Endangered Species Handbook

"Dodo oder Dronte (Didus Ineptus)"
by F. John (1890)

It's Too Late:

It's Too Late

http://www.endangeredspecieshandbook.org/dinos_invertebrates.php

Introduction

Skeptics ask why it should matter whether the tiger (*Panthera tigris*) or other endangered species become extinct. Aren't all extinctions natural events? Yet enormous differences exist between the extinctions of the dinosaurs and other animals that faded out eons ago and those of recently disappeared species. Dinosaurs proliferated into a great diversity of species and dominated other life over a period of many years. Some dinosaur families endured tens of millions of years on Earth Œ others far less Œ before fading into extinction. It is difficult to grasp the reality of their immense sojourn, as some species existed for only a hundred thousand years. The Ornithischia, one major group of dinosaurs, had an enormous number of living species 135 million years ago at the dawn of the Cretaceous Period, but slowly died out over the next 60 million years. The last of the line became extinct some 65 million years ago as the last of the dinosaurs expired.

Extinctions of dinosaurs and millions of other species that disappeared from Earth at that time were natural in origin. These extinctions had many causes; changes in climate resulting from meteors colliding with Earth may have killed off the last dinosaurs. Many scientists believe the impact raised a dust cloud that blocked sunlight and reduced the enormous amounts of vegetation needed by the dinosaurs, and it may have cooled the climate as well. Another major cause of ancient extinctions was the movement of the Earth's tectonic plates, which broke up huge land masses into smaller ones. Some species became isolated on islands too small for their habitat requirements, and stronger species caused the extinctions of weaker or less adaptable species when continents were joined. Continents and islands moved into different climate zones as well. The Earth's climate and atmosphere have undergone major changes over the ages and species that could not adapt have fallen into extinction. Volcanic eruptions have spurred extinctions by inundating land with lava and cooling the climate with dust. Islands produced by volcanic eruptions have risen from ocean bottoms, become covered with vegetation and home to unique wildlife, only to sink into the sea some time later.

In the past, ecological roles left empty by extinctions were soon filled by the evolution of new species. After the last of the dinosaurs died out some 65 million years ago, mammals and other animals proliferated on Earth. The overall diversity of species remained stable or increased. At present, however, diversity of life on Earth is in steep decline as species are dying out without being replaced.

The Recent Picture: A Rapid Rise in Extinctions

The current extinction rate is estimated to be up to a thousand times higher than prehistory rates (Leakey and Lewin 1995, Stearns and Stearns 1999). This phenomenon has been described as the sixth wave of extinctions by scientists Richard Leakey and Roger Lewin Œ ecosystems are being disrupted around the world, and the wondrous tapestry of living things that supports human existence is unraveling.

Since 1500, approximately 375 species of invertebrates, 81 species of fish (Hilton-Taylor 2000) and 291 species of mammals, birds, reptiles and amphibians (see Appendix) have become extinct. About three-fourths of vertebrates other than fish have disappeared since 1800, while only 80 species died out in the previous three centuries. These figures represent a minimum number. An estimated 5 million species of animals and plants exist in tropical rainforests, a conservative figure that may apply to insects alone, according to biologist Edward O. Wilson (1988). About half of these species are restricted or localized in distribution (Wilson 1988). With this in mind, at the present

rate of destruction of tropical forests, some 17,500 species are being lost per year Œ a rate 1,000 to 10,000 times greater than extinction rates prior to human intervention (Wilson 1988).

Human activity lies at the root of this potentially catastrophic phenomenon. Killing for food or sport, as well as conditions created by humans, such as habitat destruction and competition, predation and disease from introduced animals, is responsible for the vast majority of these extinctions. It is with this perspective that we can see the present situation as an *unnatural* event, not linked to climatic changes, meteors or volcanic eruptions, but a result of human-caused changes wrought in the Earth's environments and by direct extermination.

Plants

Extinctions of plants and trees can have a direct impact on human society. A sap found in 1997 by Dr. John Burley, research director of Harvard University's Arnold Arboretum, was tested by the National Cancer Institute and determined to be 100 percent effective in preventing cell replication of the AIDS virus (Stocker 1996). The plant sample came from an ancient swamp forest tree in Sarawak, a Malaysian state on the island of Borneo. When Dr. Burley returned to the spot a year later for another specimen from the tree, only a stump remained, and no other trees of the same species could be found (Stocker 1996). The substance is being reproduced synthetically, but it is not known whether it will be as effective as the original compound (Stocker 1996).

Sarawak's forests grew undisturbed for 180 million years, but they are now rapidly disappearing along with the rest of Borneo's ancient forests. Commercial loggers have felled tens of thousands of these old growth, towering trees in Indonesia and other tropical rainforests for the manufacture of disposable packing crates and chopsticks for Japanese and Chinese markets. Borneo's forests are also being consumed by fires set by wealthy landowners to clear land for palm plantations, or by settlers for farmland, eliminating an untold number of plants. Some tropical tree species have wide distributions over thousands of square miles, but many occupy extremely small areas. This was dramatically illustrated in the disappearance of this tree. Thousands of compounds that could cure diseases or be of great economic and ecological importance may be lost on a daily basis as the world's forests are destroyed at this unprecedented rate.

Plant extinctions have accelerated in the past few centuries. An estimated 5,050 taxa of plants, including species, varieties and other taxonomic groups, have become extinct worldwide since 1700, according to Ghillean T. Prance of the Royal Botanical Gardens Kew (Prance 1990). This implies at least 17 plants have been lost per year since 1700. Yet however high this rate appears to be, it is probably a low estimate. A 1998 study by botanists Kerry S. Walter and Harriet J. Gillett for the International Union for the Conservation of Nature (IUCN) found that 380 species, a number that does not include varieties and other taxa, have recently become extinct. These authors admit their extinction total may be low as a result of lack of data, and they did not define the time period covered.

· The data lacks exact numbers of plant extinctions. Plants rarely leave signs of their existence as vertebrates do, since bones are the basis of much data on animal extinctions. Non-woody plants, which make up the majority of plants, leave little trace when they die, and are soon consumed by microbes. This is especially true in tropical areas, where plant matter is consumed very quickly. We know of ancient plants by chance events, such as the preservation of pollen grains or other plant parts in peat, mud, amber or fossilized stone. When numbers of plant extinctions are estimated, the diversity and status of habitat are important considerations. Moreover, only a small percentage of all plants have been scientifically described. What is known is a great many regions of the Earth that once had very diverse endemic plants have been destroyed within the past few centuries, and a majority was not thoroughly assessed.

Botanical wealth is often discovered and destroyed soon after. In Ecuador's mountain ridges, botanists Al Gentry and Calaway Dodson of the Missouri Botanical Garden in St. Louis discovered many unique plants in 1978 on a crest

known as Centinela Ridge in a 20 square kilometer cloud forest in the foothills of the Andes. Among the plants were 38 endemic species, many of which were unusually dark•leafed (Forsyth 1990). The two scientists found a total of 90 related plants growing under the forest canopy with epiphytic plants, such as bromeliads and orchids, on the trunks and branches of the trees (Wilson 1992). These cloud forests and paramos Œ treeless, mossy areas in the northern Andes Œ are centers for unique species. At the time they discovered the plants, Gentry and Dodson observed farmers from the valley below clearing the forests, as they have done on 96 percent of the Pacific ridges of the Andes (Wilson 1992). Gradually, the clearing moved up to Centinela Ridge. By 1986, the botanical oasis had disappeared; in its place were cacao and other crops (Wilson 1992). These lost species might have provided compounds to treat cancers, or been an ancestor of an agricultural plant, such as a perennial tomato, but they exist now only as pressed specimens taken by the botanists.

Near Centinela Ridge is Rio Palenque; once an extensive cloud forest, it is now diminished. It was among the most botanically diverse forests in the world Š 600 species per square kilometer (Forsyth 1990). Ornithologists and birdwatchers came from all over to see the 336 bird species of Palenque's diverse habitats (Forsyth 1990). The endangered harpy eagle was one spectacular native bird that disappeared when the forest was cleared (Forsyth 1990).

Cloud forests are found in tropical Asia, Africa and Latin America. These ecosystems shelter such rarities as the iridescent green and red resplendent quetzal of Central America, but this ecosystem has nearly disappeared. An impressive variety of orchids, mosses and dwarf trees grow in these misty, cool environments. Should global warming continue, cloud forests will be among the first type of forest to disappear altogether, extinguishing thousands of unique life forms in the process.

Introduction of alien species of plants can overwhelm native species and cause their extinction (Prance 1990). In Indonesia, a type of non-native grass called imperata (*Imperata cylindrica*) grows aggressively in deforested areas, spreading into forests. Once established, imperata obstructs the regeneration of native plants and trees (Prance 1990), many of which exist nowhere else. Imperata has also displaced endemic plants in other parts of the world. In Australia, exotic plants are a major factor; they have eliminated at least 117 plant taxa and endangered another 1,931 (Prance 1990). Ironically, native Australian plants have caused extinctions after they became established in parts of South Africa and the Florida Everglades.

Plants have also disappeared as a result of pollution in the form of acid rain caused by power plant emissions, heavy metal (especially lead) accumulations and other toxins in the air (Prance 1990). Forests in North America and Eurasia have been susceptible to pollution, and in some areas, all forms of vegetation have died out.

Livestock overgrazing is responsible for the extinctions of countless plants, and endemic island species are among the most vulnerable. Such plants may occupy only a few acres. The South Atlantic island of St. Helena lost at least 10 kinds of endemic trees after the introduction of goats onto the island in 1513; the St. Helena redwood (*Trochetia erythroxylon*) became reduced to a single tree in the wild (Prance 1990). Fortunately, it was saved by propagation at the Royal Botanic Gardens Kew in London and cultivated specimens have been reintroduced (Prance 1990). The sandalo (*Drypetes caustica*), a fragrant type of sandalwood tree that once grew abundantly on the island of Juan Fernandez, the site of *Robinson Crusoe*, became extinct by 1916 after centuries of heavy logging and destruction of seedlings by goats (Prance 1990).

The Mascarene Islands, east of Madagascar in the southern Indian Ocean, have been the scene of many plant extinctions. One of the three main islands, Mauritius, was home to the famous dodo. Ebony once covered the plains and mountain slopes of this island, but during colonization of the islands from the early 17th century onward by Holland, France and Britain, extraction of a huge volume of timber denuded valleys and all accessible places (Parnell *et al.* 1986). As early as 1671, Mauritius had appointed a chief woodcutter to oversee the cutting of the island's forests. Unfortunately, this had little effect on forest clearance. Of the dense tropical evergreen forests that once covered the lowlands, only a few patches remain in inaccessible areas. Trees 20 meters or more in height grew in the uplands of the island, their branches heavy with thick growths of lianas and orchids. On the ground, ferns and mosses

sprung up luxuriantly.

Today, only a single tract remains of this habitat, the Black River Gorges reserve (Sayer *et al*. 1992). By 1874, these islands, once described as verdant "earthly paradises," were dry and comparatively barren, with a vegetation composed mainly of weeds (Parnell *et al*. 1986). Only about 30 square kilometers of Mauritius forest survives since 93 percent was destroyed (Sayer *et al*. 1992). The mangrove forests that once lined Mauritius' shores have disappeared along the West Coast because they were cut for firewood. Rodrigues, a small island off the coast of Mauritius that was once a wildlife haven, lost virtually all its forests. Reunion, the third island, was also settled and heavily logged. About 61 percent of its forests, including virtually all its lowland forests, have been cleared; only 100 square kilometers remain (Sayer *et al*. 1992). A few remnants of montane forest have been protected by the French government, which controls the island.

Mauritius, Rodrigues and Reunion have lost many native plant species. Of 1,296 native plants, 53 species are extinct and 393 of the surviving species are threatened, according to the *1997 IUCN Red List of Threatened Plants* (Walter and Gillett 1998). Little remains of its ebony forests, and eight ebony tree species are virtually extinct (Simon 1995). The islands have lost six of their beautiful orchid species, and 13 more are threatened (Walter and Gillett 1998). Mauritius and Rodrigues have been described as the "Islands of the Living Dead" by authors Beverly and Stephen Stearns because at least 30 plant species have ceased reproducing in the wild, living on the edge of extinction (Stearns and Stearns 1999). One, *Ramosmania heterophylla*, described in 1874, was not seen again until 1982 when botanist Wendy Strahm found the last specimen growing by a roadside. She fenced it off to protect it, only to learn this made local people consider it a "magic plant" that cured all diseases and maladies (Stearns and Stearns 1999). They cut off small pieces Š despite its fencing Š and have nearly obliterated it. Luckily Strahm took cuttings and sent one to Kew Gardens in England for propagation; it now grows there, but does not seed because the plant is defective (Stearns and Stearns 1999). A critically endangered tree, *Elaeocarpus bojeri*, native to Mauritius, has delicate, bell-like flowers with a scalloped fringe. Strahm's photograph illustrating these flowers appears on the cover of the *1997 IUCN Red List of Threatened Plants* (Walter and Gillett 1998). It epitomizes the status of many Mascarene plants in need of dramatic rescue programs, as well as the need to prevent extinctions, such as that of a rare Rodrigues tree hibiscus (*Hibiscus liliflorus*); the species became extinct in 1982 after it was reduced to a single plant growing on the top of a mountain (Stearns and Stearns 1999).

Two endangered native wild coffee plants of Mauritius (*Coffea macrocarpa* and *Coffea myrtifolia*) might invigorate domestic species stricken with disease if they are protected from extinction, illustrating another reason to preserve native plants. The wild ancestors of domestic grains and crops retain many characteristics lost in cultivated varieties, such as resistance to drought, insects and disease. An outbreak of cornleaf blight in the United States in 1970 cost farmers almost $1 billion, and the disease was not halted until a wild corn species was interbred with the domestic strain (Fenyvesi 1995). A perennial variety of maize (wild corn) found in a Mexican forest could be hybridized with domestic corn to save farmers from replanting each year. Other crops saved by crossbreeding with tropical forest wild stock include sugarcane, coffee, cocoa and banana (Schreiber *et al*. 1989). Yet with the accelerating rate of plant extinctions and destruction of native plant ecosystems, many such ancestor species may be lost.

All ecosystems are plant-based. Plants produce oxygen, making life on Earth possible, and perform a vital task for other life forms by absorbing vast amounts of toxins and carbon dioxide. They are the source of thousands of important medicines, and discoveries of new medicinal uses of plants are being made on a regular basis. Disappearance of individual species of plants can impoverish or even collapse entire ecosystems when they are key to the survival of many species of animals or form an intrinsic link in an ecosystem.

Not only do many plants fade to extinction undocumented by botanists, but only a small percentage of living plants have been scientifically described. Botanists have identified more than 250 thousand types of living plants other than algae, fungi and bacteria, but most scientists agree these represent perhaps a tenth of all living plants. Almost 10 percent of surviving species are considered threatened with extinction. Some 34 thousand plant species are listed in

the *1997 IUCN Red List* (Walter and Gillett 1998). Many of these plants have not been seen for years and may be declared extinct in the near future, or are clinging to life with only a few individuals left. Preservation of the planet's great diversity of plants to prevent further extinctions should be a priority of the first order.

Invertebrates

Invertebrates are key members of many ecosystems. Insects pollinate plants, while mollusks and gastropods form the basis of many aquatic food chains. Documentation of invertebrate extinctions is incomplete, but a minimum of 375 species (approximately eight crustaceans, 72 insects, 31 bivalves and 260 gastropods, snails and related species) have become extinct worldwide in the past few hundred years, according to the *2000 IUCN Red List of Threatened Species* (Hilton-Taylor 2000). Massive destruction of many habitats, especially islands with endemic species such as land snails, has eliminated hundreds of these creatures.

Extinct bivalves include mollusks native to the southeastern United States, the world's center of diversity for freshwater mussels. Dam construction turned clear, fast-flowing rivers into still ponds, destroying prime mussel habitat. Channelization, in which the natural curves of a river are straightened and its surrounding vegetation bulldozed from its banks, wreaked havoc in aquatic ecosystems. Biologically rich rivers became muddy, sterile ditches. These government-sponsored anti-flood programs took place during the first half of the 20th century, causing numerous extinctions of mussels and crayfish.

At the time, few people lamented the disappearance of these mussels, some of which were the size of dinner plates. They grew in huge masses on river bottoms, serving as keystone species in river ecosystems by providing habitats for fish, crayfish and huge river snails. Birds and aquatic mammals fed on the fish and other aquatic wildlife produced by these mussels; these large bivalves also cleansed the water with their filtering gills. Water pollution from industry and coal mining and sedimentation from logging have contributed to their extinction. Additionally, mussels are over-harvested because of their commercial value in the cultured pearl industry Œ their shells are harvested and broken into tiny pieces that are inserted into living oysters to stimulate the growth of pearls. These combined threats have pushed many species to extinction and others to endangered status. Their demise has caused species dependent on mussels for reproduction and habitat to disappear as well.

Scores of colorful endemic land snail species have died out in the Hawaiian Islands, other Polynesian and Indian Ocean islands and various southern Atlantic Ocean islands. These snails were once prolific in native forests, but naturalists and shell collectors took many thousands of them during the 19th century Œ until the 1920s, when it became too difficult to find them (Stearns and Stearns 1999). One individual, J.T. Gulick, the son of Hawaiian missionaries, "ransacked" the islands for tens of thousands of these colorful land snails, collecting 44,500 in three years (Stearns and Stearns 1999). He alone caused the extinction of numerous species on the islands by encouraging rural residents to collect for him and by buying shells by the thousands, believing himself to be an important naturalist. He was among the collectors who scoured the woods where these shells clung to trees and low bushes by the hundreds (Stearns and Stearns 1999). Many were striped, while others were solid shades of ivory, yellow-gold and deep brown. Some collections were of no scientific value because the locations where they were obtained were not noted. No similar species remain in the wild today (Stearns and Stearns 1999).

In more recent times, exotic species of snails have been introduced onto islands for various purposes, preying on the native species. One expert estimated that when Captain Cook arrived in Hawaii in 1778, there were between 800 and 1,000 species of endemic Hawaiian snails from 11 families, but at present, only about 200 remain (Stearns and Stearns 1999). Recent extinctions have been caused by deforestation and predation by exotic snails, including the giant African snail, introduced by the Hawaii Department of Agriculture to prey on another exotic snail. Native snails

feed mainly in endemic Hawaiian trees, another reason they have failed to adapt to the introduction of exotic trees and bushes. Unusual among invertebrates, these snails reproduce slowly, one species needing 19 years just to replace itself (Stearns and Stearns 1999). At least 49 species have become extinct in recent times, according to the Nature Conservancy's book, *Precious Heritage: the Status of Biodiversity in the United States* (Stein *et al*. 2000). The remaining species of Hawaiian land snail are endangered, and species are disappearing regularly from the wild, preyed on by exotic snails or rats and losing their host trees to logging (Stearns and Stearns 1999). Conservation programs have not been well-funded, as these are among the least well-known of Hawaiian wildlife.

On the island of Moorea in the Society Islands, the giant African snail was introduced as a food source, but when it became overpopulated, a carnivorous snail, *Euglandia rosea*, was introduced to prey on it. Instead, the latter species preyed voraciously on native tree snails, exterminating all 11 species; it is now in the process of eliminating the native snails of Tahiti (Wilson 1992).

Butterfly populations have declined from loss of host plants, pesticide use, over-collecting and loss of species upon which they depend. The Xerces Blue (*Glaucopsyche xerces*) is the only native species in the United States to have become extinct in recent times. It disappeared in the early 1940s, and the Xerces Society, dedicated to preserving butterflies, was named after it. It is one of 38 butterfly species that recently disappeared around the world (Baillie and Groombridge 1996).

Invertebrates play key roles in many of the world's ecosystems as food sources, for people as well as animals. Some, such as coral and mollusks, create habitats for thousands of species. Butterflies, mollusks and snails are among the planet's most beautiful creatures, yet conservation programs often neglect these important species.

Vertebrates

Vertebrate extinctions worldwide since 1500 total at least 372 species of mammals, birds, reptiles, amphibians and fish. The largest number Œ 157 species Œ were birds, while 100 mammal species, 28 reptile species, 6 amphibians and 81 fish species disappeared. The number and rate of extinctions have increased gradually in recent centuries, as the table "Extinct Species of Birds, Mammals, Reptiles and Amphibians" illustrates. Fewer than 80 of these vertebrates became extinct from 1500 through the 18th century, while in only the 19th century, 98 species of birds, mammals and reptiles died off. The rate accelerated during the 20th century; based on incomplete information, at least 115 vertebrates Š already 17 species more than in the past century Š were lost. (See Appendix for list of species and their dates of extinctions.) This total will be far greater when the toll for the 20th century is finalized.

229 species, almost 80 percent of the 291 extinct mammals, birds, reptiles and amphibians, were native to islands, mostly located far from the nearest land mass, such as the Hawaiian Islands, Mascarene Islands and New Zealand. (See Table fiThe Geography of Extinction.fl) Many of these island species were distinctive and unusual, the products of thousands and even millions of years of evolution in isolation. Few left close relatives.

Some islands are fragments of ancient continents, broken off more than 100 million years ago, with resident wildlife and plants. New Zealand, Madagascar, the Seychelles and the larger islands of the Caribbean are examples of this phenomenon. In exceptional circumstances, original inhabitants survived; some evolved into different forms, while others remained almost unchanged. Additional plants and animals arrived by air, ocean current or clinging to masses of vegetation or floating logs, perhaps every thousand years. Few of these survived, but occasionally these new colonists were able to adapt to the new environment and thrive. Other islands were formed by volcanic eruptions or coral reefs growing atop extinct volcanoes. Virtually all native fauna and flora of these islands, which include the Hawaiian, Mascarene and Galapagos Islands, were colonizers. The majority of extinct island species were flightless

birds, tortoises and other species unable to flee when European ships and their crews arrived in search of commodities such as spices, timber and fur animals. They were killed for food and sometimes found their habitats destroyed by logging or the many species of animals brought to the islands. They were successful species in adapting to their environment and surviving for long periods, even radiating into entire new families of animals, but nothing had prepared them for the drastic changes humans caused, or the high mortality from hunting or persecution.

Sixty-two mammals, birds, reptiles and amphibians, as well as all but one of 81 species of fish, were native to mainland areas. The continent with the largest number of non-fish extinctions is Australia, with 24 species, 22 of which were mammals, killed off by introduced animals and loss of habitat (see Mammals section in the table: fiThe Geography of Extinctionfl). Non-native species caused the extinctions of many fish in the United States, Mexico and Africa. Killing by persecution or commercial purposes, such as for furs, meat or sport, caused extinctions in Africa, North America, Australia, Europe and Asia. Capture for pets and killing eliminated birds in the Caribbean, Australia and South America. The clearing of forests eliminated a number of tropical birds in Asia and South America. Elimination of wetland habitats was the major cause of the extinction of amphibians and fish, especially those that were ecologically isolated, such as cave fish or desert spring species.

Extinct Species of Birds, Mammals, Reptiles and Amphibians
1500 to present

100-Year Periods	Mammals	Birds	Reptiles	Amphibians	Total
1500-1599	0	6	0	0	6
1600-1699	14	15	3	0	32
1700-1799	13	26	3	0	42
1800-1899	31	56	10	0	97
1900-2000	42	54	12	6	114
TOTALS	100	157	28	6	291

Fish Extinctions

The *2000 IUCN Red List* lists a total of 81 species of fish that have become extinct over the past 400 years. In addition, a large number of fish have been extinguished in Central and South American lakes Œ scientists are still compiling information. About 20 percent of the world's freshwater fish are indeed either extinct or in steep decline (Wilson 1992).

No version of the *IUCN Red List* has listed many species reported as apparently extinct by biologists around the world. In peninsular Malaysia, where 266 freshwater species were known to exist, a search found only 122 (Wilson 1992). In the Philippines, where massive environmental destruction has taken place, Lake Lanao on Mindanao is famous for its diversity of endemic cyprinid fish. Yet out of 18 species of three genera, an investigation found only three species of one genus (Wilson 1992). These extinctions were apparently caused by overfishing and competition

from introduced species (Wilson 1992).

During this century, several mass extinctions of endemic fish have taken place when the creatures™ sole habitat was destroyed. Lakes in East Africa, the Americas and Russia have either been drained Œ as in the Russia™s Aral Sea Œ or native species have been crowded out or preyed upon by introduced exotic fish.

Africa's Great Rift Valley, a product of movement in the Earth's crust eons ago, is home to several lakes of great biological diversity. Lake Tanganyika has more than 140 endemic species of fish, Lake Victoria has more than 200 and Lake Malawi has at least 500 (McNeeley *et al*. 1990). These three lakes, home to hundreds of members of the colorful cichlid family, rank three, two and one respectively in the world for their diversity of fish (Myers 1979). The lakes have been separated for millions of years, and although Lake Malawi and Lake Tanganyika are only 320 kilometers apart, they have not a single cichlid fish species in common (Myers 1979). Each of these three lakes empties into great rivers; Lake Tanganyika flows into the Zaire, Lake Victoria into the Nile and Lake Malawi into the Zambezi (Kingdon 1989). Most ancient is Lake Tanganyika, 3 to 6 million-years-old and twice the age of Lake Malawi, which is half as old as Lake Victoria (Kingdon 1989). Lake Tanganyika is the second deepest lake in the world at 1,500 meters; only Siberia's Lake Baikal is deeper (Kingdon 1989).

Lake Victoria is a shallow, enormous lake, covering an area the size of Ireland or the state of Maine (Kingdon 1989). Evolution of cichlid fish in these lakes over the ages produced an extremely rich fauna. From a few ancestor species, these fish flourished into an extraordinary diversity, each species filling a different ecological niche. Their diets are extremely varied and may include plankton, crustaceans, mollusks or fish eggs (larvae) and even other fish (Kingdon 1989). Cichlids brood their eggs in their mouths Œ up to a thousand at a time Œ protecting them from their many natural enemies. They exhibit a great range in color, including silver, sapphire and turquoise blue, orange and yellow, and they are patterned in stripes, bars, dots or circles. Resembling the fish one might see in a coral reef, many are popular in home aquariums (Kingdon 1989). Various kinds of tilapia, which are also cichlids, form a major part of the diet of Africans living around these lakes, and they are being raised in aquaculture projects around the world.

These beautiful fish and their ancient ecosystems are now disappearing. The major cause is the Nile perch (*Lates niloticus*), Africa's largest freshwater fish, at more than 6 feet in length. Since 1960, the Uganda Game and Fisheries Department has introduced thousands of these fish as a food source for the local people, despite objections from the East African Fisheries Research Organization (Simon 1995). Even as a food fish, the Nile perch is not rated highly by the local Africans, who prefer the smaller tilapia, which they preserve by drying in the sun (Simon 1995). The flesh of the Nile perch is so oily that it must be smoked, and more and more trees must be cut down for this purpose (Simon 1995). An ecological disaster occurred after its introduction; although intended to increase the lake's productivity of fish, the opposite happened. Gradually, this predatory fish became the dominant species in the lake, and completely destroyed the endemic cichlid fish fauna and fishery (Simon 1995). Of the more than 300 varieties of *Haplochromis* genus cichlid fish (including subspecies) endemic to Lake Victoria, almost two-thirds died out, and the rest became endangered (Simon 1995). Fifty known extinctions have beset Lake Victoria's endemic cichlids. One species, *Haplochromis pyrrhocephalus*, has become extinct in the lake Œ it exists only as a captive colony in the Horniman Museum in London (Simon 1995). Extinctions of the surviving cichlids continue because of predation by the Nile perch and siltation of the lake from erosion of farmland soil on its shores. This prevents these fish from mating because they are not able to recognize the brilliant colors and patterns of their potential mates (Yoon 1997).

The introduction of exotic fish threatens many freshwater species, and overfishing is virtually eliminating a large number of saltwater species. Research on the latter is lacking, but it is likely that many of the 156 species listed as ficriticalfl in the *2000 IUCN Red List* will be listed as extinct in the near future.

Amphibian Extinctions

Six species of amphibians Œ all frogs Œ are known to have become extinct since 1500. No recorded amphibian extinctions have taken place on islands, despite the large number of endemic amphibians native to large islands such as Madagascar, New Zealand, Cuba and Puerto Rico. Many of these, however, now face this threat. Yet it is likely that amphibian extinctions occurred as a result of the draining of wetlands or due to their use in growing rice following the colonization of the latter islands by native peoples thousands of years ago. The extinct frogs were mainland species, and all disappeared during the 20th century. The Israel painted frog (*Discoglossus nigriventer*) became extinct around 1940, when Lake Huleh, its sole habitat, was drained for agriculture. The Vegas Valley leopard frog (*Rana fisheri*) disappeared in 1960 when its desert spring habitat was destroyed by groundwater pumping for agriculture. Two Mexican frogs endemic to wetlands north of Mexico City died out by 1979 after their wetlands were drained for the construction of homes. The best known extinction in recent times is that of the beautiful golden toad (*Bufo periglenes*), which is acknowledged by most experts to have disappeared from its rainforest home on a Costa Rican mountain in the late 1980s. This species had been featured in National Geographic Society films and articles, and was also the subject of a research study when it suddenly died out.

A large number of frogs Œ at least 20 species Œ have not been seen for many years, and many may soon be declared extinct. Some of these are among the most unusual examples of evolution on Earth. In a few pristine areas, frogs have mysteriously vanished. An Ecuadorian biologist reported in the 1990s that a dozen species he had been studying in a high altitude meadow disappeared without a trace. Experts are in disagreement over the causes of the vanishing of so many frog species. Many species are believed to be victims of ozone depletion, which increases the amount of ultraviolet radiation reaching the Earth, destroying frog eggs and often adult frogs as well. Other scientists believe frogs are disappearing from a combination of causes, including disease possibly induced by an immune system lowered by pollutants, pesticides and habitat destruction.

Reptile Extinctions

All but one reptile extinction have occurred on islands. At least 28 island reptiles have died out since 1600. A large number of reptile extinctions took place in the Mascarene Islands, a group of islands in the Indian Ocean, east of Madagascar (see Appendix for more on Mascarene Island extinctions). Thousands of large tortoises were slaughtered for food by European settlers and visiting ships' crews during the 17th century. All three Mascarene Islands and most of their satellite islets were densely populated by various species of tortoises. Each island had species with differently shaped shells: domed for feeding on low vegetation, and high•fronted for other vegetation (Day 1981).

Francois Leguat described Rodrigues' tortoises in the early 18th century: "There are such plenty of Land•Turtles on this Isle that sometimes you see 2,000 to 3,000 of them in a Flock; so that you can go above a hundred paces on their backs without setting foot on the ground. They meet together in the evening in shady places and lie so close that one would think those spots were paved with them" (Day 1981). The large tortoises must have numbered in the hundreds of thousands, judging from the quantity taken by ships to provision their crews and to trade for commodities. Each weighed about 100 pounds, and naval ships vied with one another for rights to them. The tortoises were plundered indiscriminately. Far more were killed than needed by crews and passengers (Durrell 1977). One expert estimated that at least 10 thousand tortoises were taken per year from Rodrigues island alone. Many died en route, as in the case of one shipment of December 6, 1761, in which the ship fiL'Oiseaufl arrived with a cargo of only 3,800 tortoises still living out of the 5,000 shipped (Durrell 1977). The Mauritian tortoises were extinct by 1700,

the two Reunion species by 1773, and the Rodrigues species in 1800 (Day 1981). The last of the tortoises were killed off by pigs consuming the young tortoises and rooting up their eggs in the sand (Day 1981). Eight tortoise species, including three giant tortoises, became extinct (see Table "Extinct Wildlife of the Mascarene Islands").

In all, 13 Mascarene reptile species disappeared forever. The blind cave snake and three skinks or geckoes also disappeared. The most recent extinction was the Round Island Boa, which inhabited an islet off the coast of Mauritius. Livestock and rabbits stripped the vegetation, which caused the extinction of this snake by 1975. No native tortoises or turtles still exist on the Mascarenes. The remaining species of boa and the four gecko and skink species are highly threatened, according to the *2000 IUCN Red List.*

Elsewhere in the world, reptiles have been eliminated mainly as a result of the combined effects of non-native species, such as rats, cats and mongooses. Predators prey and compete for habitat and vegetation, livestock overgraze and settlers destroy habitats. Nine species of iguanas and snakes of the Caribbean became extinct after introduced species of mongoose and rats demolished them. The iguanas were also hunted heavily for food by local people. A number of iguana species barely survive on various Caribbean islands, having become restricted to tiny islets off the main islands where rats, cats and livestock are not present. Four Caribbean reptiles have disappeared. A lizard (*Ameiva major*) and a snake (*Dromicus cursor*) were native to Martinique and became extinct in 1960 and 1962 respectively; the other two were native to Jamaica. A tree snake (*Alsophis ater*) was probably eliminated by forest destruction and predation by the introduced mongoose. The Jamaican iguana (*Cyclura collei*), thought to be extinct, was recently rediscovered, but the species is still highly endangered. The single reptile extinction on a mainland area was a South African lizard, Eastwood's longtailed seps (*Tetradactylus eastwoodae*) Œ it disappeared in 1913.

Bird Extinctions

A bleak picture has emerged, showing a dramatic rise in the rate of bird extinctions over the past 200 years. At least 157 species of birds have become extinct since 1500, and many more have not been seen in decades. In pre-history, approximately one bird disappeared each century (Leakey and Lewin 1995), but the present rate is many times that. During the 17th century, 15 birds disappeared, increasing to 26 birds in the 18th century (at an average rate of about one bird every four years); this was 26 times the pre-history rate. Nineteenth century extinctions totaled 56 bird species, or about a bird every other year. Data for the 20th century is still being totaled, but 54 birds have already been declared extinct since 1900 Œ already almost as many as the entire 19th century™s toll. Thus, the rate of avian extinctions has likely more tripled since the 18th century. A large number of birds have not been seen in the wild for many decades and will likely soon be declared extinct; a period up to 50 years between the last sighting and formal declaration of a species' extinction is generally accorded, unless thorough surveys verify the species is indeed gone.

An important dimension of these extinctions is the fact that birds are considered indicators of the planet's health. Birds are sensitive to environmental pollution, habitat loss and other signs of deterioration, as illustrated when canaries were used by coal miners to test for the presence of lethal methane gas. Their extinctions will also affect the ecosystems in which they once lived, since many birds pollinate plants or disperse seeds, and without them, these plants die off. The story of the dodo (*Raphus cucullatus*) is an example of such a relationship.

Some of the most amazing and unusual species that ever lived are among the birds that have become extinct since 1600. Many of these extraordinary birds evolved on remote islands without human inhabitants over periods of millions of years. The heaviest bird ever to have lived on Earth was the Great elephant bird (*Aepyornis maximus*) of Madagascar, the last of many related species of elephant birds. Some experts maintain this giant bird disappeared prior to 1500 (Brooks 2000), but observers spoke of its continued presence on the island after 1600. The giant moas

of New Zealand are thought by some to have persisted until the 19th century, while others believe they died out a thousand years ago, within a few centuries after the arrival of the Maori people. The brawny great moa (*Didornis torosus*) of New Zealand was perhaps the last of many species of moas, the largest of which was the tallest known bird, some 12 feet in height. It was hunted to extinction like its relatives. Some said it persisted until 1670. Another extraordinary New Zealand bird was unique in that males and females had beaks that were completely different in both size and shape: the colorful huia (*Heteralocha acutirostris*) became extinct early in the 20th century, mainly from the effects of forest destruction and hunting for its feathers, which were sold in the European markets for ladies' hats.

The Mascarene Islands, which remained uninhabited by humans until the 17th century, once had an unparalleled diversity of birds, including an array of many odd flightless birds such as the famous dodo. Flightless herons and storks fished in the streams, and enormous parrots Œ their beaks as large as their heads Œ lumbered about in search of fruits and seeds. Each island had its own distinctive parrot species. Some of the native parrots had not become flightless, and each of the seven or so species occupied its own ecological niche. Gray parrots with bright red beaks, small gray parakeets and two types of lime green parrots with very long tails swooped about in large flocks (Fuller 1987).

Large numbers of the flightless, turkey•sized dodos waddled about on Mauritius. The birds, weighing about 50 pounds and covered with grayish, downy feathers, fed on hard-shelled seeds. Of all birds that have become extinct, this species is perhaps the most famous. The dodo™s common name apparently came from fidodoor,fl a Dutch word meaning sluggard, and dodaers, a lubber, or awkward sailor (Halliday 1978). The creature's original scientific name was *Didus ineptus*, indicating its inability to flee humans or defend itself.

In fact, the dodo was the final result of thousands Š perhaps millions Š of years of evolution in isolation on an island with no land predators. Wild pigeons of an unknown species landed by chance on Mauritius at some early date and became resident, gradually evolving into a gigantic form of the original immigrant. The dodo may have evolved from New Guinea and Pacific Islands tooth•billed pigeons that landed in the Mascarenes, according to some zoologists (Halliday 1978). Tooth-billed pigeons also have curious hooked beaks, although the dodo's 9 inch beak was far more massive. Yet whatever its ancestry, the dodo became flightless in its predator•free environment. Its feathers lost their sheen and aerodynamic quality and came to resemble the down of nestling birds.

Mauritius was first visited in the early 16th century by Portuguese sailors, and was later settled by the Dutch, who brought pigs, goats and cattle. These domestic animals soon multiplied and overran the islands. Pigs rooted in forests, devouring rare flora, and cattle and goats overran the fragile tropical vegetation. Rats swam from ships and colonized the main islands; they preyed on flightless birds, eating their eggs and young, even climbing trees to devour nesting songbirds. Mongooses native to Asia were brought to Mauritius, which presented a lethal threat to native birds and other wildlife. Long-tailed macaques (*Macaca fascicularis*) were imported as pets at some point from Southeast Asia and then released into the forests of Mauritius, spreading throughout the island and preying on native birds. Settlers also cut the trees needed by native birds for habitat and food. The delicate plants, forests and vulnerable wildlife were devastated by this onslaught.

Portuguese and then Dutch seamen and colonists slaughtered thousands of dodos, using them as a major source of food. They cut down the seed-bearing trees dodos fed upon, and their eggs and chicks may have been preyed on by rats and introduced macaques (Fuller 1987). Settlement began in 1634, and within less than 30 years, the once-common dodos were slaughtered to extinction. The settlements failed and Mauritius remained uninhabited for a period of time.

The last account of wild dodos dates from 1662. A Dutchman named Volquard Iversen was deserted on Mauritius soon after both the early settlement and the penal colony failed (Quammen 1996). Iversen and his shipmates scoured the island for food and found no dodos, but they did see some on a small islet off the coast. He described them as "larger than geese but not able to fly. Instead of wings they had small flaps; but they could run very fast" (Quammen 1996). The islet protected the last few dodos from human hunters and introduced predators, and until then, the tiny

population had remained undetected. Iversen's party waded through the shallow water to the islet and captured a dodo. "When we held one by the leg he let out a cry, others came running forward to help the prisoner, and they were themselves caught" (Quammen 1996). These were the last of their species. Altruism, a trait that has helped many animals survive through mutual aid, has also caused extinctions. Human hunters have taken advantage of this, killing animals that come to the aid of each other.

In the centuries since its demise, the dodo has come to symbolize extinction, but many still think of this bird as stupid, giving rise to the expression "dumb as a dodo." Animals are frequently deemed stupid if their natural defenses against humans are inadequate, or vicious if they are able to defend themselves. Yet this bird so many people have described with disdain came to the rescue of its fellows, even at the risk of its own life, and was an extremely successful species within its environment. If the word dodo must be seen symbolically, then it would be more reasonable to equate it with human stupidity, because our own species wantonly destroyed this extraordinary bird. In the opinion of Errol Fuller (1987), author of the authoritative book *Extinct Birds*, "The dodo was one of the most fantastic creatures ever to have lived."

In 1973, Dr. Stanley Temple, an ornithologist, made a remarkable discovery about the dodo. He noticed that a beautiful tree native to the island, the calvaria or tambalacoque tree, was reduced to 13 dying specimens, all more than 300 years old. Gerald Durrell (1977) described these trees as at least 50 feet tall, with massive crowns and silvery, gnarled trunks; cracks appeared in their buttress roots. Since no young trees were located, it occurred to Dr. Temple that no seeds had germinated since the 17th century when the dodo became extinct. Apparently, stones found in the dodo™s gizzard by sailors butchering it for food might have been able to abrade the thick shell covering the seeds. Dr. Temple fed some of the seeds to domestic turkeys, which were presumed to have similar digestive systems, and of 10 seeds recovered from feces or regurgitation, three sprouted when planted (Anon. 1978).

Some scientists now believe this tree could germinate without the dodo. A surviving parakeet is thought to be able to crack its hard-pitted seeds, and the extinct Mauritius flying fox and some of the extinct parrots were able to do so as well(Quammen 1996). Dr. Wendy Strahm, in her botanical work on Mauritius, has found young trees of this species that germinated in the past 300 years, although they are quite rare (Quammen 1996). Another scientist, Anthony S. Cheke, believes seed germination has continued, but at a low rate Œ perhaps too low to maintain the species long-term. The rarity of the tambalacoque tree was considered to be due to seed predation by rats, deer browsing on saplings, rooting by pigs and perhaps browsing by the introduced macaque monkeys (Quammen 1996). Yet dodos were likely major seed distributors of this tree in the pre-human environment, and their role has not been successfully replaced ecologically. The introduction of a veritable zoo of non-indigenous species has reaped havoc on a variety of native plants.

The dodo's close relatives on neighboring islands are far less known. On Reunion, a bird called the Reunion solitaire (*Raphus solitarius*) was described by early visitors to the island as resembling the Mauritius dodo, except its beak was somewhat smaller, its plumage was white and the tips of the wings and the tail were black (Fuller 1987). One traveler, M. Carre, said in 1699: "The beauty of its plumage is a delight to see. It is of changeable color which verges upon yellow" (Fuller 1987). Two were taken aboard ship as a present to the French king, but both refused to drink or eat and soon died. M. Carre noted in his description that "The flesh is exquisite; it forms one of the best dishes in this country, and might form a dainty at our tables" (Fuller 1987). This was an ominous prediction of its final fate. The Reunion solitaire probably died out about 1715 as a result of being slaughtered for food.

On tiny Rodrigues, yet another dodo-like bird existed. Far more is known of this species, whose bones have been found in caves on the island. Its beak was shorter and its neck was longer, but it also apparently evolved from pigeon ancestors (Halliday 1978). It was called the Rodrigues solitaire or solitary (*Pezophaps solitaria*) for its habit of feeding alone on leaves and fruit in secluded places. Errol Fuller's description in *Extinct Birds* evokes its once peaceful existence: "In this tranquil kingdom generations of solitarys must have lived enjoying extraordinary peace and seclusion until their world was shattered by the coming of man."

Francois Leguat, a Huguenot refugee, left extensive descriptions of these birds when he spent two years on Rodrigues after he was marooned there with a small group of followers in 1691 (Fuller 1987). "They walk with such stately form and good grace," Leguat wrote, "that one cannot help admiring and loving them" (Fuller 1987). He watched them nesting and feeding their chicks until they fledged at several months. The male and female defended their territory, driving other solitaires away with a dramatic display in which a bird pirouetted for four to five minutes while whirring its wings violently to produce a loud rattling noise that could be heard 200 yards away (Halliday 1978). If this impressive display did not frighten other birds away, they used knobby growths at the joints of their flightless wings in combat with other solitaires (Halliday 1978). Some wing bones now found in museums have healed fractures, an indication of the violence of these encounters (Halliday 1978).

Leguat saw the parents of solitaires escorting their single chick to a gathering of some 30 other solitaire families, where the adults would leave the chicks. Tim Halliday wrote in *Vanishing Birds* (1978) that he believes what Leguat witnessed was actually a sort of nursery gathering, similar to that which flamingos and some penguins organize while adults go off to feed. Although these birds were able to hide in foliage and could run quickly, hunters chased them down and butchered every last bird. People slaughtering them found stones in their gizzards Œ even in those of very young nestlings. How they got there remains a mystery, since the stones were too large to have passed down the gullet (Halliday 1978). The last solitaire was seen around 1746, and the species was deemed extinct by the 1760s (Brooks 2000).

The origin and affinities of these three species of pigeon-like birds in the Mascarene Islands will be disputed by scientists for some time to come. Tim Halliday (1978) conjectured that the dodo may have evolved from a pigeon, such as the tooth-billed pigeon (*Didunculus strigirostris*) of the Pacific Œwhich has a similar but far smaller hooked bill Œ or that they were related to rails. It is also possible the dodo had one ancestor and the solitaires had another. What is not disputed is that they left no close relatives. No living birds on Earth are related to the dodo and the solitaire, or bear any strong resemblance to them.

Other flightless native birds of the Mascarenes disappeared as well: all the huge parrots, three kinds of owls, three rails, several small pigeons, two night herons, a stork and an ibis. Little is known about many of these birds, but two of the rails were described in detail. The Rodrigues or Leguat's rail (*Aphanapteryx leguati*) had bright gray plumage flecked with white and gray, a curved red bill, red legs and feet and a red ring surrounding the eye (Taylor 1998). The bird™s call consisted of a long whistle, but when pursued, the rail gave an alarm call that sounded like a person with a hiccup (Taylor 1998). This species fed on tortoise eggs and, like the related Mauritian red rail (*Aphanapteryx bonasia*), could be lured by holding out a red object and trapped when the bird came to attack the lure (Taylor 1998). They were described as delicious, and were killed to the last bird. Among flighted species lost were a type of weaver, a starling and a falcon (Brooks 2000; Fuller 1987; Greenway 1967). The total of 31 extinct birds is more than that of any other island group or continent.

However extraordinary such a toll may seem for a group of small islands, it may represent only a percentage of Mascarene avian extinctions. Stanley Temple estimated that prior to the arrival of humans, 68 species of birds lived on the three main islands and, of these, 45 species (66 percent) became extinct after 1600 (Temple 1981). The 14 species not officially included among the extinct birds of these islands were described by travelers but have not yet been authenticated. The majority lived on Mauritius. Future archeologists are certain to discover far more about the birdlife that once inhabited these islands, and genetic studies of specimens from which DNA can be extracted may help identify their origins.

The Hawaiian Islands vie with the Mascarenes for numbers of extinctions. At least 21 species and many more subspecies have become extinct since 1600. One of these was native to the remote swamps of Kauai. The Kauai Oo (*Moho braccatus*) had pitch black plumage brightened by several long, canary yellow feathers. The male had a haunting, fluted call. The species dwindled as forests were cut, and by 1960, only 12 birds were known to remain. A single pair survived by the 1980s. The female disappeared after a hurricane in 1985 (Brooks 2000), and the male lived on a few more years as the last member of his species. He was seen singing and building a nest with each final

year, trying to attract a mate who never came (Daws 1993). He was last seen in 1987 (Brooks 2000).

The Kauai Oo was the last of a group of dramatic songbirds that once lived on all the major islands. The Hawaiian honeycreepers found only here evolved from one or a small number of ancestor species Œ likely a New World finch, warbler or honeyeater Œ into an estimated 40 to 50 brilliantly colored birds, before the arrival of the Hawaiian people. Some species were probably eliminated after they were killed in tremendous numbers for their feathers, then made into elaborate headdresses and cloaks for Hawaiian royalty, but the major cause of their extinction was the destruction of their forests by European settlers. As the honeycreepers retreated to smaller and smaller habitats, often surrounded by ranchland, sugar cane and pineapple farms, their habitats and food trees disappeared. Their fragmented populations were susceptible to avian malaria, which spread throughout the islands in the 20th century, brought by exotic cage birds that had escaped or been released by their owners. Thousands of birds died of the disease. The extinction toll of native birds within the past few hundred years stands at 21 species, in addition to even more subspecies. Twenty-three honeycreepers survive, but most are so endangered they are not expected to survive more than a few more decades. One critically endangered honeycreeper, the po'o-uli (*Melamprosops phaeosoma*), has a total population of three birds: two males and one female live in a reserve and the adjacent Haleakala National Park on Maui (BI 2000). This small, masked brown-and-white bird, discovered in 1973 by a graduate student, once numbered 200 individuals before it underwent a drastic decline between 1975 and 1985 as a result of avian malaria and habitat destruction by feral pigs within its reserve (BI 2000). All three birds live in separate home ranges, and the species has little chance of survival.

Rails are the most characteristic of all island land birds. These compact and stocky creatures are most frequently seen in wetland habitats, but some live in forests or grasslands. Almost all islands in tropical latitudes have or had endemic rails or fossil evidence of their past presence. Larger islands have several native rails, and it has been estimated that as many as 2,000 flightless rails inhabited Polynesian and western Pacific islands alone, prior to their colonization or visits by humans who exterminated them. Many of these instances were in prehistoric times by Maori, Hawaiians and other native peoples (Taylor 1998). Some 23 species of island rails, virtually all flightless, have been exterminated since 1500 Š far more than any other avian family (see Appendix).

Rails are not likely candidates for colonizing islands because they are, in the words of S. Dillon Ripley (1977), an authority on rails, "loath to fly." When frightened, they usually do not take wing, but disappear into matted vegetation. When they do fly for short distances, it is rather feebly, and their legs dangle down. How could they have reached islands thousands of miles from the mainland? Some rails are long-distance migrants, while other species disperse in erratic patterns (Taylor 1998). Rails tend to travel in groups at night and are often blown off course. European rails on their way to Africa have ended up far from their wintering site (Taylor 1998). European Corncrakes, for example, have landed, exhausted, on ships in the Indian Ocean or even off New Zealand (Ripley 1977). North American Purple Gallinules, colorful rails of southern marshes, have flown to tiny Tristan da Cunha island halfway between South America and Africa in the South Atlantic (Ripley 1977). The Common Moorhen (*Gallinula chloropus*) of Eurasia, North and South America and Africa has colonized St. Helena, the Azores, the Seychelles, the Marianas and Hawaii, among other islands. These colonizing rails usually become flightless if they have are no enemies, such as native predators. Some become the size of large chickens. Once flightless, however, they are vulnerable to predation by animals brought by humans.

The Laysan rail or crake (*Porzana palmeri*) was driven to extinction by imported rabbits who rendered Laysan Island devegetated. Biologists transported it to nearby Midway Island, where it flourished until World War II, when the island became a naval base. The navy personnel were entranced by this utterly fearless and agile bird that sprung into people's laps or onto the mess table in search of crumbs of food. Unfortunately, the species perished soon after 1942, when rats from a naval landing craft apparently ate the rail's eggs and preyed on its young. A few of the rails had been returned to Laysan Island after rabbits were removed, but the vegetation had not recovered sufficiently and the birds did not survive (Ripley 1977). Most other island rails have died out from similar causes.

Since about one-third of the world's birds are endemic to islands, and they have been reduced by 30 to 50 percent

since humans came to these islands. Their extinctions represent a true biological catastrophe, in the words of Storrs Olson, an authority on extinct birds (Taylor 1998). The vast majority of avian extinctions in the past 500 years have been island birds Œ victims of predation, competition from introduced animals and disease from cagebirds. Many were also killed for food or trade. Non-indigenous species are still causing bird extinctions on islands. In all, 137 of the 157 bird extinctions (87 percent) since 1500 have been island species, and human activities and animals introduced by humans have been responsible. Island species have been more vulnerable to extinction than mainland species because of their small populations and limited habitats. Many were flightless or slow-moving species, unable to flee predators, including humans. Some were specialized in their diet and habitat and could not adapt to changes made in their environment.

Mammal Extinctions

Cuba, Puerto Rico, Hispaniola and Jamaica had a variety of unusual native rodents and shrew-like insectivores prior to the arrival of European explorers and settlers in the 1600s; many were ancient species. When native Caribbean populations settled the islands after the Ice Ages, rodents as big as marmots inhabited the larger islands. A type of giant sloth lived in Puerto Rico, and a rodent nearly the size of the American black bear inhabited the small islands of Anguilla and St. Martin until it was apparently hunted to extinction by natives (Olson 1978). Cuba, Puerto Rico and Hispaniola were once attached to the mainland of Central America, but this large land mass became separated and drifted off into the Caribbean. Some of the native fauna and flora present more than a million years ago survived until a few thousand years ago, and tiny frogs and butterflies from that period persist today.

When Europeans colonized the Caribbean islands, they began cutting forests and replacing them with huge plantations of sugar cane, other crops and grazing land for livestock. They imported thousands of slaves to farm the land. Mongooses were brought on the islands to control snakes, but they preyed on native mammals and birds instead; rats arrived in ship holds and did the same. Fifteen mammals have become extinct on Hispaniola, the island divided between present day Haiti and the Dominican Republic Œ this island suffered the highest number of mammal extinctions of any Caribbean island. Forests have been nearly obliterated on Haiti, which is another cause of extinctions. Cuba, Puerto Rico and Jamaica have likewise lost the majority of their forest cover, as well as many native mammals, including bats, rodents and insectivores. Jamaica was home to a monkey (*Xenothrix mcgregori*), making it the only Caribbean island with a native primate. It was hunted and its forest habitat was cut by European colonists, and it died out in the 1750s. Various species of hutias, large rodents found on most major islands, became extinct as well. Hutias remain on a few Caribbean islands but are close to extinction from forest destruction and predation by introduced mammals.

Most of the 40 mammals that became extinct on Caribbean islands after 1600 were rodents and insectivores. A muskrat and a rice rat became extinct on Martinique when Mt. Pelee erupted in 1902 Œ one of the few examples of a naturally caused modern extinction. Hutias, large rodents that resemble South American agoutis, proliferated into a variety of species on the large islands of the Greater Antilles. Settlement, deforestation and hunting caused at least five species of hutias to become extinct, and the few remaining species are now highly endangered.

The first mammal to disappear after 1600 was a massive wild cow called an auroch (*Bos primagenius*). This species, native to most of Europe, lived in the deciduous forests that once covered most of the continent. The auroch

was also hunted for its meat and died out about 1627. Several other wild cattle related to the auroch survive in Southeast Asia, but they are critically endangered. The tarpan (*Equus gmelini*), a wild horse of Europe, gradually became rare and restricted from hunting and destruction of its native forests during the Middle Ages. The last wild tarpans were killed off in 1851 (Day 1981). Both the auroch and the tarpan are depicted by Pleistocene humans in magnificent cave paintings found in southern Spain and France.

The Steller's sea cow (*Hydrodamalis stelleri*) was an enormous 24 to 30 feet long marine mammal, similar in appearance to the dugong and the manatee. The sea cow was larger, however, and swam in the cold arctic waters of the Bering Sea, enduring temperatures that would kill its closest relatives. The slow and sluggish sea cows were killed off only 27 years after their discovery. They were first seen by the shipwrecked crew of the explorer Vitus Bering in 1741 in the vicinity of Bering Island in the Commander Islands, off the eastern coast of Russia's Kamchatka Peninsula. These sea cows were tame and easy to spear and harpoon by the ship crews who killed most of the population, calculated at only about 1,500. This animal showed extreme protectiveness toward its fellows and strong bonds between mates. The naturalist Georg Wilhelm Steller, after whom the species was named, described their behavior on being harpooned.

. . . Some of them tried to upset the boat [when another sea cow was struck] with their backs, while others pressed down the rope and endeavored to break it, or strove to remove the hook from the wound in the back by blows of their tail, in which they actually succeeded several times. It is most remarkable proof of their conjugal affection that the male, after having tried with all his might, although in vain, to free the female caught by the hook, and in spite of the beating we gave him, nevertheless followed her to the shore, and that several times, even after she was dead, he shot unexpectedly up to her like a speeding arrow. Early next morning, when we came to cut up the meat and bring it to the dugout we found the male by the female, and the same I observed on the third day when I went there by myself for the sole purpose of examining the intestine (Day 1981).

Australia has been the scene of more mammal extinctions than any other continent or island group. Beginning in the 19th century, Australia's mammals disappeared in large numbers. Native marsupials and rodents were gradually eliminated by massive habitat destruction and predation from animals introduced by European settlers. Twenty-two mammals became extinct after 1600. A wide variety of marsupials, from small species to wallabies, was extinguished within a century of settlement. Some, like the thylacine, or Tasmanian wolf (*Thylacinus cyanocephalus*), were deliberately persecuted by livestock ranchers under the misapprehension that the species presented a threat to flocks.

The crescent nailtail wallaby (*Onychogalea lunata*) was native to the gum forests of western Australia where John Gilbert, a 19th century museum collector, found the animal common in thick scrub, "where it is occasionally seen sunning itself" (Strahan 1995). This small marsupial weighed less than 20 pounds and looked like a miniature kangaroo. It rested in hollows in soft ground beneath shrubs during the day, feeding mainly at night on roots and coarse grass (Nowak 1999). When chased, it would run to a hollow tree with a hole in the bottom and clamber up the sides until it got high up within the trunk; aborigines used smoke to chase them out and then killed them for food (Strahan 1995). The aborigines also hunted these animals by building brush fences and enclosures and driving the animals into areas where people waited with clubs (Strahan 1995). In spite of hunting, this wallaby was fairly common until 1900, and many were collected for museums (Strahan 1995). It disappeared from the southern portion of its range early in the century after intensive forest clearance and development of the country for agriculture. Gradually, it became very rare, and disappeared altogether from the wild in the 1960s (Nowak 1999, Strahan 1995). Some experts suggested the removal of the thickets where these wallabies sheltered during the heat of the day left them homeless and vulnerable to predation (Nowak 1999).

Millions of acres of eucalyptus forests and mulga woodlands of southern and western Australia were clearcut by settlers beginning in the 19th century, opening up the land to wildfires (Lines 1991). The devastation of these habitats was described in *Taming the Great South Land. A History of the Conquest of Nature in Australia*, by W.J. Lines (1991). The combination of this habitat destruction, hunting and introduced predators, such as feral dogs, was responsible for the extinction of the Crescent Nailtail wallaby and many other native marsupials.

Various endemic Australian rodents and bats died out as well, and many of the remaining native mammals are become confined to tiny islands off the coasts Œ the only habitats where introduced animals are absent. Australia is like an island in having been isolated from other land masses for millions of years, and the majority of its mammals are endemic to the continent. In fact, it is often referred to as the "Island Continent." If Australian extinctions are included among those on islands, 87 percent of all extinctions of vertebrates other than fish have occurred on islands.

In Asia, the freshwater baiji dolphin species was until recently found throughout the Yangtze River and its surrounding lakes and tributaries. Unfortunately, the exponential growth of the Chinese population posed a variety of threats to its survival. A lack of information, growing threats and the species' small population size eventually led to the baiji's decline, despite protective efforts. Baiji dolphins were last officially sighted in 2004, and a 2006 expedition deemed the species "functionally extinct."

THE GEOGRAPHY OF EXTINCTION (chart)

Source: Table of Extinct Species in the Appendix of this book. Sources of information are listed with the table.

Note: See the Appendix for the list of these species in chronological order, and the references that describe these animals and their extinctions, as well as those that include illustrations of the extinct species.

The following account chronicles some of the many extinctions and destructions of natural ecosystems that have taken place in North America over the past few hundred years. Great biological treasures have been stolen from future generations, and the processes by which they were lost are typical of those occurring elsewhere in the world. The

sudden loss of the most abundant and prominent wildlife species of the continent created a profound shock in the public early in the century that set the stage for today's conservation and humane programs. This concern may turn the tide for species that could suffer the fate of the passenger pigeon (*Ectopistes migratorius*) and others, but unless public opinion is better translated into public policy regarding the land and wildlife, further losses will occur and the lessons that might have been learned will be ignored. A strong and pragmatic commitment to preserve what remains of the natural world on the continent, based on a realization that our fate is linked to nature's fate, is essential to prevent further extinctions.

Epitaphs for North America's Lost Species and Environments

After the loss of the majority of large Pleistocene mammals, native peoples in North America became conservationists of the remaining wildlife and the continent's environment. Many tribal religions deified animals and believed they embodied the spirits of their people. They hunted and fished on a subsistence basis. This resulted in relatively few animal extinctions over the tens of thousands of years that passed before settlement by Europeans in the 16th century. The land that awaited new settlers was spectacular in its beauty and abundance of wildlife. Over the next three centuries, however, an unprecedented level of slaughter and drastic environmental alteration destroyed many of these natural treasures.

An Abundance of Wildlife

Early European voyagers landing on the East Coast of North America were astounded to see animals in numbers they had never before witnessed. Fish swarmed in the millions. Captain John Smith came upon vast schools of fish in tributaries of the Potomac River, near the Chesapeake Bay, in 1608: "–in diverse places that abundance of fish lying so thick with their heads above the water [that] as for want of nets (our barge driving among them) we attempted to catch them with a frying pan, but we found it a bad instrument to catch fish with. Neither better fish, more plenty, nor more variety for small fish had any of us ever seen in any place so swimming in the water–" (Hawke 1970). Lobsters were so prolific that one haul of a fisherman's net would bring in more than 100; settlers used them as fertilizer and fish bait. Huge sturgeon 10 feet long swam up major rivers to spawn along the East Coast. Offshore, whales and herds of dolphins migrated along the coasts. The northern right whale (*Eubalaena glacialis*) fed on plankton in shallow lagoons as it migrated to its breeding grounds off Florida. The now-extinct Atlantic gray whale (*Eschrichtius robustus*) was a common marine resident, swimming and feeding offshore. At the present sites of Boston, New York and Philadelphia, vast saltwater marshes surrounded river deltas. Shorebirds and waterfowl darkened the sky with their millions.

Along the craggy rock•strewn coasts of Maine and the Canadian maritime provinces lived a large mink, almost double the size of the American species found elsewhere in the country. Unlike any other type of mink in the world, the animal was a coastal species that soon became known to colonists and fur trappers as the sea mink (*Mustela macrodon*). One sea mink killed in 1867 measured 32.5 inches in length, enormous in comparison to the American mink, which does not exceed 23 inches (Mowat 1981). The sea mink's pelt had twice the value of the inland species in the fur trade (Allen 1942).

An early account by the English naturalist Joseph Banks, who traveled to Newfoundland in 1766 to study the local fauna, described the sea mink as "bigger than a Fox, tho not much, in make and shape nearest compared to an Italian Greyhound, legs long, tail long and tapering" (Mowat 1981). It is unlikely that the sea mink was as long•legged as a greyhound, but available information indicates it was quite different from any closely related species. Bones from the

sea mink have been found along the coast of Maine and New Brunswick (Allen 1942). The fur traders decimated these minks long before scientific or biological studies could be carried out. One early observer described the avid pursuit of sea minks in Maine:

> *Some seventy•five years ago, and for many years thereafter, my father, who was a fur•buyer, used to have nearly all the furs taken on the islands of Penobscot Bay . . . these sea mink used to bring considerably more than others on account of their great size . . . they were persistently hunted . . . with dogs trained for the purpose. As the price of mink rose, they were hunted more and grew scarcer, 'til in the sixties, when mink skins brought eight or ten dollars apiece, parties who made a business of hunting nearly or quite exterminated the race. Some of these men went from island to island, hunting any small ledge where a mink could live. They carried their dogs with them, and besides guns, shovels, pick•axes and crow•bars, took a good supply of pepper and brimstone. If they took refuge in holes or cracks of the ledges, they were usually dislodged by working with shovels and crow•bars, and the dogs caught them when they came out. If they were in the crevices of the rocks where they could not be got at and their eyes could be seen to shine, they were shot and pulled out by means of an iron rod with a screw at the end. If they could not be seen, they were usually driven out by firing in charges of pepper. If this failed, then they were smoked with brimstone, in which case they either came out or were suffocated in their holes. Thus in a short time they were nearly exterminated* (Beard 1947).

The last known sea mink was killed in 1880, and its pelt was sold to a fur buyer in Jonesport, Maine (Mowat 1981). Only fragments of bones and teeth found in excavations of Indian cooking sites attest to its existence (Nowak 1999).

A beautiful North American waterfowl species also disappeared. The male Labrador duck (*Camptorhynchus labradorius*) had striking black•and•white plumage, while the female was mousy brown. During the 19th century, these birds were often seen in fall and winter off New York's Long Island and on the New Jersey coast. Named for the Canadian peninsula where naturalists of the day assumed that they bred, eggs reported to belong to this species had been seen by a naturalist, but the nests were never found (Greenway 1967). This duck had a soft bill, and inside its mouth, lamellae filtered its food. The Labrador duck was assumed to have a specialized diet, possibly of small surface invertebrates that it filtered while dabbling at the surface. The ducks also fed on mollusks, as hunters discovered when they caught them with fishing lines baited with mussels (Fuller 1987).

Labrador ducks were strong flyers who flew in tight, small flocks (Day 1981). Along with virtually all waterfowl of the day, they were shot for the feather and food markets. Gunners killed entire flocks of waterfowl, bringing them to market, where they were heaped in piles. The ducks were killed for no purpose, since they were not sought after as food and considered too "fishy" by most customers. Many of the birds shot by hunters were left to rot, unsold at markets (Day 1981, Greenway 1967). The Labrador duck, first described scientifically in 1789, was always considered rare, and the last known specimen was a bird shot off Long Island 86 years later, during the autumn of 1875. This male is kept in the US National Museum of Natural History (Fuller 1987). The Labrador duck was apparently hunted to extinction, a victim of the totally unrestricted waterfowl hunting that characterized the 19th century, based on its prevalence in game markets (Day 1981).

Further north, a flightless bird walked upright on its flippered feet. At a length of 3 feet, the great auk (*Alca*

impennis) was the size of a large penguin, and could have been mistaken for one. Like many northern seabirds, it had a black back and white belly, but each side of its face was dramatically marked with a large, white oval. Its bill was long and hooked. Great auks were far larger than any of their cousins Œ the murres, puffins and guillemots of the North Atlantic. At one time, these birds ranged along most of the coasts and islands of the North Atlantic, from northern France through Scandinavia, England, Scotland and Iceland, to North America's eastern coast as far south as Martha's Vineyard, Massachusetts (Greenway 1967). Based on fossil evidence, great auks were once as numerous as most other sea birds of the region (Greenway 1967).

The very oldest bones, excavated on the island of Jersey in the English Channel, are between 70 and 90 thousand-years-old (Greenway 1967). As the only flightless bird in the North Atlantic, it was once widespread and numerous. When people approached the birds while they were on land nesting, great auks would immediately waddle to the water's edge and dive in. They were rapid and expert swimmers, using their wings to propel them. When cornered on land, however, they were helpless. Both parents raised the chicks, and they refused to desert their nests, even when attacked. For centuries, hunters took advantage of this trait, pursuing and killing them during their breeding season. Ship crews slaughtered thousands for provisions and took live birds on board for future meals.

Gradually over the centuries, great auks disappeared from most European coastlines and offshore islands as a result of hunting. The last record in the British Isles was on St. Kilda, an island west of northern Scotland, where some local residents captured a Great Auk in 1821; although kept captive with a string attached to its foot, it managed to escape (Fuller 1987). Twenty years later, as recounted by an older resident, another auk was found asleep on a rock on the same island and captured, kept for three days, and then killed because these superstitious people feared that it was a witch (Greenway 1967).

Great auk feathers were harvested in grisly "factories" on Funk Island off Newfoundland in the 18th century. Collectors built pens of piled boulders into which they would drive the hapless great auks from their nests. Once the auks were cornered in the pens, the men would swing spiked clubs at the birds, killing or wounding them (Day 1981). The birds were then thrown over the enclosure walls into piles near the fires; there the dead and wounded birds were dropped into boiling cauldrons or thrown directly on the fires (Day 1981). The boiling water caused the feathers to float to the surface, where they were scooped up and stuffed into bags; the corpses were next dragged down to the water where they were dumped (Day 1981). Some observers, including Captain George Cartwright, an early colonist on Labrador, watched boats coming ashore laden with hundreds of carcasses from Funk Island. He wrote in July 1785, "If a stop is not soon put to that practice, the whole breed will be diminished to almost nothing" (Birkhead 1994). By 1800, all the island's great auks had been killed. The ashes and pens still remain on Funk Island as the only reminder of this extraordinary bird.

Islands off Iceland and Newfoundland became the last refuges of the great auk. When word spread in the 19th century that the species was nearing extinction, hunters went in search of them for museums and egg collections. The eggs and skins of the Garefowl, as it was known to Europeans, were sold at auction in London and to European museums for very high prices. Hundreds of English pounds were offered for each egg, encouraging fishermen to comb islets for the last of the nesting birds. The only remaining birds known to survive were killed on Eldey Island off southwest Iceland on June 2, 1844; three Icelandic fishermen who discovered two birds, a breeding pair with a single egg, strangled the adults and threw them into a boat (Birkhead 1994). These last great auks were killed for their skins, which were sold to a dealer (Birkhead 1994).

Other marine creatures barely avoided extinction during the period of unregulated killing of wildlife that began in the 1600s. The Atlantic walrus (*Odobenus rosmarus rosmarus*) herd off the Canadian coast numbered at least a quarter of a million animals prior to European exploitation. Between 1633 and 1642, vessels from the Massachusetts Bay Colony made a number of expeditions to Sable Island off Nova Scotia to kill the walruses for their tusks and oil. Glover Allen (1942), in *Extinct and Vanishing Mammals of the Western Hemisphere*, chronicles one sealing voyage in 1641 in which 12 men who spent eight months on Sable Island returned with "400 pair of sea horse teeth, which were esteemed and worth 300 pounds." The walrus colonies in the Gulf of St. Lawrence numbered seven or eight thousand

at that time; they were killed off by American sealers, who worked at night while the walruses slept on land (Allen 1942). Gradually, the Atlantic walrus became exterminated in all areas on the continent. From 1925 to 1931, the last large population in the Canadian Arctic on Baffin Island was devastated by the killing of 175 thousand animals (Nowak 1999). Although finally given protection, the species has not shown a substantial recovery because of the high kill by native peoples, which equals annual recruitment in the western Atlantic (Nowak 1999). Only 25 thousand walruses remain in this region. Russia classifies the species as vulnerable and the population in the Laptev Sea as rare (Nowak 1999). They may have increased somewhat along the coast of Norway, in the Svalbard region and Barents Sea (Nowak 1999).

Although the Pacific gray whale has now recovered from near•extinction from whaling, few people are aware that this species once lived in the Atlantic as well (Allen 1942, Mowat 1981). Large numbers of Atlantic gray whales migrated along North America's eastern coast until as late as the end of the 18th century (Mowat 1981). Whalers of the 1740s saw whales whose descriptions matched those of the gray whale, but the existence of this species was not verified until fossil remains were uncovered (Allen 1942, Mowat 1981). Early Basque whalers had eliminated gray whales from European waters centuries before (Mowat 1981). Atlantic gray whales swam south along the shore of the coasts of Maine, Massachusetts and Long Island, down to the Florida Keys, where their calves were born (Mowat 1981). This whale, known as the "Scrag" in the Northeast, was a familiar species off the coasts of Nova Scotia and Maine in early colonial times. It gave rise to place names such as the Scrag Islands, Scrag Rocks and Scrag Harbor Œ now known as Sag Harbor (Mowat 1981). These whales fed in shallow bays on abundant bottom•dwelling crustaceans, making them easy prey for whalers. They were killed beginning in the early 1600s by harpooners off Nantucket Island, Cape Cod and Long Island Sound in the shallow shoals of their migration route (Mowat 1981). By the early 1700s, New England whalers had completely eliminated this whale (Mowat 1981).

Beginning in 1609, Samuel de Champlain sailed down the St. Lawrence River to the Great Lakes (Peck 1990). Other explorers and settlers established trading posts and villages. Furs were major items of trade, and soon beaver and other furbearers were traded in the millions by the French and English. Early travelers found wild turkeys (*Melagris gallopavo*) so abundant boys threw stones at them for recreation (Peck 1990). Two French explorers observed great numbers of fish in the Great Lakes and the upper Mississippi River, which soon became exploited. Vast numbers of cisco, members of the Salmonidae family, once lived in the Great Lakes. The Blackfin Cisco (*Coregonus nigripinnus*) and Deepwater Cisco (*Coregonus johannae*), native to Lake Michigan and Lake Huron, were considered "jumbo herring" by fishermen from early times (Day 1981). By the late 19th century, large fishing vessels with huge nets caught up to 15 million tons from one lake alone per year; one net haul might yield as much as 10 tons in a day (Day 1981). Fishing continued, even in winter, through ice holes, and prior to the availability of freezing facilities, dumping of unsold catches amounted to many tons (Day 1981). These fish became commercially extinct after World War I, and subsequently were declared extinct by the World Conservation Union, along with another Great Lakes species, the longjaw cisco (*Coregonus alpenae*) (Baillie and Groombridge 1996).

This overfishing was repeated in the Atlantic waters off New England and southern Canada. Cod, halibut and flounder abounded here, providing ample fish for centuries to local fishing communities. Huge cod weighing 180 pounds and halibut the size of barn doors were often caught in these times. Factory fishing ships began fishing here in the 1950s and soon depleted the stocks. National legislation banned these vessels from the Atlantic coast and smaller vessels took their place. With few restrictions on take Š and far too many fishermen Š the stocks crashed in the 1980s and early 1990s. With the encouragement of the National Marine Fisheries Service (NMFS), fishermen turned to small sharks known as dogfish. Within a few years, they also became depleted because of their extremely slow reproductive rate, a fact apparently not appreciated by the NMFS. Fishery conservation legislation has been enacted, but these stocks may never return to former abundance.

Some fisherman are being compensated for their boats by a federal program, in order to ease fishing pressure on remaining stocks, but others are turning to small fish, such as menhaden. These fish are fed on by humpback whales (*Megaptera novaeangliae*), threatened species not yet recovered from past whaling, as well as by puffins and other seabirds. Many seabirds are undergoing population decline as a result of a dwindling food supply and the drowning

risk posed by fishing nets. Shorebirds, too, are affected by overfishing. Horseshoe crabs (*Limulus polyphemus*) lay their eggs along the east coast each year, providing abundant food for shorebirds on their northward migration, and for many types of other wildlife as well. These crabs are captured by the millions for use as fish bait, which has reduced their numbers dangerously in some areas. The shorebirds have also declined precipitously in recent years, some species by 90 percent. Entire food chains are being disrupted as a result of over exploitation of the sea. Ocean pollution has contaminated Atlantic coastal waters, causing die-offs of dolphins, fish and manatees.

All along the East Coast, colonists built cities at river deltas, which were surrounded by vast salt marshes. These locations were considered prime seaport and manufacturing sites, and the marshes were filled in and polluted. Tens of thousands more acres of marshes along the Northeast coast have been ruined by construction of drainage ditches to control mosquitoes and halt malaria. In fact, these ditches created habitat for mosquito breeding and caused the water level in the marshes to drop. Waterbird populations declined sharply as a result, and they no longer filled their role as fish and shellfish nurseries, water filterers and flood controls. In a recent development, dikes in 10 thousand acres of marshes on Long Island are being blocked to open normal flow channels between marsh and bay, and exotic reeds are being removed (Lambert 1997). The marshes that have been returned to their natural state showed an immediate tripling in the number of waterfowl wintering there, and a doubling of wading birds such as ibis, egrets and herons; shorebird populations quintupled; these marshes have at least 130 species of breeding birds, and 300 species use them for wintering or migration (Lambert 1997). The marshes give a glimpse of the wealth of wildlife that once inhabited eastern coasts; with similar programs, they can be restored to help build up stock of fish and shellfish.

In most areas, however, housing and development now occupy the sand dunes and former marshes. Some barrier islands off the coasts, which buffer the beaches against the erosion effects of storms, have been preserved in portions of the East Coast, such as Virginia, North Carolina and Georgia. Elsewhere, roads, houses and businesses clutter these islands, and development has endangered many native birds. Georgia's beautiful coastal marshes were given official protection after they were nearly destroyed by phosphate mining, when it was shown that their value as shrimp and fish nurseries far outweighed their short-term value for phosphate.

At the southern tip of the United States, the Florida Everglades, one of the largest wetlands in the world, once provided nesting and feeding ground for millions of egrets, herons, pelicans and other waterbirds. This sawgrass wilderness sheltered vast numbers of American alligators (*Alligator mississipiensis*). Cougars, known as Florida panthers (*Felis concolor coryi*), were common, and preyed on the small Everglades white-tailed deer. Water diversion projects for agriculture and the new human population of Miami and coastal cities resulted in a drying out of the Everglades. Exotic plants have proliferated in the marshes, overwhelming the native grasses and choking waterways. Ninety percent of the populations of waterbirds disappeared. The Florida panther recently became extinct in Everglades National Park, one of its last refuges. The alligator has recovered from nearly disastrous hide hunting in Florida, but remains rare in many parts of its original range. A project to restore some of the waterflow to the Everglades was enacted into law in the 1990s (see Aquatic Ecosystems chapter).

The American crocodile (*Crocodylus acutus*), a saltwater species inhabiting coastal areas, was once numerous in Florida Bay and in the mangroves of the Keys. Today, this is one of the most endangered species in the country, numbering fewer than 400 animals. Early hide hunting reduced them and, in this century, pollution and loss of mangroves in their habitat have pushed this species close to extinction.

Many Everglades bird species are also endangered, and one has recently become extinct Š the dusky seaside sparrow (*Melospiza maritima nigriscens*). This sparrow, with its unusually dark coloration, was a victim of the massive destruction of wetlands in Florida. By the time it received the protection of the US Endangered Species Act, this subspecies was nearly extinct. Its limited habitat of spartina grass on Florida's central Atlantic coast had been flooded for mosquito control and drained for the construction of nearby NASA facilities (Ehrlich *et al*. 1992). In an 11th-hour attempt to save these little sparrows, a captive breeding program was set up, mating them with a related subspecies to preserve some of their genes. The last purebred dusky seaside sparrow died at the age of 13 in 1987 (Ehrlich *et al*. 1992). The breeding program was not successful, and by 1997, the related subspecies had also become

endangered.

Two spectacular waterbirds, the American flamingo (*Phoenicopterus ruber*), and the scarlet ibis (*Guara rubra*), were once residents of south Florida. Both species were eliminated in the 19th century when, as William T. Hornaday (1913) observed, they "attracted the evil eyes of the 'milliner's taxidermists.'" The feather trade of the late 19th century nearly exterminated the majority of North America's wading birds and many of its seabirds through unregulated slaughter for plumes to adorn ladies' hats. Egrets, roseate spoonbills, herons, terns and other birds with long or colorful feathers were killed indiscriminately. In 1900, the Lacey Act and state laws extended protection to these birds by banning sale and interstate commerce, and the Migratory Bird Treaty Act, signed with Canada in 1918, protected native North American non•game birds from capture, killing and sale.

The Eastern Forests

Ancient hardwood forests stretched for thousands of square miles in eastern North America. Massive oaks, chestnuts, hickories, walnuts and beech trees dominated, some reaching heights of more than 100 feet, with trunks 20 or more feet in circumference. Giant hemlocks and many kinds of pine dominated some areas. The passenger pigeon was the most abundant denizen of these forests, and its range extended from southern Canada, New England and the Great Lakes west to the Great Plains and south to Virginia. The slim bird was somewhat smaller than the familiar rock dove or common pigeon found in cities worldwide, with a long, pointed tail. The male's plumage was beautiful; his back, wings and head were bluish•gray with black streaks and spots, which contrasted with a rich, pinkish tinge on his lower throat. His breast feathers became paler on the belly, and a patch of pink or purple•pink iridescence shone at his neck. His eyes were bright red surrounded by purplish skin, and his legs and feet were red (Goodwin 1983). The female was a duller version of the male, browner gray above, light gray on the breast, with a smaller iridescent pink patch on the neck, more profuse black spots on the wings and gray skin surrounding her orange eyes (Goodwin 1983).

This is the only pigeon Š living or extinct Š that flocked and nested in vast numbers, darkening the sky during their migrations. When Europeans first encountered passenger pigeons, they were dumbfounded by their numbers. One immigrant, Pehr Kalm, described their passage in the spring of 1749: "on the 11th, 12th, 15th, 16th, 17th, 18th and 22nd of March . . . there came from the north an incredible multitude of these pigeons to Pennsylvania and New Jersey. Their number, while in flight, extended three or four English miles in length, and more than one such mile in breadth, and they flew so closely together that the sky and the sun were obscured by them, the daylight becoming sensibly diminished by their shadow" (Fuller 1987). When the pigeons landed on trees, their weight was sometimes so great that not only would large limbs break off, but entire trees would topple. Prior to settlement of the continent by Europeans, as many as 5 *billion* birds inhabited Kentucky, Ohio and Indiana alone (Blaugrund and Stebbins 1993).

Passenger pigeons were migratory, as their scientific name, *Ectopistes migratorius*, suggested, but not in the manner of most birds, who migrate from an ancestral nesting area to an ancestral wintering area. Instead, immense columns of birds flew as a unit at speeds estimated as high as 60 miles per hour in wide areas in search of nut trees and seeds. John James Audubon, famed illustrator of American birds, described flights in the 1830s that covered the sky for days in some areas, while in other years, none would be seen in the same area (Blaugrund and Stebbins 1993). The forests that once stretched nearly unbroken across eastern North America were crucial to the survival of the passenger pigeon flocks. Nut trees (oaks, hickories and beeches) produced large crops only every few years. In order to locate adequate feeding supplies, the pigeons covered great distances.

John James Audubon visited a roost in Kentucky accompanied by some pigeon hunters in 1831:

Many trees two feet in diameter, I observed, were broken off at no great distance from the ground; and the branches of many of the largest and tallest had given way, as if the forest had been swept by a tornado. Every thing proved to me that the number of birds resorting to this part of the forest must be immense beyond conception . . . Suddenly there burst forth a general cry of 'Here they come!' The noise which they made, though yet distant, reminded me of a hard gale at sea passing through the rigging of a close•reefed vessel. I felt a current of air that surprised me. Thousands were soon knocked down by the pole men. The birds continued to pour in . . . The pigeons, arriving by thousands, alighted everywhere, one above another, until solid masses as large as hogsheads, were formed on the branches all round. Here and there the perches gave way under the weight with a crash, and falling to the ground, destroyed hundreds of the birds beneath, forcing down the dense groups with which every stick was loaded. It was a scene of uproar and confusion. I found it quite useless to speak, or even to shout to those persons who were nearest to me. Even the reports of the guns were seldom heard, and I was made aware of the firing only by seeing the shooters reloading (Schorger 1973).

Once they located a forest with abundant food, they nested in huge aggregations. One colony in Wisconsin was estimated to cover more than 750 square miles, with 136 million nesting birds (Wilcove 1991). Audubon wrote of their courtship, "the tenderness and affection displayed by these birds toward their mates are in the highest degree" and painted two birds "billing" for his *Birds of America* series (Blaugrund and Stebbins 1993). Some described their courtship songs as a series of bell•like notes (Fuller 1987).

Their nests, constructed of loose sticks, held their single white egg. A tree could hold many nests, which the birds placed on strong branches close to the trunk. The flocks rarely nested in the same area two years running, and dispersed as soon as nesting was over; this may have been to prevent natural predators from increasing enough to have a serious impact on their numbers (Wilcove 1991). Also, their food supply tended to be abundant only every few years in a given area. These great colonies made easy targets for legions of meat and market hunters, beginning in the 1600s. By the 18th century, naturalists began to observe that nesting colonies were disappearing; the last great nesting in New England took place near Lunenburg, Massachusetts, in 1851 (Wilcove 1991). By the 1860s, the large flocks had been hunted out of coastal New York State and Pennsylvania. The few laws that were enacted to protect them in the Northeast were not enforced (Wilcove 1991). Season after season, pigeon hunters killed millions of these birds, destroying one colony after another.

Neltje Blanchan, in the 1904 book *Birds That Hunt and Are Hunted*, documented that unlimited netting, even during the nesting season, had resulted in sending more than 1 million pigeons to market from a single roost at the height of the hunting; an equal number of birds were wounded or left starving, helpless, naked chicks behind. Hunters shipped 100 thousand pounds of pigeons to market from a nesting colony near Grand Rapids, Michigan (Wilcove 1991). Audubon and other observers of the time described the brutal hunting methods: young birds were knocked out of their nests with poles, and captive pigeons, whose eyelids had been sewn shut, were tethered to lure wild pigeons to the ground where they were netted (Wilcove 1991). Nesting trees were cut down or set afire, and sulphur was burned under nesting trees to kill the birds (Wilcove 1991). Blanchan (1904) described the glut of pigeons at markets as so great that the price per barrel scarcely paid for their transportation. The pigeon meat was often fed to hogs.

By the late 1800s, it had become evident to some that the killing was having a disastrous effect on the passenger pigeons. The warnings went unheeded, however. In Ohio, a bill submitted in 1857 to protect the passenger pigeon received the following report from a Select Committee of the Senate: "The passenger pigeon needs no protection. Wonderfully prolific, having the vast forests of the North as its breeding grounds, traveling hundreds of miles in search of food, it is here to•day and elsewhere to•morrow, and no ordinary destruction can lessen them, or be missed from the myriads that are yearly produced" (Hornaday 1913).

The final and precipitous decline of passenger pigeons began in the 1870s, a decade which began with some large flocks still attempting to nest in the Great Lakes area. In 1878, naturalists estimated that some 50 million pigeons survived, but with continued heavy hunting, only one large nesting colony in Wisconsin remained in 1887 (Wilcove

1991). This colony dispersed within two weeks after beginning to nest when hunters began shooting at them (Wilcove 1991). By the 1890s, only scattered individual pigeons Œ who were apparently unable to breed or forage successfully Œ remained. In 1892, one observer noted, "The extermination of the passenger pigeon has progressed so rapidly during the past twenty years that it looks now as if their total extermination might be accomplished within the present century" (Blanchan 1904). This statement proved correct. The incredible wildlife spectacle that flights of billions of passenger pigeons presented, ended completely on March 24, 1900, when the last wild bird was killed in Pike County, Ohio (Wilcove 1991).

The reason for the sudden crash in passenger pigeon numbers has been the subject of controversy in the years since. Two ornithologists from the University of Minnesota, David E. Blockstein and Harrison B. Tordoff, believe during the last 20 years prior to its wild extinction, hunters were able to disturb or destroy virtually every nesting colony. Each year, the adult birds that were able to escape previous hunting and attempt breeding were harassed or chased off the nest, or their fledglings were killed (Wilcove 1991). The adults not killed were relatively long-lived, averaging a lifespan of about 20 years, but because their numbers were not replaced by succeeding generations, when they died off, the species became extinct (Wilcove 1991). Blockstein and Tordoff noted some Passenger Pigeons nested in small groups, escaping the attention of hunters, but they conjectured that without the protection provided by large colonies, these birds rarely succeeded in producing fledgling chicks, and were easy targets for predators (Wilcove 1991). This explanation seems logical, and clearly, the birds were unable to survive in small, scattered groups, dependent on a large colony for successful reproduction. Other factors may also have entered in. It may be that only in the presence of large numbers of their own kind was instinctive breeding behavior stimulated.

A captive passenger pigeon named Martha, about 29-years-old and the last of her species, died at 1 p.m. on September 1, 1914 at the Cincinnati Zoological Gardens. This is perhaps the only species for which the exact minute of its extinction is known (Fuller 1987).

Logging and settlement of the eastern hardwood forests destroyed forever the ancient habitat of these lovely pigeons. Even if the passenger pigeon was somehow recreated, the huge expanses of nut and seed-bearing trees it required have since been cut. More than 99 percent of virgin woodland in the East has been logged, first by settlers, and later by commercial loggers. The colonists of New England, after destroying the forests, found farming the rocky soil difficult and unproductive. The short growing season, often interrupted by frosts, further limited agriculture there. Most of these farms were abandoned, and today, second-growth forest covers the region. However, it is composed of different species of trees than the original old-growth forest and is far poorer in wildlife.

The American chestnut (*Castanea dentata*) once comprised a third of eastern hardwood forests; a huge tree 100 feet tall with a spreading canopy, it had girths up to 12 feet (Jonas 1993) and produced bountiful crops of chestnuts. American chestnuts grew east of the Mississippi River from Maine south to Georgia. Of the 12 species of chestnut trees worldwide, the American was known for yielding the tastiest nuts (Jonas 1993). After heavy logging, older trees became confined to wilderness areas and towns, where they were greatly admired as shade trees. In 1904, the spores of a fungus known as chestnut blight were accidentally introduced to the country, probably on seedlings of imported Chinese chestnut trees (Jonas 1993). The blight destroyed the remaining chestnuts in the eastern forests, leaving only stumps. These stumps still sprout shoots that grow up to 20 feet until they, too, succumb to the blight (Jonas 1993). Only a few unblighted American chestnut trees remain in the country. On the West Coast, a small number of the trees were planted out of their natural range, and the blight did not reach them (Jonas 1993). Progress is being made in breeding disease-resistant strains of this tree (see Forests chapter and Projects section).

