hora 1981). By late summer or early fall, the fertilized female flowers develop into fruits. These are round or egg-shaped, brown or dark-tan, hard-shelled "nuts", each containing one embryo that is enclosed in a pericarp, or shell. These nuts are enclosed in an involucre (or husk) which consists of 2 more-or-less united hairy bracts (figures 1 and 2). The seeds are naturally dispersed by animals or birds. Large seedcrops are produced at irregular intervals, usually every 2 or 3 years (NBV 1946; Vines 1960).

Collection of fruits. Hazelnuts may be eaten by rodents, larger animals, or some birds even before they are fully mature. To reduce such losses, fruits should be picked as soon as the edges of the husks begin to turn brown, which may be as early as mid-August.

Extraction and storage of seeds. The fruits should be spread out in thin layers on wire-mesh screens to dry in a room with high humidity for about 1 month. A macerator can be used to separate the nut from the husk. The machine is operated without water, and the nuts and husks pour out of the spout (Horvath 1999). An aspirator or screen cleaning machine is then needed to separate the husk debris from the nut. Alternatively, a brush machine can be used to dehisce the nut in a square-wire cylinder and a vacuum to suck out the dust, with the seeds flowing out the opening in the door (Maloney 1999). Yields and number of seeds per weight vary even within the species (table 3).

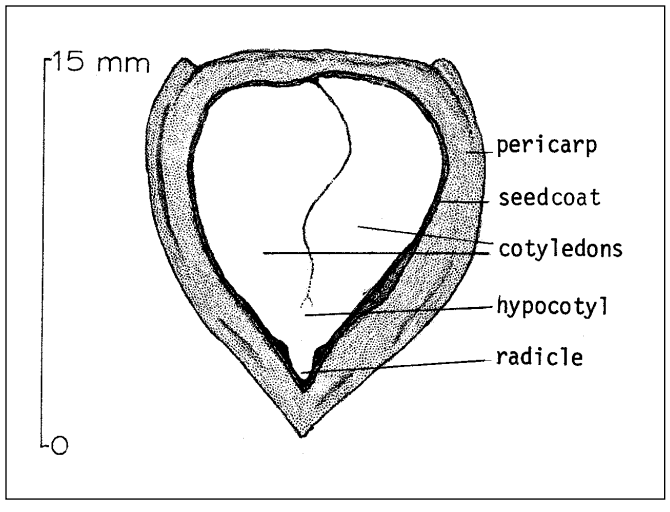
Figure 2—*Corylus cornuta* var. *californica*, California hazel: longitudinal section through a fruit.

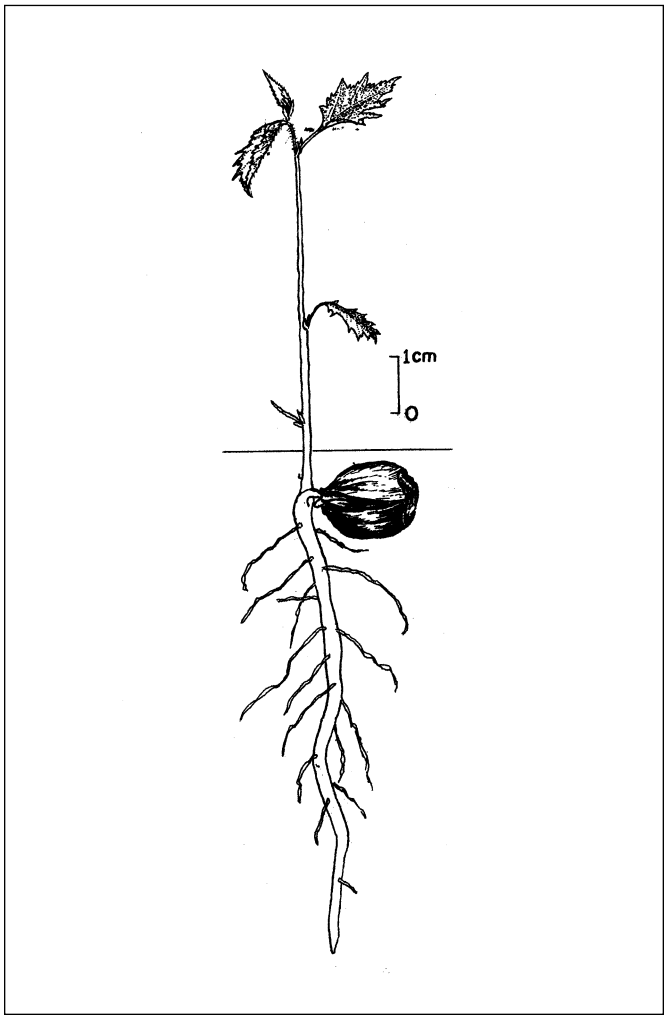


Because some dormancy is apparently induced by drying the nuts, seeds of hazel species were once thought to be recalcitrant and intolerant of any drying (Hong and Ellis 1996). Recommendations usually were to keep the hazelnuts moist after collection and store them moist over winter (stratification) before planting in the spring (Heit 1967; NBV 1946). Seeds of hazel species are now considered as orthodox in storage behavior, even though moist storage will prevent deep embryo dormancy for at least several months. Seeds of this genus will also remain viable for a year in unsealed containers at room temperature. Most of the viability of American hazelnut and some of beaked hazelnuts (Brinkman 1974) will be retained if seeds are stored in sealed containers at 5 °C. There are no long-term storage data for hazelnuts.

Pregermination treatments. Newly harvested hazelnuts are not dormant, but inhibitors present in the testa and pericarp are carried to the cotyledons and subsequently through the cotyledonary petioles into the embryonic axis (Bradbeer 1978; Jarvis 1975). Numerous studies have been

carried out on the nature of dormancy in European hazel, with most of them concerning the balance of gibberellins and inhibitors and starch synthesis (Arias and others 1976; Bradbeer and Pinnfield 1966; Jarvis 1975; Jarvis and Wilson 1978; Jeavons and Jarvis 1984; Li and Ross 1990). Stratification remains the method used to overcome dormancy, however. Hazel seeds require 2 to 6 months of prechilling before germination will occur (Heit 1968a&b). Three months of cold stratification has proven effective (Dirr and Heuser 1987). Stratification removes the block to gibberellin biosynthesis which begins when the seed is transferred to higher temperatures (Bradbeer and others 1978). In nurseries this can be accomplished by fall-sowing or by stratifying outdoors over winter before planting. Seeds may benefit from alternations of warm and cold stratification. Freshly harvested seeds of European hazel that were warm stratified for 3 weeks followed by 3 weeks at 4 °C germinated best (Dirr and Heuser 1987).

Figure 3—*Corylus cornuta* var. *californica*, California hazel: seedling development 30 days after germination.



Germination tests. Germination is hypogeal (figure 3). The seeds have a dormant embryo and germinate slowly without pretreatment. In one experiment, unstratified seeds of American hazel germinated throughout a year (Brinkman 1974). Giberillic acid (10^{-4} M) applied to European hazel seeds increased the germination from 64% for the control to 86% at 20 °C (Arias and others 1976). Seedlots of this species soaked in ethanol and then 0.1% (w/v) mercuric chloride, when put in a lighted chamber germinated 70% compared to seedlots germinated in total darkness, which germinated at only 9% (Jeavons and Jarvis 1996). Results of limited tests are listed in table 4.

Viability testing by staining the seeds with tetrazolium chloride (TZ) is the preferred method of ascertaining the seed's quality (ISTA 1993). Seeds should be cracked and soaked in water for 18 hours. After 1 to 2 mm of the cotyledons is cut off at the distal ends and the seeds are split longitudinally, the embryos should be incubated for 12 to 15 hours in 1% TZ, or 18 to 24 hours in a 0.5% solution. Some unstained tissue is allowed in viable seeds, but interpretation is difficult. Standard germination tests can also be performed once the pericarp is removed and the seeds are prechilled for 2 months at 3 to 5 °C (ISTA 1993).

Nursery practice. Although spring-sowing of stratified seeds is feasible, most nurseries plant hazel seeds in the fall (Sus 1925). In Holland, seeds of European hazel are mixed with moist sand for several months before sowing in the fall (NBV 1946). In Tennessee, good results with this species were obtained by storing fresh seed dry at 3 °C until planting in October; average tree percent was 98 based on 80% viability (Zarger 1968). Two seedlots of American hazel planted in November and December gave tree percents of 63 and 48, based on 70 and 60% viability. Seeds of both species were sown 2.5 cm (1 in) deep in drills and covered with 2.5 to 3.75 cm (1 to 1.5 in) of sawdust. In this report, the seedbeds had been fumigated with methyl bromide; other fumigants are now recommended. If seedling densities are kept low, from 43 to 65/m^2 (4 to 6/ft^2), hazel can be outplanted when 1 year old. European hazel and horticultural varieties are frequently propagated by cuttings, grafting, and tissue culture (Dirr and Heuser 1987).

Hazels are attacked by several fungi. The powdery mildew of hardwoods—*Phyllactinia guttata* (Wallr.:Fr.) Lév. (synonym *Phyllactinia corylea* (Pers.) P. Karst.)—will defoliate the plant. More serious attacks by the fungal parasite *Nematospora coryli* Peglion cause malformation of the nuts (Hora 1981). Hazelnuts are also attacked by the brown rot of pome and stone fruits—*Monilinia fructigena* Honey in Whetzel (synonym *Sclerotinia fructigena* Aderhold. ex Sacc.)—which enters through punctures caused by *Balaninus nuceum*, the nut weevil (Hora 1981).

C

Anacardiaceae—Sumac family

Cotinus P. Mill.

smoketree or smokebush

Paula M. Pijut

Dr. Pijut is a research plant physiologist at the USDA Forest Service's North Central Research Station, Hardwood Tree Improvement and Regeneration Center, West Lafayette, Indiana

Growth habit, occurrence, and use. The genus *Cotinus* P. Mill—smoketree— includes 3 or 4 species of deciduous, polygamous or dioecious, small trees or shrubs, widely distributed through central and southern Europe to the Himalayas, southwest China, and the southeastern United States (Hillier 1991; Krüssmann 1984). The smoketrees are cultivated primarily for ornamental purposes. The durable wood of American smoketree has been used for fence posts (Koller and Shadow 1991; LHBH 1976) and it also yields a yellow dye that was widely used during the Civil War (Vines 1960). Common smoketree is used in Bulgarian medicine for its anti-inflammatory, antibacterial, and wound-healing properties (Tsankova and others 1993). The 2 species of interest are described in table 1.

Common smoketree is an upright, spreading, multistemmed shrub that is grown because of its many ornamental landscape qualities and its adaptability to widely divergent soils and pH ranges (Dirr 1990). Several cultivars produce a long period of midsummer floral and fruit ornamentation, showy plumose inflorescences, and vivid autumn foliage color (Dirr 1990; Hillier 1991; Koller and Shadow 1991; Krüssmann 1984). Of special note are 'Nordine Red', the hardiest of the purple-leaf smokebushes, and 'Royal Purple', a cultivar with rich maroon-red foliage and purplish red inflorescences (Dirr 1990). The foliage of this last cultivar accumulates anthocyanin pigments in response to ultraviolet light of wavelengths between 300 and 400 nm and low temperatures (Oren-Shamir and Levi-Nissim 1997).

American smoketree is a large, upright shrub or small, round-headed tree with bluish to dark green leaves that turn a brilliant yellow, orange, red, and reddish purple color in the fall (Dirr 1990). The bark of the American smoketree is a beautiful gray to gray-brown, and scaly mature trunks (that is, with a fishlike scale effect), providing pattern and detail in the winter landscape (Dirr 1990; Koller and Shadow 1991). For a review of *Cotinus* and discussion of selected cultivars, see Tripp (1994).

Flowering and fruiting. The small, usually infertile, yellowish flowers, which bloom in June to July (April to May for American smoketree), are borne in large, terminal panicles (Krüssmann 1984). The pedicels and peduncles lengthen after flowering and are clad with fine hairs, creating the smokelike effect that gives the plant its common name (LHBH 1976). The plumelike inflorescences often persist through September (Dirr 1990). The fruit (figures 1 and 2) is a dry, reticulate drupe about 3 to 6 mm in length, light red-brown in color (ripening to near black), containing a thick, bony stone (Rudolf 1974). Seedcrops are produced annually but are often poor. The kidney-shaped drupe ripens in the fall, which is usually August to October for common

smoketree and June to September for American smoketree (Rudolf 1974).

Collection of fruits; extraction, cleaning, and storage of seeds. The fruits should be harvested by hand as soon as they are ripe (Rudolf 1974). Seeds of common smoketree that are collected green during late August–September and sown immediately can produce high germination percentages the following spring (Dirr and Heuser 1987). Seeds collected from purple-leaf forms produce a mixture of green-leaf and purple-leaf seedlings (Dirr and Heuser 1987). Dry fruits should be run through a hammermill and the debris fanned out (Rudolf 1974). The number of cleaned seeds per seed weight for common smoketree ranges between 99,978 to 118,999/kg (45,350 to 53,978/lb) with 75% germination and 97% purity, depending upon cleaning techniques (Allen 1994). The average number of cleaned seeds per weight for American smoketree is 111,111/kg (50,400/lb) (Rudolf 1974).