Another eastern hardwood, the stately American elm (*Ulmus americana*), which reaches heights of 60 to 120 feet, has a slim, straight trunk and a broad, graceful crown. It is also nearly extinct; it was attacked by a fungal infection known as Dutch elm disease, which is gradually killing off these trees. First seen in 1930, the disease spread west. It is still in the process of eliminating trees throughout their range in North America from Nova Scotia to Saskatchewan, south to Florida and west to Texas (Jonas 1993). A disease-resistant strain of this tree has also been bred, and the trees are being distributed for free by a nonprofit organization (see Forests chapter and Projects section).

American beeches (*Fagus grandifolia*) were perhaps the most important food tree for wildlife, producing massive amounts of beech nuts on which passenger pigeons, wild turkeys, black bears and other wildlife fed. At 50 to 70 feet tall, beeches have short, wide trunks that begin branching 10 feet from the ground and form enormous, wide crowns (Jonas 1993). The species is still fairly widespread, but old American beeches, which can live 400 years and grow to enormous girths, are extremely rare in woodland settings where they have been logged out.

Ironically, the colonists could have lived well off the land they found if they had not destroyed both the forests and much of the wildlife within a few centuries. The abundant nuts produced by hardwoods, which had nourished the passenger pigeons, also provided food to Native Americans. Many tribes had learned to remove the tannin from acorns so it could be ground into nutritious high-protein flour. Beechnuts, chestnuts, walnuts, hickory nuts, wild fruits and seeds provided excellent food for people as well as wildlife.

European settlers destroyed this rich ecosystem by commercializing the resources, turning ancient forests into short-term logging profits and wild birds, deer and furbearers into commodities. Had another road been taken, the natural environment would have endured with ample resources for all to live on. Many native tribes had cleared some forests for agriculture, but the vast majority remained in their natural state. Settlers, later supported by government policy, claimed ownership of the East and then proceeded to oust native peoples or relegate them to tiny reservations. This resulted in the killing of hundreds of thousands of natives and the extinction of many tribes.

The new Americans, in adopting the European approach to nature, tamed the wilderness and began a program of eliminating natural predators. They considered the reverence with which Native Americans had treated all living things to be a weakness. At the time of European colonization in the 17th century, almost no natural forests remained in Western Europe. Large predators had been eliminated from most of Western Europe, and most wildlife had been crowded out, killed off or confined to private estates where the animals were considered the property of landowners, providing food and sport to the upper classes. Moreover, this wildlife was hardly wild, but semi-tame. Deer lacked predators, the woods on estates were stocked with game birds and the streams with salmon and trout by gamekeepers. The vast majority of European settlers came from the lower and middle classes; they had previously been denied the right to hunt and were eager to do so with abandon. This was another motivation for the relentless slaughter that decimated wildlife during this period.

Benjamin Franklin hoped to make the wild turkey the official symbol of the United States. When colonists arrived, the species was abundant in eastern forests. Uncontrolled hunting and the cutting of forests eliminated these birds from state after state: Connecticut by 1813, Massachusetts by 1851, New York in the mid•1800s, South Dakota by 1875, Ohio by 1880, Wisconsin by 1881, Michigan by 1897, Illinois by 1903, and Iowa by 1907 (Burger 1978, Peters and Lovejoy 1990). Fortunately, the species was not destroyed altogether, and it has been reintroduced into many parts of its original range through transplants from remnant populations.

Once the eastern forests echoed with the howls of gray wolves (*Canis lupus*), common throughout the continent except the Southeast, where the smaller red wolf (*Canis rufus*) roamed. Both these wolves were deliberately persecuted into extinction by colonists who placed bounties on their heads, effectively eliminating them from the wild in the eastern United States prior to the 20th century (see Persecution and Hunting chapter). Seven races of the gray wolf are now extinct, bountied and poisoned by settlers. Around 1911, the Newfoundland race, *Canis lupus beothucus*, was the first to become extinct. This pure white, large wolf had a scientific name inspired by the Beothuk Indian tribe of Newfoundland; both the wolf and the tribe were exterminated by Europeans (Day 1981).

The red wolf became extinct in the wild in the 1970s, after centuries of persecution and habitat loss. Two subspecies, the Florida black wolf (*Canis rufus floridanus*) and the Texas red wolf (*Canis rufus rufus*), are extinct, and only one race survives. The last members of the species were taken into captivity and bred successfully. A reintroduction program in portions of its original range has brought the species back, and about 100 red wolves now live in the wild. The cruelty with which the gray wolf was eliminated is described in detail in the Persecution and

Hunting chapter. Another predator once common in these forests north of Florida was the Eastern cougar (*Felis concolor couguar*). It was also bountied and hunted until it became extinct throughout the eastern United States.

In the northern woods, eastern subspecies of the American bison, elk, caribou, moose and white•tailed deer were extremely common. The hunting by Native Americans armed with bows and arrows did not, apparently, cause declines. The guns brought by Europeans, however, decimated their numbers. An unrestricted slaughter of these ungulates went on for centuries. The white-tailed deer became endangered, disappearing from the eastern forests, first from the vicinity of towns and habitations, then from wilderness areas. The other ungulates died out altogether in New England and the middle Atlantic area. The Eastern elk (*Cervus elaphus canadensis*) became extinct. One cause for the disappearance of this huge member of the deer family was hunting to obtain its teeth, which a private organization, the Fraternal Order of the Elks, used as watch•chain insignia (Day 1981). Not only were these animals hunted for food and sale in meat markets by the colonists, but an active export trade in deer and elk skins sprang up. Records show an average of 100,000 of these skins exported to England each year between 1778 and 1808 (Poland 1892). Several small populations of reintroduced elk inhabit Pennsylvania, North Carolina, Tennessee and Virginia.

Hunting caused the extinction of the Eastern bison (*Bison bison pennsylvanicus*) by 1800. This race of bison was larger than the plains bison and very dark; some of the bulls were coal black with grizzly white hair around the nose and eyes (Allen 1942). The last herd of Eastern bison was slaughtered in Union County, Pennsylvania in the winter of 1799 to 1800, as the animals huddled helplessly in the deep snow; the last individuals of this race were killed near Charleston, West Virginia in 1825 (Allen 1942).

Caribou (*Rangifer tarandus*) and moose (*Alces alces*), native to northern New England and southern Canada, were hunted to extinction in the United States in colonial times, surviving only in Canada (Allen 1942). The white•tailed deer has reoccupied its former range in the northeastern United States and, in fact, these deer have become overpopulated as a result of a lack of natural predators (see Persecution and Hunting chapter). The moose has been reintroduced in recent years to New England and is gradually dispersing southward. Attempts to reintroduce caribou in Maine have failed.

The heath hen (*Tympanuchus cupido cupido*) was another casualty of colonial settlement. This eastern subspecies of the greater prairie chicken, a grouse•like bird, was native to forest edges, grassland and heath in portions of the Northeast, from Massachusetts to Pennsylvania and New Jersey (Greenway 1967). Pursued by market hunters, these birds became a staple food for colonists. Heath hens were so common in Massachusetts in colonial times that Governor Winthrop ordered his servants not to have them served more often than a few times a week (Greenway 1967). By 1830, the last mainland Massachusetts heath hen was shot in the western part of the state. In New York State, a 1791 law banned hunting of these birds during spring and summer, but the law was flouted, and market hunting on Long Island resulted in its extinction there by 1844 (Greenway 1967). Overhunting in New Jersey and Pennsylvania killed off the last birds in these states by the 1860s. The last population of these birds survived on Martha's Vineyard island off the Massachusetts coast and, although protected from hunting, fire and predation gradually eliminated them by 1932 (Greenway 1967).

The existence of brilliantly colored parakeets flying in large flocks in eastern North America was an unexpected surprise for European colonists settling the country. They had thought such birds lived only in tropical regions. Yet these parakeets obviously had adapted to winter snows and frigid nights. The species was named the Carolina parakeet (*Conuropsis carolinensis*) and had a long, graceful tail and a bright yellow and orange head. Its green wings were tinged with yellow, set off by its overall forest green plumage. Eastern parakeets belonged to the subspecies *Conuropsis carolinensis carolinensis* and ranged from Florida to southern Virginia, while western parakeets, *Conuropsis carolinensis ludovicianus*, had a wide distribution from the Mississippi-Missouri River drainage south to Texas, east to Mississippi and north to western New York State and the Great Lakes region (Forshaw 1989). These birds flew in enormous flocks and may have numbered in the millions prior to European settlement.

Like conures (*Aratinga* genus), native to the Caribbean and Latin America, Carolina parakeets could give away

their presence by loud and raucous calling. Because they fed on many types of wild seeds and fruits and were able to endure freezing temperatures, they were among the few species in the parrot family able to survive in harsh climates, with the ability to tolerate temperatures as low as -25 F. (Cokinos 2000). Early travelers in Kansas described the appearance of screaming bands of these parakeets during swirling winter snowstorms; flocks settled in groves of cottonwood and walnut trees, delighting travelers with their vocalizing and dazzling colors (McKinley 1985). Large, hollow trees were among their favorite roosting spots, and flocks of birds would cling to the inside of the trees with their beaks and feet (Forshaw 1989). In early morning, the birds would climb to the top branches of their roosting trees, to the accompaniment of much chattering, and then fly off to feed for several hours. When they saw a fruit or seeding tree, the flock would spiral down until they almost reached the ground, and then rise up to alight on the branches. In the afternoons, they sheltered in groves of trees, often near streams where they drank and bathed (Forshaw 1989).

These parakeets may have been most abundant in the South and the major river valleys of the Midwest. Early naturalists described them perched in huge Bald Cypress trees, their bright plumage contrasting with the pale green, feathery foliage. They would hover and flutter on the tops of these cypresses, extracting the seeds (McKinley 1985). Travelers in the southern hardwood forests and swamps, as well as in pine woods, found them very numerous. In Florida's St. John's River area, where mid-19th century observers saw large flocks, many were killed by plantation owners for food (McKinley 1985).

In Audubon's painting of Carolina Parakeets, these extremely sociable birds are clustered in a tree, feeding on Cockleburs (*Cenchrus tribuloides*), their favorite food (Blaugrund and Stebbins 1993). Only recently have the true colors of this bird, as depicted by Audubon, been revealed by a publication of his original watercolors, which shows their plumage in shades of vivid green, yellow and reddish orange. In the lithographs of previous editions, these colors were drab and dull (Blaugrund and Stebbins 1993).

As their forests were cut and prairies plowed for farms, the parakeets turned to raiding crops and orchards. Flocks would converge on farms at times of harvest, alighting on stacks of grain sheaves. So dense were the perching and feeding birds that they made the stacks look as if "brilliantly colored carpets had been thrown on them," according to Audubon (Forshaw 1989). For these raids on farms, they received "severe retaliations" from farmers; Carolina parakeets were easily approached and never learned to fly away from humans. Farmers would shoot entire flocks, killing 10 or 20 at each discharge (Forshaw 1989). When one was shot, the others refused to leave their wounded or dead flock mate. Audubon described these massacres: "The living birds, as if conscious of the death of their companions, sweep over their bodies, screaming as loud as ever, but still return to the stack to be shot at, until so few remain alive, that the farmer does not consider it worth his while to spend more on ammunition" (Poattie 1940).

Like many members of the parrot family, Carolina parakeets attempted to aid others of their kind who were stricken or threatened by predators. This behavior contributed to their survival in natural conditions, and only the devastating killing power of guns hastened their extinction. Audubon described procuring a basketful of the parakeets with a few shots in 1831 in order to choose good specimens for drawing the figures for his watercolors of North American birds (Fuller 1987). Thousands more of these parakeets were captured for the pet trade and killed for museum collections. At least 675 of the eastern race alone are found in museums. In the last decades of the 19th century, amateur collectors of specimen birds and their eggs proliferated around the country, and dealers in specimens earned large sums from the sale of rare birds. The rarer the bird, the higher the price paid, further endangering the species. Many birds were killed for specimens by collectors who failed to note the location and date of the killing (McKinley 1985). Molting adults and juvenile birds were thrown out, and the physical appearance of the latter birds remains unrecorded (McKinley 1985). One German taxidermist, August Koch, visited the home of a friend in Florida in 1887 and shot some of these parakeets in the back yard of his host as they fed on mulberries (McKinley 1985). A tree that appeared to be sporting "yellow flowers with red centers," turned out to be a flock of parakeets roosting in the early evening, and he shot two birds for his collection (McKinley 1985). Another hunter was led by a Seminole Indian to a "parakeet tree," a large, hollow cypress tree near Lake Okeechobee in Florida, where he shot "as many specimens as my ammunition would allow" (McKinley 1985).

In spite of the keen interest in the species by scientists, naturalists and members of the public, few observations were made of the behavior of these parakeets while they were still common. Almost nothing is known of their life history, flock movements, breeding seasons, nesting, feeding or ecology (McKinley 1985). It is known, however, that they were long-lived, based on the survival of the last captive specimens, which were at least 32 years old. Although a few bred in captivity, they often abandoned their eggs, and no captive-bred birds survived (Forshaw 1989). In spite of large numbers captured for sale as cage birds, no serious effort was made to perpetuate the species through captive breeding, which might have prevented their extinction.

As early as 1831, Audubon noticed a decline: "Our parakeets are very rapidly diminishing in number; and in some districts, where twenty-five years ago they were plentiful, scarcely any are now to be seen" (Forshaw 1989). Flocks of several hundred had commonly been seen when the country was first settled. Within about 90 years, by the 1880s, they had declined both in range and number, with only small flocks or pairs remaining (Forshaw 1989). Persecution by farmers was a major cause Š and perhaps the most important factor Š in the decline of the Carolina parakeet in the view of parrot ornithologist, Joseph Forshaw (1989). The last flocks sought refuge in the forests and remote swamps of Florida, where collectors and trappers pursued them (Forshaw 1989). Other factors played important roles as well. Thousands were killed for sport or for their feathers to decorate ladies™ hats. Their nesting and roosting trees were cut by settlers and loggers, and their food plants were plowed under by farmers (Cokinos 2000). European honeybees, armed with stingers and introduced by colonists, also may have driven them from their hollow trees as they rapidly spread throughout the country, seeking hive sites (Cokinos 2000). These hollow tree-roosting sites may have been crucial to their survival in cold weather; the birds crowded together side-by-side for warmth. The giant hollow cypresses and sycamores, oaks and other hardwoods in the old-growth forests of the eastern United States, crucial habitat to so many species of wildlife, were among the first trees cut in bottomland swamps and forests.

A few Carolina parakeets survived into the first years of the 20th century, with sightings reported in the Panhandle and the Kissimmee Prairie of north-central Florida (McKinley 1985). The last wild specimen was taken in either 1901 or 1904; the date is still in dispute (Cokinos 2000). A flock of 13 of these birds was seen near Lake Okeechobee, Florida in 1920, and two eminent ornithologists, Alexander Sprunt and Robert Porter Allen, went in search of the last members of the species in 1936. They reported seeing a flock along the Santee River in South Carolina, but the National Audubon Society later dismissed the account (Forshaw 1989). In any case, the area was later destroyed for construction of a power project (Forshaw 1989). No confirmed sightings were made after about 1920, although a black-and-white home movie made in 1937 showed some parakeets in the Okefenokee Swamp of southeastern Georgia that *may* have been of this species (McKinley 1985). Had the Carolina parakeet been accorded legal protection and reserves set aside during the 19th century, this spectacular species would almost certainly still be alive.

A pair of Carolina parakeets kept at the Cincinnati Zoological Gardens Œthe same zoo that housed Martha, the last passenger pigeon Œ was the last known members of their species. Sixteen of these parakeets were purchased by this zoo in the 1880s for $2.50 per bird (Fuller 1987). Over the years, the birds laid eggs, but none hatched or were even incubated, and gradually they died off until only a pair was left Š cage-mates for 32 years (Fuller 1987). In the late summer of 1917, the female, Lady Jane, died. Incas, the male, became listless after her death, and in February 1918, he died of grief, the keepers claimed (Fuller 1987).

The old-growth pine and mixed hardwood forests of the Southeast, as well as Cuba, were home to a large and noisy bird that may have disappeared. The ivory•billed woodpecker (*Campephilus principalis*), at 18 to 21 inches long, is the largest woodpecker in the United States or Canada and the second largest in the world. Elegant in appearance, both male and female are predominantly black, with stripes of white feathers on both sides of the neck; the lower half of their wings is white, as is the enormous bill for which the species was named (Short 1982). Their drumming on dead tree trunks once reverberated in the forests as they removed strips of bark a foot or more long to uncover beetle larvae. They also drummed as a territorial signal, trumpeted and made a call that sounded like a child™s tin horn. Their vocal repertoire also included a soft call between male and female perched side-by-side while changing places

incubating eggs in their high nest holes (Cokinos 2000). Never heard by scientists observing them in the wild, the ivory-billed woodpeckers uttered an extraordinary screech when captured and transported away from their forest, as described by ornithologist and artist Alexander Wilson early in the 19th century (Cokinos 2000). Wounding an adult male to use as a subject for a painting, he was astonished to hear him utter fia loudly reiterated and most piteous note, exactly resembling the violent crying of a young childfl (Cokinos 2000). The bird continued to scream loudly as he was carried in a container to a town nearby, alarming people who took the noise for that of a child. Wilson rented a room where he planned to paint him, and the frantic bird began drumming on the wall, breaking off huge chunks of plaster, and damaged a mahogany table. Although offered food, the distraught bird refused to eat and died within three days (Cokinos 2000).

The ivory-bill's decline came as a result of heavy logging begun in the 18th century, which destroyed millions of acres of old-growth pine and hardwood bottomland forest in the Southeast. Each pair required a territory of at least 6 square miles of mature forest, and as their forest disappeared, ivory-billed woodpeckers became so rare that few were seen after 1900 (Cokinos 2000). Hunting also made inroads into their populations. These birds made large targets and were so conspicuous and noisy that they attracted the attention of meat and sport hunters in the 19th century. At that time, few people walked in the woods without a gun; most people took shots at any large bird or mammal.

Over-collecting of specimens by museums was another factor in the extinction of the ivory-billed woodpecker. Its size, beauty and natural rarity brought museum collectors from around the world to scour forests in the South for the last specimens of this bird. There are 400 known museum specimens worldwide (Day 1981), and most of these were taken in the last years of the 19th century, when the species had become extremely rare. Nineteenth century museum curators often sent collectors out to obtain specimens of very rare animals after they received word that the species was headed toward extinction. Responsible modern natural history museum curators do not routinely collect rare animals, but reach agreements to allow very limited collection of newly discovered species, usually only by the scientist who made the discovery. Most museums now loan specimens to scientists who wish to examine them.

Dr. Lester Short (1982), an authority on woodpeckers, believes the ivory-billed woodpecker's original habitat was probably the virgin pine forests that once covered much of the Southeast. They had become confined to hardwood swamp forests in Louisiana, which was probably not ideal habitat for them (Short 1982). Upon the discovery of a small number of Ivory-bills in a forest along the Tensas River in Louisiana, Cornell University scientists organized an expedition to film and record these birds. They later designated a young Ph.D. ornithologist, James T. Tanner, to study these last birds in the wild. In his study, *The Ivory-billed Woodpecker*, published in 1942, he estimated that at that time, no more than 22 of these woodpeckers remained in the United States. His investigation centered on the only known population of ivory-billed woodpeckers in the 120 square mile old growth forest. The Cornell team filmed the birds drumming on trees and recorded their various calls. This film is part of Stouffer Productions' fiAt the Crossroadsfl film. (See Video section, Endangered Species, General.) These recordings are retained in the Cornell Ornithological Library of bird songs, along with motion pictures of a pair of woodpeckers.

Tanner documented the presence of seven pairs and four young in 1934. He also traveled extensively in the Southeast, where ivory-billed woodpeckers were seen in the past, asking local people for sightings and listening for their unique calls; he was unsuccessful. From 1931 to 1939, the last remaining birds raised 19 young. They declined as he was observing them, however, and by 1939, only six ivory-billed woodpeckers Š one pair, one young bird and three males Š remained in these woodlands (Cokinos 2000). They had lost the majority of their habitat after the Singer Company sold the logging rights for these 80 thousand acres to Chicago Mills in 1937, and the old growth forest was rapidly leveled. Some of the birds may have been shot for the $1,000 collectors were willing to pay (Cokinos 2000). In the early 1940s, the National Audubon Society™s president appealed directly to President Franklin Roosevelt to spare the ivory-bills™ last habitat, and the Secretary of the Interior was ordered to consider the matter (Cokinos 2000). Various federal agencies and the War Production Board agreed these trees could be spared for the war effort. These agencies and four state governors urged Chicago Mills to protect this forest (Cokinos 2000). The State of Louisiana offered the company $200 thousand as compensation in December 1943, but it refused, and attempts in the US Congress to pass legislation to mandate protection of the Singer woodlands failed as well (Cokinos 2000). This company remained indifferent to the fate of the woodpeckers, red wolves, mountain lions, black bears

and abundant birdlife being destroyed to produce chests to ship tea to the English Army (Cokinos 2000).

Unknown to conservationists and government agencies was the fact that it was already too late. Richard Pough, a National Audubon Society employee, was sent to search for any remaining ivory-billed woodpeckers in the Singer woodlands in December 1943. He saw the last ivory-billed woodpecker, a lone female, and noted in January 1944: fiIt is sickening to see what a waste a lumber company can make of what was a beautiful forest. Watched them cutting the last stand of the finest sweet gum on Monday. One log was 6 feet in diameter at the buttfl (Cokinos 2000). This may have been the same female and her fledgling chick seen by Tanner in 1941, the only birds remaining at that time (Cokinos 2000). A wildlife artist, Don Eckelberry, heard of the disastrous situation for this species and traveled to the Singer woodlands to paint this female ivory-billed woodpecker. His observations constitute the last authenticated sightings of the species in the United States (Cokinos 2000).

Many searches have been made throughout its once wide range, which extended from southeastern Oklahoma and Missouri north to Indiana and east through northern Florida. Sightings have been made of these birds over the years in Florida and Mississippi, but none was authenticated by photographs or recordings (Cokinos 2000). The last 20th century observation was made on April Fool™s Day, April 1, 1999, by a forestry student along the Louisiana-Mississippi state line, in the Pearl River basin (Cokinos 2000). He claimed to have seen a male and female at close range in a swamp forest (Cokinos 2000). Subsequent searches of this forest by ornithologists and others failed to find any trace of ivory-billed woodpeckers (Cokinos 2000).

There is slim hope that the species might survive either in the United States or in Cuba. These birds were seen in Cuba™s southeastern pine forests during the early 1980s, but this population dwindled and disappeared by 1991 in spite of a reserve that had been set aside for it (Collar *et al.* 1994). In 1998, evidence of its possible survival in Cuba consisted of some likely sightings in the Sierra Maestra highlands, where it had never been seen before (BI 2000; Garrido and Kirkconnell 2000). Although unlikely, it would be a truly exciting event if the magnificent ivory-billed woodpecker survived in spite of the almost total loss of its habitat.

Bachman's warbler (*Vermivora bachmanii*), a small yellow songbird of the southeastern United States, has not been seen for decades. John James Audubon painted a pair of these birds without ever having seen them alive. The species was discovered in 1833 by his close friend, John Bachman (Blaugrund and Stebbins 1993). Audubon's painting was based on specimens sent to him by Bachman. He depicted the Bachman's warbler posed stiffly on a Franklinia tree (*Franklinia altamaha*), an equally mysterious species with large white flowers. Discovered in the South in 1765 by the noted botanists William and John Bartram, this beautiful tree was named in honor of Benjamin Franklin (Blaugrund and Stebbins 1993). In spite of thorough searches in the area in Georgia where the tree was found, the Franklinia was never seen in the wild again (Blaugrund and Stebbins 1993). Fortunately, the Bartrams had taken cuttings of the tree for cultivation, and this tree is now grown in botanical gardens and nurseries throughout the world. Bachman™s warbler became very rare after 1920.

Originally, these warblers ranged from the lower Mississippi River and east Texas, north to southern Indiana, and along the east coast from Georgia north to southern Maryland (Hamel 1995). The species' original habitat was southern bottomland, hardwood forest with extensive cane (*Arundinaria gigantea*) thickets (Hamel 1995). Clearance of these forests in the 19th century and first decades of the 20th century, both in the United States and in Cuba, where it wintered, eliminated the majority of its habitat. It is not known to what extent it used canebrakes and bamboo thickets growing on bottomlands, but these were the last habitats in which it was seen.

A 19th century observer of Bachman's Warblers, O. Widmann, entered bottomland forests in the Mississippi Alluvial Valley, and wrote in 1897, "I had no trouble in finding several singing males on the day of my arrival– In the wildness of his home it takes several minutes to follow him over fallen trees and around impenetrable thickets or pools of water" (Hamel 1995). Widmann saw its nest "tied very slightly to a vertical blackberry vine of fresh growth– From above, it was entirely hidden by branchlets of latest growth– to reach the place it was necessary to go through pools of water and heaps of fallen trees and brush. Such sheltered places are probably chosen to avoid the

danger of being trampled down by hogs and cattle roving in these woods" (Hamel 1995). This wild region was a mixed habitat of sweetgum, blackgum, tulip trees, mulberry, ashes, cottonwood, hackberry and hardwoods; Bachman's warblers were seen mainly in the higher portions, which were also those first cleared (Hamel 1995).

Approximately 400 scientific specimens were collected for museums, and this may have reduced its population at a time when it was already rare (Hamel 1995). The last nest was found in 1937, and much of this species' life history remains a mystery. Intensive searches have been carried out by biologists for this bird; a total of 7,000 hours were spent between 1975 and 1979 combing likely habitat areas in South Carolina, Missouri and Arkansas. In 8,000 hectares (19,768 acres) of apparently suitable habitat, no Bachman's warblers were seen or heard (Hamel 1995). As recently as 1980, an unconfirmed sighting was reported in Cuba, but the last confirmed sighting of a Bachman's warbler was in 1961 near Charleston, South Carolina (Hamel 1995). An unconfirmed sighting was made in 1988, but none have been seen since (BI 2000).

Endless Grassland

Stretching more than 1,000 miles from Illinois west to the Rocky Mountains, and from southern Canada south to Texas, the North American Prairie seemed endless. In the Midwest, tallgrass prairie interspersed with oak trees dominated, and farther west, in a north-to-south band, was an immense shortgrass prairie. Through its center flowed the Mississippi and Missouri Rivers, their confluence creating one of the world's greatest rivers. Lining the rivers were hardwood forest swamps from the Mississippi Delta at the Gulf of Mexico north to the Missouri River, where river otters, muskrats, beaver, mink and raccoon abounded. A vast mosaic of wetlands, known as "prairie potholes," dotted the northern Plains states and, during the spring, turned into ponds and marshes, making them perfect breeding areas for millions of waterfowl and shorebirds.

An estimated 50 million American bison (*Bison bison*) thundered across the prairie in a spectacle rivaling the migration of today's East African wildebeests, and far exceeding them in number. While the passenger pigeon may have been the most numerous bird in Earth's history, the bison is considered the most numerous large mammal to ever have lived on the planet. Coexisting with these bison were Plains tribes of Native Americans Š Pawnee, Blackfoot, Crow, Ojibwa, Sioux, Mandan, Comanche and others.

In 1804, President Thomas Jefferson commissioned Meriwether Lewis and William Clark to travel across the newly acquired Louisiana Territory west to the Pacific to conduct the first natural history survey of the American West. Clark described the prairie near the Missouri River as "rich, covered with grass from 5 to 8 feet high, interspersed with copses of hazel, plums, currents, –raspberries and grapes of different kinds" (Peck 1990). Lewis's journal entry records his awe of the landscape: "Nor do I believe that there is in the universe a similar extent of country. As we passed on, it seemed as if those scenes of visionary enchantment would never end."

Throughout their travels they saw "immense herds of buffalo, deer, elk and antelopes," some "so gentle that we pass near them without appearing to excite any alarm among them" (Peck 1990). Wolves and foxes were common, along with animals they had never seen before Š pronghorn antelope, jackrabbits, prairie dogs, coyotes, grizzly bears and many beautiful prairie birds (Peck 1990). One of the purposes of their journey was to assess the marketable potential of the wildlife, especially furbearers. Their observations paved the way for the fur trade and slaughter of wildlife that effectively eliminated large mammals from the Great Plains by the end of the century.

A visual record of the original prairie was made by various artists, the most famous of which was George Catlin, whose magnificent portraits of the Native Americans, American bison and landscapes preserve them for posterity. It

was Catlin who proposed this wild land be protected:

Nature has nowhere presented more beautiful and lovely scenes, than those of the vast prairies of the West; and of man and beast, no nobler specimens than those who inhabit themŠthe Indian and the buffaloŠjoint and original tenants of the soil . . . And what a splendid contemplation too, when one imagines them as they might in future be seen (by some great protecting policy of government) preserved in their pristine beauty and wildlife, in a magnificent park . . . A nation's Park, containing man and beast, in all the wild freshness of their nature's beauty (Peck 1990).

The world's first national park, Yellowstone National Park, was set aside in 1872, protecting some 2 million acres of mixed grassland and forest and the last wild bison in Montana and Wyoming, but Native Americans were excluded. The huge prairie park, as envisioned by Catlin in the central part of the continent, has not been established. It would have been a biological treasure for future generations. A tallgrass prairie national park was established in the 1990s, and perhaps in the future, a large national park will preserve portions of the once vast shortgrass prairie.

The US government encouraged the slaughter of bison as part of a deliberate campaign to vanquish the Plains tribes by removing their means of subsistence; the slaughter was also a free•for•all hunting spree by crews working on the transcontinental railroad after 1830 (Allen 1942). Thousands of bison were killed just for their tongues, which were considered a delicacy. The commercialization of the bison sealed its fate. In 1840, the American Fur Company sent 67,000 robes of bison hides to St. Louis, a fur trading center (Allen 1942). In the upper Missouri country, 250 thousand bison were killed annually until the 1870s; during this decade, just as in the case of the passenger pigeon, the slaughters turned the tide for the species (Allen 1942).

With the completion of the railroad, the great herd became split in half, and migrations that once took them from Montana to Texas were ended by a shooting spree lasting until the late 1880s (Allen 1942). In Dec. 1877 and Jan. 1878, the "last great slaughter" took place on the isolated southern herd of Kansas, Oklahoma and Texas; 100 thousand hides were taken by an army of hunters, wiping out this herd (Allen 1942).

Only the protection of two small herds in Yellowstone National Park and Wood Buffalo National Park in Alberta, Canada, totaling about 541 individual bison, prevented the extinction of the species (Allen 1942). Even the 300 bison in Yellowstone were nearly killed off by poachers between 1890 and 1893; 270 animals were shot illegally, leaving only 30 in the park (Hornaday 1913). These few wild bison stayed as far as possible from tourist routes, and by 1912 the herd had grown to 49 (Hornaday 1913). Since then, herds have been re•established in several parks in the West. There are now more than 150 thousand bison, but the majority is ranched animals, bred for docility. Even these represent a tiny fraction of their former numbers. Pure strains of American bison can be found only in the herds of Yellowstone and Wood Buffalo National Parks.

Other grassland wildlife was slaughtered for the meat trade. Among the millions of shorebirds that migrated through the Great Plains and bred there was a mousy brown, medium•sized bird known as the Eskimo curlew (*Numenius borealis*). These birds were known to many market hunters as "prairie pigeons" or "doughbirds" because of the thick layer of fat the bird added before migration (Ehrlich *et al*. 1992). This bird became the prairie equivalent of the passenger pigeon Œ an ominous comparison that signaled its ultimate fate. Eskimo curlews were once the second most numerous species of wading bird in North America Š numbering in the hundreds of thousands, possibly in the millions. Their destruction was so rapid that nesting and breeding areas were never fully documented. Only a few nests were found in arctic prairies of northwestern Canada between the Mackenzie and the Coppermine Rivers (Greenway 1967), but no one knew whether this was their prime nesting area. Their breeding behavior, number of eggs and chicks and related information remain undocumented.

Eskimo curlews flew in compact flocks and, when landing to rest and feed, were extremely tame and approachable. They were known to eat berries and Rocky Mountain grasshoppers (*Melanoplus spretus*) in burnt areas of prairie grass (BI 2000). This insect later became extinct, and prairies were plowed into agricultural fields (BI

2000). Eskimo curlews™ fall migration along the Atlantic coast through Labrador took them 8,000 miles to winter on the pampas of Argentina, southern Brazil and Chile (BI 2000). They were heavily hunted along the way. On one migration in 1872, three men in Cape Cod and Nantucket killed $300 worth of curlews they sold for 6 cents per bird [5,000 birds] to local meat markets (Hornocker 1913). In the spring, the birds would return through Central America and the Great Plains (Hayman *et al*. 1986). During the spring migration, they again became targets for the hunters. If a flock was shot at, the birds would fly only a short way before landing again, and they often returned to the same spot, resulting in the slaughter of entire flocks (Schreiber *et al*. 1989). The meat market hunters could fire a single shot that would bring down dozens of Eskimo curlews (Peck 1990). This hunting endangered them (Ehrlich *et al*. 1992) and, in spite of a ban on hunting in 1916, no recovery took place (BI 2000).

Their wintering habitat had been plowed as well, beginning in the late 19th century when their pampas in Argentina were used to produce export crops for Russia (Schreiber *et al*. 1989). Their populations plummeted from loss of habitat and unrestricted hunting, and fewer and fewer curlews managed to reach their northern breeding grounds. By the turn of the century, Eskimo curlews had become extremely rare. None has been seen in South America since 1939 (BI 2000). Several birds were shot in Barbados on their southern migration in 1964, and during the 1980s through 1996, various unconfirmed sightings were made (BI 2000). There is little hope that the Eskimo curlew survives.

Dominant among all the prairie predators, the grizzly bear (*Ursus arctos horribilis*) towered more than 10 feet tall when standing upright. Very common on the prairie, these bears ranged over most of western North America, from the Arctic Circle to northern Mexico. They were common in many types of grassland. All the subspecies except *Ursus arctos horribilis* became extinct south of Canada. In spite of its great strength and intelligence, in addition to the difficulty explorers and settlers had in killing it, these great bears were hunted to near extinction. Lacking cover in most of the Great Plains, the bears made large targets as they foraged for their primarily vegetarian diet, and were eliminated here first. Hunters made expeditions to kill these animals, and wrote articles and memoirs of their hunting prowess as they eliminated grizzly bears from one area after another. South of Alaska, only Yellowstone National Park and Glacier National Park harbored grizzly bears by the 1940s (Allen 1942).

Fur trapping intensified in the 19th century, with professional trappers combing the countryside, setting leghold traps and spreading poison to kill the most valuable furbearers such as beaver and river otter. Within a short time, both these animals had disappeared from large parts of the country, including most of the Midwest. The American beaver (*Castor canadensis*) is a keystone species in aquatic environments, creating habitat for otters and other wildlife with their dams. In fact, the range of the river otter in North America nearly coincides with that of the beaver. Trappers killed beavers in their lodges and dynamited dams to scare them into the open until these once common rodents became rare in many parts of the country. Their fur was highly valued and used in the manufacturing of top hats in England and Europe. The relentless trapping wiped these animals out throughout much of the country, and the beaver ponds that once dotted the landscape disappeared, greatly altering ecosystems for the worse. Otter fur was even more valuable because of its durability and waterproof qualities, and these animals, which had never been abundant, disappeared from two-thirds of their original range south of Canada (Nilsson 1985). River otters play an important role in aquatic ecosystems by culling overpopulated fish populations.

Other predators, such as the gray wolf, the kit (*Vulpes macrotis*) and the swift fox (*Vulpes velox*), were nearly eliminated from the United States south of Alaska. Fur trapping was followed by persecution in the form of predator control programs to benefit livestock ranchers. The gray wolves of the prairie were often white or pale gray and were entirely eliminated here (see Persecution and Hunting chapter).

The fleetest animal in North America nearly became extinct. The pronghorn (*Antilocapra americana*), a species found only on this continent, is not a typical antelope, but the last survivor of a family of ungulates long extinct. Once abundant throughout the Great Plains and in the deserts of the Southwest and Mexico, they may have numbered as many as 40 million animals prior to European settlement (Peters and Lovejoy 1990). Pronghorns travel in herds able to "fairly fly over the ground," in the words of Glover Allen (1942), when fleeing predators. Their natural curiosity,

an urge to investigate any unfamiliar object, may have contributed to their near•extinction. One hunter told of luring the pronghorns within gunshot by donning a white sheet and approaching them on all fours (Allen 1942). George Catlin painted natives luring them close by waving a feather on a stick.

By the turn of the century, so many pronghorn had been shot by settlers and meat hunters that the species was reduced to endangered status (Allen 1942). William T. Hornaday, director of the New York Zoological Park and a prominent conservationist who had saved the American bison from extinction in the early part of the century, predicted in 1913: "The Prong•horned Antelope, unique and wonderful, will be one of the first species of North American big game to become totally extinct. We may see this come to pass within twenty years. They cannot be bred in protection, save in very large fenced ranges. They are delicate, capricious and easily upset. They die . . . at the drop of a hat" (Hornaday 1913). Fortunately, his prediction did not come to pass, and total legal protection of the last pronghorns saved the species from extinction. Yellowstone National Park was crucial to the species' survival, and the bison™s as well, by protecting remnant herds. These herds provided the stock from which pronghorns were reintroduced to areas where they had been eliminated (Allen 1942). Today, they are fairly common in the western states of Montana, Wyoming and Colorado and found in smaller numbers in other parts of the West (see Grasslands, Shrublands and Deserts chapter for more on this species).

Another victim of the hunting slaughters of the 19th century was the Badlands bighorn sheep (*Ovis canadensis auduboni*), once numerous in the rugged hill country of the upper Missouri and Little Missouri Rivers in North and South Dakota and parts of Nebraska (Allen 1942). Weighing about 344 pounds, the males had massive curved horns that trophy hunters sought. While they grazed on the prairie near the high buttes, they were ambushed by hunters who cut off their escape. Even President Theodore Roosevelt contributed to their extinction by hunting them in the early 1880s (Allen 1942). The last record of this grayish brown sheep in North Dakota was an old ram killed about 1905, and the dates of extinction of the South Dakota and Nebraska populations are unknown (Allen 1942). Rocky Mountain bighorn sheep, another race of this species, have been reintroduced into the South Dakota Badlands.

Prairie streams and clear•flowing rivers provided habitat for several unique species of fish. The harelip sucker (*Lagochila laura*), whose downturned mouth had a large disk with which it fed on the stream bottoms, became extinct in 1893 when grasslands were plowed and streamsides disturbed; the water became turbid and muddy, causing the fish to literally asphyxiate in the silt•laden water (Day 1981).

Today, the tallgrass prairies have become wheat and corn fields, crisscrossed by highways, and dotted with towns and cities. More than 90 percent of the original prairies are gone (Peters and Lovejoy 1990). Even in the few areas where native grasses were not plowed under, diversity of grass species has declined from 200 to 30 species in most areas because of heavy livestock grazing (Peck 1990). Tallgrass prairie reserves have been established in Wisconsin, Kansas and Oklahoma. In the latter state, a herd of 300 bison was released in the early 1990s in virgin tallgrass prairie in Oklahoma by The Nature Conservancy after an absence of more than 100 years. Many National Grasslands were established in the range of the shortgrass prairie, primarily for livestock, but after many decades of grazing, rodent and predator control, this land bears little resemblance to the original prairie (see Grasslands, Shrublands and Deserts chapter).

Western Landscapes

In the southwestern United States and northern Mexico, deserts harbor a great wealth of species. The Mojave, Sonoran and Chihuahuan Deserts of the southwest differ from one another in their vegetation, topography and wildlife. All are dotted with deep springs and oases, each having endemic species of fish Œ vestiges from ancient

times when seas covered the land. The Sonoran Desert, most verdant of the three, is studded with giant Saguaro cacti (*Sereus giganteus*), more than 60 feet tall and found nowhere else on Earth, along with many other unique and beautiful desert plants. Deer, pronghorn, bighorn sheep and a variety of predators Š from grizzly bears and jaguars to gray wolves and coyotes Š lived in this desert, the most botanically rich in the world. Bird life was also prolific, and desert tortoises sheltered in burrows during the day. Mountain ranges jut from the Chihuahuan Desert to the south, and the Mojave of California is characterized by an extremely hot and arid climate, in which many unusual plants and animals manage to survive.

In southeastern Utah and Nevada, pinyon•juniper vegetation once covered thousands of square miles. The US Department of Interior's Bureau of Land Management has converted millions of acres into shrubland for the benefit of cattle. The pinyon pines, whose nuts have been a source of food for native tribes for thousands of years, have been destroyed in large part by chaining, wherein chains are stretched between two bulldozers, which then drag them across the pine-juniper bushes and trees, uprooting them. This ecosystem is home to desert tortoises and a wide variety of birds and small mammals, but today, the diversity and abundance of wildlife has been greatly diminished.

Much of the deserts are federally owned, and management has been primarily to benefit livestock owners and other users. Portions of the Mojave Desert and more than a million acres of spectacular Utah cliffs and desert have recently been made a National Reserve. These areas will not receive strict protection, however, since oil drilling and other activities, such as livestock grazing, will be allowed.

Streaming through the dry Southwest, the mighty Colorado River carved the vast Grand Canyon in Arizona as the land was thrust up and sunk with movements of the Earth over millions of years of geologic time. Some of the oldest rock formations have been dated at more than 1 billion years. These eons are etched in the Canyon's layered slopes. This canyon is one of the great natural wonders of the world, a wilderness of pastel-hued cliffs and beautiful vistas. Plateaus surrounding the canyon are geographically isolated, and many endemic animals inhabit these pine forests. In the Colorado River's turbid waters, a large number of unique fish evolved. The river has been dammed throughout its course, however, to supply water for irrigation, cities and suburban homes, as well as to generate electricity. One-fourth of the Colorado's water is used to irrigate the crops of California's Imperial Valley. The delta of this once immense river was described in 1922 by the conservationist Aldo Leopard as teeming with wildlife. That same year the Colorado River Pact was signed, which gradually removed its flow. Today the delta in northern Mexico is almost dry. The endemic fish and birds of the Colorado River system have been decimated by these projects. Some are being conserved under US Endangered Species Act programs conducted by the Fish and Wildlife Service. The dams that pepper the river turn the once warm and silty water cold and clear, a new habitat that native fish find intolerable.

The Sonoran Desert's unique and beautiful plant life has declined in the decades since 1970 because of unrestricted development for suburban housing; much of it is for retired persons seeking a dry and sunny climate. New houses, roads and commercial centers are gobbling up tens of thousands of acres, and in the process, the venerable giant Saguaros and other desert vegetation are bulldozed. These new communities use enormous amounts of water piped from the Colorado River and several diverted desert rivers. These desert oases turned to dust, eliminating their wildlife and plants. One of the few desert-nesting bald eagle populations became extinct as a result of the Central Arizona Project, which diverted water for agriculture and towns. Most residents in the Southwest have eliminated natural desert vegetation and planted grass lawns in front of their homes, which require almost constant watering and heavy use of chemical fertilizers, pesticides and herbicides Œ pollutants of the water table.

Merriam's elk (*Cervus canadensis merriami*) was native to various mountain ranges of southern Arizona and New Mexico. The antlers of this elk were the largest of all the elk races, and the animal was described as more pale and reddish than the Rocky Mountain elk (Allen 1942). Vulnerable because of its restricted range, it was hunted by cattle ranchers in the late 1800s, and crowded out by livestock. The last individuals were killed around 1906 in the Chiricahua Mountains of southeastern Arizona, where they had sought refuge in high altitudes (Allen 1942).

Thousands of elk and bighorn sheep died from diseases brought by domestic cattle. Lacking natural resistance,

entire populations died soon after they came into contact with domestic cattle and sheep that carried disease. Native Americans also died by the thousands because of diseases Œ from measles to small pox Œ brought by colonists and settlers. A number of tribes that had inhabited the West for thousands of years became extinct. In some cases, the tribes lost their land and dwindled to extinction.

West of the Rocky Mountains an unbelievably rich and beautiful land awaited settlers. The Sacramento and San Joaquin Rivers flow through the huge Central Valley, an area covering thousands of square miles. Prior to settlement, breathtaking vistas of wildflowers and grasslands grazed by innumerable elk and mule deer were framed by distant snowy mountains. The largest lake west of the Mississippi River, Lake Tulare, covered much of this river valley. Shallow and seasonal, this lake swelled after spring rains to serve as a breeding ground for an estimated 100 million waterfowl. Early naturalists spoke of the birds darkening the sky for days.

Spanish colonists established vast cattle ranches, beginning in the 1600s in what is now California. After Mexico lost this territory at the end of the Mexican War in 1848, American settlers poured into the region and agriculture began on a grand scale. In the late 1800s, California became thickly settled. The grasslands, deer, elk and the distinctive California grizzly bears that roamed California's valleys were eliminated by hunting and habitat destruction. The grizzly bears, still pictured on California's flag, were hunted to extinction (Nowak 1999). The Central Valley soon became California's bread basket, with agriculture displacing the tule elk (*Cervus canadensis nannodes*), whose range once extended throughout the San Joaquin and Sacramento Valleys, half the length of the state. As a result of hunting and loss of its habitat, the small herds of remaining elk became confined to a tule marsh area near Tulare Lake (Allen 1942). Transplants to other areas have not succeeded, and this subspecies remains very rare. Ninety•five percent of the wetlands of California's Central Valley and marshes that once dotted the coastline have been filled in for farms and development. Tulare Lake and its millions of ducks disappeared completely from drainage and water pumping, becoming the world's largest artificial farm, irrigated by water piped from elsewhere in the state. The Central Valley Project, an immense system of ditches, canals and pipelines, pumped water from the rivers in the Sierra Nevada Mountains to supply Los Angeles with water, devastating salmon and other wildlife. The Sacramento River once had an estimated 2 million salmon, and a fishery, but today they are nearly extinct as a result of the water diversion and dams.

California has incurred the greatest loss of wetlands of any state. Damming and diking of waterways to divert water for irrigation in the Central Valley resulted in the extinction of a foot•long fish once caught for the fish markets of San Francisco. The thicktail chub (*Gila crassicauda*) was very common until the 1880s, but by the 1920s, it had been driven to extinction (Day 1981). San Francisco Bay, the largest wetland and estuary on the West Coast, has been greatly altered by water diversion projects and drainage for agriculture and building. The bay has a great number of endemic species and races of birds and fish, and many of these have disappeared or become extremely rare. Federal protection under the US Endangered Species Act for many of these species may prevent their extinction.

North America's largest bird, the California condor (*Gymnogyps californianus*), soared over coasts and inland valleys Œ as far north as Washington State. This bird came close to extinction as a result of hunting and accidental poisoning (see Persecution and Hunting chapter). The last wild birds were captured for captive breeding, and young birds have been released to the wild. It will be years before it is known whether this giant vulture will survive and breed in the wild. In the foothills of the Sierras grew thousands of immense sequoias (*Sequoia gigantea*), trees that can live for more than 4,000 years. At a height of up to 300 feet tall, these trees attain a girth of 100 feet and support wood weighing 600 tons, making them the most massive and heaviest organisms that have ever lived (Jonas 1993). Sequoias take 3,000 years to attain full growth, sprouting from a seed only a quarter inch long. These trees were logged, reducing them greatly until they received legal protection. Sequoia National Forest was declared a National Monument by President Bill Clinton in 2000 to stop logging of other types of trees in the forest, which was threatening the root systems and survival of these ancient Sequoias. It is now illegal to cut a Sequoia.

In northern California, Oregon and Washington, ancient forests of hemlocks, pines, cedars and coast redwoods (*Sequoia sempervirens*) had grown undisturbed for thousands of years. Redwoods are the tallest trees on Earth,

reaching heights of more than 365 feet and measuring up to 58 feet in circumference (Jonas 1993). These forests once lined 2,000 miles of Pacific coastal region from northern California through British Columbia, ending in southeastern Alaska, covering 70 thousand square miles. Centuries of logging have reduced these forests to only about 5 percent of their former size in the United States, and less than 40 percent in Canada (Middleton 1992). Commercial logging began in the 19th century and has proceeded throughout this century, clear cutting millions of acres of redwoods, Douglas Fir and other evergreens in forests, cutting in a few hours trees that took a thousand or more years to grow. Once cut, these forests need hundreds Š if not thousands Š of years to regenerate to their former biological richness. The land where these forests once stood has been converted to other uses, precluding their regrowth.
Loggers are still fighting conservationists over the fate of the last five percent of Pacific Northwest old-growth forests and their endangered residents (see Forests chapter). Although the sequoias and coast redwoods have escaped extinction, they are far rarer than they once were, and the redwoods continue to be cut to be made into lawn furniture and decks.

A race of bison native to these forests, the Oregon bison (*Bison bison oregonus*), was distinct in being slightly larger than the Plains bison, with longer and straighter horns (Allen 1942). Once native to southern Idaho, northern Nevada to southeastern Oregon and northeastern California, they died out soon after the arrival of the early explorers. Although the history is unclear, tales from the Native Americans indicate that arms supplied to them by explorers were used to hunt these animals to extinction by the mid•1800s (Allen 1942).

Wetland Drainage: Page 2

Thousands of years of drainage, pollution, diversion and overuse of the rivers and wetlands in the Middle East have destroyed once verdant areas such as the site of ancient Babylon in present-day Iraq. The single exception, until recently, was the 6,000-square-mile delta of reeds, lagoons and marsh south of the confluence of the Tigris and Euphrates Rivers on the Persian Gulf in Iraq. This wilderness maze was inhabited by the reed homes of the Shiite marsh Arabs (Hedges 1993). They fished from small boats woven from marsh plants, a lifestyle unchanged for thousands of years (Dugan 1993). After the 1989 Persian Gulf War, Iraq's President Saddam Hussein ordered that the swamps be drained to vanquish the Shiites, who had opposed his government (Hedges 1993, Lewis 1993). The Iraqi portion of these marshes has also been polluted by oil spillage from the war. Within a few years, approximately 90 percent of these ancient wetlands were drained and soon dried out in the desert sun. Observers flying in small aircraft have documented that these wetlands now resemble dusty fields.

The best known animal resident of Iraq's marshes may be Maxwell's otter (*Lutra perspicillata maxwellii*), named for the charming otter who inspired the story *Ring of Bright Water*, by Gavin Maxwell (1961). This male otter had been captured in these marshes and brought by the author to the British Isles after many misadventures in trains and hotel rooms. When examined by zoologists, he was determined to be an endemic and distinct race of the smooth-coated otter. The fate of Maxwell's otters may not be learned for many years to come. Other victims of the destruction of Mesopotamian marshes may be the birdlife: several million waterfowl wintered in the wetland (BI 1993). Endangered and rare birds that winter here include the dalmatian pelican, pygmy cormorant (*Phalacrocorax*

pygmaeus), marbled teal (*Marmaronetta angustirostris*), white-tailed eagle (*Haliaeetus albicilla*), imperial eagle (Aquila heliaca) and slender-billed curlew (*Numenius tenuirostris*), according to BirdLife International (1993). Two endemic breeding birds are also at great risk. The Iraq babbler (*Turdoides altirostis*) and the Basra reed warbler (*Acrocephalus griseldis*) are restricted to these marshes in southeastern Iraq and adjoining southwestern Iran. The latter bird is listed as near-threatened in *Threatened Birds of the World* (BI 2000). Although no status surveys have been made in the breeding range of the Basra reed warbler, the number of these birds seen in wintering habitat in Kenya has declined in recent years (BI 2000). A small portion of these marshes remains in adjoining Iran, but it cannot support a fraction of the wildlife that inhabited the Iraqi marshlands.

The worst oil spill in history took place in the Persian Gulf as Iraqi President Saddam Hussein, enraged at losing the war with Kuwait, opened and set afire that country's oil wells to spill 500 million gallons of oil into the delicate Gulf (Earle 1995). This represented 45 times the amount released by the *Exxon Valdez*. It added to the 250,000 barrels of oil released into the Persian Gulf every year for the past decade. The 1991 spill killed cormorants and other sea birds, sea turtles and dugongs. The fires belched toxic chemicals into the air and water in thick black clouds that darkened the sky at noon. Every plant and animal within many miles became coated with black soot. Marine scientist Sylvia Earle witnessed a bird in the midst of this hellish landscape as it swooped into a pool of oil, lured by a struggling dragonfly. "The bird barely moved, succumbing at once to shock, the slimy embrace gluing feathers, clogging nostrils, searing bright eyes, snuffing life" (Earle 1995). The 400-mile coastline of Kuwait, an expanse of marshes and mangroves, became covered in thick black oil, leaving only a few areas of untouched beaches protected by a causeway (Earle 1995). Tens of thousands of migrating shorebirds died in this oil along with a host of invertebrates and fish, and since much of the oil sank and attached itself to sand and mud, the oil killed for many years (Earle 1995). The most common coral in the Persian Gulf, staghorn, released eggs that were killed by the oil, and most of the adult coral in the region of the spill died or bleached (Earle 1995).

Source: Table of Extinct Species in the Appendix of this book. Sources of information are listed with the table.

Note: See the Appendix for the list of these species in chronological order, and the references that describe these animals and their extinctions, as well as those that include illustrations of the extinct species.

The following account chronicles some of the many extinctions and destructions of natural ecosystems that have taken place in North America over the past few hundred years. Great biological treasures have been stolen from future generations, and the processes by which they were lost are typical of those occurring elsewhere in the world. The sudden loss of the most abundant and prominent wildlife species of the continent created a profound shock in the

public early in the century that set the stage for today's conservation and humane programs. This concern may turn the tide for species that could suffer the fate of the passenger pigeon (*Ectopistes migratorius*) and others, but unless public opinion is better translated into public policy regarding the land and wildlife, further losses will occur and the lessons that might have been learned will be ignored. A strong and pragmatic commitment to preserve what remains of the natural world on the continent, based on a realization that our fate is linked to nature's fate, is essential to prevent further extinctions.

It's Too Late

Introduction

Skeptics ask why it should matter whether the tiger (*Panthera tigris*) or other endangered species become extinct. Aren't all extinctions natural events? Yet enormous differences exist between the extinctions of the dinosaurs and other animals that faded out eons ago and those of recently disappeared species. Dinosaurs proliferated into a great diversity of species and dominated other life over a period of many years. Some dinosaur families endured tens of millions of years on Earth Œ others far less Œ before fading into extinction. It is difficult to grasp the reality of their immense sojourn, as some species existed for only a hundred thousand years. The Ornithischia, one major group of dinosaurs, had an enormous number of living species 135 million years ago at the dawn of the Cretaceous Period, but slowly died out over the next 60 million years. The last of the line became extinct some 65 million years ago as the last of the dinosaurs expired.

Extinctions of dinosaurs and millions of other species that disappeared from Earth at that time were natural in origin. These extinctions had many causes; changes in climate resulting from meteors colliding with Earth may have killed off the last dinosaurs. Many scientists believe the impact raised a dust cloud that blocked sunlight and reduced the enormous amounts of vegetation needed by the dinosaurs, and it may have cooled the climate as well. Another major cause of ancient extinctions was the movement of the Earth's tectonic plates, which broke up huge land masses into smaller ones. Some species became isolated on islands too small for their habitat requirements, and stronger species caused the extinctions of weaker or less adaptable species when continents were joined. Continents and islands moved into different climate zones as well. The Earth's climate and atmosphere have undergone major changes over the ages and species that could not adapt have fallen into extinction. Volcanic eruptions have spurred extinctions by inundating land with lava and cooling the climate with dust. Islands produced by volcanic eruptions have risen from ocean bottoms, become covered with vegetation and home to unique wildlife, only to sink into the sea some time later.

In the past, ecological roles left empty by extinctions were soon filled by the evolution of new species. After the last of the dinosaurs died out some 65 million years ago, mammals and other animals proliferated on Earth. The overall diversity of species remained stable or increased. At present, however, diversity of life on Earth is in steep decline as species are dying out without being replaced.

The Recent Picture: A Rapid Rise in Extinctions

The current extinction rate is estimated to be up to a thousand times higher than prehistory rates (Leakey and Lewin 1995, Stearns and Stearns 1999). This phenomenon has been described as the sixth wave of extinctions by scientists Richard Leakey and Roger Lewin Œ ecosystems are being disrupted around the world, and the wondrous tapestry of living things that supports human existence is unraveling.

Since 1500, approximately 375 species of invertebrates, 81 species of fish (Hilton-Taylor 2000) and 291 species of mammals, birds, reptiles and amphibians (see Appendix) have become extinct. About three-fourths of vertebrates other than fish have disappeared since 1800, while only 80 species died out in the previous three centuries. These figures represent a minimum number. An estimated 5 million species of animals and plants exist in tropical rainforests, a conservative figure that may apply to insects alone, according to biologist Edward O. Wilson (1988). About half of these species are restricted or localized in distribution (Wilson 1988). With this in mind, at the present rate of destruction of tropical forests, some 17,500 species are being lost per year Œ a rate 1,000 to 10,000 times greater than extinction rates prior to human intervention (Wilson 1988).

Human activity lies at the root of this potentially catastrophic phenomenon. Killing for food or sport, as well as conditions created by humans, such as habitat destruction and competition, predation and disease from introduced animals, is responsible for the vast majority of these extinctions. It is with this perspective that we can see the present situation as an *unnatural* event, not linked to climatic changes, meteors or volcanic eruptions, but a result of human-caused changes wrought in the Earth's environments and by direct extermination.

Plants

Extinctions of plants and trees can have a direct impact on human society. A sap found in 1997 by Dr. John Burley, research director of Harvard University's Arnold Arboretum, was tested by the National Cancer Institute and determined to be 100 percent effective in preventing cell replication of the AIDS virus (Stocker 1996). The plant sample came from an ancient swamp forest tree in Sarawak, a Malaysian state on the island of Borneo. When Dr. Burley returned to the spot a year later for another specimen from the tree, only a stump remained, and no other trees of the same species could be found (Stocker 1996). The substance is being reproduced synthetically, but it is not known whether it will be as effective as the original compound (Stocker 1996).

Sarawak's forests grew undisturbed for 180 million years, but they are now rapidly disappearing along with the rest of Borneo's ancient forests. Commercial loggers have felled tens of thousands of these old growth, towering trees in Indonesia and other tropical rainforests for the manufacture of disposable packing crates and chopsticks for Japanese and Chinese markets. Borneo's forests are also being consumed by fires set by wealthy landowners to clear land for palm plantations, or by settlers for farmland, eliminating an untold number of plants. Some tropical tree species have wide distributions over thousands of square miles, but many occupy extremely small areas. This was dramatically illustrated in the disappearance of this tree. Thousands of compounds that could cure diseases or be of great economic and ecological importance may be lost on a daily basis as the world's forests are destroyed at this unprecedented rate.

Plant extinctions have accelerated in the past few centuries. An estimated 5,050 taxa of plants, including species, varieties and other taxonomic groups, have become extinct worldwide since 1700, according to Ghillean T. Prance of the Royal Botanical Gardens Kew (Prance 1990). This implies at least 17 plants have been lost per year since 1700. Yet however high this rate appears to be, it is probably a low estimate. A 1998 study by botanists Kerry S. Walter and Harriet J. Gillett for the International Union for the Conservation of Nature (IUCN) found that 380 species, a number that does not include varieties and other taxa, have recently become extinct. These authors admit their extinction total may be low as a result of lack of data, and they did not define the time period covered.

· The data lacks exact numbers of plant extinctions. Plants rarely leave signs of their existence as vertebrates do, since bones are the basis of much data on animal extinctions. Non-woody plants, which make up the majority of plants, leave little trace when they die, and are soon consumed by microbes. This is especially true in tropical areas, where plant matter is consumed very quickly. We know of ancient plants by chance events, such as the preservation of pollen grains or other plant parts in peat, mud, amber or fossilized stone. When numbers of plant extinctions are estimated, the diversity and status of habitat are important considerations. Moreover, only a small percentage of all plants have been scientifically described. What is known is a great many regions of the Earth that once had very diverse endemic plants have been destroyed within the past few centuries, and a majority was not thoroughly assessed.

Botanical wealth is often discovered and destroyed soon after. In Ecuador's mountain ridges, botanists Al Gentry and Calaway Dodson of the Missouri Botanical Garden in St. Louis discovered many unique plants in 1978 on a crest known as Centinela Ridge in a 20 square kilometer cloud forest in the foothills of the Andes. Among the plants were 38 endemic species, many of which were unusually dark•leafed (Forsyth 1990). The two scientists found a total of 90 related plants growing under the forest canopy with epiphytic plants, such as bromeliads and orchids, on the trunks and branches of the trees (Wilson 1992). These cloud forests and paramos Œ treeless, mossy areas in the northern Andes Œ are centers for unique species. At the time they discovered the plants, Gentry and Dodson observed farmers from the valley below clearing the forests, as they have done on 96 percent of the Pacific ridges of the Andes (Wilson 1992). Gradually, the clearing moved up to Centinela Ridge. By 1986, the botanical oasis had disappeared; in its place were cacao and other crops (Wilson 1992). These lost species might have provided compounds to treat cancers, or been an ancestor of an agricultural plant, such as a perennial tomato, but they exist now only as pressed specimens taken by the botanists.

Near Centinela Ridge is Rio Palenque; once an extensive cloud forest, it is now diminished. It was among the most botanically diverse forests in the world Š 600 species per square kilometer (Forsyth 1990). Ornithologists and birdwatchers came from all over to see the 336 bird species of Palenque's diverse habitats (Forsyth 1990). The endangered harpy eagle was one spectacular native bird that disappeared when the forest was cleared (Forsyth 1990).

Cloud forests are found in tropical Asia, Africa and Latin America. These ecosystems shelter such rarities as the iridescent green and red resplendent quetzal of Central America, but this ecosystem has nearly disappeared. An impressive variety of orchids, mosses and dwarf trees grow in these misty, cool environments. Should global warming continue, cloud forests will be among the first type of forest to disappear altogether, extinguishing thousands of unique life forms in the process.

Introduction of alien species of plants can overwhelm native species and cause their extinction (Prance 1990). In Indonesia, a type of non-native grass called imperata (*Imperata cylindrica*) grows aggressively in deforested areas, spreading into forests. Once established, imperata obstructs the regeneration of native plants and trees (Prance 1990), many of which exist nowhere else. Imperata has also displaced endemic plants in other parts of the world. In Australia, exotic plants are a major factor; they have eliminated at least 117 plant taxa and endangered another 1,931 (Prance 1990). Ironically, native Australian plants have caused extinctions after they became established in parts of South Africa and the Florida Everglades.

Plants have also disappeared as a result of pollution in the form of acid rain caused by power plant emissions, heavy metal (especially lead) accumulations and other toxins in the air (Prance 1990). Forests in North America and Eurasia have been susceptible to pollution, and in some areas, all forms of vegetation have died out.

Livestock overgrazing is responsible for the extinctions of countless plants, and endemic island species are among the most vulnerable. Such plants may occupy only a few acres. The South Atlantic island of St. Helena lost at least 10 kinds of endemic trees after the introduction of goats onto the island in 1513; the St. Helena redwood (*Trochetia erythroxylon*) became reduced to a single tree in the wild (Prance 1990). Fortunately, it was saved by propagation at the Royal Botanic Gardens Kew in London and cultivated specimens have been reintroduced (Prance 1990). The

sandalo (*Drypetes caustica*), a fragrant type of sandalwood tree that once grew abundantly on the island of Juan Fernandez, the site of *Robinson Crusoe*, became extinct by 1916 after centuries of heavy logging and destruction of seedlings by goats (Prance 1990).

The Mascarene Islands, east of Madagascar in the southern Indian Ocean, have been the scene of many plant extinctions. One of the three main islands, Mauritius, was home to the famous dodo. Ebony once covered the plains and mountain slopes of this island, but during colonization of the islands from the early 17th century onward by Holland, France and Britain, extraction of a huge volume of timber denuded valleys and all accessible places (Parnell *et al.* 1986). As early as 1671, Mauritius had appointed a chief woodcutter to oversee the cutting of the island's forests. Unfortunately, this had little effect on forest clearance. Of the dense tropical evergreen forests that once covered the lowlands, only a few patches remain in inaccessible areas. Trees 20 meters or more in height grew in the uplands of the island, their branches heavy with thick growths of lianas and orchids. On the ground, ferns and mosses sprung up luxuriantly.

Today, only a single tract remains of this habitat, the Black River Gorges reserve (Sayer *et al*. 1992). By 1874, these islands, once described as verdant "earthly paradises," were dry and comparatively barren, with a vegetation composed mainly of weeds (Parnell *et al*. 1986). Only about 30 square kilometers of Mauritius forest survives since 93 percent was destroyed (Sayer *et al*. 1992). The mangrove forests that once lined Mauritius' shores have disappeared along the West Coast because they were cut for firewood. Rodrigues, a small island off the coast of Mauritius that was once a wildlife haven, lost virtually all its forests. Reunion, the third island, was also settled and heavily logged. About 61 percent of its forests, including virtually all its lowland forests, have been cleared; only 100 square kilometers remain (Sayer *et al*. 1992). A few remnants of montane forest have been protected by the French government, which controls the island.

Mauritius, Rodrigues and Reunion have lost many native plant species. Of 1,296 native plants, 53 species are extinct and 393 of the surviving species are threatened, according to the *1997 IUCN Red List of Threatened Plants* (Walter and Gillett 1998). Little remains of its ebony forests, and eight ebony tree species are virtually extinct (Simon 1995). The islands have lost six of their beautiful orchid species, and 13 more are threatened (Walter and Gillett 1998). Mauritius and Rodrigues have been described as the "Islands of the Living Dead" by authors Beverly and Stephen Stearns because at least 30 plant species have ceased reproducing in the wild, living on the edge of extinction (Stearns and Stearns 1999). One, *Ramosmania heterophylla*, described in 1874, was not seen again until 1982 when botanist Wendy Strahm found the last specimen growing by a roadside. She fenced it off to protect it, only to learn this made local people consider it a "magic plant" that cured all diseases and maladies (Stearns and Stearns 1999). They cut off small pieces Š despite its fencing Š and have nearly obliterated it. Luckily Strahm took cuttings and sent one to Kew Gardens in England for propagation; it now grows there, but does not seed because the plant is defective (Stearns and Stearns 1999). A critically endangered tree, *Elaeocarpus bojeri*, native to Mauritius, has delicate, bell-like flowers with a scalloped fringe. Strahm's photograph illustrating these flowers appears on the cover of the *1997 IUCN Red List of Threatened Plants* (Walter and Gillett 1998). It epitomizes the status of many Mascarene plants in need of dramatic rescue programs, as well as the need to prevent extinctions, such as that of a rare Rodrigues tree hibiscus (*Hibiscus liliflorus*); the species became extinct in 1982 after it was reduced to a single plant growing on the top of a mountain (Stearns and Stearns 1999).

Two endangered native wild coffee plants of Mauritius (*Coffea macrocarpa* and *Coffea myrtifolia*) might invigorate domestic species stricken with disease if they are protected from extinction, illustrating another reason to preserve native plants. The wild ancestors of domestic grains and crops retain many characteristics lost in cultivated varieties, such as resistance to drought, insects and disease. An outbreak of cornleaf blight in the United States in 1970 cost farmers almost $1 billion, and the disease was not halted until a wild corn species was interbred with the domestic strain (Fenyvesi 1995). A perennial variety of maize (wild corn) found in a Mexican forest could be hybridized with domestic corn to save farmers from replanting each year. Other crops saved by crossbreeding with tropical forest wild stock include sugarcane, coffee, cocoa and banana (Schreiber *et al*. 1989). Yet with the accelerating rate of plant extinctions and destruction of native plant ecosystems, many such ancestor species may be

lost.

All ecosystems are plant-based. Plants produce oxygen, making life on Earth possible, and perform a vital task for other life forms by absorbing vast amounts of toxins and carbon dioxide. They are the source of thousands of important medicines, and discoveries of new medicinal uses of plants are being made on a regular basis. Disappearance of individual species of plants can impoverish or even collapse entire ecosystems when they are key to the survival of many species of animals or form an intrinsic link in an ecosystem.

Not only do many plants fade to extinction undocumented by botanists, but only a small percentage of living plants have been scientifically described. Botanists have identified more than 250 thousand types of living plants other than algae, fungi and bacteria, but most scientists agree these represent perhaps a tenth of all living plants. Almost 10 percent of surviving species are considered threatened with extinction. Some 34 thousand plant species are listed in the *1997 IUCN Red List* (Walter and Gillett 1998). Many of these plants have not been seen for years and may be declared extinct in the near future, or are clinging to life with only a few individuals left. Preservation of the planet's great diversity of plants to prevent further extinctions should be a priority of the first order.

Invertebrates

Invertebrates are key members of many ecosystems. Insects pollinate plants, while mollusks and gastropods form the basis of many aquatic food chains. Documentation of invertebrate extinctions is incomplete, but a minimum of 375 species (approximately eight crustaceans, 72 insects, 31 bivalves and 260 gastropods, snails and related species) have become extinct worldwide in the past few hundred years, according to the *2000 IUCN Red List of Threatened Species* (Hilton-Taylor 2000). Massive destruction of many habitats, especially islands with endemic species such as land snails, has eliminated hundreds of these creatures.

Extinct bivalves include mollusks native to the southeastern United States, the world's center of diversity for freshwater mussels. Dam construction turned clear, fast-flowing rivers into still ponds, destroying prime mussel habitat. Channelization, in which the natural curves of a river are straightened and its surrounding vegetation bulldozed from its banks, wreaked havoc in aquatic ecosystems. Biologically rich rivers became muddy, sterile ditches. These government-sponsored anti-flood programs took place during the first half of the 20th century, causing numerous extinctions of mussels and crayfish.

At the time, few people lamented the disappearance of these mussels, some of which were the size of dinner plates. They grew in huge masses on river bottoms, serving as keystone species in river ecosystems by providing habitats for fish, crayfish and huge river snails. Birds and aquatic mammals fed on the fish and other aquatic wildlife produced by these mussels; these large bivalves also cleansed the water with their filtering gills. Water pollution from industry and coal mining and sedimentation from logging have contributed to their extinction. Additionally, mussels are over-harvested because of their commercial value in the cultured pearl industry Œ their shells are harvested and broken into tiny pieces that are inserted into living oysters to stimulate the growth of pearls. These combined threats have pushed many species to extinction and others to endangered status. Their demise has caused species dependent on mussels for reproduction and habitat to disappear as well.

Scores of colorful endemic land snail species have died out in the Hawaiian Islands, other Polynesian and Indian Ocean islands and various southern Atlantic Ocean islands. These snails were once prolific in native forests, but naturalists and shell collectors took many thousands of them during the 19th century Œ until the 1920s, when it became too difficult to find them (Stearns and Stearns 1999). One individual, J.T. Gulick, the son of Hawaiian missionaries, "ransacked" the islands for tens of thousands of these colorful land snails, collecting 44,500 in three

years (Stearns and Stearns 1999). He alone caused the extinction of numerous species on the islands by encouraging rural residents to collect for him and by buying shells by the thousands, believing himself to be an important naturalist. He was among the collectors who scoured the woods where these shells clung to trees and low bushes by the hundreds (Stearns and Stearns 1999). Many were striped, while others were solid shades of ivory, yellow-gold and deep brown. Some collections were of no scientific value because the locations where they were obtained were not noted. No similar species remain in the wild today (Stearns and Stearns 1999).

In more recent times, exotic species of snails have been introduced onto islands for various purposes, preying on the native species. One expert estimated that when Captain Cook arrived in Hawaii in 1778, there were between 800 and 1,000 species of endemic Hawaiian snails from 11 families, but at present, only about 200 remain (Stearns and Stearns 1999). Recent extinctions have been caused by deforestation and predation by exotic snails, including the giant African snail, introduced by the Hawaii Department of Agriculture to prey on another exotic snail. Native snails feed mainly in endemic Hawaiian trees, another reason they have failed to adapt to the introduction of exotic trees and bushes. Unusual among invertebrates, these snails reproduce slowly, one species needing 19 years just to replace itself (Stearns and Stearns 1999). At least 49 species have become extinct in recent times, according to the Nature Conservancy's book, *Precious Heritage: the Status of Biodiversity in the United States* (Stein *et al*. 2000). The remaining species of Hawaiian land snail are endangered, and species are disappearing regularly from the wild, preyed on by exotic snails or rats and losing their host trees to logging (Stearns and Stearns 1999). Conservation programs have not been well-funded, as these are among the least well-known of Hawaiian wildlife.

On the island of Moorea in the Society Islands, the giant African snail was introduced as a food source, but when it became overpopulated, a carnivorous snail, *Euglandia rosea*, was introduced to prey on it. Instead, the latter species preyed voraciously on native tree snails, exterminating all 11 species; it is now in the process of eliminating the native snails of Tahiti (Wilson 1992).

Butterfly populations have declined from loss of host plants, pesticide use, over-collecting and loss of species upon which they depend. The Xerces Blue (*Glaucopsyche xerces*) is the only native species in the United States to have become extinct in recent times. It disappeared in the early 1940s, and the Xerces Society, dedicated to preserving butterflies, was named after it. It is one of 38 butterfly species that recently disappeared around the world (Baillie and Groombridge 1996).

Invertebrates play key roles in many of the world's ecosystems as food sources, for people as well as animals. Some, such as coral and mollusks, create habitats for thousands of species. Butterflies, mollusks and snails are among the planet's most beautiful creatures, yet conservation programs often neglect these important species.

Vertebrates

Vertebrate extinctions worldwide since 1500 total at least 372 species of mammals, birds, reptiles, amphibians and fish. The largest number Œ 157 species Œ were birds, while 100 mammal species, 28 reptile species, 6 amphibians and 81 fish species disappeared. The number and rate of extinctions have increased gradually in recent centuries, as the table "Extinct Species of Birds, Mammals, Reptiles and Amphibians" illustrates. Fewer than 80 of these vertebrates became extinct from 1500 through the 18th century, while in only the 19th century, 98 species of birds, mammals and reptiles died off. The rate accelerated during the 20th century; based on incomplete information, at least 115 vertebrates Š already 17 species more than in the past century Š were lost. (See Appendix for list of species and their dates of extinctions.) This total will be far greater when the toll for the 20th century is finalized.

229 species, almost 80 percent of the 291 extinct mammals, birds, reptiles and amphibians, were native to islands,

mostly located far from the nearest land mass, such as the Hawaiian Islands, Mascarene Islands and New Zealand. (See Table fiThe Geography of Extinction.fl) Many of these island species were distinctive and unusual, the products of thousands and even millions of years of evolution in isolation. Few left close relatives.

Some islands are fragments of ancient continents, broken off more than 100 million years ago, with resident wildlife and plants. New Zealand, Madagascar, the Seychelles and the larger islands of the Caribbean are examples of this phenomenon. In exceptional circumstances, original inhabitants survived; some evolved into different forms, while others remained almost unchanged. Additional plants and animals arrived by air, ocean current or clinging to masses of vegetation or floating logs, perhaps every thousand years. Few of these survived, but occasionally these new colonists were able to adapt to the new environment and thrive. Other islands were formed by volcanic eruptions or coral reefs growing atop extinct volcanoes. Virtually all native fauna and flora of these islands, which include the Hawaiian, Mascarene and Galapagos Islands, were colonizers. The majority of extinct island species were flightless birds, tortoises and other species unable to flee when European ships and their crews arrived in search of commodities such as spices, timber and fur animals. They were killed for food and sometimes found their habitats destroyed by logging or the many species of animals brought to the islands. They were successful species in adapting to their environment and surviving for long periods, even radiating into entire new families of animals, but nothing had prepared them for the drastic changes humans caused, or the high mortality from hunting or persecution.

Sixty-two mammals, birds, reptiles and amphibians, as well as all but one of 81 species of fish, were native to mainland areas. The continent with the largest number of non-fish extinctions is Australia, with 24 species, 22 of which were mammals, killed off by introduced animals and loss of habitat (see Mammals section in the table: fiThe Geography of Extinctionfl). Non-native species caused the extinctions of many fish in the United States, Mexico and Africa. Killing by persecution or commercial purposes, such as for furs, meat or sport, caused extinctions in Africa, North America, Australia, Europe and Asia. Capture for pets and killing eliminated birds in the Caribbean, Australia and South America. The clearing of forests eliminated a number of tropical birds in Asia and South America. Elimination of wetland habitats was the major cause of the extinction of amphibians and fish, especially those that were ecologically isolated, such as cave fish or desert spring species.

Extinct Species of Birds, Mammals, Reptiles and Amphibians
1500 to present

100-Year Periods	Mammals	Birds	Reptiles	Amphibians	Total
1500-1599	0	6	0	0	6
1600-1699	14	15	3	0	32
1700-1799	13	26	3	0	42
1800-1899	31	56	10	0	97
1900-2000	42	54	12	6	114
TOTALS	100	157	28	6	291

Fish Extinctions

The *2000 IUCN Red List* lists a total of 81 species of fish that have become extinct over the past 400 years. In addition, a large number of fish have been extinguished in Central and South American lakes Œ scientists are still compiling information. About 20 percent of the world's freshwater fish are indeed either extinct or in steep decline (Wilson 1992).

No version of the *IUCN Red List* has listed many species reported as apparently extinct by biologists around the world. In peninsular Malaysia, where 266 freshwater species were known to exist, a search found only 122 (Wilson 1992). In the Philippines, where massive environmental destruction has taken place, Lake Lanao on Mindanao is famous for its diversity of endemic cyprinid fish. Yet out of 18 species of three genera, an investigation found only three species of one genus (Wilson 1992). These extinctions were apparently caused by overfishing and competition from introduced species (Wilson 1992).

During this century, several mass extinctions of endemic fish have taken place when the creatures™ sole habitat was destroyed. Lakes in East Africa, the Americas and Russia have either been drained Œ as in the Russia™s Aral Sea Œ or native species have been crowded out or preyed upon by introduced exotic fish.

Africa's Great Rift Valley, a product of movement in the Earth's crust eons ago, is home to several lakes of great biological diversity. Lake Tanganyika has more than 140 endemic species of fish, Lake Victoria has more than 200 and Lake Malawi has at least 500 (McNeeley *et al*. 1990). These three lakes, home to hundreds of members of the colorful cichlid family, rank three, two and one respectively in the world for their diversity of fish (Myers 1979). The lakes have been separated for millions of years, and although Lake Malawi and Lake Tanganyika are only 320 kilometers apart, they have not a single cichlid fish species in common (Myers 1979). Each of these three lakes empties into great rivers; Lake Tanganyika flows into the Zaire, Lake Victoria into the Nile and Lake Malawi into the Zambezi (Kingdon 1989). Most ancient is Lake Tanganyika, 3 to 6 million-years-old and twice the age of Lake Malawi, which is half as old as Lake Victoria (Kingdon 1989). Lake Tanganyika is the second deepest lake in the world at 1,500 meters; only Siberia's Lake Baikal is deeper (Kingdon 1989).

Lake Victoria is a shallow, enormous lake, covering an area the size of Ireland or the state of Maine (Kingdon 1989). Evolution of cichlid fish in these lakes over the ages produced an extremely rich fauna. From a few ancestor species, these fish flourished into an extraordinary diversity, each species filling a different ecological niche. Their diets are extremely varied and may include plankton, crustaceans, mollusks or fish eggs (larvae) and even other fish (Kingdon 1989). Cichlids brood their eggs in their mouths Œ up to a thousand at a time Œ protecting them from their many natural enemies. They exhibit a great range in color, including silver, sapphire and turquoise blue, orange and yellow, and they are patterned in stripes, bars, dots or circles. Resembling the fish one might see in a coral reef, many are popular in home aquariums (Kingdon 1989). Various kinds of tilapia, which are also cichlids, form a major part of the diet of Africans living around these lakes, and they are being raised in aquaculture projects around the world.

These beautiful fish and their ancient ecosystems are now disappearing. The major cause is the Nile perch (*Lates niloticus*), Africa's largest freshwater fish, at more than 6 feet in length. Since 1960, the Uganda Game and Fisheries Department has introduced thousands of these fish as a food source for the local people, despite objections from the East African Fisheries Research Organization (Simon 1995). Even as a food fish, the Nile perch is not rated highly by the local Africans, who prefer the smaller tilapia, which they preserve by drying in the sun (Simon 1995). The flesh of the Nile perch is so oily that it must be smoked, and more and more trees must be cut down for this purpose (Simon 1995). An ecological disaster occurred after its introduction; although intended to increase the lake's productivity of fish, the opposite happened. Gradually, this predatory fish became the dominant species in the lake, and completely

destroyed the endemic cichlid fish fauna and fishery (Simon 1995). Of the more than 300 varieties of *Haplochromis* genus cichlid fish (including subspecies) endemic to Lake Victoria, almost two-thirds died out, and the rest became endangered (Simon 1995). Fifty known extinctions have beset Lake Victoria's endemic cichlids. One species, *Haplochromis pyrrhocephalus*, has become extinct in the lake Œ it exists only as a captive colony in the Horniman Museum in London (Simon 1995). Extinctions of the surviving cichlids continue because of predation by the Nile perch and siltation of the lake from erosion of farmland soil on its shores. This prevents these fish from mating because they are not able to recognize the brilliant colors and patterns of their potential mates (Yoon 1997).

The introduction of exotic fish threatens many freshwater species, and overfishing is virtually eliminating a large number of saltwater species. Research on the latter is lacking, but it is likely that many of the 156 species listed as ficriticalfl in the *2000 IUCN Red List* will be listed as extinct in the near future.

Amphibian Extinctions

Six species of amphibians Œ all frogs Œ are known to have become extinct since 1500. No recorded amphibian extinctions have taken place on islands, despite the large number of endemic amphibians native to large islands such as Madagascar, New Zealand, Cuba and Puerto Rico. Many of these, however, now face this threat. Yet it is likely that amphibian extinctions occurred as a result of the draining of wetlands or due to their use in growing rice following the colonization of the latter islands by native peoples thousands of years ago. The extinct frogs were mainland species, and all disappeared during the 20th century. The Israel painted frog (*Discoglossus nigriventer*) became extinct around 1940, when Lake Huleh, its sole habitat, was drained for agriculture. The Vegas Valley leopard frog (*Rana fisheri*) disappeared in 1960 when its desert spring habitat was destroyed by groundwater pumping for agriculture. Two Mexican frogs endemic to wetlands north of Mexico City died out by 1979 after their wetlands were drained for the construction of homes. The best known extinction in recent times is that of the beautiful golden toad (*Bufo periglenes*), which is acknowledged by most experts to have disappeared from its rainforest home on a Costa Rican mountain in the late 1980s. This species had been featured in National Geographic Society films and articles, and was also the subject of a research study when it suddenly died out.

A large number of frogs Œ at least 20 species Œ have not been seen for many years, and many may soon be declared extinct. Some of these are among the most unusual examples of evolution on Earth. In a few pristine areas, frogs have mysteriously vanished. An Ecuadorian biologist reported in the 1990s that a dozen species he had been studying in a high altitude meadow disappeared without a trace. Experts are in disagreement over the causes of the vanishing of so many frog species. Many species are believed to be victims of ozone depletion, which increases the amount of ultraviolet radiation reaching the Earth, destroying frog eggs and often adult frogs as well. Other scientists believe frogs are disappearing from a combination of causes, including disease possibly induced by an immune system lowered by pollutants, pesticides and habitat destruction.

Reptile Extinctions

All but one reptile extinction have occurred on islands. At least 28 island reptiles have died out since 1600. A large number of reptile extinctions took place in the Mascarene Islands, a group of islands in the Indian Ocean, east of Madagascar (see Appendix for more on Mascarene Island extinctions). Thousands of large tortoises were slaughtered for food by European settlers and visiting ships' crews during the 17th century. All three Mascarene Islands and most of their satellite islets were densely populated by various species of tortoises. Each island had species with differently

shaped shells: domed for feeding on low vegetation, and high•fronted for other vegetation (Day 1981).

Francois Leguat described Rodrigues' tortoises in the early 18th century: "There are such plenty of Land•Turtles on this Isle that sometimes you see 2,000 to 3,000 of them in a Flock; so that you can go above a hundred paces on their backs without setting foot on the ground. They meet together in the evening in shady places and lie so close that one would think those spots were paved with them" (Day 1981). The large tortoises must have numbered in the hundreds of thousands, judging from the quantity taken by ships to provision their crews and to trade for commodities. Each weighed about 100 pounds, and naval ships vied with one another for rights to them. The tortoises were plundered indiscriminately. Far more were killed than needed by crews and passengers (Durrell 1977). One expert estimated that at least 10 thousand tortoises were taken per year from Rodrigues island alone. Many died en route, as in the case of one shipment of December 6, 1761, in which the ship fiL'Oiseaufl arrived with a cargo of only 3,800 tortoises still living out of the 5,000 shipped (Durrell 1977). The Mauritian tortoises were extinct by 1700, the two Reunion species by 1773, and the Rodrigues species in 1800 (Day 1981). The last of the tortoises were killed off by pigs consuming the young tortoises and rooting up their eggs in the sand (Day 1981). Eight tortoise species, including three giant tortoises, became extinct (see Table "Extinct Wildlife of the Mascarene Islands").

In all, 13 Mascarene reptile species disappeared forever. The blind cave snake and three skinks or geckoes also disappeared. The most recent extinction was the Round Island Boa, which inhabited an islet off the coast of Mauritius. Livestock and rabbits stripped the vegetation, which caused the extinction of this snake by 1975. No native tortoises or turtles still exist on the Mascarenes. The remaining species of boa and the four gecko and skink species are highly threatened, according to the *2000 IUCN Red List.*

Elsewhere in the world, reptiles have been eliminated mainly as a result of the combined effects of non-native species, such as rats, cats and mongooses. Predators prey and compete for habitat and vegetation, livestock overgraze and settlers destroy habitats. Nine species of iguanas and snakes of the Caribbean became extinct after introduced species of mongoose and rats demolished them. The iguanas were also hunted heavily for food by local people. A number of iguana species barely survive on various Caribbean islands, having become restricted to tiny islets off the main islands where rats, cats and livestock are not present. Four Caribbean reptiles have disappeared. A lizard (*Ameiva major*) and a snake (*Dromicus cursor*) were native to Martinique and became extinct in 1960 and 1962 respectively; the other two were native to Jamaica. A tree snake (*Alsophis ater*) was probably eliminated by forest destruction and predation by the introduced mongoose. The Jamaican iguana (*Cyclura collei*), thought to be extinct, was recently rediscovered, but the species is still highly endangered. The single reptile extinction on a mainland area was a South African lizard, Eastwood's longtailed seps (*Tetradactylus eastwoodae*) Œ it disappeared in 1913.

Bird Extinctions

A bleak picture has emerged, showing a dramatic rise in the rate of bird extinctions over the past 200 years. At least 157 species of birds have become extinct since 1500, and many more have not been seen in decades. In pre-history, approximately one bird disappeared each century (Leakey and Lewin 1995), but the present rate is many times that. During the 17th century, 15 birds disappeared, increasing to 26 birds in the 18th century (at an average rate of about one bird every four years); this was 26 times the pre-history rate. Nineteenth century extinctions totaled 56 bird species, or about a bird every other year. Data for the 20th century is still being totaled, but 54 birds have already been declared extinct since 1900 Œ already almost as many as the entire 19th century™s toll. Thus, the rate of avian extinctions has likely more tripled since the 18th century. A large number of birds have not been seen in the wild for many decades and will likely soon be declared extinct; a period up to 50 years between the last sighting and formal declaration of a species' extinction is generally accorded, unless thorough surveys verify the species is indeed gone.

An important dimension of these extinctions is the fact that birds are considered indicators of the planet's health. Birds are sensitive to environmental pollution, habitat loss and other signs of deterioration, as illustrated when canaries were used by coal miners to test for the presence of lethal methane gas. Their extinctions will also affect the ecosystems in which they once lived, since many birds pollinate plants or disperse seeds, and without them, these plants die off. The story of the dodo (*Raphus cucullatus*) is an example of such a relationship.

Some of the most amazing and unusual species that ever lived are among the birds that have become extinct since 1600. Many of these extraordinary birds evolved on remote islands without human inhabitants over periods of millions of years. The heaviest bird ever to have lived on Earth was the Great elephant bird (*Aepyornis maximus*) of Madagascar, the last of many related species of elephant birds. Some experts maintain this giant bird disappeared prior to 1500 (Brooks 2000), but observers spoke of its continued presence on the island after 1600. The giant moas of New Zealand are thought by some to have persisted until the 19th century, while others believe they died out a thousand years ago, within a few centuries after the arrival of the Maori people. The brawny great moa (*Didornis torosus*) of New Zealand was perhaps the last of many species of moas, the largest of which was the tallest known bird, some 12 feet in height. It was hunted to extinction like its relatives. Some said it persisted until 1670. Another extraordinary New Zealand bird was unique in that males and females had beaks that were completely different in both size and shape: the colorful huia (*Heteralocha acutirostris*) became extinct early in the 20th century, mainly from the effects of forest destruction and hunting for its feathers, which were sold in the European markets for ladies' hats.

The Mascarene Islands, which remained uninhabited by humans until the 17th century, once had an unparalleled diversity of birds, including an array of many odd flightless birds such as the famous dodo. Flightless herons and storks fished in the streams, and enormous parrots Œ their beaks as large as their heads Œ lumbered about in search of fruits and seeds. Each island had its own distinctive parrot species. Some of the native parrots had not become flightless, and each of the seven or so species occupied its own ecological niche. Gray parrots with bright red beaks, small gray parakeets and two types of lime green parrots with very long tails swooped about in large flocks (Fuller 1987).

Large numbers of the flightless, turkey•sized dodos waddled about on Mauritius. The birds, weighing about 50 pounds and covered with grayish, downy feathers, fed on hard-shelled seeds. Of all birds that have become extinct, this species is perhaps the most famous. The dodo™s common name apparently came from fidodoor,fl a Dutch word meaning sluggard, and dodaers, a lubber, or awkward sailor (Halliday 1978). The creature's original scientific name was *Didus ineptus*, indicating its inability to flee humans or defend itself.

In fact, the dodo was the final result of thousands Š perhaps millions Š of years of evolution in isolation on an island with no land predators. Wild pigeons of an unknown species landed by chance on Mauritius at some early date and became resident, gradually evolving into a gigantic form of the original immigrant. The dodo may have evolved from New Guinea and Pacific Islands tooth•billed pigeons that landed in the Mascarenes, according to some zoologists (Halliday 1978). Tooth-billed pigeons also have curious hooked beaks, although the dodo's 9 inch beak was far more massive. Yet whatever its ancestry, the dodo became flightless in its predator•free environment. Its feathers lost their sheen and aerodynamic quality and came to resemble the down of nestling birds.

Mauritius was first visited in the early 16th century by Portuguese sailors, and was later settled by the Dutch, who brought pigs, goats and cattle. These domestic animals soon multiplied and overran the islands. Pigs rooted in forests, devouring rare flora, and cattle and goats overran the fragile tropical vegetation. Rats swam from ships and colonized the main islands; they preyed on flightless birds, eating their eggs and young, even climbing trees to devour nesting songbirds. Mongooses native to Asia were brought to Mauritius, which presented a lethal threat to native birds and other wildlife. Long-tailed macaques (*Macaca fascicularis*) were imported as pets at some point from Southeast Asia and then released into the forests of Mauritius, spreading throughout the island and preying on native birds. Settlers also cut the trees needed by native birds for habitat and food. The delicate plants, forests and vulnerable wildlife were devastated by this onslaught.

Portuguese and then Dutch seamen and colonists slaughtered thousands of dodos, using them as a major source of food. They cut down the seed-bearing trees dodos fed upon, and their eggs and chicks may have been preyed on by rats and introduced macaques (Fuller 1987). Settlement began in 1634, and within less than 30 years, the once-common dodos were slaughtered to extinction. The settlements failed and Mauritius remained uninhabited for a period of time.

The last account of wild dodos dates from 1662. A Dutchman named Volquard Iversen was deserted on Mauritius soon after both the early settlement and the penal colony failed (Quammen 1996). Iversen and his shipmates scoured the island for food and found no dodos, but they did see some on a small islet off the coast. He described them as "larger than geese but not able to fly. Instead of wings they had small flaps; but they could run very fast" (Quammen 1996). The islet protected the last few dodos from human hunters and introduced predators, and until then, the tiny population had remained undetected. Iversen's party waded through the shallow water to the islet and captured a dodo. "When we held one by the leg he let out a cry, others came running forward to help the prisoner, and they were themselves caught" (Quammen 1996). These were the last of their species. Altruism, a trait that has helped many animals survive through mutual aid, has also caused extinctions. Human hunters have taken advantage of this, killing animals that come to the aid of each other.

In the centuries since its demise, the dodo has come to symbolize extinction, but many still think of this bird as stupid, giving rise to the expression "dumb as a dodo." Animals are frequently deemed stupid if their natural defenses against humans are inadequate, or vicious if they are able to defend themselves. Yet this bird so many people have described with disdain came to the rescue of its fellows, even at the risk of its own life, and was an extremely successful species within its environment. If the word dodo must be seen symbolically, then it would be more reasonable to equate it with human stupidity, because our own species wantonly destroyed this extraordinary bird. In the opinion of Errol Fuller (1987), author of the authoritative book *Extinct Birds*, "The dodo was one of the most fantastic creatures ever to have lived."

In 1973, Dr. Stanley Temple, an ornithologist, made a remarkable discovery about the dodo. He noticed that a beautiful tree native to the island, the calvaria or tambalacoque tree, was reduced to 13 dying specimens, all more than 300 years old. Gerald Durrell (1977) described these trees as at least 50 feet tall, with massive crowns and silvery, gnarled trunks; cracks appeared in their buttress roots. Since no young trees were located, it occurred to Dr. Temple that no seeds had germinated since the 17th century when the dodo became extinct. Apparently, stones found in the dodo™s gizzard by sailors butchering it for food might have been able to abrade the thick shell covering the seeds. Dr. Temple fed some of the seeds to domestic turkeys, which were presumed to have similar digestive systems, and of 10 seeds recovered from feces or regurgitation, three sprouted when planted (Anon. 1978).

Some scientists now believe this tree could germinate without the dodo. A surviving parakeet is thought to be able to crack its hard-pitted seeds, and the extinct Mauritius flying fox and some of the extinct parrots were able to do so as well(Quammen 1996). Dr. Wendy Strahm, in her botanical work on Mauritius, has found young trees of this species that germinated in the past 300 years, although they are quite rare (Quammen 1996). Another scientist, Anthony S. Cheke, believes seed germination has continued, but at a low rate Œ perhaps too low to maintain the species long-term. The rarity of the tambalacoque tree was considered to be due to seed predation by rats, deer browsing on saplings, rooting by pigs and perhaps browsing by the introduced macaque monkeys (Quammen 1996). Yet dodos were likely major seed distributors of this tree in the pre-human environment, and their role has not been successfully replaced ecologically. The introduction of a veritable zoo of non-indigenous species has reaped havoc on a variety of native plants.

The dodo's close relatives on neighboring islands are far less known. On Reunion, a bird called the Reunion solitaire (*Raphus solitarius*) was described by early visitors to the island as resembling the Mauritius dodo, except its beak was somewhat smaller, its plumage was white and the tips of the wings and the tail were black (Fuller 1987). One traveler, M. Carre, said in 1699: "The beauty of its plumage is a delight to see. It is of changeable color which

verges upon yellow" (Fuller 1987). Two were taken aboard ship as a present to the French king, but both refused to drink or eat and soon died. M. Carre noted in his description that "The flesh is exquisite; it forms one of the best dishes in this country, and might form a dainty at our tables" (Fuller 1987). This was an ominous prediction of its final fate. The Reunion solitaire probably died out about 1715 as a result of being slaughtered for food.

On tiny Rodrigues, yet another dodo-like bird existed. Far more is known of this species, whose bones have been found in caves on the island. Its beak was shorter and its neck was longer, but it also apparently evolved from pigeon ancestors (Halliday 1978). It was called the Rodrigues solitaire or solitary (*Pezophaps solitaria*) for its habit of feeding alone on leaves and fruit in secluded places. Errol Fuller's description in *Extinct Birds* evokes its once peaceful existence: "In this tranquil kingdom generations of solitarys must have lived enjoying extraordinary peace and seclusion until their world was shattered by the coming of man."

Francois Leguat, a Huguenot refugee, left extensive descriptions of these birds when he spent two years on Rodrigues after he was marooned there with a small group of followers in 1691 (Fuller 1987). "They walk with such stately form and good grace," Leguat wrote, "that one cannot help admiring and loving them" (Fuller 1987). He watched them nesting and feeding their chicks until they fledged at several months. The male and female defended their territory, driving other solitaires away with a dramatic display in which a bird pirouetted for four to five minutes while whirring its wings violently to produce a loud rattling noise that could be heard 200 yards away (Halliday 1978). If this impressive display did not frighten other birds away, they used knobby growths at the joints of their flightless wings in combat with other solitaires (Halliday 1978). Some wing bones now found in museums have healed fractures, an indication of the violence of these encounters (Halliday 1978).

Leguat saw the parents of solitaires escorting their single chick to a gathering of some 30 other solitaire families, where the adults would leave the chicks. Tim Halliday wrote in *Vanishing Birds* (1978) that he believes what Leguat witnessed was actually a sort of nursery gathering, similar to that which flamingos and some penguins organize while adults go off to feed. Although these birds were able to hide in foliage and could run quickly, hunters chased them down and butchered every last bird. People slaughtering them found stones in their gizzards Œ even in those of very young nestlings. How they got there remains a mystery, since the stones were too large to have passed down the gullet (Halliday 1978). The last solitaire was seen around 1746, and the species was deemed extinct by the 1760s (Brooks 2000).

The origin and affinities of these three species of pigeon-like birds in the Mascarene Islands will be disputed by scientists for some time to come. Tim Halliday (1978) conjectured that the dodo may have evolved from a pigeon, such as the tooth-billed pigeon (*Didunculus strigirostris*) of the Pacific Œwhich has a similar but far smaller hooked bill Œ or that they were related to rails. It is also possible the dodo had one ancestor and the solitaires had another. What is not disputed is that they left no close relatives. No living birds on Earth are related to the dodo and the solitaire, or bear any strong resemblance to them.

Other flightless native birds of the Mascarenes disappeared as well: all the huge parrots, three kinds of owls, three rails, several small pigeons, two night herons, a stork and an ibis. Little is known about many of these birds, but two of the rails were described in detail. The Rodrigues or Leguat's rail (*Aphanapteryx leguati*) had bright gray plumage flecked with white and gray, a curved red bill, red legs and feet and a red ring surrounding the eye (Taylor 1998). The bird™s call consisted of a long whistle, but when pursued, the rail gave an alarm call that sounded like a person with a hiccup (Taylor 1998). This species fed on tortoise eggs and, like the related Mauritian red rail (*Aphanapteryx bonasia*), could be lured by holding out a red object and trapped when the bird came to attack the lure (Taylor 1998). They were described as delicious, and were killed to the last bird. Among flighted species lost were a type of weaver, a starling and a falcon (Brooks 2000; Fuller 1987; Greenway 1967). The total of 31 extinct birds is more than that of any other island group or continent.

However extraordinary such a toll may seem for a group of small islands, it may represent only a percentage of Mascarene avian extinctions. Stanley Temple estimated that prior to the arrival of humans, 68 species of birds lived

on the three main islands and, of these, 45 species (66 percent) became extinct after 1600 (Temple 1981). The 14 species not officially included among the extinct birds of these islands were described by travelers but have not yet been authenticated. The majority lived on Mauritius. Future archeologists are certain to discover far more about the birdlife that once inhabited these islands, and genetic studies of specimens from which DNA can be extracted may help identify their origins.

The Hawaiian Islands vie with the Mascarenes for numbers of extinctions. At least 21 species and many more subspecies have become extinct since 1600. One of these was native to the remote swamps of Kauai. The Kauai Oo (*Moho braccatus*) had pitch black plumage brightened by several long, canary yellow feathers. The male had a haunting, fluted call. The species dwindled as forests were cut, and by 1960, only 12 birds were known to remain. A single pair survived by the 1980s. The female disappeared after a hurricane in 1985 (Brooks 2000), and the male lived on a few more years as the last member of his species. He was seen singing and building a nest with each final year, trying to attract a mate who never came (Daws 1993). He was last seen in 1987 (Brooks 2000).

The Kauai Oo was the last of a group of dramatic songbirds that once lived on all the major islands. The Hawaiian honeycreepers found only here evolved from one or a small number of ancestor species Œ likely a New World finch, warbler or honeyeater Œ into an estimated 40 to 50 brilliantly colored birds, before the arrival of the Hawaiian people. Some species were probably eliminated after they were killed in tremendous numbers for their feathers, then made into elaborate headdresses and cloaks for Hawaiian royalty, but the major cause of their extinction was the destruction of their forests by European settlers. As the honeycreepers retreated to smaller and smaller habitats, often surrounded by ranchland, sugar cane and pineapple farms, their habitats and food trees disappeared. Their fragmented populations were susceptible to avian malaria, which spread throughout the islands in the 20th century, brought by exotic cage birds that had escaped or been released by their owners. Thousands of birds died of the disease. The extinction toll of native birds within the past few hundred years stands at 21 species, in addition to even more subspecies. Twenty-three honeycreepers survive, but most are so endangered they are not expected to survive more than a few more decades. One critically endangered honeycreeper, the po'o-uli (*Melamprosops phaeosoma*), has a total population of three birds: two males and one female live in a reserve and the adjacent Haleakala National Park on Maui (BI 2000). This small, masked brown-and-white bird, discovered in 1973 by a graduate student, once numbered 200 individuals before it underwent a drastic decline between 1975 and 1985 as a result of avian malaria and habitat destruction by feral pigs within its reserve (BI 2000). All three birds live in separate home ranges, and the species has little chance of survival.

Rails are the most characteristic of all island land birds. These compact and stocky creatures are most frequently seen in wetland habitats, but some live in forests or grasslands. Almost all islands in tropical latitudes have or had endemic rails or fossil evidence of their past presence. Larger islands have several native rails, and it has been estimated that as many as 2,000 flightless rails inhabited Polynesian and western Pacific islands alone, prior to their colonization or visits by humans who exterminated them. Many of these instances were in prehistoric times by Maori, Hawaiians and other native peoples (Taylor 1998). Some 23 species of island rails, virtually all flightless, have been exterminated since 1500 Š far more than any other avian family (see Appendix).

Rails are not likely candidates for colonizing islands because they are, in the words of S. Dillon Ripley (1977), an authority on rails, "loath to fly." When frightened, they usually do not take wing, but disappear into matted vegetation. When they do fly for short distances, it is rather feebly, and their legs dangle down. How could they have reached islands thousands of miles from the mainland? Some rails are long-distance migrants, while other species disperse in erratic patterns (Taylor 1998). Rails tend to travel in groups at night and are often blown off course. European rails on their way to Africa have ended up far from their wintering site (Taylor 1998). European Corncrakes, for example, have landed, exhausted, on ships in the Indian Ocean or even off New Zealand (Ripley 1977). North American Purple Gallinules, colorful rails of southern marshes, have flown to tiny Tristan da Cunha island halfway between South America and Africa in the South Atlantic (Ripley 1977). The Common Moorhen (*Gallinula chloropus*) of Eurasia, North and South America and Africa has colonized St. Helena, the Azores, the Seychelles, the Marianas and Hawaii, among other islands. These colonizing rails usually become flightless if they

have are no enemies, such as native predators. Some become the size of large chickens. Once flightless, however, they are vulnerable to predation by animals brought by humans.

The Laysan rail or crake (*Porzana palmeri*) was driven to extinction by imported rabbits who rendered Laysan Island devegetated. Biologists transported it to nearby Midway Island, where it flourished until World War II, when the island became a naval base. The navy personnel were entranced by this utterly fearless and agile bird that sprung into people's laps or onto the mess table in search of crumbs of food. Unfortunately, the species perished soon after 1942, when rats from a naval landing craft apparently ate the rail's eggs and preyed on its young. A few of the rails had been returned to Laysan Island after rabbits were removed, but the vegetation had not recovered sufficiently and the birds did not survive (Ripley 1977). Most other island rails have died out from similar causes.

Since about one-third of the world's birds are endemic to islands, and they have been reduced by 30 to 50 percent since humans came to these islands. Their extinctions represent a true biological catastrophe, in the words of Storrs Olson, an authority on extinct birds (Taylor 1998). The vast majority of avian extinctions in the past 500 years have been island birds Œ victims of predation, competition from introduced animals and disease from cagebirds. Many were also killed for food or trade. Non-indigenous species are still causing bird extinctions on islands. In all, 137 of the 157 bird extinctions (87 percent) since 1500 have been island species, and human activities and animals introduced by humans have been responsible. Island species have been more vulnerable to extinction than mainland species because of their small populations and limited habitats. Many were flightless or slow-moving species, unable to flee predators, including humans. Some were specialized in their diet and habitat and could not adapt to changes made in their environment.

Mammal Extinctions

Cuba, Puerto Rico, Hispaniola and Jamaica had a variety of unusual native rodents and shrew-like insectivores prior to the arrival of European explorers and settlers in the 1600s; many were ancient species. When native Caribbean populations settled the islands after the Ice Ages, rodents as big as marmots inhabited the larger islands. A type of giant sloth lived in Puerto Rico, and a rodent nearly the size of the American black bear inhabited the small islands of Anguilla and St. Martin until it was apparently hunted to extinction by natives (Olson 1978). Cuba, Puerto Rico and Hispaniola were once attached to the mainland of Central America, but this large land mass became separated and drifted off into the Caribbean. Some of the native fauna and flora present more than a million years ago survived until a few thousand years ago, and tiny frogs and butterflies from that period persist today.

When Europeans colonized the Caribbean islands, they began cutting forests and replacing them with huge plantations of sugar cane, other crops and grazing land for livestock. They imported thousands of slaves to farm the land. Mongooses were brought on the islands to control snakes, but they preyed on native mammals and birds instead; rats arrived in ship holds and did the same. Fifteen mammals have become extinct on Hispaniola, the island divided between present day Haiti and the Dominican Republic Œ this island suffered the highest number of mammal extinctions of any Caribbean island. Forests have been nearly obliterated on Haiti, which is another cause of extinctions. Cuba, Puerto Rico and Jamaica have likewise lost the majority of their forest cover, as well as many native mammals, including bats, rodents and insectivores. Jamaica was home to a monkey (*Xenothrix mcgregori*), making it the only Caribbean island with a native primate. It was hunted and its forest habitat was cut by European colonists, and it died out in the 1750s. Various species of hutias, large rodents found on most major islands, became extinct as well. Hutias remain on a few Caribbean islands but are close to extinction from forest destruction and predation by introduced mammals.

Most of the 40 mammals that became extinct on Caribbean islands after 1600 were rodents and insectivores. A muskrat and a rice rat became extinct on Martinique when Mt. Pelee erupted in 1902 Œ one of the few examples of a naturally caused modern extinction. Hutias, large rodents that resemble South American agoutis, proliferated into a variety of species on the large islands of the Greater Antilles. Settlement, deforestation and hunting caused at least five species of hutias to become extinct, and the few remaining species are now highly endangered.

The first mammal to disappear after 1600 was a massive wild cow called an auroch (*Bos primagenius*). This species, native to most of Europe, lived in the deciduous forests that once covered most of the continent. The auroch was also hunted for its meat and died out about 1627. Several other wild cattle related to the auroch survive in Southeast Asia, but they are critically endangered. The tarpan (*Equus gmelini*), a wild horse of Europe, gradually became rare and restricted from hunting and destruction of its native forests during the Middle Ages. The last wild tarpans were killed off in 1851 (Day 1981). Both the auroch and the tarpan are depicted by Pleistocene humans in magnificent cave paintings found in southern Spain and France.

The Steller's sea cow (*Hydrodamalis stelleri*) was an enormous 24 to 30 feet long marine mammal, similar in appearance to the dugong and the manatee. The sea cow was larger, however, and swam in the cold arctic waters of the Bering Sea, enduring temperatures that would kill its closest relatives. The slow and sluggish sea cows were killed off only 27 years after their discovery. They were first seen by the shipwrecked crew of the explorer Vitus Bering in 1741 in the vicinity of Bering Island in the Commander Islands, off the eastern coast of Russia's Kamchatka Peninsula. These sea cows were tame and easy to spear and harpoon by the ship crews who killed most of the population, calculated at only about 1,500. This animal showed extreme protectiveness toward its fellows and strong bonds between mates. The naturalist Georg Wilhelm Steller, after whom the species was named, described their behavior on being harpooned.

. . . Some of them tried to upset the boat [when another sea cow was struck] with their backs, while others pressed down the rope and endeavored to break it, or strove to remove the hook from the wound in the back by blows of their tail, in which they actually succeeded several times. It is most remarkable proof of their conjugal affection that the male, after having tried with all his might, although in vain, to free the female caught by the hook, and in spite of the beating we gave him, nevertheless followed her to the shore, and that several times, even after she was dead, he shot unexpectedly up to her like a speeding arrow. Early next morning, when we came to cut up the meat and bring it to the dugout we found the male by the female, and the same I observed on the third day when I went there by myself for the sole purpose of examining the intestine (Day 1981).

Australia has been the scene of more mammal extinctions than any other continent or island group. Beginning in the 19th century, Australia's mammals disappeared in large numbers. Native marsupials and rodents were gradually eliminated by massive habitat destruction and predation from animals introduced by European settlers. Twenty-two mammals became extinct after 1600. A wide variety of marsupials, from small species to wallabies, was extinguished within a century of settlement. Some, like the thylacine, or Tasmanian wolf (*Thylacinus cyanocephalus*), were deliberately persecuted by livestock ranchers under the misapprehension that the species presented a threat to flocks.

The crescent nailtail wallaby (*Onychogalea lunata*) was native to the gum forests of western Australia where John Gilbert, a 19th century museum collector, found the animal common in thick scrub, "where it is occasionally seen

sunning itself" (Strahan 1995). This small marsupial weighed less than 20 pounds and looked like a miniature kangaroo. It rested in hollows in soft ground beneath shrubs during the day, feeding mainly at night on roots and coarse grass (Nowak 1999). When chased, it would run to a hollow tree with a hole in the bottom and clamber up the sides until it got high up within the trunk; aborigines used smoke to chase them out and then killed them for food (Strahan 1995). The aborigines also hunted these animals by building brush fences and enclosures and driving the animals into areas where people waited with clubs (Strahan 1995). In spite of hunting, this wallaby was fairly common until 1900, and many were collected for museums (Strahan 1995). It disappeared from the southern portion of its range early in the century after intensive forest clearance and development of the country for agriculture. Gradually, it became very rare, and disappeared altogether from the wild in the 1960s (Nowak 1999, Strahan 1995). Some experts suggested the removal of the thickets where these wallabies sheltered during the heat of the day left them homeless and vulnerable to predation (Nowak 1999).

Millions of acres of eucalyptus forests and mulga woodlands of southern and western Australia were clearcut by settlers beginning in the 19th century, opening up the land to wildfires (Lines 1991). The devastation of these habitats was described in *Taming the Great South Land. A History of the Conquest of Nature in Australia*, by W.J. Lines (1991). The combination of this habitat destruction, hunting and introduced predators, such as feral dogs, was responsible for the extinction of the Crescent Nailtail wallaby and many other native marsupials.

Various endemic Australian rodents and bats died out as well, and many of the remaining native mammals are become confined to tiny islands off the coasts Œ the only habitats where introduced animals are absent. Australia is like an island in having been isolated from other land masses for millions of years, and the majority of its mammals are endemic to the continent. In fact, it is often referred to as the "Island Continent." If Australian extinctions are included among those on islands, 87 percent of all extinctions of vertebrates other than fish have occurred on islands.

In Asia, the freshwater baiji dolphin species was until recently found throughout the Yangtze River and its surrounding lakes and tributaries. Unfortunately, the exponential growth of the Chinese population posed a variety of threats to its survival. A lack of information, growing threats and the species' small population size eventually led to the baiji's decline, despite protective efforts. Baiji dolphins were last officially sighted in 2004, and a 2006 expedition deemed the species "functionally extinct."

THE GEOGRAPHY OF EXTINCTION (chart)

Source: Table of Extinct Species in the Appendix of this book. Sources of information are listed with the table.

Note: See the Appendix for the list of these species in chronological order, and the references that describe these animals and their extinctions, as well as those that include illustrations of the extinct species.

The following account chronicles some of the many extinctions and destructions of natural ecosystems that have taken place in North America over the past few hundred years. Great biological treasures have been stolen from future generations, and the processes by which they were lost are typical of those occurring elsewhere in the world. The sudden loss of the most abundant and prominent wildlife species of the continent created a profound shock in the public early in the century that set the stage for today's conservation and humane programs. This concern may turn the tide for species that could suffer the fate of the passenger pigeon (*Ectopistes migratorius*) and others, but unless public opinion is better translated into public policy regarding the land and wildlife, further losses will occur and the lessons that might have been learned will be ignored. A strong and pragmatic commitment to preserve what remains of the natural world on the continent, based on a realization that our fate is linked to nature's fate, is essential to prevent further extinctions.

Epitaphs for North America's Lost Species and Environments

After the loss of the majority of large Pleistocene mammals, native peoples in North America became conservationists of the remaining wildlife and the continent's environment. Many tribal religions deified animals and believed they embodied the spirits of their people. They hunted and fished on a subsistence basis. This resulted in relatively few animal extinctions over the tens of thousands of years that passed before settlement by Europeans in the 16th century. The land that awaited new settlers was spectacular in its beauty and abundance of wildlife. Over the next three centuries, however, an unprecedented level of slaughter and drastic environmental alteration destroyed many of these natural treasures.

An Abundance of Wildlife

Early European voyagers landing on the East Coast of North America were astounded to see animals in numbers they had never before witnessed. Fish swarmed in the millions. Captain John Smith came upon vast schools of fish in tributaries of the Potomac River, near the Chesapeake Bay, in 1608: "–in diverse places that abundance of fish lying so thick with their heads above the water [that] as for want of nets (our barge driving among them) we attempted to catch them with a frying pan, but we found it a bad instrument to catch fish with. Neither better fish, more plenty, nor more variety for small fish had any of us ever seen in any place so swimming in the water–" (Hawke 1970). Lobsters were so prolific that one haul of a fisherman's net would bring in more than 100; settlers used them as fertilizer and fish bait. Huge sturgeon 10 feet long swam up major rivers to spawn along the East Coast. Offshore, whales and herds of dolphins migrated along the coasts. The northern right whale (*Eubalaena glacialis*) fed on plankton in shallow lagoons as it migrated to its breeding grounds off Florida. The now-extinct Atlantic gray whale (*Eschrichtius robustus*) was a common marine resident, swimming and feeding offshore. At the present sites of Boston, New York

and Philadelphia, vast saltwater marshes surrounded river deltas. Shorebirds and waterfowl darkened the sky with their millions.

Along the craggy rock•strewn coasts of Maine and the Canadian maritime provinces lived a large mink, almost double the size of the American species found elsewhere in the country. Unlike any other type of mink in the world, the animal was a coastal species that soon became known to colonists and fur trappers as the sea mink (*Mustela macrodon*). One sea mink killed in 1867 measured 32.5 inches in length, enormous in comparison to the American mink, which does not exceed 23 inches (Mowat 1981). The sea mink's pelt had twice the value of the inland species in the fur trade (Allen 1942).

An early account by the English naturalist Joseph Banks, who traveled to Newfoundland in 1766 to study the local fauna, described the sea mink as "bigger than a Fox, tho not much, in make and shape nearest compared to an Italian Greyhound, legs long, tail long and tapering" (Mowat 1981). It is unlikely that the sea mink was as long•legged as a greyhound, but available information indicates it was quite different from any closely related species. Bones from the sea mink have been found along the coast of Maine and New Brunswick (Allen 1942). The fur traders decimated these minks long before scientific or biological studies could be carried out. One early observer described the avid pursuit of sea minks in Maine:

> *Some seventy•five years ago, and for many years thereafter, my father, who was a fur•buyer, used to have nearly all the furs taken on the islands of Penobscot Bay . . . these sea mink used to bring considerably more than others on account of their great size . . . they were persistently hunted . . . with dogs trained for the purpose. As the price of mink rose, they were hunted more and grew scarcer, 'til in the sixties, when mink skins brought eight or ten dollars apiece, parties who made a business of hunting nearly or quite exterminated the race. Some of these men went from island to island, hunting any small ledge where a mink could live. They carried their dogs with them, and besides guns, shovels, pick•axes and crow•bars, took a good supply of pepper and brimstone. If they took refuge in holes or cracks of the ledges, they were usually dislodged by working with shovels and crow•bars, and the dogs caught them when they came out. If they were in the crevices of the rocks where they could not be got at and their eyes could be seen to shine, they were shot and pulled out by means of an iron rod with a screw at the end. If they could not be seen, they were usually driven out by firing in charges of pepper. If this failed, then they were smoked with brimstone, in which case they either came out or were suffocated in their holes. Thus in a short time they were nearly exterminated* (Beard 1947).

The last known sea mink was killed in 1880, and its pelt was sold to a fur buyer in Jonesport, Maine (Mowat 1981). Only fragments of bones and teeth found in excavations of Indian cooking sites attest to its existence (Nowak 1999).

A beautiful North American waterfowl species also disappeared. The male Labrador duck (*Camptorhynchus labradorius*) had striking black•and•white plumage, while the female was mousy brown. During the 19th century, these birds were often seen in fall and winter off New York's Long Island and on the New Jersey coast. Named for the Canadian peninsula where naturalists of the day assumed that they bred, eggs reported to belong to this species had been seen by a naturalist, but the nests were never found (Greenway 1967). This duck had a soft bill, and inside its mouth, lamellae filtered its food. The Labrador duck was assumed to have a specialized diet, possibly of small

surface invertebrates that it filtered while dabbling at the surface. The ducks also fed on mollusks, as hunters discovered when they caught them with fishing lines baited with mussels (Fuller 1987).

Labrador ducks were strong flyers who flew in tight, small flocks (Day 1981). Along with virtually all waterfowl of the day, they were shot for the feather and food markets. Gunners killed entire flocks of waterfowl, bringing them to market, where they were heaped in piles. The ducks were killed for no purpose, since they were not sought after as food and considered too "fishy" by most customers. Many of the birds shot by hunters were left to rot, unsold at markets (Day 1981, Greenway 1967). The Labrador duck, first described scientifically in 1789, was always considered rare, and the last known specimen was a bird shot off Long Island 86 years later, during the autumn of 1875. This male is kept in the US National Museum of Natural History (Fuller 1987). The Labrador duck was apparently hunted to extinction, a victim of the totally unrestricted waterfowl hunting that characterized the 19th century, based on its prevalence in game markets (Day 1981).

Further north, a flightless bird walked upright on its flippered feet. At a length of 3 feet, the great auk (*Alca impennis*) was the size of a large penguin, and could have been mistaken for one. Like many northern seabirds, it had a black back and white belly, but each side of its face was dramatically marked with a large, white oval. Its bill was long and hooked. Great auks were far larger than any of their cousins Œ the murres, puffins and guillemots of the North Atlantic. At one time, these birds ranged along most of the coasts and islands of the North Atlantic, from northern France through Scandinavia, England, Scotland and Iceland, to North America's eastern coast as far south as Martha's Vineyard, Massachusetts (Greenway 1967). Based on fossil evidence, great auks were once as numerous as most other sea birds of the region (Greenway 1967).

The very oldest bones, excavated on the island of Jersey in the English Channel, are between 70 and 90 thousand-years-old (Greenway 1967). As the only flightless bird in the North Atlantic, it was once widespread and numerous. When people approached the birds while they were on land nesting, great auks would immediately waddle to the water's edge and dive in. They were rapid and expert swimmers, using their wings to propel them. When cornered on land, however, they were helpless. Both parents raised the chicks, and they refused to desert their nests, even when attacked. For centuries, hunters took advantage of this trait, pursuing and killing them during their breeding season. Ship crews slaughtered thousands for provisions and took live birds on board for future meals.

Gradually over the centuries, great auks disappeared from most European coastlines and offshore islands as a result of hunting. The last record in the British Isles was on St. Kilda, an island west of northern Scotland, where some local residents captured a Great Auk in 1821; although kept captive with a string attached to its foot, it managed to escape (Fuller 1987). Twenty years later, as recounted by an older resident, another auk was found asleep on a rock on the same island and captured, kept for three days, and then killed because these superstitious people feared that it was a witch (Greenway 1967).

Great auk feathers were harvested in grisly "factories" on Funk Island off Newfoundland in the 18th century. Collectors built pens of piled boulders into which they would drive the hapless great auks from their nests. Once the auks were cornered in the pens, the men would swing spiked clubs at the birds, killing or wounding them (Day 1981). The birds were then thrown over the enclosure walls into piles near the fires; there the dead and wounded birds were dropped into boiling cauldrons or thrown directly on the fires (Day 1981). The boiling water caused the feathers to float to the surface, where they were scooped up and stuffed into bags; the corpses were next dragged down to the water where they were dumped (Day 1981). Some observers, including Captain George Cartwright, an early colonist on Labrador, watched boats coming ashore laden with hundreds of carcasses from Funk Island. He wrote in July 1785, "If a stop is not soon put to that practice, the whole breed will be diminished to almost nothing" (Birkhead 1994). By 1800, all the island's great auks had been killed. The ashes and pens still remain on Funk Island as the only reminder of this extraordinary bird.

Islands off Iceland and Newfoundland became the last refuges of the great auk. When word spread in the 19th century that the species was nearing extinction, hunters went in search of them for museums and egg collections. The

eggs and skins of the Garefowl, as it was known to Europeans, were sold at auction in London and to European museums for very high prices. Hundreds of English pounds were offered for each egg, encouraging fishermen to comb islets for the last of the nesting birds. The only remaining birds known to survive were killed on Eldey Island off southwest Iceland on June 2, 1844; three Icelandic fishermen who discovered two birds, a breeding pair with a single egg, strangled the adults and threw them into a boat (Birkhead 1994). These last great auks were killed for their skins, which were sold to a dealer (Birkhead 1994).

Other marine creatures barely avoided extinction during the period of unregulated killing of wildlife that began in the 1600s. The Atlantic walrus (*Odobenus rosmarus rosmarus*) herd off the Canadian coast numbered at least a quarter of a million animals prior to European exploitation. Between 1633 and 1642, vessels from the Massachusetts Bay Colony made a number of expeditions to Sable Island off Nova Scotia to kill the walruses for their tusks and oil. Glover Allen (1942), in *Extinct and Vanishing Mammals of the Western Hemisphere*, chronicles one sealing voyage in 1641 in which 12 men who spent eight months on Sable Island returned with "400 pair of sea horse teeth, which were esteemed and worth 300 pounds." The walrus colonies in the Gulf of St. Lawrence numbered seven or eight thousand at that time; they were killed off by American sealers, who worked at night while the walruses slept on land (Allen 1942). Gradually, the Atlantic walrus became exterminated in all areas on the continent. From 1925 to 1931, the last large population in the Canadian Arctic on Baffin Island was devastated by the killing of 175 thousand animals (Nowak 1999). Although finally given protection, the species has not shown a substantial recovery because of the high kill by native peoples, which equals annual recruitment in the western Atlantic (Nowak 1999). Only 25 thousand walruses remain in this region. Russia classifies the species as vulnerable and the population in the Laptev Sea as rare (Nowak 1999). They may have increased somewhat along the coast of Norway, in the Svalbard region and Barents Sea (Nowak 1999).

Although the Pacific gray whale has now recovered from near•extinction from whaling, few people are aware that this species once lived in the Atlantic as well (Allen 1942, Mowat 1981). Large numbers of Atlantic gray whales migrated along North America's eastern coast until as late as the end of the 18th century (Mowat 1981). Whalers of the 1740s saw whales whose descriptions matched those of the gray whale, but the existence of this species was not verified until fossil remains were uncovered (Allen 1942, Mowat 1981). Early Basque whalers had eliminated gray whales from European waters centuries before (Mowat 1981). Atlantic gray whales swam south along the shore of the coasts of Maine, Massachusetts and Long Island, down to the Florida Keys, where their calves were born (Mowat 1981). This whale, known as the "Scrag" in the Northeast, was a familiar species off the coasts of Nova Scotia and Maine in early colonial times. It gave rise to place names such as the Scrag Islands, Scrag Rocks and Scrag Harbor Œ now known as Sag Harbor (Mowat 1981). These whales fed in shallow bays on abundant bottom•dwelling crustaceans, making them easy prey for whalers. They were killed beginning in the early 1600s by harpooners off Nantucket Island, Cape Cod and Long Island Sound in the shallow shoals of their migration route (Mowat 1981). By the early 1700s, New England whalers had completely eliminated this whale (Mowat 1981).

Beginning in 1609, Samuel de Champlain sailed down the St. Lawrence River to the Great Lakes (Peck 1990). Other explorers and settlers established trading posts and villages. Furs were major items of trade, and soon beaver and other furbearers were traded in the millions by the French and English. Early travelers found wild turkeys (*Melagris gallopavo*) so abundant boys threw stones at them for recreation (Peck 1990). Two French explorers observed great numbers of fish in the Great Lakes and the upper Mississippi River, which soon became exploited. Vast numbers of cisco, members of the Salmonidae family, once lived in the Great Lakes. The Blackfin Cisco (*Coregonus nigripinnus*) and Deepwater Cisco (*Coregonus johannae*), native to Lake Michigan and Lake Huron, were considered "jumbo herring" by fishermen from early times (Day 1981). By the late 19th century, large fishing vessels with huge nets caught up to 15 million tons from one lake alone per year; one net haul might yield as much as 10 tons in a day (Day 1981). Fishing continued, even in winter, through ice holes, and prior to the availability of freezing facilities, dumping of unsold catches amounted to many tons (Day 1981). These fish became commercially extinct after World War I, and subsequently were declared extinct by the World Conservation Union, along with another Great Lakes species, the longjaw cisco (*Coregonus alpenae*) (Baillie and Groombridge 1996).

This overfishing was repeated in the Atlantic waters off New England and southern Canada. Cod, halibut and flounder abounded here, providing ample fish for centuries to local fishing communities. Huge cod weighing 180 pounds and halibut the size of barn doors were often caught in these times. Factory fishing ships began fishing here in the 1950s and soon depleted the stocks. National legislation banned these vessels from the Atlantic coast and smaller vessels took their place. With few restrictions on take Š and far too many fishermen Š the stocks crashed in the 1980s and early 1990s. With the encouragement of the National Marine Fisheries Service (NMFS), fishermen turned to small sharks known as dogfish. Within a few years, they also became depleted because of their extremely slow reproductive rate, a fact apparently not appreciated by the NMFS. Fishery conservation legislation has been enacted, but these stocks may never return to former abundance.

Some fisherman are being compensated for their boats by a federal program, in order to ease fishing pressure on remaining stocks, but others are turning to small fish, such as menhaden. These fish are fed on by humpback whales (*Megaptera novaeangliae*), threatened species not yet recovered from past whaling, as well as by puffins and other seabirds. Many seabirds are undergoing population decline as a result of a dwindling food supply and the drowning risk posed by fishing nets. Shorebirds, too, are affected by overfishing. Horseshoe crabs (*Limulus polyphemus*) lay their eggs along the east coast each year, providing abundant food for shorebirds on their northward migration, and for many types of other wildlife as well. These crabs are captured by the millions for use as fish bait, which has reduced their numbers dangerously in some areas. The shorebirds have also declined precipitously in recent years, some species by 90 percent. Entire food chains are being disrupted as a result of over exploitation of the sea. Ocean pollution has contaminated Atlantic coastal waters, causing die-offs of dolphins, fish and manatees.

All along the East Coast, colonists built cities at river deltas, which were surrounded by vast salt marshes. These locations were considered prime seaport and manufacturing sites, and the marshes were filled in and polluted. Tens of thousands more acres of marshes along the Northeast coast have been ruined by construction of drainage ditches to control mosquitoes and halt malaria. In fact, these ditches created habitat for mosquito breeding and caused the water level in the marshes to drop. Waterbird populations declined sharply as a result, and they no longer filled their role as fish and shellfish nurseries, water filterers and flood controls. In a recent development, dikes in 10 thousand acres of marshes on Long Island are being blocked to open normal flow channels between marsh and bay, and exotic reeds are being removed (Lambert 1997). The marshes that have been returned to their natural state showed an immediate tripling in the number of waterfowl wintering there, and a doubling of wading birds such as ibis, egrets and herons; shorebird populations quintupled; these marshes have at least 130 species of breeding birds, and 300 species use them for wintering or migration (Lambert 1997). The marshes give a glimpse of the wealth of wildlife that once inhabited eastern coasts; with similar programs, they can be restored to help build up stock of fish and shellfish.

In most areas, however, housing and development now occupy the sand dunes and former marshes. Some barrier islands off the coasts, which buffer the beaches against the erosion effects of storms, have been preserved in portions of the East Coast, such as Virginia, North Carolina and Georgia. Elsewhere, roads, houses and businesses clutter these islands, and development has endangered many native birds. Georgia's beautiful coastal marshes were given official protection after they were nearly destroyed by phosphate mining, when it was shown that their value as shrimp and fish nurseries far outweighed their short-term value for phosphate.

At the southern tip of the United States, the Florida Everglades, one of the largest wetlands in the world, once provided nesting and feeding ground for millions of egrets, herons, pelicans and other waterbirds. This sawgrass wilderness sheltered vast numbers of American alligators (*Alligator mississipiensis*). Cougars, known as Florida panthers (*Felis concolor coryi*), were common, and preyed on the small Everglades white-tailed deer. Water diversion projects for agriculture and the new human population of Miami and coastal cities resulted in a drying out of the Everglades. Exotic plants have proliferated in the marshes, overwhelming the native grasses and choking waterways. Ninety percent of the populations of waterbirds disappeared. The Florida panther recently became extinct in Everglades National Park, one of its last refuges. The alligator has recovered from nearly disastrous hide hunting in Florida, but remains rare in many parts of its original range. A project to restore some of the waterflow to the Everglades was enacted into law in the 1990s (see Aquatic Ecosystems chapter).

The American crocodile (*Crocodylus acutus*), a saltwater species inhabiting coastal areas, was once numerous in Florida Bay and in the mangroves of the Keys. Today, this is one of the most endangered species in the country, numbering fewer than 400 animals. Early hide hunting reduced them and, in this century, pollution and loss of mangroves in their habitat have pushed this species close to extinction.

Many Everglades bird species are also endangered, and one has recently become extinct Š the dusky seaside sparrow (*Melospiza maritima nigriscens*). This sparrow, with its unusually dark coloration, was a victim of the massive destruction of wetlands in Florida. By the time it received the protection of the US Endangered Species Act, this subspecies was nearly extinct. Its limited habitat of spartina grass on Florida's central Atlantic coast had been flooded for mosquito control and drained for the construction of nearby NASA facilities (Ehrlich *et al*. 1992). In an 11th-hour attempt to save these little sparrows, a captive breeding program was set up, mating them with a related subspecies to preserve some of their genes. The last purebred dusky seaside sparrow died at the age of 13 in 1987 (Ehrlich *et al*. 1992). The breeding program was not successful, and by 1997, the related subspecies had also become endangered.

Two spectacular waterbirds, the American flamingo (*Phoenicopterus ruber*), and the scarlet ibis (*Guara rubra*), were once residents of south Florida. Both species were eliminated in the 19th century when, as William T. Hornaday (1913) observed, they "attracted the evil eyes of the 'milliner's taxidermists.'" The feather trade of the late 19th century nearly exterminated the majority of North America's wading birds and many of its seabirds through unregulated slaughter for plumes to adorn ladies' hats. Egrets, roseate spoonbills, herons, terns and other birds with long or colorful feathers were killed indiscriminately. In 1900, the Lacey Act and state laws extended protection to these birds by banning sale and interstate commerce, and the Migratory Bird Treaty Act, signed with Canada in 1918, protected native North American non•game birds from capture, killing and sale.

The Eastern Forests

Ancient hardwood forests stretched for thousands of square miles in eastern North America. Massive oaks, chestnuts, hickories, walnuts and beech trees dominated, some reaching heights of more than 100 feet, with trunks 20 or more feet in circumference. Giant hemlocks and many kinds of pine dominated some areas. The passenger pigeon was the most abundant denizen of these forests, and its range extended from southern Canada, New England and the Great Lakes west to the Great Plains and south to Virginia. The slim bird was somewhat smaller than the familiar rock dove or common pigeon found in cities worldwide, with a long, pointed tail. The male's plumage was beautiful; his back, wings and head were bluish•gray with black streaks and spots, which contrasted with a rich, pinkish tinge on his lower throat. His breast feathers became paler on the belly, and a patch of pink or purple•pink iridescence shone at his neck. His eyes were bright red surrounded by purplish skin, and his legs and feet were red (Goodwin 1983). The female was a duller version of the male, browner gray above, light gray on the breast, with a smaller iridescent pink patch on the neck, more profuse black spots on the wings and gray skin surrounding her orange eyes (Goodwin 1983).

This is the only pigeon Š living or extinct Š that flocked and nested in vast numbers, darkening the sky during their migrations. When Europeans first encountered passenger pigeons, they were dumbfounded by their numbers. One immigrant, Pehr Kalm, described their passage in the spring of 1749: "on the 11th, 12th, 15th, 16th, 17th, 18th and 22nd of March . . . there came from the north an incredible multitude of these pigeons to Pennsylvania and New Jersey. Their number, while in flight, extended three or four English miles in length, and more than one such mile in breadth, and they flew so closely together that the sky and the sun were obscured by them, the daylight becoming sensibly diminished by their shadow" (Fuller 1987). When the pigeons landed on trees, their weight was sometimes

so great that not only would large limbs break off, but entire trees would topple. Prior to settlement of the continent by Europeans, as many as 5 *billion* birds inhabited Kentucky, Ohio and Indiana alone (Blaugrund and Stebbins 1993).

Passenger pigeons were migratory, as their scientific name, *Ectopistes migratorius*, suggested, but not in the manner of most birds, who migrate from an ancestral nesting area to an ancestral wintering area. Instead, immense columns of birds flew as a unit at speeds estimated as high as 60 miles per hour in wide areas in search of nut trees and seeds. John James Audubon, famed illustrator of American birds, described flights in the 1830s that covered the sky for days in some areas, while in other years, none would be seen in the same area (Blaugrund and Stebbins 1993). The forests that once stretched nearly unbroken across eastern North America were crucial to the survival of the passenger pigeon flocks. Nut trees (oaks, hickories and beeches) produced large crops only every few years. In order to locate adequate feeding supplies, the pigeons covered great distances.

John James Audubon visited a roost in Kentucky accompanied by some pigeon hunters in 1831:

Many trees two feet in diameter, I observed, were broken off at no great distance from the ground; and the branches of many of the largest and tallest had given way, as if the forest had been swept by a tornado. Every thing proved to me that the number of birds resorting to this part of the forest must be immense beyond conception . . . Suddenly there burst forth a general cry of 'Here they come!' The noise which they made, though yet distant, reminded me of a hard gale at sea passing through the rigging of a close•reefed vessel. I felt a current of air that surprised me. Thousands were soon knocked down by the pole men. The birds continued to pour in . . . The pigeons, arriving by thousands, alighted everywhere, one above another, until solid masses as large as hogsheads, were formed on the branches all round. Here and there the perches gave way under the weight with a crash, and falling to the ground, destroyed hundreds of the birds beneath, forcing down the dense groups with which every stick was loaded. It was a scene of uproar and confusion. I found it quite useless to speak, or even to shout to those persons who were nearest to me. Even the reports of the guns were seldom heard, and I was made aware of the firing only by seeing the shooters reloading (Schorger 1973).

Once they located a forest with abundant food, they nested in huge aggregations. One colony in Wisconsin was estimated to cover more than 750 square miles, with 136 million nesting birds (Wilcove 1991). Audubon wrote of their courtship, "the tenderness and affection displayed by these birds toward their mates are in the highest degree" and painted two birds "billing" for his *Birds of America* series (Blaugrund and Stebbins 1993). Some described their courtship songs as a series of bell•like notes (Fuller 1987).

Their nests, constructed of loose sticks, held their single white egg. A tree could hold many nests, which the birds placed on strong branches close to the trunk. The flocks rarely nested in the same area two years running, and dispersed as soon as nesting was over; this may have been to prevent natural predators from increasing enough to have a serious impact on their numbers (Wilcove 1991). Also, their food supply tended to be abundant only every few years in a given area. These great colonies made easy targets for legions of meat and market hunters, beginning in the 1600s. By the 18th century, naturalists began to observe that nesting colonies were disappearing; the last great nesting in New England took place near Lunenburg, Massachusetts, in 1851 (Wilcove 1991). By the 1860s, the large flocks had been hunted out of coastal New York State and Pennsylvania. The few laws that were enacted to protect them in the Northeast were not enforced (Wilcove 1991). Season after season, pigeon hunters killed millions of these birds, destroying one colony after another.

Neltje Blanchan, in the 1904 book *Birds That Hunt and Are Hunted*, documented that unlimited netting, even during the nesting season, had resulted in sending more than 1 million pigeons to market from a single roost at the height of the hunting; an equal number of birds were wounded or left starving, helpless, naked chicks behind. Hunters shipped 100 thousand pounds of pigeons to market from a nesting colony near Grand Rapids, Michigan (Wilcove 1991). Audubon and other observers of the time described the brutal hunting methods: young birds were knocked out of their nests with poles, and captive pigeons, whose eyelids had been sewn shut, were tethered to lure wild pigeons to

the ground where they were netted (Wilcove 1991). Nesting trees were cut down or set afire, and sulphur was burned under nesting trees to kill the birds (Wilcove 1991). Blanchan (1904) described the glut of pigeons at markets as so great that the price per barrel scarcely paid for their transportation. The pigeon meat was often fed to hogs.

By the late 1800s, it had become evident to some that the killing was having a disastrous effect on the passenger pigeons. The warnings went unheeded, however. In Ohio, a bill submitted in 1857 to protect the passenger pigeon received the following report from a Select Committee of the Senate: "The passenger pigeon needs no protection. Wonderfully prolific, having the vast forests of the North as its breeding grounds, traveling hundreds of miles in search of food, it is here to•day and elsewhere to•morrow, and no ordinary destruction can lessen them, or be missed from the myriads that are yearly produced" (Hornaday 1913).

The final and precipitous decline of passenger pigeons began in the 1870s, a decade which began with some large flocks still attempting to nest in the Great Lakes area. In 1878, naturalists estimated that some 50 million pigeons survived, but with continued heavy hunting, only one large nesting colony in Wisconsin remained in 1887 (Wilcove 1991). This colony dispersed within two weeks after beginning to nest when hunters began shooting at them (Wilcove 1991). By the 1890s, only scattered individual pigeons Œ who were apparently unable to breed or forage successfully Œ remained. In 1892, one observer noted, "The extermination of the passenger pigeon has progressed so rapidly during the past twenty years that it looks now as if their total extermination might be accomplished within the present century" (Blanchan 1904). This statement proved correct. The incredible wildlife spectacle that flights of billions of passenger pigeons presented, ended completely on March 24, 1900, when the last wild bird was killed in Pike County, Ohio (Wilcove 1991).

The reason for the sudden crash in passenger pigeon numbers has been the subject of controversy in the years since. Two ornithologists from the University of Minnesota, David E. Blockstein and Harrison B. Tordoff, believe during the last 20 years prior to its wild extinction, hunters were able to disturb or destroy virtually every nesting colony. Each year, the adult birds that were able to escape previous hunting and attempt breeding were harassed or chased off the nest, or their fledglings were killed (Wilcove 1991). The adults not killed were relatively long-lived, averaging a lifespan of about 20 years, but because their numbers were not replaced by succeeding generations, when they died off, the species became extinct (Wilcove 1991). Blockstein and Tordoff noted some Passenger Pigeons nested in small groups, escaping the attention of hunters, but they conjectured that without the protection provided by large colonies, these birds rarely succeeded in producing fledgling chicks, and were easy targets for predators (Wilcove 1991). This explanation seems logical, and clearly, the birds were unable to survive in small, scattered groups, dependent on a large colony for successful reproduction. Other factors may also have entered in. It may be that only in the presence of large numbers of their own kind was instinctive breeding behavior stimulated.

A captive passenger pigeon named Martha, about 29-years-old and the last of her species, died at 1 p.m. on September 1, 1914 at the Cincinnati Zoological Gardens. This is perhaps the only species for which the exact minute of its extinction is known (Fuller 1987).

Logging and settlement of the eastern hardwood forests destroyed forever the ancient habitat of these lovely pigeons. Even if the passenger pigeon was somehow recreated, the huge expanses of nut and seed-bearing trees it required have since been cut. More than 99 percent of virgin woodland in the East has been logged, first by settlers, and later by commercial loggers. The colonists of New England, after destroying the forests, found farming the rocky soil difficult and unproductive. The short growing season, often interrupted by frosts, further limited agriculture there. Most of these farms were abandoned, and today, second-growth forest covers the region. However, it is composed of different species of trees than the original old-growth forest and is far poorer in wildlife.

The American chestnut (*Castanea dentata*) once comprised a third of eastern hardwood forests; a huge tree 100 feet tall with a spreading canopy, it had girths up to 12 feet (Jonas 1993) and produced bountiful crops of chestnuts. American chestnuts grew east of the Mississippi River from Maine south to Georgia. Of the 12 species of chestnut trees worldwide, the American was known for yielding the tastiest nuts (Jonas 1993). After heavy logging, older trees

became confined to wilderness areas and towns, where they were greatly admired as shade trees. In 1904, the spores of a fungus known as chestnut blight were accidentally introduced to the country, probably on seedlings of imported Chinese chestnut trees (Jonas 1993). The blight destroyed the remaining chestnuts in the eastern forests, leaving only stumps. These stumps still sprout shoots that grow up to 20 feet until they, too, succumb to the blight (Jonas 1993). Only a few unblighted American chestnut trees remain in the country. On the West Coast, a small number of the trees were planted out of their natural range, and the blight did not reach them (Jonas 1993). Progress is being made in breeding disease-resistant strains of this tree (see Forests chapter and Projects section).

Another eastern hardwood, the stately American elm (*Ulmus americana*), which reaches heights of 60 to 120 feet, has a slim, straight trunk and a broad, graceful crown. It is also nearly extinct; it was attacked by a fungal infection known as Dutch elm disease, which is gradually killing off these trees. First seen in 1930, the disease spread west. It is still in the process of eliminating trees throughout their range in North America from Nova Scotia to Saskatchewan, south to Florida and west to Texas (Jonas 1993). A disease-resistant strain of this tree has also been bred, and the trees are being distributed for free by a nonprofit organization (see Forests chapter and Projects section).

American beeches (*Fagus grandifolia*) were perhaps the most important food tree for wildlife, producing massive amounts of beech nuts on which passenger pigeons, wild turkeys, black bears and other wildlife fed. At 50 to 70 feet tall, beeches have short, wide trunks that begin branching 10 feet from the ground and form enormous, wide crowns (Jonas 1993). The species is still fairly widespread, but old American beeches, which can live 400 years and grow to enormous girths, are extremely rare in woodland settings where they have been logged out.

Ironically, the colonists could have lived well off the land they found if they had not destroyed both the forests and much of the wildlife within a few centuries. The abundant nuts produced by hardwoods, which had nourished the passenger pigeons, also provided food to Native Americans. Many tribes had learned to remove the tannin from acorns so it could be ground into nutritious high-protein flour. Beechnuts, chestnuts, walnuts, hickory nuts, wild fruits and seeds provided excellent food for people as well as wildlife.

European settlers destroyed this rich ecosystem by commercializing the resources, turning ancient forests into short-term logging profits and wild birds, deer and furbearers into commodities. Had another road been taken, the natural environment would have endured with ample resources for all to live on. Many native tribes had cleared some forests for agriculture, but the vast majority remained in their natural state. Settlers, later supported by government policy, claimed ownership of the East and then proceeded to oust native peoples or relegate them to tiny reservations. This resulted in the killing of hundreds of thousands of natives and the extinction of many tribes.

The new Americans, in adopting the European approach to nature, tamed the wilderness and began a program of eliminating natural predators. They considered the reverence with which Native Americans had treated all living things to be a weakness. At the time of European colonization in the 17th century, almost no natural forests remained in Western Europe. Large predators had been eliminated from most of Western Europe, and most wildlife had been crowded out, killed off or confined to private estates where the animals were considered the property of landowners, providing food and sport to the upper classes. Moreover, this wildlife was hardly wild, but semi-tame. Deer lacked predators, the woods on estates were stocked with game birds and the streams with salmon and trout by gamekeepers. The vast majority of European settlers came from the lower and middle classes; they had previously been denied the right to hunt and were eager to do so with abandon. This was another motivation for the relentless slaughter that decimated wildlife during this period.

Benjamin Franklin hoped to make the wild turkey the official symbol of the United States. When colonists arrived, the species was abundant in eastern forests. Uncontrolled hunting and the cutting of forests eliminated these birds from state after state: Connecticut by 1813, Massachusetts by 1851, New York in the mid•1800s, South Dakota by 1875, Ohio by 1880, Wisconsin by 1881, Michigan by 1897, Illinois by 1903, and Iowa by 1907 (Burger 1978, Peters and Lovejoy 1990). Fortunately, the species was not destroyed altogether, and it has been reintroduced into many parts of its original range through transplants from remnant populations.

Once the eastern forests echoed with the howls of gray wolves (*Canis lupus*), common throughout the continent except the Southeast, where the smaller red wolf (*Canis rufus*) roamed. Both these wolves were deliberately persecuted into extinction by colonists who placed bounties on their heads, effectively eliminating them from the wild in the eastern United States prior to the 20th century (see Persecution and Hunting chapter). Seven races of the gray wolf are now extinct, bountied and poisoned by settlers. Around 1911, the Newfoundland race, *Canis lupus beothucus*, was the first to become extinct. This pure white, large wolf had a scientific name inspired by the Beothuk Indian tribe of Newfoundland; both the wolf and the tribe were exterminated by Europeans (Day 1981).

The red wolf became extinct in the wild in the 1970s, after centuries of persecution and habitat loss. Two subspecies, the Florida black wolf (*Canis rufus floridanus*) and the Texas red wolf (*Canis rufus rufus*), are extinct, and only one race survives. The last members of the species were taken into captivity and bred successfully. A reintroduction program in portions of its original range has brought the species back, and about 100 red wolves now live in the wild. The cruelty with which the gray wolf was eliminated is described in detail in the Persecution and Hunting chapter. Another predator once common in these forests north of Florida was the Eastern cougar (*Felis concolor couguar*). It was also bountied and hunted until it became extinct throughout the eastern United States.

In the northern woods, eastern subspecies of the American bison, elk, caribou, moose and white•tailed deer were extremely common. The hunting by Native Americans armed with bows and arrows did not, apparently, cause declines. The guns brought by Europeans, however, decimated their numbers. An unrestricted slaughter of these ungulates went on for centuries. The white-tailed deer became endangered, disappearing from the eastern forests, first from the vicinity of towns and habitations, then from wilderness areas. The other ungulates died out altogether in New England and the middle Atlantic area. The Eastern elk (*Cervus elaphus canadensis*) became extinct. One cause for the disappearance of this huge member of the deer family was hunting to obtain its teeth, which a private organization, the Fraternal Order of the Elks, used as watch•chain insignia (Day 1981). Not only were these animals hunted for food and sale in meat markets by the colonists, but an active export trade in deer and elk skins sprang up. Records show an average of 100,000 of these skins exported to England each year between 1778 and 1808 (Poland 1892). Several small populations of reintroduced elk inhabit Pennsylvania, North Carolina, Tennessee and Virginia.

Hunting caused the extinction of the Eastern bison (*Bison bison pennsylvanicus*) by 1800. This race of bison was larger than the plains bison and very dark; some of the bulls were coal black with grizzly white hair around the nose and eyes (Allen 1942). The last herd of Eastern bison was slaughtered in Union County, Pennsylvania in the winter of 1799 to 1800, as the animals huddled helplessly in the deep snow; the last individuals of this race were killed near Charleston, West Virginia in 1825 (Allen 1942).

Caribou (*Rangifer tarandus*) and moose (*Alces alces*), native to northern New England and southern Canada, were hunted to extinction in the United States in colonial times, surviving only in Canada (Allen 1942). The white•tailed deer has reoccupied its former range in the northeastern United States and, in fact, these deer have become overpopulated as a result of a lack of natural predators (see Persecution and Hunting chapter). The moose has been reintroduced in recent years to New England and is gradually dispersing southward. Attempts to reintroduce caribou in Maine have failed.

The heath hen (*Tympanuchus cupido cupido*) was another casualty of colonial settlement. This eastern subspecies of the greater prairie chicken, a grouse•like bird, was native to forest edges, grassland and heath in portions of the Northeast, from Massachusetts to Pennsylvania and New Jersey (Greenway 1967). Pursued by market hunters, these birds became a staple food for colonists. Heath hens were so common in Massachusetts in colonial times that Governor Winthrop ordered his servants not to have them served more often than a few times a week (Greenway 1967). By 1830, the last mainland Massachusetts heath hen was shot in the western part of the state. In New York State, a 1791 law banned hunting of these birds during spring and summer, but the law was flouted, and market hunting on Long Island resulted in its extinction there by 1844 (Greenway 1967). Overhunting in New Jersey and Pennsylvania killed off the last birds in these states by the 1860s. The last population of these birds survived on

Martha's Vineyard island off the Massachusetts coast and, although protected from hunting, fire and predation gradually eliminated them by 1932 (Greenway 1967).

The existence of brilliantly colored parakeets flying in large flocks in eastern North America was an unexpected surprise for European colonists settling the country. They had thought such birds lived only in tropical regions. Yet these parakeets obviously had adapted to winter snows and frigid nights. The species was named the Carolina parakeet (*Conuropsis carolinensis*) and had a long, graceful tail and a bright yellow and orange head. Its green wings were tinged with yellow, set off by its overall forest green plumage. Eastern parakeets belonged to the subspecies *Conuropsis carolinensis carolinensis* and ranged from Florida to southern Virginia, while western parakeets, *Conuropsis carolinensis ludovicianus*, had a wide distribution from the Mississippi-Missouri River drainage south to Texas, east to Mississippi and north to western New York State and the Great Lakes region (Forshaw 1989). These birds flew in enormous flocks and may have numbered in the millions prior to European settlement.

Like conures (*Aratinga* genus), native to the Caribbean and Latin America, Carolina parakeets could give away their presence by loud and raucous calling. Because they fed on many types of wild seeds and fruits and were able to endure freezing temperatures, they were among the few species in the parrot family able to survive in harsh climates, with the ability to tolerate temperatures as low as -25 F. (Cokinos 2000). Early travelers in Kansas described the appearance of screaming bands of these parakeets during swirling winter snowstorms; flocks settled in groves of cottonwood and walnut trees, delighting travelers with their vocalizing and dazzling colors (McKinley 1985). Large, hollow trees were among their favorite roosting spots, and flocks of birds would cling to the inside of the trees with their beaks and feet (Forshaw 1989). In early morning, the birds would climb to the top branches of their roosting trees, to the accompaniment of much chattering, and then fly off to feed for several hours. When they saw a fruit or seeding tree, the flock would spiral down until they almost reached the ground, and then rise up to alight on the branches. In the afternoons, they sheltered in groves of trees, often near streams where they drank and bathed (Forshaw 1989).

These parakeets may have been most abundant in the South and the major river valleys of the Midwest. Early naturalists described them perched in huge Bald Cypress trees, their bright plumage contrasting with the pale green, feathery foliage. They would hover and flutter on the tops of these cypresses, extracting the seeds (McKinley 1985). Travelers in the southern hardwood forests and swamps, as well as in pine woods, found them very numerous. In Florida's St. John's River area, where mid-19th century observers saw large flocks, many were killed by plantation owners for food (McKinley 1985).

In Audubon's painting of Carolina Parakeets, these extremely sociable birds are clustered in a tree, feeding on Cockleburs (*Cenchrus tribuloides*), their favorite food (Blaugrund and Stebbins 1993). Only recently have the true colors of this bird, as depicted by Audubon, been revealed by a publication of his original watercolors, which shows their plumage in shades of vivid green, yellow and reddish orange. In the lithographs of previous editions, these colors were drab and dull (Blaugrund and Stebbins 1993).

As their forests were cut and prairies plowed for farms, the parakeets turned to raiding crops and orchards. Flocks would converge on farms at times of harvest, alighting on stacks of grain sheaves. So dense were the perching and feeding birds that they made the stacks look as if "brilliantly colored carpets had been thrown on them," according to Audubon (Forshaw 1989). For these raids on farms, they received "severe retaliations" from farmers; Carolina parakeets were easily approached and never learned to fly away from humans. Farmers would shoot entire flocks, killing 10 or 20 at each discharge (Forshaw 1989). When one was shot, the others refused to leave their wounded or dead flock mate. Audubon described these massacres: "The living birds, as if conscious of the death of their companions, sweep over their bodies, screaming as loud as ever, but still return to the stack to be shot at, until so few remain alive, that the farmer does not consider it worth his while to spend more on ammunition" (Poattie 1940).

Like many members of the parrot family, Carolina parakeets attempted to aid others of their kind who were stricken or threatened by predators. This behavior contributed to their survival in natural conditions, and only the

devastating killing power of guns hastened their extinction. Audubon described procuring a basketful of the parakeets with a few shots in 1831 in order to choose good specimens for drawing the figures for his watercolors of North American birds (Fuller 1987). Thousands more of these parakeets were captured for the pet trade and killed for museum collections. At least 675 of the eastern race alone are found in museums. In the last decades of the 19th century, amateur collectors of specimen birds and their eggs proliferated around the country, and dealers in specimens earned large sums from the sale of rare birds. The rarer the bird, the higher the price paid, further endangering the species. Many birds were killed for specimens by collectors who failed to note the location and date of the killing (McKinley 1985). Molting adults and juvenile birds were thrown out, and the physical appearance of the latter birds remains unrecorded (McKinley 1985). One German taxidermist, August Koch, visited the home of a friend in Florida in 1887 and shot some of these parakeets in the back yard of his host as they fed on mulberries (McKinley 1985). A tree that appeared to be sporting "yellow flowers with red centers," turned out to be a flock of parakeets roosting in the early evening, and he shot two birds for his collection (McKinley 1985). Another hunter was led by a Seminole Indian to a "parakeet tree," a large, hollow cypress tree near Lake Okeechobee in Florida, where he shot "as many specimens as my ammunition would allow" (McKinley 1985).

In spite of the keen interest in the species by scientists, naturalists and members of the public, few observations were made of the behavior of these parakeets while they were still common. Almost nothing is known of their life history, flock movements, breeding seasons, nesting, feeding or ecology (McKinley 1985). It is known, however, that they were long-lived, based on the survival of the last captive specimens, which were at least 32 years old. Although a few bred in captivity, they often abandoned their eggs, and no captive-bred birds survived (Forshaw 1989). In spite of large numbers captured for sale as cage birds, no serious effort was made to perpetuate the species through captive breeding, which might have prevented their extinction.

As early as 1831, Audubon noticed a decline: "Our parakeets are very rapidly diminishing in number; and in some districts, where twenty-five years ago they were plentiful, scarcely any are now to be seen" (Forshaw 1989). Flocks of several hundred had commonly been seen when the country was first settled. Within about 90 years, by the 1880s, they had declined both in range and number, with only small flocks or pairs remaining (Forshaw 1989). Persecution by farmers was a major cause Š and perhaps the most important factor Š in the decline of the Carolina parakeet in the view of parrot ornithologist, Joseph Forshaw (1989). The last flocks sought refuge in the forests and remote swamps of Florida, where collectors and trappers pursued them (Forshaw 1989). Other factors played important roles as well. Thousands were killed for sport or for their feathers to decorate ladies™ hats. Their nesting and roosting trees were cut by settlers and loggers, and their food plants were plowed under by farmers (Cokinos 2000). European honeybees, armed with stingers and introduced by colonists, also may have driven them from their hollow trees as they rapidly spread throughout the country, seeking hive sites (Cokinos 2000). These hollow tree-roosting sites may have been crucial to their survival in cold weather; the birds crowded together side-by-side for warmth. The giant hollow cypresses and sycamores, oaks and other hardwoods in the old-growth forests of the eastern United States, crucial habitat to so many species of wildlife, were among the first trees cut in bottomland swamps and forests.

A few Carolina parakeets survived into the first years of the 20th century, with sightings reported in the Panhandle and the Kissimmee Prairie of north-central Florida (McKinley 1985). The last wild specimen was taken in either 1901 or 1904; the date is still in dispute (Cokinos 2000). A flock of 13 of these birds was seen near Lake Okeechobee, Florida in 1920, and two eminent ornithologists, Alexander Sprunt and Robert Porter Allen, went in search of the last members of the species in 1936. They reported seeing a flock along the Santee River in South Carolina, but the National Audubon Society later dismissed the account (Forshaw 1989). In any case, the area was later destroyed for construction of a power project (Forshaw 1989). No confirmed sightings were made after about 1920, although a black-and-white home movie made in 1937 showed some parakeets in the Okefenokee Swamp of southeastern Georgia that *may* have been of this species (McKinley 1985). Had the Carolina parakeet been accorded legal protection and reserves set aside during the 19th century, this spectacular species would almost certainly still be alive.

A pair of Carolina parakeets kept at the Cincinnati Zoological Gardens Œthe same zoo that housed Martha, the last

passenger pigeon Œ was the last known members of their species. Sixteen of these parakeets were purchased by this zoo in the 1880s for $2.50 per bird (Fuller 1987). Over the years, the birds laid eggs, but none hatched or were even incubated, and gradually they died off until only a pair was left Š cage-mates for 32 years (Fuller 1987). In the late summer of 1917, the female, Lady Jane, died. Incas, the male, became listless after her death, and in February 1918, he died of grief, the keepers claimed (Fuller 1987).

The old-growth pine and mixed hardwood forests of the Southeast, as well as Cuba, were home to a large and noisy bird that may have disappeared. The ivory•billed woodpecker (*Campephilus principalis*), at 18 to 21 inches long, is the largest woodpecker in the United States or Canada and the second largest in the world. Elegant in appearance, both male and female are predominantly black, with stripes of white feathers on both sides of the neck; the lower half of their wings is white, as is the enormous bill for which the species was named (Short 1982). Their drumming on dead tree trunks once reverberated in the forests as they removed strips of bark a foot or more long to uncover beetle larvae. They also drummed as a territorial signal, trumpeted and made a call that sounded like a child™s tin horn. Their vocal repertoire also included a soft call between male and female perched side-by-side while changing places incubating eggs in their high nest holes (Cokinos 2000). Never heard by scientists observing them in the wild, the ivory-billed woodpeckers uttered an extraordinary screech when captured and transported away from their forest, as described by ornithologist and artist Alexander Wilson early in the 19th century (Cokinos 2000). Wounding an adult male to use as a subject for a painting, he was astonished to hear him utter fia loudly reiterated and most piteous note, exactly resembling the violent crying of a young childfl (Cokinos 2000). The bird continued to scream loudly as he was carried in a container to a town nearby, alarming people who took the noise for that of a child. Wilson rented a room where he planned to paint him, and the frantic bird began drumming on the wall, breaking off huge chunks of plaster, and damaged a mahogany table. Although offered food, the distraught bird refused to eat and died within three days (Cokinos 2000).

The ivory-bill's decline came as a result of heavy logging begun in the 18th century, which destroyed millions of acres of old-growth pine and hardwood bottomland forest in the Southeast. Each pair required a territory of at least 6 square miles of mature forest, and as their forest disappeared, ivory-billed woodpeckers became so rare that few were seen after 1900 (Cokinos 2000). Hunting also made inroads into their populations. These birds made large targets and were so conspicuous and noisy that they attracted the attention of meat and sport hunters in the 19th century. At that time, few people walked in the woods without a gun; most people took shots at any large bird or mammal.

Over-collecting of specimens by museums was another factor in the extinction of the ivory-billed woodpecker. Its size, beauty and natural rarity brought museum collectors from around the world to scour forests in the South for the last specimens of this bird. There are 400 known museum specimens worldwide (Day 1981), and most of these were taken in the last years of the 19th century, when the species had become extremely rare. Nineteenth century museum curators often sent collectors out to obtain specimens of very rare animals after they received word that the species was headed toward extinction. Responsible modern natural history museum curators do not routinely collect rare animals, but reach agreements to allow very limited collection of newly discovered species, usually only by the scientist who made the discovery. Most museums now loan specimens to scientists who wish to examine them.

Dr. Lester Short (1982), an authority on woodpeckers, believes the ivory-billed woodpecker's original habitat was probably the virgin pine forests that once covered much of the Southeast. They had become confined to hardwood swamp forests in Louisiana, which was probably not ideal habitat for them (Short 1982). Upon the discovery of a small number of Ivory-bills in a forest along the Tensas River in Louisiana, Cornell University scientists organized an expedition to film and record these birds. They later designated a young Ph.D. ornithologist, James T. Tanner, to study these last birds in the wild. In his study, *The Ivory-billed Woodpecker*, published in 1942, he estimated that at that time, no more than 22 of these woodpeckers remained in the United States. His investigation centered on the only known population of ivory-billed woodpeckers in the 120 square mile old growth forest. The Cornell team filmed the birds drumming on trees and recorded their various calls. This film is part of Stouffer Productions' fiAt the Crossroadsfl film. (See Video section, Endangered Species, General.) These recordings are retained in the Cornell Ornithological Library of bird songs, along with motion pictures of a pair of woodpeckers.

Tanner documented the presence of seven pairs and four young in 1934. He also traveled extensively in the Southeast, where ivory-billed woodpeckers were seen in the past, asking local people for sightings and listening for their unique calls; he was unsuccessful. From 1931 to 1939, the last remaining birds raised 19 young. They declined as he was observing them, however, and by 1939, only six ivory-billed woodpeckers Š one pair, one young bird and three males Š remained in these woodlands (Cokinos 2000). They had lost the majority of their habitat after the Singer Company sold the logging rights for these 80 thousand acres to Chicago Mills in 1937, and the old growth forest was rapidly leveled. Some of the birds may have been shot for the $1,000 collectors were willing to pay (Cokinos 2000). In the early 1940s, the National Audubon Society™s president appealed directly to President Franklin Roosevelt to spare the ivory-bills™ last habitat, and the Secretary of the Interior was ordered to consider the matter (Cokinos 2000). Various federal agencies and the War Production Board agreed these trees could be spared for the war effort. These agencies and four state governors urged Chicago Mills to protect this forest (Cokinos 2000). The State of Louisiana offered the company $200 thousand as compensation in December 1943, but it refused, and attempts in the US Congress to pass legislation to mandate protection of the Singer woodlands failed as well (Cokinos 2000). This company remained indifferent to the fate of the woodpeckers, red wolves, mountain lions, black bears and abundant birdlife being destroyed to produce chests to ship tea to the English Army (Cokinos 2000).

Unknown to conservationists and government agencies was the fact that it was already too late. Richard Pough, a National Audubon Society employee, was sent to search for any remaining ivory-billed woodpeckers in the Singer woodlands in December 1943. He saw the last ivory-billed woodpecker, a lone female, and noted in January 1944: fiIt is sickening to see what a waste a lumber company can make of what was a beautiful forest. Watched them cutting the last stand of the finest sweet gum on Monday. One log was 6 feet in diameter at the buttfl (Cokinos 2000). This may have been the same female and her fledgling chick seen by Tanner in 1941, the only birds remaining at that time (Cokinos 2000). A wildlife artist, Don Eckelberry, heard of the disastrous situation for this species and traveled to the Singer woodlands to paint this female ivory-billed woodpecker. His observations constitute the last authenticated sightings of the species in the United States (Cokinos 2000).

Many searches have been made throughout its once wide range, which extended from southeastern Oklahoma and Missouri north to Indiana and east through northern Florida. Sightings have been made of these birds over the years in Florida and Mississippi, but none was authenticated by photographs or recordings (Cokinos 2000). The last 20th century observation was made on April Fool™s Day, April 1, 1999, by a forestry student along the Louisiana-Mississippi state line, in the Pearl River basin (Cokinos 2000). He claimed to have seen a male and female at close range in a swamp forest (Cokinos 2000). Subsequent searches of this forest by ornithologists and others failed to find any trace of ivory-billed woodpeckers (Cokinos 2000).

There is slim hope that the species might survive either in the United States or in Cuba. These birds were seen in Cuba™s southeastern pine forests during the early 1980s, but this population dwindled and disappeared by 1991 in spite of a reserve that had been set aside for it (Collar *et al.* 1994). In 1998, evidence of its possible survival in Cuba consisted of some likely sightings in the Sierra Maestra highlands, where it had never been seen before (BI 2000; Garrido and Kirkconnell 2000). Although unlikely, it would be a truly exciting event if the magnificent ivory-billed woodpecker survived in spite of the almost total loss of its habitat.

Bachman's warbler (*Vermivora bachmanii*), a small yellow songbird of the southeastern United States, has not been seen for decades. John James Audubon painted a pair of these birds without ever having seen them alive. The species was discovered in 1833 by his close friend, John Bachman (Blaugrund and Stebbins 1993). Audubon's painting was based on specimens sent to him by Bachman. He depicted the Bachman's warbler posed stiffly on a Franklinia tree (*Franklinia altamaha*), an equally mysterious species with large white flowers. Discovered in the South in 1765 by the noted botanists William and John Bartram, this beautiful tree was named in honor of Benjamin Franklin (Blaugrund and Stebbins 1993). In spite of thorough searches in the area in Georgia where the tree was found, the Franklinia was never seen in the wild again (Blaugrund and Stebbins 1993). Fortunately, the Bartrams had taken cuttings of the tree for cultivation, and this tree is now grown in botanical gardens and nurseries throughout the world. Bachman™s warbler became very rare after 1920.

Originally, these warblers ranged from the lower Mississippi River and east Texas, north to southern Indiana, and along the east coast from Georgia north to southern Maryland (Hamel 1995). The species' original habitat was southern bottomland, hardwood forest with extensive cane (*Arundinaria gigantea*) thickets (Hamel 1995). Clearance of these forests in the 19th century and first decades of the 20th century, both in the United States and in Cuba, where it wintered, eliminated the majority of its habitat. It is not known to what extent it used canebrakes and bamboo thickets growing on bottomlands, but these were the last habitats in which it was seen.

A 19th century observer of Bachman's Warblers, O. Widmann, entered bottomland forests in the Mississippi Alluvial Valley, and wrote in 1897, "I had no trouble in finding several singing males on the day of my arrival– In the wildness of his home it takes several minutes to follow him over fallen trees and around impenetrable thickets or pools of water" (Hamel 1995). Widmann saw its nest "tied very slightly to a vertical blackberry vine of fresh growth– From above, it was entirely hidden by branchlets of latest growth– to reach the place it was necessary to go through pools of water and heaps of fallen trees and brush. Such sheltered places are probably chosen to avoid the danger of being trampled down by hogs and cattle roving in these woods" (Hamel 1995). This wild region was a mixed habitat of sweetgum, blackgum, tulip trees, mulberry, ashes, cottonwood, hackberry and hardwoods; Bachman's warblers were seen mainly in the higher portions, which were also those first cleared (Hamel 1995).

Approximately 400 scientific specimens were collected for museums, and this may have reduced its population at a time when it was already rare (Hamel 1995). The last nest was found in 1937, and much of this species' life history remains a mystery. Intensive searches have been carried out by biologists for this bird; a total of 7,000 hours were spent between 1975 and 1979 combing likely habitat areas in South Carolina, Missouri and Arkansas. In 8,000 hectares (19,768 acres) of apparently suitable habitat, no Bachman's warblers were seen or heard (Hamel 1995). As recently as 1980, an unconfirmed sighting was reported in Cuba, but the last confirmed sighting of a Bachman's warbler was in 1961 near Charleston, South Carolina (Hamel 1995). An unconfirmed sighting was made in 1988, but none have been seen since (BI 2000).

Endless Grassland

Stretching more than 1,000 miles from Illinois west to the Rocky Mountains, and from southern Canada south to Texas, the North American Prairie seemed endless. In the Midwest, tallgrass prairie interspersed with oak trees dominated, and farther west, in a north-to-south band, was an immense shortgrass prairie. Through its center flowed the Mississippi and Missouri Rivers, their confluence creating one of the world's greatest rivers. Lining the rivers were hardwood forest swamps from the Mississippi Delta at the Gulf of Mexico north to the Missouri River, where river otters, muskrats, beaver, mink and raccoon abounded. A vast mosaic of wetlands, known as "prairie potholes," dotted the northern Plains states and, during the spring, turned into ponds and marshes, making them perfect breeding areas for millions of waterfowl and shorebirds.

An estimated 50 million American bison (*Bison bison*) thundered across the prairie in a spectacle rivaling the migration of today's East African wildebeests, and far exceeding them in number. While the passenger pigeon may have been the most numerous bird in Earth's history, the bison is considered the most numerous large mammal to ever have lived on the planet. Coexisting with these bison were Plains tribes of Native Americans Š Pawnee, Blackfoot, Crow, Ojibwa, Sioux, Mandan, Comanche and others.

In 1804, President Thomas Jefferson commissioned Meriwether Lewis and William Clark to travel across the newly acquired Louisiana Territory west to the Pacific to conduct the first natural history survey of the American

West. Clark described the prairie near the Missouri River as "rich, covered with grass from 5 to 8 feet high, interspersed with copses of hazel, plums, currents, –raspberries and grapes of different kinds" (Peck 1990). Lewis's journal entry records his awe of the landscape: "Nor do I believe that there is in the universe a similar extent of country. As we passed on, it seemed as if those scenes of visionary enchantment would never end."

Throughout their travels they saw "immense herds of buffalo, deer, elk and antelopes," some "so gentle that we pass near them without appearing to excite any alarm among them" (Peck 1990). Wolves and foxes were common, along with animals they had never seen before Š pronghorn antelope, jackrabbits, prairie dogs, coyotes, grizzly bears and many beautiful prairie birds (Peck 1990). One of the purposes of their journey was to assess the marketable potential of the wildlife, especially furbearers. Their observations paved the way for the fur trade and slaughter of wildlife that effectively eliminated large mammals from the Great Plains by the end of the century.

A visual record of the original prairie was made by various artists, the most famous of which was George Catlin, whose magnificent portraits of the Native Americans, American bison and landscapes preserve them for posterity. It was Catlin who proposed this wild land be protected:

Nature has nowhere presented more beautiful and lovely scenes, than those of the vast prairies of the West; and of man and beast, no nobler specimens than those who inhabit themŠthe Indian and the buffaloŠjoint and original tenants of the soil . . . And what a splendid contemplation too, when one imagines them as they might in future be seen (by some great protecting policy of government) preserved in their pristine beauty and wildlife, in a magnificent park . . . A nation's Park, containing man and beast, in all the wild freshness of their nature's beauty (Peck 1990).

The world's first national park, Yellowstone National Park, was set aside in 1872, protecting some 2 million acres of mixed grassland and forest and the last wild bison in Montana and Wyoming, but Native Americans were excluded. The huge prairie park, as envisioned by Catlin in the central part of the continent, has not been established. It would have been a biological treasure for future generations. A tallgrass prairie national park was established in the 1990s, and perhaps in the future, a large national park will preserve portions of the once vast shortgrass prairie.

The US government encouraged the slaughter of bison as part of a deliberate campaign to vanquish the Plains tribes by removing their means of subsistence; the slaughter was also a free•for•all hunting spree by crews working on the transcontinental railroad after 1830 (Allen 1942). Thousands of bison were killed just for their tongues, which were considered a delicacy. The commercialization of the bison sealed its fate. In 1840, the American Fur Company sent 67,000 robes of bison hides to St. Louis, a fur trading center (Allen 1942). In the upper Missouri country, 250 thousand bison were killed annually until the 1870s; during this decade, just as in the case of the passenger pigeon, the slaughters turned the tide for the species (Allen 1942).

With the completion of the railroad, the great herd became split in half, and migrations that once took them from Montana to Texas were ended by a shooting spree lasting until the late 1880s (Allen 1942). In Dec. 1877 and Jan. 1878, the "last great slaughter" took place on the isolated southern herd of Kansas, Oklahoma and Texas; 100 thousand hides were taken by an army of hunters, wiping out this herd (Allen 1942).

Only the protection of two small herds in Yellowstone National Park and Wood Buffalo National Park in Alberta, Canada, totaling about 541 individual bison, prevented the extinction of the species (Allen 1942). Even the 300 bison in Yellowstone were nearly killed off by poachers between 1890 and 1893; 270 animals were shot illegally, leaving only 30 in the park (Hornaday 1913). These few wild bison stayed as far as possible from tourist routes, and by 1912 the herd had grown to 49 (Hornaday 1913). Since then, herds have been re•established in several parks in the West. There are now more than 150 thousand bison, but the majority is ranched animals, bred for docility. Even these represent a tiny fraction of their former numbers. Pure strains of American bison can be found only in the herds of Yellowstone and Wood Buffalo National Parks.

Other grassland wildlife was slaughtered for the meat trade. Among the millions of shorebirds that migrated through the Great Plains and bred there was a mousy brown, medium•sized bird known as the Eskimo curlew (*Numenius borealis*). These birds were known to many market hunters as "prairie pigeons" or "doughbirds" because of the thick layer of fat the bird added before migration (Ehrlich *et al*. 1992). This bird became the prairie equivalent of the passenger pigeon Œ an ominous comparison that signaled its ultimate fate. Eskimo curlews were once the second most numerous species of wading bird in North America Š numbering in the hundreds of thousands, possibly in the millions. Their destruction was so rapid that nesting and breeding areas were never fully documented. Only a few nests were found in arctic prairies of northwestern Canada between the Mackenzie and the Coppermine Rivers (Greenway 1967), but no one knew whether this was their prime nesting area. Their breeding behavior, number of eggs and chicks and related information remain undocumented.

Eskimo curlews flew in compact flocks and, when landing to rest and feed, were extremely tame and approachable. They were known to eat berries and Rocky Mountain grasshoppers (*Melanoplus spretus*) in burnt areas of prairie grass (BI 2000). This insect later became extinct, and prairies were plowed into agricultural fields (BI 2000). Eskimo curlews™ fall migration along the Atlantic coast through Labrador took them 8,000 miles to winter on the pampas of Argentina, southern Brazil and Chile (BI 2000). They were heavily hunted along the way. On one migration in 1872, three men in Cape Cod and Nantucket killed $300 worth of curlews they sold for 6 cents per bird [5,000 birds] to local meat markets (Hornocker 1913). In the spring, the birds would return through Central America and the Great Plains (Hayman *et al*. 1986). During the spring migration, they again became targets for the hunters. If a flock was shot at, the birds would fly only a short way before landing again, and they often returned to the same spot, resulting in the slaughter of entire flocks (Schreiber *et al*. 1989). The meat market hunters could fire a single shot that would bring down dozens of Eskimo curlews (Peck 1990). This hunting endangered them (Ehrlich *et al*. 1992) and, in spite of a ban on hunting in 1916, no recovery took place (BI 2000).

Their wintering habitat had been plowed as well, beginning in the late 19th century when their pampas in Argentina were used to produce export crops for Russia (Schreiber *et al*. 1989). Their populations plummeted from loss of habitat and unrestricted hunting, and fewer and fewer curlews managed to reach their northern breeding grounds. By the turn of the century, Eskimo curlews had become extremely rare. None has been seen in South America since 1939 (BI 2000). Several birds were shot in Barbados on their southern migration in 1964, and during the 1980s through 1996, various unconfirmed sightings were made (BI 2000). There is little hope that the Eskimo curlew survives.

Dominant among all the prairie predators, the grizzly bear (*Ursus arctos horribilis*) towered more than 10 feet tall when standing upright. Very common on the prairie, these bears ranged over most of western North America, from the Arctic Circle to northern Mexico. They were common in many types of grassland. All the subspecies except *Ursus arctos horribilis* became extinct south of Canada. In spite of its great strength and intelligence, in addition to the difficulty explorers and settlers had in killing it, these great bears were hunted to near extinction. Lacking cover in most of the Great Plains, the bears made large targets as they foraged for their primarily vegetarian diet, and were eliminated here first. Hunters made expeditions to kill these animals, and wrote articles and memoirs of their hunting prowess as they eliminated grizzly bears from one area after another. South of Alaska, only Yellowstone National Park and Glacier National Park harbored grizzly bears by the 1940s (Allen 1942).

Fur trapping intensified in the 19th century, with professional trappers combing the countryside, setting leghold traps and spreading poison to kill the most valuable furbearers such as beaver and river otter. Within a short time, both these animals had disappeared from large parts of the country, including most of the Midwest. The American beaver (*Castor canadensis*) is a keystone species in aquatic environments, creating habitat for otters and other wildlife with their dams. In fact, the range of the river otter in North America nearly coincides with that of the beaver. Trappers killed beavers in their lodges and dynamited dams to scare them into the open until these once common rodents became rare in many parts of the country. Their fur was highly valued and used in the manufacturing of top hats in England and Europe. The relentless trapping wiped these animals out throughout much of the country, and the beaver ponds that once dotted the landscape disappeared, greatly altering ecosystems for the worse. Otter fur was

even more valuable because of its durability and waterproof qualities, and these animals, which had never been abundant, disappeared from two-thirds of their original range south of Canada (Nilsson 1985). River otters play an important role in aquatic ecosystems by culling overpopulated fish populations.