Information on smoketree seed storage is limited, but the indications are strong that these seeds are orthodox in storage behavior. One report states that seeds of common smoketree can be stored dry for several years in open or sealed containers at room temperature (Heit 1967, cited by Rudolf 1974). However, the best practice is to store dry seeds in a metal or rigid plastic container that is then sealed and stored in a refrigerator at 0 to 5 °C (Macdonald 1986). Seeds stored in this manner will be viable for a number of years.

Pregermination treatments. Smoketree seeds have both a hard seedcoat and an internal dormancy, thus causing slow and irregular germination. Seeds can be stimulated to germinate more uniformly by sulfuric acid scarification followed by cold stratification (table 2). Seeds from a recent introduction (Dummer hybrids) that were acid-scarified for 3 hours (no cold stratification given) and then planted germinated in 12 days (Dirr 1990).

Germination tests. Pretreated smoketree seeds may be tested for 30 days in sphagnum flats or in seed germinators (Rudolf 1974). Average test results for 2 species are shown in table 3. Tetrazolium staining can be used for rapid estimates. Seeds should be soaked in water for 24 hours before breaking open the seed coat and staining 24 hour at 30 °C in a 1% solution (Enescv 1991).

Nursery practice and seedling care. Smoketree seeds are fall-sown without pretreatment if the fruits are slightly green (Dirr 1990; Macdonald 1986; Rudolf 1974) or with pretreatment in the spring at a rate of 430/m^2 (40/ft^2) (Rudolf 1974). The seed should be covered with 6 to 9 mm ($^1/_4$ to $^3/_8$ in) of soil, and fall-sown beds should be mulched with sawdust (Rudolf 1974). Seedlings may be planted as 1+0 stock (Rudolf 1974).

Several references noted that common smoketree should be propagated by vegetative methods, because many seedlings are male plants lacking the showy flowering panicles (Dirr 1990; Dirr and Heuser 1987; Hartmann and others 1990; Macdonald 1986). In general, softwood cuttings taken in early June to July, treated with 1 to 3 g/liter (1,000 to 3,000 ppm) indole-3-butyric acid solution, and placed in a well-drained medium under mist will root in about 4 to 8 weeks (Blakesley and others 1991, 1992; Dirr 1990; Dirr and Heuser 1987; Hartmann and others 1990; Kelley and

Foret 1977; Macdonald 1986; Siftar 1981). Rooted cuttings must be overwintered without disturbance and transplanted in the spring. Spellerberg (1985, 1986) reported improved shoot growth and higher rooting percentages of common smoke tree cv. 'Royal Purple' cuttings when they were taken in April from mother plants forced under glass than cuttings taken in June from outdoor-grown plants. After rooting, shoot growth was promoted by longer photoperiods, higher carbon dioxide levels, and gibberellic acid treatments. Howard (1996) reported that rooting of 'Royal Purple" cuttings was confined to the period of active shoot growth (late May to early August), and a small benefit was noted with severe stock plant pruning. Common smoketree can also be successfully propagated by French or continuous layering (Macdonald 1986).

C

Rosaceae—Rose family

Cotoneaster Medik.

cotoneaster

Paul E. Slabaugh and Nancy L. Shaw

Dr. Slabaugh (deceased) retired from the USDA Forest Service's Rocky Mountain Forest and Range Experiment Station; Dr. Shaw is a research botanist at the USDA Forest Service's Rocky Mountain Research Station, Forestry Sciences Laboratory, Boise, Idaho

Growth habit, occurrence, and use. The genus *Cotoneaster* includes about 50 species of shrubs and small trees native to the temperate regions of Europe, northern Africa, and Asia (excepting Japan) (Cumming 1960). Growth habits range from nearly prostrate to upright. Cold-hardy types are more or less deciduous, whereas those native to warmer regions are evergreen (Heriteau 1990). Cotoneasters are valued as ornamentals for their glossy green foliage, attractive fruits, and interesting growth habits. Fall foliage color is often a showy blend of orange and red. Cotoneasters are adapted to sunny locations with moderately deep and moderately well-drained silty to sandy soils. Several hardy species are commonly used in mass plantings, hedges, shelterbelts, wildlife plantings, windbreaks, recreational areas, and along transportation corridors on the northern Great Plains, the southern portions of adjoining Canadian provinces, and occasionally in the Intermountain region and other areas (Plummer and others 1968; Shaw and others 2004; Slabaugh 1974). They require little maintenance and provide ground cover, soil stabilization, snow entrapment, and aesthetic values. Peking cotoneaster provides food and cover for wildlife (Johnson and Anderson 1980; Kufeld and others 1973; Leach 1956; Miller and others 1948). Six species used in conservation plantings are described in table 1 (Hoag 1965; Nonnecke 1954; Plummer and others 1977; Rheder 1940; USDA SCS 1988; Zucker 1966). Use of cotoneasters in some areas may be limited due to their susceptibility to fire blight (infection with the bacterium *Erwinia amylovora*), borers (*Chrysobothris femorata* (*Olivier*)), lace bugs (*Corythucha cydonia* (Fitch)), and red spiders (*Oligonychus platani* (McGregor)(Griffiths 1994; Krüssmann 1986; Wyman 1986).

Cotoneasters are apomictic and will, therefore, propagate true from seed (Wyman 1986). However, because of the apomictic habit, many variants occur within each species (Everett 1982). This variability has been exploited in cultivar

development (Krüssmann 1986; LHBH 1976). A number of hybrids have also been developed as ornamentals.

Flowering and fruiting. Cotoneaster flowers are perfect, regular, and white to pink. They develop singly or several to many together in corymbs produced at the ends of leafy lateral branchlets. Flowers are small, but in some species attractive due to their abundance. Fruits are black or red berrylike pomes that ripen in late summer or early fall and often persist into winter (Wyman 1949) (figure 1). The fruits contain 1 to 5 seeds (Rehder 1940) (figures 2 and 3), averaging 3 for Peking, hedge, and black cotoneasters; 2 for cranberry and rock cotoneasters; and 2 or 3 for European cotoneasters (Uhlinger 1968, 1970). Phenological data are provided in table 2.

Collection of fruits. Ripe fruits are collected by hand stripping or flailing in early autumn, preferably after leaf fall. Fruit firmness and color (table 3) are good criteria of ripeness. Leslie (1954) recommends that fruits of Peking, hedge, and black cotoneasters be collected slightly green. The minimum fruit-bearing age of hedge cotoneaster is 3 years. Fruit crops are produced annually.

Extraction, cleaning, and storage of seeds. Seeds may be extracted by macerating fresh fruits and skimming off or screening out the pulp. Seeds are best cleaned while fresh, because it is difficult to remove dry fleshy material by maceration. Most empty seeds can be eliminated by floating the seedlot twice in water (Uhlinger 1968, 1970). Seeds may be removed from dried fruits by abrasion (Slabaugh 1974) and the debris separated using a 2-screen fanning machine. Number of seeds per weight for 3 species are provided in table 4. About 0.5 kg (1 lb) of cleaned seeds of European cotoneaster are obtained from 2.7 kg (6 lb) of fruits (USDA SCS 1988). Seeds of the cotoneasters are orthodox in storage behavior. Leslie (1954) and USDA SCS (1988) recommend that seeds of cotoneasters be stored dry in sealed containers in a cool place. Seeds of European cotoneaster, however, can be stored in an unheated warehouse for at least 16 years without loss of viability (Jorgensen 1996; Plummer 1968).

Pregermination treatments. Seeds of many cotoneasters exhibit double dormancy due to their hard, impermeable seedcoats and the physiological condition of their embryos. First-year germination is enhanced by acid scarification followed by warm incubation and wet prechilling (USDA SCS 1988) (table 5). Addition of a commercial compost activator to the wet prechilling medium reportedly improved emergence of spreading cotoneaster—*C. divaricatus* Rehd. & Wilson (Cullum and Gordon 1994).

*Wet prechilling was preceded by 90 days of warm incubation at 21 °C.

Duration of effective pretreatments varies with species, seedlot, and year due to differences in seedcoat thickness and degree of embryo dormancy. Meyer (1988), for example, found that seeds of cranberry and spreading cotoneasters scarified for 1.5 hours in concentrated sulfuric acid germinated over an increasing range of incubation temperatures as the duration of wet prechilling at 2 °C increased from 0 to 4 months. After 4 months of prechilling, germination of both species occurred at constant incubation temperatures from 4.5 to 26.5 °C. This variability in response adds to the difficulty of securing prompt, consistent germination (Uhlinger 1968, 1970).

Germination tests. Table 6 lists germination test conditions and results for 4 cotoneaster species (see table 5 for pretreatments). The effect of light on germination of seeds of Peking, hedge, and black cotoneasters varies among seedlots, but germination of black cotoneaster was generally improved by exposure to cool-white fluorescent light (Uhlinger 1968, 1970). Pretreatment with gibberellic acid partially replaced the effect of light (Uhlinger 1968, 1970).

Because of the dormancy in these seeds, the International Seed Testing Association recommends use of tetrazolium staining rather than germination tests for evaluation of seed quality (ISTA 1993). Seeds are stained by first soaking them in water for 18 hours, then removing the distal third of the seeds with a transverse cut; and finally placing the seeds in a 1.0% solution of tetrazolium chloride for 20 to 24 hours. Viable seeds usually stain completely, but seeds are considered viable if only the radicle tip and the distal third of the cotyledons are unstained (ISTA 1993).

The excised embryo method may also be used to test seed germinability of spreading cotoneaster (Smith 1951). Seeds are first scarified in sulfuric acid for 3 hours, then soaked in 27 °C tapwater for 2 days before the embryos are excised and incubated under conditions favorable for germination.

Nursery practice. Seeds of cotoneaster species may be given appropriate scarification pretreatments and seeded in midsummer to provide the warm incubation and overwinter wet-prechilling required to relieve dormancy and permit germination in the spring. Scarified seeds provided with warm incubation pretreatment in the laboratory may be fall-planted; however, scarification, warm incubation, and wet prechilling in the laboratory are required for spring-planting. A seeding rate of 250 seeds/m^2 (23/ft^2) is recommended for producing lining-out stock of rock cotoneaster (Macdonald 1993); 100 to 130 seeds/m^2 (10 to 12/ft^2) are recommended for European cotoneaster var. 'Centennial' (USDA SCS 1988). Seeds of this variety are planted 0.3 cm (0.1 in) deep and covered with 1.5 to 2 cm (3/5 to 4/5 in) of soil (USDA SCS 1988). European and hedge cotoneaster seedbeds may be mulched with hay or other suitable material (Hinds 1969; USDA SCS 1988). Filtered shade until August is recommended for seedlings of Peking, hedge, and black cotoneasters (Leslie 1954). For hedge cotoneaster, an average seedling yield of 30% was obtained in a North Dakota nursery (Hinds 1969). Seedlings of this species are usually ready for outplanting after 2 growing seasons.

Cotoneasters are propagated vegetatively from softwood and occasionally from hardwood cuttings (Dirr and Heuser 1987; Wyman 1986). Cuttings are taken from June to August (Dirr and Heuser 1987) and treated with 1,000 to 3,000 ppm IBA. Macdonald (1993) recommended that heel cuttings be used when evergreen species are rooted in cold frames. Cuttings, particularly those of evergreen species, root readily and are easily transplanted and overwintered. Layering and grafting are also used to obtain small numbers of plants.

Field planting. Nursery stock is generally used to establish conservation plantings. Wildland seedings of Peking cotoneaster have been only marginally successful

(Shaw and others 2004). Germination is erratic and seedlings grow slowly, particularly if the site is not kept weed-free.

Bareroot plantings of European cotoneaster Centennial may be established using 1+0 or 2+0 bareroot seedlings with stem diameters of 0.5 to 1.3 cm ($^1/_5$ to $^1/_3$ in) just above the root collar (USDA SCS 1988). Seedlings should be planted in fallowed ground at 1.2- to 1.5-m (4- to 5-ft) spacings immediately after the soil thaws in spring. At least 5 years of weed control are often required. Average survival ranges from 70 to 95% (USDA SCS 1988). Fruit-producing stands are obtained in 3 to 4 years.

Rosaceae—Rose family

Crataegus L.

hawthorn, haw, thorn, thorn-apple

F. Todd Lasseigne and Frank A. Blazich

Dr. Lasseigne is executive director of the Paul J. Ciener Botanical Garden, Kernersville, North Carolina; Dr. Blazich is alumni distinguished graduate professor of plant propagation and tissue culture at North Carolina State University's Department of Horticultural Science, Raleigh, North Carolina

Growth habit, occurrence, and uses. The genus *Crataegus* L. is a complex group of trees and shrubs native to northern temperate zones (Mabberley 1997), mostly between latitudes 30° and 50°N (Phipps 1983). Although most species can attain tree-sized proportions, hawthorns in general do not form large trees or exist as canopy dominants in forests (Little 1980a&b). Some species are decidedly shrubby, whereas others can grow to heights of 12 m (table 1). There are about 250 currently recognized species, with most native to the New World (about 200 species), and the remainder (about 50 species) native to the Old World (Christensen 1992; Phipps and others 1990). Species native to the United States, as well as those that have been introduced and naturalized and some of those grown horticulturally, are included herein (table 1).