Other predators, such as the gray wolf, the kit (*Vulpes macrotis*) and the swift fox (*Vulpes velox*), were nearly eliminated from the United States south of Alaska. Fur trapping was followed by persecution in the form of predator control programs to benefit livestock ranchers. The gray wolves of the prairie were often white or pale gray and were entirely eliminated here (see Persecution and Hunting chapter).

The fleetest animal in North America nearly became extinct. The pronghorn (*Antilocapra americana*), a species found only on this continent, is not a typical antelope, but the last survivor of a family of ungulates long extinct. Once abundant throughout the Great Plains and in the deserts of the Southwest and Mexico, they may have numbered as many as 40 million animals prior to European settlement (Peters and Lovejoy 1990). Pronghorns travel in herds able to "fairly fly over the ground," in the words of Glover Allen (1942), when fleeing predators. Their natural curiosity, an urge to investigate any unfamiliar object, may have contributed to their near•extinction. One hunter told of luring the pronghorns within gunshot by donning a white sheet and approaching them on all fours (Allen 1942). George Catlin painted natives luring them close by waving a feather on a stick.

By the turn of the century, so many pronghorn had been shot by settlers and meat hunters that the species was reduced to endangered status (Allen 1942). William T. Hornaday, director of the New York Zoological Park and a prominent conservationist who had saved the American bison from extinction in the early part of the century, predicted in 1913: "The Prong•horned Antelope, unique and wonderful, will be one of the first species of North American big game to become totally extinct. We may see this come to pass within twenty years. They cannot be bred in protection, save in very large fenced ranges. They are delicate, capricious and easily upset. They die . . . at the drop of a hat" (Hornaday 1913). Fortunately, his prediction did not come to pass, and total legal protection of the last pronghorns saved the species from extinction. Yellowstone National Park was crucial to the species' survival, and the bison™s as well, by protecting remnant herds. These herds provided the stock from which pronghorns were reintroduced to areas where they had been eliminated (Allen 1942). Today, they are fairly common in the western states of Montana, Wyoming and Colorado and found in smaller numbers in other parts of the West (see Grasslands, Shrublands and Deserts chapter for more on this species).

Another victim of the hunting slaughters of the 19th century was the Badlands bighorn sheep (*Ovis canadensis auduboni*), once numerous in the rugged hill country of the upper Missouri and Little Missouri Rivers in North and South Dakota and parts of Nebraska (Allen 1942). Weighing about 344 pounds, the males had massive curved horns that trophy hunters sought. While they grazed on the prairie near the high buttes, they were ambushed by hunters who cut off their escape. Even President Theodore Roosevelt contributed to their extinction by hunting them in the early 1880s (Allen 1942). The last record of this grayish brown sheep in North Dakota was an old ram killed about 1905, and the dates of extinction of the South Dakota and Nebraska populations are unknown (Allen 1942). Rocky Mountain bighorn sheep, another race of this species, have been reintroduced into the South Dakota Badlands.

Prairie streams and clear•flowing rivers provided habitat for several unique species of fish. The harelip sucker (*Lagochila laura*), whose downturned mouth had a large disk with which it fed on the stream bottoms, became extinct in 1893 when grasslands were plowed and streamsides disturbed; the water became turbid and muddy, causing the fish to literally asphyxiate in the silt•laden water (Day 1981).

Today, the tallgrass prairies have become wheat and corn fields, crisscrossed by highways, and dotted with towns and cities. More than 90 percent of the original prairies are gone (Peters and Lovejoy 1990). Even in the few areas where native grasses were not plowed under, diversity of grass species has declined from 200 to 30 species in most areas because of heavy livestock grazing (Peck 1990). Tallgrass prairie reserves have been established in Wisconsin, Kansas and Oklahoma. In the latter state, a herd of 300 bison was released in the early 1990s in virgin tallgrass prairie in Oklahoma by The Nature Conservancy after an absence of more than 100 years. Many National Grasslands were

established in the range of the shortgrass prairie, primarily for livestock, but after many decades of grazing, rodent and predator control, this land bears little resemblance to the original prairie (see Grasslands, Shrublands and Deserts chapter).

Western Landscapes

In the southwestern United States and northern Mexico, deserts harbor a great wealth of species. The Mojave, Sonoran and Chihuahuan Deserts of the southwest differ from one another in their vegetation, topography and wildlife. All are dotted with deep springs and oases, each having endemic species of fish Œ vestiges from ancient times when seas covered the land. The Sonoran Desert, most verdant of the three, is studded with giant Saguaro cacti (*Sereus giganteus*), more than 60 feet tall and found nowhere else on Earth, along with many other unique and beautiful desert plants. Deer, pronghorn, bighorn sheep and a variety of predators Š from grizzly bears and jaguars to gray wolves and coyotes Š lived in this desert, the most botanically rich in the world. Bird life was also prolific, and desert tortoises sheltered in burrows during the day. Mountain ranges jut from the Chihuahuan Desert to the south, and the Mojave of California is characterized by an extremely hot and arid climate, in which many unusual plants and animals manage to survive.

In southeastern Utah and Nevada, pinyon•juniper vegetation once covered thousands of square miles. The US Department of Interior's Bureau of Land Management has converted millions of acres into shrubland for the benefit of cattle. The pinyon pines, whose nuts have been a source of food for native tribes for thousands of years, have been destroyed in large part by chaining, wherein chains are stretched between two bulldozers, which then drag them across the pine-juniper bushes and trees, uprooting them. This ecosystem is home to desert tortoises and a wide variety of birds and small mammals, but today, the diversity and abundance of wildlife has been greatly diminished.

Much of the deserts are federally owned, and management has been primarily to benefit livestock owners and other users. Portions of the Mojave Desert and more than a million acres of spectacular Utah cliffs and desert have recently been made a National Reserve. These areas will not receive strict protection, however, since oil drilling and other activities, such as livestock grazing, will be allowed.

Streaming through the dry Southwest, the mighty Colorado River carved the vast Grand Canyon in Arizona as the land was thrust up and sunk with movements of the Earth over millions of years of geologic time. Some of the oldest rock formations have been dated at more than 1 billion years. These eons are etched in the Canyon's layered slopes. This canyon is one of the great natural wonders of the world, a wilderness of pastel-hued cliffs and beautiful vistas. Plateaus surrounding the canyon are geographically isolated, and many endemic animals inhabit these pine forests. In the Colorado River's turbid waters, a large number of unique fish evolved. The river has been dammed throughout its course, however, to supply water for irrigation, cities and suburban homes, as well as to generate electricity. One-fourth of the Colorado's water is used to irrigate the crops of California's Imperial Valley. The delta of this once immense river was described in 1922 by the conservationist Aldo Leopard as teeming with wildlife. That same year the Colorado River Pact was signed, which gradually removed its flow. Today the delta in northern Mexico is almost dry. The endemic fish and birds of the Colorado River system have been decimated by these projects. Some are being conserved under US Endangered Species Act programs conducted by the Fish and Wildlife Service. The dams that pepper the river turn the once warm and silty water cold and clear, a new habitat that native fish find intolerable.

The Sonoran Desert's unique and beautiful plant life has declined in the decades since 1970 because of unrestricted development for suburban housing; much of it is for retired persons seeking a dry and sunny climate. New houses, roads and commercial centers are gobbling up tens of thousands of acres, and in the process, the venerable giant

Saguaros and other desert vegetation are bulldozed. These new communities use enormous amounts of water piped from the Colorado River and several diverted desert rivers. These desert oases turned to dust, eliminating their wildlife and plants. One of the few desert-nesting bald eagle populations became extinct as a result of the Central Arizona Project, which diverted water for agriculture and towns. Most residents in the Southwest have eliminated natural desert vegetation and planted grass lawns in front of their homes, which require almost constant watering and heavy use of chemical fertilizers, pesticides and herbicides Œ pollutants of the water table.

Merriam's elk (*Cervus canadensis merriami*) was native to various mountain ranges of southern Arizona and New Mexico. The antlers of this elk were the largest of all the elk races, and the animal was described as more pale and reddish than the Rocky Mountain elk (Allen 1942). Vulnerable because of its restricted range, it was hunted by cattle ranchers in the late 1800s, and crowded out by livestock. The last individuals were killed around 1906 in the Chiricahua Mountains of southeastern Arizona, where they had sought refuge in high altitudes (Allen 1942).

Thousands of elk and bighorn sheep died from diseases brought by domestic cattle. Lacking natural resistance, entire populations died soon after they came into contact with domestic cattle and sheep that carried disease. Native Americans also died by the thousands because of diseases Œ from measles to small pox Œ brought by colonists and settlers. A number of tribes that had inhabited the West for thousands of years became extinct. In some cases, the tribes lost their land and dwindled to extinction.

West of the Rocky Mountains an unbelievably rich and beautiful land awaited settlers. The Sacramento and San Joaquin Rivers flow through the huge Central Valley, an area covering thousands of square miles. Prior to settlement, breathtaking vistas of wildflowers and grasslands grazed by innumerable elk and mule deer were framed by distant snowy mountains. The largest lake west of the Mississippi River, Lake Tulare, covered much of this river valley. Shallow and seasonal, this lake swelled after spring rains to serve as a breeding ground for an estimated 100 million waterfowl. Early naturalists spoke of the birds darkening the sky for days.

Spanish colonists established vast cattle ranches, beginning in the 1600s in what is now California. After Mexico lost this territory at the end of the Mexican War in 1848, American settlers poured into the region and agriculture began on a grand scale. In the late 1800s, California became thickly settled. The grasslands, deer, elk and the distinctive California grizzly bears that roamed California's valleys were eliminated by hunting and habitat destruction. The grizzly bears, still pictured on California's flag, were hunted to extinction (Nowak 1999). The Central Valley soon became California's bread basket, with agriculture displacing the tule elk (*Cervus canadensis nannodes*), whose range once extended throughout the San Joaquin and Sacramento Valleys, half the length of the state. As a result of hunting and loss of its habitat, the small herds of remaining elk became confined to a tule marsh area near Tulare Lake (Allen 1942). Transplants to other areas have not succeeded, and this subspecies remains very rare. Ninety•five percent of the wetlands of California's Central Valley and marshes that once dotted the coastline have been filled in for farms and development. Tulare Lake and its millions of ducks disappeared completely from drainage and water pumping, becoming the world's largest artificial farm, irrigated by water piped from elsewhere in the state. The Central Valley Project, an immense system of ditches, canals and pipelines, pumped water from the rivers in the Sierra Nevada Mountains to supply Los Angeles with water, devastating salmon and other wildlife. The Sacramento River once had an estimated 2 million salmon, and a fishery, but today they are nearly extinct as a result of the water diversion and dams.

California has incurred the greatest loss of wetlands of any state. Damming and diking of waterways to divert water for irrigation in the Central Valley resulted in the extinction of a foot•long fish once caught for the fish markets of San Francisco. The thicktail chub (*Gila crassicauda*) was very common until the 1880s, but by the 1920s, it had been driven to extinction (Day 1981). San Francisco Bay, the largest wetland and estuary on the West Coast, has been greatly altered by water diversion projects and drainage for agriculture and building. The bay has a great number of endemic species and races of birds and fish, and many of these have disappeared or become extremely rare. Federal protection under the US Endangered Species Act for many of these species may prevent their extinction.

North America's largest bird, the California condor (*Gymnogyps californianus*), soared over coasts and inland valleys Œ as far north as Washington State. This bird came close to extinction as a result of hunting and accidental poisoning (see Persecution and Hunting chapter). The last wild birds were captured for captive breeding, and young birds have been released to the wild. It will be years before it is known whether this giant vulture will survive and breed in the wild. In the foothills of the Sierras grew thousands of immense sequoias (*Sequoia gigantea*), trees that can live for more than 4,000 years. At a height of up to 300 feet tall, these trees attain a girth of 100 feet and support wood weighing 600 tons, making them the most massive and heaviest organisms that have ever lived (Jonas 1993). Sequoias take 3,000 years to attain full growth, sprouting from a seed only a quarter inch long. These trees were logged, reducing them greatly until they received legal protection. Sequoia National Forest was declared a National Monument by President Bill Clinton in 2000 to stop logging of other types of trees in the forest, which was threatening the root systems and survival of these ancient Sequoias. It is now illegal to cut a Sequoia.

In northern California, Oregon and Washington, ancient forests of hemlocks, pines, cedars and coast redwoods (*Sequoia sempervirens*) had grown undisturbed for thousands of years. Redwoods are the tallest trees on Earth, reaching heights of more than 365 feet and measuring up to 58 feet in circumference (Jonas 1993). These forests once lined 2,000 miles of Pacific coastal region from northern California through British Columbia, ending in southeastern Alaska, covering 70 thousand square miles. Centuries of logging have reduced these forests to only about 5 percent of their former size in the United States, and less than 40 percent in Canada (Middleton 1992). Commercial logging began in the 19th century and has proceeded throughout this century, clear cutting millions of acres of redwoods, Douglas Fir and other evergreens in forests, cutting in a few hours trees that took a thousand or more years to grow. Once cut, these forests need hundreds Š if not thousands Š of years to regenerate to their former biological richness. The land where these forests once stood has been converted to other uses, precluding their regrowth.
Loggers are still fighting conservationists over the fate of the last five percent of Pacific Northwest old-growth forests and their endangered residents (see Forests chapter). Although the sequoias and coast redwoods have escaped extinction, they are far rarer than they once were, and the redwoods continue to be cut to be made into lawn furniture and decks.

A race of bison native to these forests, the Oregon bison (*Bison bison oregonus*), was distinct in being slightly larger than the Plains bison, with longer and straighter horns (Allen 1942). Once native to southern Idaho, northern Nevada to southeastern Oregon and northeastern California, they died out soon after the arrival of the early explorers. Although the history is unclear, tales from the Native Americans indicate that arms supplied to them by explorers were used to hunt these animals to extinction by the mid•1800s (Allen 1942).

Wetland Drainage: Page 2

Thousands of years of drainage, pollution, diversion and overuse of the rivers and wetlands in the Middle East have destroyed once verdant areas such as the site of ancient Babylon in present-day Iraq. The single exception, until recently, was the 6,000-square-mile delta of reeds, lagoons and marsh south of the confluence of the Tigris and Euphrates Rivers on the Persian Gulf in Iraq. This wilderness maze was inhabited by the reed homes of the Shiite

marsh Arabs (Hedges 1993). They fished from small boats woven from marsh plants, a lifestyle unchanged for thousands of years (Dugan 1993). After the 1989 Persian Gulf War, Iraq's President Saddam Hussein ordered that the swamps be drained to vanquish the Shiites, who had opposed his government (Hedges 1993, Lewis 1993). The Iraqi portion of these marshes has also been polluted by oil spillage from the war. Within a few years, approximately 90 percent of these ancient wetlands were drained and soon dried out in the desert sun. Observers flying in small aircraft have documented that these wetlands now resemble dusty fields.

The best known animal resident of Iraq's marshes may be Maxwell's otter (*Lutra perspicillata maxwellii*), named for the charming otter who inspired the story *Ring of Bright Water*, by Gavin Maxwell (1961). This male otter had been captured in these marshes and brought by the author to the British Isles after many misadventures in trains and hotel rooms. When examined by zoologists, he was determined to be an endemic and distinct race of the smooth-coated otter. The fate of Maxwell's otters may not be learned for many years to come. Other victims of the destruction of Mesopotamian marshes may be the birdlife: several million waterfowl wintered in the wetland (BI 1993). Endangered and rare birds that winter here include the dalmatian pelican, pygmy cormorant (*Phalacrocorax pygmaeus*), marbled teal (*Marmaronetta angustirostris*), white-tailed eagle (*Haliaeetus albicilla*), imperial eagle (Aquila heliaca) and slender-billed curlew (*Numenius tenuirostris*), according to BirdLife International (1993). Two endemic breeding birds are also at great risk. The Iraq babbler (*Turdoides altirostis*) and the Basra reed warbler (*Acrocephalus griseldis*) are restricted to these marshes in southeastern Iraq and adjoining southwestern Iran. The latter bird is listed as near-threatened in *Threatened Birds of the World* (BI 2000). Although no status surveys have been made in the breeding range of the Basra reed warbler, the number of these birds seen in wintering habitat in Kenya has declined in recent years (BI 2000). A small portion of these marshes remains in adjoining Iran, but it cannot support a fraction of the wildlife that inhabited the Iraqi marshlands.

The worst oil spill in history took place in the Persian Gulf as Iraqi President Saddam Hussein, enraged at losing the war with Kuwait, opened and set afire that country's oil wells to spill 500 million gallons of oil into the delicate Gulf (Earle 1995). This represented 45 times the amount released by the *Exxon Valdez*. It added to the 250,000 barrels of oil released into the Persian Gulf every year for the past decade. The 1991 spill killed cormorants and other sea birds, sea turtles and dugongs. The fires belched toxic chemicals into the air and water in thick black clouds that darkened the sky at noon. Every plant and animal within many miles became coated with black soot. Marine scientist Sylvia Earle witnessed a bird in the midst of this hellish landscape as it swooped into a pool of oil, lured by a struggling dragonfly. "The bird barely moved, succumbing at once to shock, the slimy embrace gluing feathers, clogging nostrils, searing bright eyes, snuffing life" (Earle 1995). The 400-mile coastline of Kuwait, an expanse of marshes and mangroves, became covered in thick black oil, leaving only a few areas of untouched beaches protected by a causeway (Earle 1995). Tens of thousands of migrating shorebirds died in this oil along with a host of invertebrates and fish, and since much of the oil sank and attached itself to sand and mud, the oil killed for many years (Earle 1995). The most common coral in the Persian Gulf, staghorn, released eggs that were killed by the oil, and most of the adult coral in the region of the spill died or bleached (Earle 1995).

Source: Table of Extinct Species in the Appendix of this book. Sources of information are listed with the table.

Note: See the Appendix for the list of these species in chronological order, and the references that describe these animals and their extinctions, as well as those that include illustrations of the extinct species.

The following account chronicles some of the many extinctions and destructions of natural ecosystems that have taken place in North America over the past few hundred years. Great biological treasures have been stolen from future generations, and the processes by which they were lost are typical of those occurring elsewhere in the world. The sudden loss of the most abundant and prominent wildlife species of the continent created a profound shock in the public early in the century that set the stage for today's conservation and humane programs. This concern may turn the tide for species that could suffer the fate of the passenger pigeon (*Ectopistes migratorius*) and others, but unless public opinion is better translated into public policy regarding the land and wildlife, further losses will occur and the lessons that might have been learned will be ignored. A strong and pragmatic commitment to preserve what remains of the natural world on the continent, based on a realization that our fate is linked to nature's fate, is essential to prevent further extinctions.

Vanishing Species

The Unraveling Tapestry

Now that prairies are plowed under and deserts are filled with subdivisions, the net effect of this recent massive habitat destruction and wildlife slaughter is being assessed. An incomplete tally in the United States, including Hawaii, totals at least 99 species of animals and 240 plants presumed extinct during the past 400 years (Stein *et al*. 2000). This high rate of extinctions reflects the losses of species and ecosystems described in Chapter 1, as well as those of Hawaii. The Nature Conservancy, which established Natural Heritage Programs in every state to monitor native species, has compiled this and related data to alert the public of the urgent need to preserve the country's natural heritage (Stein and Flack 1997; Stein *et al*. 2000). Its examination of the status of 20,439 US plants and animals found 7,817 species (38 percent) to be either vulnerable, imperiled or critically imperiled (Stein *et al*. 2000). These conclusions were published in a book co-authored with the Association for Biodiversity Information, entitled *Precious Heritage: The Status of Biodiversity in the United States* (Stein *et al.* 2000). This book also illustrates many of these beautiful plants and animals and threatened ecosystems. It found more species in danger than the *2000 IUCN Red List* due to slightly different categories, such as imperiled and critically imperiled, rather than critical and endangered, used in IUCN lists. The latter organization also defines threatened species in terms of the rate of their decline, rather than their actual status.

-

Precious Heritage found endemic species, defined as those restricted to the bounds of the United States, and breeding endemics, or those breeding only in the United States, were even more threatened than those with wide distributions. Of the 875 endemic vertebrates in the lower 48 states, almost half (47 percent) are of conservation concern, compared to only 24 percent of all US vertebrate species (Stein *et al*. 2000). 90 percent of Hawaii™s endemics are imperiled in this study. Freshwater species such as mussels, crayfish, beetles and dragonflies are also in steep decline (Stein *et al.* 2000). More than 5,090 plants (33 percent of all native species) are threatened.

Other studies are examining natural ecosystems in the country. The National Biological Service of the US Department of the Interior reported in 1995 that during the 20th century alone, half the natural ecosystems of the lower 48 states became degraded to the point of endangerment (Stevens 1995). More than 1,700 biologists participated in this study, part of a massive biological survey of America's plants and animals (Stevens 1995). Along with the loss of the tall grass prairies and oak savannahs, more than 60 million acres of longleaf pine forests in the Southeast have been cut, and much of this land has been planted with tree farms, creating biologically sterile regions. Northeastern old-growth hardwood forests, likewise, are critically endangered, and survive only in scattered remnants (Stevens 1995). Grasslands in Long Island, the Northeast and California are threatened ecosystems, as are coastal prairies in Louisiana and sedge meadows in Wisconsin. Streams in the Mississippi plain have been greatly damaged as well (Stevens 1995). Fifty-eight natural communities have declined by 85 to 98 percent, and 38 others have declined by 70 to 84 percent (Stevens 1995). The National Biological Service has identified 126 endangered species through this study. Each imperiled ecosystem is home to many threatened species, a reflection of their loss of habitat. This study underlined the importance of preserving large areas instead of small tracts of land, although the latter may be the only way to protect some highly endangered species, such as plants that have become greatly restricted in range.

A 1997 study by the joint United States and Canadian branches of the World Wildlife Fund (WWF), "A Conservation Assessment of the Terrestrial Ecoregions of North America," appraised the ecoregions of the continent including Hawaii (Luoma 1997). Ecoregions are areas defined by major habitat types and, unlike ecosystems, are confined to particular areas. Eastern old-growth forests, for example, are ecosystems scattered over a great area amongst other ecosystems, while southeastern conifer forests constitute an ecoregion. This study found 13 of the continent's 116 ecoregions to be imperiled "hot spots," harboring enormous biological diversity (Luoma 1997). These include Florida's pine scrub, the conifer forests of the Southeast, Appalachia's mixed mesophytic forests, the

tallgrass prairie and California coastal sage and chaparral (Luoma 1997). These findings were echoed in the world survey of threatened areas with great biological diversity, *Hotspots*, sponsored by Conservation International (Mittermeier *et al*. 1999). The latter book is illustrated with spectacular color photographs of many disappearing landscapes and species of endangered hotspots, such as the California coastal region.

An inventory of rare, endangered and extinct North American plants and animals, being compiled by the National Biological Service, has verified that the impoverishment of America's natural ecosystems has affected not just isolated species, but entire communities of species. It predicts a steady increase in the number of threatened species because of continued destruction of natural habitats. Habitat loss is the greatest threat to US wildlife and plants, but trade, persecution and pollution play roles as well. Agriculture was ranked as the primary threat to native US species by The Nature Conservancy study, threatening about 45 percent of plants and animals, while development of land followed, threatening about 34 percent; water projects were the next major threat, and livestock grazing, pollutants, road building, logging and mining had important, but lesser, effects on species and ecosystems (Stein *et al*. 2000).

Threatened species tend to be located in certain "hot spots" in the United States. The one with the largest number of species is Hawaii, with 5,000 populations of species considered imperiled by The Nature Conservancy (Stein *et al*. 2000). In the continental United States, a preponderance of threatened species occurs in the Florida Panhandle, central Florida and the Florida Keys, the Appalachian Mountains, the Cumberlands and Southern Ridge, Cape Cod and Martha's Vineyard, southern California, the Pacific Northwest and southeastern Alaska, as mapped in *Precious Heritage. The Status of Biodiversity in the United States* (Stein *et al*. 2000; page 166). The Cumberlands and Southern Ridge and Valley of northern Alabama and southeastern Tennessee have the country's largest number of imperiled species--186--mainly as a result of the mussels, crayfish and freshwater snails of this region. The Central Appalachian Forest to the northeast has 154 threatened species, with a high percentage of aquatic species as well, including many rare salamanders and woodland plants. The Great Basin Desert of Utah and neighboring states is another species-rich area, with 113 threatened species, while the California South Coast sagebrush ecosystem has 138 threatened species found nowhere else on Earth (Stein *et al*. 2000). (See Grasslands, Shrublands and Deserts chapter).

The list of US species in danger of extinction grows longer each year, with a dramatic rise in the number of imperiled invertebrates in the 20th century. Fully 68 percent of freshwater mussels, more than 100 species, are threatened, making them the most endangered group of native animals. Fifty percent of native crayfish are threatened, according to the Nature Conservancy (Clancy 1997). The majority of surviving species are highly endangered from alteration of their clear, fast-flowing rivers and streams by federally sponsored dams, channeling and diking that have turned most waterways in the Southeast into muddy ditches and artificial lakes. Pollution and introduction of non-indigenous species of mollusks and crustaceans competing for food have also played roles in the decline of some of these mussels and crayfish. The Hawaiian Islands are home to a variety of colorful and endemic tree snails. Introduction of exotic snail species and habitat destruction have already extinguished many of these, and endangered others.

Many species of butterflies, which are important pollinators, are in decline. The Xerces Blue (*Glaucopsyche xerces*), a beautiful butterfly native to California, became extinct in the 1940s (Stein *et al*. 2000). Eight moth species and two other mainland butterflies are possibly extinct, as are 50 bee species native to Hawaii (Stein *et al*. 2000). Eight mainland butterfly species are critically endangered, and 109 are threatened, according to The Nature Conservancy (Stein *et al*. 2000). Dragonflies and damselflies, which predate the dinosaurs, have also lost ground. Two Hawaiian species are possibly extinct, and 79 more are considered imperiled (Stein *et al*. 2000).

Seventeen species of freshwater fish are extinct or possibly extinct, and the United States leads the world in the number of threatened freshwater fish: The Nature Conservancy lists 283 species (Stein *et al*. 2000). Habitat loss in the form of dams, river diversion and channeling, as well as pollution, has played major roles endangering these fish. Logging has destroyed many clear rivers and streams where salmon and trout breed. The majority of rivers and bodies of water are still polluted despite the Clean Water Act, and contaminants have caused malformations and high mortalities in fish populations. Introductions of non-indigenous fish for sport fishing have imperiled a large number

of species. Brown Trout from Europe and Rainbow Trout placed in areas where they are not native have severely threatened native trout, such as the Cutthroat Trout of western lakes and rivers. In many cases, multiple factors combine to push native fish toward extinction.

The United States is second only to Australia in the number of threatened reptiles and amphibians. The Nature Conservancy lists 51 imperiled reptiles and 82 imperiled amphibian species (Stein. 2000). This amounts to an estimated 40 percent of US amphibians, and 18 percent of native reptiles--extremely high rates. Amphibians are declining worldwide from various causes including habitat loss, pollution, disease, pesticides and ultraviolet radiation from thinning of the Earth's ozone layer.

The total of 71 US bird species that BirdLife International's research placed in various categories of threat includes 33 species from the Hawaiian Islands (BI 2000). The Nature Conservancy found an even greater number through their intensive Natural Heritage Program research: 83 species of birds at risk in the United States, or about 11 percent of all native species (Stein *et al*. 2000). This is a smaller percentage than for reptiles and amphibians but, when analyzed by region, a large percentage of Hawaii's birds are threatened. A steady increase in the number of threatened birds has occurred in this century. The major causes threatening US mainland and seabirds are destruction of habitat, pesticides and pollution. In the Hawaiian Islands, introduced animals, disease and destruction of forests and wetlands are the major threats to endemic birds, as well as to plant life and invertebrate fauna.

The Nature Conservancy considers 65 species of US mammals, or about 16 percent of all native mammals, to be threatened (Stein *et al*. 2000). The loss of habitat from development, logging, livestock grazing, mining and other forms of destruction is the foremost threat to mammals. Added to this, pollution affects many aquatic mammals, and predator and rodent control programs to benefit livestock and agricultural interests affect foxes, wolves, and prairie dogs. A growing number of bats have been added to the list of threatened US mammals, an indication of a loss of habitat, as a result of caves being disturbed or vandalized, loss of large roosting trees to logging, pesticide use, and persecution by those not aware of bats™ ecological importance and who have exaggerated ideas of their supposed threats to humans.

Although lists of native North American threatened plants are far from complete, they reflect the rate at which ecosystems have become imperiled. The Nature Conservancy found 6,460 United States vascular plants to be imperiled (Stein *et al*. 2000). Of these, a very large number--1,385--are Critically Imperiled, 1,341 Imperiled and 3,338 species Vulnerable. Hawaii is a center for threatened plants. The *1997 IUCN Red List of Threatened Plants* found a somewhat smaller number of threatened US plants; 4,488 species, or 29 percent of native plants. Still, the United States had the highest number of endangered plants of any country in the world (Walter and Gillett 1998). In terms of the percent of native plants that are threatened, only St. Helena, Mauritius, and the Seychelles had higher rates (Walter and Gillett 1998) Few countries of the world have legislation similar to the US Endangered Species Act, which has helped hundreds of endangered plants.

Many US plants are adapted to specific types of soil or microclimates, and human disturbances can threaten them. Prairie plants are among the most threatened. California's grasslands have been reduced by more than 90 percent, leaving many endangered plants; it has many endemic species in its southern chaparral and shrubland, which are being bulldozed to make way for new housing developments. The state's mild climate and varied landscape have given rise to great diversity, which is extremely threatened. Of 25 presumed and 21 possibly extinct species in the state, about half, or 24, are plants (Stein and Flack 1997). Although endemic plants are not as numerous on the mainland as in some island habitats, North America is home to a great many unique and beautiful plants, which are finally beginning to receive the conservation attention they deserve.

Research is uncovering potential economic value in some native plants. One threatened US plant, the Scrub Mint (*Dicerandra frutescens*), yields a natural insecticide in its oil that repels a wide variety of insects, from ants to cockroaches (Aylsworth 1998). This white-flowered plant is presently restricted to a few hundred acres in central Florida, and it only came under scrutiny in the 1990s, when a Cornell biologist, Dr. Thomas Eisner, discovered its

potential as a natural insecticide (Aylsworth 1990). This mint may be protected from extinction in time, thanks in large part to Eisner's research.

In spite of some sizeable natural areas in the United States preserved by the Wilderness Act and as federal or state land holdings, the country has become increasingly urbanized and cultivated for agriculture. Americans have gradually altered the landscape so that much of it, especially in the East, now resembles Western Europe's heavily populated countries where wilderness has been all but eliminated.

Recent ecological research on the effects of suburban sprawl on the environment have shown it to crowd out as many species as more densely populated areas (Revkin 1997). Diversity of species declines in these areas as green lawns, manicured gardens and asphalt cover the land and pollute the ground water with pesticides, fertilizers and herbicides and kill off beneficial insects and other animals. Developers drain beaver ponds and wetlands and turn streams and rivers into concrete-lined ditches. With each acre lost, species decline. The brilliantly colored warblers and songbirds of eastern forests, for example, have been severely affected by fragmentation of both their breeding and wintering habitats. For the majority of such declining species, endangered listing comes only when they have been reduced to a small fraction of their original populations. The species that are listed by the IUCN or The Nature Conservancy in various categories of threat have reached a point where their very survival is at risk. In some cases, species, which were once described as naturally rare, are very restricted in distribution, especially plants and fish inhabiting desert springs or mollusks found only in a particular river system. For the majority of threatened US wildlife, however, their status a few hundred years ago would have been described as secure. It is all the more indicative of a crisis situation regarding American biodiversity that so many species, and such large percentages of their classes or types, are now headed toward extinction.

Should all US species currently threatened become extinct, a biological tragedy will take place. Preventing such a catastrophe has not yet captured the public™s attention or involved a zealous effort on the part of the US government. Important work on biodiversity studies is being done by various federal agencies, but the major burden of activism regarding preservation of endangered species and the environment has fallen to private conservation organizations.

The WWF report entitled "A Conservation Assessment of the Terrestrial Ecoregions of North America," accuses the US government of "doing a worse job of protecting its biological resources than many poorer countries with few resources for biodiversity conservation" (Luoma 1997). It concludes that the wealthiest country in the world places the preservation of its natural resources among its lowest priorities.

Without detailed information on the biodiversity of this country, it will be impossible to protect it, yet funds are inadequate to carry out a comprehensive assessment. Many opponents of the biodiversity studies in Congress have expressed fear that they would be used to expand the list of species on the Endangered Species Act and obstruct development programs. They succeeded in blocking formation of the National Biological Service, which Clinton Administration Secretary of the Interior Bruce Babbitt had to create administratively. The constant deterioration of the land through development, pollution and introduction of exotic species makes these studies all the more timely. This is a critical time of rapid environmental destruction and a turning point for many species which, without urgent protective action, will follow the deadly trails of the Passenger Pigeon, Carolina Parakeet, Sea Mink and hundreds of other lost plants and animals.

The US Endangered Species Act is one of the strongest and most effective laws in the world and has been a model for similar legislation globally. Many countries, including Canada, still lack national endangered species laws. Although private organizations acquire habitat and carry out many important programs, the legal protection the Endangered Species Act provides is key to the protection of many endangered species and their habitats. It has been responsible for saving a number of species, including the California Condor (*Gyps californianus*), Black-footed Ferret (*Mustela nigripes*), Whooping Crane (*Grus americana*) and numerous other animals and plants. The law has helped fund research, captive breeding, protection in the wild, reintroduction programs, land acquisition and law enforcement protection.

The law must be reauthorized regularly by Congress, however, and at these times, efforts to weaken or even fail to authorize it threaten its effectiveness and very existence. The strong support the law has received from the US public is not always evident in the halls of Congress, where commercial interests and lobbyists have had considerable influence. To date, the law has survived, although it has been amended and weakened somewhat since its enactment. The blocking of listings on the Endangered Species Act by its opponents has become the major means of thwarting the Act. Lawsuits have been filed by both opponents and proponents of the law demanding either delisting of species or listing and critical habitat designation. A virtual impasse has resulted in a moratorium on listing new species which the Department of the Interior declared in 2000.

Many listings have been thwarted by commercial interests. In a recent case, a proposal to list the Lynx (*Lynx canadensis*) on the Endangered Species Act was not acted upon by the Fish and Wildlife Service without a lengthy struggle. This species has greatly declined from its once large range in the lower 48 states. Heavy trapping for its valuable fur and logging of its habitat of mature pine forests have reduced its populations to fewer than 1,000 animals. The majority of Lynx remain in Montana, Idaho, Washington and Maine. Although the Fish and Wildlife Service's (FWS) own biologists found this population to be endangered, they were overruled by headquarters whose bureaucrats decided to refuse to list the species on the Endangered Species Act (Cushman 1998). Petitions by conservationists urging Endangered Species Act listing for the Lynx were ignored, and only when a lawsuit was filed against FWS did the tide begin to turn in this endangered cat's favor. Conservationists won the suit in 1997, but the FWS, in an unprecedented action, declined to list the Lynx, stating that other species had higher priority for listing. Loggers and commercial timber companies oppose listing the Lynx, fearing that areas would be set aside as critical habitat where no tree cutting would be allowed, and many conservationists believed that FWS had succumbed to these pressures. Finally, in February 1998, the Service and several conservation groups reached an agreement to list the Lynx on the Endangered Species Act to take effect in 1999 (Cushman 1998). President Clinton declared a moratorium on new road building in national forests lands in 2000, which will greatly aid the Lynx and other threatened species of these forests, such as the Wolverine and Marten.

The Public Employees for Environmental Responsibility (PEER) issued a report in December 1997 accusing the FWS of failing to protect more than 300 species awaiting listing. Only listings of plants have increased in recent years, leaving a growing number of animals in need of federal listing (Stein *et al*. 2000). The Nature Conservancy's biological surveys have uncovered a far greater number of endangered and threatened species in the United States than are listed by the Endangered Species Act, especially plants.

On the positive side, an increase in the number of endangered species added to the Endangered Species Act has been seen in recent years. The Endangered Species Act, in spite of shortcomings, is vital to the preservation of endangered species in the United States, and it is in grave danger of being weakened so much that it will become ineffective. Various proposals in 2001 made by the Bush Administration would make it nearly impossible for citizens to sue the government to force listing of endangered species (Jehl 2001). The majority of species on the Endangered Species Act were listed as a result of citizen suits (Jehl 2001, Gorov 2001). The Fish and Wildlife Service claims to be unable to perform its duties because of the large number of legal challenges. The law has not been reauthorized since 1991, and proposed changes might leave actions regarding endangered species to the discretion of the Department of the Interior, rather than basing them on biological status. Under the new plan, citizens could petition for listings, but the government would not have to respond promptly, nor would it have to act on designating critical habitats for endangered and threatened species (Gorov 2001). So little money--$6.4 million--is budgeted for listing that a stalemate is inevitable. Other proposals by the Bush Administration would cut overall spending on endangered species programs by $11 million, leaving the Office of Endangered Species without the means to accomplish its purpose (Gorov 2001).

A number of private organizations have aided in preserving endangered and endemic plants not listed on the Endangered Species Act. The Nature Conservancy and its state Natural Heritage Programs have purchased or arranged purchase of hundreds of thousands of acres of land for threatened plants. Arboretums and botanical gardens,

such as the Missouri and the New York Botanical Gardens, also are active in this regard. Lady Bird Johnson helped found the extremely effective organization, the National Wildflower Research Center, which aids in the conservation of wildflowers. In the northeast, the New England Plant Conservation Program has spent six years collecting seeds from some 500 rare plants for a seed bank. The New England Wild Flower Society has been instrumental in this program, and many sanctuaries throughout the region are preserving threatened plants.

The actions of individual states under their state endangered species laws and Natural Heritage Programs have also been crucial to the survival of many species that are threatened within a state or region, but might not qualify for federal listing. Programs to reintroduce Bald Eagles (*Haliaeetus leucocephalus*), Peregrine Falcons (*Falco peregrinus*), threatened fish and River Otters (*Lutra canadensis*) have brought back these species in many areas where they had been eliminated by pesticides, over-trapping, pollution or water projects. Many programs have involved cooperation between state and federal endangered species officials.

Habitat Conservation Plans (HCPs) are agreements worked out between landowners and the Fish and Wildlife Service for listed endangered species under a 1982 amendment to the Endangered Species Act. In essence, they are the result of deals made among developers, state and county officials, Fish and Wildlife Service representatives and local citizen groups on large tracts of land, in which portions of endangered species' habitats are protected, while development is allowed on the rest. HCPs are a permanent contract that cannot be amended, even if biological information is revealed showing that they were in error. These HCPs have been the center of much controversy, considered by some conservationists to compromise the principles of the Endangered Species Act, and by others to be an excellent means of protecting species. HCPs are not presently published in the *Federal Register* prior to signing by the Secretary of the Interior, which would subject them to public comment.

In 1997, a team of 119 scientists, financed by the National Science Foundation and the American Institute for Biological Sciences, carried out careful appraisals of signed HCPs and reported on their conclusions. They found that crucial scientific knowledge was lacking about many of the species involved in these agreements (Yoon 1997). They also found misuse of scientific methods and biological data which will end in harming, rather than helping, many species (Yoon 1997). Dr. Peter Kareiva, a University of Washington ecologist who organized the study, concluded that many HCPs should not have been written, and only about half correctly employed science (Yoon 1997). Of 206 HCPs examined in total, 44 of them in detail, one-third lacked information as basic as life span of species, and the vast majority did not include data on rates of population rise and decline and habitat changes (Yoon 1997). The most glaring problem seen by the scientists was the failure of HCPs to correctly assess the impact of losses to species' populations, mainly as a result of untested methods of appraising impacts. One plan proposed to protect Utah Prairie Dogs (*Cynomys parvidens*) by moving animals to a new location using a method already known to result in the deaths of 97 percent of the relocated animals within three months (Yoon 1997). An HCP for the Desert Tortoise (*Gopherus agassizi*) in Nevada allowed the killing of hundreds of these threatened reptiles by bulldozing their burrows and habitat, while protecting only minimal amounts of habitat.

A major problem faced by those trying to save endangered species is the fact that the vast majority live on privately owned land, and arrangements must be made with owners to insure the survival of these species. Many people believe that protecting these species involves major restrictions on the use of their land and, therefore do not want to enter into Habitat Conservation Plans. Ideally, however, protecting a threatened butterfly or plant on a private ranch, for example, would only involve identifying the habitat, the host plants for the butterfly, and preventing destruction through excavations or other major alteration of the land. In many cases, cattle grazing is compatible with protection of rare species, since the land is not plowed, which can destroy plant life. Ranchers in southern Arizona have cooperated in protecting the land through preventing overgrazing and maintaining riverbank vegetation and springs for rare frogs and birds. For many endangered species, conservation easements are an excellent solution for their protection. These easements involve the payment of funds to the landowner by private organizations, or local, state or federal governments to let the land remain undeveloped and help enhance it as wildlife habitat. This is an especially good solution for farmers who are afraid of losing their land after years of crop failure or low market prices. Innovation has marked many arrangements now being made to protect endangered and endemic species.

The US public as a whole supports the protection of endangered species, which helps explain the Endangered Species Act's survival under strong opposition. Polls conducted in November 1994 by Peter D. Hart Research Associates found that 57 percent of the public wanted to maintain the Endangered Species Act in its present form, and only 32 percent wanted to relax requirements. A September 1995 CNN poll asked which was more important, saving endangered species or saving jobs: 48 percent replied endangered species, and 40 percent, jobs. A Gallup poll carried out for CNN in April 2001 found that support remained strong. It asked Americans whether they supported environmental and wildlife protection even if it meant higher prices or more jobs, and again, a majority supported conservation. They were also asked to rank environmental protection in terms of its importance as an issue, and most placed it near the bottom of the list. When asked whether it would be an important issue in 25 years, however, the majority said it would be among the most important issues. This reflects a failure to understand the ongoing wave of extinctions that is eliminating many of the Earth's most fragile plants and animals and its possible effect on humans.

Thus, education is extremely important, especially its role in relating American lifestyles and waste of resources to the extinction and endangerment of species. A 2001 film, "Natural Connections" (Howard Rosen Productions, shown on PBS), addresses this issue as well as the gradual diminution of biodiversity. The overconsumption that Americans take for granted impoverishes nature in the US as well as in other countries that export their tropical hardwoods; cut flowers; leather from cows grazed in former rainforests; non-organic, sun-grown coffee; minerals; and handcrafts from scarce materials to this country. Other products are manufactured as a result of polluting the environment and, like coated paper cups or pulp magazines, are used once and thrown away. To maintain such a throw-away lifestyle, millions of trees are cut each year in the United States and elsewhere, disrupting ecosystems and threatening wildlife. Pollution is created from mines that poison rivers, and manufacturing and power plants that spew dioxin and greenhouse gases into the air. The urgency that gave rise to legislation early in the 20th century that protected native birds and other wildlife from overexploitation for commercial purposes was enacted after the extinctions of the Passenger Pigeon and Carolina Parakeet, and near-extinction of the American Bison (*Bison bison*) and other animals from 19th century slaughters. It would be tragic if a similar wildlife or environmental catastrophe were needed to spur strong action to preserve the world's genetic and biological heritage.

Threatened Species of the World

The *2000 IUCN Red List* found 3,507 vertebrates and 1,928 invertebrates in high degrees of threat worldwide (Hilton-Taylor 2000). Plants classified as Critical, Endangered or Vulnerable totaled 5,611 species. These are minimum figures because only birds and mammals have been thoroughly examined for status. When assessments are carried out on the remaining species, the list will doubtless grow far longer.

Many of the most magnificent, graceful, beautiful and zoologically curious animals on Earth are threatened with extinction. A growing number of these, such as sea turtles, sharks and crocodiles, have survived virtually unchanged for hundreds of millions of years, and if not for the human activities that are pushing them toward extinction, they would likely survive millions more.

Almost all the graceful cranes, on Earth since the Miocene Epoch, are endangered from loss of habitat and hunting. The entire family of prehistoric-looking rhinoceros is teetering on the brink of extinction. New Zealand's extraordinary and primitive kiwis and ancient tuatara lizards, which have survived since the dinosaur epochs, may be lost in the next few decades. Eleven of the 16 species of penguins are now threatened, nine in higher categories (BI 2000). Seabirds of many types, including the majority of albatross, are now listed.

The most surprising finding was the high number of mammals listed: 2,046 species, of which 1,130 species were in higher categories of threat (Critical, Endangered and Vulnerable). Thus, of the approximately 4,000 species of mammals, 28 percent are highly threatened, and more than half are in some degree of threat. They are the most imperiled class of animals. Twelve percent of birds, or one in eight species, are listed in higher categories of threat (1,186 species), and an additional 809 species are in lesser categories (Near-Threatened, Conservation Dependent, or Data Deficient), totaling 1,995 species or about 18 percent of the world's birds (BI 2000). Reptiles are a group less well assessed, but 750 species are at risk in all categories, according to the *2000 IUCN Red List*. Amphibians, which number about 4,550 species worldwide, have a minimum of 226 threatened species, and a large additional number that have not been thoroughly assessed. Likewise, very few marine fish are listed by the IUCN because so little is known of their status. Some progress is being made in assessing marine fish, especially coral reef fish and sharks and rays. By 2003, a complete assessment of the shark family is planned by IUCN (Hilton-Taylor 2000). Approximately 1,183 fish are listed in the most recent *IUCN Red List* in various categories of threat. The majority of these are freshwater species, which represent 6 percent of all known fish.

The rate at which animals and plants are declining has reached such proportions that even familiar species considered common with stable populations only a decade ago are now threatened. The African Lion (*Panthera leo*) and many African antelope, Giraffes and wildebeests are in serious decline, or exist only in parks and reserves, categorized as Conservation Dependent.

Animals listed as Near-Threatened or Data Deficient totaled 3,324 species, of which 2,364 species are vertebrates in the *2000 IUCN Red List*. The grand total of 8,759 vertebrates in all categories comprises 20 percent of all mammals, birds, reptiles, amphibians and fish on Earth. In the early 1980s, only 1,000 vertebrates were listed by the IUCN. This means that in just 20 years, this total has risen by almost 900 percent.

Plants have been assessed in several reports. The *1997 IUCN Red List of Threatened Plants* (Walter and Gillett 1998) was supplemented--and many species reassessed--by the *2000 IUCN Red List* (Hilton-Taylor 2000). Plants from Cameroon, the Galapagos, Mauritius and South Africa were added to the 2000 list. A total of 6,932 plants were listed in all categories, 5,611 in higher categories of threat. In spite of these major undertakings, only conifers were thoroughly assessed. The 1997 study, using one type of definition based on status alone, found 30 percent of all conifers to be either Endangered or Vulnerable; the 2000 reappraisal, using new criteria, determined that 16 percent were threatened (Hilton-Taylor 2000). When far more species of plants are assessed, The Nature Conservancy study of US plants (Stein *et al*. 2000), which found one-third of plants to be threatened, may be indicative of a great decline in the world's plants.

As in the case of animals, many of the Earth's oldest species of plants are at high risk of extinction. Trees that predated the dinosaurs and survive in pockets in Chile, New Zealand, New Caledonia, Australia, New Guinea and parts of Southeast Asia are being destroyed, with little knowledge of their extreme botanical importance. Many of these are among the largest trees in the world, rivaling the Redwoods in height and the Sequoias in girth (see Forests chapter). Others, such as the monkey puzzle tree family, are extremely bizarre in appearance, and may contain important compounds for medicines. Beautiful primitive flowers, the protea, are also greatly threatened, with many species growing in South Africa. Tree ferns, palms and hundreds of orchid species are also highly threatened. The island of Mauritius has a large number of threatened plants, many of which are quite unique.

Many zoologists and conservationists are now resigned to the rising level of extinctions and believe that, within a century, 80 percent of all species living today will be extinct. Such predictions may be overly pessimistic, but unless the public is made more aware of the precarious status of a growing number of plants and animals and demands strong action, the prognosis may be fulfilled.

What is Threatening Species?

Human activities are at the root of virtually all extinction threats. Destruction of fragile habitats, wetlands, coral reefs, tropical and temperate forests, rivers and grasslands has accelerated in recent years due to human population increases and commercial exploitation of forests, ocean fish and other wildlife, as well as the introduction of non-native species, either intentionally or accidentally. The massive pollution and chemical contamination of air, water and soil--and even the atmosphere that surrounds the Earth--are altering the climate and bringing about unforeseen declines in wildlife and plants.

Human Tragedy and the Looting of Virunga's Treasures

What is Threatening Species? Human Population Growth

Burgeoning human populations provide the major impetus for destruction of the last havens for rare species. In 1650, when Dodos were still common on the island of Mauritius, the world's human population totaled about 500 million, half of India's present population. Two hundred years later, the number had doubled to 1 billion. In 1900, the world's population totaled 1.6 billion. Since then, it has taken shorter periods for the world's population to double, and at present it doubles approximately every 37 years. In 2000, 6 billion people lived on Earth, a number expected to rise to

between 8.5 and 9.4 billion by 2050. While population growth has leveled off in parts of Europe, Russia and Australia, it continues to rise in the United States, mainly as a result of immigration. The highest rates of growth, 3 percent or more, occur in Africa, Asia and Latin America, where environmental deterioration has been severe. The similarity between the astronomic rise in human population and the extinction rate of animals and plants is not accidental.

Settlers in increasing numbers are entering tropical forests, grasslands and other wild areas teeming with wildlife, and clearing them for grazing livestock and planting crops. Loggers in the Brazilian and Central African rainforest wildernesses are building roads to transport entire forests of trees, some thousands of years old, to be sold in markets in North America, Europe and Asia. The roads open up the forests to settlers and hunters, endangering countless species of animals. Commercial exploitation of forests has increased rapidly since the 1980s, with logs turned into pulp for paper, expensive lawn furniture, paneling, shipping cartons, and even concrete molds that are used once by builders and thrown away. Rivers are becoming increasingly polluted from human waste that goes untreated in many parts of the world, and billions of people scratch out a living by subsistence farming, cutting trees for fuel and grazing livestock.

These poverty-stricken people have caused the limits of the Sahara and Sahel in Africa to expand by depleting wildlife and trees, and have razed forests in India, China, Indonesia, Thailand, Ecuador, Central America, Mexico and West Africa. Still, many go hungry because they have far outstripped what the land could supply sustainably. For the wealthier nations, an appetite for material goods and demand for a high standard of living have encouraged a market for precious resources, such as tropical lumber and wildlife products, that has expanded in recent years with the World Trade Organization (WTO) globalized economy. In order to repay loans granted to them by international funds, many poor nations strip their forests and grow exportable crops on the land. In the United States, urban sprawl and overexploitation of forests and other resources have threatened a host of animals and plants. Water is diverted for these new towns, endangering native fish and forests. In Arizona, the Sonoran Desert, a botanical world treasure, is now being destroyed by the expanding cities of Phoenix and Tucson.

The needs of the growing numbers of people worldwide have spawned many ill-conceived and environmentally destructive projects. Indonesia and Brazil opened up the most biologically rich forests on Earth to farming by people living in overpopulated cities. The soil is poor in tropical forests, and they must keep clearing land to find new areas for crops, gradually destroying vast areas once teeming with wildlife. China has moved people into western grasslands, where they have eliminated wildlife and caused massive erosion and desertification with agriculture and overgrazing of livestock. Dust storms from this region have been circling the globe in recent years. China has also commissioned the world's largest dam, Three Gorges--on the Yangtze River--in an attempt to control floods and generate electricity. In the process, a very rare freshwater dolphin, a sturgeon, and hundreds of rare plants will become extinct, and the dam's lake will fill with untreated sewage. The problem of overpopulation has not been well understood or coped with in the majority of countries where populations are now outstripping food supply.

In most parts of the world, however, people have deforested the habitats and killed prey species of wide-ranging wildlife that have nowhere else to go. Asian Elephants (*Elaphus maximus*) and Tigers (*Panthera tigris*), for example, have been deprived of habitat and food and crowded into areas too small for their requirements. When they rampaged into people's gardens or killed livestock, they were killed and their body parts sold for high prices. Both species are now endangered, their populations fragmented and in steep decline. This is a pattern that has been seen with large animals, especially predators, throughout the world. Animals or plants with low populations as a result of restricted habitat size or specialized requirements for survival have been pushed to the brink of extinction as humans moved into their habitats.

Only a few countries have national policies to encourage stable populations. In some countries with populations that far exceed the ability of the land to adequately sustain them, wars have broken out, providing an apocalyptic vision of a violent future for the Earth should present trends continue. A scientific study, *Environmental Change and Violent Conflict* (Homer-Dixon *et al*. 1993), predicted that as human populations increase and resources decrease, wars will

occur with ever greater frequency. Population Action International, a Washington, DC-based organization, calculated in 1997 that although human population growth has slowed somewhat, water resources remain under serious threat. This organization's report warns that by 2050, people in the Middle East and parts of Africa, where populations continue to grow at high rates, will be engaged in bitter, violent conflicts over water. The story of the Rwandan war, described later in this chapter, reflects this cause and effect. Overpopulation causes human suffering, permanent damage to the land from overuse, and the destruction of the very species that might prove life-saving. A few countries, such as Singapore, launched education programs decades ago, urging people to have smaller families for a better quality of life. The rate of population increase in this tiny country is now less than 1 percent, and literacy is 91 percent.

Medical advances preventing disease and early mortality in people around the world, combined with growth in agricultural output, have played a major role in the nearly four-fold rise in human population since 1900. The World Health Organization (WHO) has scoured the planet eradicating disease but is not required to educate people about birth control methods. This has decreased natural mortality and fueled population booms. The majority of international aid projects lack overview, coordination with one another and long-term planning. Supplying high-yield grain and financing irrigation projects to poor nations, without providing birth control education, results in a doubling of populations within a generation, which negates any rise in the standard of living and education levels. By encouraging livestock and agriculture in dryland areas, with little knowledge about the natural environment or its capacity to support large numbers of people, wildlife and plants are displaced or killed, and in years of drought, crop failures result, causing starvation. The human suffering brings international aid with emergency food, and instead of relocating people to other areas, these programs encourage replanting and a repetition of the misfortune.

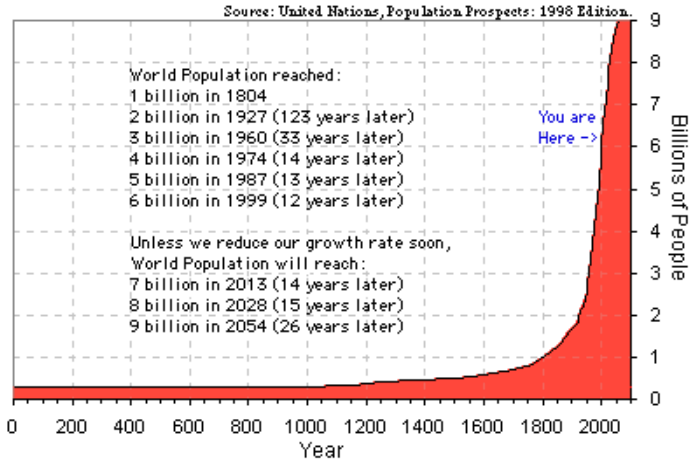
Ethiopia and Somalia are examples of such policy failures. These countries were covered in a mosaic of grasslands and forests teeming with endemic wildlife early in the 20th century. An influx of large numbers of people and livestock, encouraged by aid programs, denuded this region to arid desert. The vast numbers of wildlife have largely disappeared or become endangered as the extensive grasslands, rivers, lakes and highland forests disappeared because of overgrazing, farming in areas too dry to produce crops and deforestation for firewood (see Grasslands, Shrublands and Deserts chapter). With low human and livestock population densities, these areas could have remained ecological treasures.

The Population Institute of Washington, DC, warns that although some countries have shown declining rates of population increase, especially those in Western Europe and North America, this will not result in an overall decline in world population because of greater human longevity, continued high birth rates in at least 74 countries and a high survival rate (Holmes 1997).

The top 10 countries in terms of overall numbers of people have 59 percent of the world's population. More than 30 percent of all births in 1997 took place in India, a country expected to overtake China as the world's most populous nation by 2050 (Holmes 1997). A 1997 World Bank report, "The World Food Situation: Recent Developments, Emerging Issues and Long-Term Prospects," concluded that food stocks are not keeping up with need (Crossette 1997b). Demand for meat is increasing, placing further stresses on natural systems since livestock consume enormous amounts of grasses and grain, cause damage to vegetation and often pollute water systems; grain production is reaching the limit of potential yields, especially in Asia (Crossette 1997b).

The most densely populated country in the world, Bangladesh, with 127.5 million people, has about half the population of the United States in an area the size of Wisconsin. It has a density of almost 3,000 people per square mile, and a population growth rate of 2 percent a year. Ninety percent of the people in Bangladesh's countryside are illiterate and malnourished in spite of decades of international aid projects. Bangladesh is now totally dependent on foreign aid for minimum nutrition, and the land is being worked to maximize yields, using large quantities of fertilizer, irrigation and pesticides. The once vast mangrove forests that serve as fish and shellfish nurseries, and habitat for Tigers and other endangered species, are being destroyed piecemeal, cut for firewood (Worker 1996).

Funds to encourage birth control around the world have been deleted from US budgets by those opposed to abortion, thus thwarting all types of programs of education, birth control methods and related issues. Most organizations working to lower birth rates around the world use almost no funds for abortion, yet they find their funds cut for all family planning programs. This obstructionism has been a major setback to those working to stabilize the world's populations. The United Nations Population Fund has continued to carry out family planning programs, but with inadequate funds.



What is Threatening Species? Habitats Under Threat

Habitat destruction is the foremost threat to wildlife. In broad terms, more than 85 percent of IUCN-listed birds, mammals and plants are threatened by habitat destruction and degradation (Hilton-Taylor 2000). The greatest number of threatened species listed in the *2000 IUCN Red List* inhabit terrestrial areas. They total 9,256 highly threatened species. The largest single terrestrial group is plants, with 5,607 species; birds follow, with 1,144 species; with mammals having only slightly fewer threatened species, 1,111 (Hilton-Taylor 2000). The vast majority of threatened birds and mammals are terrestrial species. The destruction of forests is the single most important threat to birds, affecting 75 percent (BI 2000). At least 900 of the 1,144 threatened birds inhabit tropical rainforests, with almost half of those species restricted to lowland rainforests, and 35 percent in montane rainforest (BI 2000). Authors of *Threatened Birds of the World* (BI 2000) found that the vast majority--86 percent--of rainforest birds cannot tolerate much habitat destruction, and 45 percent require near-pristine habitat. Only 3 percent are highly tolerant of habitat alteration (BI 2000). Unsustainable selective logging affects 31 percent of threatened birds. In many tropical forests, logging and forest burning are taking place without any restrictions, totally eliminating habitats of rare rainforest birds. A total of 4.5 million square kilometers, or 20 percent of the world's forests, were cleared from 1960 to 1990 (BI 2000), and since then, forests--especially tropical forests--have continued their decline. Although some forests may return to old-growth hundreds or thousands of years in the future, much of the land is being converted to agriculture, grazing land, housing, cities, industry and roads and is unlikely ever to revert to forest.

Likewise, more than half, or about 57 percent, of threatened mammals inhabit tropical rainforests, 35 percent in lowland, and about 22 percent in montane rainforest (Hilton-Taylor 2000). Less than 10 percent of threatened birds and mammals are native to temperate mixed forests, coniferous forest and temperate broadleaf forests, according to the IUCN. A very small number of threatened mammals, about 3 percent, inhabit tropical degraded forest, a sign of the unsuitability of this habitat (Hilton-Taylor 2000).

Forests are also home to a wide variety of threatened frogs, salamanders, tree snails and insects, although studies of

which type of forest each inhabits have not been done by the IUCN. Many endangered plants are tropical species, native to islands such as Madagascar and Indonesia, where endemic plants such as orchids and palms abound, and habitat destruction is severe. The United States leads the world in threatened plant species, with 4,669 identified by the IUCN in its 1997 study (Walter and Gillett 1998) and 7,817 species listed by The Nature Conservancy (Stein *et al.* 2000). Many of the latter are in Hawaii, another tropical island with a high percentage of threatened plants. Lobelias are known for their beautiful flowers, and the ancestor species that arrived in the Hawaiian Islands radiated into 273 species, some of which grew to the heights of small trees. One-quarter are gone, and another 124 of the surviving species are threatened with extinction or possibly are extinct (Walter and Gillett 1998). Of the remaining lobelias, only 27 percent now have sizeable enough populations to keep them from extinction; the loss of their pollinators, most of whom were honeycreepers, is a major cause (Buchmann and Nabhan 1996). The honeycreepers lost their forest habitats to clearance by settlers, and as they faded into extinction--one species after another--lobelia plants they had pollinated disappeared or became endangered. These ecological webs exist throughout nature.

The IUCN found that 91 percent of plants identified as threatened were endemic, with their entire distribution restricted to a specific country (Walter and Gillett 1998). A total of 32,242 threatened or extinct species of plants occur in one country alone, while 2,368 occur in two countries, and only 709 plant species occur in more than two countries. Only scanty information on threatened plants is available from most countries in South America, Africa and Asia, which are expected to have large percentages of their native plants found to be threatened when assessed (Walter and Gillett 2000).

Grasslands, shrublands and savannahs are the second most important habitat for threatened birds, home to 383 species, or 32 percent of all listed species (BI 2000). Two-thirds of these birds inhabit shrublands; 43 percent, grasslands; and 8 percent, savannah (BI 2000). Three-fourths are tropical birds, whose habitats are threatened by livestock overgrazing, human settlement and farming (BI 2000). Some 17 percent of threatened mammals inhabit grasslands, while another 8 percent are shrubland species, and about 7 percent are native to desert and semi-desert (Hilton-Taylor 2000).

Freshwater habitats, such as rivers, marshes, bogs, streams and ponds are the second most important biome, after terrestrial, for threatened species. At least 1,946 threatened species, the largest number being fish (627 species) inhabit these areas (Hilton-Taylor 2000). Freshwater crustaceans (409 species) and mollusks (420 species) are major inhabitants of these aquatic areas, as are 131 amphibians, 111 reptiles, 78 birds and 31 mammals, according to the *2000 IUCN Red List*. The United States, with its extensive water projects--dams, levees, diverted and channelized rivers--harbors large numbers of threatened crustaceans and mollusks, as discussed above.

Frogs make up the majority of threatened amphibians and have been in decline for several decades. Their habitats are being destroyed at an unprecedented rate as wetlands are filled in--half of US wetlands that were present in colonial times--are gone. Thailand has lost almost all its wetlands, and Southeast Asian lakes and marshes are being drained at an unprecedented rate, threatening frogs and other wildlife. Frogs have been on Earth for 190 million years, but at the present rate of decline, the majority of the approximately 4,500 species will be gone within decades. In addition to habitat loss, a variety of threats are eliminating them (see Non-Native Species, Trade and Pollution sections below).

What is Threatening Species? Non-Native Species Introductions

Invasive species, or alien, non-native animals and plants introduced into ecosystems, present the most important threat to plants. The large numbers of threatened species that have limited distributions are highly vulnerable to the possibility of invasive species eliminating them from the wild. Islands have the greatest percentage of their native plants in danger of extinction. St. Helena, a small island in the South Atlantic, leads these in percentages, with 13

percent extinct or extinct in the wild, and 68 of 165 native plants and trees threatened (Walter and Gillett 1998). Livestock played a role in the extinctions and present status of many native plants (see Chapter 1). Mauritius follows, with 39.2 percent of native plants in danger, or 294 of 750 species (Walter and Gillett 1998). Other islands with many native plants threatened by exotic species include the Seychelles, Jamaica, French Polynesia, Pitcairn, Reunion and New Caledonia (Walter and Gillett 1998). Of the latter islands, all but French Polynesia and Pitcairn formed part of Gondwana, and many of the plants at stake are very ancient in origin.

One endemic Mauritian palm, *Hyophorbe amaricaulis*, has been reduced to a single plant. Although it grows vigorously and produces male and female flowers at different times, no fertile seeds are produced (Stearns and Stearns 1999). At the National Agricultural Station in Ireland, botanists cultivated the tiny embryonic growths found within the immature fruits; it is hoped that clones of the palm can be grown to adulthood (Parnell *et al*. 1986). Introduced animals and plants have taken over Mauritius and Rodrigues so completely that a number of species have been reduced to as few as two remaining plants.

Hawaii's native forests and plants have fared poorly, too. Native sandalwood forests were cut by early settlers, endangering several species. The most fragrant of these trees, the Iliahi (*Santalum haleakalae*), is now restricted to the dry lava slopes of eastern Maui. Its carmine red clusters of flowers have the same aroma as its fragrant heartwood (Daws 1993).

Seven or eight types of lobelia plants of the genus *Delissea* once flourished in Hawaii, and all became extinct by 1966 except one, *Delissea undulata*, which had become reduced to only a few plants. Conservationists fenced these plants in 1967 from the browsing cattle and rooting pigs, and they were thought secure (Carlquist 1980), but by 1995, the species' population had declined to a single plant. Botanists found it hanging by a few roots inside a sinkhole, the fence damaged and broken. The fence was repaired, and botanists are germinating seeds, hoping to prevent its extinction (Royte 1995). Another Hawaiian plant, *Cyanea pennatifida*, is in the same perilous status. Native to the mountains of Oahu, it also became reduced to a single plant, which was not producing its green flower. A botanist took a small sample of plant tissue and successfully cloned it in a test tube (Lipske 1997). Dozens of these plants have been cultivated from the slip, some of which were reintroduced into a preserve in 1995 (Lipske 1997).

Two hundred native Hawaiian plants are listed either on the US Endangered Species Act or are candidate species. Some 115 species have only 20 individual plants scattered in different areas or just one population of 50 or fewer plants in one location (Lipske 1997). Livestock and exotic plants have destroyed these plants and their habitats. One of these extraordinarily rare plants has been eliminated from all its original range, and the last members of the species cling to a single vertical cliff along the coast of Kauai, with its roots growing horizontally into rugged rocks (Carlquist 1980). This unusual lobelia, *Brighamia insignis*, has a thick, woody stem which tapers to a rosette of leaves, and it has lost its natural pollinator, which may have been a bird or an insect. Located 2,000 feet above crashing surf, it is out of reach of goats and pigs, but difficult for botanists to reach. This spectacular landscape is now this lobelia's sole habitat. Each year, botanists Steve Perlman and Ken Wood risk their lives by scaling the cliff, using climbers' ropes, to collect pollen from the plants with a brush. They then rappel to a neighboring plant to pollinate it, and months later, they must climb back up to collect the seeds, which are being placed into cultivation (Daws 1993; Royte 1995). Some of these seeds have successfully grown into plants at the National Tropical Botanical Garden on Kauai (Lipske 1997). This may be the most arduous and life-threatening plant conservation program in the world.

On the island of Guam, the forests have not been destroyed, but the bird life has been virtually eliminated by an insidious exotic animal that arrived in the 1960s or earlier. Several Brown Tree Snakes (*Boiga irregularis*) somehow secreted themselves in a shipment from their native Indonesia, and once on the island, they began to multiply. These snakes proved to be an environmental nightmare of the worst proportions, climbing trees and killing and consuming nestling and adult birds, and increasing at alarming rates. They have also caused major problems for the people of Guam. Ascending telephone poles, Brown Snakes short electrical wires. Between 1978 and 1990 alone, 1,000 power outages on the island were caused by these snakes (Jaffe 1994). A major threat to children, they enter homes, biting babies in cribs, and consuming pets. Untold millions of these snakes now live in virtually every environment in

Guam. By 1981, these snakes had eliminated native birds from most of the island except for a remote part in the north. The snakes obliterated nearly the entire avifauna of Guam, an estimated 750,000 birds. Once a verdant tropical island teeming with birds, the forests have fallen silent. Three birds became extinct: the Guam Flycatcher (*Myiagra freycineti*) and two distinct subspecies of birds that survive on other islands: the Guam Bridled White-eye (*Zosterops conspicillatus conspicillatus*) and the striking chestnut, black-and-white Guam Rufous Fantail (*Rhipidura rufifrons uraniae*) (Jaffe 1994). The flycatcher was the greatest loss because it left no subspecies on neighboring islands. The Guam Kingfisher (*Halcyon cinnamomina miyakoensis*) became extinct on the island as well, but fortunately, a small number had been taken into captivity. These kingfishers have been kept at several US zoos, but although they have produced some young, they have exhibited abnormal behavior, such as cannibalizing their chicks, and some have succumbed to avian tuberculosis.

The Guam Rail (*Gallirallus owstoni*) escaped extinction by a hair's breadth. The rail's population declined to about 2,000 birds by 1981, and in 1983, fewer than 100 remained; the last wild birds disappeared by 1987. The Guam Division of Aquatic and Wildlife Resources captured 19 rails in 1984 and, after captive breeding and holding, began releases in 1995 of 30 to 50 rails every three months on the neighboring island of Rota (Line 1995). Rota, a 209-square-mile island, is snake-free, but only one-fourth the size of Guam. Its forest is mainly intact (Line 1995). In 1999, the introduced Guam Rails bred on Rota for the first time (BI 2000). A small area of 24 hectares on Guam has been fenced off from snakes, and Guam Rails introduced there have also bred (BI 2000). About 180 birds survive in 14 zoos in the United States (BI 2000).

To date, no effective control has been found to rid Guam of the Brown Tree Snake. Metal bands on nesting trees of endangered birds and high-voltage electrical wires meant to kill them on contact have hardly made a dent in their populations. A native bird at the edge of extinction, the Marianas Crow (*Corvus kubaryi*), declined on Guam from 351 birds in 1981 to just seven in 1999 (BI 2000). On neighboring Rota, only 592 survived in 1995, down from 1,318 in 1981 (BI 2000). Guam still has a high percentage of forest cover and many aquatic habitats intact. Among the few mammals on Guam, the Marianas Flying-fox (*Pteropus mariannus mariannus*) has also declined, with a population in the mid-1990s of only about 300 animals. They suffered the effects of heavy hunting by the people of Guam for food, and the Brown Tree Snake is now killing juvenile bats. The endemic Guam Flying-fox (*Pteropus tokudae*) is now extinct, last seen in 1968. It was a probable victim of unrelenting hunting by natives for food but may have been killed off by the Brown Tree Snake. Shrews and other rodents and monitor lizards are disappearing from Guam as well (Jaffe 1994). Since many of the birds and bats served as pollinators of native trees and plants, these species may die out as a result.

Invasive species, mainly those introduced by humans onto islands, caused virtually all avian extinctions over the past few hundreds years. Today, almost 30 percent of threatened birds, or 298 species, are affected by introduced predators, particularly cats, rats, mongooses and other animals (BI 2000). Livestock introduced into avian habitats represents a major threat to 72 species of birds, and 71 bird species have been adversely affected by the introduction of invasive plants that eliminated the food or habitat of plants on which these birds depended (BI 2000). Pathogens, such as diseases and parasites, brought into avian habitats by various means threaten an additional 69 species of birds (BI 2000).

Introduced species threaten fewer mammals, about 69 species, or 10 percent of those listed by the *2000 IUCN Red List* (Hilton-Taylor 2000). This may be because far fewer mammals inhabit islands, compared to the number of native birds, especially flightless ones. Even sizeable islands, such as New Zealand, had very few native mammals prior to human colonization. Madagascar is an exception, with a very large diversity of primates and other mammals, a large number of which are now extinct because of invasive species, along with many other factors (See Islands chapter).

What is Threatening Species? Persecution, Hunting and Trade

A total of 367 species of birds are threatened by hunting for food (233 species) and trapping for the cage bird trade (111 species) (BI 2000). The majority of birds that are threatened by meat and feather hunting are Asian pheasants, grouse, partridges, bustards, guans, megapodes and other large birds (BI 2000). The family of birds most threatened by trapping for the cage bird trade is the parrot family, Psittacidae, with 57 percent of threatened species trapped for this trade (BI 2000). These parrots are native to Mexico, Central and South America, Africa, Asia and Australia, and some have been pushed to the edge of extinction (See Trade chapter). The Spix's Macaw (*Cyanopsitta spixii*), for example, had been reduced from several hundred birds in the wild in Brazil to a single male when he, too, was illegally trapped in late 2000. This species is now extinct in the wild.

Hunting and capture for commercial purposes threatens 212 mammal species (Hilton-Taylor 2000). Many mammals have been endangered by hunting and persecution, including a number of large predators. The number of bats on the threatened list has grown dramatically in recent years, with many fruit bats threatened by killing for food, and others by vandals or those who persecute them for supposed threats to human health. Trade affects about 29 percent of threatened mammals (Hilton-Taylor 2000). Both the Asian (*Elephas maximus*) and African Elephant (*Loxodonta africana*) species have been reduced to endangered status primarily as a result of killing for their ivory and meat. The 1989 listing of the African Elephant on Appendix I of the Convention on International Trade in Endangered Species (CITES) succeeded in putting an end to more than 90 percent of trade in ivory, which was pushing this species rapidly toward extinction. Since then, the ban has been weakened by pressure from ivory traders, and CITES allowed trade in stockpiled ivory taken from smugglers in southern Africa. This had the immediate result of increasing poaching of elephants throughout the continent, in anticipation of a lifting of the ban.

All rhinoceros species, two native to Africa and three to Asia, are critically endangered. Populations of the five species together total only about 12,000 animals, a result of heavy hunting for their horns, which are used in Traditional Medicine (TM) and as handles for daggers in the Middle East (see Trade chapter). The toll of animal species killed for meat, trade and the TM market numbers in the millions, of which a growing number are threatened. Tigers, Leopards and other wild cats, snakes, pangolins, monkeys, birds of prey, deer, seahorses, and turtles, and many other species are killed to supply this market. The Tiger is poached throughout its range because its body parts are worth $10,000 or more when sold in this market and as trophies. This species is killed in parts of its range by slow-acting poisons and leghold traps for trade, and predator control when it has hunted livestock after its natural prey was killed off. Species like the Tiger, which require large territories and are suffering high mortality from hunting throughout its range, as well as loss of habitat, are in imminent danger of extinction. Several conservation programs are attempting to stem the tide in favor of the Tiger and reduce demand for its body parts in TM. Stricter laws are needed throughout the world, however, to protect endangered animals. The bushmeat trade is a major threat to Central and West African mammals and a wide spectrum of species in Southeast Asia (see Persecution and Hunting chapter).

A thriving trade in terrarium frogs has resulted in a worldwide market for many species of these amphibians. The world's largest frog, the Goliath Frog (*Conraura goliath*) of Central Africa, weighs 7.2 pounds and reaches a length of at least 32 inches; it is found along major rivers in dense tropical rainforest in Equatorial Guinea and southwest Cameroon (FWS 1991). Throughout its range it is very rare, and it has unusual habitat requirements. It needs rapids and cascades with sandy bottoms and very clean, oxygen-rich water; deforestation has reduced this habitat. Collectors have offered huge sums up to $2,500 for capture and export of Goliath Frogs--as personal pets or for public exhibition. One US dealer imported 50 of these frogs and attempted to enter them in the Frog Jump Jubilee in Calaveras County, California (FWS 1991). The Endangered Species Act lists this species as Threatened throughout its range. The IUCN lists it as Vulnerable on the *2000 IUCN Red List*. Hundreds of other species are collected for

this trade, threatening many, including various mantella frogs of Madagascar, coveted for their golden color (See Islands chapter).

Although more reptiles than amphibians are killed for their skins, amphibians are now also being taken in large numbers for this purpose. In 1985, the United States imported more than 11,000 frog and toad hides and products worth $350,000 for the luxury trade in frog skin wallets, toad leather boots and other items (Fitzgerald 1989). Most of these skins come from a large Malaysian frog (*Rana macrodon*), but the Black-spined Toad (*Bufo melanosticus*) and other species are used as well (Fitzgerald 1989). Such products are extremely difficult to identify by species, making enforcement difficult.

Frogs are killed by the millions for high school biology class anatomy lessons, an unnecessary toll because computer programs and films now provide this information (see Projects section). For the restaurant trade, frogs are killed in even greater numbers. Indonesia and Vietnam are the major sources of frogs for restaurants and food markets in Europe and the United States. Prior to export bans, Bangladesh and India captured many millions of frogs each year for the restaurant trade. Several documentary films have recorded the process of removing the frogs' legs in Bangladesh and Indonesia; the same methods were used in each country. Once captured and gathered in large containers, the frogs' back legs are sliced off with a sharp knife or machete, and the still-living frogs are tossed into heaps, where they continue to struggle for long periods before dying. An increase in malaria was documented in Bangladesh after the frog trade caused declines in wild populations; the frogs had been controlling mosquito populations.

The Indian Bullfrog (*Rana tigerina*), a species native to southern Asia, was listed on Appendix II of CITES after heavy trade depleted it. Some of these shipments were seized: In July 1997, a shipment from Vietnam containing the legs of 450,000 Indian Bullfrogs was intercepted in Holland as a CITES violation; the container with the frogs' legs weighed almost 20 tons and was en route to a wholesaler in Canada. This shipment alone represented frogs from vast areas in Vietnam, depleting wetlands of these ecologically important amphibians. Even in US National Parks, frogs are commercially hunted. In Florida, for example, frog hunters in airboats capture millions of frogs during night hunts. In February and March 1996, 6 tons of frogs were taken from Big Cypress National Preserve for sale to restaurants and for private consumption, according to environmental groups which have petitioned the National Park Service (NPS) to end or limit this hunt (Dodds 1996).

The reptile product trade placed virtually all large crocodilians on the endangered list by the early 1970s after imports of millions of skins for luggage, shoes and handbags nearly caused extinctions of species in South America, Africa and Asia. Although controlled to some degree by CITES, a large percentage of trade is illegal, composed of protected species (see Trade chapter). The luxury trade in these products is now threatening many snakes as well as lizards, whose skins can be sold for very high prices. These reptiles, which play important roles in nature--culling rats and other rodents and preventing overpopulations of fish--are taken from the wild. Snakes are being captured in such numbers for this trade and for the Asian medicine and restaurant trades that they have disappeared from areas where they had been common. (See fiEndangered and Threatened Species of Mammals, Birds, Reptiles and Amphibiansfl in the Appendix for an extensive list of these reptiles now threatened with extinction.)

What is Threatening Species? Pollution and Disease

Pollution by acid rain and acid from coal mines that drains into streams and rivers, heavy metals, PCBs, dioxin and other toxic chemicals, have killed off all life in waterways in many parts of the world. PCBs and pesticides have caused serious genetic malformations in frogs, birds and fish.

Frogs have been dying from fungal diseases and the indirect effect of other pollutants, which are eliminating entire species. Necropsies done on frogs from Australia and Panama, which were found dying, have revealed the presence of the same fungus, chytrid (Morell 2001). It is considered responsible for the extinction of several Australian frogs, including the extraordinary Gastric-brooding Frog (*Rheobatrachus silus*) and three other species, and has infected frogs in Panama as well, eliminating populations and possibly species (Morell 2001). This fungus has been detected in 44 species of Australian frogs and is apparently spreading in many parts of the world. Other fungi and viruses have eliminated frogs in the United States (Morell 2001). These diseases have long been in the environment, and it is not yet clear why they have become so toxic and virulent to frogs. Frogs have thin skin and easily absorb chemicals, making them vulnerable, but apparently their immune systems have been weakened, as well. Frogs and toads are also threatened by pesticides, which have been shown to cause grotesque deformities and mortality. Many types of pollution, including acid rain, heavy metals and fertilizers, have eliminated frogs in many parts of Europe and Canada (Morell 2001). Ultraviolet radiation (UV) suppresses frogs' immune systems and kills eggs as well as adults. Andrew Blaustein (1994), an American biologist, conducted experiments that proved UV to be responsible for wiping out many species of frogs in the US West who laid their eggs in the open. The eggs were thus exposed to this radiation, which has intensified as a result of the decrease in the ozone layer caused by chloroflourocarbons, used by industry in air conditioners and refrigerators, among other industrial uses (see Aquatic Ecosystems chapter).

Hawaiian birds have been seriously affected by avian malaria, brought to the islands by captive cage birds, as discussed in Chapter 1. This disease continues to threaten the surviving species of native birds, and is a major cause of the wave of extinctions that is claiming one species after another of these beautiful songbirds (BI 2000). Several species, such as the Nukupu'u (*Hemignathus lucidus*), are now in Critical status, possibly extinct on both Kauai and Maui where, until the 1990s, a few birds were seen in their montane forests (BI 2000). Feral pigs in their habitats facilitate the spread of alien plants and introduced, disease-carrying mosquitoes (BI 2000).

What is Threatening Species? Traits of Vulnerable Species

By identifying the traits that characterize species likely to become endangered or fade to extinction, it is possible to afford them and their habitats extra protection and carefully monitor their status. The tragic losses of so many of these "red flag" species should be avoided in the future, and can be, with remedial action. Ideally, species should be conserved when their populations are still healthy, before they become genetically impoverished and their populations fragmented. The list below includes some of the characteristics many extinct and endangered species possess. Undoubtedly, the more we learn about the causes pushing wildlife and plants to extinction, the longer such a list will become.

1. Endemic species, or animals and plants that are restricted to a relatively small area, such as an island, are inherently vulnerable to extinction. They have incurred the greatest number of extinctions in the past 400 years. Changes in their habitat or losses to their populations can eliminate them. Many of these species were confined to areas that measured only a few square miles. Mainland species, likewise, can be endemic to small areas. The Slender-billed Grackle (*Cassidix palustris*) once inhabited a single marsh near Mexico City. The marsh was filled about 1910, spelling extinction for this bird. Many endangered species fall into this category.

2. Specialization of habitat or diet has caused much extinction. Animals that depend on a certain type of habitat or food source and cannot adjust to alterations, whether natural or human-caused, are extinction-prone. The Ivory•billed Woodpecker requires large expanses of old-growth forests with many dead and dying trees. The endangered Kirtland's Warbler (*Dendroica kirtlandii*) of Michigan will colonize only one type of forest: stands of jackpine trees that are eight to 22 years old on well•drained, sandy soil. This habitat must now be artificially maintained to prevent the bird™s extinction. The Palila (*Loxoides bailleui*), a Hawaiian honeycreeper, is dependent on the mamane tree for

feeding, which has declined as a result of logging and destruction of seedlings by introduced game species and livestock. Many endangered plants require specific soil type, climate, drainage and sunlight exposure. For those species that require unbroken stretches of habitat, such as old-growth forest, endangerment or extinction can result if the forest is fragmented.

3. Long•lived species with low reproductive rates and low natural mortality are vulnerable to extinction. Fast-reproducing species that have many young at frequent intervals and high natural mortality rates tend to be more resilient to population losses and recover quickly if their habitat has not been destroyed. Not all vertebrates fall easily into these categories, but many do, and these groupings can be at least one indication that is useful in terms of predicting which species will become endangered when their populations are reduced. Slow-reproducing animals decline rapidly from losses in their numbers, and since they often do not breed until a relatively advanced age and have few young, many decline to extinction. In some cases, such animals do not recover their former abundance, or recover very slowly. A few of these animals, including sea turtles, lay many eggs, but only a small percentage of the hatchlings survive to adulthood. Although few of the now extinct animals were ever studied in the wild, enough is known of related species to guess that many fell into this category. The Steller's Sea Cow (*Hydromalis stelleri*), for example, was a member of the Order Sirenia of manatees and Dugongs. The surviving species have few natural enemies, do not breed until age 7 to 10 years old, and have only one young every five years. Hunting caused the extinction of Steller's Sea Cow in the space of a few years, eliminating the only cold-water member of this family. Hunting threatens surviving species of this family in many areas. Manatees and Dugongs are very slow-moving, making them easy targets. The Steller's Sea Cow may have numbered only a few thousand animals in its limited distribution near islands in the Bering Sea. Even when able to swim away, they refused to leave their mates, beaching themselves on the shores next to the slain mate. Such animals can probably not tolerate any hunting. Manatees and Dugongs, likewise, need strict protection.

Many large birds, including condors, eagles and large parrots such as macaws, have low reproductive rates. The Cuban Red Macaw (*Ara tricolor*), became extinct in 1885. If its breeding biology resembled other large macaws, it was long•lived, reaching an age up to 80 years, had only one or two chicks a year and did not breed every year. Scientists have recently discovered that even in an immense national park in Peru, wild macaws produce so few young that any losses in their numbers cause declines in their populations. This helps to explain why so many birds of prey and parrots are endangered. Passenger Pigeons were long•lived, laid only one egg, and may not have nested every year. Likewise, turtles and tortoises are long-lived, with at least one species, the Galapagos Tortoise (*Geochelone nigra*) documented as living to more than 165 years in captivity. Some shark species do not breed until the age of 20 years and produce only a few young.

4. Flightless birds and slow•moving animals are helpless in the face of hunting pressure and predation by introduced predators and humans. Unwary animals, such as many island species that have evolved in the absence of predators fall into this category. Flightless birds, such as the Great Auk, Great Elephant Bird, Dodo, many Pacific Island rails and tortoises, are among species that lack defenses or cannot quickly escape predators, human or other. In addition to being flightless, many extinct birds lacked defensive behavior or the instinct to hide in underbrush as a result of their having evolved in predator-free environments. Predators introduced into their habitats, as occurred on many islands, soon eliminated them. Even the thick shells of tortoises were not effective defenses against predators such as rats, who ate young tortoises, and humans easily captured these slow-moving animals. Although our attitudes are more humane toward these vulnerable animals today than hundreds of years ago, tortoises and sea turtles are still killed for trade or by vandals for sport. Some surviving flightless birds on islands have official protection and a better future than they had in previous centuries, while others do not.

5. Large animals have been vulnerable to overhunting since the Pleistocene Epoch. In recent centuries, whales were added to the list of large species unable to escape guns or harpoons. The largest lemur and bird species of Madagascar were killed off by the Malagasy immigrants thousands of years ago, as were many large flightless birds by the Maori when they first arrived in New Zealand. Large animals are often killed merely because they make large targets or for trophies for those who enjoy slaughtering animals. Animals of large size require considerable amounts

of habitat and are, therefore, naturally more rare than species with smaller habitat requirements. When human populations rise and wilderness is replaced with towns and industry, large animals are the first to disappear, due either to loss of habitat and prey or because they are killed as potential threats. Most of the largest mammals on Earth are now on the endangered list of the *2000 IUCN Red List*, including both species of elephants, all the rhinoceros species, and many large antelope and big cats such as the Tiger, Cheetah, Leopard and Lion. They have declined from hunting or persecution and are being crowded out of their habitats by human activities. Large animals are often keystone species at the top of their food chains or play important roles in ecosystems. Their absence is indicative of damaged or incomplete ecosystems. Elephants are important in spreading seeds of many plants through their dung, and large predators play a major role in the health and physical characteristics of their prey. The African savannahs without Lions, Leopards and Cheetahs would soon be overpopulated and overgrazed by their numerous prey species. The Elk of Yellowstone National Park became overpopulated in the absence of the Gray Wolf, and grazed certain plants so heavily that some bird species and other wildlife disappeared and certain tree species became rare. In spite of the wolves™ importance to ecosystems, they are killed with impunity by livestock owners and others who consider them threats.

6. Wild animals and plants which have a value as food, pets, ceremonial objects or marketable products to humans are prime candidates for extinction. The list of animals that have been hunted to extinction for food is long. Within the past 400 years, many large land tortoises, the Great Elephant Bird, moas, Steller's Sea Cow, Auroch and Quagga were all extinguished by hunting for food. The unique Huia bird of New Zealand had plumes that were sold for large sums, helping to drive its limited population to extinction. Hawaiian songbirds were hunted to extinction for their colorful feathers, which were used in ceremonial headdresses and capes. Within the past decade, trade has increased as a threat to wildlife with the rise in Asian economies. This has fueled the Traditional Medicine markets, which consume vast numbers of animals, threatening many of them. The vacuuming of the seas by commercial fisheries has resulted in depletions and endangerments. The once abundant sturgeon of the Caspian Sea, for example, sources of Beluga and other expensive caviar, are now critically endangered as a result of unrestricted fishing and poaching for the luxury gourmet market. The bushmeat markets of West and Central Africa sell tons of slaughtered monkeys, forest antelope, Chimpanzees, Gorillas and other wildlife, devastating species whose tropical forest habitats are being logged. Hunting for food is also a major threat as firearms become available to native peoples who once used primitive weapons. Southeast Asian wildlife is under siege by people who once hunted only for their own purposes but now find that a wide range of wildlife can be sold in local meat markets or for Traditional Medicine. They set nooses and traps, killing rare monkeys and antelope, birds, snakes, turtles and tortoises, pangolins and lorises, clearing out the forests of wildlife. The pet trade is driving many colorful tropical birds, reptiles and primates to endangered status. Luxury goods, such as high-priced reptile products, provide an incentive to hunt--legally or illegally--lizards, crocodiles and snakes for this market, endangering many species. Trophy hunting of endangered species by wealthy hunters is a major threat to a growing number of animals, especially since the largest specimens are killed; these are the ones that should be left to breed. The higher the value of the animal or product, the greater the threat to that species.

7. Altruism, or the unselfish care for members of one's own species, highly admired as a human trait, has been fatal to many animals--the Passenger Pigeon, Dodo, Carolina Parakeet and Steller's Sea Cow, for example. In their evolutionary history, this behavior served to preserve bonds between animals and to frighten off predators. When confronted with guns or other weapons wielded by humans, however, animals that come to the aid of fallen mates or flockmates can be easily killed themselves. Refusal to leave their wounded fellows hastened the extinction of many species. Endangered species with these traits include wolves, gorillas, whales and elephants.

8. Species breeding in colonies or requiring large numbers of their own kind for protection, to locate food sources or for other means of survival, are vulnerable to extinction. The Passenger Pigeon was a colonial nesting bird and could only survive among large numbers of its own species, flocking and seeking food sources over large areas. When flocks were fragmented, these separated populations declined to critically low levels, even though their total numbers may have been in the tens of thousands. The Passenger Pigeon may have become critically endangered as soon as its migrations, feeding and nesting behavior were interrupted, even though it appeared to observers at the time

to be plentiful. These pigeons had longevity of several decades, and failure to reproduce would take some time to be noticed in the overall population. But when there is little or no introduction of young into a population over a period, it can suddenly crash with little warning, as the Passenger Pigeons did. Wild parrots tend to feed, roost and spend their time preening and in courtship as a flock. For some species, these flocks number in the thousands of birds. When netted or caught by various means for the pet trade, which threatens a large number of species, their flocks are broken up and they are no longer able to function as a group. Their breeding is curtailed or stopped altogether, and they may no longer fly in groups seeking fruiting trees or mineral licks when they fear being captured. Flamingos require large numbers of their own kind for feeding, flocking, migrations and breeding, and their populations crash if any of their survival requirements are not met.

Many species of birds have breeding strategies in which male birds will not breed unless they are able to display courtship behavior in the company of other males, vying for the approval of females. Birds of paradise, cocks•of•the•rock in South America, prairie chickens and grouse of North America are among birds that display for the benefit of females, who choose among them. Such birds require specific conditions to breed, and habitat alterations, reductions in their populations or hunting pressure that keeps them from exposing themselves in the open can prevent their breeding.

Mammals, reptiles and amphibians also have male contests of strength, agility or other mark of superiority of species. Wild sheep and deer vie for females by head butting and challenging one another. Many types of tropical frogs emerge during the breeding season to form groups that display to one another for the benefit of females. Male Plowshare Tortoises joust with one another in attempts to upend the rival and will not breed if only a single male and a female are placed together. Without rivals for competitions, male breeding behavior may not be triggered, preventing reproduction.

Zoos and zoologists are only beginning to understand some of the instinctive responses necessary for breeding. Our traditional concept that a compatible pair of animals will reproduce is often incorrect, and populations of animals must not be allowed to be so reduced that their natural breeding behavior and other survival needs are not met.

Thus, while population numbers can provide important information about the status of a species, without additional information, such as the traits mentioned above, the data can be extremely misleading and inapplicable. The number of individuals surviving in a species, when known, must also be placed into a context greater than their rate of decline and habitat status. Unless the entire breeding biology, behavior and other aspects of species' survival needs are taken into account, extinction cannot be predicted, or status properly evaluated.

Some species now extinct suffered from several of the above factors, which hastened their extinction. The Passenger Pigeon, for example, required enormous amounts of food, mainly from nut-bearing trees in old-growth forests, and was relatively long•lived, killed for food and commercial sale, and lived colonially. Elephants and manatees are among endangered species with many vulnerable traits, including large size, altruism, slow-reproduction, low natural mortality and longevity. They are also slow-moving and valuable in trade and as food sources.

These traits indicate only vulnerability to extinction caused by humans, not species likely to become extinct through natural selection. Sea turtles, for example, have lived on Earth for more than 200 million years. By any standard, they are a superbly successful, adaptable species that, prior to recent exploitation, showed no signs of decline. Their vulnerability lies in their inability to flee rapidly in the water or while laying eggs onshore when preyed on by humans.

Many endemic species occupy very limited habitats and have small populations but have not been listed as threatened if their environments or populations have not declined. The majority of these species have prospered for thousands of years in stable environments, and only the intrusion of human-related activities and domestic animals upset this equilibrium. Such species are extremely vulnerable to even minor habitat destruction or hunting pressure

and should be carefully monitored for losses in their populations.

Because of human technology and weaponry, all animals have become vulnerable. Animals that for thousands of years used natural camouflage, stealth and intelligence to escape from natural predators, have become easy prey for human hunters and fishermen. Predators, never in their evolutionary history preyed upon, now find themselves targeted by hunters, trappers and poisoners. Sonar locates fish schools and whales, and heat detectors and night-view binoculars observe animals in darkness. Cleverly constructed blinds hide hunters from view. Animal scents are used to lure wildlife, and hunters imitate animal sounds or use tape recordings of their calls to lure them to traps or within shooting range. Some hunters use the signals emitted by radio transmitters placed in wild animal collars by biologists for tracking, to hone in and pursue them to their deaths. Guns equipped with telescopic sights can fire at targets mile away, killing animals before they are even aware of the hunter. Other weapons include sophisticated traps, nets, snares, guns, harpoon guns and high•speed vehicles and boats, with which people can run down, maim and kill even the swiftest and most intelligent animals. These devices give humans such an advantage that they render the natural protections animals have evolved over eons completely ineffective. Hunters are able to kill the fittest and strongest specimens through these means. In the process, we are changing the course of evolution from survival of the fittest to survival of animals that are tolerated by humans and those able to persist in an increasingly polluted, damaged and ecologically impoverished natural environment.

Those species whose populations have become greatly reduced are vulnerable to extinction through genetic impoverishment and inbreeding. Such species usually remain rare or gradually fade into extinction as fertility declines. The critical low level which results in extinction is different with each species and cannot be predicted with certainty.

Just as the story of North America's lost species and environments is illustrative of many similar tragedies, the account below of the civil war in Rwanda and the former Zaire encapsulates the major threats to wildlife and the environment. It also makes abundantly clear that the survival of humans, animals and the environment are intrinsically linked. The influence of countries that contribute foreign aid to poor nations half a world away, and interfere in their politics, is another important element that can greatly affect the survival of wildlife and the natural world.

Human Tragedy and the Looting of Virunga's Treasures: Page 1

The mist•enshrouded Virunga Mountains of East Africa tower over dense highland vegetation. Far below, crystalline lakes ringed by marsh reeds glisten in the sun. Shy forest African Elephants walk along mountain paths in single file. Groups of endangered Mountain Gorillas (*Gorilla gorilla beringei*) feed in forest glades. Three hundred fifty of these magnificent animals, almost half their world population, reside here (Fisher 2001). The western edge of these mountains is protected in the vast 12,800•square•mile Virunga National Park, bordering western Rwanda. Some 766 species of birds reside here, more than are native to the United States and Canada combined. Iridescent sunbirds feed on the flowers of giant lobelias, and more than 200 species of mammals live in the park (Bonner 1994). Many of the species native to the park are found nowhere else on Earth. This ecological treasure is Africa's first national park, set aside in 1925. Virunga was closed to visitors other than scientists until very recently. In the 1970s, it became a World Heritage Site, a designation by the United Nations Educational, Scientific and Cultural Organization (UNESCO) for places deserving special recognition and protection.

In the early spring of 1994, political upheaval in the region caused a civil war that wreaked massive ecological damage and loss of wildlife in this natural paradise. Rival tribes in neighboring Rwanda clashed violently after the country's President was killed in an airplane crash caused by a rocket launch (Wright 2001). There were suspicions

that his death had been arranged by his enemies. In an attempt to overthrow the minority-run Tutsi government, the Hutu majority began slaughtering Tutsi tribal members. Within months, more than 500,000 people, most of them Tutsis, were slaughtered in an appalling genocide that began with armed conflicts between army soldiers and rebels and accelerated to violence between neighbors. People of all ages were victims, many killed by slashes from machetes or battered to death with clubs. The Hutu failed in their attempt to overthrow the ruling Tutsi tribe and fled in panic west to neighboring Zaire, home of Virunga National Park.

Some 2 million Rwandan Hutu refugees flowed in a steady stream into eastern Zaire, just south of the park. Injured and starving, they crowded into camps where international aid organizations fed them and attempted to control cholera and other infectious diseases. Within days, scenes that might evoke visions of Dante's *Inferno* were televised by news organizations to viewers around the world. Gaunt, frantic people were seen scrambling frantically for food supplies or lying listlessly in the final stages of starvation and disease. Estimates of total mortality from the war, starvation and disease exceeded 1 million people (Wright 2001). Many of the surviving refugees were afraid to return to Rwanda and remained in the refugee camps or built settlements on hills near Virunga National Park. To supply firewood to these 700,000 or more refugees, 30,000 people went into the rainforest each day, cutting down tens of thousands of trees (Bonner 1994). Rwandan soldiers and others began a thriving business selling firewood throughout the refugee camps. By November 1994, 112 square miles of the park had become partly or completely deforested, and little was done by Zairean troops or park authorities to curb the destruction (Bonner 1994). One forest ranger said, "Trees used to block the views everywhere. Now I see hills I didn't even know existed." An estimated 230 truckloads of trees left the park every day (Salopek 1995).

In December 1994, the World Heritage Committee placed Virunga National Park on a list of "World Heritage in Danger.fl Along with the forest cutting, park wildlife was killed for food by both refugees and Zairean soldiers, who had gone unpaid for months by the failing government. In mid-1995, more than 12,000 of Virunga National Park's Hippopotamuses (*Hippopotamus amphibius*) were killed for their meat and their ivory teeth, reportedly by Zairean soldiers using semiautomatic weapons. By late September 1995, there were still 700,000 Rwandan refugees camped near the park, removing 600 metric tons of firewood from the park each day (Lang 1995). Michel Leusch, Environmental Coordinator for the United Nations High Commissioner for Refugees in nearby Goma, said, "The quantity of biomass may be recovered in time, but some things, like rare plants and animals, have disappeared and cannot be replaced" (Lang 1995).

The government of Zaire began closing refugee camps in January 1996, with more than 1 million refugees still resident in 40 camps along the border with Rwanda. Another 700,000 Rwandan refugees stayed in camps in Tanzania and Burundi (McKinley 1996). Although millions of dollars were donated to supply food and medication, no aid funds were allocated for alternate fuel for these refugees, such as solar cookers and propane gas stoves that would have helped prevent the devastation of Virunga's forests. This highlights the need for an international ecological rescue fund that could ameliorate such tragedies, as well as safeguard wildlife from slaughter. In late 1996, Zairean troops attempted to force the last of the Rwandan refuges back into their country, causing open warfare to break out, and the last of the United Nations relief workers were forced to abandon the area. By mid-1997, hundreds of thousands of Rwandan Hutus had dispersed through the forests of Zaire, living off the land. Thousands of Hutus, jailed on their return to Rwanda, were placed on trial in an international tribunal in 2001 for their actions during the massacre.

Human Tragedy and the Looting of Virunga's Treasures: Page 2

A major underlying cause of Rwanda's civil war and the great suffering of its people is its uncontrolled population growth. In 1973, Rwanda's population reached 3,980,000 in a country whose total area is only 10,169 square

miles--smaller than Maryland (Anon. 1975). This resulted in a ratio of 391 persons per square mile, one of the densest in the world. Populations continued to grow, however, and by 1992, they topped 8,206,000, with a density of 806 persons per square mile (Anon. 1994a). The country became increasingly crowded, as arable land became scarce. Competition for land had become intense. Much of Rwanda is eroded and barren, the thin tropical topsoil producing crops for only a few years after the forest has been cleared. Only 22 percent of the land remains forested (Wright 2001). Farmers slash and burn more forest for planting when land ceases to produce crops or grazing grasses. Steep, erodable slopes are being plowed right up to the limits of protected parks and reserves. The feuding between Hutu and Tutsi might have been peacefully settled if not for the extreme poverty and overpopulation. The average per capita income in 1999 was $720 per year (Wright 2001).

The war™s massacres killed almost 1 million people, leaving an estimated 7.2 million people by 2,000, according to unofficial estimates (Wright 2001). Unless birth control becomes widely accepted in Rwanda, human populations will rise to an estimated 11 million people within a few decades. Some experts believe that nearly 22 million people will occupy Rwanda by 2020 (Anon. 1994a). By the latter estimate, there will be 2,163 persons per square mile in Rwanda, far more than its land can support. By contrast, the population density in the United States in 2000 was 76 persons per square mile, and Canada's, 8 persons per square mile (Wright 2001).

Human Tragedy and the Looting of Virunga's Treasures: Page 3

The effects of burgeoning human populations on wildlife and the once magnificent forests that covered the region have been tragic. Long before the forests of the Virunga Mountains became divided into the separate countries of Zaire, Rwanda and Uganda, and before the forests were replaced by agriculture in the latter two countries, thousands of Mountain Gorillas inhabited the region. As human populations rose, Gorillas declined to their present endangered status. These peaceful primates wander in the forest throughout most of the daylight hours, feeding on the luxuriant vegetation. As the largest and most powerful of all primates, the Gorilla male has an enormous chest, 20 inches across and up to 5.7 feet (1.75 meters) in circumference. He weighs up to 605 pounds, while females are much smaller, about half the weight of the male (Nowak 1999). The Mountain Gorillas' forests can become quite cold at night, and to adapt, they have developed longer, thicker hair than the Lowland and other races of Gorillas.

Gorillas travel in family groups led by silverbacks, named for the whitish-gray hair on their backs. These are the strongest and largest males, usually more than 20 years old, who guide and protect the band. Males compete for this role as soon as they are teenagers. Silverbacks father the babies in the family group, although sometimes females mate with "outside" males. These groups often travel long distances to locate fruiting trees and edible plants and tubers. Almost entirely vegetarian, Gorillas eat 40 pounds of food a day, feeding on 70 or more species of leaves, bark, fruit, roots, fungi, flowers and bamboo. They rarely drink water, obtaining moisture from the dew-laden plants, and the only animal matter they consume consists of insects. Gorillas consider army ants a delicacy and occasionally eat grubs and other insects.

In Rwanda's north, contiguous to Virunga National Park, where about 250 Mountain Gorillas survive, Volcanoes National Park, a 48-square-mile forest reserve, is home to about 100 Mountain Gorillas (Fisher 2001). The latter forest was once much larger, but the needs of agriculture had greater priority, and some 65 square miles were carved out of the park, squeezing the Gorillas into a fraction of their original range in the country.

Human Tragedy and the Looting of Virunga's Treasures: Page 4

In neighboring Uganda, the small Mgahinga Gorilla National Park, a 34-square-kilometer reserve, protects 40 more Mountain Gorillas. Some 25 kilometers north is a beautiful cloud forest, Bwindi Impenetrable Forest National Park, covering 330 square kilometers, in an area of high biological diversity (Butynski and Kalina 1993). This forest has the greatest number of trees of any in East Africa and so many endemic plants that it has been selected by the IUCN Plants Programme as one of Africa's most important forests (Butynski and Kalina 1993). Birds, butterflies, amphibians and reptiles found nowhere else inhabit the Bwindi Impenetrable Forest. It also protects a population of 300 Mountain Gorillas who have smaller bodies, longer limbs, hands and feet than those of Zaire: Their skulls and trunks differ also, and they are somewhat different genetically from other populations (Croke 1995, Drewes 1997). Scientists are now considering naming these Gorillas a separate subspecies. Destruction of forest and other habitats outside Uganda's and Rwanda's parks is extensive, making these last natural areas crucial to the survival of the Mountain Gorillas.

Uganda's decades of chaos under President Idi Amin decimated the wildlife of this lovely country bordering Lake Victoria. Murchison Falls and Queen Elizabeth National Park once had magnificent concentrations of elephants, hippos and other large mammals, but by 1997, little remained, having been slaughtered by rebel groups or refugees from neighboring countries (Drewes 1997). Uganda's Ministry of Tourism, Wildlife and Antiquities conducted an aerial survey of Uganda's remote northern regions to determine whether some wildlife might remain to restock other areas, but they found "absolutely nothing" (Drewes 1997). Uganda has recently made a commitment to restore its wildlife and has reintroduced many large ungulates, trucked in from Kenya, into its national parks.

Human Tragedy and the Looting of Virunga's Treasures: Page 5

Although Gorillas share more than 98 percent of human genes, making them, along with the two species of chimpanzees, our closest relatives, until the 1960s, they remained mysterious, threatening creatures in the view of the public, depicted as monsters in movies. During the 19th century, explorers and hunters killed them as ferocious symbols of savagery. The work of American biologists Dr. George Schaller and, later, Dian Fossey, who entered the forests of the Mountain Gorillas as observers and researchers, changed this image forever. Films and books of the National Geographic Society and others revealed the gentleness and intelligence of these magnificent primates to people around the world, and gradually, conservation programs began to replace trophy hunting.

Schaller, who began his research in the 1960s in Virunga National Park, wrote about these primates in *The Mountain Gorilla*, published in 1963 by the University of Chicago Press, and a popular version, *The Year of the Gorilla*, in 1964. He provided the first scientific observations of these remarkable animals and recalled his encounters with them in a 1995 *National Geographic* article:

> *I approached them with empathy and respect, wanting nothing from them but peace and proximity. And they accepted my presence with an astounding generosity of spirit. The recent decades have been a turning point, indeed a revolution, in our relationship with animals. Humans have begun to overcome cross-species barriers, achieving intimacy with humpback whales, chimpanzees, lions, mountain sheep, wolves. The gorillas of popular image were a fantasy . . . No one who looks into a gorilla's eyes--intelligent, gentle, vulnerable--can remain unchanged, for the gap between ape and human vanishes; we know that the gorilla still lives* within us. Do gorillas also recognize this ancient connection? (Schaller 1995).

In the 1960s, Virunga National Park sheltered the largest population of Mountain Gorillas, numbering some 450. They declined to 275 by the 1970s, and to 250 by 1981, a result of poaching. The Mountain Gorilla Project, begun in 1978 by Schaller and a consortium of conservation organizations, including the New York Zoological Society and the African Wildlife Foundation, sought to stop the Gorilla's decline toward extinction. Funding went toward anti-poaching programs, education of local people, and ecotours (Schaller 1995). With non-threatening visitors to the park, many Gorillas grew tame. They were given names by park rangers and scientists and became familiar to tourists who came from around the world to see them. The conservation program and ecotourism succeeded in nearly eliminating poaching, and Virunga's Gorillas increased to 320 by the late 1980s (Schaller 1995). The Gorilla Project also operated in Uganda, where the government ejected 2,000 farmers from 3,500 acres, offering to compensate them with 10 percent of the revenue from tourists who come to see the gorillas (Salopek 1995).

Human Tragedy and the Looting of Virunga's Treasures: Page 6

Fossey's early research was sponsored by the famed anthropologist Louis Leakey, who had earlier convinced Jane Goodall to go to Tanzania to study Chimpanzees (*Pan troglodytes*). Both researchers changed forever our views of these fellow primates. Fossey began her research in the 1970s in the mountains of Rwanda, making friends with a family of Mountain Gorillas. The silverback male of this troop, whom she named Digit, became so trusting that he was filmed by the National Geographic Society gingerly taking her pen and then her notebook, returning them to her, and then lying down and going to sleep by her side (see Video--Mammals). These immensely strong animals never harmed any of the thousands of people, from rangers and scientists to tourists, who visited the reserve over several decades. When they felt their family was threatened, they made shows of aggression, pounding their chests or rushing headlong through the bushes toward the potential threat, whether human or another male Gorilla, but stopping short of physical blows. Humans, however, misinterpreted their displays, shooting and killing many silverbacks.

Commercialization of Gorillas--the high value of their young in the exotic pet trade and the many thousands of dollars offered by zoos to obtain illegally captured specimens--has presented a major threat to the species for many decades. Local people enter parks and reserves to shoot adults guarding the young, remove the animals™ heads and hands, and grab the traumatized babies. Other Gorillas are killed accidentally by illegal wire snares set in the parks for antelope and small mammals. Although efforts had been made in many parks to stop the killing of Gorillas, not until December 1977 did international attention become focused on this grisly and cruel activity. Six Rwandans, with their hunting dogs, entered the reserve armed with spears to kill Gorillas. They encountered Digit, who boldly rushed at them, pounding his chest. This allowed his family to escape, but cost him his life. The Rwandans speared him five times until he died, and then cut off his head. Gruesome photos of Digit's headless body received enormous publicity in the media, causing shock and dismay in millions of people who had seen photos of him in gentle communication with Fossey, as well as films produced by the National Geographic Society about her research. His death served to inspire both compassion and renewed conservation efforts for these beleaguered primates.

Fossey's Karisoke Research Center expanded, and thousands of tourists came to glimpse the Mountain Gorillas in their forest home. The threat of poachers remained, however, and Fossey, after a fervent campaign to prevent further Gorilla killings, was herself killed. Her murder has never been conclusively solved, but Rwandans are the major suspects. She is buried in the reserve next to the grave of Digit. Fossey recounted her experiences with Gorillas in a book, *Gorillas in the Mist*, which was later made into a commercial film of the same title. The silverback star of this film was named Mrithi. Not long after the film was made, in May 1992, he, too, was shot and killed by Rwandan soldiers, surrounded by his family of 11. Even after being wounded, he managed to drag himself some 6 feet toward his attackers before collapsing and dying.

Human Tragedy and the Looting of Virunga's Treasures: Page 7

During the 1980s, the country of Rwanda had adopted Mountain Gorillas as an international symbol of wildlife protection during the 1980s, and when civil war broke out in the spring of 1994, both sides promised to spare them--promises that were not kept. In April 1994, the Rwandan civil war forced the staff of biologists at the Karisoke Research Center to depart (Perlez 1994). By early July, most of the wardens of the Rwandan Office of Tourism and Volcanoes National Park fled also, but a few dedicated guards refused to leave the Gorillas and remained. Soon after, Rwandan soldiers entered the park and ransacked the offices, destroying records and books and throwing computers out windows but, fortunately, sparing the lives of the guards and the Gorillas. The war claimed at least one Gorilla that year, however, when a male named Mkono was killed by a buried land mine (Tuxill 1997).

The staff of Volcanoes National Park was devastated by the war. Two-thirds of Rwanda's park employees died or remained in exile after the war ended, and 48 of 50 vehicles were destroyed (Salopek 1995). When surviving employees returned, many of them having been rescued from the masses of people living in refugee camps, with the help of United Nations personnel, they were delighted to see the Mountain Gorillas again. Nshogoza, a park employee who has spent 18 of his 44 years at Karisoke and has known generations of Gorillas, told a *National Geographic* writer, "When I was a boy, I heard that gorillas were men who were very bad and who went to live in the forest. But the gorillas are better than us. They are peaceful. They have no tribes. When they fight, it is for a good reason. We cut one another with machetes for zero" (Salopek 1995). To honor these guards, the park received the $50,000 J. Paul Getty Wildlife Conservation Award in May 1996, the money to be managed by the International Gorilla Conservation Program. Some was spent detecting and defusing more than 75 mines and booby traps left after the war, and other funds restored tourism in the park.

The Mountain Gorillas of Virunga National Park had been safe for a decade, but in 1995, Rwandan refugees, probably members of the routed army, entered their misty, forest home. In August and September 1995, three Gorillas--two silverbacks and one female--were found shot to death at point-blank range. One of these, named Marcel by the park scientists, was the most popular of Virunga's Gorillas, totally tame and gentle. He was so habituated to tourists that they could approach within a few feet of him, and hundreds of films and photos had been taken of him over the years. The bodies of Marcel and his mate were found sprawled out on the ground, full of bullet holes. "If someone comes in with a gun, the gorillas won't move out of the way," said Popol Verhoestraete, a field officer for the conservation program (Lang 1995). The killers left the bodies intact. These two Gorillas died trying to save their baby from poachers, who allegedly planned to sell him to a zoo. The park guards finally located this young Gorilla and seized him from the poachers, who were arrested. They carried the baby, who had become terrified and disoriented, in a small cage back to the family group. Not knowing if the frightened young Gorilla could survive without his parents, they released him, prepared to recapture him if things did not go well. After hesitating, he heard the sounds of his family and ran to join them. The leaderless and traumatized family group moved off into the forest.

Human Tragedy and the Looting of Virunga's Treasures: Page 8

Illegal snares have been threatening wildlife in these parks for generations. In the 1960s, Schaller saw two Gorillas in a group of 11 that had each lost one of their hands to snares (Schaller 1995). In Virunga National Park in mid-1995, a young male Gorilla was seen with a wire snare wrapped tightly around his foot, cutting off circulation, which threatened his life with septicemia (Salopek 1995). Just as the guards were preparing to capture him to remove

the snare, they saw a huge male silverback watching over him. They waited until the right moment and darted the young Gorilla with a tranquilizer, taking him to a local veterinarian, who saved the Gorilla™s foot (Salopek 1995).

In another snare incident in 1995, a very young female Gorilla was caught by the wrist in a snare set by Rwandans who entered Virunga to trap forest antelope. A film by Bruce Davidson, "Mountain Gorilla," shown on the fiNational Geographic Explorer" television series (September 14, 1996), chronicled the trauma of this tiny Gorilla, who struggled in vain to free herself, crying out and screaming in fear and pain. The park rangers thought that she might have been in the snare, which was tied to a tree, at least 24 hours before they discovered her. She was surrounded by her family, but her relatives could not bite through the snare because it was made of strong nylon cord from food sacks donated to the refugees. The silverback male, Ndingutse, tried again and again to free the baby, and her mother held her to comfort her screams, but there was nothing they could do to release her. Finally, the park guards, who had been standing nearby, were able to approach when Ndingutse moved away for a moment, and cut the cord. She escaped, but faced the threat of becoming snared again, and the cord remained around her wrist, a threat to her circulation as she grew.

The snares are usually attached to bamboo poles, bent over to spring when set off. Davidson filmed Ndingutse's brother, a 7-year old named Luwawa, in an extremely intelligent and protective reaction to a snare he encountered. When Luwawa saw the snare, he circled it, obviously aware of what it was. Waiting for the rest of his family to arrive and witness the act, he reached over and snapped the pole like a twig, avoiding the noose and disarming it. Against guns, he had no defense, however. Soon after, Luwawa was found shot dead on the slopes of Virunga National Park. His brother Salama had been killed months earlier. Only his bones and skull, picked clean of meat, remained when park rangers found him. The slaughter of these silverbacks traumatized the five to 10 females in their groups and left the babies and young without a strong male to protect them. They became shy and confused, hiding from humans, and even other Gorillas. In 1996, another two Mountain Gorillas were killed, bringing the toll for the previous 17 months to 10, causing havoc and psychological trauma in the families left behind and irreparable genetic damage to these highly endangered animals. In neighboring Uganda, more of these gentle Gorillas died--four adults in Bwindi Impenetrable Forest were speared to death by poachers in 1995 (Salopek 1995). The expulsion of farmers to enlarge the park for Gorillas caused great resentment, and perhaps precipitated this carnage. Tourists who came to see the Mountain Gorillas in this new Bwindi National Park in March 1999 met disaster when Hutu rebels ambushed and killed eight people in one group. This was thought to be the end of Mountain Gorilla tourism in Uganda, but with increased protection of tourists, they are gradually returning. Poaching declined after the deaths of Gorillas and tourists, and by 2000, the Mountain Gorillas in the Virunga Mountains in both parks totaled 358 (Fisher 2001). Tourists coming to Rwanda's Volcanoes National Park are still in some danger when not in groups guarded by soldiers, however (Fisher 2001).

Human Tragedy and the Looting of Virunga's Treasures: Page 9

The fact that Gorillas are gentle, kind and intelligent beings makes these cruelties all the more horrific. Millions of people saw a television report on August 16, 1996, showing Binty, a female Lowland Gorilla at a Midwestern US zoo, saving a little boy who had fallen into the exhibit and was lying unconscious; she picked him up and carried him gently to a door where keepers entered, setting him down in front of it. People were overwhelmed by her act of good will, as well as by her quick reaction. Many viewers had no idea that Gorillas would want to help a human in need, nor that she would use such good judgment in rescuing the boy, who recovered completely.

Koko, a captive Lowland Gorilla taught American Sign Language by Francine Patterson, president of the Gorilla Foundation, has learned some 800 signs and uses descriptive, imaginative language in naming unfamiliar objects, such as "finger-bracelet" for ring. She also paints, and when asked what one of her more colorful creations (reproduced on

page one of *The New York Times*) depicted, she signed "bird" (Boxer 1997). We are only beginning to learn about these primates, but without strong protection, they may soon become extinct in the wild at the hands of humans.

Human Tragedy and the Looting of Virunga's Treasures: Page 10

Many Africans have little respect for Gorillas. Hunters in Cameroon, when asked by researchers why they shoot Gorillas, replied "What's wrong with killing a Gorilla? They're fierce." One of the hunters told reporter Michael McRae that he was sure Gorillas were plentiful: "In Cameroon there are a million Gorillas. Three weeks ago, I saw sixty in one day. I shot three and then stopped . . . Why should I feel bad for a Gorilla? He is just a stupid animal" (McRae 1997). Education and an alternate source of income might change the opinions of these hunters. They have the same views Westerners had before research studies and films introduced people to the true nature of these primates.

As far as their abundance, there are hardly a million Gorillas in Cameroon, in all of Africa or the world. Gorillas are declining toward extinction. Their total population is estimated at well under 100,000 and declining (McRae 1997). The Lowland Gorilla and Mountain Gorilla are considered separate species by the *2000 IUCN Red List*, and both are classified Endangered. The US Endangered Species Act considers Gorillas to be a single species (*Gorilla gorilla)* and lists them as Endangered. Likewise, CITES lists Gorillas as a single species on Appendix I. The species is officially protected from hunting throughout its range, but national legislation is almost never enforced. The Lowland Gorilla is declining rapidly as a result of logging, killing for the bushmeat trade, and possibly ebola disease. Adults are often killed to obtain babies, which are traded on the black market to zoos in many countries. Hundreds of Lowland Gorillas are being slaughtered in Cameroon and other parts of their range, causing immeasurable trauma and cruelty to their close-knit societies, as well as ecological harm. The Moabi tree, a very important species for its fruits, seed oil, bark and wood, produces enormous seeds that Gorillas disperse (Tuxill 1997). African Forest Elephants are also crucial to the survival of Moabi trees, spreading their seeds, and they, too, are threatened with extinction.

The bushmeat trade is wiping out many other species of wildlife in wide areas around African villages. People set wire snares throughout the forest, into which rare deer, antelope, primates, wild pigs and a variety of animals blunder, struggling for days in great pain until the trappers arrive to kill them with knives. Even apart from the cruelty and conservation issues, the bushmeat and pet trades are not even lucrative. People make only a hand-to-mouth living from them, selling rare apes for a few dollars to traders, and other animals for a few cents. They are killing off their wildlife heritage while remaining in poverty.

Local people receive almost no benefit from logging, which is permanently devastating the old-growth forests. Tourists do not want to visit logged-over areas which have a fraction of the wildlife of unlogged forests and, in the case of clearcutting, an ugly, barren landscape. Trophy hunting, which is increasing in rainforests of Africa because of lobbying by the Safari Club and other organizations, is further reducing the wildlife. These hunters kill the largest and rarest animals--the prime specimens that should be left to perpetuate the species--and cause wildlife to become frightened and shy.

Mountain Gorillas are not killed for the bushmeat trade, but are shot for their body parts. None exist in captivity. These endangered gorillas are monitored within Rwanda's Volcanoes National Park by numerous researchers of the Karisoke Research Center, run by the Dian Fossey Gorilla Fund International. They are conducting a variety of different projects studying breeding, genetics and other aspects of their lives. One researcher noted the extreme devotion the Gorillas have for one another. Amahoro, meaning Peace, a 14-year-old silverback in the park, became lethargic and could not keep up with the group (Williamson 2001). Another male became his constant companion, and sometimes two males helped him along. The International Gorilla Conservation Programme was contacted for

veterinary assistance. A veterinarian arrived and examined Amahoro from a distance, because he was defended by two other males (Williamson 2001). The next day, he was barely able to move and began coughing; the troop gathered around him, chest-beating in anxiety (Williamson 2001). After calls to gorilla veterinarians in the United Kingdom and the United States, the veterinarian decided that his problem was an infection in need of antibiotic treatment, which was administered by dart; he recovered fully (Williamson 2001).

Because of the international importance of the Mountain Gorillas and their precarious status, researchers from the National Aeronautics and Space Administration (NASA) began scanning their habitat in August 1994 during a 10-day environmental space satellite mission (Anon. 1994b). Overlaying the NASA images with data collected from navigation satellites and standard topographical maps is now providing an extremely detailed overview of the Mountain Gorilla's habitat. The habitat now protected totals only 285 square miles, not a large area for the 658 remaining Mountain Gorillas.

One wonders what their lives were like thousands of years ago when they roamed over vast, montane forests undisturbed. They may have shown behavior that has disappeared under these new conditions. During some parts of the year, they might have frequented the lowlands, feeding on trees or other vegetation that has long ago disappeared, replaced by farmer's fields. It is possible that they are not receiving adequate nutrition from the plants in their reduced habitat. Their restricted ranges may be causing inbreeding. These Gorillas have suffered great psychological harm from the constant threat of death from hunters, never knowing when they may be confronted and killed. The loss of many family members to snares and shooting traumatized these sensitive and devoted primates.

Human Tragedy and the Looting of Virunga's Treasures: Page 11

Another important Gorilla habitat in southern Zaire was invaded by many of the 400,000 Rwandan refugees who fled to this area in 1994. This magnificent protected area--Kahuzi•Biega National Park--covers some 2,085 square miles (Jay 1994). It is also a World Heritage Site. The large mammals of this park were surveyed in 1994 by the Zairean Institute for the Conservation of Nature and the Wildlife Conservation Society (Jay 1994). Preliminary data indicated that the rare Grauer's Gorilla (*Gorilla gorilla graueri*), a subspecies of the Lowland Gorilla, was found in fairly large numbers--at least 1,000 animals (Jay 1994). Elephants were also numerous (Jay 1994), and the park has many rare birds (Collar *et al*. 1994). One camp of 50,000 refugees blocked a narrow corridor of forest that served as a migration route for elephants and lone male Gorillas between major sections of the park (Jay 1994). The Wildlife Conservation Society conducted a long-term study of the effects of hunting on wildlife in the park, supplemented by a 10-month United Nations probe, which released a report in April 2001 (Lauria 2001). Gorilla numbers have plummeted here also, killed for food and trophies. As ABC News filmed one of the few remaining Gorilla families in Kahuzi-Biega National Park during the summer of 2001, a male Silverback charged the camera crew. Only a decade ago, Gorillas were tame and securely protected in this area. The UN investigation determined that Rwandan forces and others have slaughtered all but two of 350 elephant families in the park for the illegal ivory trade (Lauria 2000). This poaching was part of an organized network of corruption now looting parks and natural areas in the renamed Democratic Republic of the Congo of diamonds, gold, timber and wildlife (Lauria 2001).

Human Tragedy and the Looting of Virunga's Treasures: Page 12

In April 1995, a third natural area in Rwanda, Akagera National Park, became threatened when 700,000 cattle and 250,000 Tutsi herders moved 15 to 20 miles into the park (Lorch 1995). Because of a lack of arable land, Rwandans have sought out parks as the last remaining unoccupied territory. Akagera National Park, located on the eastern border of the country, has a wide variety of fragile habitats, from swamps and savannah to forest and hills, harboring

gazelles, Giraffes, African Elephants and Leopards (Lorch 1995). Rwandan authorities did not exclude the herdsmen and their livestock but tried to convince them to cull their herds (Lorch 1995). In southern Rwanda's Nyungwe Forest, the Wildlife Conservation Society's colobus project, which protected groups of hundreds of these monkeys, was also devastated. In February 1995, investigators found that one-fourth of a 120-member colobus group had been killed during the war, many for their long fur, which was used in marriage rituals (Fine 1995). Researchers came upon animal snares and concluded that this national park would no longer be protected as such, but would become a multiple-use forest (Fine 1995).

Uganda's rare wildlife also incurred losses from Rwanda's war and Burundi's civil strife in a ripple effect. An extremely endangered bird of the Virunga Mountains, the Congo Bay Owl (*Phodilus prigoginei*), was recently rediscovered after being thought extinct. Not seen since 1951, it was seen in Uganda's Itombwe forest in mid-1996 by scientists from the Wildlife Conservation Society. A type of barn owl, the Bay Owl was previously known only from a specimen collected in Zaire's Kivu province in 1951 (BI 2000, Hart 1996). The owl is restricted to a small area of mixed rainforest and savannah near the Rwandan border (BI 2000). Dr. John A. Hart, the zoologist who found the bird, saw farmers clearing the surrounding forest to create new farmland; they had entered the area seeking refuge from the civil wars in neighboring Rwanda and Burundi (Hart 1996). Although the total population of the Bay Owl is not known, it is presumed to be extremely small, and its future survival is uncertain. This area has no protected status and the entire known habitat of the endangered Congo Bay Owl is being degraded by clearing for livestock grazing and farming (BI 2000).

Some of Rwanda's refugees fled to Tanzania as well. More than 535,000 Rwandans traveled south into that country, staying in refugee camps near the border until December 1996, when the Tanzanian government demanded that they return to Rwanda. Former Hutu soldiers, fearing possible imprisonment for war crimes, convinced many refugees to travel east instead, into the heart of Tanzania's Burigi National Reserve. Once there, they stripped vegetation, killed large numbers of animals, began planting crops, and caused an increase in violent crime in local villages (AP 1996). At this point, the Tanzanian army routed them forcibly, and a stream of refugees many miles long was pushed back into Rwanda.

By 2001, a state of anarchy prevailed in the region, with these countries still at war. A United Nations report concluded that business and military leaders from Uganda and Rwanda were looting forests and parks in the Democratic Republic of the Congo for natural resources and meat (Lauria 2001). The New York-based International Rescue Committee reported in May 2001 that an estimated 2.5 million people have died as an indirect result of the previous three years of civil war in the Democratic Republic of the Congo (Salopek 2001). The fighting drove hundreds of thousands of people into the forests, where they lived off the land, dying of rampant disease and malnutrition in the rebel-held jungles (Salopek 2001). Gangs of poachers entered these rainforests, placing snares to capture elephants, Leopards, antelope, wild pigs, and monkeys for the bushmeat, fur and ivory markets in large cities. A camp of these poachers, many of whom come from neighboring countries, was encountered in the travels of Wildlife Conservation Society biologist Michael Fay. Fay and his group, including National Geographic Society filmmakers, came upon a sizeable camp with a very large Leopard skin stretched out on pegs, with hundreds of antelope and monkey bodies being cooked on open fires. Fay was so irate that he burned the entire camp and all the skins (shown on National Geographic Explorer, April 2001, entitled "Extreme Africa"). Although laws ban such killing, no game wardens patrol these forests, which were not part of a national park. Fay's intention in traveling across Central Africa, as described in *National Geographic* (Quammen 2001), was to show the world the great treasure being plundered by loggers and meat hunters before it is too late to save this large rainforest.

Human Tragedy and the Looting of Virunga's Treasures: Page 13

The future of wildlife in Rwanda, the Democratic Republic of the Congo and surrounding countries remains

extremely uncertain. The region is a microcosm of struggles that may soon be commonplace as human populations continue to rise and compete for dwindling land and resources. Markets as far away as Europe and North America buy the timber, minerals and ivory that are being exploited here at the expense of the environment. At the present rates of loss, little wilderness or natural forest will remain anywhere in the world. The damage done to parks and reserves by tree cutting, clearing land, and killing native wildlife, especially for commercial purposes, devastates biodiversity and endangers species reliant on these refuges, which are often their last remaining habitats. The World Conservation Union issued a report in 2001 on the urgent need to protect the world's 17,000 large nature preserves from intrusion by poor farmers, who have nowhere else to go (Revkin 2001). Half of these preserves now have people cutting forests and tilling land in biological hotspots and areas with large numbers of endangered species (Revkin 2001). At least 900 million people earn less than $1 per day, and 630 million live in areas of high biological diversity, according to the report's author, Jeff McNeely (Revkin 2001). Organizations, such as Future Harvest, which co-authored the study, are attempting to help poor farmers by providing means to enrich soil through fertilizers and rotating crops to maintain corridors of undisturbed land as wildlife habitat, and to grow shade crops, such as coffee and cocoa, which maintain forests (Revkin 2001).

John Terborgh (1999), a Duke University scientist, chronicled massive destruction of parks by farmers, logging, livestock and squatters in *Requiem for Nature*. This book paints a gloomy picture of wanton neglect, insufficient funding and failure by governments to protect parks and reserves, many of which harbor endangered species and magnificent landscapes. In Peru, for example, national park officials in the capitol city were not even aware of the existence of the Cerros de Amotape National Park. When Terborgh visited the park, he found it had been logged by the army, and cattle grazed throughout. Yet this dry tropical forest is one of the most important centers for endemic plants and animals in the world (Terborgh 1999). Similar tragedies are occurring in Mexico, where logging trucks leave the spectacular montane Nevado de Colima National Park loaded with giant tree trunks, and cows consume all the new tree saplings from the few remaining old alder trees (Terborgh 1999).

In Colombia's Tayrona National Park, six park officials have been killed by rebels and squatters, drug traffickers, loggers and others, who are destroying it; 20 percent of Colombia's 22.2 million acres of parkland is in the hands of squatters or has been deeded to private interests (Terborgh 1999). Colombia has an extremely rich diversity of tropical birds and mammals, and much of the pressure on its parks is a result of the US market for drugs, which offers poor people a far greater income than they can earn through traditional farming. The Santa Marta region in Colombia's northeast has an extraordinary wealth of birds and other species found nowhere else. The endangered Santa Marta Parakeet (Pyrrhura viridicata); Santa Marta Sabrewing (*Campylopterus phainopeplus*), a hummingbird; and the Santa Marta Bush-tyrant (*Myiotheretes pernix*), a flycatcher, are among these (BI 2000). Conversion of forest to marijuana and coca plantations, compounded by US-sponsored government herbicide spraying programs to kill drug crops threaten these and other species of the area. Spraying contaminates the soil and water, and often the small aircraft destroy natural forest and traditional crops instead of the target drug crops. In March 2001, four governors from Colombian provinces protested the $1 billion US herbicide spraying program, saying it was jeopardizing the health and food supply of farmers (Marquis 2001). They asserted that the defoliation ruined food crops and alienated people from their national government, while not succeeding in curbing the narcotics trade (Marquis 2001). The Santa Marta region has already lost 85 percent of its forest habitat (BI 2000). Rebels have taken over much of the area, clearing forest for drug crops and killing members of native tribes, who have traditionally tried to protect the forest and wildlife.

The Democratic Republic of the Congo is in the early stages of a similar anarchy involving rebels and forest destruction. The late President Mobutu and other high officials acquired immense fortunes by siphoning off the nation's mineral and tax revenues and foreign aid funds. They purchased palaces and estates around the world and lived sumptuous lifestyles. Almost none of the revenue from the rich mineral industry went to public works, with the result that the majority of the country's people are illiterate and poorly fed and housed. Even the streets of the capital city are unpaved and littered with trash. Mobutu's personal fortune is estimated at $3 billion by some, and as much as $10 billion by others (Sachs and Rotberg 1997). This country had been a territory of Belgium, known as the Belgian Congo, prior to its independence in 1960. Over the next three decades, the United States and European nations

supported Mobutu's regime, which became increasingly autocratic and corrupt. Any opposition was quickly suppressed. By the mid-1970s, the country neared financial ruin (French 1997). The United States, the International Monetary Fund and the African Development Bank supported Mobutu's regime until the end of his reign (Rotberg 1997). The funds were spent mainly for military purposes and for Mobutu's personal enrichment.

Strong opposition to his regime came from an opponent, Laurent Kabila, who drove Mobutu from office in 1997 and renamed the country, the fiDemocratic Republic of the Congo.fl Mobutu died September 7, 1997, in Morocco, where he had taken refuge. He left the country $14 billion in debt, a sum almost three times the country's gross national product (Sachs and Rotberg 1997). During the struggle among Mobutu's forces, Rwandans and Kabila™s soldiers in Virunga National Park, four Mountain Gorillas were killed, one silverback and three members of his family. The International Gorilla Conservation Program reported that these Gorillas, who were tame and accustomed to tourists in Virunga National Park, were shot in crossfire when Rwandans entered the park and encountered Kabila's soldiers. Kabila was assassinated in 2000, replaced by his son, who was educated in Tanzania. He has moderated some of his father's extreme programs and appears to want to end the conflicts that are dividing the countries of Central and East Africa.

The new government plans to rebuild 50,000 kilometers (31,000 miles) of roads (Wallis 1998). Loggers supply local hunters with weapons, ammunition and a ready market for the meat of Gorilla, Chimpanzee and other protected and endangered species (Pearce 1995). In a growing trend, more and more Central and West African towns are becoming dependent on bushmeat. A study in the neighboring country of the Congo documented that a single town of 10,000 people consumed nearly 6 tons of wild animals every week (Counsell 1997). In Gabon, some 8 million pounds of bushmeat are sold annually, half in urban areas (Tuxill 1997). Recent research has determined that even selective logging has damaged ecosystems in tropical African rainforests, and hunting has eliminated keystone species, such as forest elephants, that spread the seeds of many forest trees (Counsell 1997). Logging also leads to uncontrolled hunting as roads open up wilderness areas.

The Democratic Republic of the Congo has major reserves of cobalt, copper, cadmium, diamonds, gold, and coltan, an extremely valuable material used in making cell phones and computer games. The mining of these resources has damaged large areas of forest as thousands of people vie for high-paying jobs. The mining is uncontrolled by the government, as deals are brokered between international corporations and rebel leaders or even with foreign governments, such as Rwanda, which controls the $250 million per year coltan trade.

Endangered Pygmy Chimpanzees, or Bonobos (*Pan paniscus*), are endemic to these forests in a relatively small portion of the Democratic Republic of the Congo, and their habitat is being decimated by loggers, who construct a maze of new roads (Kingdon 1997). Remarkably intelligent and peaceful, primatologists consider Bonobos to be unique in behavior and ecology; they represent a profoundly important example of evolution (De Waal 1997). Numbering only about 13,000 animals, they are declining and classified as Endangered by the IUCN. No major reserve has been set aside for them. Another rare animal of the region, the Bongo (*Tragelaphus eurycerus*), a beautiful, striped forest antelope, is listed as Endangered in the eastern part of its range in Kenya, and Near-Threatened in the Democratic Republic of the Congo, as logging operations have surrounded the boundaries of an important reserve for this species (Counsell 1997; Hilton-Taylor 2000).

Wildlife Conservation Society biologist Fay finished his 1,200-mile voyage through many unexplored regions of the Democratic Republic of the Congo and neighboring Gabon in the spring of 2001. He found Chimpanzees and Gorillas that had never seen humans and approached his group with curiosity, and other areas where these great apes were completely absent, perhaps as a result of ebola disease (Quammen 2001). Impenetrable swamps and miles of tangled shrub, giant trees alive with insects, birds and lizards, abundant signs of forest elephants and buffalo, networks of streams and spectacular vistas of vast waterfalls and distant mountains still exist in the region, yet loggers, gold miners, poachers and displaced people are increasing in number, destroying this wilderness bit by bit.

A sign of the future, should logging and bushmeat hunting continue, was a traumatized, orphaned monkey, tethered

on a rope in a hunter's camp. Seen by Fay's group, its photograph appears on the cover of *National Geographic* (March 2001). This young Mandrill (*Mandrillus sphinx*) had perhaps witnessed the slaughter of its entire family and was now in a strange and abusive environment without its fellows. This species is threatened in the wild and listed as Vulnerable by the IUCN. Among the largest of all monkeys, Mandrills weigh up to 54 kilograms and live only in the rainforests of Cameroon, Equatorial Guinea, Gabon and the Democratic Republic of the Congo (Nowak 1999). The adult male has an extremely dramatic appearance, his face spectacularly marked with electric blue ridges beneath his eyes, set off by a bright red stripe that goes down the middle of his nose and covers a large, round nose patch surrounding his nostrils. His face is framed by a mane of grizzled, olive-brown fur. The female is a somewhat smaller and less flamboyant version of the male. These are the only primates that move about on the ground in very large groups, numbering up to 600 animals. They feed on a large variety of plants, roots, fungi, invertebrates and, occasionally vertebrates (Kingdon 1997). Their sole habitat--undisturbed, primary rainforest--is disappearing rapidly. They are intensively hunted in some areas for the male's shaggy mane, which is used for capes and headdresses (Nowak 1999).

Mandrills are also killed for bushmeat, which is their most immediate threat, according to biologist Jonathan Kingdon (1997). Mandrill meat is more highly valued in these markets than beef, and hunters employ dogs, guns, spotlights, deep-freezers and trucks to harvest them, especially in the Democratic Republic of the Congo and Gabon (Kingdon 1997). These magnificent primates may be important seed dispersers, yet research has only begun on their wild ecology. They may vanish from their once vast realm before their role in the African rainforest is understood.

These ecological and political crises were long in the making. Decades ago, international funds such as the World Bank could have developed environmentally friendly industries, such as ecotourism, in Rwanda, Uganda and Zaire, with a large percentage of the profits going to local people. Aid organizations could have funded or encouraged these nations to promote literacy and conservation education and to provide birth control education. Foreign aid to Zaire by the United States and European countries could have gone toward helping the people of that country achieve economic independence, while promoting environmental protection.

Human Tragedy and the Looting of Virunga's Treasures: Page 14

There is worldwide interest and concern for the survival and conservation of the Mountain Gorillas and other wildlife of the Democratic Republic of the Congo, Rwanda and Uganda and an enormous potential market for ecotourism in many parts of these countries that would benefit both the people and the wildlife. Mountain Gorillas have attracted $10 million in tourism revenues to Rwanda (Tuxill 1997). The forests of all three countries, as well as those to the west in Cameroon, the Ivory Coast, the Congo (as distinct from the new Democratic Republic of the Congo), and Gabon harbor many zoological curiosities that could attract tourists, such as enormous Goliath Frogs, largest of all frogs, now threatened from over-collecting and habitat loss. Beautiful Congo Peafowl (*Afropavo congenis*), the only pheasant species in Africa, are endemic to the Democratic Republic of the Congo, resident in the Kahuzi-Biega National Park and several other reserves (BI 2000). Threatened by hunting, these large, crested birds would be a big attraction for bird-watchers. Other unusual wildlife, such as tiny forest antelope less than 2 feet tall, inhabit these rainforests, where towering trees draped in mosses and orchids have crested eagles nesting in their crowns. At the forest floor, blizzards of butterflies drink at streamsides, while colorful lizards flit up tree trunks. One innovative approach to wilderness protection could acquaint people around the world with such natural treasures without their having to travel. It could also help local people with funding. It is the use of videocameras connected to satellites that record wildlife and landscapes for the Internet. Internet users pay small fees to tune into these videocameras and their websites. A large portion of the funds could be given to local people. This popular new technology has helped South African national parks with their expenses. Small cameras can be placed in extremely remote areas and can be operated on solar power. They have virtually no impact on the environment, unlike large numbers of ecotourists.

One method of protecting endangered forests, which play an important role in reducing global warming, is the US Initiative on Joint Implementation, which encourages public utility companies to invest voluntarily in forest conservation. Through the Carbon Sequestration Program, sizeable expanses of tropical forests, which absorb enormous amounts of carbon dioxide, are being protected. Wisconsin Electric Power Company, Detroit Edison, PacifiCorp and Cinergy donated $2.6 million in 1995 for a 15,035-acre forest in Belize, adjacent to the Rio Bravo Conservation and Management Area. American Electric Power in Indiana is cooperating with PacifiCorp and British Petroleum to protect 5 million acres of Bolivian forests from logging (Passell 1997). This approach protects large amounts of forest in a cost effective manner: the estimated cost of sequestering 1 ton of carbon this way is just 37 cents, less than 1 percent of most emissions-reducing technology, according to *The New York Times* (Passell 1997). General Motors has helped purchase 30,000 acres of forest in southeastern Brazil, home of the tiny Golden-lion Tamarin (*Leontopithecus rosalia*). More than 90 percent of this forest, known as the Atlantic Coastal Forest, has been destroyed, and it is one of the world's greatest centers of biodiversity (Mittermier *et al*. 1999). This program should be used in conjunction with reduction of emissions from power plants and vehicles--not as a substitute.

In another cooperative venture to save tropical rainforests, US chocolate makers are urging owners of small farms to grow cacao, a crop that is grown in the shade of large trees (Yoon 1998). A worldwide shortage of chocolate has resulted from the spread of diseases in large-scale cocoa plantations in tropical regions around the world. Such diseases do not spread or take root when crops are grown in smaller, shaded areas which have a natural diversity of plants and animals, including insect-eating birds and reptiles (Yoon 1998). With the world's sweetest tooth, the United States consumes 629,000 tons of chocolate per year, far outstripping its nearest competitor, Germany, where 285,000 tons are eaten annually, according to the International Cocoa Organization. The American Cocoa Research Institute, the Smithsonian Migratory Bird Center and various candy companies, including Mars, Cadbury, Nestle and Hershey, are all cooperating in strategies that promise to conserve tropical trees and wildlife, and grow cacao plants in ecological ways (Yoon 1998). Huge plantations of cacao in Brazil and elsewhere have lost as much as 80 percent of their crop to fungal and other diseases in recent years, diseases that often spread in large plantings of a single crop.

Scientists have long noted that birds are abundant in small forested cacao and organic coffee farms, and they are encouraging this new cooperation to protect tropical birds as well as the hundreds of species of North American and European birds that winter in tropical countries. Shade-grown, organic coffee is also helping to save rainforests. A trend away from traditional shade-grown coffee into new strains that are grown in the sun, has resulted in the clearing of millions of acres of rainforest to grow this coffee for markets such as the United States. To counter this trend, some organic companies, organizations and institutions, such as the Smithsonian, are taking a strong stand urging people to buy shade-grown coffee to protect rainforests and migratory birds from North America that winter in Latin American forests. This coffee is sold in many natural food markets and chains, such as Trader Joe's. The restaurants and coffeehouses, such as Starbucks, that still use sun-grown coffee should be encouraged to sell shade-grown coffee to help preserve forests and wildlife.

Debt-for-nature swaps can provide relief for countries saddled by debt from loans made by the World Bank and other international funds. Through these swaps, a portion of a nation's debt is paid by the donor, which may be a conservation organization or other entity, in exchange for the establishment of parks. These swaps have been undertaken in Madagascar and several other countries. A growing movement to convince donor countries to forgive these debts is being waged by conservation and human rights organizations. Should these debts be erased, much environmental degradation would be avoided, since many destructive programs are carried out solely to pay off debt. One such program, called "Avanca Brasil" or "Advance Brazil," envisions a massive development program in the Amazon Basin, crisscrossing the forest with roads and railroads and damming rivers to produce energy (EII 2001). A minimum of 28 percent of this great forest would be destroyed and, more likely, at least 42 percent (EII 2001). Just since 1995, 5 million acres of Amazon forest have been leveled for development (EII 2001). These forests, a major factor in preventing global warming through absorption of carbon dioxide, produce vast amounts of oxygen and harbor a large percentage of the world's biodiversity.

If no positive steps are taken, these last sizeable rainforests will be gone, and severe climatic and ecological harm will result. The great forests of Central Africa are also in the process of being destroyed. World-class national parks, such as Virunga, may be completely destroyed within a generation by illegal logging, squatters and bushmeat hunting.

Earth's Worth

Governments around the world grant logging or mining contracts on a daily basis. Thousand-year-old forests and wildernesses covering vast areas are bargained away in deals made between corporate representatives and government officials, often through bribery. The fates of the native wildlife and plants of these regions hinge on the type and level of exploitation. Wildlife, plants, and their habitats survive or die out as a result of decisions made by politicians, most of whom have no understanding of the importance of preserving diversity and extensive areas of natural landscape. At the present rate of destruction, wilderness will soon be gone, carved up and exploited for commercial purposes or destroyed by settlers.

Earth's Worth: Page 1

Citizens of the wealthiest countries represent some 20 percent of the world's peoples, but consume 80 percent of the planet's resources. The high standards of living that are enjoyed in North America, Western Europe and Japan depend in large part on importation of low-priced raw materials from poor countries. International corporations have few laws restricting their activities, which are causing major damage to forests, rivers, lakes and other environments. Moreover, the market provided by Europe and North America and, most recently, by some countries in East Asia, encourages fast-paced exploitation. Many of the recent logging contracts signed in Africa, Russia and South America have been negotiated to repay debts incurred from loans from the International Monetary Fund, World Bank or other funds. These loans are often for the construction of dams, factories or mines that primarily benefit third parties, such as large corporations. To repay the loans on schedule, countries are pressured to exploit their natural resources, forests and minerals, which are sold at low prices. Such loans rarely help nations develop according to their avowed intention, but send poor countries into an ever escalating debt that requires more and more forest cutting and other exploitation for short-term gains.

The US government's foreign aid tends to encourage mega-projects that do not help the populations of developing countries. Development that is environmentally friendly, based on small-scale business or ecotourism, is of far greater value in helping people as well as preserving wildlife. The decades that have passed since the publication of E.F. Schumacher's 1973 book, *Small is Beautiful. Economics as if People Mattered*, have only validated the philosophy of helping people through small-scale grassroots programs. Economic development programs that respect both people and the environment by finding means through which people can be economically secure, maintain their culture and live in their ancestral regions without destruction to natural ecosystems, should be the model in the future. The concept of small-scale eco-development has been endorsed by various conservation organizations, and use of solar

cookers, bio-gas and fertilizer from livestock manure, development of crafts and other small-scale industries, education on crop rotation and use of crops adapted to particular areas, preserving forests to prevent erosion and not living in flood plains are examples of this approach. A wide variety of organizations are carrying out such programs in many parts of the world. Such approaches are also needed in North America and Europe, where conservation education has failed to teach such basic principles, and government officials lack basic knowledge about the environment.

Earth's Worth: Page 2

Subsidies provide another disincentive to conservation. On a worldwide basis, governments spend $700 to $900 billion per year on subsidies that actually encourage the destruction of forests and other natural areas (Grossfeld 1997). In the United States, the taxpayer pays for road building in national forests to enable logging companies to enter wilderness areas. The Forest Service charges these companies a fraction of the retail value of these trees--sometimes $10 or less for a giant tree worth $25,000. Yet almost no subsidies or tax benefits are paid for the use of recycled materials, such as paper, that would save the cutting of thousands of trees. For this reason, it is cheaper in the United States and many other countries to cut forests for paper than recycle used paper, and to obtain minerals from mines rather than from recycled metals. To further the lack of logic of this situation, one US government department encourages environmental destruction through taxpayer dollars™ subsidies for logging and mining, while others spend public funds to clean up the pollution and preserve species that become endangered from these activities.

A coalition of 26 organizations compiled information on US subsidies that have negative effects on the environment, entitled "Green Scissors '98." It found that the United States spends $49 billion every five years on subsidies and environmentally destructive programs. The report recommended drastic slashing in these "polluter pork" programs to protect the environment and save taxpayers billions of dollars of misspent money each year. The Institute for Research on Public Expenditure in the Netherlands produced a report in 1997 entitled *Subsidizing Unsustainable Development: Undermining the Earth with Public Funds*. After a lengthy examination of subsidies around the world, which range from inexpensive irrigation water to free land for settlers and mining operations, this study concluded that subsidies are economically counterproductive and disastrous to the environment, resulting in deforestation, overfishing, polluting and other destructive activities (Crossette 1997a). Many species are endangered as a byproduct of these subsidies.

Earth's Worth: Page 3

The gross national product of a country is considered the major yardstick by which economic success is measured, and the natural world is traditionally valued in terms of the revenues it produces when exploited. This rigid and limited evaluation was recently examined and found lacking by a team of 13 ecologists, economists and geographers, who analyzed the monetary value of ecological systems to human society. They sought to place specific values on 17 types of environmental services that 11 ecosystems provide to humans each year (Stevens 1997b). Among these ecosystems were open oceans, estuaries, seagrass and algae beds, coral reefs, tropical and temperate forests, grasslands and rangelands, tidal marshes and mangroves, wetlands, lakes and rivers (Stevens 1997b).

In a report published in the scientific journal *Nature*, these specialists estimated the total global value of these ecosystems and their production at $16 trillion to $54 trillion per year, with $33 trillion the most likely figure; by contrast, the gross national product (all the goods and services produced by the world's peoples each year) was estimated at a mere $18 trillion (Stevens 1997b). They rated the value of nature's climate regulation at $684 billion,

natural raw materials at $721 billion, pollination by natural pollinators at $117 billion, recreation and ecotourism provided by nature at $815 billion, soil retention and formation at $53 billion, water supply at $1.7 trillion, and food production at $1.4 trillion. Thus, ecosystems such as forests, which provide several of these ecological services, such as climate regulation, ecotourism, soil retention and water supply, are worth far more left standing than cut as lumber for short-term profit. Wildlife performs services as well, including natural pollination, attraction of ecotourism and recreation such as bird-watching, and others such as seed dispersal and soil enrichment. The linkages between particular ecosystems and local economies were systematically analyzed in this study; for example, the Louisiana shrimp catch depends on wetlands as nurseries, and these wetlands also provide flood control and other services in their overall value (Stevens 1997b).

If the costs of destroying these ecosystems were computed when development was considered, such as the loss in flood control and water pollution filtration by wetlands, the researchers concluded that society would be more likely to protect them from destruction. They pointed out that when a wetland is filled in for a shopping center, the dollar value of that habitat in preventing floods and cleansing water is not figured in, resulting in a gradual erosion of natural wealth (Stevens 1997b). The heavy rains that ravaged many parts of the world in 1997 and 1998, caused by El Nino's effect on the weather, produced floods and mudslides in areas where forests had been cut and wetlands filled. Hundreds of lives were lost, and property damage totaled billions of dollars. Areas with forest and extensive wetlands were hardly damaged. Some wetlands are being restored in the United States--river courses returned to natural curves, and flood plains protected from building, in the realization that the lost income from not developing these areas is more than compensated for by the protection from natural disaster they provide, which creates economic stability in developed areas located far from wetlands.

However important such economic analyses are in re-evaluating our destruction of ecosystems, preserving nature cannot be reduced to economic calculations. If this is the sole basis of conservation, it could lead to destructive manipulations in the environment designed to accommodate complex economic theories. The major lesson to be learned from these new ways of looking at Earth's use to humans is that we have grossly underestimated life-giving ecosystems and their wild fauna and flora. They have evolved over a period of millions of years, and we must respect and preserve them in as natural a state as possible.

Although people in the United States are far more aware of the ecological value of wetlands and forests, this seems to have had little effect on preserving such valuable ecosystems. Trees are still cleared on steep slopes and other fragile areas, for example. This causes landslides and mudslides and floods, resulting in destruction of homes, roads, farmland and other valuable assets, as well as siltation and pollution of waterways. Yet there is little thought given to banning this practice by law. The World Resources Institute in Washington, DC, has calculated that the loss of value from deforestation is four times as high as the value of the timber extracted, and the depletion of soils, forests and fisheries examined in this study resulted in a 25 to 30 percent reduction in potential economic growth (Stevens 1997b).

A 1997 collection of articles, *Nature's Services: Societal Dependence on Natural Ecosystems* (Island Press), edited by Dr. Gretchen C. Daily, a biologist at Stanford University, concludes that many ecosystems, once destroyed, are either irreplaceable or take thousands of years to replenish, such as ancient aquifers or old-growth forests. Daily concluded that we cannot afford to wait to act until we have disrupted the planet's life-support system beyond repair (Stevens 1997b). Some 20 scientists contributed to this book, including Dr. Norman Myers, author of many books on the value of wild plants to medicine and agriculture. He documented the multibillion-dollar insurance value that wild grains provide in disease resistance (Daily 1997). Katherine Ewel of the Forest Service discussed the lower cost of treating sewage in constructed wetlands, as compared to treatment plants, and Gary Nabhan and Stephen Buchmann found that wild pollinators save American farmers $1.6 billion annually (Daily 1997). This book's experts make a strong case for protecting environments in a natural state and provide evidence that we are only beginning to appreciate the complexity of these ecosystems. This can apply, for example, to commonly accepted mitigation rules used in US wetland-filling cases, in which a wetland is created for one that is destroyed. Ecologists consider that the natural wetland is far more complex and irreplaceable than the man-made one, and they should not be considered

equal under the law.

Earth's Worth: Page 4

In the United States, many politicians and businessmen have opposed environmental and endangered species legislation on the grounds that these laws reduce the profits of commercial ventures. They propose that every developer whose project is blocked by such legislation should receive financial compensation from public funds. These businessmen calculated the value of their financial loss on the appraised value of their land, and added potential profits lost. In 2001, for example, farmers in California sued the Fish and Wildlife Service to compensate for water it lost when a water allotment was diverted for endangered salmon and smelt (Russell 2001). The court ruled in favor of the farmers and ordered the government to pay them the value of the lost water, arguing that the government is constitutionally prohibited from taking property without paying for it (Russell 2001). This ruling could end in negating the effectiveness of habitat protection under the Endangered Species Act for lack of sufficient funding. Ecologically, farmers depriving endangered fish of habitat are impoverishing entire aquatic ecosystems and, in all probability, polluting waters with pesticides and other chemicals in the process. Yet if the value of maintaining the ecosystem in the San Francisco Bay area was calculated in terms of the millions saved in flood damage control, water purification, production of shrimp and other fish, the ecological values would far outweigh short-term commercial losses. If environmental protection laws were written in terms of ecological values, destroying natural ecosystems for the economic benefit of a few would not be allowed.

When the Northern Spotted Owl (*Strix occidentalis caurina*), native to old-growth forests in the Pacific Northwest, was listed as Threatened on the Endangered Species Act and large sections of its habitat protected, it became a focal point, polarizing pro-logging and anti-logging activists. Owl haters urged others to kill these birds, who were blamed for ending the logging industry, with bumper stickers such as "Kill an Owl, Save a Job." Such venom totally obscured the fact that the forests were being overcut and that logging jobs were destined to be cut anyway, as the last old-growth disappeared under the saw. A state in the heart of this owl's range, Oregon, found that decreasing logging ended in helping its economy; an influx of technological businesses provided better salaries than those paid for logging jobs (Egan 1994). The Governor of the state supported the logging restrictions as helping to maintain the overall quality of life in the state, preventing floods and attracting tourists, which are supplying another large segment of the state's revenues. Yet pro-business interests continue to fuel the fires, writing books which conclude that it is easy to understand why a landowner, having an eagle or Spotted Owl nesting, could be tempted to destroy a nest or even kill an endangered animal. Such people maintain that the owner of such land might be expected to destroy it by logging or development prior to designation of Critical Habitat for the species in order to be able to reap profits. The Northern Spotted Owl has, in fact, declined since it was listed on the Endangered Species Act, mainly as a result of Habitat Conservation Plans that have been detrimental to its populations, but also, very likely, illegal killing played a role.

One conservative critic of the Endangered Species Act noted that the Act "has undoubtedly caused the deliberate destruction of millions of other endangered plants and animals" (Jacoby 1998). This explains, according to the critic, why after 25 years, 97 percent of the endangered species list remains endangered (Jacoby 1998). If so many endangered animals are being killed deliberately, enforcement of the Act is urgently needed. Such attitudes are extremely detrimental to the survival of endangered species and should be addressed. Although many animals are being killed, the main reason these species remain endangered is a deteriorating environment and a half-hearted commitment on the part of the US government and the public to saving these threatened species.

A study of America's environmental laws and their effect on the economy was conducted by the nonprofit Institute for Southern Studies, a social policy research group. It concluded: "At the policy level, the choice is really not jobs versus the environment. The states that do the most to protect their natural resources also wind up with the strongest

economies and best jobs" (Smothers 1994).

Earth's Worth: Page 5

Ecotourism and non-destructive recreational uses of nature are among the most valuable of all services nature provides, according to the study mentioned above, and many countries have seen dramatic rises in their revenues from tourism in recent years. In 1995, Botswana earned $100 million from tourism; South Africa reported $6 billion in tourism revenues. Kenya earned $452 million the same year, which paid the wages of 13 percent of its population. One tour company, the Conservation Corporation of Africa, or Conscorp, works out arrangements with local villages in which it promises to build schools and clinics near its lodges, employing many local people in the process. It also buys seeds for farmers to plant vegetables to sell to its lodges and brings villagers from the area into the reserve to educate them about wildlife and ecotourism. Conscorp runs some 22 small--but expensive--lodges in Africa from Kenya to Zanzibar, none of which allows game hunting; its revenues topped $30 million in 1996. Costa Rica, one of the world's primary ecotourist countries, has set aside 25 percent of its land for conservation, and ecotourism draws 1 million visitors per year, who spent some $800 million in the country (CNN special: "What Price Nature?" March 2001). This industry continues to grow at a rate of 20 percent a year, with visitors coming to its cloud forests, tree canopy tours and beaches where sea turtles nest.

In terms of the value of animals, the income from exploitation is dramatically lower than that from ecotourism. African Elephants, for example, when killed for trophies, earn some $4,000 to $20,000 for governments in fees, and the tusks sell for an average of $2,000 apiece. From ecotourism, however, an East African elephant produces an estimated $1 million during its 60 years (Currey and Moore 1994). A 1989 analysis found that the viewing value of tourists who come to Kenya to see elephants is estimated at a minimum of $25 to $30 million per year (Brody 1994). Tourists come from around the world to see these massive animals, and the governments of most African countries place a higher value on live elephants than dead ones. Trophy hunting also kills off the big bull elephants, which are the main breeding animals, as well as large matriarchs, who play a crucial role in guiding and protecting herds. These are the very elephants tourists come to see.

Endangered species in the United States also draw many tourists who travel long distances to see Whooping Cranes in their wintering marshes in Aransas, Texas**;** Gray Wolves in Yellowstone National Park; and California Condors newly reintroduced near the Grand Canyon.

Whales are extremely valuable in ecotourism. They are becoming major money-earners to the increasing numbers of whale-watching tours worldwide. In 1992, 37 countries conducted whale watching tours, and the United States alone earned $260 million. Since then, whale-watching has grown in popularity. A study by the International Fund for Animal Welfare found that in 1998, revenues from whale-watching exceeded $1 billion, with 9 million people participating in 87 countries and 500 communities. By contrast, a single Minke Whale sells for about $100,000 (Talmadge 2000), a one-time profit from these long-lived animals that is far less than they would produce during their lifetimes. Yet wealthy countries, such as Norway and Japan, are still killing whales, catering to whalers, who form a tiny segment of their populations.

Bird- and wildlife-watching and feeding have become major industries in the United States. A Fish and Wildlife Service survey found that in 1991, Americans who watched, photographed and fed birds and other wildlife spent $18.1 billion (Blom 1997). The spending generated nearly $40 billion in total economic activity and supported 766,999 jobs (Blom 1997). Equipment sales for wildlife appreciation totaled $10.6 billion, followed by $7.5 billion spent on travel-related goods and services, and $1.5 billion on wild bird feed (Blom 1997). A 1996 survey found that while only 3 million people in the United States hunted migratory birds, 25 million Americans were considered avid bird-watchers who would drive a mile or more to observe or photograph birds, and 50 to 60 million people in the

United States watch birds at their feeders.

The Fish and Wildlife Service found in a 1996 survey that wildlife watchers, fishers and hunters spent $100 billion on equipment, travel, and publications. When total economic profits were analyzed by the Fish and Wildlife Service in terms of hunters vs. bird-watchers, the bird-watchers spent some $14 billion on all aspects of bird-watching, while bird hunters spent $1.3 billion. *American Demographics* magazine estimated that an even greater amount, $18 billion, was spent by American birders on their hobby. In economic output, Ducks Unlimited, a hunting organization, estimated that bird hunting generated $3.6 billion, while non-consumptive use of birds earned $15.9 billion.

Earth's Worth: Page 6

Consumptive users of wildlife, such as hunters, make up a small minority of the public, approximately 14 million, or 5 percent, and fewer than 1 percent are trappers, yet these interests control state wildlife departments and heavily influence the Fish and Wildlife Service. The fees from hunting licenses fund the majority of state wildlife departments. These departments manage all wildlife within a state, in spite of the fact that only a small number are hunted or trapped, with the result that habitats are manipulated to benefit hunted animals, such as deer, by encouraging shrub and second-growth forest, while species needing old-growth forest, such as woodpeckers, decline as these forests are cut. Endangered species are conserved by state Natural Heritage Programs, but funding is often miniscule in comparison with the fees from hunting. Funding sources include income tax rebates, vanity license plate revenues and grants from general funds, but generally do not begin to fill the need for habitat acquisition, education and conservation programs and research. Greater funding is needed for these programs, perhaps through a small tax, such as the less than 1 percent sales tax in Missouri for wildlife and conservation programs. It generates more than $100 million annually. A tax for non-game and endangered species would provide major funding for these state programs, which fill an important role not played by federal Endangered Species Act programs.

The recent phenomenon of tropical forest ecotourism has produced other comparisons in revenues of exploitative vs. non-consumptive use of wildlife. Dr. Charles Munn, an ornithologist with the Wildlife Conservation Society is studying macaws in Peru's massive Manu National Park, which is the size of Massachusetts. He estimates that a wild macaw is worth $165,000 a year, based on revenues from the growing number of tourists who come to see these colorful, long-tailed parrots in spectacular flights (Munn 1992). A bird trapper receives only a few dollars for a wild macaw which, if sent to a pet store in Europe, might sell for $1,000. Income from the pet trade goes primarily to a small number of exporters, importers and retailers. It does not protect the habitat of the birds, nor does it pay for population surveys to prevent depletions. Moreover, from capture onward, these wild birds are treated very inhumanely, causing high rates of injury and mortality. The capture of wild birds for the pet trade is banned by the majority of the world's nations, but the few that continue it contribute to depletion of wild bird populations, smuggling, and their inhumane treatment (see Trade chapter).

Under Munn's calculations, the value of each macaw in the wild over the period of its life, which averages about 50 years or more, totals some $8,250,000--an enormous sum. This money flows into local economies of villages and towns near the park, local hotels, taxis, restaurants and other businesses. For many poor areas, such income provides much needed services and raises the standard of living. Tourist money is also spent in cities where visitors arrive, and constitutes a major portion of airlines' revenues. Manu National Park has been declared a Biosphere Reserve in recognition of its importance as a center of biodiversity. Its 7,000 square miles protect a large portion of Peru's tropical rainforest. Manu's ecotourism companies are considered models for sharing revenues with local people and protecting indigenous tribes (Munn 1994). These companies have tours geared toward viewing certain spectacular or endangered species, such as Giant Otters (*Pteroneura brasiliensis*) (Munn 1994).

Earth's Worth: Page 7

Although some abuses of the land have resulted from ecotourism, including large numbers of people who can overwhelm delicate habitats, these situations are rare and can be rectified. Ecotourism helps far more animals and habitats than it hurts and, often in an indirect way. An important byproduct of tourism is the protection it accords animals in the areas visited, especially outside national parks and reserves, where most wildlife is on the decline. The presence of tourists tends to deter poachers, and in a growing number of areas, revenues accrue to local people from tourists™ use of restaurants, gift shops, taxis and other businesses. This encourages residents to cooperate in protecting the wildlife and the environment. This applies as much to African savannahs, as to North America or Europe. The non-profit Eco-Tourism Society, located in North Bennington, Vermont, distributes information on responsible travel that does not result in ecological damage and respects local residents. It recommends that tours share profits with residents.

Many conservation organizations now run ecotours and issue pamphlets, such as the National Audubon Society's guidelines for environmentally responsible travel, which describes dangers to specific habitats, such as coral reefs, and suggests non-intrusive viewing and tours that enhance local conservation. Trade in local wildlife is prohibited. The Wildlife Conservation Society has proposed that a fee from tourists be set aside for a land bank to fund national parks in Central America.

As ecotourism rises in its importance to national economies, whale-watchers, tropical forest visitors, coral reef divers and others will demand pristine environments with diverse wildlife. This will be a strong force in favor of passage of strict environmental laws around the world. Moreover, the value of wilderness increases as more and more tourists seek out undeveloped areas. Governments should no longer consider wilderness as wasteland, but as a precious commodity.

The economical arguments in favor of preserving the natural world are strong, but we should be equally motivated by our affinities for our fellow creatures and the natural world. Our ties with nature are very deep and span millions of years. Modern technology has made us forget the awe with which we once regarded the Earth and has encouraged a false sense of superiority and complacency.

Actions and Attitudes

Biologists, conservationists, government officials and many members of the public are regarding the rise in the number of extinctions and endangered species with great alarm. The United Nations has found that species and habitats are being lost at an "unprecedented rate" (Stevens 1997c). The need for effective action has never been greater. Fortunately, concurrent with the general deterioration of the environment and wildlife populations, programs for the preservation of rare species have mushroomed, along with a new compassion for animals. These programs address the status of a small number of species, and if expanded to include a far greater percentage of threatened species, the extinction rate would decline.

Some conservation efforts to preserve endangered species have had remarkable success, while others have had mixed results. The expenditure of large sums of money to save some endangered species has not automatically resulted in an increase in their numbers. It is a common misconception that endangered species, once accorded legal and habitat protection, will survive and increase in number. Unfortunately, many species have died out in spite of conservation measures on their behalf. Through examination of failed programs, fewer mistakes can be made in the

future.

Actions and Attitudes: Page 1

The Javan Tiger (*Panthera tigris sondaica*), for example, was given legal protection and reserves in the 1920s and 1930s, yet it was poached to extinction. If a single facet of a conservation plan is lacking, faulty or unfunded, this can spell extinction for the animal or plant. A reserve for this Tiger was set aside too late, when it was nearly gone. As Indonesia's most heavily populated island, Java had little forested land left, and by 1972, only four or five Tigers survived (Matthiessen 1997). With a very limited population under constant threat from poachers and big game hunters, these Tigers needed intensive anti-poaching protection and biological surveys, which they never received. Without well-equipped and motivated park rangers, research and surveys, education of local people and the goal of conserving Tigers established as a major priority of the Indonesian government, there was no chance of saving these cats. The last Javan Tiger was seen in 1976 (Matthiessen 1997).

Since the 1970s, Tigers have experienced precipitous declines throughout their remaining Asian range. Killed for their "magical" bones and body parts, which are used for Traditional Medicine as well as for potions that are intended to impart virility and strength, these magnificent cats are snared, trapped, poisoned and shot in devastating numbers, estimated at a minimum of one Tiger per day of the fewer than 5,000 that survive. A Tiger is now worth at least $50,000 in Traditional Medicine, placing a price on the head of every wild Tiger. Many experts are predicting the Tigers™ extinction outside of zoos within a few years. One program, however, has shown success in stemming this decline. In Russia's Far East, strong anti-poaching programs and intensive research and survey projects have halted the decline of the largest subspecies, the magnificent Siberian Tiger. This work has been funded by outside organizations including the Global Survival Network, a Washington, DC, organization, and other groups.

Only about 250 Siberian Tigers survived in the wild in the early 1990s, and with 50 or more being killed by poachers each year, their future seemed dim. The Russian government, in economic chaos, was unable to pay wardens a reasonable salary. Many resorted to illegalities to take advantage of the high value of dead Tigers. The open border with China brought an influx of smugglers and traders offering bribes of $5,000 or more to wardens and poor villagers for killing a Tiger. With the infusion of some $750,000 from conservation organizations since 1993 and help from the US Fish and Wildlife Service, well-armed and well-paid wardens now patrol most of the Siberian Tiger's habitat in modern vehicles. Without this outside funding, which must be continued indefinitely, poaching would have extinguished the remaining wild Siberian Tigers. Biological research on these Tigers is being carried out by the Idaho-based Hornocker Wildlife Institute, along with Russian scientists. These studies have surveyed their populations and obtained the first estimate of their habitat needs which, for males, is at least 450 square miles. One

female Siberian Tiger named Lena, being radio-tracked by these researchers, was killed by poachers. Her four young cubs would have starved to death, but they were located when signals were received from the still-operational radio collar, which had been cut off Lena's body and placed next to the cubs. The terrified and hungry cubs were taken into captivity, and the three survivors were sent to US zoos.

Siberian Tiger poaching is finally decreasing. Russian conservation groups are conducting educational programs for local people and investigating suspected poachers along with Russian government officials (GSN 1997). Recent population surveys indicate an increase in Siberian Tigers, and conservation plans are falling into place (Galster and Eliot 1999). The Tiger's prey of deer and wild boar has been heavily poached, and the plan calls for anti-poaching work to preserve these animals (GSN 1997). Tiger biologists have drawn up a plan for a huge sanctuary in the region, suggesting habitat corridors linking isolated Tiger populations, and proposing an end to clearcutting of forests (GSN 1997). Without urgent protective measures, this magnificent cat will disappear. (See Forests chapter for more on this Tiger and its habitat).

Actions and Attitudes: Page 2

For some endangered animals, CITES has been crucial in preventing their extinction. After a prolonged controversy, the African Elephant was upgraded from Appendix II to Appendix I in 1989, which effectively ended the ivory trade that resulted in the slaughter of these intelligent animals, the toll reaching almost 1 million animals for the 1970s and 1980s. The 1996 *IUCN Red List* classified the species as Endangered for the first time, upgraded from Vulnerable status in the 1994 *IUCN Red List*. This status was maintained in the *2000 IUCN Red List*. The ivory trade reduced these slow-reproducing animals, who have a single calf only once every five years, from 3 to 5 million in the 1930s and 1940s to only 300,000 to 500,000 today (Onishi 2001). The high price of ivory in the 1980s encouraged the poaching of elephants outside parks, and when these were killed off, poachers entered national parks, often armed with machine guns. Almost all the large bulls and most of the older females were killed for their tusks, leaving traumatized teenage elephants without leaders and protectors and orphaned infants who starved to death.

In the majority of African countries where elephants survive, they are zealously protected for their value in tourist revenue and for their ecological value as keystone species. Many officials of these countries have said that they do not want future generations to learn about elephants only through books. Yet several southern African countries--Namibia, Zimbabwe and Botswana--which stockpiled ivory from the 1980s trade and from culls carried out to limit elephants, succeeded in 1997 in convincing delegates at the CITES Conference to allow sale of 65 tons of this ivory to Japan. Japan's sponsorship of much of the costs of the 1997 Conference, which took place in Zimbabwe, paved the way for the decision. The President of Zimbabwe made personal requests to delegates to allow the sale. Although CITES authorities enacted controls on the conditions of the sale of this ivory, it was predicted that the decision would open the door to further killing of elephants and ivory smuggling. This proved correct. African Elephants began to be poached again during the late 1990s in Kenya, the Democratic Republic of the Congo and other countries. An elephant orphanage in Kenya received an unprecedented number of orphaned calves at this time. Their mothers had been killed for their ivory in national parks. Some of this ivory is sold locally, and much is smuggled out of Africa.

A large confiscation of tusks was made in Los Angeles in May 2001; these tusks, many of which were very small and obviously from young elephants, had been smuggled from Nigeria in hollowed-out furniture. This indicates that allowing some sale of ivory opens the door to unrestricted slaughter and smuggling that will place the species in a critical--and perhaps lethal--decline toward extinction. When ivory was allowed to be sold on a quota basis in the 1970s, this "regulated" trade failed completely to prevent unregulated slaughter as the price soared. In many parts of Africa, poachers are killing elephants for a trade that may be resuming. Ivory is openly sold in Cameroon, and in Burkina Faso, a West African country north of Ghana, where only 3,000 to 4,000 elephants remain, ivory traders are

selling carvings and jewelry in the capital city (Onishi 2001). One trader even complained that sales had not recovered as a result of the 1989 ivory ban, with larger carvings taking months to sell because tourists are no longer as interested in buying ivory (Onishi 2001). When asked about the need to conserve these endangered animals, he said that like humans, some die, but the species does not become extinct (Onishi 2001). Few Africans have been taught about how close African Elephants came to extinction as a result of the ivory trade, nor about their key role in spreading the seeds of trees and creating waterholes for wildlife. It is also likely that only a small percentage of Africans are aware of the species' immense intelligence and altruism. If these facts were better known, it is likely that most Africans would want to protect these great animals. They are in imminent danger of disappearing from West Africa.

As they attempt to forage in land that is now being tilled or used as grazing land, Asian and African Elephants are killed and harassed by farmers and villagers outside national parks. Wildlife corridors are being proposed in many parts of the world to ease such problems. As human populations grow, invading the last retreats of wildlife, parks and reserves are becoming islands amid development, agriculture and cities. Without corridors of natural habitat linking these islands, wildlife will decline in diversity and abundance. A new national park in Mozambique will link with South Africa's Kruger National Park and provide a corridor and additional habitat for Kruger's elephant populations. Other international parks in southern Africa have opened or are scheduled. Some conservationists have proposed that these parks form the southern end of a wide corridor north to Kenya. This would be an excellent solution to the declining habitat faced by many large mammals of eastern Africa. In the Western Hemisphere, the Atlantic Biological Corridor Project and the Mesoamerican Biological Corridor seek to protect wide swaths of land between Mexico and Colombia to prevent the extinction of wide-ranging animals, such as Jaguars and Cougars. Along Texas' border with Mexico, most of an extremely biologically rich area has been plowed under, and the Fish and Wildlife Service is trying to purchase the remnants of this once rich habitat to link it with adjacent habitat in Mexico for use by endangered wildlife.

Actions and Attitudes: Page 3

In the American West, Grizzly Bears may someday be able to roam from Yellowstone to Yukon in a project known as Y to Y, an immense corridor that would prevent the present isolation of this species into pockets of fragmented habitat surrounded by hostile cattle ranchers. The Wildlife Conservation Society has initiated a program it calls "Living Landscapes," which involves local people living in areas surrounding parks and reserves. It promotes the conservation of animals that have ranges extending beyond the parks in order to help conserve these species, allowing them to be part of functioning ecosystems. This sometimes involves curtailing their own hunting. White-lipped Peccaries, for example, a type of wild pig, are important seed dispersers of trees in Latin American rainforests and also create open spaces on the forest floor by rooting for food. Yet they are heavily hunted for their meat and pelts. Only through an education program in which the local people themselves understand the effects of their hunting and are permitted to manage the land, can the species and its habitat be protected. This organization is applying such approaches to regional conservation in 50 sites in Latin America, Asia, Africa and North America (WCS 2001).

Actions and Attitudes: Page 4

Another fundamental element to the future survival of wildlife in a world crowded with humans is tolerance and a belief that the Earth must be shared. Public opinion has been crucial in land use and protection of natural habitats and landscapes so that wildlife and plants were allowed to survive, even in parts of the world with overcrowding where land was at a premium. Fewer species are threatened in parts of the world where wildlife is respected and considered part of the landscape. In Africa, wildlife flourished when native peoples were the guardians of the land, prior to the

18th century when Europeans entered as colonial rulers. European rule resulted in overhunting and development of large-scale ranches and farms that were fenced, creating a drastic decline in wildlife.

Native Americans have a less proprietary view of nature than Europeans, and many tribes believe in spiritual connections with trees and animals. They treat nature's assets as gifts, for which they express gratitude. In the intervening centuries since colonization of North America by Europeans who failed to respect nature, views have come full circle for many Americans. Wilderness and nature preservation have become high priorities, based on both scientific discoveries about how ecosystems function and a growing desire by people to appreciate nature. Some scientists believe that connections with nature have been an intrinsic part of human nature for millions of years. Dr. Edward O. Wilson calls this "biophilia," or "love of living things," and cites it as a primary human trait. Such ties to nature have nurtured new conservation zeal to help preserve disappearing wildlife and landscapes.

For some people, however, even the most basic ecological and evolutionary principles are refuted in favor of views that justify exploitation and species' extinctions. They describe conservationists as irrational "tree huggers," and animal lovers as "bunny huggers." Anti-environmentalists have formed organizations in the United States, operating collectively as the fiWise Usefl movement. Many elected government officials share these views, and have voted for legislation that fails to protect endangered species and results in destruction of important wildlife habitat. US Congresswoman Helen Chenoweth, a Republican from Idaho, believes that there should be a public referendum regarding which animals can live and which will be allowed to go extinct (Egan 1996). Chenoweth stated to *The New York Times*: "A species goes out of existence every 20 seconds. Surely a new species must come into existence every 20 seconds. There's no way human beings can regulate that dynamic" (Egan 1996). Humans can, indeed, affect the "dynamic," as they have for millennia, and when species are lost, their loss is our loss. Evolutionary biologists would be dumbfounded at her statement. Although species are passing into extinction at a fast rate, new ones are not evolving every 20 seconds, nor even every 20 years or every 200 years, unless one considers the mutations of viruses and bacteria to be new species. Once the Tiger or Right Whale--or any of Earth's myriad species--becomes extinct, it is gone forever. The film "Jurassic Park," which concerned the recreation of dinosaurs from their DNA, is total fiction. Science has not found a way to clone species from DNA obtained from dead animals because the DNA becomes scrambled after death. Nor are such scientific feats anticipated in the near future.