Historically, the taxonomy of the hawthorn genus has been rife with disagreement and confusion. The circumscriptions of species have varied widely, and authors of various floristic treatments have misidentified species that occur in regions treated in their works (Phipps 1998c). The genus has vexed so many authors that early experts on the group termed the situation "the Crataegus problem" (Eggleston 1910; Palmer 1932). Nearly 1,500 "species" were described in North America alone, mostly by W. W. Ashe, C. D. Beadle, and C. S. Sargent, from the 1890s through the 1910s (Christensen 1992; Phipps 1988; Phipps and others 1990; Robertson 1974). Palmer later reduced the number of species of hawthorns, such that only 20 to 100 were recognized, a range followed by subsequent authors (Phipps 1988). Recently, taxonomists have taken a middle approach, recognizing 100 to 200 species in North America (Kartesz 1994a&b; Phipps and others 1990), a larger number than that accepted in treatments of 20 to 30 years ago. Two primary references—Kartesz (1994a) and Phipps and others (1990)—offer the most complete survey of North American hawthorns (excluding Mexico).

Crataegus belongs to the subfamily Maloideae in the Rosaceae, a natural group of complex genera with the ability to interbreed freely (or hybridize), as they all possess the basal chromosome number of 17 (Phipps and others 1991; Robertson 1974; Robertson and others 1991). Authors have long regarded hybridization and apomixis as potential explanatory factors for the speciation phenomenon existing in hawthorns (Phipps 1988; Radford and others 1968; Vines 1960). Robertson (1974) related empirically derived data that implicated apomixis and hybridization as causes of the variation found within the genus. Specifically, he cited (1) widespread occurrence of pollen sterility; (2) cytological proof of triploidy or polyploidy in > 75% of plants observed; (3) similarity between offspring produced from triploid or pollen-sterile plants and parental plants; and (4) the ability of flowers that have stigmas removed at anthesis to set fruit.

Many authors allude to the existence of putative hybrids in New World hawthorns (Elias 1987; Harlow and others 1996; Jacobson 1996; Kartesz 1994a&b; Knees and Warwick 1995; LHBH 1976; Little 1980a&b; Phipps 1984; Vines 1960). However, despite widespread documentation of hybrid species complexes existing in Eurasia (Christensen 1992), few scientifically verified examples of hybrid species in North American hawthorns are known (Phipps 1998a). Several recent studies now demonstrate unequivocal proof that both apomixis and polyploidy are implicated in the complex variation seen in this genus in North America (Dickinson 1985; Muniyamma and Phipps 1979a&b, 1984, 1985; Phipps 1984). Apomixis and hybridization are also known in other Rosaceous genera, including *Alchemilla* L. (lady's-mantle), *Cotoneaster* Medik. (cotoneaster), *Potentilla* L. (cinquefoil), and *Rubus* L. (blackberries and raspberries) (Mabberley 1997).

Around the world, hawthorns are used for a wide range of purposes. Many hawthorn species are grown for their

edible fruits in Asia, Central America, and various Mediterranean countries (Everett 1981; Guo and Jiao 1995; Mabberley 1997; Usher 1974). The fruits of some species contain higher concentrations of vitamin C than do oranges (*Citrus* L. spp.) (Morton 1981).

In recent years, cultivation of mayhaws native to the southeastern United States—including eastern, western, and rufous mayhaws—has increased (Bush and others 1991; Payne and Krewer 1990; Payne and others 1990). Mayhaws are atypical among the hawthorns in their early flowering period (from late February through mid-March) and their early fruit ripening dates (May) (table 2) (Payne and Krewer 1990). At least 12 cultivars have been selected for improved fruit size, yield, and ease of harvest, and these are grown for production of jellies, juices, preserves, and wine. Vitamin contents are comparable to those found in manzanilla (*Crataegus mexicana* Moc. & Sesse ex DC.) (Payne and others 1990), a species used for medicinal purposes in Central America (Morton 1981). However, until propagation, production, and harvest techniques are improved, limited supplies of fruits derived from orchard-grown plants will necessitate further collection of fruit from native stands (Bush and others 1991). Other North American *Crataegus* species cultivated for fruit production are black, yellow, and downy hawthorns (Mabberley 1997; Usher 1974).

Many hawthorn taxa are grown in North America and Europe solely as ornamental plants because of their small stature, brilliant flowers in spring, and brightly colored fruits in fall (Bean 1970; Christensen 1992; Dirr 1998; Everett 1981; Flint 1997; Griffiths 1994; Jacobson 1996; Knees and Warwick 1995; Krüssmann 1984; Mabberley 1997). In the United States, the most commonly encountered hawthorn taxa in cultivation include Washington,'Winter King', cockspur, plumleaf, and Lavalle hawthorns (*C.* × *lavallei* Henriq. ex Lav.) (Bir 1992; Dirr 1998; Everett 1981; Flint 1997). One caution, however, is necessary with regard to cultivated hawthorns. Because only a partial understanding of the taxonomy of native populations of hawthorns now exists, especially in North America, it is likely that identities of many cultivated hawthorns may be either incorrect or imprecisely defined.

Hawthorns are important for wildlife. They offer good nesting sites for birds because of their dense branching and their thorns, which deter predators (Martin and others 1961). Fruits of many species are consumed by songbirds, game birds, small mammals, and ungulates (Shrauder 1977). Hawthorns are recommended commonly by professionals as landscaping and shelterbelt plants that can attract wildlife (Bir 1992; Elias 1987; Foote and Jones 1989; Morgenson 1999; Petrides 1988).

Flowering and fruiting. Flowers always appear after leaf emergence and are borne either in flat-topped inflorescences termed corymbs or in globular inflorescences termed umbels (Phipps 1988). Flower color is usually white, but rarely, pink-flowered variants are found in horticultural selections. From 1 to 25 flowers can be produced per inflorescence (Christensen 1992; Phipps 1988). Flowers usually contain 5 petals and 5 to 20 stamens and have a fetid odor in many species.

Hawthorn fruits are known as pomes, although the seeds and their bony endocarps are termed pyrenes, or nutlets (figures 1 and 2). Between 1 and 5 pyrenes are produced in each pome. Although most species produce flowers in spring and fruits in fall, mayhaws are notable for their early flowering and fruit ripening period. Some species drop fruits in autumn, and others have fruits that persist through winter. Timing of these events is important to horticulturists and wildlife and game managers (table 2).

Collection of fruits, seed extraction, cleaning, and storage. Mature fruits of most hawthorn species are collected readily from the ground in autumn, whereas fruits of species that tend to hold their fruits through the winter must be hand-picked from the trees (Brinkman 1974). Harvested fruits can be macerated to separate the seeds from the fleshy pericarp (Munson 1986). The macerated pericarp material can be removed by water flotation, and the seeds should then be air-dried. Seed yield data are available for only a few species, and there is considerable variability among them (table 3).

As an alternative to macerating the fruits and subsequently storing the seeds, fermenting freshly collected, undried fruits of western mayhaw for 4 or 8 days yielded 93% germination. However, fermentation periods > 8 days adversely affected seed germination (Baker 1991). Most other reports stated that acid scarification and/or cold stratification are obligatory to enhance seed germination. Fermentation treatments may prove extremely beneficial in reducing the time required to produce seedlings of hawthorns. However, further research on a wide range of hawthorns is needed before making general conclusions about the usefulness of such treatments.

After extracting, cleaning, and drying, the seeds should be stored under refrigerated conditions (Dirr and Heuser 1987; Hartmann and others 2002). All indications are that hawthorn seeds are orthodox in storage behavior, but reports on long-term seed viability during storage do not all agree.

Table 2—*Crataegus,* hawthorn: phenology of flowering and fruiting, and color of ripe fruit

Species	Flowering	Fruit ripening	Color of ripe fruit*
C. aestivalis	Mar	May–June	Lustrous, scarlet
C. x anomala	May	Sept–Oct	Bright crimson
C. berberifolia	Mar–Apr	Oct	Orange with red face
C. brachyacantha	Apr–May	Aug	Bright blue with white wax

* Color of ripe fruit is highly arbitrary and varies in interpretation amoung authors due to lack of standardization. Accurate determinations of fruit color cannot be ascertained from herbarium specimens.

† Plants growing in Boston, Massachusetts, not in native habitat.

Dirr and Heuser (1987) stated that seeds of hawthorns, in general, can remain viable for 2 to 3 years in cold storage. St. John (1982), however, noted decreased seed viability in oneseed, cockspur, plumleaf, and scarlet hawthorns after storage for 2 years and recommended that seeds be stored for no more than 1 year. Bir (1992) found decreases in seed viability of Washington hawthorn after cold storage for 1 year. However, Christensen (1992) observed that under natural conditions, seeds of Eurasian species may require from 2 to 6 years to germinate.

Pregermination treatments and germination tests. Seeds of many hawthorns exhibit double dormancy (Hartmann and others 2002). Therefore, pregermination treatments usually consist of acid scarification followed by a period of cold stratification (Brinkman 1974; Hartmann and others 2002). Many authors also recommend periods of warm stratification for selected species (Brinkman 1974; Dirr and Heuser 1987; Morgenson 1999; St. John 1982; Young and Young 1992). Brinkman (1974) stated that "all" seeds of hawthorns exhibit embryo dormancy, therefore

requiring cold stratification. This is reflected in the general recommendation by Hartmann and others (2002) that, following acid scarification, seeds should be stratified for 5 months at 4 °C. However, Kosykh (1972) reported that acid scarification and cold stratification for 6 months did not enhance germination of several species of hawthorns occurring in the Russian Crimea. In *C. mexicana*, cold stratification failed to enhance germination in seeds that were pretreated with 1 or 3 minutes of hot-water soaking at 80 °C (Felipe Isaac and others 1989). The fermentation work by Baker (1991) with western mayhaw also demonstrated high germination percentages without pretreating the seeds via acid scarification or cold stratification. Phipps (1998c) commented that hawthorns native to warm temperate climates possessed only endocarp dormancy, whereas those species native to regions with colder climates displayed embryo dormancy in addition to endocarp dormancy. In a large and geographically widely distributed group such as hawthorn, these different observations are not surprising.

Differences in endocarp thickness have been noted by several authors. Endocarp thickness in oneseed hawthorn varies not only among individual trees, but also over years (St. John 1982). Some species (for example, Washington hawthorn) lack thickened endocarps and can germinate without acid scarification (Bir 1992; Brinkman 1974; Dirr and Heuser 1987; Hartmann and others 2002). In contrast, other hawthorns exhibit highly thickened endocarps (up to 0.5 cm) and require up to 7 to 8 hours of acid scarification (Dirr and Heuser 1987) before other germination pretreatments can be imposed. Table 4 summarizes pregermination treatments that have been tested on various species of *Crataegus*.

Tipton and Pedroza (1986) studied germination requirements of Tracy hawthorn and failed to achieve germination > 54% in seeds pretreated with acid scarification for up to 4.5 hours, in combination with other pretreatments (table 4). They speculated that a combination of longer durations of acid scarification (for example, > 4.5 hours), lower germination chamber temperatures (for example, < 16 °C), shorter durations of warm stratification (for example, 0 to 60 days), and longer durations of cold stratification (for example, 100 to 322 days) might improve germination in this species. The low germination percentages observed may have been due to embryo decay caused by excessively long periods of warm stratification or high temperatures in the germination chamber, in combination with incomplete modification of the endocarp due to an inadequate duration of acid scarification. Interestingly, some seeds germinated during cold stratification before being placed into the germination chambers.

Morgenson (1999) noted differential responses of 3 hawthorns to acid scarification, as well as warm and cold stratification pretreatments. Specifically, he found that

Table 3—*Crataegus,* hawthorn: seed yield data

Species	Provenance	Seed wt/fruit wt		Average cleaned seeds/wt		Samples
		kg/kg	lb/100 lb	/kg	/lb

although 2 hours of acid scarification did not enhance seed germination of Arnold and downy hawthorns, some beneficial effects on seed germination in fireberry hawthorn were noted, especially in combination with warm and cold stratification pretreatments. Germination of both Arnold and downy hawthorn seeds was optimized under a 60-day warm and 120-day (or more) cold stratification regime, with 37 and 51% germination occurring, respectively. For fireberry hawthorns, 90 to 120 days of warm stratification, followed by 120 to 180 days of cold stratification resulted in 18 to 27% germination. In all 3 species tested, extreme radicle elongation was observed in some treatments, for example, in all 120-day cold stratification combination treatments for fireberry hawthorns, and in some 60 and 120-day cold stratification combination treatments for Arnold and downy hawthorns.

In *C. azarolus* L., cold stratification treatments reduced abscisic acid (ABA) content in seeds, especially during the first 20 days, but only yielded 24% germination (Qrunfleh 1991). Work in England with oneseed, cockspur, plumleaf, and scarlet hawthorns resulted in as much as 80% germination (see table 4 for pregermination treatments) (St. John 1982). Using alternating 3-month periods of warm stratification at 21°C and cold stratification at 4 °C, seeds of oneseed hawthorn exhibited 31% germination after a warm-cold cycle and 55% after a cold-warm-cold-warm-cold cycle (Deno 1993). Utilizing these alternating cold-warm regimes with Washington hawthorn, 50% germination was attained with a warm-cold scheme, and 51% germination occurred with cold stratification only (Deno 1993). This latter result for Washington hawthorn agreed with data reported by Brinkman (1974). Studying seeds of downy hawthorn sown into old-field vegetation patches, Burton and Bazzaz (1991) noted a negative correlation between germination percentage and the quantity of plant litter on the soil surface. This suggested that seed germination in downy hawthorn may be inhibited by the presence of organic acids or allelochemicals released by decaying organic matter.

Official seed testing prescriptions are in place for only 2 species. AOSA (1993) recommends 2 hours of soaking in concentrated sulfuric acid, followed by 90 days of incubation at room temperature and then 120 days of moist-prechilling for downy hawthorn. Germination should then be tested on moist blotters or creped paper at 20/30 °C for 14 days. For oneseed hawthorn, ISTA (1993) prescribes 90 days of incubation at 25 °C, followed by 9 months of moist-prechilling at 3 to 5 °C. Germination is to be tested in sand at 20/30 °C for 28 days. Both organizations also allow tetrazolium staining to determine viability as an alternative to actual tests. For all hawthorn species, ISTA (1996) recommends cutting transversely one-third from the distal end of the seeds, then incubating for 20 to 24 hours in a 1% solution at 30 °C. The embryos must be excised for evaluation. Maximum unstained tissue is one-third the distal end and the radicle tip. Some germination test results are summarized in table 5.

Because hawthorns produce apomictic seeds, reports have appeared on clonal production of plants by seed propagation (Hartmann and others 2002). In western mayhaw, this phenomenon occurs widely because of the production of nucellar embryos and may be exploitable for production of superior clones (Payne and Krewer 1990; Payne and others 1990). Further study of apomixis in *Crataegus* is needed.

Nursery practice. Hawthorns are produced in nurseries utilizing both sexual and asexual propagation techniques. In horticulture, sexual propagation of hawthorns (via seeds) is important for production of large numbers of rootstocks, to which superior, clonal scions (often cultivars) are budded (Bush and others 1991; Dirr and Heuser 1987). In particular, this is necessary for rapid build-up of clonal orchards of desirable species of hawthorns (such as those with potential pomological interest), for which there are limited scion material and little knowledge of vegetative propagation by stem cuttings. Western mayhaw is a good example of such a species (Bush and others 1991). Brinkman (1974)

recommended that if controlled seed pretreatment regimes (such as stored refrigerated conditions) are not used by nurseries, seeds should be sown in early fall (versus spring) to satisfy any potential requirements for cold stratification. This may be an adequate generalization for many hawthorns, although it is important to note the aforementioned exceptions for those species (for example, those from warm temperate climates) that will germinate either in shorter time periods without the cumbersome waiting periods involved in cold stratification or through innovative seed pretreatment techniques such as fermentation.

Research on vegetative propagation of hawthorns by stem cuttings is limited. Dirr and Heuser (1987) reported previous efforts as being "rarely successful," whereas Dirr

(1998) and Hartmann and others (2002) make no mention of stem cutting propagation. However, 35% rooting was achieved utilizing softwood stem cuttings of 2 cultivars of western mayhaw—'Super Spur' and 'T.O. Super Berry'—treated with 8,000 ppm of the potassium (K) salt of indolebutyric acid (IBA) in combination with 2,000 ppm of the K salt of naphthaleneacetic acid (NAA) (Payne and Krewer 1990). Hardwood stem cuttings of this species (no clone specified) exhibited poor rooting, with callus visible 12 weeks after sticking cuttings, and ultimately only 10% rooting occurring (Bush and others 1991). However, softwood stem cuttings taken from new growth in mid-spring (in Calhoun, Louisiana) rooted in percentages > 80% in 8 weeks under intermittent mist. No differences in rooting occurred for cuttings treated with talc formulations of 0, 3,000, or 8,000 ppm IBA (Bush and others 1991). Clearly, these latter results suggest potential for developing readily producible clonal hawthorns by stem cuttings. If so, this could reduce the importance of seed-propagated hawthorns.

Vegetative propagation of hawthorns by grafting and budding is used widely in the horticulture industry. T-budding is one of the most viable vegetative propagation procedures employed for a wide range of cultivars of hawthorns (Dirr and Heuser 1987; Hartmann and others 2002). Root-grafting is also mentioned (Hartmann and others 2002) but rarely practiced. In the United States, Washington hawthorn is the "universal" rootstock, due to the fact that (a) seedlings are commonly available (because seeds of this hawthorn species germinate more easily than those of other species) and (b) bark-slippage occurs over a long season (late summer to early fall) (Dirr and Heuser 1987). Cultivars budded onto Washington hawthorn can be expected to grow 0.9 to 1.2 m in the growing season following budding (Dirr and Heuser 1987). Cultivars of European species (for example, English and oneseed hawthorns) should be budded onto rootstocks of European species, whereas hawthorns native to North America should be budded onto rootstocks of North American species (Dirr and Heuser 1987; Hartmann and others 2002). Aside from these constraints, T-budded hawthorns appear to be highly compatible across many species.

Several grafting procedures are employed (rather than budding procedures) in production of plants of mayhaw. Cleft grafts for larger rootstocks or whip-and-tongue grafts for small diameter rootstocks are used widely in late winter (Payne and Krewer 1990). In Louisiana, cleft grafting is the most popular grafting method used for western mayhaw (Bush and others 1991). Other species, such as parsley, cockspur, Washington, and yellow hawthorns, also can be used as rootstocks for mayhaws (in particular, western mayhaw) due to graft compatibility (Payne and Krewer 1990).

Brinkman (1974) called for additional trials on hawthorns to acquire more knowledge on seed biology. However, little comprehensive research has been conducted in the intervening 30 years on this subject. Much work remains to be done before a comprehensive understanding of propagation of hawthorns will be possible.

Taxodiaceae—Redwood family

Cryptomeria japonica (L. f.) D. Don

sugi or cryptomeria

Gerald A. Walters and John K. Francis

Dr. Walters retired from the USDA Forest Service; Dr. Francis retired from the USDA Forest Service's International Institute of Tropical Forestry

Synonyms. *C. fortunei* Hooibrenk, *C. mairei* (Leveille) Nakai, *C. kawaii* Hayata, *Cupressus japonica* L. f., *Cupressus mairei* Leveille.

Other common names. Japanese cryptomeria, Japanese-cedar, goddess-of-mercy-fir, peacock-pine.

Growth habit, occurrence, and use. *Cryptomeria* is a monotypic genus native of Japan and China (Streets 1956). *Sugi—Cryptomeria japonica* [L. f.] D. Don—has been cultivated there since about 1300 A.D. for timber, shelterbelts, and environmental forestry. It was introduced to Hawaii for the same purposes about 1870 by Japanese immigrants (Carlson and Bryan 1959). An evergreen tree, it reaches heights of 36 to 46 m (Carlson and Bryan 1959; Dallimore and Jackson 1967; Troup 1921). Its wood is soft and fragrant; the red heartwood is strong and durable (Dallimore and Jackson 1967). It is used for boxes, poles, and general construction (Tsutsumi and others 1982). This species is also used for Christmas trees (Carlson and Bryan 1959; Dallimore and Jackson 1967).

Flowering and fruiting. Sugi is a monoecious species, with the male and female strobili located on different parts of the same branch. The female strobili are formed in fall and are fertilized when pollen is shed the following spring (Dallimore and Jackson 1967). Seed weight and percentage filled seeds are higher and seedling growth rate is greater when flowers are wind-pollinated (outcrossed) rather than selfed (Tabachi and Furukoshi 1983). In the native range in Japan, female cones begin to open between late January and mid-February and flower for 54 to 57 days. The male strobili begin to open about 25 days after the female strobili (Hashizume 1973). The solitary cones are globular and measure 13 to 19 mm in diameter. In Hawaii, cones ripen from July to September.

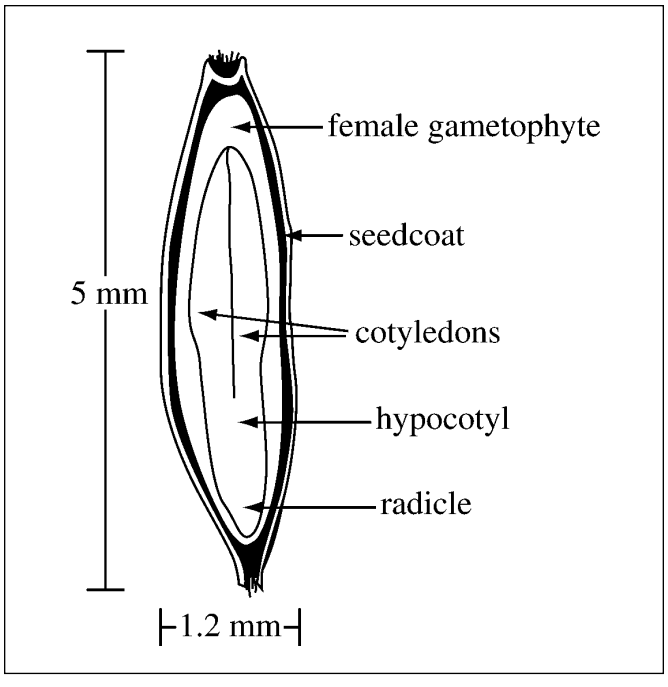
Seeds are shed during the same periods (Walters 1974). The seeds are dark brown and triangular, measuring 4 to 6 mm long and about 3 mm wide (Dallimore and Jackson 1967) (figures 1 and 2). Trees generally begin to produce seeds when 15 to 20 years old (Carlson and Bryan 1959). A 3-year-old orchard of rooted cuttings in Japan that was sprayed with gibberellic acid produced 1,082 kg/ha of seeds (967 lb/ac) 11 months later; 46% of the seeds were sound and 45% germinated (Itoo and Katsuta 1986).

Collection, cleaning, and storage. When the cones turn from grayish brown to reddish brown, they are ripe and should be picked. Cones should be immediately spread out to finish ripening. As the cones dry, seeds fall into trays; agitation aids in seed extraction. Seeds can be separated from chaff by winnowing. The number of seeds per weight ranges from 700,000 to 1,200,000/kg (320,000 to 550,000/lb) (Walters 1974; Ohmasa 1956). The optimal moisture content for storage is 10% (Shi 1985). After drying, the seeds should be stored in sealed polyethylene bags at 2 to 5 °C (Walters 1974). A drying agent placed in the bag aids storage (Ohmasa 1956).

Germination. Sugi seed germination is considered poor to very poor (Parry 1956). In Japan, the standard of sowing—30 g/m² (0.1 oz/ft²)—is based on 30% germination (Ohmasa 1956). Sugi seeds should be soaked in cold water (0 °C) for about half a day, then put moist into plastic bags, and stored at 1 °C for 60 to 90 days before sowing (Walters 1974). Bags should be left open for adequate aeration. A mild fungicide can be added (Ohmasa 1956). Constant day/night temperature, whether high or low, adversely affects germination (RFC 1973). Germination is better in

Figure 1—*Cryptomeria japonica*, sugi: seed.

Figure 2—*Cryptomeria japonica*, sugi: longitudinal section through a seed.



seeds kept in the light than seeds kept in the dark (Chettri and others 1987). Official test prescriptions for sugi call for germination on top of moist blotters at alternating temperatures of 20 and 30 °C for 28 days; no pretreatment is necessary (ISTA 1993).

Nursery and field practice. Sugi seeds are sown in Hawaii from November to March. Sowing is by the broadcast method or by using a planter that has been adjusted to the proper seed size. The planter places seeds in rows about 15 to 20 cm (6 to 7 in) apart. Seeds are covered with 3 to 6 mm (1 to $2^1/_2$ in) of soil (Ohmasa 1956; Walters 1974). No mulch is used in Hawaii (Walters 1974), but a single layer of straw is used in Japan (Ohmasa 1956). The seedbeds are given about 75% shade for about 2 months (Walters 1974). Seedling density in the beds is about 220 to 330 seedlings/m^2 (20 to 30/ft^2). Frost damage to seedlings in early winter can be avoided by shading or shortening the daily period of exposure to solar radiation (Horiuchi and Sakai 1978). Seedlings are outplanted as 1+0 stock in Hawaii (Walters 1974). Sugi can be started from cuttings (Carlson 1959). In an experiment in which the trees were measured after more than 26 years, there was no significant difference in any measure of growth between trees started from seeds and those started from cuttings (Yang and Wang 1984).

Cupressaceae—Cypress family

Cupressus L.

cypress

LeRoy C. Johnson and Robert P. Karrfalt

Mr. Johnson retired from the Pacific Southwest Forest and Range Experiment Station; Mr. Karrfalt is director of the USDA Forest Service's National Seed Laboratory, Dry Branch, Georgia

Growth habit, occurrence, and use. The true cypresses—genus *Cupressus* L.—are evergreen trees or shrubs native to the warm temperate areas of the Northern Hemisphere. The genus comprises about 15 species distributed throughout the western United States, Mexico, northern Central America, the Mediterranean region, northern Africa, and from southern Asia to Japan (Bailey 1923; Dallimore and Jackson 1967; Little 1966, 1979; Raizada and Sahni 1960; Wolf and Wagener 1948). The species native to North America are referred to as New World cypresses and those native to Europe, Africa, and Asia, as Old World cypresses (Gauseen 1968; Wolf and Wagener 1948).