Actions and Attitudes: Page 5

The basic problem that many people find in protecting endangered species is the question of land ownership and the inconvenience that they fear may result when animal or plant habitat is protected. Congresswoman Chenoweth would find agreement among many people living along the Massachusetts coast, who are unwilling to share the beaches with a tiny endangered bird. This bird has caused storms of controversy between its protectors and recreational beach users. The Piping Plover (*Charadrius melodus*), a shorebird, nests on sandy beaches along Eastern coasts, the Mississippi River and the Great Lakes. It has been crowded out of the majority of its nesting sites by the hordes of people who come to swim, sunbathe and drive off-road vehicles. Beaches have been altered or developed for various commercial purposes as well, including levee construction for flood control. In 1985, the species numbered only a few thousand birds and was listed on the Endangered Species Act as Endangered in the Great Lakes, and as Threatened elsewhere in its range. The numbers of this species along the Atlantic coast, from southern Canada to South Carolina, reached 1,377 birds in 1998, and throughout its range, only about 5,913 birds survive (BI 2000). In Massachusetts, where most beaches are public, local authorities and even federal and state enforcement officers were reticent to enforce the law to protect the nesting plovers. Even when parent birds managed to raise chicks, the chicks were often run over by vehicles when they fell into the deep ruts on the beach made by tire tracks, unable to climb up the six inches of vertical sand or flee an oncoming vehicle in time. Plans in 1989 to fence a portion of the beach in Plymouth to protect the nesting birds met with such anger and public protests from beach-users that they were abandoned. In 1991, only a single chick survived in the state, with few beaches strictly protected. Unleashed dogs

killed some of the chicks, but most were run over by cars and all-terrain vehicles.

On Nantucket island, a Massachusetts Audubon Society warden fenced in the nests of two Piping Plovers in 1994, causing such anger from off-road vehicle drivers that they called the police, who threatened to arrest the warden. Neither the state, which protects the species, nor the Fish and Wildlife Service came to the rescue of the Piping Plovers by supporting the actions of the warden. Vandals ripped down the protective fencing. Endangered Least Terns (*Sterna antillarum*) nesting on the same beach produced 24 chicks that year. In one day, 20 were run over. This finally convinced the local selectmen to close that portion of the beach to off-road vehicles, which allowed all eight Piping Plover chicks to survive. The citizens of Nantucket voted the following year to defeat a selectmen proposal to allow vehicle use on the beach, which would have exempted the area from state law protecting the plovers. In 1995, three pairs of Piping Plovers nested successfully on Nantucket, and state restrictions began going into effect to protect their nests.

In Massachusetts, nests increased from 139 in 1986, to 445 in 1995 (Allen 1996a). In a step backward, the state of Massachusetts eased restrictions on beach vehicles in 1996, giving what conservationists called "plover-squashing permits" (Allen 1996b). The Massachusetts Audubon Society estimated that at least 33 plovers would be legally killed each year under the new regulations. Another loss for Piping Plovers was the firing in September 1997 of the town of Plymouth's Beach Manager, who had spent more than a decade protecting these birds from off-road vehicles. This was done to appease recreational dune buggy users. The ban, which closed part of the beach until mid-August to allow the chicks to survive, was lifted. A civil complaint was filed in US District court in April 1998 to force the town of Plymouth to enforce the Endangered Species Act and protect nesting plovers. The following month, a judge ordered the town to prohibit off-road vehicles on the beach from May 19 through August 31, unless strict measures are enacted to protect the nesting birds.

At least one conflict concerning this endangered bird in 1997 had a happy ending. The Cape Cod town of Barnstable's Fourth of July fireworks were nearly canceled by the Fish and Wildlife Service for fear that they would disturb the nesting plovers. A local businessman offered the use of several barges from which to detonate the fireworks. The barges were towed far from shore, and the fireworks proceeded as scheduled. Conrad Troy, owner of Tucker-Roy Marine Towing and Salvaging, Inc., who had been contacted by the Massachusetts Audubon Society for his help, said; fiIf I was an endangered species, I would hope someone would come help me out. We can keep the piping plovers happy and the kids who want to see the fireworks happy" (Anand 1997).

These controversies are indications of a growing trend in which animals, especially endangered species, are no longer eliminated or killed in the United States without protest when they come into conflict with people. Listing a species on the Endangered Species Act is a major step. It is not an end in itself, however. Listing scarcely helped the plovers in the Plymouth beaches, however, because the law was not enforced when opposed by drivers of off-road vehicles and beach users. Only the combination of publicity, local support for the birds and demand for strict protection have resulted in protection of plover nests and habitat preservation. A large contingent of volunteers now works on behalf of these tiny birds. Such cases provide examples of what is needed to prevent extinctions.

Conflicts over protection of endangered species are sure to increase in the future. Only if the public support is stronger on behalf of wildlife than the influence of those who are indifferent or oppose endangered species protection, can endangered species survive. Public support for the less attractive and charismatic species, such as insects, fish, bats and nondescript plants, will come only through effective conservation education.

Actions and Attitudes: Page 6

Another highly endangered species that nests on beaches has been the subject of a successful reintroduction

program sponsored by the Fish and Wildlife Service in cooperation with the Mexican government. The Kemp's Ridley (*Lepidochelys kempi*), smallest and rarest of all sea turtles, became endangered from killing for its meat and shell. Killed off by poachers in Texas, where it once nested, a long and difficult program was initiated to return these turtles to Padre Island. Thousands of eggs laid by the last 500 nesting females on the turtles™ only remaining nesting beach along the Caribbean coast of Mexico were taken to Texas for hatching. It is not known how sea turtles learn to return to their natal beaches after spending many years at sea, and all precautions were taken to convince the hatchling turtles that they had been hatched in Texas, not Mexico. The eggs were not even allowed to touch the sand on their Mexican beaches. Between 1978 and 1988, when the program was halted for lack of visible success, a total of 22,000 eggs had been taken to Padre Island, hatched, kept in captivity until they were about a year old and then released to the sea. In 1996, to the delight of conservationists, two female Ridley Turtles that had been released 12 and 14 years previously, returned to lay eggs on Padre Island. They were recognized by a special marking the US Fish and Wildlife Service had made on each shell identifying the year the turtles were hatched. By 1999, 16 nests of returning Ridley Turtles were found by volunteers and members of the recovery team who monitor the beach 24 hours a day during the summer nesting season. This is the first known case of successful reintroduction of sea turtles. Numbers of these turtles have increased to about 9,000 in 2001, but they are still only a fraction of the 40,000 filmed nesting on a Mexican beach on a single day in the 1940s.

Actions and Attitudes: Page 7

Dramatic rescues of endangered species have become commonplace on the island of Mauritius through the efforts of teams headed by Dr. Carl Jones, a scientist working for the Wildlife Preservation Trust, founded by famed author and conservationist, Gerald Durrell. This island harbors some of the world's most endangered birds, and by the 1970s, conservationists had become resigned to the imminent extinction of several of these endemic birds and other endangered animals. In steep decline, they seemed to be following on the path of the Dodo. Crucial to the success of the efforts to reverse this trend was the agreement signed by the government of Mauritius with four conservation organizations in the 1980s, including the Wildlife Preservation Trust, to cooperate in preserving the island's natural heritage. A conservation program in the 1970s to protect the Mauritian Pink Pigeon (*Columba mayeri*) had failed, and the remaining 33 birds were dying off. Captive-bred birds failed to breed, and wild birds were dying from various causes. Jones arrived on the island in the 1980s and, after years of concerted effort in cooperation with a small staff, brought the wild population from a low of 10 birds to approximately 375 birds in 2000. Pink Pigeons now nest at four sites on Mauritius, and another on Ile aux Aigrettes, an islet off the coast (BI 2000). This spectacular increase was the result of a program in which exotic monkeys, rats, mongooses and feral cats were removed from the roosting and nesting grounds of these beautiful, pale pink birds. Captive-bred birds released to the wild were given food until they were independent, and nests were carefully monitored for predation, falling eggs and other mishaps (BI 2000). The program hopes to increase these pigeons to a population of 500 birds within five years.

The Mauritius Parakeet (*Psittacula eques*), once the most endangered parakeet in the world, became reduced to a total population of only six birds in 1978 (BI 2000). The captive-breeding program set up to preserve them in the 1970s was not successful, and the last wild birds were dying out. Jones and other experts in parrot breeding set up a new captive-breeding program and gave the few wild birds strict protection from the many threats that appeared almost certain to cause their extinction. These included an almost total loss of forest habitat, including old trees with nest holes; a lack of available food; monkeys and rats preying on nestlings; infestations by nest fly larvae; and competition for nest sites with various introduced birds and bees (BI 2000). In spite of these overwhelming odds, these lime green parakeets are making a slow recovery. A forest habitat of 8,000 acres has been made into a national park where exotic species have been excluded and captive breeding is now succeeding. At first, the wild parakeets refused to nest in boxes set out for them and would not try to find other nest sites if their nest tree were destroyed during hurricanes. Fortunately, a few pairs did nest, and habitat improvements were made, such as the planting of fruit trees as a food source. Through these and other efforts, the wild and captive populations rose to between 85 and

90 birds by 1997 (Hoyo *et al*. 1997). Numbers continued to rise, and by 2000, 106 to 126 birds survived (BI 2000). This is one of the world's most impressive conservation stories. The vast majority of birds whose populations have declined so drastically experience genetic impoverishment or become prone to other threats by failing to respond to conservation programs. The recent extinctions of Hawaii's honeycreepers and other native birds are testament to the failure of many 11th-hour programs to conserve critically endangered birds. Although still listed as Critical by BirdLife International (2000) and the IUCN, the Mauritius Parakeet may be reclassified as Endangered, should present trends continue (BI 2000).

A third endangered bird of this island, the Mauritius Kestrel (*Falco punctatus*), a small falcon, numbered only four birds in 1974, coming the closest to extinction of any Mauritian bird. Yet today the species is numerous, having almost completely recovered. Through captive breeding and restocking birds to the wild using methods employed in the United States for Peregrine Falcons, and with the help of the Peregrine Fund, hundreds of captive-bred birds have been released to the wild and fed at release sites until they gradually sought wild prey. By 1995, these kestrels totaled 286 birds (Jones and Hartley 1995). Control measures have been successful in reducing exotic species that preyed on them. The population of Mauritius Kestrels reached 145 to 200 breeding pairs in 2000; the species totals from 500 to 800 individual birds who live in three subpopulations in various parts of the island (BI 2000). Jones has also worked to restore habitats for various endangered lizards that are captive bred at the headquarters of the Jersey Wildlife Preservation Trust. These small, iridescent geckoes had become restricted to out-islets, where they survived because introduced predators were absent. Unfortunately, rabbits were released on Round Island, habitat for several of these endangered reptiles, and they multiplied to pest proportions, leaving almost no natural vegetation. Many of these lizards were captured just in the nick of time, and bred in captivity, as the last of their habitat was being consumed. After removal of the rabbits and replanting of native species, these lizards are now being reintroduced.

Actions and Attitudes: Page 8

Specimens of a highly endangered fruit bat of the small Mascarene island of Rodrigues, the Rodrigues Flying-fox (*Pteropus rodricensis*), were captured for captive breeding when wild populations became threatened by killing for food by local people. It amazed researchers studying them when a female exhibited mid-wife protective behavior seen only in a few other animals, such as dolphins and elephants. One of the females in the process of a difficult breach birth was aided by the other, who fanned her, cradled her in her wings, and showed her the proper position to cling to the cage bar during the three-hour delivery (McFarling 1994). Wild populations of this species are listed as Critical by the *2000 IUCN Red List*. Other flying foxes that once inhabited these islands are now extinct, and the Rodrigues Flying-fox is the last to survive. Without the emergency rescue of some of these foxes, the altruism and devotion of these animals would probably not have been recognized.

Actions and Attitudes: Page 9

The elimination of introduced animals, from goats, cattle and pigs to cats and exotic plants, has been carried out on many islands and island-like environments around the world to preserve native species on the brink of extinction. The governments of Australia and New Zealand, in particular, have rescued a number of critically endangered species. Lord Howe Island, located off the northeastern coast of Australia, once harbored diverse wildlife. After settlement, and introduction of rats and other exotic species, forest clearance and other threats, numerous extinctions of native animals occurred, and most of its surviving species are endangered. Efforts on the part of the government to return the island to its near-original state, with total protection of the remaining tropical forests, coral reefs and other habitats, is underway. Ecotourism has been developed on the island, but the number of visitors is kept at a level that will not harm the island's endemic fauna and flora. Cats may not be kept by the limited number of residents as pets

because of their threat to native birds, and exotic animals are being eliminated from the wild. The endangered, flightless Lord Howe Rails (*Gallirallus sylvestris*), highly vulnerable to predation by cats and other predators, are now gradually increasing with strict protection. Once found throughout the island, these rails became restricted to mountain areas after they were eliminated by feral pigs, goats, cats, dogs and the introduced Masked Owl (*Tyto novaehollandiae*) elsewhere on the island. Captive breeding has been successful, and after work to eliminate exotic animals, these rails were reintroduced to several of their original habitats at lower elevations (BI 2000). The population numbers about 130 birds, with a potential living space for up to 220 birds (BI 2000).

In some cases, control programs for exotic species on islands are not done humanely. Wire snares and poison have been employed rather than live-catch traps, for example. Humane organizations should be consulted by governments to employ humane methods in ridding islands of non-native animals.

The Black Robin (*Petroica traversi*), a beautiful songbird resident on the Chatham Islands off New Zealand, numbered just five birds in 1980, with only one breeding pair (BI 2000). Rats and cats colonized the island after settlement, and deforestation had destroyed the species' habitat. A tree-planting project in which 120,000 trees were planted on Mangere Island, one of its prime habitats, was undertaken (BI 2000). Supplemental feeding and nest protection from introduced Starlings (*Sturnus vulgarus*) and seabirds, which were preying on them, helped somewhat. Real progress began with the use of an unusual program in which eggs of the Black Robin were placed in the nests of other species to raise them and allow the original female, who became known as "Old Blue" and lived 12 years, to lay more eggs. Birds of a related species, the Tomtit (*Petroica macrocephala*), raised these robins, and chicks were successfully reintroduced to Mangere Island (BI 2000). Such cross-fostering has failed with species such as the Whooping Crane, whose eggs were cross-fostered to Sandhill Cranes, because the chicks when mature, tried to mate with Sandhill Cranes instead of members of their own species, having become imprinted. In this case, the chicks bred with members of their own species, and numbers rose to 259 in 2000 (BI 2000). They were all descended from the original pair of birds. The New Zealand Department of Conservation, which had overseen the breeding program, found through DNA studies that the birds are nearly identical genetically (Hutching 1997). Further studies will attempt to discover immune responses and other signs of inbreeding, but outwardly, these robins are thriving, with a 70 percent survival rate and normal fertility (Hutching 1997). Species with such low genetic variability tend to be extremely vulnerable to extinction, having little ability to adjust to changes in their environment or food supply.

Actions and Attitudes: Page 10

More and more countries are taking a keen interest in the preservation of wildlife, and some have ancient protective traditions. The Asian country of Bhutan has a Buddhist ethic of not harming living things. It is the only Himalayan country to have protected the majority of its forests. Rhododendron species 40 feet tall grow there, and the rivers still flow clear, without erosion and siltation. Species that are rare elsewhere in the region still survive in Bhutan. One of its protected areas, Jigme Dorji National Park, is the size of Switzerland and preserves spectacular mountains and cascading waterfalls. It is part of a Bhutanese government plan to create a nationwide system of reserves to protect the country's natural heritage (Adams 1994). Although erosion and destruction of some of the native fir and rhododendron forests have occurred, Bhutanese people support the government's "go slow" approach to development and its plan to preserve wilderness (Adams 1994). A wintering population of endangered Black-necked Cranes (*Grus nigricollis*) is zealously protected by the Bhutanese who live in the valley where the cranes come each year; they regard the birds as integral to their lives and believe that, without them, their harvests will fail. These people miss the cranes™ calling when the birds migrate in the spring, and say that the valley seems empty and silent without them (Greenway 1997). The Environment Ministry watches over the cranes as well and is extremely strict about issuing permits for activities that might harm them.

New approaches may save some of these threatened tropical areas. Australia's Rainforest Information Center has

created an Internet website which plays rock and roll music; its sponsors pay to preserve the rainforest (EII 2001). The organization is focusing on saving several endangered forests in Ecuador, including Los Cedros Biological Reserve and portions of the Madre Selva (EII 2001). The Natural Resources Defense Council has created a list of BioGems (www.savebiogems.org), the 12 most endangered wildlands in North and Latin America. It publicizes threats, such as proposed dams and logging, to generate thousands of letters and e-mails to governments, loggers, utilities and others. The Macal River Valley in Belize, threatened by a dam project, has been saved through this program. The US Duke Energy International company decided to withdraw from Belize after the torrent of protests (NRDC 2001). Boise Cascade planned a major wood chip mill in Chile, which would have consumed 1,200 acres of endangered temperate rainforest a year, with endangered Alerce trees, the massive South American counterpart to the Sequoia. The forests also sheltered tiny Pudu deer and rare birds. The company announced that it would cancel its plans "as a result of unfavorable market conditions" (NRDC 2001). Conservation International (CI) played an important role in the designation by the South American country of Suriname of much of its vast interior, a pristine rainforest, as a reserve. CI, through its scientific studies, was able to show the country's leaders that, kept intact rather than being logged, this rainforest would prove far more valuable for future generations. This organization has accomplished similar feats in Bolivia and other parts of the world, where it also carries out important biological inventories.

An example of cooperating with local people for conservation of wildlife is the administration of the Mara Reserve of Kenya. This reserve is run by the Maasai people through a council which mandates that tourist funds go directly for social services of the tribe; in turn, the Maasai, who live outside the reserve, allow wildlife to move freely without fencing or harassment that is common elsewhere in Africa where livestock is raised (Gakahu 1994). In this reserve are endangered Cheetahs and Black Rhinos, along with 30 species of ungulates, including large numbers of elephants (Gakahu 1994). Local villages in many parts of Kenya are establishing landowner associations that receive funds from tourism to protect wildlife and benefit local economies (Gakahu 1994).

Actions and Attitudes: Page 11

Teaching people that their local wildlife is important to protect as a source of pride has had excellent results in a program in the Caribbean funded by RARE Center for Tropical Bird Conservation, an organization headquartered at Philadelphia's Academy of Sciences. It has employed innovative education and conservation programs to preserve St. Lucia Parrots or Amazons (*Amazona versicolor*), the forests and other wildlife of the island. Biologist Paul Butler, who began this program, has instilled conservation enthusiasm and pride in the people of the island of St. Lucia for these beautiful and rare parrots. His dynamic program has resulted in the naming of this species as the national bird, as well as education programs so successful that children know its scientific name, habitat and need for protection. They enjoy singing songs about the parrots and dressing up in parrot costumes. The people of St. Lucia now understand that the forest and other wildlife must not be destroyed. Art and essay contests are conducted in schools and towns to publicize this parrot, and St. Lucia Parrots are used as logos for many businesses. Forest cutting has been banned, and a substantial portion of the island has been set aside in reserves. This has resulted in an increase from fewer than 300 to between 350 and 500 birds (BI 2000). The Saint Lucia government is dedicated to protecting the parrots and their habitat, and a new ecotourism industry has sprung up. These programs have meant an end to the rampant smuggling of these beautiful, rare parrots, an activity that had been thought uncontrollable because they could be sold for $20,000 per bird to collectors. Protecting the forest for the parrots also resulted in conserving other threatened wildlife of the island and precious watershed. Another native species, the spectacular Giant Swallowtail butterfly, is illustrated on billboards prominently located near towns with the message, "It's ours . . . take care!!!" (Lipske 1994). This approach to conserving endemic wildlife has been adopted on other Caribbean islands, and Butler trains local conservation officers and teachers to continue the programs elsewhere (Butler 1992, Lipske 1994). A film about these programs, "Caribbean Cool," is described in the Video section, and RARE has published a manual, *Promoting Protection Through Pride*, with advice on how to carry out such programs.

Educating children to respect the environment and conserve endangered species leaves a lasting impression if begun in grade school and continued throughout schooling. Children have an innate sympathy and love for animals, and become enthusiastic conservationists. Education about national laws and native wildlife and plants of the region encourages students to have a lifelong desire to protect them and a sense of guardianship that results in opposition to actions that would harm them. Environmental education is required in about two-thirds of US states, from grade school onward. Some schools require special training in environmental science for all teachers. A few high schools are teaching courses in ecology for college credit. The North American Association for Environmental Education has issued detailed guidelines for educators to assess textbooks and other materials for fairness and accuracy, and review by experts (Cushman 1997).

Some conservation organizations have been formed by scientists, such as the highly effective International Crane Foundation and Bat Conservation International. Entertainers have also become involved in conservation. The rock music star Sting, for example, became concerned about the destruction of rainforests and founded the Rainforest Foundation, an organization to raise money to purchase or protect thousands of acres of this endangered habitat, while at the same time informing young people about the importance of these forests to the world. Students and concerned individuals have also founded organizations to protect individual species or particular environments, such as prairies or wetlands. These organizations have raised millions of dollars for rainforest protection and helped many endangered animals.

A number of effective conservation programs began as grassroots organizations established by an individual or a small group of people who wanted to protect a species. Individuals have educated, lobbied and helped raise funds for the purchase of habitat, making extremely important contributions to the preservation of threatened species. The beautiful bluebirds of North America were in steep decline until Lawrence Zeleny began his nesting box program. He popularized and distributed nesting boxes for bluebirds with an entry hole just a fraction of an inch too small for the aggressive European Starlings to enter. The latter birds are taking over the tree nest holes of all three species of North American bluebirds. Starlings are also a threat to several native species of woodpeckers. Through the nest box program promoted by Girl and Boy Scout troops and other organizations, these colorful birds have increased and may again be abundant, familiar residents of orchards, woodland edges and grasslands. Such citizen projects keep species in decline from reaching endangered status. Once endangered, a species' genetic diversity is threatened, and multi-million-dollar state and federal rescue programs, which are not always successful, must be set up to help them.

Only a small percentage of endangered species have such programs in place to aid their populations and protect their habitat, and individuals can make important contributions by volunteering for organizations working to preserve species and their habitats or by founding an ad hoc group. The majority of species listed on the *2000 IUCN Red List* or on Natural Heritage would be far more likely to avoid extinction if conservation programs were created for them, with help from both individuals and organizations. The species most in need are invertebrates and plants, which form the majority of all endangered species and receive the least funding. Within each region or county, little-known endangered species may be fading out without the aid of any organization or individual. Organizations such as The Nature Conservancy, Conservation International, scientists with the IUCN or state Natural Heritage programs provide highly specific information on threatened species in various parts of the world.

Restoration of original ecosystems will become more and more important as natural landscapes decline. The Nature Conservancy, which has purchased millions of acres of land to preserve resident endangered plants and animals, reintroduced the American Bison to its 30,000-acre tallgrass prairie in Oklahoma, and is reintroducing native flowers, plants and animals to restore at least a portion of this magnificent ecosystem. After decades of failed bills proposed in Congress, legislation was finally enacted in 1996 establishing the nation's first tallgrass prairie park of more than 10,000 acres in Kansas. Individuals can also contribute to restoration of ecosystems. Books, such as *Noah's Garden. Restoring the Ecology of Our Own Back Yards*, by Sara Stein (1993), and many magazine articles have called attention to the effects of suburbanization, and the poisoning of native wildlife with pesticides and herbicides used on lawns. They suggest means of bringing back natural ecosystems.

Actions and Attitudes: Page 12

However effective private organizations are, they cannot begin to have the effect of preserving habitat that governments have. As the owner of millions of acres of parks and reserves, the US government plays a major role in habitat and species preservation. The Land and Water Conservation Fund was established in 1964 to purchase and preserve federal lands, with money coming from oil and gas leases on the coasts. Each year, some $900 million is deposited in this fund, and more than 5 million acres have been preserved in many threatened environments. In 1998, $699 million was approved for spending on land purchases, including $250 million for acquiring the ancient Headwaters Redwood Forest in California to save it from planned logging, as well as $65 million for the New World Mine site near Yellowstone National Park to save it from a huge Canadian gold mine.

National Wildlife Refuges are vital habitat for thousands of threatened and declining species and were first set aside during the Theodore Roosevelt Administration to protect endangered sea birds being killed for their plumes. Now refuges and preserves are key to the survival of Red Wolves, Bald Eagles, Whooping Cranes, Florida Panthers and numerous rare plants, butterflies and other wildlife. In many of these refuges, oil drilling and other exploitation occurs, causing damage to ecosystems and threatened wildlife. The protection these refuges receive is far less stringent than that of national parks and monuments. In some refuges, high-speed roads cut through the middle of marshes where an array of rails, turtles and wetland species end up run over by vehicles. In the largest refuge, the Arctic National Wildlife Refuge, most of the land is open to oil drilling, where water and air pollution have been severe problems. The calving ground of a herd of some 100,000 Caribou within the refuge has been proposed for oil drilling, in spite of the opposition of the majority of the US public. With greater support from the public, laws governing these refuges and their funding might be strengthened to better preserve wildlife.

Some imaginative solutions to the funding problem have been developed. A number of organizations have adoption programs for wild animals. Northern Right and Humpback Whales, for example, identified individually by their markings by scientists studying them, can be sponsored by members of the public, who are then informed of news about their adopted animal. The funds are applied to research and conservation of the species. Grizzly Bears, Tigers, Gray Wolves and other animals may be adopted through a growing number of organizations. Earthwatch, in Watertown, Massachusetts, sponsors thousands of research expeditions by scientists, many of them studying endangered species, through funds from volunteers who pay for the privilege of accompanying the scientists and helping in the research. Endangered species of Brazil's Atlantic Forest, Florida Manatees, rare butterflies and coral reefs are among the many projects Earthwatch helps fund. This organization also awards hundreds of scholarships to students, and teachers who participate can turn the experience into a study program for their students.

Actions and Attitudes: Page 13

A great blossoming in natural history information has erupted in recent years. Internet websites, accessible to all, have been dedicated to endangered species research programs, biological studies, organizations devoted to helping animals and data compilations. The Internet sets up communications between people around the world, in which education, advice, and even funding help for threatened species and ecosystems can be arranged. Critical situations threatening species can be publicized immediately around the world. On the Internet, students and the public can follow the movements of individual sea turtles, great whales and many other animals equipped with radio transmitters sending signals to satellites. Libraries can be accessed, and websites set up by state, federal and private entities provide highly specific information on endangered species and the environment. Experts may be consulted through these sites. In a recent case, a man in Lebanon came upon an injured eagle with a gunshot wound; he took the bird

home and logged on to the National Geographic Society's website (see Teachers™ Aids in the Appendix for lists of websites) to find Joe Blanton's "Glad You Asked" column. Blanton put him in touch with the Wildlife Center of Virginia, whose staff at its state-of-the-art animal hospital gave him advice on care for the eagle. The man reported that the bird recovered and was released (reported in *National Geographic* June 1997). The possibilities of educating and dispensing information around the world are enormous, and with imagination, many of the problems discussed above might be solved through the free interchange of ideas of people on the Internet.

The Internet is only one new tool for conservationists. Laser discs can combine films and books and be interactive in teaching about subjects such as endangered Chimpanzees. CD-ROMs, although not yet available for many endangered species, contain--on one disc--still photos, films and printed information about a species; heretofore one might have to visit many libraries, rent or buy films by mail and spend many hours to obtain such information sources.

Books, television programs and films about the natural world have opened new doors to the public in the past decade. Natural history films, in particular, are another major influence on education and even public policy. They present views of true wilderness, natural wildlife behavior and conservation lessons. They may have had a significant influence on convincing the public of the need to pass such laws as the Endangered Species Act. Films of the slaughter of spotted cats, American Alligator, and the plight of declining species around the world aroused many people to write their Representatives and Senators in support of legislation to prevent species from becoming extinct.

Films of truly wild places may have played a role in the growth in bird watching and ecotourism, and probably in the changes that have taken place in zoos, with barred cages giving way to more natural exhibits. Having seen films of these animals in the wild, the public was no longer content to see them in such unnatural conditions, behaving so abnormally. Situations once commonplace, such as a pacing Tiger in a barred cage, a single elephant in a dusty, small enclosure, rocking back and forth, now result in protests that have changed zoo exhibits and animal treatment for the better.

The crucial steps that must be taken in the future involve the dissemination of knowledge and concern about endangered species to the general public, who are poorly informed about the enormity and possible effects on their lives of issues such as overpopulation and disappearing species. Although public awareness has increased about environmental decay and the effect that humans have in causing species' extinctions and endangering them, most people still tend to act as if nature will bounce back and will continue to function normally, no matter how extreme the damage. This is a naive point of view. Scientists have not defined the threshold beyond which total ecological collapse will occur in any given area. Also unknown is the number of species that can be extinguished before biological systems become dysfunctional (Leakey and Lewin 1995).

Newspapers, television and other media should be encouraged to publicize these issues further, rather than catering to what they might consider the public's interest. As an example, US network television and newspapers have pointedly ignored human overpopulation and loss of biodiversity, while doing numerous stories on artificial means of having children, such as test tube babies and multiple births. On the positive side, new cable television channels in the United States, such as Animal Planet and BBC, add to the growing number of wildlife and environmental programs on PBS and the Discovery Channel. Unfortunately, these channels presently reach only a fraction of the audience of network television, preventing a better understanding by the public of the problems facing the world. The numbers of films being made and books written on endangered species and the environment have increased exponentially in the past decade, an indication of a growing enthusiasm for the natural world. Other indications of this trend are the rise in memberships in conservation and humane organizations, ecotourism, bird-watching, hiking and visits to national parks and preserves. If these concerns were better translated to activism and altering lifestyles to prevent harming the environment and wildlife, impending mass extinctions might be avoided.

Biodiversity Preservation

Preventing loss of diversity through the growing number and rate of extinctions is extremely important for the ecological stability of the planet. Unfortunately, it is not recognized as a key issue by the majority of people, nor by world leaders. The extraordinary wealth of plants and animals that are in the process of disappearing may represent between 5 and 30 million species, of which only about 1.3 million have been named (Wilson 1993). Insects alone may number more than 5 million species, with the majority of species living in tropical rainforests (Wilson 1993). These animals are key to the Earth's ecosystems, pollinating, fertilizing and aerating soil, and providing food for thousands of animals. Some 751,000 animal species have been identified, far more than the 248,428 plant species, yet these represent only about 15 percent of all living species, in the view of Dr. Edward O. Wilson in his classic 1993 book, *Biodiversity*. Each year, thousands of new species of insects and other invertebrates, hundreds of frogs and, surprisingly, primates, antelope and birds are discovered by science, often in disappearing habitats.

Worldwide, biological inventories, essential to the process of protecting biologically rich areas, receive inadequate funding. Wilson has estimated that more money is spent in New York City's bars in two weeks than studying biodiversity around the world each year (Farnsworth 1994). Some $57 billion is spent on drugs by Americans annually, according to the White House Office of National Drug Control Policy, while less than $1 billion are spent on inventories and biological studies, by some estimates. The lack of funding for biological surveys means that entire ecosystems are vanishing before they are even studied.

Just as many species are disappearing from neglect or uncaring development, scientists are finding and naming hundreds of new life forms, primarily through research programs of private universities and organizations. Ecosystems thought sterile, such as deep ocean environments, are now known to contain significant species diversity. Each descent of a submersible vehicle into these environments brings new discoveries, from beautiful, bioluminescent jellyfish many feet long to bizarre creatures that seem to have emerged from science fiction tales. Many of these newly described species represent previously unknown families, classes, and even phyla of animals.

Some deep sea creatures inhabit the boiling hot water emitted from cracks in the ocean floor, managing to survive what would be toxic to 99 percent of the world's animals. This environment may be similar to the one in which life itself was formed billions of years ago. These areas should be given high priority for government research funding. Studies about Earth™s diversity should not be sacrificed in US federal spending projects such as NASA probes into the possible presence of microbial life on Mars. The discovery of the Mars fifossilfl was given enormous publicity, and in early 1998, chemical studies proved that these supposed evidences of life were actually terrestrial contamination (Wilford 1998). This has not stopped the NASA program from searching for evidence of life on Mars. Tropical forests also represent frontiers to biologists in urgent need of research funding, with millions of species of birds, mammals, insects and other life forms yet undiscovered. They are proof of the importance and urgency of preventing extinctions and degradation of natural ecosystems.

Diversity is threatened by economic concerns that affect every country. Economists tend to consider revenue important--but not such intangibles as biological diversity. Yet history shows that cultures that protect their environment endure far longer than those that do not. Clive Ponting (1991), in *A Green History of the Earth*, makes this point clearly, citing the great civilizations of the past which died out after abusing the land by disrupting water supplies through deforestation, and causing imbalances in ecosystems that resulted in their decline.

Common sense about environment protection and a concern for future generations have inspired many countries and cultures to preserve biodiversity. Those cultures which have a strong bond with nature, especially a spiritual one, are the most likely to protect their environments and wildlife, even when they are impoverished and would profit from

exploiting it. With such people, economic arguments to protect nature are unnecessary, but for the vast majority of people today, short-term profits from nature are justifiable if an urgent economic need exists. In general, harm to the environment and biodiversity may be increasingly unacceptable, however. Polls taken in 2001 in the United States found strong support for environmental protection, with 58 percent of respondents believing that protecting plants and animals should take priority over preserving personal property rights, and nine in 10 saying that it is important for wilderness and open spaces to be preserved (Barabak 2001). Even when government leaders fail to act decisively to protect nature, these actions do not necessarily reflect the will of the majority.

A new activism on the part of the public and native peoples is resulting in many protections for wildlife and the environment. It is also resulting in new alignments of organizations and groups of people. Environmentalists and labor groups have united in opposing the anti-environmental aspects of the World Trade Organization, which caused member countries to reexamine their automatic endorsement of all trade to the exclusion of the environment, wildlife and job protection. Native tribes in British Columbia and conservation organizations united to publicize the impending destruction of thousand-year-old forests along the coast, home to the white "spirit bear." This coalition succeeded in 2001 in stopping logging and achieving permanent protection for some 1.5 million acres (NRDC 2001).

One proposed means of preserving wild animals and plants and their environments is the Convention on Biological Diversity, signed by more than 150 countries after it was presented at the 1992 Earth Summit held in Rio de Janeiro, Brazil. It went into effect in December 1993, after the 30th country, Mongolia, ratified it. It had been signed by 161 nations. Its purpose is to prevent extinctions and biological impoverishment, and it commits nations that ratify it to take actions to preserve species and ecosystems in the process of development.

The Convention requires nations to integrate conservation into economic and social policy to: promote the protection of entire ecosystems, set up protected areas, undertake biological inventories, preserve species throughout the country and restore degraded ecosystems. Many of the wealthy industrialized nations that do not support the Convention succeeded in having weakening clauses written into it, such as "as far as possible" and "as appropriate" (Stevens 1992). It states that nations have the "sovereign right to exploit their own resources pursuant to their own environmental policies.fl Even with its weaknesses, it remains the only international convention to have ever addressed the importance of preserving biological diversity, and as such, it sets a major precedent.

The success of the Convention on Biological Diversity will depend on how strictly it is interpreted. One clause places economic and social development, and the eradication of poverty, as the first priorities of developing countries. This could become an excuse to allow extinctions for the sake of "progress." For example, dam construction or forest clearance could be projects to alleviate poverty, but they would probably cause extinctions. The treaty also states that conservation efforts on the part of developing nations will depend on the flow of money from rich nations, although it recommends that the rich countries benefiting economically from exploitation of resources, such as pharmaceuticals, in poorer countries, should share these profits with the latter (Stevens 1992). It is this latter clause that many members of the US Congress opposed because US pharmaceutical companies did not wish to pay nations harboring medicinal plants. This is a major reason why the United States has not ratified the Convention.

To fund the programs of the Convention on Biological Diversity in developing countries, the Global Environmental Facility (GEF) has been set up, administered jointly by the United Nations Development Program (UNDP), the United Nations Environment Program (UNEP) and the World Bank. GEF raised some $2 billion from wealthy countries, and its administration has been criticized by both donor nations, which want it run in a similar manner to the World Bank, and many developing countries and environmentalists, who accuse it of "green washing" destructive environmental programs endorsed by the World Bank (Lewis 1994). The World Bank has been a major proponent of commercial logging in the last tropical rainforests of Central and West Africa, with disastrous consequences for both wildlife and native peoples.

This Convention is heavily influenced by rich donor countries, such as Japan, Canada, Norway and other European nations. Without strong opposition to the traditional approach of the World Bank in funding large dams, logging and

other such projects, the Convention will not fulfill its more positive potentials to conserve the Earth's biological heritage. Its success will depend on the strong participation of those truly interested in the preservation of nature and willing to encourage countries in this task.

At the end of the 20th century, a poll of biologists was taken, asking them what they considered the greatest threat facing the Earth today. By a wide margin, they chose the loss of biodiversity. The greatest challenge in the 21st century will be to inspire people to want to protect biological diversity, as some nations are doing. Costa Rica, for example, is engaged in a biodiversity program that will catalog virtually every resident animal and plant over the next decades and protect critical habitat areas. The United States, through the Natural Heritage Programs and hundreds of biologists whose work is compiled by the Association for Biodiversity Information, is making progress in its appraisal of the nation's biodiversity and conservation needs (Stein *et al*. 2000). Thousands of individuals are also playing a role by preserving or reintroducing native species into their local areas. In spite of great pressure to exploit the last rainforests and other fragile environments throughout the world, successes in preserving the immense treasure-trove of species that exists on Earth may be turning the tide.

Our lives depend on the proper functioning of the Earth's systems for processes such as photosynthesis, balance of oxygen and carbon, pollination of flowering plants and enrichment of the soil by organic materials. These systems require a large variety of species to function normally, and we are only beginning to understand the role of various organisms and which species are key to each ecosystem. It is not possible to say, therefore, that any species can become extinct without affecting vital life processes. By choosing which species shall survive and which are dispensable, based on economic considerations, as proposed by many politicians, is sheer folly. Irreparable damage may result from such attitudes, yet they are accepted by many governments of the world.

We are presently witnessing the breakdown of many ecosystems. Marine food chains are being destroyed by overfishing and pollution, interfering with the food supply for millions of people. Yet it seems that few of these ecological catastrophes were predicted when fishery or pollution limits were set. Likewise, wetlands are losing wading birds, frogs and fish--all natural insect controls--resulting in increases in insect-borne diseases such as malaria. Predator-prey relations are key to the health of forests and grasslands, preventing overgrazing by prey species that have lost their predators. Yet most wild cats and wolves are in decline, some close to extinction, allowing imbalances to occur. In a growing number of regions, large predators are either absent or so rare that they no longer perform their ecological role. In Yellowstone National Park, for example, the eradication of the Gray Wolf resulted in overpopulation of Elk, which over-browsed aspen and other plants that were habitat to a number of birds and other animals, resulting in their disappearance. Only with the reintroduction of wolves is the ecosystem returning to normal. The overpopulation of deer in the United States and their effect on preventing natural forest regeneration and destroying wildlife habitat is directly related to the extermination of their natural predators, wolves and Mountain Lions. In other cases, prey species, such as deer, antelope and other ungulates, are in steep decline, having been killed off by meat hunters or crowded out by livestock. These species often play important roles in dispersing seeds, as do bats, birds and rodents. One-fourth of all mammals, and one in 10 birds are imperiled. Among these are pollinators, seed dispersers, insect-eaters and prey for other species. The loss of this biodiversity is reaching such levels that it is not surprising so many ecosystems are imbalanced. It is even more alarming to contemplate that the majority of the world's reptiles, amphibians, marine fish and most invertebrates have not even been assessed by biologists.

Species' declines begin with local extinctions as they disappear from portions of their ranges. At this stage, their absence may be affecting ecological communities, but they will not be listed by the IUCN or any other listing authority until the species as a whole becomes threatened. The Gray Wolf disappeared from 90 percent of its US range before it was listed on the Endangered Species Act, by which time major ecological damage had already been done. Species receive protection, endangered listing and conservation attention at the latter stages of declines. The smaller the original range, the faster that species slides to extinction. Ecological effects can occur gradually and imperceptibly in some cases and, in others, quickly and dramatically. Most of the 34,000 plants listed by the IUCN as Threatened occupy restricted ranges and may have undergone slow declines as their pollinators and seed dispersers disappeared, or rapid declines if they were logged or their habitats destroyed. As the concept of saving ecosystems

and their myriad plants and animals gains acceptance, the importance of preserving all the strands of this complex tapestry becomes clear. The tens of thousands of animals and plants listed by the *2000 IUCN Red List* are an indication of a crisis situation, of nature going awry.

Astronauts orbiting the Earth have been overwhelmed by the beauty and fragility of the planet and its uniqueness in the universe. They have described environmental destruction visible from space. Shuttle astronaut Jay Apt (1996) spoke of seeing hundreds of pinpoints of bright lights at night that turned out to be fires emanating from forests in Africa, Madagascar and Borneo. A distant perspective enhances appreciation and desire to conserve our remarkable home. Instead of considering ourselves as separate from the environment, biologist Dr. Thomas E. Lovejoy has suggested, "We must behave as if we live *within* ecosystems, rather than perceiving nature as something confined to a few protected areas isolated within a degraded, human-dominated landscape" (Laurance and Bierregaard 1997).

Scientific study of Earth's diversity and ecology is in its early stages, and an exciting frontier awaits scientists in the ocean, tropical forests and other environments. Yet we are treating this precious living tapestry without the respect it deserves, and the unraveling of these intricate and delicate ecosystems will threaten our very existence.

Vanishing Species

http://www.endangeredspecieshandbook.org/vanishing_what.php

The Unraveling Tapestry

Now that prairies are plowed under and deserts are filled with subdivisions, the net effect of this recent massive habitat destruction and wildlife slaughter is being assessed. An incomplete tally in the United States, including Hawaii, totals at least 99 species of animals and 240 plants presumed extinct during the past 400 years (Stein *et al*. 2000). This high rate of extinctions reflects the losses of species and ecosystems described in Chapter 1, as well as

those of Hawaii. The Nature Conservancy, which established Natural Heritage Programs in every state to monitor native species, has compiled this and related data to alert the public of the urgent need to preserve the country's natural heritage (Stein and Flack 1997; Stein *et al*. 2000). Its examination of the status of 20,439 US plants and animals found 7,817 species (38 percent) to be either vulnerable, imperiled or critically imperiled (Stein *et al*. 2000). These conclusions were published in a book co-authored with the Association for Biodiversity Information, entitled *Precious Heritage: The Status of Biodiversity in the United States* (Stein *et al.* 2000). This book also illustrates many of these beautiful plants and animals and threatened ecosystems. It found more species in danger than the *2000 IUCN Red List* due to slightly different categories, such as imperiled and critically imperiled, rather than critical and endangered, used in IUCN lists. The latter organization also defines threatened species in terms of the rate of their decline, rather than their actual status.

-

Precious Heritage found endemic species, defined as those restricted to the bounds of the United States, and breeding endemics, or those breeding only in the United States, were even more threatened than those with wide distributions. Of the 875 endemic vertebrates in the lower 48 states, almost half (47 percent) are of conservation concern, compared to only 24 percent of all US vertebrate species (Stein *et al*. 2000). 90 percent of Hawaii™s endemics are imperiled in this study. Freshwater species such as mussels, crayfish, beetles and dragonflies are also in steep decline (Stein *et al.* 2000). More than 5,090 plants (33 percent of all native species) are threatened.

Other studies are examining natural ecosystems in the country. The National Biological Service of the US Department of the Interior reported in 1995 that during the 20th century alone, half the natural ecosystems of the lower 48 states became degraded to the point of endangerment (Stevens 1995). More than 1,700 biologists participated in this study, part of a massive biological survey of America's plants and animals (Stevens 1995). Along with the loss of the tall grass prairies and oak savannahs, more than 60 million acres of longleaf pine forests in the Southeast have been cut, and much of this land has been planted with tree farms, creating biologically sterile regions. Northeastern old-growth hardwood forests, likewise, are critically endangered, and survive only in scattered remnants (Stevens 1995). Grasslands in Long Island, the Northeast and California are threatened ecosystems, as are coastal prairies in Louisiana and sedge meadows in Wisconsin. Streams in the Mississippi plain have been greatly damaged as well (Stevens 1995). Fifty-eight natural communities have declined by 85 to 98 percent, and 38 others have declined by 70 to 84 percent (Stevens 1995). The National Biological Service has identified 126 endangered species through this study. Each imperiled ecosystem is home to many threatened species, a reflection of their loss of habitat. This study underlined the importance of preserving large areas instead of small tracts of land, although the latter may be the only way to protect some highly endangered species, such as plants that have become greatly restricted in range.

A 1997 study by the joint United States and Canadian branches of the World Wildlife Fund (WWF), "A Conservation Assessment of the Terrestrial Ecoregions of North America," appraised the ecoregions of the continent including Hawaii (Luoma 1997). Ecoregions are areas defined by major habitat types and, unlike ecosystems, are confined to particular areas. Eastern old-growth forests, for example, are ecosystems scattered over a great area amongst other ecosystems, while southeastern conifer forests constitute an ecoregion. This study found 13 of the continent's 116 ecoregions to be imperiled "hot spots," harboring enormous biological diversity (Luoma 1997). These include Florida's pine scrub, the conifer forests of the Southeast, Appalachia's mixed mesophytic forests, the tallgrass prairie and California coastal sage and chaparral (Luoma 1997). These findings were echoed in the world survey of threatened areas with great biological diversity, *Hotspots*, sponsored by Conservation International (Mittermeier *et al*. 1999). The latter book is illustrated with spectacular color photographs of many disappearing landscapes and species of endangered hotspots, such as the California coastal region.

An inventory of rare, endangered and extinct North American plants and animals, being compiled by the National Biological Service, has verified that the impoverishment of America's natural ecosystems has affected not just isolated species, but entire communities of species. It predicts a steady increase in the number of threatened species because of continued destruction of natural habitats. Habitat loss is the greatest threat to US wildlife and plants, but trade, persecution and pollution play roles as well. Agriculture was ranked as the primary threat to native US species by The

Nature Conservancy study, threatening about 45 percent of plants and animals, while development of land followed, threatening about 34 percent; water projects were the next major threat, and livestock grazing, pollutants, road building, logging and mining had important, but lesser, effects on species and ecosystems (Stein *et al*. 2000).

Threatened species tend to be located in certain "hot spots" in the United States. The one with the largest number of species is Hawaii, with 5,000 populations of species considered imperiled by The Nature Conservancy (Stein *et al*. 2000). In the continental United States, a preponderance of threatened species occurs in the Florida Panhandle, central Florida and the Florida Keys, the Appalachian Mountains, the Cumberlands and Southern Ridge, Cape Cod and Martha's Vineyard, southern California, the Pacific Northwest and southeastern Alaska, as mapped in *Precious Heritage. The Status of Biodiversity in the United States* (Stein *et al*. 2000; page 166). The Cumberlands and Southern Ridge and Valley of northern Alabama and southeastern Tennessee have the country's largest number of imperiled species--186--mainly as a result of the mussels, crayfish and freshwater snails of this region. The Central Appalachian Forest to the northeast has 154 threatened species, with a high percentage of aquatic species as well, including many rare salamanders and woodland plants. The Great Basin Desert of Utah and neighboring states is another species-rich area, with 113 threatened species, while the California South Coast sagebrush ecosystem has 138 threatened species found nowhere else on Earth (Stein *et al*. 2000). (See Grasslands, Shrublands and Deserts chapter).

The list of US species in danger of extinction grows longer each year, with a dramatic rise in the number of imperiled invertebrates in the 20th century. Fully 68 percent of freshwater mussels, more than 100 species, are threatened, making them the most endangered group of native animals. Fifty percent of native crayfish are threatened, according to the Nature Conservancy (Clancy 1997). The majority of surviving species are highly endangered from alteration of their clear, fast-flowing rivers and streams by federally sponsored dams, channeling and diking that have turned most waterways in the Southeast into muddy ditches and artificial lakes. Pollution and introduction of non-indigenous species of mollusks and crustaceans competing for food have also played roles in the decline of some of these mussels and crayfish. The Hawaiian Islands are home to a variety of colorful and endemic tree snails. Introduction of exotic snail species and habitat destruction have already extinguished many of these, and endangered others.

Many species of butterflies, which are important pollinators, are in decline. The Xerces Blue (*Glaucopsyche xerces*), a beautiful butterfly native to California, became extinct in the 1940s (Stein *et al*. 2000). Eight moth species and two other mainland butterflies are possibly extinct, as are 50 bee species native to Hawaii (Stein *et al*. 2000). Eight mainland butterfly species are critically endangered, and 109 are threatened, according to The Nature Conservancy (Stein *et al*. 2000). Dragonflies and damselflies, which predate the dinosaurs, have also lost ground. Two Hawaiian species are possibly extinct, and 79 more are considered imperiled (Stein *et al*. 2000).

Seventeen species of freshwater fish are extinct or possibly extinct, and the United States leads the world in the number of threatened freshwater fish: The Nature Conservancy lists 283 species (Stein *et al*. 2000). Habitat loss in the form of dams, river diversion and channeling, as well as pollution, has played major roles endangering these fish. Logging has destroyed many clear rivers and streams where salmon and trout breed. The majority of rivers and bodies of water are still polluted despite the Clean Water Act, and contaminants have caused malformations and high mortalities in fish populations. Introductions of non-indigenous fish for sport fishing have imperiled a large number of species. Brown Trout from Europe and Rainbow Trout placed in areas where they are not native have severely threatened native trout, such as the Cutthroat Trout of western lakes and rivers. In many cases, multiple factors combine to push native fish toward extinction.

The United States is second only to Australia in the number of threatened reptiles and amphibians. The Nature Conservancy lists 51 imperiled reptiles and 82 imperiled amphibian species (Stein. 2000). This amounts to an estimated 40 percent of US amphibians, and 18 percent of native reptiles--extremely high rates. Amphibians are declining worldwide from various causes including habitat loss, pollution, disease, pesticides and ultraviolet radiation from thinning of the Earth's ozone layer.

The total of 71 US bird species that BirdLife International's research placed in various categories of threat includes 33 species from the Hawaiian Islands (BI 2000). The Nature Conservancy found an even greater number through their intensive Natural Heritage Program research: 83 species of birds at risk in the United States, or about 11 percent of all native species (Stein *et al*. 2000). This is a smaller percentage than for reptiles and amphibians but, when analyzed by region, a large percentage of Hawaii's birds are threatened. A steady increase in the number of threatened birds has occurred in this century. The major causes threatening US mainland and seabirds are destruction of habitat, pesticides and pollution. In the Hawaiian Islands, introduced animals, disease and destruction of forests and wetlands are the major threats to endemic birds, as well as to plant life and invertebrate fauna.

The Nature Conservancy considers 65 species of US mammals, or about 16 percent of all native mammals, to be threatened (Stein *et al*. 2000). The loss of habitat from development, logging, livestock grazing, mining and other forms of destruction is the foremost threat to mammals. Added to this, pollution affects many aquatic mammals, and predator and rodent control programs to benefit livestock and agricultural interests affect foxes, wolves, and prairie dogs. A growing number of bats have been added to the list of threatened US mammals, an indication of a loss of habitat, as a result of caves being disturbed or vandalized, loss of large roosting trees to logging, pesticide use, and persecution by those not aware of bats™ ecological importance and who have exaggerated ideas of their supposed threats to humans.

Although lists of native North American threatened plants are far from complete, they reflect the rate at which ecosystems have become imperiled. The Nature Conservancy found 6,460 United States vascular plants to be imperiled (Stein *et al*. 2000). Of these, a very large number--1,385--are Critically Imperiled, 1,341 Imperiled and 3,338 species Vulnerable. Hawaii is a center for threatened plants. The *1997 IUCN Red List of Threatened Plants* found a somewhat smaller number of threatened US plants; 4,488 species, or 29 percent of native plants. Still, the United States had the highest number of endangered plants of any country in the world (Walter and Gillett 1998). In terms of the percent of native plants that are threatened, only St. Helena, Mauritius, and the Seychelles had higher rates (Walter and Gillett 1998) Few countries of the world have legislation similar to the US Endangered Species Act, which has helped hundreds of endangered plants.

Many US plants are adapted to specific types of soil or microclimates, and human disturbances can threaten them. Prairie plants are among the most threatened. California's grasslands have been reduced by more than 90 percent, leaving many endangered plants; it has many endemic species in its southern chaparral and shrubland, which are being bulldozed to make way for new housing developments. The state's mild climate and varied landscape have given rise to great diversity, which is extremely threatened. Of 25 presumed and 21 possibly extinct species in the state, about half, or 24, are plants (Stein and Flack 1997). Although endemic plants are not as numerous on the mainland as in some island habitats, North America is home to a great many unique and beautiful plants, which are finally beginning to receive the conservation attention they deserve.

Research is uncovering potential economic value in some native plants. One threatened US plant, the Scrub Mint (*Dicerandra frutescens*), yields a natural insecticide in its oil that repels a wide variety of insects, from ants to cockroaches (Aylsworth 1998). This white-flowered plant is presently restricted to a few hundred acres in central Florida, and it only came under scrutiny in the 1990s, when a Cornell biologist, Dr. Thomas Eisner, discovered its potential as a natural insecticide (Aylsworth 1990). This mint may be protected from extinction in time, thanks in large part to Eisner's research.

In spite of some sizeable natural areas in the United States preserved by the Wilderness Act and as federal or state land holdings, the country has become increasingly urbanized and cultivated for agriculture. Americans have gradually altered the landscape so that much of it, especially in the East, now resembles Western Europe's heavily populated countries where wilderness has been all but eliminated.

Recent ecological research on the effects of suburban sprawl on the environment have shown it to crowd out as many species as more densely populated areas (Revkin 1997). Diversity of species declines in these areas as green

lawns, manicured gardens and asphalt cover the land and pollute the ground water with pesticides, fertilizers and herbicides and kill off beneficial insects and other animals. Developers drain beaver ponds and wetlands and turn streams and rivers into concrete-lined ditches. With each acre lost, species decline. The brilliantly colored warblers and songbirds of eastern forests, for example, have been severely affected by fragmentation of both their breeding and wintering habitats. For the majority of such declining species, endangered listing comes only when they have been reduced to a small fraction of their original populations. The species that are listed by the IUCN or The Nature Conservancy in various categories of threat have reached a point where their very survival is at risk. In some cases, species, which were once described as naturally rare, are very restricted in distribution, especially plants and fish inhabiting desert springs or mollusks found only in a particular river system. For the majority of threatened US wildlife, however, their status a few hundred years ago would have been described as secure. It is all the more indicative of a crisis situation regarding American biodiversity that so many species, and such large percentages of their classes or types, are now headed toward extinction.

Should all US species currently threatened become extinct, a biological tragedy will take place. Preventing such a catastrophe has not yet captured the public™s attention or involved a zealous effort on the part of the US government. Important work on biodiversity studies is being done by various federal agencies, but the major burden of activism regarding preservation of endangered species and the environment has fallen to private conservation organizations.

The WWF report entitled "A Conservation Assessment of the Terrestrial Ecoregions of North America," accuses the US government of "doing a worse job of protecting its biological resources than many poorer countries with few resources for biodiversity conservation" (Luoma 1997). It concludes that the wealthiest country in the world places the preservation of its natural resources among its lowest priorities.

Without detailed information on the biodiversity of this country, it will be impossible to protect it, yet funds are inadequate to carry out a comprehensive assessment. Many opponents of the biodiversity studies in Congress have expressed fear that they would be used to expand the list of species on the Endangered Species Act and obstruct development programs. They succeeded in blocking formation of the National Biological Service, which Clinton Administration Secretary of the Interior Bruce Babbitt had to create administratively. The constant deterioration of the land through development, pollution and introduction of exotic species makes these studies all the more timely. This is a critical time of rapid environmental destruction and a turning point for many species which, without urgent protective action, will follow the deadly trails of the Passenger Pigeon, Carolina Parakeet, Sea Mink and hundreds of other lost plants and animals.

The US Endangered Species Act is one of the strongest and most effective laws in the world and has been a model for similar legislation globally. Many countries, including Canada, still lack national endangered species laws. Although private organizations acquire habitat and carry out many important programs, the legal protection the Endangered Species Act provides is key to the protection of many endangered species and their habitats. It has been responsible for saving a number of species, including the California Condor (*Gyps californianus*), Black-footed Ferret (*Mustela nigripes*), Whooping Crane (*Grus americana*) and numerous other animals and plants. The law has helped fund research, captive breeding, protection in the wild, reintroduction programs, land acquisition and law enforcement protection.

The law must be reauthorized regularly by Congress, however, and at these times, efforts to weaken or even fail to authorize it threaten its effectiveness and very existence. The strong support the law has received from the US public is not always evident in the halls of Congress, where commercial interests and lobbyists have had considerable influence. To date, the law has survived, although it has been amended and weakened somewhat since its enactment. The blocking of listings on the Endangered Species Act by its opponents has become the major means of thwarting the Act. Lawsuits have been filed by both opponents and proponents of the law demanding either delisting of species or listing and critical habitat designation. A virtual impasse has resulted in a moratorium on listing new species which the Department of the Interior declared in 2000.

Many listings have been thwarted by commercial interests. In a recent case, a proposal to list the Lynx (*Lynx canadensis*) on the Endangered Species Act was not acted upon by the Fish and Wildlife Service without a lengthy struggle. This species has greatly declined from its once large range in the lower 48 states. Heavy trapping for its valuable fur and logging of its habitat of mature pine forests have reduced its populations to fewer than 1,000 animals. The majority of Lynx remain in Montana, Idaho, Washington and Maine. Although the Fish and Wildlife Service's (FWS) own biologists found this population to be endangered, they were overruled by headquarters whose bureaucrats decided to refuse to list the species on the Endangered Species Act (Cushman 1998). Petitions by conservationists urging Endangered Species Act listing for the Lynx were ignored, and only when a lawsuit was filed against FWS did the tide begin to turn in this endangered cat's favor. Conservationists won the suit in 1997, but the FWS, in an unprecedented action, declined to list the Lynx, stating that other species had higher priority for listing. Loggers and commercial timber companies oppose listing the Lynx, fearing that areas would be set aside as critical habitat where no tree cutting would be allowed, and many conservationists believed that FWS had succumbed to these pressures. Finally, in February 1998, the Service and several conservation groups reached an agreement to list the Lynx on the Endangered Species Act to take effect in 1999 (Cushman 1998). President Clinton declared a moratorium on new road building in national forests lands in 2000, which will greatly aid the Lynx and other threatened species of these forests, such as the Wolverine and Marten.

The Public Employees for Environmental Responsibility (PEER) issued a report in December 1997 accusing the FWS of failing to protect more than 300 species awaiting listing. Only listings of plants have increased in recent years, leaving a growing number of animals in need of federal listing (Stein *et al*. 2000). The Nature Conservancy's biological surveys have uncovered a far greater number of endangered and threatened species in the United States than are listed by the Endangered Species Act, especially plants.

On the positive side, an increase in the number of endangered species added to the Endangered Species Act has been seen in recent years. The Endangered Species Act, in spite of shortcomings, is vital to the preservation of endangered species in the United States, and it is in grave danger of being weakened so much that it will become ineffective. Various proposals in 2001 made by the Bush Administration would make it nearly impossible for citizens to sue the government to force listing of endangered species (Jehl 2001). The majority of species on the Endangered Species Act were listed as a result of citizen suits (Jehl 2001, Gorov 2001). The Fish and Wildlife Service claims to be unable to perform its duties because of the large number of legal challenges. The law has not been reauthorized since 1991, and proposed changes might leave actions regarding endangered species to the discretion of the Department of the Interior, rather than basing them on biological status. Under the new plan, citizens could petition for listings, but the government would not have to respond promptly, nor would it have to act on designating critical habitats for endangered and threatened species (Gorov 2001). So little money--$6.4 million--is budgeted for listing that a stalemate is inevitable. Other proposals by the Bush Administration would cut overall spending on endangered species programs by $11 million, leaving the Office of Endangered Species without the means to accomplish its purpose (Gorov 2001).

A number of private organizations have aided in preserving endangered and endemic plants not listed on the Endangered Species Act. The Nature Conservancy and its state Natural Heritage Programs have purchased or arranged purchase of hundreds of thousands of acres of land for threatened plants. Arboretums and botanical gardens, such as the Missouri and the New York Botanical Gardens, also are active in this regard. Lady Bird Johnson helped found the extremely effective organization, the National Wildflower Research Center, which aids in the conservation of wildflowers. In the northeast, the New England Plant Conservation Program has spent six years collecting seeds from some 500 rare plants for a seed bank. The New England Wild Flower Society has been instrumental in this program, and many sanctuaries throughout the region are preserving threatened plants.

The actions of individual states under their state endangered species laws and Natural Heritage Programs have also been crucial to the survival of many species that are threatened within a state or region, but might not qualify for federal listing. Programs to reintroduce Bald Eagles (*Haliaeetus leucocephalus*), Peregrine Falcons (*Falco peregrinus*), threatened fish and River Otters (*Lutra canadensis*) have brought back these species in many areas where

they had been eliminated by pesticides, over-trapping, pollution or water projects. Many programs have involved cooperation between state and federal endangered species officials.

Habitat Conservation Plans (HCPs) are agreements worked out between landowners and the Fish and Wildlife Service for listed endangered species under a 1982 amendment to the Endangered Species Act. In essence, they are the result of deals made among developers, state and county officials, Fish and Wildlife Service representatives and local citizen groups on large tracts of land, in which portions of endangered species' habitats are protected, while development is allowed on the rest. HCPs are a permanent contract that cannot be amended, even if biological information is revealed showing that they were in error. These HCPs have been the center of much controversy, considered by some conservationists to compromise the principles of the Endangered Species Act, and by others to be an excellent means of protecting species. HCPs are not presently published in the *Federal Register* prior to signing by the Secretary of the Interior, which would subject them to public comment.

In 1997, a team of 119 scientists, financed by the National Science Foundation and the American Institute for Biological Sciences, carried out careful appraisals of signed HCPs and reported on their conclusions. They found that crucial scientific knowledge was lacking about many of the species involved in these agreements (Yoon 1997). They also found misuse of scientific methods and biological data which will end in harming, rather than helping, many species (Yoon 1997). Dr. Peter Kareiva, a University of Washington ecologist who organized the study, concluded that many HCPs should not have been written, and only about half correctly employed science (Yoon 1997). Of 206 HCPs examined in total, 44 of them in detail, one-third lacked information as basic as life span of species, and the vast majority did not include data on rates of population rise and decline and habitat changes (Yoon 1997). The most glaring problem seen by the scientists was the failure of HCPs to correctly assess the impact of losses to species' populations, mainly as a result of untested methods of appraising impacts. One plan proposed to protect Utah Prairie Dogs (*Cynomys parvidens*) by moving animals to a new location using a method already known to result in the deaths of 97 percent of the relocated animals within three months (Yoon 1997). An HCP for the Desert Tortoise (*Gopherus agassizi*) in Nevada allowed the killing of hundreds of these threatened reptiles by bulldozing their burrows and habitat, while protecting only minimal amounts of habitat.

A major problem faced by those trying to save endangered species is the fact that the vast majority live on privately owned land, and arrangements must be made with owners to insure the survival of these species. Many people believe that protecting these species involves major restrictions on the use of their land and, therefore do not want to enter into Habitat Conservation Plans. Ideally, however, protecting a threatened butterfly or plant on a private ranch, for example, would only involve identifying the habitat, the host plants for the butterfly, and preventing destruction through excavations or other major alteration of the land. In many cases, cattle grazing is compatible with protection of rare species, since the land is not plowed, which can destroy plant life. Ranchers in southern Arizona have cooperated in protecting the land through preventing overgrazing and maintaining riverbank vegetation and springs for rare frogs and birds. For many endangered species, conservation easements are an excellent solution for their protection. These easements involve the payment of funds to the landowner by private organizations, or local, state or federal governments to let the land remain undeveloped and help enhance it as wildlife habitat. This is an especially good solution for farmers who are afraid of losing their land after years of crop failure or low market prices. Innovation has marked many arrangements now being made to protect endangered and endemic species.

The US public as a whole supports the protection of endangered species, which helps explain the Endangered Species Act's survival under strong opposition. Polls conducted in November 1994 by Peter D. Hart Research Associates found that 57 percent of the public wanted to maintain the Endangered Species Act in its present form, and only 32 percent wanted to relax requirements. A September 1995 CNN poll asked which was more important, saving endangered species or saving jobs: 48 percent replied endangered species, and 40 percent, jobs. A Gallup poll carried out for CNN in April 2001 found that support remained strong. It asked Americans whether they supported environmental and wildlife protection even if it meant higher prices or more jobs, and again, a majority supported conservation. They were also asked to rank environmental protection in terms of its importance as an issue, and most placed it near the bottom of the list. When asked whether it would be an important issue in 25 years, however, the

majority said it would be among the most important issues. This reflects a failure to understand the ongoing wave of extinctions that is eliminating many of the Earth's most fragile plants and animals and its possible effect on humans.

Thus, education is extremely important, especially its role in relating American lifestyles and waste of resources to the extinction and endangerment of species. A 2001 film, "Natural Connections" (Howard Rosen Productions, shown on PBS), addresses this issue as well as the gradual diminution of biodiversity. The overconsumption that Americans take for granted impoverishes nature in the US as well as in other countries that export their tropical hardwoods; cut flowers; leather from cows grazed in former rainforests; non-organic, sun-grown coffee; minerals; and handcrafts from scarce materials to this country. Other products are manufactured as a result of polluting the environment and, like coated paper cups or pulp magazines, are used once and thrown away. To maintain such a throw-away lifestyle, millions of trees are cut each year in the United States and elsewhere, disrupting ecosystems and threatening wildlife. Pollution is created from mines that poison rivers, and manufacturing and power plants that spew dioxin and greenhouse gases into the air. The urgency that gave rise to legislation early in the 20th century that protected native birds and other wildlife from overexploitation for commercial purposes was enacted after the extinctions of the Passenger Pigeon and Carolina Parakeet, and near-extinction of the American Bison (*Bison bison*) and other animals from 19th century slaughters. It would be tragic if a similar wildlife or environmental catastrophe were needed to spur strong action to preserve the world's genetic and biological heritage.

Threatened Species of the World

The *2000 IUCN Red List* found 3,507 vertebrates and 1,928 invertebrates in high degrees of threat worldwide (Hilton-Taylor 2000). Plants classified as Critical, Endangered or Vulnerable totaled 5,611 species. These are minimum figures because only birds and mammals have been thoroughly examined for status. When assessments are carried out on the remaining species, the list will doubtless grow far longer.

Many of the most magnificent, graceful, beautiful and zoologically curious animals on Earth are threatened with extinction. A growing number of these, such as sea turtles, sharks and crocodiles, have survived virtually unchanged for hundreds of millions of years, and if not for the human activities that are pushing them toward extinction, they would likely survive millions more.

Almost all the graceful cranes, on Earth since the Miocene Epoch, are endangered from loss of habitat and hunting. The entire family of prehistoric-looking rhinoceros is teetering on the brink of extinction. New Zealand's extraordinary and primitive kiwis and ancient tuatara lizards, which have survived since the dinosaur epochs, may be lost in the next few decades. Eleven of the 16 species of penguins are now threatened, nine in higher categories (BI 2000). Seabirds of many types, including the majority of albatross, are now listed.

The most surprising finding was the high number of mammals listed: 2,046 species, of which 1,130 species were in higher categories of threat (Critical, Endangered and Vulnerable). Thus, of the approximately 4,000 species of mammals, 28 percent are highly threatened, and more than half are in some degree of threat. They are the most imperiled class of animals. Twelve percent of birds, or one in eight species, are listed in higher categories of threat (1,186 species), and an additional 809 species are in lesser categories (Near-Threatened, Conservation Dependent, or Data Deficient), totaling 1,995 species or about 18 percent of the world's birds (BI 2000). Reptiles are a group less well assessed, but 750 species are at risk in all categories, according to the *2000 IUCN Red List*. Amphibians, which number about 4,550 species worldwide, have a minimum of 226 threatened species, and a large additional number that have not been thoroughly assessed. Likewise, very few marine fish are listed by the IUCN because so little is known of their status. Some progress is being made in assessing marine fish, especially coral reef fish and sharks and rays.

By 2003, a complete assessment of the shark family is planned by IUCN (Hilton-Taylor 2000). Approximately 1,183 fish are listed in the most recent *IUCN Red List* in various categories of threat. The majority of these are freshwater species, which represent 6 percent of all known fish.

The rate at which animals and plants are declining has reached such proportions that even familiar species considered common with stable populations only a decade ago are now threatened. The African Lion (*Panthera leo*) and many African antelope, Giraffes and wildebeests are in serious decline, or exist only in parks and reserves, categorized as Conservation Dependent.

Animals listed as Near-Threatened or Data Deficient totaled 3,324 species, of which 2,364 species are vertebrates in the *2000 IUCN Red List*. The grand total of 8,759 vertebrates in all categories comprises 20 percent of all mammals, birds, reptiles, amphibians and fish on Earth. In the early 1980s, only 1,000 vertebrates were listed by the IUCN. This means that in just 20 years, this total has risen by almost 900 percent.

Plants have been assessed in several reports. The *1997 IUCN Red List of Threatened Plants* (Walter and Gillett 1998) was supplemented--and many species reassessed--by the *2000 IUCN Red List* (Hilton-Taylor 2000). Plants from Cameroon, the Galapagos, Mauritius and South Africa were added to the 2000 list. A total of 6,932 plants were listed in all categories, 5,611 in higher categories of threat. In spite of these major undertakings, only conifers were thoroughly assessed. The 1997 study, using one type of definition based on status alone, found 30 percent of all conifers to be either Endangered or Vulnerable; the 2000 reappraisal, using new criteria, determined that 16 percent were threatened (Hilton-Taylor 2000). When far more species of plants are assessed, The Nature Conservancy study of US plants (Stein *et al*. 2000), which found one-third of plants to be threatened, may be indicative of a great decline in the world's plants.

As in the case of animals, many of the Earth's oldest species of plants are at high risk of extinction. Trees that predated the dinosaurs and survive in pockets in Chile, New Zealand, New Caledonia, Australia, New Guinea and parts of Southeast Asia are being destroyed, with little knowledge of their extreme botanical importance. Many of these are among the largest trees in the world, rivaling the Redwoods in height and the Sequoias in girth (see Forests chapter). Others, such as the monkey puzzle tree family, are extremely bizarre in appearance, and may contain important compounds for medicines. Beautiful primitive flowers, the protea, are also greatly threatened, with many species growing in South Africa. Tree ferns, palms and hundreds of orchid species are also highly threatened. The island of Mauritius has a large number of threatened plants, many of which are quite unique.

Many zoologists and conservationists are now resigned to the rising level of extinctions and believe that, within a century, 80 percent of all species living today will be extinct. Such predictions may be overly pessimistic, but unless the public is made more aware of the precarious status of a growing number of plants and animals and demands strong action, the prognosis may be fulfilled.

What is Threatening Species?

Human activities are at the root of virtually all extinction threats. Destruction of fragile habitats, wetlands, coral reefs, tropical and temperate forests, rivers and grasslands has accelerated in recent years due to human population increases and commercial exploitation of forests, ocean fish and other wildlife, as well as the introduction of non-native species, either intentionally or accidentally. The massive pollution and chemical contamination of air, water and soil--and even the atmosphere that surrounds the Earth--are altering the climate and bringing about

unforeseen declines in wildlife and plants.

Human Tragedy and the Looting of Virunga's Treasures

What is Threatening Species? Human Population Growth

Burgeoning human populations provide the major impetus for destruction of the last havens for rare species. In 1650, when Dodos were still common on the island of Mauritius, the world's human population totaled about 500 million, half of India's present population. Two hundred years later, the number had doubled to 1 billion. In 1900, the world's population totaled 1.6 billion. Since then, it has taken shorter periods for the world's population to double, and at present it doubles approximately every 37 years. In 2000, 6 billion people lived on Earth, a number expected to rise to between 8.5 and 9.4 billion by 2050. While population growth has leveled off in parts of Europe, Russia and Australia, it continues to rise in the United States, mainly as a result of immigration. The highest rates of growth, 3 percent or more, occur in Africa, Asia and Latin America, where environmental deterioration has been severe. The similarity between the astronomic rise in human population and the extinction rate of animals and plants is not accidental.

Settlers in increasing numbers are entering tropical forests, grasslands and other wild areas teeming with wildlife, and clearing them for grazing livestock and planting crops. Loggers in the Brazilian and Central African rainforest wildernesses are building roads to transport entire forests of trees, some thousands of years old, to be sold in markets in North America, Europe and Asia. The roads open up the forests to settlers and hunters, endangering countless species of animals. Commercial exploitation of forests has increased rapidly since the 1980s, with logs turned into pulp for paper, expensive lawn furniture, paneling, shipping cartons, and even concrete molds that are used once by builders and thrown away. Rivers are becoming increasingly polluted from human waste that goes untreated in many

parts of the world, and billions of people scratch out a living by subsistence farming, cutting trees for fuel and grazing livestock.

These poverty-stricken people have caused the limits of the Sahara and Sahel in Africa to expand by depleting wildlife and trees, and have razed forests in India, China, Indonesia, Thailand, Ecuador, Central America, Mexico and West Africa. Still, many go hungry because they have far outstripped what the land could supply sustainably. For the wealthier nations, an appetite for material goods and demand for a high standard of living have encouraged a market for precious resources, such as tropical lumber and wildlife products, that has expanded in recent years with the World Trade Organization (WTO) globalized economy. In order to repay loans granted to them by international funds, many poor nations strip their forests and grow exportable crops on the land. In the United States, urban sprawl and overexploitation of forests and other resources have threatened a host of animals and plants. Water is diverted for these new towns, endangering native fish and forests. In Arizona, the Sonoran Desert, a botanical world treasure, is now being destroyed by the expanding cities of Phoenix and Tucson.

The needs of the growing numbers of people worldwide have spawned many ill-conceived and environmentally destructive projects. Indonesia and Brazil opened up the most biologically rich forests on Earth to farming by people living in overpopulated cities. The soil is poor in tropical forests, and they must keep clearing land to find new areas for crops, gradually destroying vast areas once teeming with wildlife. China has moved people into western grasslands, where they have eliminated wildlife and caused massive erosion and desertification with agriculture and overgrazing of livestock. Dust storms from this region have been circling the globe in recent years. China has also commissioned the world's largest dam, Three Gorges--on the Yangtze River--in an attempt to control floods and generate electricity. In the process, a very rare freshwater dolphin, a sturgeon, and hundreds of rare plants will become extinct, and the dam's lake will fill with untreated sewage. The problem of overpopulation has not been well understood or coped with in the majority of countries where populations are now outstripping food supply.

In most parts of the world, however, people have deforested the habitats and killed prey species of wide-ranging wildlife that have nowhere else to go. Asian Elephants (*Elaphus maximus*) and Tigers (*Panthera tigris*), for example, have been deprived of habitat and food and crowded into areas too small for their requirements. When they rampaged into people's gardens or killed livestock, they were killed and their body parts sold for high prices. Both species are now endangered, their populations fragmented and in steep decline. This is a pattern that has been seen with large animals, especially predators, throughout the world. Animals or plants with low populations as a result of restricted habitat size or specialized requirements for survival have been pushed to the brink of extinction as humans moved into their habitats.

Only a few countries have national policies to encourage stable populations. In some countries with populations that far exceed the ability of the land to adequately sustain them, wars have broken out, providing an apocalyptic vision of a violent future for the Earth should present trends continue. A scientific study, *Environmental Change and Violent Conflict* (Homer-Dixon *et al*. 1993), predicted that as human populations increase and resources decrease, wars will occur with ever greater frequency. Population Action International, a Washington, DC-based organization, calculated in 1997 that although human population growth has slowed somewhat, water resources remain under serious threat. This organization's report warns that by 2050, people in the Middle East and parts of Africa, where populations continue to grow at high rates, will be engaged in bitter, violent conflicts over water. The story of the Rwandan war, described later in this chapter, reflects this cause and effect. Overpopulation causes human suffering, permanent damage to the land from overuse, and the destruction of the very species that might prove life-saving. A few countries, such as Singapore, launched education programs decades ago, urging people to have smaller families for a better quality of life. The rate of population increase in this tiny country is now less than 1 percent, and literacy is 91 percent.

Medical advances preventing disease and early mortality in people around the world, combined with growth in agricultural output, have played a major role in the nearly four-fold rise in human population since 1900. The World Health Organization (WHO) has scoured the planet eradicating disease but is not required to educate people about

birth control methods. This has decreased natural mortality and fueled population booms. The majority of international aid projects lack overview, coordination with one another and long-term planning. Supplying high-yield grain and financing irrigation projects to poor nations, without providing birth control education, results in a doubling of populations within a generation, which negates any rise in the standard of living and education levels. By encouraging livestock and agriculture in dryland areas, with little knowledge about the natural environment or its capacity to support large numbers of people, wildlife and plants are displaced or killed, and in years of drought, crop failures result, causing starvation. The human suffering brings international aid with emergency food, and instead of relocating people to other areas, these programs encourage replanting and a repetition of the misfortune.

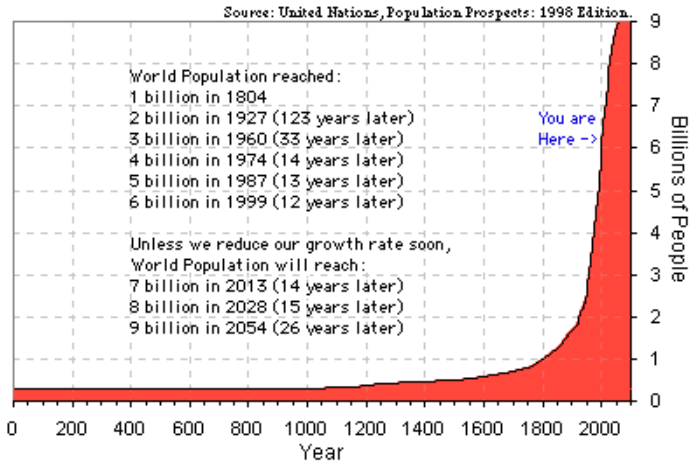
Ethiopia and Somalia are examples of such policy failures. These countries were covered in a mosaic of grasslands and forests teeming with endemic wildlife early in the 20th century. An influx of large numbers of people and livestock, encouraged by aid programs, denuded this region to arid desert. The vast numbers of wildlife have largely disappeared or become endangered as the extensive grasslands, rivers, lakes and highland forests disappeared because of overgrazing, farming in areas too dry to produce crops and deforestation for firewood (see Grasslands, Shrublands and Deserts chapter). With low human and livestock population densities, these areas could have remained ecological treasures.

The Population Institute of Washington, DC, warns that although some countries have shown declining rates of population increase, especially those in Western Europe and North America, this will not result in an overall decline in world population because of greater human longevity, continued high birth rates in at least 74 countries and a high survival rate (Holmes 1997).

The top 10 countries in terms of overall numbers of people have 59 percent of the world's population. More than 30 percent of all births in 1997 took place in India, a country expected to overtake China as the world's most populous nation by 2050 (Holmes 1997). A 1997 World Bank report, "The World Food Situation: Recent Developments, Emerging Issues and Long-Term Prospects," concluded that food stocks are not keeping up with need (Crossette 1997b). Demand for meat is increasing, placing further stresses on natural systems since livestock consume enormous amounts of grasses and grain, cause damage to vegetation and often pollute water systems; grain production is reaching the limit of potential yields, especially in Asia (Crossette 1997b).

The most densely populated country in the world, Bangladesh, with 127.5 million people, has about half the population of the United States in an area the size of Wisconsin. It has a density of almost 3,000 people per square mile, and a population growth rate of 2 percent a year. Ninety percent of the people in Bangladesh's countryside are illiterate and malnourished in spite of decades of international aid projects. Bangladesh is now totally dependent on foreign aid for minimum nutrition, and the land is being worked to maximize yields, using large quantities of fertilizer, irrigation and pesticides. The once vast mangrove forests that serve as fish and shellfish nurseries, and habitat for Tigers and other endangered species, are being destroyed piecemeal, cut for firewood (Worker 1996).

Funds to encourage birth control around the world have been deleted from US budgets by those opposed to abortion, thus thwarting all types of programs of education, birth control methods and related issues. Most organizations working to lower birth rates around the world use almost no funds for abortion, yet they find their funds cut for all family planning programs. This obstructionism has been a major setback to those working to stabilize the world's populations. The United Nations Population Fund has continued to carry out family planning programs, but with inadequate funds.



What is Threatening Species? Habitats Under Threat

Habitat destruction is the foremost threat to wildlife. In broad terms, more than 85 percent of IUCN-listed birds, mammals and plants are threatened by habitat destruction and degradation (Hilton-Taylor 2000). The greatest number of threatened species listed in the *2000 IUCN Red List* inhabit terrestrial areas. They total 9,256 highly threatened species. The largest single terrestrial group is plants, with 5,607 species; birds follow, with 1,144 species; with mammals having only slightly fewer threatened species, 1,111 (Hilton-Taylor 2000). The vast majority of threatened birds and mammals are terrestrial species. The destruction of forests is the single most important threat to birds, affecting 75 percent (BI 2000). At least 900 of the 1,144 threatened birds inhabit tropical rainforests, with almost half of those species restricted to lowland rainforests, and 35 percent in montane rainforest (BI 2000). Authors of *Threatened Birds of the World* (BI 2000) found that the vast majority--86 percent--of rainforest birds cannot tolerate much habitat destruction, and 45 percent require near-pristine habitat. Only 3 percent are highly tolerant of habitat alteration (BI 2000). Unsustainable selective logging affects 31 percent of threatened birds. In many tropical forests, logging and forest burning are taking place without any restrictions, totally eliminating habitats of rare rainforest birds. A total of 4.5 million square kilometers, or 20 percent of the world's forests, were cleared from 1960 to 1990 (BI 2000), and since then, forests--especially tropical forests--have continued their decline. Although some forests may return to old-growth hundreds or thousands of years in the future, much of the land is being converted to agriculture, grazing land, housing, cities, industry and roads and is unlikely ever to revert to forest.

Likewise, more than half, or about 57 percent, of threatened mammals inhabit tropical rainforests, 35 percent in lowland, and about 22 percent in montane rainforest (Hilton-Taylor 2000). Less than 10 percent of threatened birds and mammals are native to temperate mixed forests, coniferous forest and temperate broadleaf forests, according to the IUCN. A very small number of threatened mammals, about 3 percent, inhabit tropical degraded forest, a sign of the unsuitability of this habitat (Hilton-Taylor 2000).

Forests are also home to a wide variety of threatened frogs, salamanders, tree snails and insects, although studies of which type of forest each inhabits have not been done by the IUCN. Many endangered plants are tropical species, native to islands such as Madagascar and Indonesia, where endemic plants such as orchids and palms abound, and habitat destruction is severe. The United States leads the world in threatened plant species, with 4,669 identified by the IUCN in its 1997 study (Walter and Gillett 1998) and 7,817 species listed by The Nature Conservancy (Stein *et al.* 2000). Many of the latter are in Hawaii, another tropical island with a high percentage of threatened plants. Lobelias are known for their beautiful flowers, and the ancestor species that arrived in the Hawaiian Islands radiated into 273 species, some of which grew to the heights of small trees. One-quarter are gone, and another 124 of the surviving

species are threatened with extinction or possibly are extinct (Walter and Gillett 1998). Of the remaining lobelias, only 27 percent now have sizeable enough populations to keep them from extinction; the loss of their pollinators, most of whom were honeycreepers, is a major cause (Buchmann and Nabhan 1996). The honeycreepers lost their forest habitats to clearance by settlers, and as they faded into extinction--one species after another--lobelia plants they had pollinated disappeared or became endangered. These ecological webs exist throughout nature.

The IUCN found that 91 percent of plants identified as threatened were endemic, with their entire distribution restricted to a specific country (Walter and Gillett 1998). A total of 32,242 threatened or extinct species of plants occur in one country alone, while 2,368 occur in two countries, and only 709 plant species occur in more than two countries. Only scanty information on threatened plants is available from most countries in South America, Africa and Asia, which are expected to have large percentages of their native plants found to be threatened when assessed (Walter and Gillett 2000).

Grasslands, shrublands and savannahs are the second most important habitat for threatened birds, home to 383 species, or 32 percent of all listed species (BI 2000). Two-thirds of these birds inhabit shrublands; 43 percent, grasslands; and 8 percent, savannah (BI 2000). Three-fourths are tropical birds, whose habitats are threatened by livestock overgrazing, human settlement and farming (BI 2000). Some 17 percent of threatened mammals inhabit grasslands, while another 8 percent are shrubland species, and about 7 percent are native to desert and semi-desert (Hilton-Taylor 2000).

Freshwater habitats, such as rivers, marshes, bogs, streams and ponds are the second most important biome, after terrestrial, for threatened species. At least 1,946 threatened species, the largest number being fish (627 species) inhabit these areas (Hilton-Taylor 2000). Freshwater crustaceans (409 species) and mollusks (420 species) are major inhabitants of these aquatic areas, as are 131 amphibians, 111 reptiles, 78 birds and 31 mammals, according to the *2000 IUCN Red List*. The United States, with its extensive water projects--dams, levees, diverted and channelized rivers--harbors large numbers of threatened crustaceans and mollusks, as discussed above.

Frogs make up the majority of threatened amphibians and have been in decline for several decades. Their habitats are being destroyed at an unprecedented rate as wetlands are filled in--half of US wetlands that were present in colonial times--are gone. Thailand has lost almost all its wetlands, and Southeast Asian lakes and marshes are being drained at an unprecedented rate, threatening frogs and other wildlife. Frogs have been on Earth for 190 million years, but at the present rate of decline, the majority of the approximately 4,500 species will be gone within decades. In addition to habitat loss, a variety of threats are eliminating them (see Non-Native Species, Trade and Pollution sections below).

What is Threatening Species? Non-Native Species Introductions

Invasive species, or alien, non-native animals and plants introduced into ecosystems, present the most important threat to plants. The large numbers of threatened species that have limited distributions are highly vulnerable to the possibility of invasive species eliminating them from the wild. Islands have the greatest percentage of their native plants in danger of extinction. St. Helena, a small island in the South Atlantic, leads these in percentages, with 13 percent extinct or extinct in the wild, and 68 of 165 native plants and trees threatened (Walter and Gillett 1998). Livestock played a role in the extinctions and present status of many native plants (see Chapter 1). Mauritius follows, with 39.2 percent of native plants in danger, or 294 of 750 species (Walter and Gillett 1998). Other islands with many native plants threatened by exotic species include the Seychelles, Jamaica, French Polynesia, Pitcairn, Reunion and New Caledonia (Walter and Gillett 1998). Of the latter islands, all but French Polynesia and Pitcairn formed part of Gondwana, and many of the plants at stake are very ancient in origin.

One endemic Mauritian palm, *Hyophorbe amaricaulis*, has been reduced to a single plant. Although it grows vigorously and produces male and female flowers at different times, no fertile seeds are produced (Stearns and Stearns 1999). At the National Agricultural Station in Ireland, botanists cultivated the tiny embryonic growths found within the immature fruits; it is hoped that clones of the palm can be grown to adulthood (Parnell *et al*. 1986). Introduced animals and plants have taken over Mauritius and Rodrigues so completely that a number of species have been reduced to as few as two remaining plants.

Hawaii's native forests and plants have fared poorly, too. Native sandalwood forests were cut by early settlers, endangering several species. The most fragrant of these trees, the Iliahi (*Santalum haleakalae*), is now restricted to the dry lava slopes of eastern Maui. Its carmine red clusters of flowers have the same aroma as its fragrant heartwood (Daws 1993).

Seven or eight types of lobelia plants of the genus *Delissea* once flourished in Hawaii, and all became extinct by 1966 except one, *Delissea undulata*, which had become reduced to only a few plants. Conservationists fenced these plants in 1967 from the browsing cattle and rooting pigs, and they were thought secure (Carlquist 1980), but by 1995, the species' population had declined to a single plant. Botanists found it hanging by a few roots inside a sinkhole, the fence damaged and broken. The fence was repaired, and botanists are germinating seeds, hoping to prevent its extinction (Royte 1995). Another Hawaiian plant, *Cyanea pennatifida*, is in the same perilous status. Native to the mountains of Oahu, it also became reduced to a single plant, which was not producing its green flower. A botanist took a small sample of plant tissue and successfully cloned it in a test tube (Lipske 1997). Dozens of these plants have been cultivated from the slip, some of which were reintroduced into a preserve in 1995 (Lipske 1997).