Most New World cypresses are restricted in their occurrence (table 1). McNab and Sargent cypresses are often associated with serpentine soils (Griffin and Stone 1967; Hardham 1962). Arizona cypress and its subspecies are found in large stands confined mainly to north slopes, coves, benches, and canyon bottoms (Sudworth 1915). All reach their maximum sizes in moist, sheltered canyon bottoms. Of the 10 species, subspecies, and varieties native to California, none grow in large pure stands.

In the United States, cypresses are commercially propagated mainly for landscaping, Christmas trees, erosion control, windbreaks, and to a minor extent for lumber, fenceposts, fuelwood, and railroad ties. A factor limiting the widespread planting of cypresses in some parts of the United States is the cypress canker—*Seiridium cardinale* (W. Wegener) Sutton & I. Gibson—which attacks most species of cypress (Wolf and Wagener 1948). In California, this disease has eliminated some plantations of Monterey cypress. Only resistant species or strains of cypress should be planted where the cypress canker disease exists. In the South, Arizona cypress was at one time seriously considered for Christmas tree production (Goggans and Posey 1968; Grigsby 1969; Linnartz 1964; Posey and Goggans 1967), but its susceptibility to a foliage blight caused by *Cercospora sequoiae* Ellis & Everh. (Hepting 1971) has eroded this interest.

In Africa and New Zealand, Mexican and Monterey cypresses are planted for lumber and pulp production (Bannister 1962; Bannister and Orman 1960; Paterson 1963). Mexican cypress has become commercially important in Ethiopia, Kenya, and Tanzania (Bergsten and Sundberg 1990). Himalayan cypress is planted for timber, fuelwood, windbreaks, and animal fodder in Asia (Von Carlowitz 1986).

Italian cypress is the most widely planted of all the cypresses. It has been cultivated since ancient times (Bailey 1923; Bolotin 1964a); its columnar form and dark green foliage make it a popular tree for planting in formal gardens, along roads, and in cemeteries. This variety is propagated by seeds or cuttings. Seeds collected from pure stands or isolated columnar form varieties will breed true (Bolotin 1964b). The unusually narrow crown results from the ascending branches, which almost parallel the main trunk (table 2).

Monterey cypress is also extensively used in landscaping in spite of its high susceptibility to cypress canker disease. The rapid growth, lush green foliage, and dense crown make it ideally suited for planting around buildings, in windbreaks, and along roadsides.

Flowering and fruiting. Cypresses are monoecious. Staminate and ovulate strobili are produced on the ends of short twigs or branchlets. The staminate strobili are 3 to 7 mm long, cylindrical or oblong, and light green or rarely red. They become yellow as pollen-shedding time nears. Ovulate strobili at time of pollination are less than 6 mm long, subglobose to cylindrical, erect, greenish, and have 6 to 12 (rarely 14) distichously arranged scales. At maturity they may be 15 to 25 mm long.

Pollen is shed in late fall, winter, and spring. Planted trees of Arizona and Guadeloupe cypresses growing in the Eddy Arboretum, Placerville, California, shed their pollen in

Sources: Johnson (1974), Sargent (1965), Sudworth (1967).

October and November (Johnson 1974). Native trees of Sargent cypress at Bonnie Doon, California, pollinate in December, and Monterey cypress at Point Cypress, California, pollinate in March (Johnson 1974).

The ovulate cones and their seeds ripen the second year, some 15 to 18 months after pollination. Mature cones (figure 1) are up to 30 mm in diameter, woody or leathery, and the peltate scales usually have a central mucro. Each cone produces 12 to 150 seeds (table 3).

Precocious cone production characterizes this genus. Male cones have developed on 1- and 2-year-old seedlings of Gowen and Mendocino cypresses, respectively (McMillan 1952). Female cone production often begins on trees younger than 10 years (Magini and Tulstrup 1955; McMillan 1952), but collectable quantities are usually not produced at such an early age. Treatment of seedlings of some species with various gibberellins can stimulate precocious flowering to a great degree. Mendocino, Mexican, and

Table 2—*Cupressus*, cypress: growth habit, height, cone and seed ripeness criteria

Species	Growth habit	Height at maturity (m)	Year first cultivated	Color ripeness criteria: Cones	Color ripeness criteria: Seed
C. arizonica	Straight central leader	15–21	1882	Dull gray to brown, sometimes purple	Medium to dark brown or deep purplish brown
ssp. *arizonica*	Straight trunk with or without turned up side branches	8–15	ca. 1909	Glaucous bloom over rich dark brown	Medium tan to brown or red brown
ssp. *nevadensi*	Erect tree with pyramidal crown	6–15	1930	Glaucous or silver gray	Rich light tan
ssp. *stephensonii*	Erect tree with straight central leader	9–15	1900	Dull gray or brown	Very dark brown
C. bakeri	Single stem, narrow crown	9–15	1917	Grayish to dull brown	Light tan
C. forbesii	Erect, irregularly branched tree	4.5–9	1927	Dull brown or gray	Rich dark brown
C. goveniana	Shrublike to small tree with single stem	6–18	1846	Brown to gray brown	Dull dark brown to nearly black
ssp. *pygmaea*	Shrublike to medium-sized tree	9–46	—	Weathered gray	Jet black to brownish
C. guadalupensis	Broad crown, trunk forking	12–20	ca. 1879	—	Dark brown & glaucous
C. lusitanica	Erect straight trunk with drooping branches	30	ca. 1670	Dull brown	Rich light tan
C. macnabiana	Brown crown lacking main trunk	6–12	1854	Brownish gray	Medium brown to glaucous brown
C. macrocarpa	Single trunk; symmetrical in sheltered areas	8–27	1838	Brown	Dark brown
C. sargentii	Single stem, slender or bushy tree	9–23	1908	Dull brown or gray often glaucous	Dark brown
C. sempervirens	Columnar with branches parallel to main trunk	46	B.C.	Shiny brown or grayish	—
var. *horizontalis*	Single stem with spreading crown	46	B.C.	Shiny brown or grayish	—

Sources: Dallimore and Jackson (1967), Raizada and Sahni (1960), Sargent (1965), Sudworth (1915), Wolf and Wagener (1948).

Arizona cypresses produced staminate strobili on seedlings 7 to 9 months old after foliar applications of gibberellin (GA_3), whereas the latter 2 species produced ovulate strobili at ages less than 24 months (Pharis and Morf 1967). Most native and planted cypresses produce an abundance of female cones. Guadelupe cypress rarely produces female cones under cultivation (Wolf and Wagener 1948), but the close relative, tecate cypress from Baja California, does (Johnson 1974). Occasional trees appear sterile, but this phenomenon is usually correlated with extremely heavy male cone production (Johnson 1974). Most cypresses have serotinous cones. Arizona and Italian cypresses open and shed their seeds when the cones ripen (Wolf and Wagener 1948). Cones on some trees within a stand will open and shed their seeds in July (Posey and Goggans 1967).

There is little information on the cone and seed insects that damage seed production in cypress. Larvae of the cypress bark moth—*Laspeyresia cupressana* Kearfott—are known to feed on maturing seeds of Gowen and Monterey cypresses and have earned the common name of "seedworm." Similar damage has been recorded on Monterey cypress from larvae of the moth *Henricus macrocarpan*a Walsingham (Hedlin and others 1980). Over a dozen microorganisms have been identified in association with cypress seeds (Mittal and others 1990), but their effects on seed production, if any, are not known.

Cypress seeds vary widely in shape and size (figures 2 and 3). Length with wings attached ranges from 2 to 8 mm; width dimensions are slightly less. Seeds are flattened or lense shaped, and the wings are tegumentary extensions of the seedcoat. Seed length within a cone of Sargent cypress ranged from 2 to 5 mm (Johnson 1974). X-ray examination of bulk collections of several species showed that the smallest seeds were hollow (Johnson 1974). This phenomenon is most likely caused by lack of pollination or abortion after pollination (Johnson 1974).

Seed color is an important criterion for determining ripeness and an aid in differentiating species (table 2). Some species and geographic sources within a species can be distinguished by seed color. Seeds of Mendocino cypress from the central coast of Mendocino Co., California, have shiny jet-black seedcoats; seeds of the Anchor Bay strain from southern Mendocino Co. have brownish black seedcoats. Seeds of Guadalupe and tecate cypresses have the same

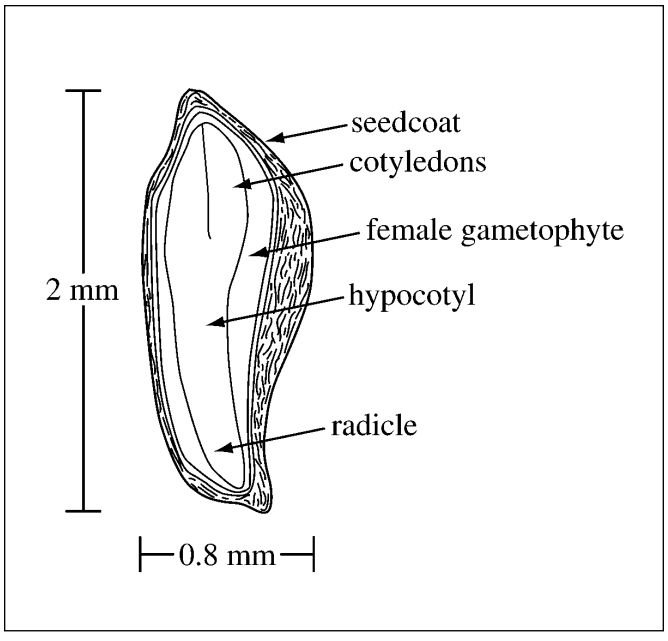
color, but seeds of Guadalupe cypress have a glaucous bloom and those of tecate cypress are shiny (Wolf and Wagener 1948).

Collection of cones. Mature cones are normally collected by hand from standing trees, usually by cutting clusters of cones with hand clippers. To ensure that the seeds are mature, only seeds from cones that matured the previous season or seeds with thoroughly darkened coats from the current season should be collected (Wolf and Wagner 1948). Goggans and others (1974) confirmed this rule in collections of Arizona cypress made in Alabama plantations. Cones that had turned gray in Alabama were over 5 years old and yielded seeds of quality not much better than immature cones. It is advisable, therefore, to collect only cones 4 years old and younger. Insect-damaged cones should not be collected because they do not readily open, and many of the seeds have been destroyed by the insects (Wolf and Wagener 1948). The time of year for collecting cones for most species is not critical if older cones are collected. Seeds of Italian cypress and some Arizona cypress sspp. are

Figure 3—*Cupressus arizonica*, Arizona cypress: longitudinal section through a seed.



shed when the cones are mature, so they must be collected as soon as they ripen. Cone and seed color aid in determining when the seeds are ripe (table 2).

Extraction and storage of seed. Cypress cones must be dried for the seeds to be released. Cones dried at room temperature 22 °C require 1 to 2 months for the scales to separate and the seeds to fall out (Posey and Goggans 1967). The process of cone opening can be speeded up by boiling the cones for 30 to 60 seconds or cutting each cone in half. Either method hastens the process of cone opening by several weeks. Clusters of cones should be cut apart so the scales can freely separate.

Sun-drying is another good method, provided the weather is hot and dry. Ripe cones of Gowen and Monterey cypresses collected in July were stored in a refrigerator at 1 °C for 2 days, then placed in trays. The cones opened and shed their seeds within 2 weeks when sun-dried in day temperatures of 32 to 35 °C with relative humidity ranging from 20 to 39% (Johnson 1974). Case-hardening is a potential hazard when sun-drying. This problem is minimized or eliminated by storing the cones for several days in a refrigerator, which will act as a desiccator.

Seeds fall out readily from completely mature cones with little or no tumbling. Insect-attacked and immature cones keep their seeds tightly attached to the cone scales, but such seeds usually have low viability and are best discarded with the cones. De-winging is not necessary, as the seeds have minute or no wings.

The percentage of filled seeds varies widely among species and among individuals within a species (table 4). Values for Arizona cypress ranged from 10 to 29% filled seeds, whereas those for the subspecies Arizona smooth cypress ranged from 1 to 49% filled seeds (Goggans and Posey 1968). Major improvements in seed quality can result from careful cleaning that minimizes loss of good seeds. This may be done with either a well-controlled air separation or a specific gravity table. Bergsten and Sundberg (1990) reported an upgrading of a Mexican cypress seedlot from 20 to 60% filled seeds with incubate-dry-separate (IDS) techniques (see chapter 3).

Cypress seeds are orthodox in storage behavior and maintain viability very well at low temperatures and moisture contents. There are no long-term storage test data available, but seeds of 7 species of cypress retained good viability during 10 to 20 years storage at temperatures of 1 to 5 °C (Johnson 1974; Schubert 1954; Toumey and Stevens 1928).

Pregermination treatments. Seeds of most cypress species exhibit some dormancy, and treatments are required for prompt germination. Ceccherini and others (1998) reported that, for 14 species of cypress, 30 days of stratification at 20 °C stimulated seed germination of all except Guadalupe cypress, and that the greatest benefit was shown by Monterey and Arizona smooth cypresses. At the USDA Forest Service's Institute of Forest Genetics at Placerville, California, seeds were stratified for 30 days at 1 °C (Johnson 1974). Stratification for 60 to 90 days has been recommended for Monterey cypress (Von Carlowitz 1986). Goggans and others (1974) also found 30 days of prechilling effective in breaking dormancy of Arizona cypress. The stratification was supplemented slightly by first soaking the seeds in a 0.1% citric acid solution. When time was short, a 72-hour water soak gave some benefit over just a 24-hour water soak. Seeds are often heavily contaminated with mold and bacteria, but control of the mold is feasible with fungicides during stratification and germination. Local extension experts should be consulted for current treatment recommendations. Treated medium and seeds can then be stored in plastic bags, jars, or petri dishes for the duration of the stratification period. Seeds stratified in a petri dish can be germinated in the same dish.

Germination. Germination should be tested with seeds placed on the top of moist blotters. ISTA (1993) recommends alternating temperatures of 30 °C (day) for 8 hours and 20 °C (night) for 16 hours for Arizona and Monterey cypresses, and a constant 20 °C for Italian cypress. Test periods of 28 days are prescribed for Arizona and Italian cypresses and 35 days for Monterey cypress.

Source: Johnson (1974).

* Soundness was determined by x-radiography examination before stratification (Johnson 1974).

Because of variable dormancy, AOSA (1998) also recommends paired tests for Arizona cypress, using unstratified and stratified (21 days) samples for each lot. Official test prescriptions have not been developed for the other cypress species, but similar conditions should be sufficient. For unstratified Himalayan cypress seeds (Rao 1988), the use of the alternating germination temperatures of 21 °C daytime and 9 °C night time gave 60% germination compared to 33% germination at constant 25 °C. Although light appears to be important, prechilling and alternating temperatures are the more significant promoters of germination. Light did not appear necessary for seeds of Arizona cypress (Goggans 1974). The seeds can be watered throughout the test with a mild solution of fungicide (the same formulation used above) with no phytotoxicity. Germination test results (table 4) have been low primarily because of the low percentages of sound seed that are common among seed lots of cypress. Good estimates of germination can be made with x-ray analysis of fresh seeds of Italian, Mexican, and Arizona cypresses (Bergsten and Sundberg 1990; Chavagnat and Bastien 1991).

Nursery practice. Fall-sowing of cypress seeds has been recommended (Johnson 1974; Wolf and Wagener 1948), but spring-sowing of stratified seeds is preferred. Germination of cypress is epigeal. Seeds should be sprinkled on the nurserybed and covered with a 4 to 5 mm (0.15 to 0.20 in) layer of soil and a light mulch. A density of 320 to 640/m^2 (30 to 60/ft^2) is recommended. Zeide (1977) was successful in direct seeding Italian cypress in Israel—annual precipitation, 447 mm (18 in)—in plots that were "mulched" with light colored stones of 2 to 5 cm ($^3/_4$ to 2 in) diameters. The seedlings grew out from under the stones.

Newly germinated cypress seedlings are particularly susceptible to damping-off fungus. When possible, nursery soil should be fumigated. As an added precaution, a fungicide should be used immediately after sowing and until the seedling stems become woody, which takes about 1 month's time. Cypresses can be outplanted as 1- or 2-year-old seedlings. A well-defined taproot and numerous lateral roots are formed in the first year. One-year-old seedlings of most species have only juvenile foliage.

Some species can be propagated vegetatively. Monterey cypress cuttings treated with indole-butyric acid (IBA) root well, whereas Italian cypress cuttings root well without treatment (Dirr and Heuser 1987).

C

Fabaceae—Pea family

Cytisus scoparius (L.) Link

Scotch broom

Susan E. Meyer

Dr. Meyer is a research ecologist at the USDA Forest Service's Rocky Mountain Research Station, Shrub Sciences Laboratory, Provo, Utah

Growth habit, occurrence, and uses. The genus *Cytisus* comprises about 80 species native to Eurasia and North Africa. Many are cultivated as ornamentals, and several of these have become more or less naturalized in the United States, especially in California (Munz and Keck 1959). Scotch broom—*C. scoparius* (L.) Link—was planted extensively for erosion control during the first half of the century (Gill and Pogge 1974) but is now considered a serious invasive weed throughout the range of its introduction in North America, Australia, and New Zealand (Bossard 1991). It has become the dominant species on several hundred thousand hectares of coastal and cis-montane vegetation, from Santa Barbara, California, north to British Columbia. It is a drought-deciduous shrub with angled, photosynthetic stems that is able to root-sprout following fire (Bossard and Rejmanek 1994; Gonzales-Andres and Ortiz 1997). It is largely useless as a browse-plant because of its toxic foliage, a feature that may permit it to increase at the expense of more palatable species (Bossard and Rejmanek 1994; Gill and Pogge 1974). It increases in response to disturbance of native vegetation and is also a serious weed problem in pine plantations in California and New Zealand.

However, because of its beauty and exceptional summer drought-hardiness, Scotch broom is considered valuable as an ornamental shrub for low-maintenance landscapes. The species is very showy in flower and its evergreen stems add interest to winter landscapes. There are over 60 named varieties (Wyman 1986).

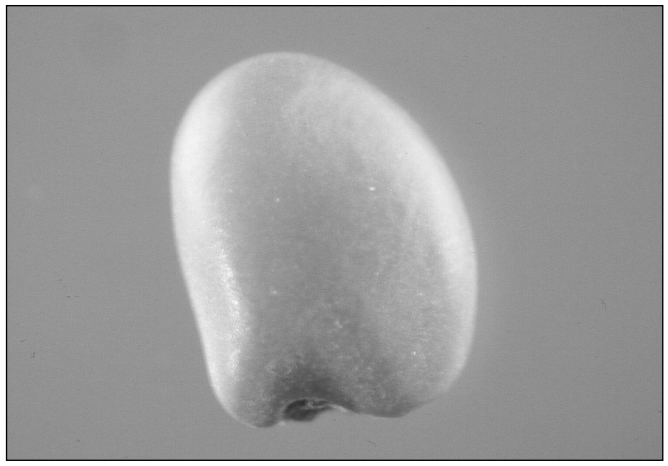
Flowering and fruiting. The perfect flowers are of typical pea-family form and appear on the plants in great profusion in May and June. Each flower must be "tripped" by an appropriate pollinator for fertilization to take place, so the mutualistic relationship with honey bees (*Apis mellifer*a L.) and native bumble bees is essentially obligatory (Parker 1997). Other native North American insects seem to ignore its fragrant blossoms, preferring to work the flowers of indigenous species. The result is that seed production may be severely pollinator-limited (Parker 1997). In spite of this, the plants may produce a prodigious number of seeds; the estimated mean annual production per plant was about 10,000 seeds in 2 California populations (Bossard and Rejmanek 1994). Host-specific pre-dispersal seed predators from Europe (a seed weevil and a bruchid beetle) have been introduced for biocontrol of Scotch broom in the Northwest, but so far these introductions have been largely ineffective, possibly because of asynchrony in the phenology of host and seed predator (Bravo 1980).

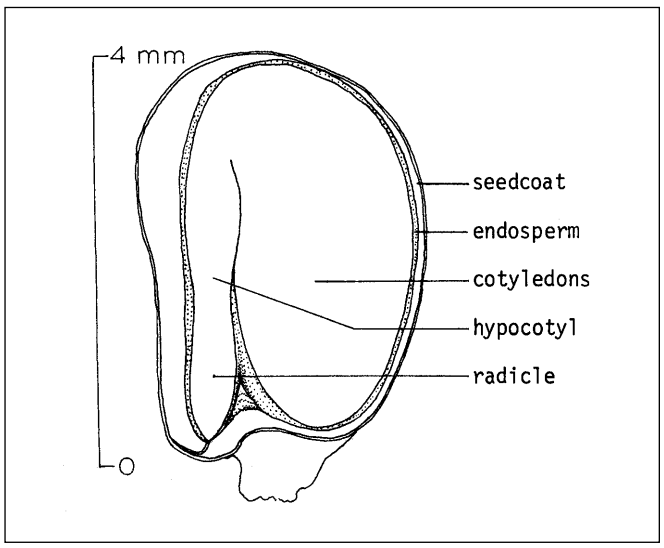
Plants reach reproductive maturity at about 4 years of age (Gill and Pogge 1974). The 5- or 6-seeded legumes (pods) ripen in August, and seeds are dispersed in September. The legumes open abruptly with a springing motion, vaulting the seeds some distance from the plant (Bossard 1991; Bossard and Rejmanek 1994). The seeds possess a strophiole or elaiosome at the hilar end (figure 1) and are secondarily dispersed by ants (Bossard 1991; Weiss 1909). At 2 California study sites, seeds were taken by mice and by ground-feeding birds, but these organisms were strictly seed predators and did not function as dispersers (Bossard 1991).

Seeds of Scotch broom have the capacity to form a persistent seed bank. Bossard (1993) found in seed retrieval experiments that 65% germinated the first year after dispersal, 20% germinated the second year, and 10% germinated the third year. About 5% of the seed population carried over for more than 3 years.

Seed collection, cleaning, and storage. After the fruits ripen but before they disperse, the legumes may be hand-stripped or picked up from beneath plants. They should be spread to dry, threshed, and screened to separate the seeds (Gill and Pogge 1974). Reported seed weights have averaged 125 seeds/g (57,500/lb) in 9 samples, and viability averaged 80% in 5 samples (Gill and Pogge 1974).

Figure 1—*Cytisus scoparius*, Scotch broom: longitudinal section through a seed (**bottom**) and exterior view (**top**).





No long-term storage data are available, but the seeds are orthodox and remain viable for many years in storage.

Germination and seed testing. Scotch broom seeds have water-impermeable (hard) seedcoats and require pretreatment in order to germinate. Once the seedcoats have been made permeable, the seeds germinate well over a wide range of temperatures and do not require any further pretreatment (Bossard 1993). Mechanical and acid scarification have been used to remove hard-seededness in this species, and the official seed-testing rules call for cutting or nicking the seedcoat at the cotyledon end, then soaking in water for 3 hours (ISTA 1993). Tests should be carried out on the tops of moist paper blotters for 28 days at 20/30 °C. More recently, the effect of heat on hard-seededness in Scotch broom has received attention. Tarrega and others (1992) report that dry-heating the seeds was as effective as mechanical scarification in terms of final percentage. Optimum time of heating varied with temperature from 1 minute at 130 °C to 15 minutes at 70 °C. Abdullah and others (1989) reported that repeated brief (3-second) immersion in boiling water resulted in complete elimination of hard-seededness, but low germination percentages indicated that some damage was occurring. They found that alternating the boiling water treatments with freezing treatments (immersion in liquid nitrogen for 15 seconds) resulted in the highest germination percentages as well as in complete removal of hard-seededness. This result was confirmed by Bossard (1993), who found that vigor of seedlings from hot/cold–treated seeds was much higher than that of seedlings from seeds subjected to dry heat only.

Nursery practice. Scotch broom is normally propagated from cuttings for ornamental planting in order to preserve varietal characters (Wyman 1986). If seed propagation is desired, seeds should be pretreated to remove hard-seededness prior to planting (Gill and Pogge 1974). The roots are delicate, and plants are more easily produced in container culture than as bareroot stock (Wyman 1986).

D

Fabaceae—Pea family

Delonix regia (Bojer ex Hook.) Raf.

flamboyan

J. A. Vozzo

Dr. Vozzo retired from the USDA Forest Service's Southern Research Station

Other common names. royal poinciana, flametree.

Occurrence and growth habit. A popular ornamental throughout the tropics, flamboyan—*Delonix regia* (Bojer ex Hook.) Raf.—is a small to medium-sized tree, typically 7 to 16 m high and up to 60 cm in diameter (Little and Wadsworth 1964). The champion Puerto Rican flamboyan, however, is 32 m high and 105 cm in diameter (Francis 1994). It grows well in moist soil derived from limestone, where it is common and reproduces well, but it is also tolerant of well-drained and somewhat droughty conditions (Francis and Liogier 1991). The species is briefly deciduous. Flamboyan has prominent buttresses and a broad, flat crown when grown in full sun. Its shallow but spreading root system limits the sites where it may be planted. The tree is susceptible to termites, shoot borers, and heart rot (Webb and others 1984). Although the genus is reported to have 3 species, flamboyan is the most cosmopolitan. A native of Madagascar, it has been planted in nearly every country in frost-free areas and is perhaps the most important flowering ornamental tropical tree of the world (Meninger 1962).

Use. This is a beautiful tree in form, shade, and flower. The flowers are predominantly red, although yellow and orange forms are cultivated; they are relatively short-lived as cut flowers. Trees remain in flower for several weeks, however. They are often seen planted along roadsides as living fence posts or as shade trees on both sides of the road that arch over the entire road. The wood is yellow-brown, weak, brittle, and soft, with a specific gravity of about 0.3. Although the species is not a good timber source, the wood is widely used as firewood. The legume (pod) is edible (Little and Wadsworth 1964; Menninger 1962; Webb and others 1984).