Two hundred native Hawaiian plants are listed either on the US Endangered Species Act or are candidate species. Some 115 species have only 20 individual plants scattered in different areas or just one population of 50 or fewer plants in one location (Lipske 1997). Livestock and exotic plants have destroyed these plants and their habitats. One of these extraordinarily rare plants has been eliminated from all its original range, and the last members of the species cling to a single vertical cliff along the coast of Kauai, with its roots growing horizontally into rugged rocks (Carlquist 1980). This unusual lobelia, *Brighamia insignis*, has a thick, woody stem which tapers to a rosette of leaves, and it has lost its natural pollinator, which may have been a bird or an insect. Located 2,000 feet above crashing surf, it is out of reach of goats and pigs, but difficult for botanists to reach. This spectacular landscape is now this lobelia's sole habitat. Each year, botanists Steve Perlman and Ken Wood risk their lives by scaling the cliff, using climbers' ropes, to collect pollen from the plants with a brush. They then rappel to a neighboring plant to pollinate it, and months later, they must climb back up to collect the seeds, which are being placed into cultivation (Daws 1993; Royte 1995). Some of these seeds have successfully grown into plants at the National Tropical Botanical Garden on Kauai (Lipske 1997). This may be the most arduous and life-threatening plant conservation program in the world.

On the island of Guam, the forests have not been destroyed, but the bird life has been virtually eliminated by an insidious exotic animal that arrived in the 1960s or earlier. Several Brown Tree Snakes (*Boiga irregularis*) somehow secreted themselves in a shipment from their native Indonesia, and once on the island, they began to multiply. These snakes proved to be an environmental nightmare of the worst proportions, climbing trees and killing and consuming nestling and adult birds, and increasing at alarming rates. They have also caused major problems for the people of Guam. Ascending telephone poles, Brown Snakes short electrical wires. Between 1978 and 1990 alone, 1,000 power outages on the island were caused by these snakes (Jaffe 1994). A major threat to children, they enter homes, biting babies in cribs, and consuming pets. Untold millions of these snakes now live in virtually every environment in Guam. By 1981, these snakes had eliminated native birds from most of the island except for a remote part in the north. The snakes obliterated nearly the entire avifauna of Guam, an estimated 750,000 birds. Once a verdant tropical island teeming with birds, the forests have fallen silent. Three birds became extinct: the Guam Flycatcher (*Myiagra freycineti*) and two distinct subspecies of birds that survive on other islands: the Guam Bridled White-eye (*Zosterops conspicillatus conspicillatus*) and the striking chestnut, black-and-white Guam Rufous Fantail (*Rhipidura rufifrons uraniae*) (Jaffe 1994). The flycatcher was the greatest loss because it left no subspecies on neighboring islands. The Guam Kingfisher (*Halcyon cinnamomina miyakoensis*) became extinct on the island as well, but fortunately, a small

number had been taken into captivity. These kingfishers have been kept at several US zoos, but although they have produced some young, they have exhibited abnormal behavior, such as cannibalizing their chicks, and some have succumbed to avian tuberculosis.

The Guam Rail (*Gallirallus owstoni*) escaped extinction by a hair's breadth. The rail's population declined to about 2,000 birds by 1981, and in 1983, fewer than 100 remained; the last wild birds disappeared by 1987. The Guam Division of Aquatic and Wildlife Resources captured 19 rails in 1984 and, after captive breeding and holding, began releases in 1995 of 30 to 50 rails every three months on the neighboring island of Rota (Line 1995). Rota, a 209-square-mile island, is snake-free, but only one-fourth the size of Guam. Its forest is mainly intact (Line 1995). In 1999, the introduced Guam Rails bred on Rota for the first time (BI 2000). A small area of 24 hectares on Guam has been fenced off from snakes, and Guam Rails introduced there have also bred (BI 2000). About 180 birds survive in 14 zoos in the United States (BI 2000).

To date, no effective control has been found to rid Guam of the Brown Tree Snake. Metal bands on nesting trees of endangered birds and high-voltage electrical wires meant to kill them on contact have hardly made a dent in their populations. A native bird at the edge of extinction, the Marianas Crow (*Corvus kubaryi*), declined on Guam from 351 birds in 1981 to just seven in 1999 (BI 2000). On neighboring Rota, only 592 survived in 1995, down from 1,318 in 1981 (BI 2000). Guam still has a high percentage of forest cover and many aquatic habitats intact. Among the few mammals on Guam, the Marianas Flying-fox (*Pteropus mariannus mariannus*) has also declined, with a population in the mid-1990s of only about 300 animals. They suffered the effects of heavy hunting by the people of Guam for food, and the Brown Tree Snake is now killing juvenile bats. The endemic Guam Flying-fox (*Pteropus tokudae*) is now extinct, last seen in 1968. It was a probable victim of unrelenting hunting by natives for food but may have been killed off by the Brown Tree Snake. Shrews and other rodents and monitor lizards are disappearing from Guam as well (Jaffe 1994). Since many of the birds and bats served as pollinators of native trees and plants, these species may die out as a result.

Invasive species, mainly those introduced by humans onto islands, caused virtually all avian extinctions over the past few hundreds years. Today, almost 30 percent of threatened birds, or 298 species, are affected by introduced predators, particularly cats, rats, mongooses and other animals (BI 2000). Livestock introduced into avian habitats represents a major threat to 72 species of birds, and 71 bird species have been adversely affected by the introduction of invasive plants that eliminated the food or habitat of plants on which these birds depended (BI 2000). Pathogens, such as diseases and parasites, brought into avian habitats by various means threaten an additional 69 species of birds (BI 2000).

Introduced species threaten fewer mammals, about 69 species, or 10 percent of those listed by the *2000 IUCN Red List* (Hilton-Taylor 2000). This may be because far fewer mammals inhabit islands, compared to the number of native birds, especially flightless ones. Even sizeable islands, such as New Zealand, had very few native mammals prior to human colonization. Madagascar is an exception, with a very large diversity of primates and other mammals, a large number of which are now extinct because of invasive species, along with many other factors (See Islands chapter).

What is Threatening Species? Persecution, Hunting and Trade

A total of 367 species of birds are threatened by hunting for food (233 species) and trapping for the cage bird trade (111 species) (BI 2000). The majority of birds that are threatened by meat and feather hunting are Asian pheasants, grouse, partridges, bustards, guans, megapodes and other large birds (BI 2000). The family of birds most threatened by trapping for the cage bird trade is the parrot family, Psittacidae, with 57 percent of threatened species trapped for this trade (BI 2000). These parrots are native to Mexico, Central and South America, Africa, Asia and Australia, and

some have been pushed to the edge of extinction (See Trade chapter). The Spix's Macaw (*Cyanopsitta spixii*), for example, had been reduced from several hundred birds in the wild in Brazil to a single male when he, too, was illegally trapped in late 2000. This species is now extinct in the wild.

Hunting and capture for commercial purposes threatens 212 mammal species (Hilton-Taylor 2000). Many mammals have been endangered by hunting and persecution, including a number of large predators. The number of bats on the threatened list has grown dramatically in recent years, with many fruit bats threatened by killing for food, and others by vandals or those who persecute them for supposed threats to human health. Trade affects about 29 percent of threatened mammals (Hilton-Taylor 2000). Both the Asian (*Elephas maximus*) and African Elephant (*Loxodonta africana*) species have been reduced to endangered status primarily as a result of killing for their ivory and meat. The 1989 listing of the African Elephant on Appendix I of the Convention on International Trade in Endangered Species (CITES) succeeded in putting an end to more than 90 percent of trade in ivory, which was pushing this species rapidly toward extinction. Since then, the ban has been weakened by pressure from ivory traders, and CITES allowed trade in stockpiled ivory taken from smugglers in southern Africa. This had the immediate result of increasing poaching of elephants throughout the continent, in anticipation of a lifting of the ban.

All rhinoceros species, two native to Africa and three to Asia, are critically endangered. Populations of the five species together total only about 12,000 animals, a result of heavy hunting for their horns, which are used in Traditional Medicine (TM) and as handles for daggers in the Middle East (see Trade chapter). The toll of animal species killed for meat, trade and the TM market numbers in the millions, of which a growing number are threatened. Tigers, Leopards and other wild cats, snakes, pangolins, monkeys, birds of prey, deer, seahorses, and turtles, and many other species are killed to supply this market. The Tiger is poached throughout its range because its body parts are worth $10,000 or more when sold in this market and as trophies. This species is killed in parts of its range by slow-acting poisons and leghold traps for trade, and predator control when it has hunted livestock after its natural prey was killed off. Species like the Tiger, which require large territories and are suffering high mortality from hunting throughout its range, as well as loss of habitat, are in imminent danger of extinction. Several conservation programs are attempting to stem the tide in favor of the Tiger and reduce demand for its body parts in TM. Stricter laws are needed throughout the world, however, to protect endangered animals. The bushmeat trade is a major threat to Central and West African mammals and a wide spectrum of species in Southeast Asia (see Persecution and Hunting chapter).

A thriving trade in terrarium frogs has resulted in a worldwide market for many species of these amphibians. The world's largest frog, the Goliath Frog (*Conraura goliath*) of Central Africa, weighs 7.2 pounds and reaches a length of at least 32 inches; it is found along major rivers in dense tropical rainforest in Equatorial Guinea and southwest Cameroon (FWS 1991). Throughout its range it is very rare, and it has unusual habitat requirements. It needs rapids and cascades with sandy bottoms and very clean, oxygen-rich water; deforestation has reduced this habitat. Collectors have offered huge sums up to $2,500 for capture and export of Goliath Frogs--as personal pets or for public exhibition. One US dealer imported 50 of these frogs and attempted to enter them in the Frog Jump Jubilee in Calaveras County, California (FWS 1991). The Endangered Species Act lists this species as Threatened throughout its range. The IUCN lists it as Vulnerable on the *2000 IUCN Red List*. Hundreds of other species are collected for this trade, threatening many, including various mantella frogs of Madagascar, coveted for their golden color (See Islands chapter).

Although more reptiles than amphibians are killed for their skins, amphibians are now also being taken in large numbers for this purpose. In 1985, the United States imported more than 11,000 frog and toad hides and products worth $350,000 for the luxury trade in frog skin wallets, toad leather boots and other items (Fitzgerald 1989). Most of these skins come from a large Malaysian frog (*Rana macrodon*), but the Black-spined Toad (*Bufo melanosticus*) and other species are used as well (Fitzgerald 1989). Such products are extremely difficult to identify by species, making enforcement difficult.

Frogs are killed by the millions for high school biology class anatomy lessons, an unnecessary toll because

computer programs and films now provide this information (see Projects section). For the restaurant trade, frogs are killed in even greater numbers. Indonesia and Vietnam are the major sources of frogs for restaurants and food markets in Europe and the United States. Prior to export bans, Bangladesh and India captured many millions of frogs each year for the restaurant trade. Several documentary films have recorded the process of removing the frogs' legs in Bangladesh and Indonesia; the same methods were used in each country. Once captured and gathered in large containers, the frogs' back legs are sliced off with a sharp knife or machete, and the still-living frogs are tossed into heaps, where they continue to struggle for long periods before dying. An increase in malaria was documented in Bangladesh after the frog trade caused declines in wild populations; the frogs had been controlling mosquito populations.

The Indian Bullfrog (*Rana tigerina*), a species native to southern Asia, was listed on Appendix II of CITES after heavy trade depleted it. Some of these shipments were seized: In July 1997, a shipment from Vietnam containing the legs of 450,000 Indian Bullfrogs was intercepted in Holland as a CITES violation; the container with the frogs' legs weighed almost 20 tons and was en route to a wholesaler in Canada. This shipment alone represented frogs from vast areas in Vietnam, depleting wetlands of these ecologically important amphibians. Even in US National Parks, frogs are commercially hunted. In Florida, for example, frog hunters in airboats capture millions of frogs during night hunts. In February and March 1996, 6 tons of frogs were taken from Big Cypress National Preserve for sale to restaurants and for private consumption, according to environmental groups which have petitioned the National Park Service (NPS) to end or limit this hunt (Dodds 1996).

The reptile product trade placed virtually all large crocodilians on the endangered list by the early 1970s after imports of millions of skins for luggage, shoes and handbags nearly caused extinctions of species in South America, Africa and Asia. Although controlled to some degree by CITES, a large percentage of trade is illegal, composed of protected species (see Trade chapter). The luxury trade in these products is now threatening many snakes as well as lizards, whose skins can be sold for very high prices. These reptiles, which play important roles in nature--culling rats and other rodents and preventing overpopulations of fish--are taken from the wild. Snakes are being captured in such numbers for this trade and for the Asian medicine and restaurant trades that they have disappeared from areas where they had been common. (See fiEndangered and Threatened Species of Mammals, Birds, Reptiles and Amphibiansfl in the Appendix for an extensive list of these reptiles now threatened with extinction.)

What is Threatening Species? Pollution and Disease

Pollution by acid rain and acid from coal mines that drains into streams and rivers, heavy metals, PCBs, dioxin and other toxic chemicals, have killed off all life in waterways in many parts of the world. PCBs and pesticides have caused serious genetic malformations in frogs, birds and fish.

Frogs have been dying from fungal diseases and the indirect effect of other pollutants, which are eliminating entire species. Necropsies done on frogs from Australia and Panama, which were found dying, have revealed the presence of the same fungus, chytrid (Morell 2001). It is considered responsible for the extinction of several Australian frogs, including the extraordinary Gastric-brooding Frog (*Rheobatrachus silus*) and three other species, and has infected frogs in Panama as well, eliminating populations and possibly species (Morell 2001). This fungus has been detected in 44 species of Australian frogs and is apparently spreading in many parts of the world. Other fungi and viruses have eliminated frogs in the United States (Morell 2001). These diseases have long been in the environment, and it is not yet clear why they have become so toxic and virulent to frogs. Frogs have thin skin and easily absorb chemicals, making them vulnerable, but apparently their immune systems have been weakened, as well. Frogs and toads are also threatened by pesticides, which have been shown to cause grotesque deformities and mortality. Many types of pollution, including acid rain, heavy metals and fertilizers, have eliminated frogs in many parts of Europe and Canada

(Morell 2001). Ultraviolet radiation (UV) suppresses frogs' immune systems and kills eggs as well as adults. Andrew Blaustein (1994), an American biologist, conducted experiments that proved UV to be responsible for wiping out many species of frogs in the US West who laid their eggs in the open. The eggs were thus exposed to this radiation, which has intensified as a result of the decrease in the ozone layer caused by chloroflourocarbons, used by industry in air conditioners and refrigerators, among other industrial uses (see Aquatic Ecosystems chapter).

Hawaiian birds have been seriously affected by avian malaria, brought to the islands by captive cage birds, as discussed in Chapter 1. This disease continues to threaten the surviving species of native birds, and is a major cause of the wave of extinctions that is claiming one species after another of these beautiful songbirds (BI 2000). Several species, such as the Nukupu'u (*Hemignathus lucidus*), are now in Critical status, possibly extinct on both Kauai and Maui where, until the 1990s, a few birds were seen in their montane forests (BI 2000). Feral pigs in their habitats facilitate the spread of alien plants and introduced, disease-carrying mosquitoes (BI 2000).

What is Threatening Species? Traits of Vulnerable Species

By identifying the traits that characterize species likely to become endangered or fade to extinction, it is possible to afford them and their habitats extra protection and carefully monitor their status. The tragic losses of so many of these "red flag" species should be avoided in the future, and can be, with remedial action. Ideally, species should be conserved when their populations are still healthy, before they become genetically impoverished and their populations fragmented. The list below includes some of the characteristics many extinct and endangered species possess. Undoubtedly, the more we learn about the causes pushing wildlife and plants to extinction, the longer such a list will become.

1. Endemic species, or animals and plants that are restricted to a relatively small area, such as an island, are inherently vulnerable to extinction. They have incurred the greatest number of extinctions in the past 400 years. Changes in their habitat or losses to their populations can eliminate them. Many of these species were confined to areas that measured only a few square miles. Mainland species, likewise, can be endemic to small areas. The Slender-billed Grackle (*Cassidix palustris*) once inhabited a single marsh near Mexico City. The marsh was filled about 1910, spelling extinction for this bird. Many endangered species fall into this category.

2. Specialization of habitat or diet has caused much extinction. Animals that depend on a certain type of habitat or food source and cannot adjust to alterations, whether natural or human-caused, are extinction-prone. The Ivory•billed Woodpecker requires large expanses of old-growth forests with many dead and dying trees. The endangered Kirtland's Warbler (*Dendroica kirtlandii*) of Michigan will colonize only one type of forest: stands of jackpine trees that are eight to 22 years old on well•drained, sandy soil. This habitat must now be artificially maintained to prevent the bird™s extinction. The Palila (*Loxoides bailleui*), a Hawaiian honeycreeper, is dependent on the mamane tree for feeding, which has declined as a result of logging and destruction of seedlings by introduced game species and livestock. Many endangered plants require specific soil type, climate, drainage and sunlight exposure. For those species that require unbroken stretches of habitat, such as old-growth forest, endangerment or extinction can result if the forest is fragmented.

3. Long•lived species with low reproductive rates and low natural mortality are vulnerable to extinction. Fast-reproducing species that have many young at frequent intervals and high natural mortality rates tend to be more resilient to population losses and recover quickly if their habitat has not been destroyed. Not all vertebrates fall easily into these categories, but many do, and these groupings can be at least one indication that is useful in terms of predicting which species will become endangered when their populations are reduced. Slow-reproducing animals decline rapidly from losses in their numbers, and since they often do not breed until a relatively advanced age and

have few young, many decline to extinction. In some cases, such animals do not recover their former abundance, or recover very slowly. A few of these animals, including sea turtles, lay many eggs, but only a small percentage of the hatchlings survive to adulthood. Although few of the now extinct animals were ever studied in the wild, enough is known of related species to guess that many fell into this category. The Steller's Sea Cow (*Hydromalis stelleri*), for example, was a member of the Order Sirenia of manatees and Dugongs. The surviving species have few natural enemies, do not breed until age 7 to 10 years old, and have only one young every five years. Hunting caused the extinction of Steller's Sea Cow in the space of a few years, eliminating the only cold-water member of this family. Hunting threatens surviving species of this family in many areas. Manatees and Dugongs are very slow-moving, making them easy targets. The Steller's Sea Cow may have numbered only a few thousand animals in its limited distribution near islands in the Bering Sea. Even when able to swim away, they refused to leave their mates, beaching themselves on the shores next to the slain mate. Such animals can probably not tolerate any hunting. Manatees and Dugongs, likewise, need strict protection.

Many large birds, including condors, eagles and large parrots such as macaws, have low reproductive rates. The Cuban Red Macaw (*Ara tricolor*), became extinct in 1885. If its breeding biology resembled other large macaws, it was long•lived, reaching an age up to 80 years, had only one or two chicks a year and did not breed every year. Scientists have recently discovered that even in an immense national park in Peru, wild macaws produce so few young that any losses in their numbers cause declines in their populations. This helps to explain why so many birds of prey and parrots are endangered. Passenger Pigeons were long•lived, laid only one egg, and may not have nested every year. Likewise, turtles and tortoises are long-lived, with at least one species, the Galapagos Tortoise (*Geochelone nigra*) documented as living to more than 165 years in captivity. Some shark species do not breed until the age of 20 years and produce only a few young.

4. Flightless birds and slow•moving animals are helpless in the face of hunting pressure and predation by introduced predators and humans. Unwary animals, such as many island species that have evolved in the absence of predators fall into this category. Flightless birds, such as the Great Auk, Great Elephant Bird, Dodo, many Pacific Island rails and tortoises, are among species that lack defenses or cannot quickly escape predators, human or other. In addition to being flightless, many extinct birds lacked defensive behavior or the instinct to hide in underbrush as a result of their having evolved in predator-free environments. Predators introduced into their habitats, as occurred on many islands, soon eliminated them. Even the thick shells of tortoises were not effective defenses against predators such as rats, who ate young tortoises, and humans easily captured these slow-moving animals. Although our attitudes are more humane toward these vulnerable animals today than hundreds of years ago, tortoises and sea turtles are still killed for trade or by vandals for sport. Some surviving flightless birds on islands have official protection and a better future than they had in previous centuries, while others do not.

5. Large animals have been vulnerable to overhunting since the Pleistocene Epoch. In recent centuries, whales were added to the list of large species unable to escape guns or harpoons. The largest lemur and bird species of Madagascar were killed off by the Malagasy immigrants thousands of years ago, as were many large flightless birds by the Maori when they first arrived in New Zealand. Large animals are often killed merely because they make large targets or for trophies for those who enjoy slaughtering animals. Animals of large size require considerable amounts of habitat and are, therefore, naturally more rare than species with smaller habitat requirements. When human populations rise and wilderness is replaced with towns and industry, large animals are the first to disappear, due either to loss of habitat and prey or because they are killed as potential threats. Most of the largest mammals on Earth are now on the endangered list of the *2000 IUCN Red List*, including both species of elephants, all the rhinoceros species, and many large antelope and big cats such as the Tiger, Cheetah, Leopard and Lion. They have declined from hunting or persecution and are being crowded out of their habitats by human activities. Large animals are often keystone species at the top of their food chains or play important roles in ecosystems. Their absence is indicative of damaged or incomplete ecosystems. Elephants are important in spreading seeds of many plants through their dung, and large predators play a major role in the health and physical characteristics of their prey. The African savannahs without Lions, Leopards and Cheetahs would soon be overpopulated and overgrazed by their numerous prey species. The Elk of Yellowstone National Park became overpopulated in the absence of the Gray Wolf, and grazed certain plants so

heavily that some bird species and other wildlife disappeared and certain tree species became rare. In spite of the wolves™ importance to ecosystems, they are killed with impunity by livestock owners and others who consider them threats.

6. Wild animals and plants which have a value as food, pets, ceremonial objects or marketable products to humans are prime candidates for extinction. The list of animals that have been hunted to extinction for food is long. Within the past 400 years, many large land tortoises, the Great Elephant Bird, moas, Steller's Sea Cow, Auroch and Quagga were all extinguished by hunting for food. The unique Huia bird of New Zealand had plumes that were sold for large sums, helping to drive its limited population to extinction. Hawaiian songbirds were hunted to extinction for their colorful feathers, which were used in ceremonial headdresses and capes. Within the past decade, trade has increased as a threat to wildlife with the rise in Asian economies. This has fueled the Traditional Medicine markets, which consume vast numbers of animals, threatening many of them. The vacuuming of the seas by commercial fisheries has resulted in depletions and endangerments. The once abundant sturgeon of the Caspian Sea, for example, sources of Beluga and other expensive caviar, are now critically endangered as a result of unrestricted fishing and poaching for the luxury gourmet market. The bushmeat markets of West and Central Africa sell tons of slaughtered monkeys, forest antelope, Chimpanzees, Gorillas and other wildlife, devastating species whose tropical forest habitats are being logged. Hunting for food is also a major threat as firearms become available to native peoples who once used primitive weapons. Southeast Asian wildlife is under siege by people who once hunted only for their own purposes but now find that a wide range of wildlife can be sold in local meat markets or for Traditional Medicine. They set nooses and traps, killing rare monkeys and antelope, birds, snakes, turtles and tortoises, pangolins and lorises, clearing out the forests of wildlife. The pet trade is driving many colorful tropical birds, reptiles and primates to endangered status. Luxury goods, such as high-priced reptile products, provide an incentive to hunt--legally or illegally--lizards, crocodiles and snakes for this market, endangering many species. Trophy hunting of endangered species by wealthy hunters is a major threat to a growing number of animals, especially since the largest specimens are killed; these are the ones that should be left to breed. The higher the value of the animal or product, the greater the threat to that species.

7. Altruism, or the unselfish care for members of one's own species, highly admired as a human trait, has been fatal to many animals--the Passenger Pigeon, Dodo, Carolina Parakeet and Steller's Sea Cow, for example. In their evolutionary history, this behavior served to preserve bonds between animals and to frighten off predators. When confronted with guns or other weapons wielded by humans, however, animals that come to the aid of fallen mates or flockmates can be easily killed themselves. Refusal to leave their wounded fellows hastened the extinction of many species. Endangered species with these traits include wolves, gorillas, whales and elephants.

8. Species breeding in colonies or requiring large numbers of their own kind for protection, to locate food sources or for other means of survival, are vulnerable to extinction. The Passenger Pigeon was a colonial nesting bird and could only survive among large numbers of its own species, flocking and seeking food sources over large areas. When flocks were fragmented, these separated populations declined to critically low levels, even though their total numbers may have been in the tens of thousands. The Passenger Pigeon may have become critically endangered as soon as its migrations, feeding and nesting behavior were interrupted, even though it appeared to observers at the time to be plentiful. These pigeons had longevity of several decades, and failure to reproduce would take some time to be noticed in the overall population. But when there is little or no introduction of young into a population over a period, it can suddenly crash with little warning, as the Passenger Pigeons did. Wild parrots tend to feed, roost and spend their time preening and in courtship as a flock. For some species, these flocks number in the thousands of birds. When netted or caught by various means for the pet trade, which threatens a large number of species, their flocks are broken up and they are no longer able to function as a group. Their breeding is curtailed or stopped altogether, and they may no longer fly in groups seeking fruiting trees or mineral licks when they fear being captured. Flamingos require large numbers of their own kind for feeding, flocking, migrations and breeding, and their populations crash if any of their survival requirements are not met.

Many species of birds have breeding strategies in which male birds will not breed unless they are able to display

courtship behavior in the company of other males, vying for the approval of females. Birds of paradise, cocks•of•the•rock in South America, prairie chickens and grouse of North America are among birds that display for the benefit of females, who choose among them. Such birds require specific conditions to breed, and habitat alterations, reductions in their populations or hunting pressure that keeps them from exposing themselves in the open can prevent their breeding.

Mammals, reptiles and amphibians also have male contests of strength, agility or other mark of superiority of species. Wild sheep and deer vie for females by head butting and challenging one another. Many types of tropical frogs emerge during the breeding season to form groups that display to one another for the benefit of females. Male Plowshare Tortoises joust with one another in attempts to upend the rival and will not breed if only a single male and a female are placed together. Without rivals for competitions, male breeding behavior may not be triggered, preventing reproduction.

Zoos and zoologists are only beginning to understand some of the instinctive responses necessary for breeding. Our traditional concept that a compatible pair of animals will reproduce is often incorrect, and populations of animals must not be allowed to be so reduced that their natural breeding behavior and other survival needs are not met.

Thus, while population numbers can provide important information about the status of a species, without additional information, such as the traits mentioned above, the data can be extremely misleading and inapplicable. The number of individuals surviving in a species, when known, must also be placed into a context greater than their rate of decline and habitat status. Unless the entire breeding biology, behavior and other aspects of species' survival needs are taken into account, extinction cannot be predicted, or status properly evaluated.

Some species now extinct suffered from several of the above factors, which hastened their extinction. The Passenger Pigeon, for example, required enormous amounts of food, mainly from nut-bearing trees in old-growth forests, and was relatively long•lived, killed for food and commercial sale, and lived colonially. Elephants and manatees are among endangered species with many vulnerable traits, including large size, altruism, slow-reproduction, low natural mortality and longevity. They are also slow-moving and valuable in trade and as food sources.

These traits indicate only vulnerability to extinction caused by humans, not species likely to become extinct through natural selection. Sea turtles, for example, have lived on Earth for more than 200 million years. By any standard, they are a superbly successful, adaptable species that, prior to recent exploitation, showed no signs of decline. Their vulnerability lies in their inability to flee rapidly in the water or while laying eggs onshore when preyed on by humans.

Many endemic species occupy very limited habitats and have small populations but have not been listed as threatened if their environments or populations have not declined. The majority of these species have prospered for thousands of years in stable environments, and only the intrusion of human-related activities and domestic animals upset this equilibrium. Such species are extremely vulnerable to even minor habitat destruction or hunting pressure and should be carefully monitored for losses in their populations.

Because of human technology and weaponry, all animals have become vulnerable. Animals that for thousands of years used natural camouflage, stealth and intelligence to escape from natural predators, have become easy prey for human hunters and fishermen. Predators, never in their evolutionary history preyed upon, now find themselves targeted by hunters, trappers and poisoners. Sonar locates fish schools and whales, and heat detectors and night-view binoculars observe animals in darkness. Cleverly constructed blinds hide hunters from view. Animal scents are used to lure wildlife, and hunters imitate animal sounds or use tape recordings of their calls to lure them to traps or within shooting range. Some hunters use the signals emitted by radio transmitters placed in wild animal collars by biologists for tracking, to hone in and pursue them to their deaths. Guns equipped with telescopic sights can fire at targets mile away, killing animals before they are even aware of the hunter. Other weapons include sophisticated traps, nets,

snares, guns, harpoon guns and high•speed vehicles and boats, with which people can run down, maim and kill even the swiftest and most intelligent animals. These devices give humans such an advantage that they render the natural protections animals have evolved over eons completely ineffective. Hunters are able to kill the fittest and strongest specimens through these means. In the process, we are changing the course of evolution from survival of the fittest to survival of animals that are tolerated by humans and those able to persist in an increasingly polluted, damaged and ecologically impoverished natural environment.

Those species whose populations have become greatly reduced are vulnerable to extinction through genetic impoverishment and inbreeding. Such species usually remain rare or gradually fade into extinction as fertility declines. The critical low level which results in extinction is different with each species and cannot be predicted with certainty.

Just as the story of North America's lost species and environments is illustrative of many similar tragedies, the account below of the civil war in Rwanda and the former Zaire encapsulates the major threats to wildlife and the environment. It also makes abundantly clear that the survival of humans, animals and the environment are intrinsically linked. The influence of countries that contribute foreign aid to poor nations half a world away, and interfere in their politics, is another important element that can greatly affect the survival of wildlife and the natural world.

Human Tragedy and the Looting of Virunga's Treasures: Page 1

The mist•enshrouded Virunga Mountains of East Africa tower over dense highland vegetation. Far below, crystalline lakes ringed by marsh reeds glisten in the sun. Shy forest African Elephants walk along mountain paths in single file. Groups of endangered Mountain Gorillas (*Gorilla gorilla beringei*) feed in forest glades. Three hundred fifty of these magnificent animals, almost half their world population, reside here (Fisher 2001). The western edge of these mountains is protected in the vast 12,800•square•mile Virunga National Park, bordering western Rwanda. Some 766 species of birds reside here, more than are native to the United States and Canada combined. Iridescent sunbirds feed on the flowers of giant lobelias, and more than 200 species of mammals live in the park (Bonner 1994). Many of the species native to the park are found nowhere else on Earth. This ecological treasure is Africa's first national park, set aside in 1925. Virunga was closed to visitors other than scientists until very recently. In the 1970s, it became a World Heritage Site, a designation by the United Nations Educational, Scientific and Cultural Organization (UNESCO) for places deserving special recognition and protection.

In the early spring of 1994, political upheaval in the region caused a civil war that wreaked massive ecological damage and loss of wildlife in this natural paradise. Rival tribes in neighboring Rwanda clashed violently after the country's President was killed in an airplane crash caused by a rocket launch (Wright 2001). There were suspicions that his death had been arranged by his enemies. In an attempt to overthrow the minority-run Tutsi government, the Hutu majority began slaughtering Tutsi tribal members. Within months, more than 500,000 people, most of them Tutsis, were slaughtered in an appalling genocide that began with armed conflicts between army soldiers and rebels and accelerated to violence between neighbors. People of all ages were victims, many killed by slashes from machetes or battered to death with clubs. The Hutu failed in their attempt to overthrow the ruling Tutsi tribe and fled in panic west to neighboring Zaire, home of Virunga National Park.

Some 2 million Rwandan Hutu refugees flowed in a steady stream into eastern Zaire, just south of the park. Injured and starving, they crowded into camps where international aid organizations fed them and attempted to control cholera and other infectious diseases. Within days, scenes that might evoke visions of Dante's *Inferno* were televised by news organizations to viewers around the world. Gaunt, frantic people were seen scrambling frantically for food

supplies or lying listlessly in the final stages of starvation and disease. Estimates of total mortality from the war, starvation and disease exceeded 1 million people (Wright 2001). Many of the surviving refugees were afraid to return to Rwanda and remained in the refugee camps or built settlements on hills near Virunga National Park. To supply firewood to these 700,000 or more refugees, 30,000 people went into the rainforest each day, cutting down tens of thousands of trees (Bonner 1994). Rwandan soldiers and others began a thriving business selling firewood throughout the refugee camps. By November 1994, 112 square miles of the park had become partly or completely deforested, and little was done by Zairean troops or park authorities to curb the destruction (Bonner 1994). One forest ranger said, "Trees used to block the views everywhere. Now I see hills I didn't even know existed." An estimated 230 truckloads of trees left the park every day (Salopek 1995).

In December 1994, the World Heritage Committee placed Virunga National Park on a list of "World Heritage in Danger.fl Along with the forest cutting, park wildlife was killed for food by both refugees and Zairean soldiers, who had gone unpaid for months by the failing government. In mid-1995, more than 12,000 of Virunga National Park's Hippopotamuses (*Hippopotamus amphibius*) were killed for their meat and their ivory teeth, reportedly by Zairean soldiers using semiautomatic weapons. By late September 1995, there were still 700,000 Rwandan refugees camped near the park, removing 600 metric tons of firewood from the park each day (Lang 1995). Michel Leusch, Environmental Coordinator for the United Nations High Commissioner for Refugees in nearby Goma, said, "The quantity of biomass may be recovered in time, but some things, like rare plants and animals, have disappeared and cannot be replaced" (Lang 1995).

The government of Zaire began closing refugee camps in January 1996, with more than 1 million refugees still resident in 40 camps along the border with Rwanda. Another 700,000 Rwandan refugees stayed in camps in Tanzania and Burundi (McKinley 1996). Although millions of dollars were donated to supply food and medication, no aid funds were allocated for alternate fuel for these refugees, such as solar cookers and propane gas stoves that would have helped prevent the devastation of Virunga's forests. This highlights the need for an international ecological rescue fund that could ameliorate such tragedies, as well as safeguard wildlife from slaughter. In late 1996, Zairean troops attempted to force the last of the Rwandan refuges back into their country, causing open warfare to break out, and the last of the United Nations relief workers were forced to abandon the area. By mid-1997, hundreds of thousands of Rwandan Hutus had dispersed through the forests of Zaire, living off the land. Thousands of Hutus, jailed on their return to Rwanda, were placed on trial in an international tribunal in 2001 for their actions during the massacre.

Human Tragedy and the Looting of Virunga's Treasures: Page 2

A major underlying cause of Rwanda's civil war and the great suffering of its people is its uncontrolled population growth. In 1973, Rwanda's population reached 3,980,000 in a country whose total area is only 10,169 square miles--smaller than Maryland (Anon. 1975). This resulted in a ratio of 391 persons per square mile, one of the densest in the world. Populations continued to grow, however, and by 1992, they topped 8,206,000, with a density of 806 persons per square mile (Anon. 1994a). The country became increasingly crowded, as arable land became scarce. Competition for land had become intense. Much of Rwanda is eroded and barren, the thin tropical topsoil producing crops for only a few years after the forest has been cleared. Only 22 percent of the land remains forested (Wright 2001). Farmers slash and burn more forest for planting when land ceases to produce crops or grazing grasses. Steep, erodable slopes are being plowed right up to the limits of protected parks and reserves. The feuding between Hutu and Tutsi might have been peacefully settled if not for the extreme poverty and overpopulation. The average per capita income in 1999 was $720 per year (Wright 2001).

The war™s massacres killed almost 1 million people, leaving an estimated 7.2 million people by 2,000, according

to unofficial estimates (Wright 2001). Unless birth control becomes widely accepted in Rwanda, human populations will rise to an estimated 11 million people within a few decades. Some experts believe that nearly 22 million people will occupy Rwanda by 2020 (Anon. 1994a). By the latter estimate, there will be 2,163 persons per square mile in Rwanda, far more than its land can support. By contrast, the population density in the United States in 2000 was 76 persons per square mile, and Canada's, 8 persons per square mile (Wright 2001).

Human Tragedy and the Looting of Virunga's Treasures: Page 3

The effects of burgeoning human populations on wildlife and the once magnificent forests that covered the region have been tragic. Long before the forests of the Virunga Mountains became divided into the separate countries of Zaire, Rwanda and Uganda, and before the forests were replaced by agriculture in the latter two countries, thousands of Mountain Gorillas inhabited the region. As human populations rose, Gorillas declined to their present endangered status. These peaceful primates wander in the forest throughout most of the daylight hours, feeding on the luxuriant vegetation. As the largest and most powerful of all primates, the Gorilla male has an enormous chest, 20 inches across and up to 5.7 feet (1.75 meters) in circumference. He weighs up to 605 pounds, while females are much smaller, about half the weight of the male (Nowak 1999). The Mountain Gorillas' forests can become quite cold at night, and to adapt, they have developed longer, thicker hair than the Lowland and other races of Gorillas.

Gorillas travel in family groups led by silverbacks, named for the whitish-gray hair on their backs. These are the strongest and largest males, usually more than 20 years old, who guide and protect the band. Males compete for this role as soon as they are teenagers. Silverbacks father the babies in the family group, although sometimes females mate with "outside" males. These groups often travel long distances to locate fruiting trees and edible plants and tubers. Almost entirely vegetarian, Gorillas eat 40 pounds of food a day, feeding on 70 or more species of leaves, bark, fruit, roots, fungi, flowers and bamboo. They rarely drink water, obtaining moisture from the dew-laden plants, and the only animal matter they consume consists of insects. Gorillas consider army ants a delicacy and occasionally eat grubs and other insects.

In Rwanda's north, contiguous to Virunga National Park, where about 250 Mountain Gorillas survive, Volcanoes National Park, a 48-square-mile forest reserve, is home to about 100 Mountain Gorillas (Fisher 2001). The latter forest was once much larger, but the needs of agriculture had greater priority, and some 65 square miles were carved out of the park, squeezing the Gorillas into a fraction of their original range in the country.

Human Tragedy and the Looting of Virunga's Treasures: Page 4

In neighboring Uganda, the small Mgahinga Gorilla National Park, a 34-square-kilometer reserve, protects 40 more Mountain Gorillas. Some 25 kilometers north is a beautiful cloud forest, Bwindi Impenetrable Forest National Park, covering 330 square kilometers, in an area of high biological diversity (Butynski and Kalina 1993). This forest has the greatest number of trees of any in East Africa and so many endemic plants that it has been selected by the IUCN Plants Programme as one of Africa's most important forests (Butynski and Kalina 1993). Birds, butterflies, amphibians and reptiles found nowhere else inhabit the Bwindi Impenetrable Forest. It also protects a population of 300 Mountain Gorillas who have smaller bodies, longer limbs, hands and feet than those of Zaire: Their skulls and trunks differ also, and they are somewhat different genetically from other populations (Croke 1995, Drewes 1997). Scientists are now considering naming these Gorillas a separate subspecies. Destruction of forest and other habitats outside Uganda's and Rwanda's parks is extensive, making these last natural areas crucial to the survival of the

Mountain Gorillas.

Uganda's decades of chaos under President Idi Amin decimated the wildlife of this lovely country bordering Lake Victoria. Murchison Falls and Queen Elizabeth National Park once had magnificent concentrations of elephants, hippos and other large mammals, but by 1997, little remained, having been slaughtered by rebel groups or refugees from neighboring countries (Drewes 1997). Uganda's Ministry of Tourism, Wildlife and Antiquities conducted an aerial survey of Uganda's remote northern regions to determine whether some wildlife might remain to restock other areas, but they found "absolutely nothing" (Drewes 1997). Uganda has recently made a commitment to restore its wildlife and has reintroduced many large ungulates, trucked in from Kenya, into its national parks.

Human Tragedy and the Looting of Virunga's Treasures: Page 5

Although Gorillas share more than 98 percent of human genes, making them, along with the two species of chimpanzees, our closest relatives, until the 1960s, they remained mysterious, threatening creatures in the view of the public, depicted as monsters in movies. During the 19th century, explorers and hunters killed them as ferocious symbols of savagery. The work of American biologists Dr. George Schaller and, later, Dian Fossey, who entered the forests of the Mountain Gorillas as observers and researchers, changed this image forever. Films and books of the National Geographic Society and others revealed the gentleness and intelligence of these magnificent primates to people around the world, and gradually, conservation programs began to replace trophy hunting.

Schaller, who began his research in the 1960s in Virunga National Park, wrote about these primates in *The Mountain Gorilla*, published in 1963 by the University of Chicago Press, and a popular version, *The Year of the Gorilla*, in 1964. He provided the first scientific observations of these remarkable animals and recalled his encounters with them in a 1995 *National Geographic* article:

> *I approached them with empathy and respect, wanting nothing from them but peace and proximity. And they accepted my presence with an astounding generosity of spirit. The recent decades have been a turning point, indeed a revolution, in our relationship with animals. Humans have begun to overcome cross-species barriers, achieving intimacy with humpback whales, chimpanzees, lions, mountain sheep, wolves. The gorillas of popular image were a fantasy . . . No one who looks into a gorilla's eyes--intelligent, gentle, vulnerable--can remain unchanged, for the gap between ape and human vanishes; we know that the gorilla still lives* within us. Do gorillas also recognize this ancient connection? (Schaller 1995).

In the 1960s, Virunga National Park sheltered the largest population of Mountain Gorillas, numbering some 450. They declined to 275 by the 1970s, and to 250 by 1981, a result of poaching. The Mountain Gorilla Project, begun in 1978 by Schaller and a consortium of conservation organizations, including the New York Zoological Society and the African Wildlife Foundation, sought to stop the Gorilla's decline toward extinction. Funding went toward anti-poaching programs, education of local people, and ecotours (Schaller 1995). With non-threatening visitors to the park, many Gorillas grew tame. They were given names by park rangers and scientists and became familiar to tourists who came from around the world to see them. The conservation program and ecotourism succeeded in nearly eliminating poaching, and Virunga's Gorillas increased to 320 by the late 1980s (Schaller 1995). The Gorilla Project also operated in Uganda, where the government ejected 2,000 farmers from 3,500 acres, offering to compensate them with 10 percent of the revenue from tourists who come to see the gorillas (Salopek 1995).

Human Tragedy and the Looting of Virunga's Treasures: Page 6

Fossey's early research was sponsored by the famed anthropologist Louis Leakey, who had earlier convinced Jane Goodall to go to Tanzania to study Chimpanzees (*Pan troglodytes*). Both researchers changed forever our views of these fellow primates. Fossey began her research in the 1970s in the mountains of Rwanda, making friends with a family of Mountain Gorillas. The silverback male of this troop, whom she named Digit, became so trusting that he was filmed by the National Geographic Society gingerly taking her pen and then her notebook, returning them to her, and then lying down and going to sleep by her side (see Video--Mammals). These immensely strong animals never harmed any of the thousands of people, from rangers and scientists to tourists, who visited the reserve over several decades. When they felt their family was threatened, they made shows of aggression, pounding their chests or rushing headlong through the bushes toward the potential threat, whether human or another male Gorilla, but stopping short of physical blows. Humans, however, misinterpreted their displays, shooting and killing many silverbacks.

Commercialization of Gorillas--the high value of their young in the exotic pet trade and the many thousands of dollars offered by zoos to obtain illegally captured specimens--has presented a major threat to the species for many decades. Local people enter parks and reserves to shoot adults guarding the young, remove the animals™ heads and hands, and grab the traumatized babies. Other Gorillas are killed accidentally by illegal wire snares set in the parks for antelope and small mammals. Although efforts had been made in many parks to stop the killing of Gorillas, not until December 1977 did international attention become focused on this grisly and cruel activity. Six Rwandans, with their hunting dogs, entered the reserve armed with spears to kill Gorillas. They encountered Digit, who boldly rushed at them, pounding his chest. This allowed his family to escape, but cost him his life. The Rwandans speared him five times until he died, and then cut off his head. Gruesome photos of Digit's headless body received enormous publicity in the media, causing shock and dismay in millions of people who had seen photos of him in gentle communication with Fossey, as well as films produced by the National Geographic Society about her research. His death served to inspire both compassion and renewed conservation efforts for these beleaguered primates.

Fossey's Karisoke Research Center expanded, and thousands of tourists came to glimpse the Mountain Gorillas in their forest home. The threat of poachers remained, however, and Fossey, after a fervent campaign to prevent further Gorilla killings, was herself killed. Her murder has never been conclusively solved, but Rwandans are the major suspects. She is buried in the reserve next to the grave of Digit. Fossey recounted her experiences with Gorillas in a book, *Gorillas in the Mist*, which was later made into a commercial film of the same title. The silverback star of this film was named Mrithi. Not long after the film was made, in May 1992, he, too, was shot and killed by Rwandan soldiers, surrounded by his family of 11. Even after being wounded, he managed to drag himself some 6 feet toward his attackers before collapsing and dying.

Human Tragedy and the Looting of Virunga's Treasures: Page 7

During the 1980s, the country of Rwanda had adopted Mountain Gorillas as an international symbol of wildlife protection during the 1980s, and when civil war broke out in the spring of 1994, both sides promised to spare them--promises that were not kept. In April 1994, the Rwandan civil war forced the staff of biologists at the Karisoke Research Center to depart (Perlez 1994). By early July, most of the wardens of the Rwandan Office of Tourism and Volcanoes National Park fled also, but a few dedicated guards refused to leave the Gorillas and remained. Soon after, Rwandan soldiers entered the park and ransacked the offices, destroying records and books and throwing computers out windows but, fortunately, sparing the lives of the guards and the Gorillas. The war claimed at least one Gorilla

that year, however, when a male named Mkono was killed by a buried land mine (Tuxill 1997).

The staff of Volcanoes National Park was devastated by the war. Two-thirds of Rwanda's park employees died or remained in exile after the war ended, and 48 of 50 vehicles were destroyed (Salopek 1995). When surviving employees returned, many of them having been rescued from the masses of people living in refugee camps, with the help of United Nations personnel, they were delighted to see the Mountain Gorillas again. Nshogoza, a park employee who has spent 18 of his 44 years at Karisoke and has known generations of Gorillas, told a *National Geographic* writer, "When I was a boy, I heard that gorillas were men who were very bad and who went to live in the forest. But the gorillas are better than us. They are peaceful. They have no tribes. When they fight, it is for a good reason. We cut one another with machetes for zero" (Salopek 1995). To honor these guards, the park received the $50,000 J. Paul Getty Wildlife Conservation Award in May 1996, the money to be managed by the International Gorilla Conservation Program. Some was spent detecting and defusing more than 75 mines and booby traps left after the war, and other funds restored tourism in the park.

The Mountain Gorillas of Virunga National Park had been safe for a decade, but in 1995, Rwandan refugees, probably members of the routed army, entered their misty, forest home. In August and September 1995, three Gorillas--two silverbacks and one female--were found shot to death at point-blank range. One of these, named Marcel by the park scientists, was the most popular of Virunga's Gorillas, totally tame and gentle. He was so habituated to tourists that they could approach within a few feet of him, and hundreds of films and photos had been taken of him over the years. The bodies of Marcel and his mate were found sprawled out on the ground, full of bullet holes. "If someone comes in with a gun, the gorillas won't move out of the way," said Popol Verhoestraete, a field officer for the conservation program (Lang 1995). The killers left the bodies intact. These two Gorillas died trying to save their baby from poachers, who allegedly planned to sell him to a zoo. The park guards finally located this young Gorilla and seized him from the poachers, who were arrested. They carried the baby, who had become terrified and disoriented, in a small cage back to the family group. Not knowing if the frightened young Gorilla could survive without his parents, they released him, prepared to recapture him if things did not go well. After hesitating, he heard the sounds of his family and ran to join them. The leaderless and traumatized family group moved off into the forest.

Human Tragedy and the Looting of Virunga's Treasures: Page 8

Illegal snares have been threatening wildlife in these parks for generations. In the 1960s, Schaller saw two Gorillas in a group of 11 that had each lost one of their hands to snares (Schaller 1995). In Virunga National Park in mid-1995, a young male Gorilla was seen with a wire snare wrapped tightly around his foot, cutting off circulation, which threatened his life with septicemia (Salopek 1995). Just as the guards were preparing to capture him to remove the snare, they saw a huge male silverback watching over him. They waited until the right moment and darted the young Gorilla with a tranquilizer, taking him to a local veterinarian, who saved the Gorilla™s foot (Salopek 1995).

In another snare incident in 1995, a very young female Gorilla was caught by the wrist in a snare set by Rwandans who entered Virunga to trap forest antelope. A film by Bruce Davidson, "Mountain Gorilla," shown on the fiNational Geographic Explorer" television series (September 14, 1996), chronicled the trauma of this tiny Gorilla, who struggled in vain to free herself, crying out and screaming in fear and pain. The park rangers thought that she might have been in the snare, which was tied to a tree, at least 24 hours before they discovered her. She was surrounded by her family, but her relatives could not bite through the snare because it was made of strong nylon cord from food sacks donated to the refugees. The silverback male, Ndingutse, tried again and again to free the baby, and her mother held her to comfort her screams, but there was nothing they could do to release her. Finally, the park guards, who had been standing nearby, were able to approach when Ndingutse moved away for a moment, and cut the cord. She escaped, but faced the threat of becoming snared again, and the cord remained around her wrist, a threat to her circulation as

she grew.

The snares are usually attached to bamboo poles, bent over to spring when set off. Davidson filmed Ndingutse's brother, a 7-year old named Luwawa, in an extremely intelligent and protective reaction to a snare he encountered. When Luwawa saw the snare, he circled it, obviously aware of what it was. Waiting for the rest of his family to arrive and witness the act, he reached over and snapped the pole like a twig, avoiding the noose and disarming it. Against guns, he had no defense, however. Soon after, Luwawa was found shot dead on the slopes of Virunga National Park. His brother Salama had been killed months earlier. Only his bones and skull, picked clean of meat, remained when park rangers found him. The slaughter of these silverbacks traumatized the five to 10 females in their groups and left the babies and young without a strong male to protect them. They became shy and confused, hiding from humans, and even other Gorillas. In 1996, another two Mountain Gorillas were killed, bringing the toll for the previous 17 months to 10, causing havoc and psychological trauma in the families left behind and irreparable genetic damage to these highly endangered animals. In neighboring Uganda, more of these gentle Gorillas died--four adults in Bwindi Impenetrable Forest were speared to death by poachers in 1995 (Salopek 1995). The expulsion of farmers to enlarge the park for Gorillas caused great resentment, and perhaps precipitated this carnage. Tourists who came to see the Mountain Gorillas in this new Bwindi National Park in March 1999 met disaster when Hutu rebels ambushed and killed eight people in one group. This was thought to be the end of Mountain Gorilla tourism in Uganda, but with increased protection of tourists, they are gradually returning. Poaching declined after the deaths of Gorillas and tourists, and by 2000, the Mountain Gorillas in the Virunga Mountains in both parks totaled 358 (Fisher 2001). Tourists coming to Rwanda's Volcanoes National Park are still in some danger when not in groups guarded by soldiers, however (Fisher 2001).

Human Tragedy and the Looting of Virunga's Treasures: Page 9

The fact that Gorillas are gentle, kind and intelligent beings makes these cruelties all the more horrific. Millions of people saw a television report on August 16, 1996, showing Binty, a female Lowland Gorilla at a Midwestern US zoo, saving a little boy who had fallen into the exhibit and was lying unconscious; she picked him up and carried him gently to a door where keepers entered, setting him down in front of it. People were overwhelmed by her act of good will, as well as by her quick reaction. Many viewers had no idea that Gorillas would want to help a human in need, nor that she would use such good judgment in rescuing the boy, who recovered completely.

Koko, a captive Lowland Gorilla taught American Sign Language by Francine Patterson, president of the Gorilla Foundation, has learned some 800 signs and uses descriptive, imaginative language in naming unfamiliar objects, such as "finger-bracelet" for ring. She also paints, and when asked what one of her more colorful creations (reproduced on page one of *The New York Times*) depicted, she signed "bird" (Boxer 1997). We are only beginning to learn about these primates, but without strong protection, they may soon become extinct in the wild at the hands of humans.

Human Tragedy and the Looting of Virunga's Treasures: Page 10

Many Africans have little respect for Gorillas. Hunters in Cameroon, when asked by researchers why they shoot Gorillas, replied "What's wrong with killing a Gorilla? They're fierce." One of the hunters told reporter Michael McRae that he was sure Gorillas were plentiful: "In Cameroon there are a million Gorillas. Three weeks ago, I saw sixty in one day. I shot three and then stopped . . . Why should I feel bad for a Gorilla? He is just a stupid animal" (McRae 1997). Education and an alternate source of income might change the opinions of these hunters. They have

the same views Westerners had before research studies and films introduced people to the true nature of these primates.

As far as their abundance, there are hardly a million Gorillas in Cameroon, in all of Africa or the world. Gorillas are declining toward extinction. Their total population is estimated at well under 100,000 and declining (McRae 1997). The Lowland Gorilla and Mountain Gorilla are considered separate species by the *2000 IUCN Red List*, and both are classified Endangered. The US Endangered Species Act considers Gorillas to be a single species (*Gorilla gorilla)* and lists them as Endangered. Likewise, CITES lists Gorillas as a single species on Appendix I. The species is officially protected from hunting throughout its range, but national legislation is almost never enforced. The Lowland Gorilla is declining rapidly as a result of logging, killing for the bushmeat trade, and possibly ebola disease. Adults are often killed to obtain babies, which are traded on the black market to zoos in many countries. Hundreds of Lowland Gorillas are being slaughtered in Cameroon and other parts of their range, causing immeasurable trauma and cruelty to their close-knit societies, as well as ecological harm. The Moabi tree, a very important species for its fruits, seed oil, bark and wood, produces enormous seeds that Gorillas disperse (Tuxill 1997). African Forest Elephants are also crucial to the survival of Moabi trees, spreading their seeds, and they, too, are threatened with extinction.

The bushmeat trade is wiping out many other species of wildlife in wide areas around African villages. People set wire snares throughout the forest, into which rare deer, antelope, primates, wild pigs and a variety of animals blunder, struggling for days in great pain until the trappers arrive to kill them with knives. Even apart from the cruelty and conservation issues, the bushmeat and pet trades are not even lucrative. People make only a hand-to-mouth living from them, selling rare apes for a few dollars to traders, and other animals for a few cents. They are killing off their wildlife heritage while remaining in poverty.

Local people receive almost no benefit from logging, which is permanently devastating the old-growth forests. Tourists do not want to visit logged-over areas which have a fraction of the wildlife of unlogged forests and, in the case of clearcutting, an ugly, barren landscape. Trophy hunting, which is increasing in rainforests of Africa because of lobbying by the Safari Club and other organizations, is further reducing the wildlife. These hunters kill the largest and rarest animals--the prime specimens that should be left to perpetuate the species--and cause wildlife to become frightened and shy.

Mountain Gorillas are not killed for the bushmeat trade, but are shot for their body parts. None exist in captivity. These endangered gorillas are monitored within Rwanda's Volcanoes National Park by numerous researchers of the Karisoke Research Center, run by the Dian Fossey Gorilla Fund International. They are conducting a variety of different projects studying breeding, genetics and other aspects of their lives. One researcher noted the extreme devotion the Gorillas have for one another. Amahoro, meaning Peace, a 14-year-old silverback in the park, became lethargic and could not keep up with the group (Williamson 2001). Another male became his constant companion, and sometimes two males helped him along. The International Gorilla Conservation Programme was contacted for veterinary assistance. A veterinarian arrived and examined Amahoro from a distance, because he was defended by two other males (Williamson 2001). The next day, he was barely able to move and began coughing; the troop gathered around him, chest-beating in anxiety (Williamson 2001). After calls to gorilla veterinarians in the United Kingdom and the United States, the veterinarian decided that his problem was an infection in need of antibiotic treatment, which was administered by dart; he recovered fully (Williamson 2001).

Because of the international importance of the Mountain Gorillas and their precarious status, researchers from the National Aeronautics and Space Administration (NASA) began scanning their habitat in August 1994 during a 10-day environmental space satellite mission (Anon. 1994b). Overlaying the NASA images with data collected from navigation satellites and standard topographical maps is now providing an extremely detailed overview of the Mountain Gorilla's habitat. The habitat now protected totals only 285 square miles, not a large area for the 658 remaining Mountain Gorillas.

One wonders what their lives were like thousands of years ago when they roamed over vast, montane forests

undisturbed. They may have shown behavior that has disappeared under these new conditions. During some parts of the year, they might have frequented the lowlands, feeding on trees or other vegetation that has long ago disappeared, replaced by farmer's fields. It is possible that they are not receiving adequate nutrition from the plants in their reduced habitat. Their restricted ranges may be causing inbreeding. These Gorillas have suffered great psychological harm from the constant threat of death from hunters, never knowing when they may be confronted and killed. The loss of many family members to snares and shooting traumatized these sensitive and devoted primates.

Human Tragedy and the Looting of Virunga's Treasures: Page 11

Another important Gorilla habitat in southern Zaire was invaded by many of the 400,000 Rwandan refugees who fled to this area in 1994. This magnificent protected area--Kahuzi•Biega National Park--covers some 2,085 square miles (Jay 1994). It is also a World Heritage Site. The large mammals of this park were surveyed in 1994 by the Zairean Institute for the Conservation of Nature and the Wildlife Conservation Society (Jay 1994). Preliminary data indicated that the rare Grauer's Gorilla (*Gorilla gorilla graueri*), a subspecies of the Lowland Gorilla, was found in fairly large numbers--at least 1,000 animals (Jay 1994). Elephants were also numerous (Jay 1994), and the park has many rare birds (Collar *et al*. 1994). One camp of 50,000 refugees blocked a narrow corridor of forest that served as a migration route for elephants and lone male Gorillas between major sections of the park (Jay 1994). The Wildlife Conservation Society conducted a long-term study of the effects of hunting on wildlife in the park, supplemented by a 10-month United Nations probe, which released a report in April 2001 (Lauria 2001). Gorilla numbers have plummeted here also, killed for food and trophies. As ABC News filmed one of the few remaining Gorilla families in Kahuzi-Biega National Park during the summer of 2001, a male Silverback charged the camera crew. Only a decade ago, Gorillas were tame and securely protected in this area. The UN investigation determined that Rwandan forces and others have slaughtered all but two of 350 elephant families in the park for the illegal ivory trade (Lauria 2000). This poaching was part of an organized network of corruption now looting parks and natural areas in the renamed Democratic Republic of the Congo of diamonds, gold, timber and wildlife (Lauria 2001).

Human Tragedy and the Looting of Virunga's Treasures: Page 12

In April 1995, a third natural area in Rwanda, Akagera National Park, became threatened when 700,000 cattle and 250,000 Tutsi herders moved 15 to 20 miles into the park (Lorch 1995). Because of a lack of arable land, Rwandans have sought out parks as the last remaining unoccupied territory. Akagera National Park, located on the eastern border of the country, has a wide variety of fragile habitats, from swamps and savannah to forest and hills, harboring gazelles, Giraffes, African Elephants and Leopards (Lorch 1995). Rwandan authorities did not exclude the herdsmen and their livestock but tried to convince them to cull their herds (Lorch 1995). In southern Rwanda's Nyungwe Forest, the Wildlife Conservation Society's colobus project, which protected groups of hundreds of these monkeys, was also devastated. In February 1995, investigators found that one-fourth of a 120-member colobus group had been killed during the war, many for their long fur, which was used in marriage rituals (Fine 1995). Researchers came upon animal snares and concluded that this national park would no longer be protected as such, but would become a multiple-use forest (Fine 1995).

Uganda's rare wildlife also incurred losses from Rwanda's war and Burundi's civil strife in a ripple effect. An extremely endangered bird of the Virunga Mountains, the Congo Bay Owl (*Phodilus prigoginei*), was recently rediscovered after being thought extinct. Not seen since 1951, it was seen in Uganda's Itombwe forest in mid-1996 by scientists from the Wildlife Conservation Society. A type of barn owl, the Bay Owl was previously known only from a specimen collected in Zaire's Kivu province in 1951 (BI 2000, Hart 1996). The owl is restricted to a small area of mixed rainforest and savannah near the Rwandan border (BI 2000). Dr. John A. Hart, the zoologist who found the

bird, saw farmers clearing the surrounding forest to create new farmland; they had entered the area seeking refuge from the civil wars in neighboring Rwanda and Burundi (Hart 1996). Although the total population of the Bay Owl is not known, it is presumed to be extremely small, and its future survival is uncertain. This area has no protected status and the entire known habitat of the endangered Congo Bay Owl is being degraded by clearing for livestock grazing and farming (BI 2000).

Some of Rwanda's refugees fled to Tanzania as well. More than 535,000 Rwandans traveled south into that country, staying in refugee camps near the border until December 1996, when the Tanzanian government demanded that they return to Rwanda. Former Hutu soldiers, fearing possible imprisonment for war crimes, convinced many refugees to travel east instead, into the heart of Tanzania's Burigi National Reserve. Once there, they stripped vegetation, killed large numbers of animals, began planting crops, and caused an increase in violent crime in local villages (AP 1996). At this point, the Tanzanian army routed them forcibly, and a stream of refugees many miles long was pushed back into Rwanda.

By 2001, a state of anarchy prevailed in the region, with these countries still at war. A United Nations report concluded that business and military leaders from Uganda and Rwanda were looting forests and parks in the Democratic Republic of the Congo for natural resources and meat (Lauria 2001). The New York-based International Rescue Committee reported in May 2001 that an estimated 2.5 million people have died as an indirect result of the previous three years of civil war in the Democratic Republic of the Congo (Salopek 2001). The fighting drove hundreds of thousands of people into the forests, where they lived off the land, dying of rampant disease and malnutrition in the rebel-held jungles (Salopek 2001). Gangs of poachers entered these rainforests, placing snares to capture elephants, Leopards, antelope, wild pigs, and monkeys for the bushmeat, fur and ivory markets in large cities. A camp of these poachers, many of whom come from neighboring countries, was encountered in the travels of Wildlife Conservation Society biologist Michael Fay. Fay and his group, including National Geographic Society filmmakers, came upon a sizeable camp with a very large Leopard skin stretched out on pegs, with hundreds of antelope and monkey bodies being cooked on open fires. Fay was so irate that he burned the entire camp and all the skins (shown on National Geographic Explorer, April 2001, entitled "Extreme Africa"). Although laws ban such killing, no game wardens patrol these forests, which were not part of a national park. Fay's intention in traveling across Central Africa, as described in *National Geographic* (Quammen 2001), was to show the world the great treasure being plundered by loggers and meat hunters before it is too late to save this large rainforest.

Human Tragedy and the Looting of Virunga's Treasures: Page 13

The future of wildlife in Rwanda, the Democratic Republic of the Congo and surrounding countries remains extremely uncertain. The region is a microcosm of struggles that may soon be commonplace as human populations continue to rise and compete for dwindling land and resources. Markets as far away as Europe and North America buy the timber, minerals and ivory that are being exploited here at the expense of the environment. At the present rates of loss, little wilderness or natural forest will remain anywhere in the world. The damage done to parks and reserves by tree cutting, clearing land, and killing native wildlife, especially for commercial purposes, devastates biodiversity and endangers species reliant on these refuges, which are often their last remaining habitats. The World Conservation Union issued a report in 2001 on the urgent need to protect the world's 17,000 large nature preserves from intrusion by poor farmers, who have nowhere else to go (Revkin 2001). Half of these preserves now have people cutting forests and tilling land in biological hotspots and areas with large numbers of endangered species (Revkin 2001). At least 900 million people earn less than $1 per day, and 630 million live in areas of high biological diversity, according to the report's author, Jeff McNeely (Revkin 2001). Organizations, such as Future Harvest, which co-authored the study, are attempting to help poor farmers by providing means to enrich soil through fertilizers and rotating crops to maintain corridors of undisturbed land as wildlife habitat, and to grow shade crops, such as coffee and cocoa, which maintain forests (Revkin 2001).

John Terborgh (1999), a Duke University scientist, chronicled massive destruction of parks by farmers, logging, livestock and squatters in *Requiem for Nature*. This book paints a gloomy picture of wanton neglect, insufficient funding and failure by governments to protect parks and reserves, many of which harbor endangered species and magnificent landscapes. In Peru, for example, national park officials in the capitol city were not even aware of the existence of the Cerros de Amotape National Park. When Terborgh visited the park, he found it had been logged by the army, and cattle grazed throughout. Yet this dry tropical forest is one of the most important centers for endemic plants and animals in the world (Terborgh 1999). Similar tragedies are occurring in Mexico, where logging trucks leave the spectacular montane Nevado de Colima National Park loaded with giant tree trunks, and cows consume all the new tree saplings from the few remaining old alder trees (Terborgh 1999).

In Colombia's Tayrona National Park, six park officials have been killed by rebels and squatters, drug traffickers, loggers and others, who are destroying it; 20 percent of Colombia's 22.2 million acres of parkland is in the hands of squatters or has been deeded to private interests (Terborgh 1999). Colombia has an extremely rich diversity of tropical birds and mammals, and much of the pressure on its parks is a result of the US market for drugs, which offers poor people a far greater income than they can earn through traditional farming. The Santa Marta region in Colombia's northeast has an extraordinary wealth of birds and other species found nowhere else. The endangered Santa Marta Parakeet (Pyrrhura viridicata); Santa Marta Sabrewing (*Campylopterus phainopeplus*), a hummingbird; and the Santa Marta Bush-tyrant (*Myiotheretes pernix*), a flycatcher, are among these (BI 2000). Conversion of forest to marijuana and coca plantations, compounded by US-sponsored government herbicide spraying programs to kill drug crops threaten these and other species of the area. Spraying contaminates the soil and water, and often the small aircraft destroy natural forest and traditional crops instead of the target drug crops. In March 2001, four governors from Colombian provinces protested the $1 billion US herbicide spraying program, saying it was jeopardizing the health and food supply of farmers (Marquis 2001). They asserted that the defoliation ruined food crops and alienated people from their national government, while not succeeding in curbing the narcotics trade (Marquis 2001). The Santa Marta region has already lost 85 percent of its forest habitat (BI 2000). Rebels have taken over much of the area, clearing forest for drug crops and killing members of native tribes, who have traditionally tried to protect the forest and wildlife.

The Democratic Republic of the Congo is in the early stages of a similar anarchy involving rebels and forest destruction. The late President Mobutu and other high officials acquired immense fortunes by siphoning off the nation's mineral and tax revenues and foreign aid funds. They purchased palaces and estates around the world and lived sumptuous lifestyles. Almost none of the revenue from the rich mineral industry went to public works, with the result that the majority of the country's people are illiterate and poorly fed and housed. Even the streets of the capital city are unpaved and littered with trash. Mobutu's personal fortune is estimated at $3 billion by some, and as much as $10 billion by others (Sachs and Rotberg 1997). This country had been a territory of Belgium, known as the Belgian Congo, prior to its independence in 1960. Over the next three decades, the United States and European nations supported Mobutu's regime, which became increasingly autocratic and corrupt. Any opposition was quickly suppressed. By the mid-1970s, the country neared financial ruin (French 1997). The United States, the International Monetary Fund and the African Development Bank supported Mobutu's regime until the end of his reign (Rotberg 1997). The funds were spent mainly for military purposes and for Mobutu's personal enrichment.

Strong opposition to his regime came from an opponent, Laurent Kabila, who drove Mobutu from office in 1997 and renamed the country, the fiDemocratic Republic of the Congo.fl Mobutu died September 7, 1997, in Morocco, where he had taken refuge. He left the country $14 billion in debt, a sum almost three times the country's gross national product (Sachs and Rotberg 1997). During the struggle among Mobutu's forces, Rwandans and Kabila™s soldiers in Virunga National Park, four Mountain Gorillas were killed, one silverback and three members of his family. The International Gorilla Conservation Program reported that these Gorillas, who were tame and accustomed to tourists in Virunga National Park, were shot in crossfire when Rwandans entered the park and encountered Kabila's soldiers. Kabila was assassinated in 2000, replaced by his son, who was educated in Tanzania. He has moderated some of his father's extreme programs and appears to want to end the conflicts that are dividing the countries of

Central and East Africa.

The new government plans to rebuild 50,000 kilometers (31,000 miles) of roads (Wallis 1998). Loggers supply local hunters with weapons, ammunition and a ready market for the meat of Gorilla, Chimpanzee and other protected and endangered species (Pearce 1995). In a growing trend, more and more Central and West African towns are becoming dependent on bushmeat. A study in the neighboring country of the Congo documented that a single town of 10,000 people consumed nearly 6 tons of wild animals every week (Counsell 1997). In Gabon, some 8 million pounds of bushmeat are sold annually, half in urban areas (Tuxill 1997). Recent research has determined that even selective logging has damaged ecosystems in tropical African rainforests, and hunting has eliminated keystone species, such as forest elephants, that spread the seeds of many forest trees (Counsell 1997). Logging also leads to uncontrolled hunting as roads open up wilderness areas.

The Democratic Republic of the Congo has major reserves of cobalt, copper, cadmium, diamonds, gold, and coltan, an extremely valuable material used in making cell phones and computer games. The mining of these resources has damaged large areas of forest as thousands of people vie for high-paying jobs. The mining is uncontrolled by the government, as deals are brokered between international corporations and rebel leaders or even with foreign governments, such as Rwanda, which controls the $250 million per year coltan trade.

Endangered Pygmy Chimpanzees, or Bonobos (*Pan paniscus*), are endemic to these forests in a relatively small portion of the Democratic Republic of the Congo, and their habitat is being decimated by loggers, who construct a maze of new roads (Kingdon 1997). Remarkably intelligent and peaceful, primatologists consider Bonobos to be unique in behavior and ecology; they represent a profoundly important example of evolution (De Waal 1997). Numbering only about 13,000 animals, they are declining and classified as Endangered by the IUCN. No major reserve has been set aside for them. Another rare animal of the region, the Bongo (*Tragelaphus eurycerus*), a beautiful, striped forest antelope, is listed as Endangered in the eastern part of its range in Kenya, and Near-Threatened in the Democratic Republic of the Congo, as logging operations have surrounded the boundaries of an important reserve for this species (Counsell 1997; Hilton-Taylor 2000).

Wildlife Conservation Society biologist Fay finished his 1,200-mile voyage through many unexplored regions of the Democratic Republic of the Congo and neighboring Gabon in the spring of 2001. He found Chimpanzees and Gorillas that had never seen humans and approached his group with curiosity, and other areas where these great apes were completely absent, perhaps as a result of ebola disease (Quammen 2001). Impenetrable swamps and miles of tangled shrub, giant trees alive with insects, birds and lizards, abundant signs of forest elephants and buffalo, networks of streams and spectacular vistas of vast waterfalls and distant mountains still exist in the region, yet loggers, gold miners, poachers and displaced people are increasing in number, destroying this wilderness bit by bit.

A sign of the future, should logging and bushmeat hunting continue, was a traumatized, orphaned monkey, tethered on a rope in a hunter's camp. Seen by Fay's group, its photograph appears on the cover of *National Geographic* (March 2001). This young Mandrill (*Mandrillus sphinx*) had perhaps witnessed the slaughter of its entire family and was now in a strange and abusive environment without its fellows. This species is threatened in the wild and listed as Vulnerable by the IUCN. Among the largest of all monkeys, Mandrills weigh up to 54 kilograms and live only in the rainforests of Cameroon, Equatorial Guinea, Gabon and the Democratic Republic of the Congo (Nowak 1999). The adult male has an extremely dramatic appearance, his face spectacularly marked with electric blue ridges beneath his eyes, set off by a bright red stripe that goes down the middle of his nose and covers a large, round nose patch surrounding his nostrils. His face is framed by a mane of grizzled, olive-brown fur. The female is a somewhat smaller and less flamboyant version of the male. These are the only primates that move about on the ground in very large groups, numbering up to 600 animals. They feed on a large variety of plants, roots, fungi, invertebrates and, occasionally vertebrates (Kingdon 1997). Their sole habitat--undisturbed, primary rainforest--is disappearing rapidly. They are intensively hunted in some areas for the male's shaggy mane, which is used for capes and headdresses (Nowak 1999).

Mandrills are also killed for bushmeat, which is their most immediate threat, according to biologist Jonathan Kingdon (1997). Mandrill meat is more highly valued in these markets than beef, and hunters employ dogs, guns, spotlights, deep-freezers and trucks to harvest them, especially in the Democratic Republic of the Congo and Gabon (Kingdon 1997). These magnificent primates may be important seed dispersers, yet research has only begun on their wild ecology. They may vanish from their once vast realm before their role in the African rainforest is understood.

These ecological and political crises were long in the making. Decades ago, international funds such as the World Bank could have developed environmentally friendly industries, such as ecotourism, in Rwanda, Uganda and Zaire, with a large percentage of the profits going to local people. Aid organizations could have funded or encouraged these nations to promote literacy and conservation education and to provide birth control education. Foreign aid to Zaire by the United States and European countries could have gone toward helping the people of that country achieve economic independence, while promoting environmental protection.

Human Tragedy and the Looting of Virunga's Treasures: Page 14

There is worldwide interest and concern for the survival and conservation of the Mountain Gorillas and other wildlife of the Democratic Republic of the Congo, Rwanda and Uganda and an enormous potential market for ecotourism in many parts of these countries that would benefit both the people and the wildlife. Mountain Gorillas have attracted $10 million in tourism revenues to Rwanda (Tuxill 1997). The forests of all three countries, as well as those to the west in Cameroon, the Ivory Coast, the Congo (as distinct from the new Democratic Republic of the Congo), and Gabon harbor many zoological curiosities that could attract tourists, such as enormous Goliath Frogs, largest of all frogs, now threatened from over-collecting and habitat loss. Beautiful Congo Peafowl (*Afropavo congenis*), the only pheasant species in Africa, are endemic to the Democratic Republic of the Congo, resident in the Kahuzi-Biega National Park and several other reserves (BI 2000). Threatened by hunting, these large, crested birds would be a big attraction for bird-watchers. Other unusual wildlife, such as tiny forest antelope less than 2 feet tall, inhabit these rainforests, where towering trees draped in mosses and orchids have crested eagles nesting in their crowns. At the forest floor, blizzards of butterflies drink at streamsides, while colorful lizards flit up tree trunks. One innovative approach to wilderness protection could acquaint people around the world with such natural treasures without their having to travel. It could also help local people with funding. It is the use of videocameras connected to satellites that record wildlife and landscapes for the Internet. Internet users pay small fees to tune into these videocameras and their websites. A large portion of the funds could be given to local people. This popular new technology has helped South African national parks with their expenses. Small cameras can be placed in extremely remote areas and can be operated on solar power. They have virtually no impact on the environment, unlike large numbers of ecotourists.

One method of protecting endangered forests, which play an important role in reducing global warming, is the US Initiative on Joint Implementation, which encourages public utility companies to invest voluntarily in forest conservation. Through the Carbon Sequestration Program, sizeable expanses of tropical forests, which absorb enormous amounts of carbon dioxide, are being protected. Wisconsin Electric Power Company, Detroit Edison, PacifiCorp and Cinergy donated $2.6 million in 1995 for a 15,035-acre forest in Belize, adjacent to the Rio Bravo Conservation and Management Area. American Electric Power in Indiana is cooperating with PacifiCorp and British Petroleum to protect 5 million acres of Bolivian forests from logging (Passell 1997). This approach protects large amounts of forest in a cost effective manner: the estimated cost of sequestering 1 ton of carbon this way is just 37 cents, less than 1 percent of most emissions-reducing technology, according to *The New York Times* (Passell 1997). General Motors has helped purchase 30,000 acres of forest in southeastern Brazil, home of the tiny Golden-lion Tamarin (*Leontopithecus rosalia*). More than 90 percent of this forest, known as the Atlantic Coastal Forest, has been destroyed, and it is one of the world's greatest centers of biodiversity (Mittermier *et al*. 1999). This program should be used in conjunction with reduction of emissions from power plants and vehicles--not as a substitute.

In another cooperative venture to save tropical rainforests, US chocolate makers are urging owners of small farms to grow cacao, a crop that is grown in the shade of large trees (Yoon 1998). A worldwide shortage of chocolate has resulted from the spread of diseases in large-scale cocoa plantations in tropical regions around the world. Such diseases do not spread or take root when crops are grown in smaller, shaded areas which have a natural diversity of plants and animals, including insect-eating birds and reptiles (Yoon 1998). With the world's sweetest tooth, the United States consumes 629,000 tons of chocolate per year, far outstripping its nearest competitor, Germany, where 285,000 tons are eaten annually, according to the International Cocoa Organization. The American Cocoa Research Institute, the Smithsonian Migratory Bird Center and various candy companies, including Mars, Cadbury, Nestle and Hershey, are all cooperating in strategies that promise to conserve tropical trees and wildlife, and grow cacao plants in ecological ways (Yoon 1998). Huge plantations of cacao in Brazil and elsewhere have lost as much as 80 percent of their crop to fungal and other diseases in recent years, diseases that often spread in large plantings of a single crop.

Scientists have long noted that birds are abundant in small forested cacao and organic coffee farms, and they are encouraging this new cooperation to protect tropical birds as well as the hundreds of species of North American and European birds that winter in tropical countries. Shade-grown, organic coffee is also helping to save rainforests. A trend away from traditional shade-grown coffee into new strains that are grown in the sun, has resulted in the clearing of millions of acres of rainforest to grow this coffee for markets such as the United States. To counter this trend, some organic companies, organizations and institutions, such as the Smithsonian, are taking a strong stand urging people to buy shade-grown coffee to protect rainforests and migratory birds from North America that winter in Latin American forests. This coffee is sold in many natural food markets and chains, such as Trader Joe's. The restaurants and coffeehouses, such as Starbucks, that still use sun-grown coffee should be encouraged to sell shade-grown coffee to help preserve forests and wildlife.

Debt-for-nature swaps can provide relief for countries saddled by debt from loans made by the World Bank and other international funds. Through these swaps, a portion of a nation's debt is paid by the donor, which may be a conservation organization or other entity, in exchange for the establishment of parks. These swaps have been undertaken in Madagascar and several other countries. A growing movement to convince donor countries to forgive these debts is being waged by conservation and human rights organizations. Should these debts be erased, much environmental degradation would be avoided, since many destructive programs are carried out solely to pay off debt. One such program, called "Avanca Brasil" or "Advance Brazil," envisions a massive development program in the Amazon Basin, crisscrossing the forest with roads and railroads and damming rivers to produce energy (EII 2001). A minimum of 28 percent of this great forest would be destroyed and, more likely, at least 42 percent (EII 2001). Just since 1995, 5 million acres of Amazon forest have been leveled for development (EII 2001). These forests, a major factor in preventing global warming through absorption of carbon dioxide, produce vast amounts of oxygen and harbor a large percentage of the world's biodiversity.

If no positive steps are taken, these last sizeable rainforests will be gone, and severe climatic and ecological harm will result. The great forests of Central Africa are also in the process of being destroyed. World-class national parks, such as Virunga, may be completely destroyed within a generation by illegal logging, squatters and bushmeat hunting.

Earth's Worth

Governments around the world grant logging or mining contracts on a daily basis. Thousand-year-old forests and wildernesses covering vast areas are bargained away in deals made between corporate representatives and government officials, often through bribery. The fates of the native wildlife and plants of these regions hinge on the type and level of exploitation. Wildlife, plants, and their habitats survive or die out as a result of decisions made by politicians, most

of whom have no understanding of the importance of preserving diversity and extensive areas of natural landscape. At the present rate of destruction, wilderness will soon be gone, carved up and exploited for commercial purposes or destroyed by settlers.

Earth's Worth: Page 1

Citizens of the wealthiest countries represent some 20 percent of the world's peoples, but consume 80 percent of the planet's resources. The high standards of living that are enjoyed in North America, Western Europe and Japan depend in large part on importation of low-priced raw materials from poor countries. International corporations have few laws restricting their activities, which are causing major damage to forests, rivers, lakes and other environments. Moreover, the market provided by Europe and North America and, most recently, by some countries in East Asia, encourages fast-paced exploitation. Many of the recent logging contracts signed in Africa, Russia and South America have been negotiated to repay debts incurred from loans from the International Monetary Fund, World Bank or other funds. These loans are often for the construction of dams, factories or mines that primarily benefit third parties, such as large corporations. To repay the loans on schedule, countries are pressured to exploit their natural resources, forests and minerals, which are sold at low prices. Such loans rarely help nations develop according to their avowed intention, but send poor countries into an ever escalating debt that requires more and more forest cutting and other exploitation for short-term gains.

The US government's foreign aid tends to encourage mega-projects that do not help the populations of developing countries. Development that is environmentally friendly, based on small-scale business or ecotourism, is of far greater value in helping people as well as preserving wildlife. The decades that have passed since the publication of E.F. Schumacher's 1973 book, *Small is Beautiful. Economics as if People Mattered*, have only validated the philosophy of helping people through small-scale grassroots programs. Economic development programs that respect both people and the environment by finding means through which people can be economically secure, maintain their culture and live in their ancestral regions without destruction to natural ecosystems, should be the model in the future. The concept of small-scale eco-development has been endorsed by various conservation organizations, and use of solar cookers, bio-gas and fertilizer from livestock manure, development of crafts and other small-scale industries, education on crop rotation and use of crops adapted to particular areas, preserving forests to prevent erosion and not living in flood plains are examples of this approach. A wide variety of organizations are carrying out such programs in many parts of the world. Such approaches are also needed in North America and Europe, where conservation education has failed to teach such basic principles, and government officials lack basic knowledge about the environment.

Earth's Worth: Page 2

Subsidies provide another disincentive to conservation. On a worldwide basis, governments spend $700 to $900 billion per year on subsidies that actually encourage the destruction of forests and other natural areas (Grossfeld

1997). In the United States, the taxpayer pays for road building in national forests to enable logging companies to enter wilderness areas. The Forest Service charges these companies a fraction of the retail value of these trees--sometimes $10 or less for a giant tree worth $25,000. Yet almost no subsidies or tax benefits are paid for the use of recycled materials, such as paper, that would save the cutting of thousands of trees. For this reason, it is cheaper in the United States and many other countries to cut forests for paper than recycle used paper, and to obtain minerals from mines rather than from recycled metals. To further the lack of logic of this situation, one US government department encourages environmental destruction through taxpayer dollars™ subsidies for logging and mining, while others spend public funds to clean up the pollution and preserve species that become endangered from these activities.

A coalition of 26 organizations compiled information on US subsidies that have negative effects on the environment, entitled "Green Scissors '98." It found that the United States spends $49 billion every five years on subsidies and environmentally destructive programs. The report recommended drastic slashing in these "polluter pork" programs to protect the environment and save taxpayers billions of dollars of misspent money each year. The Institute for Research on Public Expenditure in the Netherlands produced a report in 1997 entitled *Subsidizing Unsustainable Development: Undermining the Earth with Public Funds*. After a lengthy examination of subsidies around the world, which range from inexpensive irrigation water to free land for settlers and mining operations, this study concluded that subsidies are economically counterproductive and disastrous to the environment, resulting in deforestation, overfishing, polluting and other destructive activities (Crossette 1997a). Many species are endangered as a byproduct of these subsidies.

Earth's Worth: Page 3

The gross national product of a country is considered the major yardstick by which economic success is measured, and the natural world is traditionally valued in terms of the revenues it produces when exploited. This rigid and limited evaluation was recently examined and found lacking by a team of 13 ecologists, economists and geographers, who analyzed the monetary value of ecological systems to human society. They sought to place specific values on 17 types of environmental services that 11 ecosystems provide to humans each year (Stevens 1997b). Among these ecosystems were open oceans, estuaries, seagrass and algae beds, coral reefs, tropical and temperate forests, grasslands and rangelands, tidal marshes and mangroves, wetlands, lakes and rivers (Stevens 1997b).

In a report published in the scientific journal *Nature*, these specialists estimated the total global value of these ecosystems and their production at $16 trillion to $54 trillion per year, with $33 trillion the most likely figure; by contrast, the gross national product (all the goods and services produced by the world's peoples each year) was estimated at a mere $18 trillion (Stevens 1997b). They rated the value of nature's climate regulation at $684 billion, natural raw materials at $721 billion, pollination by natural pollinators at $117 billion, recreation and ecotourism provided by nature at $815 billion, soil retention and formation at $53 billion, water supply at $1.7 trillion, and food production at $1.4 trillion. Thus, ecosystems such as forests, which provide several of these ecological services, such as climate regulation, ecotourism, soil retention and water supply, are worth far more left standing than cut as lumber for short-term profit. Wildlife performs services as well, including natural pollination, attraction of ecotourism and recreation such as bird-watching, and others such as seed dispersal and soil enrichment. The linkages between particular ecosystems and local economies were systematically analyzed in this study; for example, the Louisiana shrimp catch depends on wetlands as nurseries, and these wetlands also provide flood control and other services in their overall value (Stevens 1997b).

If the costs of destroying these ecosystems were computed when development was considered, such as the loss in flood control and water pollution filtration by wetlands, the researchers concluded that society would be more likely to protect them from destruction. They pointed out that when a wetland is filled in for a shopping center, the dollar value

of that habitat in preventing floods and cleansing water is not figured in, resulting in a gradual erosion of natural wealth (Stevens 1997b). The heavy rains that ravaged many parts of the world in 1997 and 1998, caused by El Nino's effect on the weather, produced floods and mudslides in areas where forests had been cut and wetlands filled. Hundreds of lives were lost, and property damage totaled billions of dollars. Areas with forest and extensive wetlands were hardly damaged. Some wetlands are being restored in the United States--river courses returned to natural curves, and flood plains protected from building, in the realization that the lost income from not developing these areas is more than compensated for by the protection from natural disaster they provide, which creates economic stability in developed areas located far from wetlands.

However important such economic analyses are in re-evaluating our destruction of ecosystems, preserving nature cannot be reduced to economic calculations. If this is the sole basis of conservation, it could lead to destructive manipulations in the environment designed to accommodate complex economic theories. The major lesson to be learned from these new ways of looking at Earth's use to humans is that we have grossly underestimated life-giving ecosystems and their wild fauna and flora. They have evolved over a period of millions of years, and we must respect and preserve them in as natural a state as possible.

Although people in the United States are far more aware of the ecological value of wetlands and forests, this seems to have had little effect on preserving such valuable ecosystems. Trees are still cleared on steep slopes and other fragile areas, for example. This causes landslides and mudslides and floods, resulting in destruction of homes, roads, farmland and other valuable assets, as well as siltation and pollution of waterways. Yet there is little thought given to banning this practice by law. The World Resources Institute in Washington, DC, has calculated that the loss of value from deforestation is four times as high as the value of the timber extracted, and the depletion of soils, forests and fisheries examined in this study resulted in a 25 to 30 percent reduction in potential economic growth (Stevens 1997b).

A 1997 collection of articles, *Nature's Services: Societal Dependence on Natural Ecosystems* (Island Press), edited by Dr. Gretchen C. Daily, a biologist at Stanford University, concludes that many ecosystems, once destroyed, are either irreplaceable or take thousands of years to replenish, such as ancient aquifers or old-growth forests. Daily concluded that we cannot afford to wait to act until we have disrupted the planet's life-support system beyond repair (Stevens 1997b). Some 20 scientists contributed to this book, including Dr. Norman Myers, author of many books on the value of wild plants to medicine and agriculture. He documented the multibillion-dollar insurance value that wild grains provide in disease resistance (Daily 1997). Katherine Ewel of the Forest Service discussed the lower cost of treating sewage in constructed wetlands, as compared to treatment plants, and Gary Nabhan and Stephen Buchmann found that wild pollinators save American farmers $1.6 billion annually (Daily 1997). This book's experts make a strong case for protecting environments in a natural state and provide evidence that we are only beginning to appreciate the complexity of these ecosystems. This can apply, for example, to commonly accepted mitigation rules used in US wetland-filling cases, in which a wetland is created for one that is destroyed. Ecologists consider that the natural wetland is far more complex and irreplaceable than the man-made one, and they should not be considered equal under the law.

Earth's Worth: Page 4

In the United States, many politicians and businessmen have opposed environmental and endangered species legislation on the grounds that these laws reduce the profits of commercial ventures. They propose that every developer whose project is blocked by such legislation should receive financial compensation from public funds. These businessmen calculated the value of their financial loss on the appraised value of their land, and added potential profits lost. In 2001, for example, farmers in California sued the Fish and Wildlife Service to compensate for water it lost when a water allotment was diverted for endangered salmon and smelt (Russell 2001). The court ruled in favor of

the farmers and ordered the government to pay them the value of the lost water, arguing that the government is constitutionally prohibited from taking property without paying for it (Russell 2001). This ruling could end in negating the effectiveness of habitat protection under the Endangered Species Act for lack of sufficient funding. Ecologically, farmers depriving endangered fish of habitat are impoverishing entire aquatic ecosystems and, in all probability, polluting waters with pesticides and other chemicals in the process. Yet if the value of maintaining the ecosystem in the San Francisco Bay area was calculated in terms of the millions saved in flood damage control, water purification, production of shrimp and other fish, the ecological values would far outweigh short-term commercial losses. If environmental protection laws were written in terms of ecological values, destroying natural ecosystems for the economic benefit of a few would not be allowed.