Flowering and fruiting. Showy flowers follow a dry season when the tree is almost leafless. The 5-pointed calyx is hairy and borne on racemes 15 to 25 cm long. Flowers are commonly red but may be white, yellow, orange, or yellow and vary from 8 to 25 cm across. Although flowers form after the dry season and during the wet season, they persist during leaf emergence so that the crown appears feathery green while the colorful flowers are dominant. The hard legumes are 35 to 50 cm long, 6 cm wide, and 5 mm thick, and they hang tenuously on trees year-round. When mature, the legumes split into 2 parts lengthwise and are dark brown to black (Little and Wadsworth 1964); seeds (figures 1 and 2) are shed at that time. There are about 4,500 seeds/kg (2,040/lb) from Puerto Rican sources (Marrero 1949), whereas Colombian sources report only 2,000 to 3,000 seeds/kg (900 to 1,360/lb) (Navarette nd).

Collection, extraction, and storage. Pruning poles should be used to collect dark brown to black legumes. Legumes open naturally on trees after about 6 months. If unopened legumes are collected, they should be dried in the sun for 1 month; then the woody legumes should be forced open and the seeds removed. Seeds are relatively loosely attached in lateral grooves inside the legume. Dry seeds store very well in either open or closed containers and do not require refrigerated storage (Francis 1994). Seeds stored for 12 months at 26 °C germinated at 60% (Marrero 1949). Webb and others (1984) reported viability after 4 years storage but do not give germination rate or percentage germination.

Figure 1—*Delonix regia*, flamboyan: mature seed.

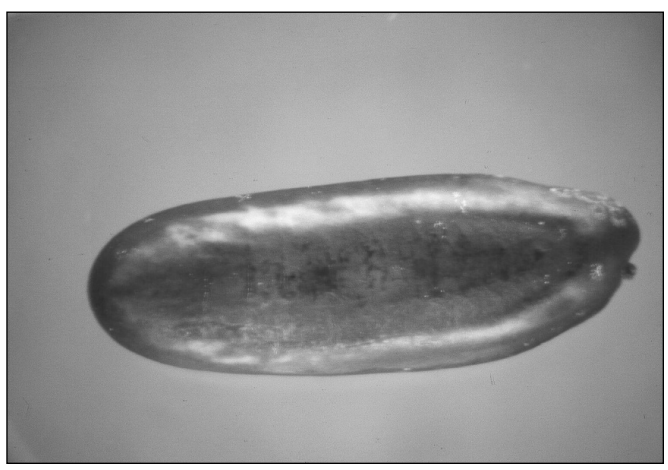

Figure 2—*Delonix regia*, flamboyan: longitudinal section through a seed.

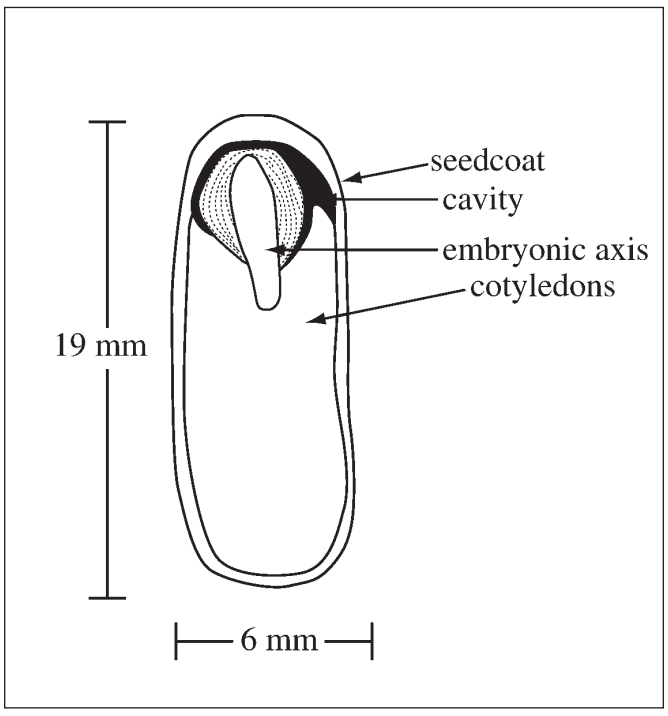

Germination. Scarification—with either hot water, sulfuric acid, or abrasion—is required for germination. Millat-E-Mustafa (1989) recommends 90 °C water for 10 seconds followed by 24 hours of imbibition. A concentrated sulfuric acid soak for 0.5 to 5 hours improved germination for Duarte (1974), whereas a hot-wire scarification proved superior to other means described by Sandiford (1988). Seeds subjected to the various scarification treatments reported here had germination values superior to those of their respective controls. Within 8 days of fresh collections, expect 76% germination after 9 weeks.

Nursery practice. Seedlings (figure 3) are ready for outplanting after 3 to 4 months of growth in plastic nursery bags during the wet season. Saplings are also grown to 2 m, then "balled and burlaped" for large ornamental potted plants. Mature flowering and fruiting trees may be grown in 3 to 5 years in good sites (Francis 1994).

D

Papaveraceae—Poppy family

Dendromecon Benth.

bushpoppy

W. Gary Johnson and Donald L. Neal

Mr. Johnson retired from the USDA Forest Service's National Seed Laboratory; Dr. Neal retired from the USDA Forest Service's Pacific Southwest Forest and Range Experiment Station

Growth habit, occurrence, and use. Bushpoppies (also known as treepoppies) are openly branched, evergreen shrubs from 0.6 to 2.5 m high, sometimes to 6 m. They have a woody base with gray or white shreddy-barked stems. The 2.5- to 10-cm-long leaves are mostly lanceolate, 3 to 8 times longer than wide (LHBH 1976). Environmental factors and shoot growth pattern affect leaf size (Bullock 1989). The 2 species considered here grow on dry chaparral slopes, ridges, and washes below 1,830 m. One species is found in California's Channel Islands and the other in the coastal range, from Sonoma County to the Sierra San Pedro Martir, Baja California, Mexico, and in the west foothills of the Sierra Nevada, from Shasta County to Tulare County (table 1). Bush-poppies rely on seed production to propagate. No lignotuber is formed on sprouts that appear after burning, so regrowth after fire is rare (Bullock 1989). The genus is useful for watershed protection (Sampson and Jespersen 1963) and for forage. Goats are especially fond of bushpoppies, and deer (*Odocoileus* spp.) and sheep eat the sprouts after fire.

Flowering and fruiting. Flowers are bisexual, yellow, showy, and solitary on stalks. At several locations, the shrubs first flowered in their second spring (Bullock 1989). Flowers appear in April through June and sometimes into August (Munz and Keck 1959). Bullock (1989) reports that the shrubs flower profusely from February through April in the Santa Monica Mountains. Several populations produce a few flowers throughout the year. Fruits are linear, grooved capsules measuring 5 to 10 cm long, with 2 valves that separate incompletely at maturity. Ripe fruits (those that explode when grasped) may be collected in May, June, and July (Neal 1974). Fruits are dehiscence, scattering the seeds (figure 1) up to several meters from the shrub, and ants disperse the seeds, some below and others above the ground. Concentrations of seeds can be found around the entrances of harvester ant—*Pogonomyrmex* and *Veromessor* spp.—nests (Bullock 1989).

Collection, cleaning, and storage. The black seeds are almost spherical, 2 to 4 mm in diameter, with a slightly

Figure 1—*Dendromecon harfordii*, island bushpoppy: seeds.

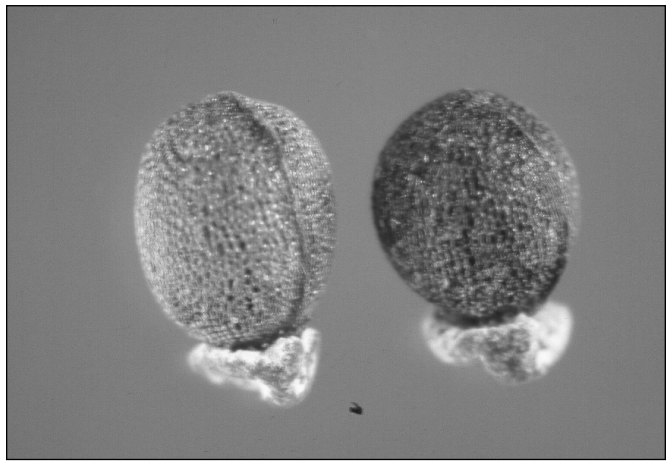

Table 1—*Dendromecon,* bush-poppy: nomenclature and occurrence

Source: Munz and Keck (1959).

pitted, hard, brittle testa. The seeds are dispersed by ants; the prominent caruncle is removed and used by the ants for food. The endosperm is oily, and the minute embryo rudimentary (Berg 1966) (figure 2). The mean number of seeds per fruit ranged from 2.9 to 10.7 in 14 populations (Bullock 1989). In 2 samples of cleaned seeds, purity was 77% and soundness was 97%. There were 92,400 to 114,400 seeds/kg (42,000 to 52,000/lb) (Neal 1974). Four other samples had purities of 99.4 to 99.9%, with an average of 99.4%, and 100,300 to 106,300 seeds/kg, with an average of 103,200/kg (45,600 to 48,300/lb, average 46,900/lb) (Vivrette 1996). Bullock found that seed weights varied greatly among the 14 populations studied, ranging from 10.1 to 15.8 mg (Bullock 1989). Vivrette reported seed weights ranging from 9.38 to 9.90 mg, average 9.70 mg, on 4 samples (Vivrette 1996). Bullock's slightly heavier fresh seeds may have had attached caruncles or a higher moisture content than Vivrette's laboratory samples.

There are no reports of seed storage of these species, but they likely can be stored at low moisture contents and near-freezing temperatures.

Germination pretreatments. Bushpoppy seeds have been sown in a moist medium at temperatures alternating diurnally from 4.5 °C (night) to 21 °C (day). Germination started after 50 days at these temperatures and reached 21% at 102 days after sowing (Mirov and Krabel 1939; Neal 1974). Vivrette reported no germination in of 9 samples tested for 21 days at 15 °C. A few seeds germinated on blotters moistened with 400 ppm GA_3 (gibberellic acid). Total viable seeds as determined by staining in tetrazolium chloride ranged from 11 to 50%, average 27% (Vivrette 1996). Emery recommended fire treatment or 1 $^1/_2$ to 2 months of stratification and stated that 3 months of stratification with a diurnal fluctuation from 8 to 21 °C may improve germination (Emery 1988).

Nursery practice. Fire-treated bushpoppy seeds give the most reliable germination in nurseries (Emery 1988; Everett 1957). Seeds to be fire-treated should be sown in the fall in a slightly moist nurserybed. The seeds should be then covered with a layer of milled peat or sand 1 to 2 times as thick as the seeds' diameter and not watered. Then, a 10- to 15-cm (4- to 6-in) layer of dry pine needles or excelsior should be placed over the bed and burned. The seedbed should be watered after it has cooled. If wooden flats are being used, 2 layers of aluminum foil will protect the wood during the burning (Emery 1988).

D

Ebenaceae—Ebony family

Diospyros L.

persimmon

David F. Olson, Jr., R. L. Barnes, and W. Gary Johnson

Drs. Olson and Barnes retired from the USDA Forest Service's Southeastern Forest Experiment Station; Mr. Johnson retired from the USDA Forest Service's National Seed Laboratory

Growth habit, occurrence, and use. Nearly 200 species of persimmons—*Diospyros* L.—are widely distributed, mostly in tropical regions. Only 2 persimmons—common persimmon and Texas persimmon—are native to the 48 contiguous states. Two others are grown in mild regions: Japanese persimmon for fruit and date-plum for root stock (table 1). Other persimmons are native to the tropical regions of the United States—*Diospyros hillebrandii* (Seem.) Fosberg and *D. sandwicensis* (A. DC.) Fosberg in Hawaii (Little and Skolman 1989) and *D. revoluta* Poir. and *D. sintenisii* (Krug & Urban) Standl. in Puerto Rico (Little and others 1974).

Common persimmon is a small to medium-sized deciduous tree, normally attaining a height of 9 to 18 m at maturity (Sargent 1965). It occurs in open woods and as an invader of old fields from Connecticut west through southern Ohio to eastern Kansas, and south to Florida and Texas (Sargent 1965). Common persimmon develops best in the rich bottom lands along the Mississippi River and its tributaries and in coastal river valleys. In these optimum habitats, common persimmon trees often attain heights of 21 to 24 m and diameters of 51 to 61 cm (Morris 1965).

In past years, persimmon wood was used extensively for weaver's shuttles, golf club heads, and other products requiring hard, smooth-wearing wood (Olson and Barnes 1974). At present, such uses have diminished because of the use of laminates and other substitute materials.

The fruits are exceedingly astringent when green, but delicious when thoroughly ripe (Harlow and Harrar1958); they are eaten by humans, animals, and birds. The common persimmon is a valuable honey plant and has been cultivated for its handsome foliage and fruit since 1629. Several varieties have been developed for fruit production (Harlow and Harrar 1958).

Texas persimmon is a shrub or small tree of south Texas and northeast Mexico, usually 1.8 to 3 m tall but sometimes reaching 12 m, with 4-cm-long leaves (Everitt 1984; LHBH 1976). The fruits are important wildlife food, but the shrub is considered as undesirable in rangelands of the Southwest (Everitt 1984).

Japanese persimmon (*kaki*) and date-plum are small persimmons from Asia grown commercially in the milder regions of the United States. Japanese persimmon grows to 14 m, with 18-cm-long leaves and large delicious fruit; many varieties are listed. Date-plum grows to 14 m, with leaves 13 cm long; it is often used as a rootstock for Japanese persimmon (LHBH 1976).

Sources: LHBH (1976), Sargent (1965).

Flowering and fruiting. Male and female flowers are borne on different plants, but a few plants have bisexual flowers. The female flowers are solitary, with 4 to many staminodes. The male flowers are in cymes or clusters with 4 to many stamens. The fruits are juicy, 1- to 10-seeded berries with enlarged, persistent calyxes at the base (LHBH 1976).

Common persimmon has small, dioecious, axillary flowers borne after the leaves from March to mid-June, depending on the latitude (Little and Delisle 1962; Morris 1965; Olson and Barnes 1974; Radford and others 1964). Flowers are most common in April and May and are pollinated by insects.

The fruits are green before ripening and may vary in color when ripe from green, yellow, orange, and yellowish brown to dark reddish purple and black (Olson and Barnes 1974; Sargent 1965) (figure 1). The fruit is a 2- to 5-cm plumlike berry, glaucous and with a conspicuous, persistent calyx, that contains 3 to 8 seeds (Olson and Barnes 1974; Sargent 1965). The fruits ripen from September to November; the flat, brown seeds, about 15 mm long, are dispersed from the time of ripening until late winter (Little and Delisle 1962; Olson and Barnes 1974; Morris 1965; Radford and others 1964) (figures 1 and 2). The seeds are disseminated by birds and animals that feed on the fruits, and to some extent, by overflow water in low bottom lands (Morris 1965).

Seed bearing may begin at age 10, but the optimum seed-bearing age is 25 to 50 years (Little and Delisle 1962; Morris 1965; Olson and Barnes 1974). Good seedcrops are borne about every 2 years, with light crops in intervening years (Olson and Barnes 1974).

Figure 1—*Diospyros virginiana*, common persimmon: mature fruit and a single seed.

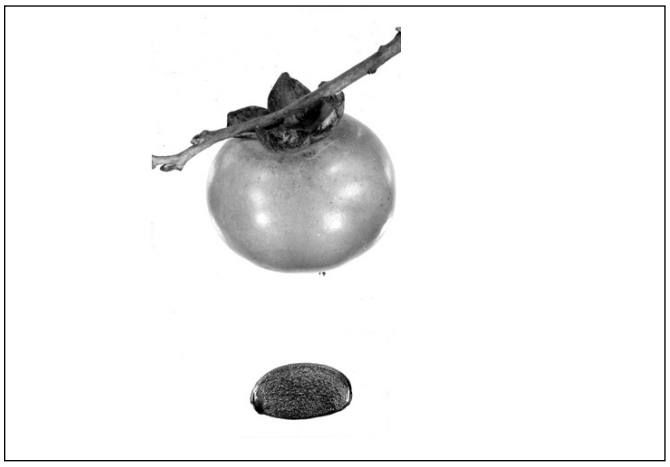

Figure 2—*Diospyros virginiana*, common persimmon: longitudinal section through a seed.

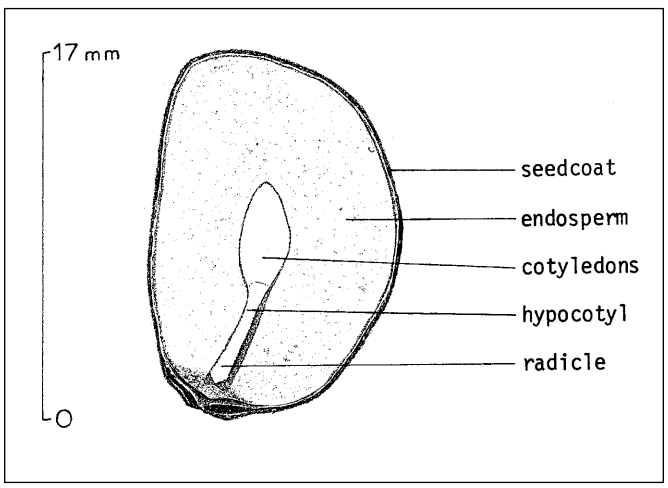

The small Texas persimmon flowers have 5 lobes. The black, globe-shaped fruits are 2.5 cm in diameter and have dark flesh (LHBH 1976). Animals and birds eat the fruits and disseminate the seeds (Everitt 1984).

Japanese persimmon flowers are yellowish white, about 2 cm long. Male flowers have 16 to 24 stamens and female flowers have 8 staminodes. The orange to reddish fruits are variable in shape, to 7.6 cm in diameter, with orange flesh (LHBH 1976).

Date-plum flowers are reddish to greenish, 7.5 mm long, with 4 lobes. Male flowers have 16 stamens. The small, yellow, globe-shaped fruits are 12.5 mm in diameter and turn blackish as they ripen (LHBH 1976).

Collection of fruits; extraction and storage of seeds. The fruits of common persimmon may be collected by picking them or shaking them from the trees as soon as they are ripe and soft in texture. They may also be picked from the ground after natural fall. If the fruits have started to dry, they should be softened by soaking in water (Myatt and others 1988). The seeds are easily removed by running the fruits with water through a macerator and allowing the pulp to float away or by rubbing and washing the pulp through 6.4-mm ($^1/_4$-in) mesh hardware cloth (Olson and Barnes 1974). For small quantities, ripe fruits can be placed in plastic bags and left until the pulp turns to juice, which can then be drained away before drying the seeds (Dirr and Heuser 1987).

After being cleaned, the seeds should be spread out to dry for a day or two. Spreading the seeds on screens to dry is common (Myatt and others 1988). Prolonged storage requires thorough drying. After the seeds are dried, they should be passed over a 9.9-mm (#25) screen on an air-

screen cleaner to remove trash and twigs. Use of a gravity table with high air may also be necessary (Myatt and others 1988). The seeds can then be safely stored in sealed dry containers at 5 °C (Engstrom and Stoeckler 1941).

One hundred kilograms (220 pounds) of fruit of the common persimmon will yield 10 to 30 kg (22 to 66 lbs) of cleaned seeds (Olson and Barnes 1974); the number of seeds per weight ranges from 1,460 to 3,880/kg (665 to 1,764/lb), with an average of 2,640 seeds/kg (1,200/lb) (table 2) (Aroeira 1962; Engstrom and Stoeckler 1941; Olson and Barnes 1974). Seedlots of 96% purity and 90% soundness have been obtained (Olson and Barnes 1974).

Japanese persimmon has about 3,400 seeds/kg (1,550/lb). Seeds stored at 0 °C at 45% moisture content retained the greatest viability after 18 months. Viability decreased rapidly as the seeds were dried, regardless of the speed of drying, with almost no germination at moisture contents below 10% (Kotobuki 1978). Date-plum has about 8,910 seeds/kg (4,040/lb).

Pregermination treatments. Natural germination of common persimmon usually occurs in April or May, but 2- to 3-year delays have been observed (Blomquist 1922; Olson and Barnes 1974). The main cause of the delay is the seed covering, which caps the radical, restricts the embryo, and causes a decrease in water absorption (Blomquist 1922). After removal of this cap, 100% germination was secured with mature seeds collected in the autumn (Blomquist 1922). Seed dormancy also can be broken by stratification in sand or peat for 60 to 90 days at 3 to 10 °C (Aroeira 1962; Crocker 1930; Olson and Barnes 1974; Thornhill 1968). Sulfuric acid scarification for 2 hours proved to be less effective in breaking dormancy than did stratification (Aroeira 1962).

Japanese persimmon does not have strong dormancy. Oh and others (1988) have shown that, although stratification was not essential, it improved germination. Rate of germination of date-plum seeds increased as the stratification length increased to 10 weeks (Oh and others 1988). No pretreatment is needed to germinate Texas persimmon seeds (Vora 1989).

Germination tests. Germination of stratified common persimmon seeds was tested in sand or peat flats at diurnally alternating temperatures of 20 to 30 °C. Germinative energies ranging from 54 to 94% were obtained in 20 to 34 days; and germinative capacities at 60 days varied from 62 to 100% (Olson and Barnes 1974). Payne achieved 90% uniform germination on common persimmon and date-plum by stratifying the seeds for 60 to 90 days in wet vermiculite after lightly dusting them with a fungicide. Scratching the seedcoat can shorten the stratification period (Payne 1996).

Fresh Japanese persimmon seeds taken from ripe fruits and sown immediately germinate best. Germination ranged from 20 to 77% in a study of 18 cultivars with fresh seeds sown immediately (Dirr and Heuser 1987). Date-plum seeds germinated best without light at alternating 18 to 30 °C with 10 weeks stratification at 5 °C. Germination of seeds stratified for 2 weeks was increased by treating them with 500 ppm gibberellin (GA_3) (Oh and others 1988). Fresh Texas persimmon seeds sown immediately after extraction germinated 33%. Germination was reduced with all other treatments (Dirr and Heuser 1987).

The tetrazolium chloride staining test is often used to estimate the viability of common persimmon and date-plum seeds due to the long stratification period needed to overcome dormancy. Clipping the radicle end of a seed with toenail clippers and soaking the seed for several days in water or 500 ppm GA_3 will soften it. Then it should be cut lengthwise to expose the embryo and storage tissue for staining.

Nursery practice. Common persimmon seeds may be fall-sown or stratified and sown in the spring. In Missouri, fall-sowing at a depth of 5 cm (2 in) is the normal practice, and seedbeds are mulched. Steavenson (Olson and Barnes 1974) reported a tree percent of 50%; an average tree percent of 25 to 33% is easily attainable. Seedlings of this

D

Thymelaeaceae—Mezereum family

Dirca palustris L.

eastern leatherwood

John C. Zasada, David S. Buckley, Elizabeth Ann Nauertz, and Colleen F. Matula

Dr. Zasada retired from the USDA Forest Service's North Central Research Station; Dr. Buckley is an ecologist and Ms. Nauertz is a biological technician at the USDA Forest Service's North Central Research Station, Grand Rapids, Minnesota; Ms. Matula is a botanist at the USDA Forest Service's Ottawa National Forest, Bessemer Ranger District, Bessemer, Michigan

Growth habit, occurrence, and use. Eastern leatherwood—*Dirca palustris* L.—is also known as moosewood, rope-bark, and wicopy. Its natural distribution extends from New Brunswick to Ontario in the north and from northern Florida to Louisiana in the south (Fernald 1950). Within this range, the distribution is restricted to very specific site conditions. It is found almost exclusively in mesic, relatively rich hardwood forests or mixed conifer–hardwood forests (Alban and others 1991; Curtis 1959; Fernald 1950; Ferrari 1993; Jones 2000; Kotar and others 1988; Meeker and others 1993; Neveling 1962; Rooney 1996; Soper and Heimberger 1982; Voss 1985; Weir-Koetter 1996). In aspen ecosystems across the upper Great Lakes region, leatherwood is present in stands with a relatively high aspen site index and a significant northern hardwood component (Alban and others 1991). In Ontario, the northern limit of distribution is similar to that of beech (*Fagus grandifolia* Ehrh.) and sugar maple (*Acer saccharum* Marsh.)(Soper and Heimberger 1982). The distribution of plants on a particular site can vary from apparently random to aggregated (Jones 2000). Forests in which leatherwood is common are characterized by a dense overstory that permits relatively little light to reach the forest floor during the growing season. It is often the only true understory shrub in these stands; the other woody understory species are tolerant to mid-tolerant trees—for example, sugar maple, ironwood (*Ostrya virginiana* (Mill.) K. Koch.), white ash (*Fraxinus americana* L.), eastern hemlock (*Tsuga canadensis* (L.) Carr.), and balsam fir (*Abies balsamea* (L.) Mill.)—having the capacity to grow into the overstory (Alban and others 1991; Buckley 1996; Ferrari 1993; Jones 2000).

Western leatherwood—*D. occidentalis* Gray—is very similar to eastern leatherwood (Neveling 1962). Its distribution is limited to the wooded hills of the San Francisco Bay region (Vogelman 1953). Flower descriptions and morphological comparisons of the 2 species are provided by Vogelman (1953). A related species in the Thymelaeaceae—*Daphne mezereum* L.—is an introduced species that has become established in some areas. The information presented here is for eastern leatherwood; some of it may also apply to western leatherwood.

In its natural habitat, eastern leatherwood reaches a height of 3 to 4 m and basal diameters of 5 to 10 cm. Crown width and depth of larger plants can be as much as 2 to 3 m; the largest crown volumes that we have measured are in the range of 15 to 25 m^3. Crown architecture can be fairly complex, with frequent branching and numerous apical growing points (figure 1). The largest individuals that we have observed are in old-growth northern hardwood forests where logging is prohibited and in older hardwood stands managed under a single-tree selection system. The maximum age attained by leatherwood is not known, but 30- to 50-year-old plants occur in older hardwood forests.

Figure 1—*Dirca palustris*, eastern leatherwood: mature forest-grown plant in full flower, with plant about 1.3 m tall.