When the Northern Spotted Owl (*Strix occidentalis caurina*), native to old-growth forests in the Pacific Northwest, was listed as Threatened on the Endangered Species Act and large sections of its habitat protected, it became a focal point, polarizing pro-logging and anti-logging activists. Owl haters urged others to kill these birds, who were blamed for ending the logging industry, with bumper stickers such as "Kill an Owl, Save a Job." Such venom totally obscured the fact that the forests were being overcut and that logging jobs were destined to be cut anyway, as the last old-growth disappeared under the saw. A state in the heart of this owl's range, Oregon, found that decreasing logging ended in helping its economy; an influx of technological businesses provided better salaries than those paid for logging jobs (Egan 1994). The Governor of the state supported the logging restrictions as helping to maintain the overall quality of life in the state, preventing floods and attracting tourists, which are supplying another large segment of the state's revenues. Yet pro-business interests continue to fuel the fires, writing books which conclude that it is easy to understand why a landowner, having an eagle or Spotted Owl nesting, could be tempted to destroy a nest or even kill an endangered animal. Such people maintain that the owner of such land might be expected to destroy it by logging or development prior to designation of Critical Habitat for the species in order to be able to reap profits. The Northern Spotted Owl has, in fact, declined since it was listed on the Endangered Species Act, mainly as a result of Habitat Conservation Plans that have been detrimental to its populations, but also, very likely, illegal killing played a role.

One conservative critic of the Endangered Species Act noted that the Act "has undoubtedly caused the deliberate destruction of millions of other endangered plants and animals" (Jacoby 1998). This explains, according to the critic, why after 25 years, 97 percent of the endangered species list remains endangered (Jacoby 1998). If so many endangered animals are being killed deliberately, enforcement of the Act is urgently needed. Such attitudes are extremely detrimental to the survival of endangered species and should be addressed. Although many animals are being killed, the main reason these species remain endangered is a deteriorating environment and a half-hearted commitment on the part of the US government and the public to saving these threatened species.

A study of America's environmental laws and their effect on the economy was conducted by the nonprofit Institute for Southern Studies, a social policy research group. It concluded: "At the policy level, the choice is really not jobs versus the environment. The states that do the most to protect their natural resources also wind up with the strongest economies and best jobs" (Smothers 1994).

Earth's Worth: Page 5

Ecotourism and non-destructive recreational uses of nature are among the most valuable of all services nature provides, according to the study mentioned above, and many countries have seen dramatic rises in their revenues from tourism in recent years. In 1995, Botswana earned $100 million from tourism; South Africa reported $6 billion in tourism revenues. Kenya earned $452 million the same year, which paid the wages of 13 percent of its population. One tour company, the Conservation Corporation of Africa, or Conscorp, works out arrangements with local villages in which it promises to build schools and clinics near its lodges, employing many local people in the process. It also

buys seeds for farmers to plant vegetables to sell to its lodges and brings villagers from the area into the reserve to educate them about wildlife and ecotourism. Conscorp runs some 22 small--but expensive--lodges in Africa from Kenya to Zanzibar, none of which allows game hunting; its revenues topped $30 million in 1996. Costa Rica, one of the world's primary ecotourist countries, has set aside 25 percent of its land for conservation, and ecotourism draws 1 million visitors per year, who spent some $800 million in the country (CNN special: "What Price Nature?" March 2001). This industry continues to grow at a rate of 20 percent a year, with visitors coming to its cloud forests, tree canopy tours and beaches where sea turtles nest.

In terms of the value of animals, the income from exploitation is dramatically lower than that from ecotourism. African Elephants, for example, when killed for trophies, earn some $4,000 to $20,000 for governments in fees, and the tusks sell for an average of $2,000 apiece. From ecotourism, however, an East African elephant produces an estimated $1 million during its 60 years (Currey and Moore 1994). A 1989 analysis found that the viewing value of tourists who come to Kenya to see elephants is estimated at a minimum of $25 to $30 million per year (Brody 1994). Tourists come from around the world to see these massive animals, and the governments of most African countries place a higher value on live elephants than dead ones. Trophy hunting also kills off the big bull elephants, which are the main breeding animals, as well as large matriarchs, who play a crucial role in guiding and protecting herds. These are the very elephants tourists come to see.

Endangered species in the United States also draw many tourists who travel long distances to see Whooping Cranes in their wintering marshes in Aransas, Texas**;** Gray Wolves in Yellowstone National Park; and California Condors newly reintroduced near the Grand Canyon.

Whales are extremely valuable in ecotourism. They are becoming major money-earners to the increasing numbers of whale-watching tours worldwide. In 1992, 37 countries conducted whale watching tours, and the United States alone earned $260 million. Since then, whale-watching has grown in popularity. A study by the International Fund for Animal Welfare found that in 1998, revenues from whale-watching exceeded $1 billion, with 9 million people participating in 87 countries and 500 communities. By contrast, a single Minke Whale sells for about $100,000 (Talmadge 2000), a one-time profit from these long-lived animals that is far less than they would produce during their lifetimes. Yet wealthy countries, such as Norway and Japan, are still killing whales, catering to whalers, who form a tiny segment of their populations.

Bird- and wildlife-watching and feeding have become major industries in the United States. A Fish and Wildlife Service survey found that in 1991, Americans who watched, photographed and fed birds and other wildlife spent $18.1 billion (Blom 1997). The spending generated nearly $40 billion in total economic activity and supported 766,999 jobs (Blom 1997). Equipment sales for wildlife appreciation totaled $10.6 billion, followed by $7.5 billion spent on travel-related goods and services, and $1.5 billion on wild bird feed (Blom 1997). A 1996 survey found that while only 3 million people in the United States hunted migratory birds, 25 million Americans were considered avid bird-watchers who would drive a mile or more to observe or photograph birds, and 50 to 60 million people in the United States watch birds at their feeders.

The Fish and Wildlife Service found in a 1996 survey that wildlife watchers, fishers and hunters spent $100 billion on equipment, travel, and publications. When total economic profits were analyzed by the Fish and Wildlife Service in terms of hunters vs. bird-watchers, the bird-watchers spent some $14 billion on all aspects of bird-watching, while bird hunters spent $1.3 billion. *American Demographics* magazine estimated that an even greater amount, $18 billion, was spent by American birders on their hobby. In economic output, Ducks Unlimited, a hunting organization, estimated that bird hunting generated $3.6 billion, while non-consumptive use of birds earned $15.9 billion.

Earth's Worth: Page 6

Consumptive users of wildlife, such as hunters, make up a small minority of the public, approximately 14 million, or 5 percent, and fewer than 1 percent are trappers, yet these interests control state wildlife departments and heavily influence the Fish and Wildlife Service. The fees from hunting licenses fund the majority of state wildlife departments. These departments manage all wildlife within a state, in spite of the fact that only a small number are hunted or trapped, with the result that habitats are manipulated to benefit hunted animals, such as deer, by encouraging shrub and second-growth forest, while species needing old-growth forest, such as woodpeckers, decline as these forests are cut. Endangered species are conserved by state Natural Heritage Programs, but funding is often miniscule in comparison with the fees from hunting. Funding sources include income tax rebates, vanity license plate revenues and grants from general funds, but generally do not begin to fill the need for habitat acquisition, education and conservation programs and research. Greater funding is needed for these programs, perhaps through a small tax, such as the less than 1 percent sales tax in Missouri for wildlife and conservation programs. It generates more than $100 million annually. A tax for non-game and endangered species would provide major funding for these state programs, which fill an important role not played by federal Endangered Species Act programs.

The recent phenomenon of tropical forest ecotourism has produced other comparisons in revenues of exploitative vs. non-consumptive use of wildlife. Dr. Charles Munn, an ornithologist with the Wildlife Conservation Society is studying macaws in Peru's massive Manu National Park, which is the size of Massachusetts. He estimates that a wild macaw is worth $165,000 a year, based on revenues from the growing number of tourists who come to see these colorful, long-tailed parrots in spectacular flights (Munn 1992). A bird trapper receives only a few dollars for a wild macaw which, if sent to a pet store in Europe, might sell for $1,000. Income from the pet trade goes primarily to a small number of exporters, importers and retailers. It does not protect the habitat of the birds, nor does it pay for population surveys to prevent depletions. Moreover, from capture onward, these wild birds are treated very inhumanely, causing high rates of injury and mortality. The capture of wild birds for the pet trade is banned by the majority of the world's nations, but the few that continue it contribute to depletion of wild bird populations, smuggling, and their inhumane treatment (see Trade chapter).

Under Munn's calculations, the value of each macaw in the wild over the period of its life, which averages about 50 years or more, totals some $8,250,000--an enormous sum. This money flows into local economies of villages and towns near the park, local hotels, taxis, restaurants and other businesses. For many poor areas, such income provides much needed services and raises the standard of living. Tourist money is also spent in cities where visitors arrive, and constitutes a major portion of airlines' revenues. Manu National Park has been declared a Biosphere Reserve in recognition of its importance as a center of biodiversity. Its 7,000 square miles protect a large portion of Peru's tropical rainforest. Manu's ecotourism companies are considered models for sharing revenues with local people and protecting indigenous tribes (Munn 1994). These companies have tours geared toward viewing certain spectacular or endangered species, such as Giant Otters (*Pteroneura brasiliensis*) (Munn 1994).

Earth's Worth: Page 7

Although some abuses of the land have resulted from ecotourism, including large numbers of people who can overwhelm delicate habitats, these situations are rare and can be rectified. Ecotourism helps far more animals and habitats than it hurts and, often in an indirect way. An important byproduct of tourism is the protection it accords animals in the areas visited, especially outside national parks and reserves, where most wildlife is on the decline. The presence of tourists tends to deter poachers, and in a growing number of areas, revenues accrue to local people from tourists™ use of restaurants, gift shops, taxis and other businesses. This encourages residents to cooperate in protecting the wildlife and the environment. This applies as much to African savannahs, as to North America or Europe. The non-profit Eco-Tourism Society, located in North Bennington, Vermont, distributes information on responsible travel that does not result in ecological damage and respects local residents. It recommends that tours

share profits with residents.

Many conservation organizations now run ecotours and issue pamphlets, such as the National Audubon Society's guidelines for environmentally responsible travel, which describes dangers to specific habitats, such as coral reefs, and suggests non-intrusive viewing and tours that enhance local conservation. Trade in local wildlife is prohibited. The Wildlife Conservation Society has proposed that a fee from tourists be set aside for a land bank to fund national parks in Central America.

As ecotourism rises in its importance to national economies, whale-watchers, tropical forest visitors, coral reef divers and others will demand pristine environments with diverse wildlife. This will be a strong force in favor of passage of strict environmental laws around the world. Moreover, the value of wilderness increases as more and more tourists seek out undeveloped areas. Governments should no longer consider wilderness as wasteland, but as a precious commodity.

The economical arguments in favor of preserving the natural world are strong, but we should be equally motivated by our affinities for our fellow creatures and the natural world. Our ties with nature are very deep and span millions of years. Modern technology has made us forget the awe with which we once regarded the Earth and has encouraged a false sense of superiority and complacency.

Actions and Attitudes

Biologists, conservationists, government officials and many members of the public are regarding the rise in the number of extinctions and endangered species with great alarm. The United Nations has found that species and habitats are being lost at an "unprecedented rate" (Stevens 1997c). The need for effective action has never been greater. Fortunately, concurrent with the general deterioration of the environment and wildlife populations, programs for the preservation of rare species have mushroomed, along with a new compassion for animals. These programs address the status of a small number of species, and if expanded to include a far greater percentage of threatened species, the extinction rate would decline.

Some conservation efforts to preserve endangered species have had remarkable success, while others have had mixed results. The expenditure of large sums of money to save some endangered species has not automatically resulted in an increase in their numbers. It is a common misconception that endangered species, once accorded legal and habitat protection, will survive and increase in number. Unfortunately, many species have died out in spite of conservation measures on their behalf. Through examination of failed programs, fewer mistakes can be made in the future.

Actions and Attitudes: Page 1

The Javan Tiger (*Panthera tigris sondaica*), for example, was given legal protection and reserves in the 1920s and 1930s, yet it was poached to extinction. If a single facet of a conservation plan is lacking, faulty or unfunded, this can spell extinction for the animal or plant. A reserve for this Tiger was set aside too late, when it was nearly gone. As Indonesia's most heavily populated island, Java had little forested land left, and by 1972, only four or five Tigers survived (Matthiessen 1997). With a very limited population under constant threat from poachers and big game hunters, these Tigers needed intensive anti-poaching protection and biological surveys, which they never received. Without well-equipped and motivated park rangers, research and surveys, education of local people and the goal of conserving Tigers established as a major priority of the Indonesian government, there was no chance of saving these cats. The last Javan Tiger was seen in 1976 (Matthiessen 1997).

Since the 1970s, Tigers have experienced precipitous declines throughout their remaining Asian range. Killed for their "magical" bones and body parts, which are used for Traditional Medicine as well as for potions that are intended to impart virility and strength, these magnificent cats are snared, trapped, poisoned and shot in devastating numbers, estimated at a minimum of one Tiger per day of the fewer than 5,000 that survive. A Tiger is now worth at least $50,000 in Traditional Medicine, placing a price on the head of every wild Tiger. Many experts are predicting the Tigers™ extinction outside of zoos within a few years. One program, however, has shown success in stemming this decline. In Russia's Far East, strong anti-poaching programs and intensive research and survey projects have halted the decline of the largest subspecies, the magnificent Siberian Tiger. This work has been funded by outside organizations including the Global Survival Network, a Washington, DC, organization, and other groups.

Only about 250 Siberian Tigers survived in the wild in the early 1990s, and with 50 or more being killed by poachers each year, their future seemed dim. The Russian government, in economic chaos, was unable to pay wardens a reasonable salary. Many resorted to illegalities to take advantage of the high value of dead Tigers. The open border with China brought an influx of smugglers and traders offering bribes of $5,000 or more to wardens and poor villagers for killing a Tiger. With the infusion of some $750,000 from conservation organizations since 1993 and help from the US Fish and Wildlife Service, well-armed and well-paid wardens now patrol most of the Siberian Tiger's habitat in modern vehicles. Without this outside funding, which must be continued indefinitely, poaching would have extinguished the remaining wild Siberian Tigers. Biological research on these Tigers is being carried out by the Idaho-based Hornocker Wildlife Institute, along with Russian scientists. These studies have surveyed their populations and obtained the first estimate of their habitat needs which, for males, is at least 450 square miles. One female Siberian Tiger named Lena, being radio-tracked by these researchers, was killed by poachers. Her four young cubs would have starved to death, but they were located when signals were received from the still-operational radio collar, which had been cut off Lena's body and placed next to the cubs. The terrified and hungry cubs were taken into captivity, and the three survivors were sent to US zoos.

Siberian Tiger poaching is finally decreasing. Russian conservation groups are conducting educational programs for local people and investigating suspected poachers along with Russian government officials (GSN 1997). Recent population surveys indicate an increase in Siberian Tigers, and conservation plans are falling into place (Galster and Eliot 1999). The Tiger's prey of deer and wild boar has been heavily poached, and the plan calls for anti-poaching work to preserve these animals (GSN 1997). Tiger biologists have drawn up a plan for a huge sanctuary in the region, suggesting habitat corridors linking isolated Tiger populations, and proposing an end to clearcutting of forests (GSN 1997). Without urgent protective measures, this magnificent cat will disappear. (See Forests chapter for more on this Tiger and its habitat).

Actions and Attitudes: Page 2

For some endangered animals, CITES has been crucial in preventing their extinction. After a prolonged controversy, the African Elephant was upgraded from Appendix II to Appendix I in 1989, which effectively ended the ivory trade that resulted in the slaughter of these intelligent animals, the toll reaching almost 1 million animals for the 1970s and 1980s. The 1996 *IUCN Red List* classified the species as Endangered for the first time, upgraded from Vulnerable status in the 1994 *IUCN Red List*. This status was maintained in the *2000 IUCN Red List*. The ivory trade reduced these slow-reproducing animals, who have a single calf only once every five years, from 3 to 5 million in the 1930s and 1940s to only 300,000 to 500,000 today (Onishi 2001). The high price of ivory in the 1980s encouraged the poaching of elephants outside parks, and when these were killed off, poachers entered national parks, often armed with machine guns. Almost all the large bulls and most of the older females were killed for their tusks, leaving traumatized teenage elephants without leaders and protectors and orphaned infants who starved to death.

In the majority of African countries where elephants survive, they are zealously protected for their value in tourist revenue and for their ecological value as keystone species. Many officials of these countries have said that they do not want future generations to learn about elephants only through books. Yet several southern African countries--Namibia, Zimbabwe and Botswana--which stockpiled ivory from the 1980s trade and from culls carried out to limit elephants, succeeded in 1997 in convincing delegates at the CITES Conference to allow sale of 65 tons of this ivory to Japan. Japan's sponsorship of much of the costs of the 1997 Conference, which took place in Zimbabwe, paved the way for the decision. The President of Zimbabwe made personal requests to delegates to allow the sale. Although CITES authorities enacted controls on the conditions of the sale of this ivory, it was predicted that the decision would open the door to further killing of elephants and ivory smuggling. This proved correct. African Elephants began to be poached again during the late 1990s in Kenya, the Democratic Republic of the Congo and other countries. An elephant orphanage in Kenya received an unprecedented number of orphaned calves at this time. Their mothers had been killed for their ivory in national parks. Some of this ivory is sold locally, and much is smuggled out of Africa.

A large confiscation of tusks was made in Los Angeles in May 2001; these tusks, many of which were very small and obviously from young elephants, had been smuggled from Nigeria in hollowed-out furniture. This indicates that allowing some sale of ivory opens the door to unrestricted slaughter and smuggling that will place the species in a critical--and perhaps lethal--decline toward extinction. When ivory was allowed to be sold on a quota basis in the 1970s, this "regulated" trade failed completely to prevent unregulated slaughter as the price soared. In many parts of Africa, poachers are killing elephants for a trade that may be resuming. Ivory is openly sold in Cameroon, and in Burkina Faso, a West African country north of Ghana, where only 3,000 to 4,000 elephants remain, ivory traders are selling carvings and jewelry in the capital city (Onishi 2001). One trader even complained that sales had not recovered as a result of the 1989 ivory ban, with larger carvings taking months to sell because tourists are no longer as interested in buying ivory (Onishi 2001). When asked about the need to conserve these endangered animals, he said that like humans, some die, but the species does not become extinct (Onishi 2001). Few Africans have been taught about how close African Elephants came to extinction as a result of the ivory trade, nor about their key role in spreading the seeds of trees and creating waterholes for wildlife. It is also likely that only a small percentage of Africans are aware of the species' immense intelligence and altruism. If these facts were better known, it is likely that most Africans would want to protect these great animals. They are in imminent danger of disappearing from West Africa.

As they attempt to forage in land that is now being tilled or used as grazing land, Asian and African Elephants are killed and harassed by farmers and villagers outside national parks. Wildlife corridors are being proposed in many parts of the world to ease such problems. As human populations grow, invading the last retreats of wildlife, parks and

reserves are becoming islands amid development, agriculture and cities. Without corridors of natural habitat linking these islands, wildlife will decline in diversity and abundance. A new national park in Mozambique will link with South Africa's Kruger National Park and provide a corridor and additional habitat for Kruger's elephant populations. Other international parks in southern Africa have opened or are scheduled. Some conservationists have proposed that these parks form the southern end of a wide corridor north to Kenya. This would be an excellent solution to the declining habitat faced by many large mammals of eastern Africa. In the Western Hemisphere, the Atlantic Biological Corridor Project and the Mesoamerican Biological Corridor seek to protect wide swaths of land between Mexico and Colombia to prevent the extinction of wide-ranging animals, such as Jaguars and Cougars. Along Texas' border with Mexico, most of an extremely biologically rich area has been plowed under, and the Fish and Wildlife Service is trying to purchase the remnants of this once rich habitat to link it with adjacent habitat in Mexico for use by endangered wildlife.

Actions and Attitudes: Page 3

In the American West, Grizzly Bears may someday be able to roam from Yellowstone to Yukon in a project known as Y to Y, an immense corridor that would prevent the present isolation of this species into pockets of fragmented habitat surrounded by hostile cattle ranchers. The Wildlife Conservation Society has initiated a program it calls "Living Landscapes," which involves local people living in areas surrounding parks and reserves. It promotes the conservation of animals that have ranges extending beyond the parks in order to help conserve these species, allowing them to be part of functioning ecosystems. This sometimes involves curtailing their own hunting. White-lipped Peccaries, for example, a type of wild pig, are important seed dispersers of trees in Latin American rainforests and also create open spaces on the forest floor by rooting for food. Yet they are heavily hunted for their meat and pelts. Only through an education program in which the local people themselves understand the effects of their hunting and are permitted to manage the land, can the species and its habitat be protected. This organization is applying such approaches to regional conservation in 50 sites in Latin America, Asia, Africa and North America (WCS 2001).

Actions and Attitudes: Page 4

Another fundamental element to the future survival of wildlife in a world crowded with humans is tolerance and a belief that the Earth must be shared. Public opinion has been crucial in land use and protection of natural habitats and landscapes so that wildlife and plants were allowed to survive, even in parts of the world with overcrowding where land was at a premium. Fewer species are threatened in parts of the world where wildlife is respected and considered part of the landscape. In Africa, wildlife flourished when native peoples were the guardians of the land, prior to the 18th century when Europeans entered as colonial rulers. European rule resulted in overhunting and development of large-scale ranches and farms that were fenced, creating a drastic decline in wildlife.

Native Americans have a less proprietary view of nature than Europeans, and many tribes believe in spiritual connections with trees and animals. They treat nature's assets as gifts, for which they express gratitude. In the intervening centuries since colonization of North America by Europeans who failed to respect nature, views have come full circle for many Americans. Wilderness and nature preservation have become high priorities, based on both scientific discoveries about how ecosystems function and a growing desire by people to appreciate nature. Some scientists believe that connections with nature have been an intrinsic part of human nature for millions of years. Dr. Edward O. Wilson calls this "biophilia," or "love of living things," and cites it as a primary human trait. Such ties to nature have nurtured new conservation zeal to help preserve disappearing wildlife and landscapes.

For some people, however, even the most basic ecological and evolutionary principles are refuted in favor of views

that justify exploitation and species' extinctions. They describe conservationists as irrational "tree huggers," and animal lovers as "bunny huggers." Anti-environmentalists have formed organizations in the United States, operating collectively as the fiWise Usefl movement. Many elected government officials share these views, and have voted for legislation that fails to protect endangered species and results in destruction of important wildlife habitat. US Congresswoman Helen Chenoweth, a Republican from Idaho, believes that there should be a public referendum regarding which animals can live and which will be allowed to go extinct (Egan 1996). Chenoweth stated to *The New York Times*: "A species goes out of existence every 20 seconds. Surely a new species must come into existence every 20 seconds. There's no way human beings can regulate that dynamic" (Egan 1996). Humans can, indeed, affect the "dynamic," as they have for millennia, and when species are lost, their loss is our loss. Evolutionary biologists would be dumbfounded at her statement. Although species are passing into extinction at a fast rate, new ones are not evolving every 20 seconds, nor even every 20 years or every 200 years, unless one considers the mutations of viruses and bacteria to be new species. Once the Tiger or Right Whale--or any of Earth's myriad species--becomes extinct, it is gone forever. The film "Jurassic Park," which concerned the recreation of dinosaurs from their DNA, is total fiction. Science has not found a way to clone species from DNA obtained from dead animals because the DNA becomes scrambled after death. Nor are such scientific feats anticipated in the near future.

Actions and Attitudes: Page 5

The basic problem that many people find in protecting endangered species is the question of land ownership and the inconvenience that they fear may result when animal or plant habitat is protected. Congresswoman Chenoweth would find agreement among many people living along the Massachusetts coast, who are unwilling to share the beaches with a tiny endangered bird. This bird has caused storms of controversy between its protectors and recreational beach users. The Piping Plover (*Charadrius melodus*), a shorebird, nests on sandy beaches along Eastern coasts, the Mississippi River and the Great Lakes. It has been crowded out of the majority of its nesting sites by the hordes of people who come to swim, sunbathe and drive off-road vehicles. Beaches have been altered or developed for various commercial purposes as well, including levee construction for flood control. In 1985, the species numbered only a few thousand birds and was listed on the Endangered Species Act as Endangered in the Great Lakes, and as Threatened elsewhere in its range. The numbers of this species along the Atlantic coast, from southern Canada to South Carolina, reached 1,377 birds in 1998, and throughout its range, only about 5,913 birds survive (BI 2000). In Massachusetts, where most beaches are public, local authorities and even federal and state enforcement officers were reticent to enforce the law to protect the nesting plovers. Even when parent birds managed to raise chicks, the chicks were often run over by vehicles when they fell into the deep ruts on the beach made by tire tracks, unable to climb up the six inches of vertical sand or flee an oncoming vehicle in time. Plans in 1989 to fence a portion of the beach in Plymouth to protect the nesting birds met with such anger and public protests from beach-users that they were abandoned. In 1991, only a single chick survived in the state, with few beaches strictly protected. Unleashed dogs killed some of the chicks, but most were run over by cars and all-terrain vehicles.

On Nantucket island, a Massachusetts Audubon Society warden fenced in the nests of two Piping Plovers in 1994, causing such anger from off-road vehicle drivers that they called the police, who threatened to arrest the warden. Neither the state, which protects the species, nor the Fish and Wildlife Service came to the rescue of the Piping Plovers by supporting the actions of the warden. Vandals ripped down the protective fencing. Endangered Least Terns (*Sterna antillarum*) nesting on the same beach produced 24 chicks that year. In one day, 20 were run over. This finally convinced the local selectmen to close that portion of the beach to off-road vehicles, which allowed all eight Piping Plover chicks to survive. The citizens of Nantucket voted the following year to defeat a selectmen proposal to allow vehicle use on the beach, which would have exempted the area from state law protecting the plovers. In 1995, three pairs of Piping Plovers nested successfully on Nantucket, and state restrictions began going into effect to protect their nests.

In Massachusetts, nests increased from 139 in 1986, to 445 in 1995 (Allen 1996a). In a step backward, the state of Massachusetts eased restrictions on beach vehicles in 1996, giving what conservationists called "plover-squashing permits" (Allen 1996b). The Massachusetts Audubon Society estimated that at least 33 plovers would be legally killed each year under the new regulations. Another loss for Piping Plovers was the firing in September 1997 of the town of Plymouth's Beach Manager, who had spent more than a decade protecting these birds from off-road vehicles. This was done to appease recreational dune buggy users. The ban, which closed part of the beach until mid-August to allow the chicks to survive, was lifted. A civil complaint was filed in US District court in April 1998 to force the town of Plymouth to enforce the Endangered Species Act and protect nesting plovers. The following month, a judge ordered the town to prohibit off-road vehicles on the beach from May 19 through August 31, unless strict measures are enacted to protect the nesting birds.

At least one conflict concerning this endangered bird in 1997 had a happy ending. The Cape Cod town of Barnstable's Fourth of July fireworks were nearly canceled by the Fish and Wildlife Service for fear that they would disturb the nesting plovers. A local businessman offered the use of several barges from which to detonate the fireworks. The barges were towed far from shore, and the fireworks proceeded as scheduled. Conrad Troy, owner of Tucker-Roy Marine Towing and Salvaging, Inc., who had been contacted by the Massachusetts Audubon Society for his help, said; fiIf I was an endangered species, I would hope someone would come help me out. We can keep the piping plovers happy and the kids who want to see the fireworks happy" (Anand 1997).

These controversies are indications of a growing trend in which animals, especially endangered species, are no longer eliminated or killed in the United States without protest when they come into conflict with people. Listing a species on the Endangered Species Act is a major step. It is not an end in itself, however. Listing scarcely helped the plovers in the Plymouth beaches, however, because the law was not enforced when opposed by drivers of off-road vehicles and beach users. Only the combination of publicity, local support for the birds and demand for strict protection have resulted in protection of plover nests and habitat preservation. A large contingent of volunteers now works on behalf of these tiny birds. Such cases provide examples of what is needed to prevent extinctions.

Conflicts over protection of endangered species are sure to increase in the future. Only if the public support is stronger on behalf of wildlife than the influence of those who are indifferent or oppose endangered species protection, can endangered species survive. Public support for the less attractive and charismatic species, such as insects, fish, bats and nondescript plants, will come only through effective conservation education.

Actions and Attitudes: Page 6

Another highly endangered species that nests on beaches has been the subject of a successful reintroduction program sponsored by the Fish and Wildlife Service in cooperation with the Mexican government. The Kemp's Ridley (*Lepidochelys kempi*), smallest and rarest of all sea turtles, became endangered from killing for its meat and shell. Killed off by poachers in Texas, where it once nested, a long and difficult program was initiated to return these turtles to Padre Island. Thousands of eggs laid by the last 500 nesting females on the turtles™ only remaining nesting beach along the Caribbean coast of Mexico were taken to Texas for hatching. It is not known how sea turtles learn to return to their natal beaches after spending many years at sea, and all precautions were taken to convince the hatchling turtles that they had been hatched in Texas, not Mexico. The eggs were not even allowed to touch the sand on their Mexican beaches. Between 1978 and 1988, when the program was halted for lack of visible success, a total of 22,000 eggs had been taken to Padre Island, hatched, kept in captivity until they were about a year old and then released to the sea. In 1996, to the delight of conservationists, two female Ridley Turtles that had been released 12 and 14 years previously, returned to lay eggs on Padre Island. They were recognized by a special marking the US Fish and Wildlife Service had made on each shell identifying the year the turtles were hatched. By 1999, 16 nests of returning Ridley Turtles were found by volunteers and members of the recovery team who monitor the beach 24 hours a day

during the summer nesting season. This is the first known case of successful reintroduction of sea turtles. Numbers of these turtles have increased to about 9,000 in 2001, but they are still only a fraction of the 40,000 filmed nesting on a Mexican beach on a single day in the 1940s.

Actions and Attitudes: Page 7

Dramatic rescues of endangered species have become commonplace on the island of Mauritius through the efforts of teams headed by Dr. Carl Jones, a scientist working for the Wildlife Preservation Trust, founded by famed author and conservationist, Gerald Durrell. This island harbors some of the world's most endangered birds, and by the 1970s, conservationists had become resigned to the imminent extinction of several of these endemic birds and other endangered animals. In steep decline, they seemed to be following on the path of the Dodo. Crucial to the success of the efforts to reverse this trend was the agreement signed by the government of Mauritius with four conservation organizations in the 1980s, including the Wildlife Preservation Trust, to cooperate in preserving the island's natural heritage. A conservation program in the 1970s to protect the Mauritian Pink Pigeon (*Columba mayeri*) had failed, and the remaining 33 birds were dying off. Captive-bred birds failed to breed, and wild birds were dying from various causes. Jones arrived on the island in the 1980s and, after years of concerted effort in cooperation with a small staff, brought the wild population from a low of 10 birds to approximately 375 birds in 2000. Pink Pigeons now nest at four sites on Mauritius, and another on Ile aux Aigrettes, an islet off the coast (BI 2000). This spectacular increase was the result of a program in which exotic monkeys, rats, mongooses and feral cats were removed from the roosting and nesting grounds of these beautiful, pale pink birds. Captive-bred birds released to the wild were given food until they were independent, and nests were carefully monitored for predation, falling eggs and other mishaps (BI 2000). The program hopes to increase these pigeons to a population of 500 birds within five years.

The Mauritius Parakeet (*Psittacula eques*), once the most endangered parakeet in the world, became reduced to a total population of only six birds in 1978 (BI 2000). The captive-breeding program set up to preserve them in the 1970s was not successful, and the last wild birds were dying out. Jones and other experts in parrot breeding set up a new captive-breeding program and gave the few wild birds strict protection from the many threats that appeared almost certain to cause their extinction. These included an almost total loss of forest habitat, including old trees with nest holes; a lack of available food; monkeys and rats preying on nestlings; infestations by nest fly larvae; and competition for nest sites with various introduced birds and bees (BI 2000). In spite of these overwhelming odds, these lime green parakeets are making a slow recovery. A forest habitat of 8,000 acres has been made into a national park where exotic species have been excluded and captive breeding is now succeeding. At first, the wild parakeets refused to nest in boxes set out for them and would not try to find other nest sites if their nest tree were destroyed during hurricanes. Fortunately, a few pairs did nest, and habitat improvements were made, such as the planting of fruit trees as a food source. Through these and other efforts, the wild and captive populations rose to between 85 and 90 birds by 1997 (Hoyo *et al*. 1997). Numbers continued to rise, and by 2000, 106 to 126 birds survived (BI 2000). This is one of the world's most impressive conservation stories. The vast majority of birds whose populations have declined so drastically experience genetic impoverishment or become prone to other threats by failing to respond to conservation programs. The recent extinctions of Hawaii's honeycreepers and other native birds are testament to the failure of many 11th-hour programs to conserve critically endangered birds. Although still listed as Critical by BirdLife International (2000) and the IUCN, the Mauritius Parakeet may be reclassified as Endangered, should present trends continue (BI 2000).

A third endangered bird of this island, the Mauritius Kestrel (*Falco punctatus*), a small falcon, numbered only four birds in 1974, coming the closest to extinction of any Mauritian bird. Yet today the species is numerous, having almost completely recovered. Through captive breeding and restocking birds to the wild using methods employed in the United States for Peregrine Falcons, and with the help of the Peregrine Fund, hundreds of captive-bred birds have been released to the wild and fed at release sites until they gradually sought wild prey. By 1995, these kestrels totaled

286 birds (Jones and Hartley 1995). Control measures have been successful in reducing exotic species that preyed on them. The population of Mauritius Kestrels reached 145 to 200 breeding pairs in 2000; the species totals from 500 to 800 individual birds who live in three subpopulations in various parts of the island (BI 2000). Jones has also worked to restore habitats for various endangered lizards that are captive bred at the headquarters of the Jersey Wildlife Preservation Trust. These small, iridescent geckoes had become restricted to out-islets, where they survived because introduced predators were absent. Unfortunately, rabbits were released on Round Island, habitat for several of these endangered reptiles, and they multiplied to pest proportions, leaving almost no natural vegetation. Many of these lizards were captured just in the nick of time, and bred in captivity, as the last of their habitat was being consumed. After removal of the rabbits and replanting of native species, these lizards are now being reintroduced.

Actions and Attitudes: Page 8

Specimens of a highly endangered fruit bat of the small Mascarene island of Rodrigues, the Rodrigues Flying-fox (*Pteropus rodricensis*), were captured for captive breeding when wild populations became threatened by killing for food by local people. It amazed researchers studying them when a female exhibited mid-wife protective behavior seen only in a few other animals, such as dolphins and elephants. One of the females in the process of a difficult breach birth was aided by the other, who fanned her, cradled her in her wings, and showed her the proper position to cling to the cage bar during the three-hour delivery (McFarling 1994). Wild populations of this species are listed as Critical by the *2000 IUCN Red List*. Other flying foxes that once inhabited these islands are now extinct, and the Rodrigues Flying-fox is the last to survive. Without the emergency rescue of some of these foxes, the altruism and devotion of these animals would probably not have been recognized.

Actions and Attitudes: Page 9

The elimination of introduced animals, from goats, cattle and pigs to cats and exotic plants, has been carried out on many islands and island-like environments around the world to preserve native species on the brink of extinction. The governments of Australia and New Zealand, in particular, have rescued a number of critically endangered species. Lord Howe Island, located off the northeastern coast of Australia, once harbored diverse wildlife. After settlement, and introduction of rats and other exotic species, forest clearance and other threats, numerous extinctions of native animals occurred, and most of its surviving species are endangered. Efforts on the part of the government to return the island to its near-original state, with total protection of the remaining tropical forests, coral reefs and other habitats, is underway. Ecotourism has been developed on the island, but the number of visitors is kept at a level that will not harm the island's endemic fauna and flora. Cats may not be kept by the limited number of residents as pets because of their threat to native birds, and exotic animals are being eliminated from the wild. The endangered, flightless Lord Howe Rails (*Gallirallus sylvestris*), highly vulnerable to predation by cats and other predators, are now gradually increasing with strict protection. Once found throughout the island, these rails became restricted to mountain areas after they were eliminated by feral pigs, goats, cats, dogs and the introduced Masked Owl (*Tyto novaehollandiae*) elsewhere on the island. Captive breeding has been successful, and after work to eliminate exotic animals, these rails were reintroduced to several of their original habitats at lower elevations (BI 2000). The population numbers about 130 birds, with a potential living space for up to 220 birds (BI 2000).

In some cases, control programs for exotic species on islands are not done humanely. Wire snares and poison have been employed rather than live-catch traps, for example. Humane organizations should be consulted by governments to employ humane methods in ridding islands of non-native animals.

The Black Robin (*Petroica traversi*), a beautiful songbird resident on the Chatham Islands off New Zealand,

numbered just five birds in 1980, with only one breeding pair (BI 2000). Rats and cats colonized the island after settlement, and deforestation had destroyed the species' habitat. A tree-planting project in which 120,000 trees were planted on Mangere Island, one of its prime habitats, was undertaken (BI 2000). Supplemental feeding and nest protection from introduced Starlings (*Sturnus vulgarus*) and seabirds, which were preying on them, helped somewhat. Real progress began with the use of an unusual program in which eggs of the Black Robin were placed in the nests of other species to raise them and allow the original female, who became known as "Old Blue" and lived 12 years, to lay more eggs. Birds of a related species, the Tomtit (*Petroica macrocephala*), raised these robins, and chicks were successfully reintroduced to Mangere Island (BI 2000). Such cross-fostering has failed with species such as the Whooping Crane, whose eggs were cross-fostered to Sandhill Cranes, because the chicks when mature, tried to mate with Sandhill Cranes instead of members of their own species, having become imprinted. In this case, the chicks bred with members of their own species, and numbers rose to 259 in 2000 (BI 2000). They were all descended from the original pair of birds. The New Zealand Department of Conservation, which had overseen the breeding program, found through DNA studies that the birds are nearly identical genetically (Hutching 1997). Further studies will attempt to discover immune responses and other signs of inbreeding, but outwardly, these robins are thriving, with a 70 percent survival rate and normal fertility (Hutching 1997). Species with such low genetic variability tend to be extremely vulnerable to extinction, having little ability to adjust to changes in their environment or food supply.

Actions and Attitudes: Page 10

More and more countries are taking a keen interest in the preservation of wildlife, and some have ancient protective traditions. The Asian country of Bhutan has a Buddhist ethic of not harming living things. It is the only Himalayan country to have protected the majority of its forests. Rhododendron species 40 feet tall grow there, and the rivers still flow clear, without erosion and siltation. Species that are rare elsewhere in the region still survive in Bhutan. One of its protected areas, Jigme Dorji National Park, is the size of Switzerland and preserves spectacular mountains and cascading waterfalls. It is part of a Bhutanese government plan to create a nationwide system of reserves to protect the country's natural heritage (Adams 1994). Although erosion and destruction of some of the native fir and rhododendron forests have occurred, Bhutanese people support the government's "go slow" approach to development and its plan to preserve wilderness (Adams 1994). A wintering population of endangered Black-necked Cranes (*Grus nigricollis*) is zealously protected by the Bhutanese who live in the valley where the cranes come each year; they regard the birds as integral to their lives and believe that, without them, their harvests will fail. These people miss the cranes™ calling when the birds migrate in the spring, and say that the valley seems empty and silent without them (Greenway 1997). The Environment Ministry watches over the cranes as well and is extremely strict about issuing permits for activities that might harm them.

New approaches may save some of these threatened tropical areas. Australia's Rainforest Information Center has created an Internet website which plays rock and roll music; its sponsors pay to preserve the rainforest (EII 2001). The organization is focusing on saving several endangered forests in Ecuador, including Los Cedros Biological Reserve and portions of the Madre Selva (EII 2001). The Natural Resources Defense Council has created a list of BioGems (www.savebiogems.org), the 12 most endangered wildlands in North and Latin America. It publicizes threats, such as proposed dams and logging, to generate thousands of letters and e-mails to governments, loggers, utilities and others. The Macal River Valley in Belize, threatened by a dam project, has been saved through this program. The US Duke Energy International company decided to withdraw from Belize after the torrent of protests (NRDC 2001). Boise Cascade planned a major wood chip mill in Chile, which would have consumed 1,200 acres of endangered temperate rainforest a year, with endangered Alerce trees, the massive South American counterpart to the Sequoia. The forests also sheltered tiny Pudu deer and rare birds. The company announced that it would cancel its plans "as a result of unfavorable market conditions" (NRDC 2001). Conservation International (CI) played an important role in the designation by the South American country of Suriname of much of its vast interior, a pristine rainforest, as a reserve. CI, through its scientific studies, was able to show the country's leaders that, kept intact rather

than being logged, this rainforest would prove far more valuable for future generations. This organization has accomplished similar feats in Bolivia and other parts of the world, where it also carries out important biological inventories.

An example of cooperating with local people for conservation of wildlife is the administration of the Mara Reserve of Kenya. This reserve is run by the Maasai people through a council which mandates that tourist funds go directly for social services of the tribe; in turn, the Maasai, who live outside the reserve, allow wildlife to move freely without fencing or harassment that is common elsewhere in Africa where livestock is raised (Gakahu 1994). In this reserve are endangered Cheetahs and Black Rhinos, along with 30 species of ungulates, including large numbers of elephants (Gakahu 1994). Local villages in many parts of Kenya are establishing landowner associations that receive funds from tourism to protect wildlife and benefit local economies (Gakahu 1994).

Actions and Attitudes: Page 11

Teaching people that their local wildlife is important to protect as a source of pride has had excellent results in a program in the Caribbean funded by RARE Center for Tropical Bird Conservation, an organization headquartered at Philadelphia's Academy of Sciences. It has employed innovative education and conservation programs to preserve St. Lucia Parrots or Amazons (*Amazona versicolor*), the forests and other wildlife of the island. Biologist Paul Butler, who began this program, has instilled conservation enthusiasm and pride in the people of the island of St. Lucia for these beautiful and rare parrots. His dynamic program has resulted in the naming of this species as the national bird, as well as education programs so successful that children know its scientific name, habitat and need for protection. They enjoy singing songs about the parrots and dressing up in parrot costumes. The people of St. Lucia now understand that the forest and other wildlife must not be destroyed. Art and essay contests are conducted in schools and towns to publicize this parrot, and St. Lucia Parrots are used as logos for many businesses. Forest cutting has been banned, and a substantial portion of the island has been set aside in reserves. This has resulted in an increase from fewer than 300 to between 350 and 500 birds (BI 2000). The Saint Lucia government is dedicated to protecting the parrots and their habitat, and a new ecotourism industry has sprung up. These programs have meant an end to the rampant smuggling of these beautiful, rare parrots, an activity that had been thought uncontrollable because they could be sold for $20,000 per bird to collectors. Protecting the forest for the parrots also resulted in conserving other threatened wildlife of the island and precious watershed. Another native species, the spectacular Giant Swallowtail butterfly, is illustrated on billboards prominently located near towns with the message, "It's ours . . . take care!!!" (Lipske 1994). This approach to conserving endemic wildlife has been adopted on other Caribbean islands, and Butler trains local conservation officers and teachers to continue the programs elsewhere (Butler 1992, Lipske 1994). A film about these programs, "Caribbean Cool," is described in the Video section, and RARE has published a manual, *Promoting Protection Through Pride*, with advice on how to carry out such programs.

Educating children to respect the environment and conserve endangered species leaves a lasting impression if begun in grade school and continued throughout schooling. Children have an innate sympathy and love for animals, and become enthusiastic conservationists. Education about national laws and native wildlife and plants of the region encourages students to have a lifelong desire to protect them and a sense of guardianship that results in opposition to actions that would harm them. Environmental education is required in about two-thirds of US states, from grade school onward. Some schools require special training in environmental science for all teachers. A few high schools are teaching courses in ecology for college credit. The North American Association for Environmental Education has issued detailed guidelines for educators to assess textbooks and other materials for fairness and accuracy, and review by experts (Cushman 1997).

Some conservation organizations have been formed by scientists, such as the highly effective International Crane Foundation and Bat Conservation International. Entertainers have also become involved in conservation. The rock

music star Sting, for example, became concerned about the destruction of rainforests and founded the Rainforest Foundation, an organization to raise money to purchase or protect thousands of acres of this endangered habitat, while at the same time informing young people about the importance of these forests to the world. Students and concerned individuals have also founded organizations to protect individual species or particular environments, such as prairies or wetlands. These organizations have raised millions of dollars for rainforest protection and helped many endangered animals.

A number of effective conservation programs began as grassroots organizations established by an individual or a small group of people who wanted to protect a species. Individuals have educated, lobbied and helped raise funds for the purchase of habitat, making extremely important contributions to the preservation of threatened species. The beautiful bluebirds of North America were in steep decline until Lawrence Zeleny began his nesting box program. He popularized and distributed nesting boxes for bluebirds with an entry hole just a fraction of an inch too small for the aggressive European Starlings to enter. The latter birds are taking over the tree nest holes of all three species of North American bluebirds. Starlings are also a threat to several native species of woodpeckers. Through the nest box program promoted by Girl and Boy Scout troops and other organizations, these colorful birds have increased and may again be abundant, familiar residents of orchards, woodland edges and grasslands. Such citizen projects keep species in decline from reaching endangered status. Once endangered, a species' genetic diversity is threatened, and multi-million-dollar state and federal rescue programs, which are not always successful, must be set up to help them.

Only a small percentage of endangered species have such programs in place to aid their populations and protect their habitat, and individuals can make important contributions by volunteering for organizations working to preserve species and their habitats or by founding an ad hoc group. The majority of species listed on the *2000 IUCN Red List* or on Natural Heritage would be far more likely to avoid extinction if conservation programs were created for them, with help from both individuals and organizations. The species most in need are invertebrates and plants, which form the majority of all endangered species and receive the least funding. Within each region or county, little-known endangered species may be fading out without the aid of any organization or individual. Organizations such as The Nature Conservancy, Conservation International, scientists with the IUCN or state Natural Heritage programs provide highly specific information on threatened species in various parts of the world.

Restoration of original ecosystems will become more and more important as natural landscapes decline. The Nature Conservancy, which has purchased millions of acres of land to preserve resident endangered plants and animals, reintroduced the American Bison to its 30,000-acre tallgrass prairie in Oklahoma, and is reintroducing native flowers, plants and animals to restore at least a portion of this magnificent ecosystem. After decades of failed bills proposed in Congress, legislation was finally enacted in 1996 establishing the nation's first tallgrass prairie park of more than 10,000 acres in Kansas. Individuals can also contribute to restoration of ecosystems. Books, such as *Noah's Garden. Restoring the Ecology of Our Own Back Yards*, by Sara Stein (1993), and many magazine articles have called attention to the effects of suburbanization, and the poisoning of native wildlife with pesticides and herbicides used on lawns. They suggest means of bringing back natural ecosystems.

Actions and Attitudes: Page 12

However effective private organizations are, they cannot begin to have the effect of preserving habitat that governments have. As the owner of millions of acres of parks and reserves, the US government plays a major role in habitat and species preservation. The Land and Water Conservation Fund was established in 1964 to purchase and preserve federal lands, with money coming from oil and gas leases on the coasts. Each year, some $900 million is deposited in this fund, and more than 5 million acres have been preserved in many threatened environments. In 1998, $699 million was approved for spending on land purchases, including $250 million for acquiring the ancient Headwaters Redwood Forest in California to save it from planned logging, as well as $65 million for the New World

Mine site near Yellowstone National Park to save it from a huge Canadian gold mine.

National Wildlife Refuges are vital habitat for thousands of threatened and declining species and were first set aside during the Theodore Roosevelt Administration to protect endangered sea birds being killed for their plumes. Now refuges and preserves are key to the survival of Red Wolves, Bald Eagles, Whooping Cranes, Florida Panthers and numerous rare plants, butterflies and other wildlife. In many of these refuges, oil drilling and other exploitation occurs, causing damage to ecosystems and threatened wildlife. The protection these refuges receive is far less stringent than that of national parks and monuments. In some refuges, high-speed roads cut through the middle of marshes where an array of rails, turtles and wetland species end up run over by vehicles. In the largest refuge, the Arctic National Wildlife Refuge, most of the land is open to oil drilling, where water and air pollution have been severe problems. The calving ground of a herd of some 100,000 Caribou within the refuge has been proposed for oil drilling, in spite of the opposition of the majority of the US public. With greater support from the public, laws governing these refuges and their funding might be strengthened to better preserve wildlife.

Some imaginative solutions to the funding problem have been developed. A number of organizations have adoption programs for wild animals. Northern Right and Humpback Whales, for example, identified individually by their markings by scientists studying them, can be sponsored by members of the public, who are then informed of news about their adopted animal. The funds are applied to research and conservation of the species. Grizzly Bears, Tigers, Gray Wolves and other animals may be adopted through a growing number of organizations. Earthwatch, in Watertown, Massachusetts, sponsors thousands of research expeditions by scientists, many of them studying endangered species, through funds from volunteers who pay for the privilege of accompanying the scientists and helping in the research. Endangered species of Brazil's Atlantic Forest, Florida Manatees, rare butterflies and coral reefs are among the many projects Earthwatch helps fund. This organization also awards hundreds of scholarships to students, and teachers who participate can turn the experience into a study program for their students.

Actions and Attitudes: Page 13

A great blossoming in natural history information has erupted in recent years. Internet websites, accessible to all, have been dedicated to endangered species research programs, biological studies, organizations devoted to helping animals and data compilations. The Internet sets up communications between people around the world, in which education, advice, and even funding help for threatened species and ecosystems can be arranged. Critical situations threatening species can be publicized immediately around the world. On the Internet, students and the public can follow the movements of individual sea turtles, great whales and many other animals equipped with radio transmitters sending signals to satellites. Libraries can be accessed, and websites set up by state, federal and private entities provide highly specific information on endangered species and the environment. Experts may be consulted through these sites. In a recent case, a man in Lebanon came upon an injured eagle with a gunshot wound; he took the bird home and logged on to the National Geographic Society's website (see Teachers™ Aids in the Appendix for lists of websites) to find Joe Blanton's "Glad You Asked" column. Blanton put him in touch with the Wildlife Center of Virginia, whose staff at its state-of-the-art animal hospital gave him advice on care for the eagle. The man reported that the bird recovered and was released (reported in *National Geographic* June 1997). The possibilities of educating and dispensing information around the world are enormous, and with imagination, many of the problems discussed above might be solved through the free interchange of ideas of people on the Internet.

The Internet is only one new tool for conservationists. Laser discs can combine films and books and be interactive in teaching about subjects such as endangered Chimpanzees. CD-ROMs, although not yet available for many endangered species, contain--on one disc--still photos, films and printed information about a species; heretofore one might have to visit many libraries, rent or buy films by mail and spend many hours to obtain such information sources.

Books, television programs and films about the natural world have opened new doors to the public in the past decade. Natural history films, in particular, are another major influence on education and even public policy. They present views of true wilderness, natural wildlife behavior and conservation lessons. They may have had a significant influence on convincing the public of the need to pass such laws as the Endangered Species Act. Films of the slaughter of spotted cats, American Alligator, and the plight of declining species around the world aroused many people to write their Representatives and Senators in support of legislation to prevent species from becoming extinct.

Films of truly wild places may have played a role in the growth in bird watching and ecotourism, and probably in the changes that have taken place in zoos, with barred cages giving way to more natural exhibits. Having seen films of these animals in the wild, the public was no longer content to see them in such unnatural conditions, behaving so abnormally. Situations once commonplace, such as a pacing Tiger in a barred cage, a single elephant in a dusty, small enclosure, rocking back and forth, now result in protests that have changed zoo exhibits and animal treatment for the better.

The crucial steps that must be taken in the future involve the dissemination of knowledge and concern about endangered species to the general public, who are poorly informed about the enormity and possible effects on their lives of issues such as overpopulation and disappearing species. Although public awareness has increased about environmental decay and the effect that humans have in causing species' extinctions and endangering them, most people still tend to act as if nature will bounce back and will continue to function normally, no matter how extreme the damage. This is a naive point of view. Scientists have not defined the threshold beyond which total ecological collapse will occur in any given area. Also unknown is the number of species that can be extinguished before biological systems become dysfunctional (Leakey and Lewin 1995).

Newspapers, television and other media should be encouraged to publicize these issues further, rather than catering to what they might consider the public's interest. As an example, US network television and newspapers have pointedly ignored human overpopulation and loss of biodiversity, while doing numerous stories on artificial means of having children, such as test tube babies and multiple births. On the positive side, new cable television channels in the United States, such as Animal Planet and BBC, add to the growing number of wildlife and environmental programs on PBS and the Discovery Channel. Unfortunately, these channels presently reach only a fraction of the audience of network television, preventing a better understanding by the public of the problems facing the world. The numbers of films being made and books written on endangered species and the environment have increased exponentially in the past decade, an indication of a growing enthusiasm for the natural world. Other indications of this trend are the rise in memberships in conservation and humane organizations, ecotourism, bird-watching, hiking and visits to national parks and preserves. If these concerns were better translated to activism and altering lifestyles to prevent harming the environment and wildlife, impending mass extinctions might be avoided.

Biodiversity Preservation

Preventing loss of diversity through the growing number and rate of extinctions is extremely important for the ecological stability of the planet. Unfortunately, it is not recognized as a key issue by the majority of people, nor by world leaders. The extraordinary wealth of plants and animals that are in the process of disappearing may represent between 5 and 30 million species, of which only about 1.3 million have been named (Wilson 1993). Insects alone may number more than 5 million species, with the majority of species living in tropical rainforests (Wilson 1993). These animals are key to the Earth's ecosystems, pollinating, fertilizing and aerating soil, and providing food for thousands of animals. Some 751,000 animal species have been identified, far more than the 248,428 plant species, yet these represent only about 15 percent of all living species, in the view of Dr. Edward O. Wilson in his classic 1993 book, *Biodiversity*. Each year, thousands of new species of insects and other invertebrates, hundreds of frogs and,

surprisingly, primates, antelope and birds are discovered by science, often in disappearing habitats.

Worldwide, biological inventories, essential to the process of protecting biologically rich areas, receive inadequate funding. Wilson has estimated that more money is spent in New York City's bars in two weeks than studying biodiversity around the world each year (Farnsworth 1994). Some $57 billion is spent on drugs by Americans annually, according to the White House Office of National Drug Control Policy, while less than $1 billion are spent on inventories and biological studies, by some estimates. The lack of funding for biological surveys means that entire ecosystems are vanishing before they are even studied.

Just as many species are disappearing from neglect or uncaring development, scientists are finding and naming hundreds of new life forms, primarily through research programs of private universities and organizations. Ecosystems thought sterile, such as deep ocean environments, are now known to contain significant species diversity. Each descent of a submersible vehicle into these environments brings new discoveries, from beautiful, bioluminescent jellyfish many feet long to bizarre creatures that seem to have emerged from science fiction tales. Many of these newly described species represent previously unknown families, classes, and even phyla of animals.

Some deep sea creatures inhabit the boiling hot water emitted from cracks in the ocean floor, managing to survive what would be toxic to 99 percent of the world's animals. This environment may be similar to the one in which life itself was formed billions of years ago. These areas should be given high priority for government research funding. Studies about Earth™s diversity should not be sacrificed in US federal spending projects such as NASA probes into the possible presence of microbial life on Mars. The discovery of the Mars fifossilfl was given enormous publicity, and in early 1998, chemical studies proved that these supposed evidences of life were actually terrestrial contamination (Wilford 1998). This has not stopped the NASA program from searching for evidence of life on Mars. Tropical forests also represent frontiers to biologists in urgent need of research funding, with millions of species of birds, mammals, insects and other life forms yet undiscovered. They are proof of the importance and urgency of preventing extinctions and degradation of natural ecosystems.

Diversity is threatened by economic concerns that affect every country. Economists tend to consider revenue important--but not such intangibles as biological diversity. Yet history shows that cultures that protect their environment endure far longer than those that do not. Clive Ponting (1991), in *A Green History of the Earth*, makes this point clearly, citing the great civilizations of the past which died out after abusing the land by disrupting water supplies through deforestation, and causing imbalances in ecosystems that resulted in their decline.

Common sense about environment protection and a concern for future generations have inspired many countries and cultures to preserve biodiversity. Those cultures which have a strong bond with nature, especially a spiritual one, are the most likely to protect their environments and wildlife, even when they are impoverished and would profit from exploiting it. With such people, economic arguments to protect nature are unnecessary, but for the vast majority of people today, short-term profits from nature are justifiable if an urgent economic need exists. In general, harm to the environment and biodiversity may be increasingly unacceptable, however. Polls taken in 2001 in the United States found strong support for environmental protection, with 58 percent of respondents believing that protecting plants and animals should take priority over preserving personal property rights, and nine in 10 saying that it is important for wilderness and open spaces to be preserved (Barabak 2001). Even when government leaders fail to act decisively to protect nature, these actions do not necessarily reflect the will of the majority.

A new activism on the part of the public and native peoples is resulting in many protections for wildlife and the environment. It is also resulting in new alignments of organizations and groups of people. Environmentalists and labor groups have united in opposing the anti-environmental aspects of the World Trade Organization, which caused member countries to reexamine their automatic endorsement of all trade to the exclusion of the environment, wildlife and job protection. Native tribes in British Columbia and conservation organizations united to publicize the impending destruction of thousand-year-old forests along the coast, home to the white "spirit bear." This coalition succeeded in 2001 in stopping logging and achieving permanent protection for some 1.5 million acres (NRDC 2001).

One proposed means of preserving wild animals and plants and their environments is the Convention on Biological Diversity, signed by more than 150 countries after it was presented at the 1992 Earth Summit held in Rio de Janeiro, Brazil. It went into effect in December 1993, after the 30th country, Mongolia, ratified it. It had been signed by 161 nations. Its purpose is to prevent extinctions and biological impoverishment, and it commits nations that ratify it to take actions to preserve species and ecosystems in the process of development.

The Convention requires nations to integrate conservation into economic and social policy to: promote the protection of entire ecosystems, set up protected areas, undertake biological inventories, preserve species throughout the country and restore degraded ecosystems. Many of the wealthy industrialized nations that do not support the Convention succeeded in having weakening clauses written into it, such as "as far as possible" and "as appropriate" (Stevens 1992). It states that nations have the "sovereign right to exploit their own resources pursuant to their own environmental policies.fl Even with its weaknesses, it remains the only international convention to have ever addressed the importance of preserving biological diversity, and as such, it sets a major precedent.

The success of the Convention on Biological Diversity will depend on how strictly it is interpreted. One clause places economic and social development, and the eradication of poverty, as the first priorities of developing countries. This could become an excuse to allow extinctions for the sake of "progress." For example, dam construction or forest clearance could be projects to alleviate poverty, but they would probably cause extinctions. The treaty also states that conservation efforts on the part of developing nations will depend on the flow of money from rich nations, although it recommends that the rich countries benefiting economically from exploitation of resources, such as pharmaceuticals, in poorer countries, should share these profits with the latter (Stevens 1992). It is this latter clause that many members of the US Congress opposed because US pharmaceutical companies did not wish to pay nations harboring medicinal plants. This is a major reason why the United States has not ratified the Convention.

To fund the programs of the Convention on Biological Diversity in developing countries, the Global Environmental Facility (GEF) has been set up, administered jointly by the United Nations Development Program (UNDP), the United Nations Environment Program (UNEP) and the World Bank. GEF raised some $2 billion from wealthy countries, and its administration has been criticized by both donor nations, which want it run in a similar manner to the World Bank, and many developing countries and environmentalists, who accuse it of "green washing" destructive environmental programs endorsed by the World Bank (Lewis 1994). The World Bank has been a major proponent of commercial logging in the last tropical rainforests of Central and West Africa, with disastrous consequences for both wildlife and native peoples.

This Convention is heavily influenced by rich donor countries, such as Japan, Canada, Norway and other European nations. Without strong opposition to the traditional approach of the World Bank in funding large dams, logging and other such projects, the Convention will not fulfill its more positive potentials to conserve the Earth's biological heritage. Its success will depend on the strong participation of those truly interested in the preservation of nature and willing to encourage countries in this task.

At the end of the 20th century, a poll of biologists was taken, asking them what they considered the greatest threat facing the Earth today. By a wide margin, they chose the loss of biodiversity. The greatest challenge in the 21st century will be to inspire people to want to protect biological diversity, as some nations are doing. Costa Rica, for example, is engaged in a biodiversity program that will catalog virtually every resident animal and plant over the next decades and protect critical habitat areas. The United States, through the Natural Heritage Programs and hundreds of biologists whose work is compiled by the Association for Biodiversity Information, is making progress in its appraisal of the nation's biodiversity and conservation needs (Stein *et al*. 2000). Thousands of individuals are also playing a role by preserving or reintroducing native species into their local areas. In spite of great pressure to exploit the last rainforests and other fragile environments throughout the world, successes in preserving the immense treasure-trove of species that exists on Earth may be turning the tide.

Our lives depend on the proper functioning of the Earth's systems for processes such as photosynthesis, balance of oxygen and carbon, pollination of flowering plants and enrichment of the soil by organic materials. These systems require a large variety of species to function normally, and we are only beginning to understand the role of various organisms and which species are key to each ecosystem. It is not possible to say, therefore, that any species can become extinct without affecting vital life processes. By choosing which species shall survive and which are dispensable, based on economic considerations, as proposed by many politicians, is sheer folly. Irreparable damage may result from such attitudes, yet they are accepted by many governments of the world.

We are presently witnessing the breakdown of many ecosystems. Marine food chains are being destroyed by overfishing and pollution, interfering with the food supply for millions of people. Yet it seems that few of these ecological catastrophes were predicted when fishery or pollution limits were set. Likewise, wetlands are losing wading birds, frogs and fish--all natural insect controls--resulting in increases in insect-borne diseases such as malaria. Predator-prey relations are key to the health of forests and grasslands, preventing overgrazing by prey species that have lost their predators. Yet most wild cats and wolves are in decline, some close to extinction, allowing imbalances to occur. In a growing number of regions, large predators are either absent or so rare that they no longer perform their ecological role. In Yellowstone National Park, for example, the eradication of the Gray Wolf resulted in overpopulation of Elk, which over-browsed aspen and other plants that were habitat to a number of birds and other animals, resulting in their disappearance. Only with the reintroduction of wolves is the ecosystem returning to normal. The overpopulation of deer in the United States and their effect on preventing natural forest regeneration and destroying wildlife habitat is directly related to the extermination of their natural predators, wolves and Mountain Lions. In other cases, prey species, such as deer, antelope and other ungulates, are in steep decline, having been killed off by meat hunters or crowded out by livestock. These species often play important roles in dispersing seeds, as do bats, birds and rodents. One-fourth of all mammals, and one in 10 birds are imperiled. Among these are pollinators, seed dispersers, insect-eaters and prey for other species. The loss of this biodiversity is reaching such levels that it is not surprising so many ecosystems are imbalanced. It is even more alarming to contemplate that the majority of the world's reptiles, amphibians, marine fish and most invertebrates have not even been assessed by biologists.

Species' declines begin with local extinctions as they disappear from portions of their ranges. At this stage, their absence may be affecting ecological communities, but they will not be listed by the IUCN or any other listing authority until the species as a whole becomes threatened. The Gray Wolf disappeared from 90 percent of its US range before it was listed on the Endangered Species Act, by which time major ecological damage had already been done. Species receive protection, endangered listing and conservation attention at the latter stages of declines. The smaller the original range, the faster that species slides to extinction. Ecological effects can occur gradually and imperceptibly in some cases and, in others, quickly and dramatically. Most of the 34,000 plants listed by the IUCN as Threatened occupy restricted ranges and may have undergone slow declines as their pollinators and seed dispersers disappeared, or rapid declines if they were logged or their habitats destroyed. As the concept of saving ecosystems and their myriad plants and animals gains acceptance, the importance of preserving all the strands of this complex tapestry becomes clear. The tens of thousands of animals and plants listed by the *2000 IUCN Red List* are an indication of a crisis situation, of nature going awry.

Astronauts orbiting the Earth have been overwhelmed by the beauty and fragility of the planet and its uniqueness in the universe. They have described environmental destruction visible from space. Shuttle astronaut Jay Apt (1996) spoke of seeing hundreds of pinpoints of bright lights at night that turned out to be fires emanating from forests in Africa, Madagascar and Borneo. A distant perspective enhances appreciation and desire to conserve our remarkable home. Instead of considering ourselves as separate from the environment, biologist Dr. Thomas E. Lovejoy has suggested, "We must behave as if we live *within* ecosystems, rather than perceiving nature as something confined to a few protected areas isolated within a degraded, human-dominated landscape" (Laurance and Bierregaard 1997).

Scientific study of Earth's diversity and ecology is in its early stages, and an exciting frontier awaits scientists in the ocean, tropical forests and other environments. Yet we are treating this precious living tapestry without the respect it deserves, and the unraveling of these intricate and delicate ecosystems will threaten our very existence.

Forests:

Forest

Introduction

In an Ecuadorian rainforest, great towering trees festooned with orchids whir with hummingbirds. Primitive mammals skitter up massive Australian trees of species older than the dinosaurs. The world's tallest trees grow in northern California; at the forest floor beneath them grows an intricate diversity of emerald green mosses and ferns inhabited by tiny creatures. At the southern end of the South American continent, a forest of small gnarled trees buffeted by sea winds shelters herds of short-legged Huemul deer. Kiwis, in their downy cloaks of brown feathers, probe the forest litter among giant tree ferns in New Zealand's dark rainforests, pushing their long, pointed bills into the soil to extract earthworms. Monkeys with elaborate facial patterns, in blues, reds and blacks, chatter in treetops above a plodding West African elephant herd. New Guinea's dazzling birdwing butterflies, measuring 1 foot across, flutter near moss-hung trees where iridescent birds-of-paradise display and utter resounding, eerie calls. Thousands of insects and hundreds of other life forms may inhabit a single tree, whose fruits and flowers feed countless other animals, each the product of eons of evolution and geological history. These irreplaceable forests are in imminent danger of disappearing. The most biologically diverse of these are the untouched, old-growth forests of the world, of which only 20 percent remain, largely unprotected from destruction.

Benefits of Forests

The great beauty and inspirational qualities of forests belie their important biological tasks. By producing vast amounts of oxygen and water vapor, and absorbing carbon dioxide, they help support all life on Earth. A single mature oak tree produces enough oxygen to keep eight people alive for a year. In 1995, an international team of ecologists working in Brazil documented that each hectare (2.47 acres) of undisturbed tropical rainforests absorbs 1 ton of carbon dioxide per year. The world's rainforests are thus absorbing a billion tons of carbon dioxide a year, one-sixth the amount produced by burning fossil fuels such as oil and coal, according to the National Oceanic and Atmospheric Administration (NOAA). Cutting and burning of forests around the world releases carbon dioxide into the air. The high levels of carbon dioxide in the world's atmosphere have caused increases in average global temperatures. The value of tropical forests in trapping carbon dioxide is so significant that four US utility companies have sponsored a pilot program in Belize to protect large areas of forest and plant trees; energy companies will contribute $2.6 million to a 120,000-acre reserve that will absorb 5.2 million tons of carbon dioxide gas over 40 years (Geatz 1996). The Clean Air Act allows such "pollution credits" to compensate for pollution released elsewhere. In 2000, the US government proposed a massive program of tree planting and protection of forests to compensate for the effects of global warming caused by the release of carbon dioxide and other pollutants.

The cooling effect of forests results from leaf transpiration generating moisture that rises to the atmosphere, forming clouds which release water as rain or other precipitation. When forests are cut, the climate dries as rainfall decreases and soils lose moisture. Tree roots absorb about one•half of the rain that falls, releasing the water gradually during the year (Schreiber *et al*. 1989). In countries with wet and dry seasons, water retention by trees makes the difference between deadly floods that kill thousands of people and sweep away their homes and precious topsoil, and river levels that remain stable, preserving soil and the environment. Forests stabilize the soil, preventing erosion and landslides and allowing streams and rivers to flow clear.

The leaves, bark and wood of trees have been found to contain hundreds of compounds valuable to medicine and industry. Forests produce a wealth of useful species: oils, gums, resins, tannins, waxes, edible oils, dyes, cosmetics, spices, fruits, nuts and life•saving compounds used in medicine. Spices alone are worth more than $1 billion per year

(Schreiber *et al*. 1989). Medications derived from wild plants are worth $40 billion annually (Lean and Hinrichsen 1994). Painkillers, birth•control agents and malaria drugs, as well as quinine, digitalis and morphine, are all derived from tropical forest plants. According to one study, more than 40 percent of all prescriptions in the United States still depend on natural plant sources (Swaminathan 1990). Only a small percentage of wild plants have been tested for medicinal value. In some cases, plants that might have disappeared altogether were found to be medical treasures. The Madagascar periwinkle, native to an island which has lost 80 percent of its forests to deforestation, has been the source of two potent compounds that have proven effective in the treatment of Hodgkin's disease and produce a 99 percent remission in patients with acute lymphocytic leukemia (Myers 1983). Global sales of these two drugs now exceed $180 million a year (Wilson 1992). Taxol, a compound from the Pacific Yew found in the last of North America's old-growth forests, has proven effective against ovarian and other cancers.

In the long run, forests left standing are of greater benefit than those cut and destroyed. The dollar value of natural ecological systems, of which forests make up a large part, in performing services for human society has been estimated at as much as $54 trillion, as seen in Chapter 1 ("Earth's Worth" section). Along with their role in flood prevention and climate regulation, forests provide fruits and flowers to be pollinated by wild insects and birds, and clear rivers as habitat for valuable salmon and trout fisheries (Stevens 1997b). The World Resources Institute in Washington, DC, has calculated that the loss of value from deforestation is four times as high as the value of the timber extracted and the depletion of soils, forests and fisheries amounted to an average reduction of 25 to 30 percent in potential economic growth (Stevens 1997b).

The ways in which forests function are only beginning to be understood. Great fig trees are dependent on tiny wasps to complete their reproduction, and fungi in the roots of trees play intrinsic roles in their survival. Pollinators are key to the health of forests, but for many species of trees and plants, only fragmentary information has been acquired about how they are pollinated and the conservation status of these pollinators. Understanding the interrelationships of plants and animals within these ecosystems is key to their preservation, yet forest ecology is in its infancy.

While logic would seem to mandate that such awesome and useful ecosystems be accorded great respect and legal protection, the opposite is true. They are being destroyed so rapidly by logging, dams, climatic changes caused by human activity, and pollution that the last pristine forests may soon be gone. Even minor alterations in their environments have interfered with their healthy functioning.

Cutting forests for financial gain or to resettle people from overpopulated cities provides developing countries with short-term solutions to problems and one-time profits. Neither the extremely important ecological roles that forests play, nor their value as species storehouses, are appreciated by the majority of the world's nations. The recent spate of massive landslides and floods after periods of heavy rains in countries around the world has, in most cases, been traced to logging that left hillsides and entire regions open to erosion. Millions of people have been left homeless around the world in recent years, and thousands have lost their lives to such floods. These floods may be only a prelude to far more serious and long-lasting consequences of forest destruction. Global warming will increase as forests vanish, especially with the cutting of old-growth trees, which have immense canopies for absorbing carbon dioxide and cooling the atmosphere. Higher temperatures have already brought droughts, increased desertification and caused rivers and streams to lose volume and even dry up. The loss of potential disease cures is another byproduct of destroying forests, and the destruction of these beautiful environments, with their multitude of life forms, may result in collapsed ecosystems that cannot be restored.

Forests' Retreat

As recently as 1960, forests covered one•fourth of the Earth's land surface (CEQ 1980). With continued logging

and clearance, two decades later, in 1980, only one•fifth remained forested (CEQ 1980). Since then, forests have continued their decline, losing more than 5 million square miles since 1960. During the last quarter-century alone, the world's forests have shrunk the equivalent of one-half the land area of the United States.

This destruction has threatened thousands of animals and plants with extinction. In fact, forests have the greatest number of endangered species of any ecosystem. Of all types of forests, primary, old-growth forests, especially tropical rainforests, harbor the greatest wildlife and plant diversity and the greatest number of endangered species (Collar *et al*. 1994, Collins 1990, Mittermeier *et al.* 1999a). Second-growth and mixed types of forests are also key habitats for many species, and clearing these forests has threatened thousands of plants and animals.

Forests' Retreat: Page 1

Forest destruction is often gradual, a whittling away by settlers and farmers who destroy portions of forest to grow crops using fislash-and-burn,fl in which trees are cut, set afire, and the ashes are used as fertilizer for subsistence agriculture. In tropical forests, the thin soil is fertile for only a few years, and farmers move on to clear more forests. When human populations are very small, as in the case of the native peoples of many tropical forests, their effects are not severe or permanent, as the forest grows back. Non-indigenous people, however, often remove forest cover permanently**.** They do not think of the forest as a source of life, providing food and protection, as native peoples do. The entire center of the 1,000-mile-long island of Madagascar, once a verdant paradise with giant trees and teeming with wildlife, is now a moonscape as a result of such misuse of the land. Millions of rural people in developing countries now depend on wood cut in local forests for fuel. This has been another major factor in deforestation because of the growth of human populations spreading into new regions, cutting trees and clearing away vegetation.

In the Caribbean, Europe, eastern North America, North Africa and West Asia, most of the original forest cover was destroyed prior to modern times. These forests will not return once cut, nor will their diversity. The ecology and diversity of the forests that once covered much of Europe and the eastern United States will remain unknown because they were cut prior to any biological studies. We have only descriptions of giant trees and the wildlife that inhabited these forests. In the temperate rainforests of the Pacific Northwest, however, biologists are studying the last 5 percent that survives of these magnificent**,** old-growth forests. Working in the canopies hundreds of feet above the forest floor, they are making new discoveries about these ecosystems. They have learned that lichens colonize only the oldest forests and are key to fixing nitrogen (Moffett 1997), or converting this essential gas into compounds that can be used in forming life-sustaining amino acids and proteins (Franck and Brownstone 1992). One forestry student who climbed a 2,000-year-old Sequoia found cones growing only on the outer branches, which can remain on the tree for as long as two decades**;** a rich variety of lichens grow**s** on trunks and branches (Moffett 1997). Such discoveries illustrate the importance of preserving these ancient forests.

Only a little more than a century ago, rainforest and temperate old- growth forest covered millions of square miles

in West Africa, Central and South America, Southeast Asia, Australia and the western United States. Early settlers, followed by commercial loggers and large-scale livestock and agricultural interests, permanently destroyed these complex ecosystems. In some areas, second-growth forest or shrub has replaced them. Only in Amazonia, Central Africa, Russia and northern Canada do large tracts of virgin forest remain, and these are now being logged by international corporations.

Forests' Retreat: Page 2

A major use of timber is newsprint. Every Sunday edition of *The New York Times* consumes 75,000 trees (Bohan *et al*. 1996). Each issue of *Audubon* magazine, published by the National Audubon Society bimonthly, consumes 1,500 trees to make the 150 tons of glossy paper used to print 500,000 copies, according to its own research (Webster 2001). The trees used in the making of this paper were cut after 12 years by a mechanical harvesting machine that periodically clearcuts and replants with only one type of tree, creating an unnatural monoculture (Webster 2001). To remove the cellulose, chlorine is used, which releases .004 pounds of chlorine and chlorine gases into the air (Webster 2001), less than in the past but still an environmental threat. This organization, like many using large amounts of non-recycled paper, claims that the monocultures are teeming with wildlife (Webster 2001) and, by all appearances, does not consider other alternatives for the manufacture of its magazine. Other magazines, such as *National Geographic*, also use unrecycled, glossy paper. By contrast, The Nature Conservancy decided in the 1990s to abandon use of virgin paper for their magazine, even if it meant a less glossy finish, and now prints on recycled paper. Many other conservation organizations have followed suit.

Tropical woods are also used to manufacture paper. With conservation and recycling by consumers in North America, Europe and Japan, no tropical forest trees would need to be cut for paper. The majority of newspaper used in the United States, which is the world™s largest consumer of paper, is thrown into landfills or burned (Bohan *et al.* 1996). Many tree-based products, from shipping crates to plywood and paper, could be made from other materials, both non-wood and re-used wood. Corporations feed a market hungry for inexpensive raw material. The trees are sold for almost nothing by the countries of origin, resulting in high profit margins for logging companies.

Forests' Retreat: Page 3

In the year 1500, tropical forests covered continental and island areas totaling 5.5 million square miles (Collins 1990). Today, only a fraction of this extraordinarily rich ecosystem remains. The estimates of loss vary. Some scientists count only the acreage of untouched pristine rainforest in their estimates, while others include various types of tropical forests, second-growth and disturbed forests. Satellite images, combined with aerial photography and ground surveys, are giving an ever more detailed and accurate picture of the decline of these irreplaceable forests. One reference, *The Last Rainforests*, edited by Mark Collins (1990), calculated that in 1990, only 3.3 million square miles of tropical forest remained in the world. It estimated that about 54,000 square miles were being cleared worldwide every year (Collins 1990). This authority concluded that 50 percent of all tropical forests had been lost since 1900 (Collins 1990). In the disastrous decade of the 1990s, as much as half of the remaining tropical forests were cut or burned. Although estimates of loss vary, there is general agreement that dramatic losses occurred in many parts of the world during the 20th century.

This destruction is taking place at a catastrophic rate. According to Dr. Edward O. Wilson of Harvard University, an expert in biodiversity and tropical forests, the surviving tropical forests equal the lower 48 US states in area, and a region the size of Florida is disappearing each year. The Nature Conservancy (2000) estimates that 40 million acres of tropical forests disappear every year. Settlers in many tropical forests have traditionally practiced slash-and-burn.

The soil is so thin that it becomes sterile after a few years of farming, and the farmers move on, cutting more forest. Such practices whittle away at forests, but when carried out only by small bands of natives, these cut-over acres tend to recover in time. In many areas, however, European settlers have cleared land in this manner and fertilized the soil, maintaining it as agricultural land or depleting it so severely that the forest can never grow back.

Forests' Retreat: Page 4

Cambodia's last expanses of tropical forest are being lost in a pattern typical of many countries. Intensive logging during the past 50 years has reduced forest cover in this country from 70 percent to only 35 percent (Mydans 1996b). In spite of a logging ban instituted in January 1996 and a ban on exporting logs set in place in April 1995, the country's two Prime Ministers signed secret concessions to sell off virtually all of Cambodia's remaining forests (Mydans 1996b). The ancient teak forests are being openly felled, with logs exported to neighboring countries for profits of $10 to $20 million per month and in spite of official pledges to stop this logging (Mydans 1996b). Elephants are used to haul the logs across rough terrain, and many are abused with drugs to keep them working and overloaded, causing serious injuries or death. Some have been maimed or killed by stepping on land mines. Armed guards protect these loggers and sawmill operators; regional forestry officials, who oppose the cutting, are unequipped to confront them (Mydans 1996b). Already, siltation, erosion, flooding, and destruction of agricultural fields have resulted, and Cambodia's King Norodom Sihanouk, who appears helpless to stop this situation, commented, "If this deforestation does not stop, Cambodia will be, alas, a desert country in the 21st century" (Mydans 1996b).

Asian logging companies have now turned to the pristine forests of Belize, the only sizeable forests remaining in Central America. In 1997, the government of Belize sold logging rights to Atlantic Industries, a Malaysian company, for $60 an acre to clearcut in primary, old-growth rainforest**,** principally for mahogany (Hecker 1997). The company logged in areas outside the agreed-upon area and leveled large numbers of Sapodilla trees, the source of chicle that can be tapped sustainably (Hecker 1997). The deforestation of Central America has been most extreme in El Salvador, Nicaragua and Costa Rica (Collins 1990, Harcourt and Sayer 1996). Fires set by settlers and business interests creating plantations for palm oil and tree farms, burned out of control in the late 1990s in Borneo, Sumatra, Bolivia and Brazil, destroying many ancient forests, including some in national parks.

Secret agreements between various government leaders and international logging corporations or with friends and relatives, for logging rights over large sections of forest are commonplace in many countries. Indonesia and Malaysia, for example, encourage destructive clearcuts in which conservation is not a concern, and fast-paced logging is carried out because the agreements may be negated by a change in government officials (Yates 1992). The largest remaining rainforest in West Africa, a 2.5-million-acre swath in Liberia, is being logged by a Hong Kong timber company as a result of a large bribe paid to the brother of Charles Taylor, the newly elected President of the country (Farah 2001). Such bartering away of the world's greatest treasure-houses of biological diversity is a travesty that will adversely affect the Earth's stability and the lives of many generations of people in the future. Lost will be magnificent ecosystems containing plants and animals not even discovered.

Corporate logging has emerged as the major cause of tropical forest destruction, greater even than the losses to settlers and agriculture. This logging is carried on without international controls and with inadequate national controls. This industry grows each year, and the international trade in wood, pulp and paper is now worth about $100 billion per year, making timber the third most valuable natural resource (Bohan *et al*. 1996). Of this total, a large percentage is timber from tropical forests. By the mid-1990s, scientists estimated that some 80 percent of Southeast Asia's--and a similar percentage of West African and Madagascar's--forests had been destroyed. An in-depth study of corporate logging by the Environmental Investigation Agency (EIA) estimated total sales of one of the largest corporations, Mitsubishi, at $5.3 billion in 1995, controlling a total land area of 9 million hectares (22.2 million acres) (Bohan *et al*. 1996). Mitsubishi's plywood mill in the Brazilian Amazon consumes 130,000 cubic meters of logs every

year through the intensive and unregulated harvest of virola trees (Bohan *et al*. 1996). About 75 percent of all tropical forest trees is turned into plywood for disposable packing crates, construction and furniture, according to the Rainforest Action Network (RAN) of San Francisco, California (RAN 1993). The United States alone imports several hundred million pallets of tropical hardwood each year and throws them away after a single use (Revkin 1997).

Forests' Retreat: Page 5

The promotion of a commercial approach to old-growth tropical rainforests, even "sustainable yield," is based on fragmentary and inadequate knowledge of these ecosystems. It is not known with certainty that their trees can be harvested without harm. Sustained yield forestry concerns prevention of the extinction of various tree species by controlling harvest and, to a lesser extent, protecting of watershed and soil, but not necessarily ecosystem protection. Maintaining the complex web of plants and animals that form a forest should be the prime consideration in conservation. To this end, protection from harm is the logical approach until these ecosystems are properly understood. Their ecological value will only be measurable as knowledge about their functioning and their role in the world's climate are explored in the future. In economic terms, they have great potential as tourist attractions, and the new videocam Internet business, as described in the Focus on Indonesia section below, will likely far outproduce short-term income from timber or conversion to agriculture.

An indication of the effects of this destruction is the fact that 76 percent of the 1,186 birds in higher categories of threat, or 902 species, are forest•dwellers, according to *Threatened Birds of the World*, a comprehensive report by BirdLife International, which examines bird status for the *Red Lists of Threatened Species* published by the International Union for the Conservation of Nature (IUCN) (BI 2000). All these birds are in danger of extinction. Some, such as the 182 Critical species, are in imminent danger of becoming extinct. Of the 902 forest birds, 93 percent are native to tropical forests; of these, 41 percent are found in lowland forests and 36 percent in montane moist forests, such as cloud forests (BI 2000). Three-fourths of threatened forest birds are dependent on a particular type of forest, and almost half require near-pristine habitat, with little or no disturbance, or habitat degradation (BI 2000). Only 3 percent of threatened forest birds can tolerate habitat modification. Unsustainable selective logging affects 367 forest bird species, while other threats include clearing forests for small farms (24 percent), tree plantations, clearcutting forest, livestock grazing, cutting trees for firewood, mining in forests and human settlements (BI 2000). An additional 727 bird species are classified as Near-threatened or close to qualifying as Threatened.

Likewise, forests are the major habitat for threatened mammals. The IUCN assigned habitat types to 515 (46 percent) of threatened mammals, finding that about 75 percent inhabited tropical rainforest; of these species, 35 percent in lowland and about 22 percent in montane (Hilton-Taylor 2000). (Some mammals may occupy more than one habitat). Tropical dry forest accounts for another 15 percent; tropical degraded forest, 4 percent; and tropical savannah woodland about 5 percent of threatened mammal habitats. By comparison, temperate broadleaf forest is the habitat for some 4 percent; and coniferous forests, 5 percent of threatened mammals (Hilton-Taylor 2000). The vast majority of threatened frogs and toads are also native to tropical forests.

Many species of tropical trees have been driven to extinction by habitat destruction and the exotic wood trade. The majority of Caribbean islands, which were covered in tropical rainforests when Europeans first saw them in the late 15th century, are now barren. A species of mahogany native to the Caribbean (*Swietenia mahogani*) has been so heavily exploited that no unstunted specimen remains. Elsewhere, once common species of forest plants and animals have been eliminated or endangered. Where habitats were limited on islands such as Hawaii and Mauritius, fragrant sandalwoods and other trees were cleared, and few--if any--specimens remain of the trees that once made up these forests.

Forests' Retreat: Page 6

The Rainforest Action Network has documented that 140,000 mahogany trees are being logged annually, with each tree worth about $1,500 wholesale in the United States, where most are marketed (Line 1996). RAN states that most of the mahogany trees in trade have been illegally logged from parks, conservation areas or other protected lands, causing ecological damage on a large scale.

Mahogany takes 40 years to reach harvestable size, and the majority of this wood that is traded internationally comes from wild harvested trees. Many tropical species have reached commercial extinction, and Honduran Mahogany, which grows to 130 feet with a massive canopy, is the major target of the logging industry in Central America. By having a market for mahogany, especially a lucrative one, loggers seek out these trees, even in protected national parks. Once in commerce, distinguishing legal from illegal becomes impossible.

Trees that are commercially valuable are often the very ones most important to wildlife for food sources or shelter. The largest and oldest trees produce the greatest profits and are the first to be cut. These trees provide nest holes for owls, toucans, hornbills, parrots, tiny monkeys, lorises and galagos, rare lemurs, and countless other wildlife species. Many species of wildlife use tree holes for shelter year-round. Although some birds, such as woodpeckers, can excavate nest holes, the majority of animals who shelter and nest in tree holes depend on natural cavities. These holes form when tree limbs fall off or from rotting within tree trunks. Research on wild macaws has determined that a lack of trees with nest holes plays a major role in limiting their populations. Macaws nest only in large cavities very high, usually 100 feet or more, in tall tropical trees. Only the oldest and largest trees have tree holes for the more sizeable animals, such as hornbills, macaws and families of small primates who den together.

The Harpy Eagle (*Harpia harpyja*), the world's largest eagle, is endangered in its neotropical rainforests. Its range once extended unbroken from southern Mexico through the Amazon but today it is rare or absent throughout the remaining forests. A major factor in its decline is logging of the tall, old trees it requires for nesting. These eagles need a high vantage point overlooking the treetops to spot prey and to prevent predation on their nests. Harpy Eagle chicks have a long period of fledging, and prior to their independence, they must strengthen their leg and wing muscles. Eagle parents always make their massive nests near the top of giant trees with wide branches near the nest where the chicks can exercise by running across the branches, flapping their wings. As the strongest avian predators in these forests, they must be able to kill animals as large as sloths and carry them off in their talons. Loggers spot these giant trees rising over the forest canopy and cut them for the enormous amount of wood they contain. In much of Central America, selective logging and clearcutting have destroyed many of the former haunts of this magnificent bird.

Dead trees still standing are also prime wildlife nests and shelters, but because they are considered fire hazards, they are cut routinely. Hollow limbs and fallen logs are used by many types of animals for shelter or nesting, and these are usually trimmed off by loggers. Rotting tree trunks and cavities in both standing and fallen trees support entire communities of insects and invertebrates, upon which many vertebrates depend for food, and which contribute to the forest's health.

Modern loggers use mechanized tools and machines to clearcut forests. Chainsaws can cut through the massive trunk of a thousand-year-old tree in minutes. For smaller trees, saws mounted on trucks slice their trunks like matchsticks, and machines lift the trunks onto logging trucks for transport, trimming off side limbs in the process. Every tree in a forest, ancient or young, commercially valuable or cut only to be discarded, is logged. Forests covering 1,000 square kilometers have been completely denuded in a single clearcut. Huge processing trucks sweep through the forests, creating deep ruts in the forest floor. Roads are bulldozed for this logging, opening up forests,

causing erosion to soils and flattening fragile plants. Baby birds, squirrels, bats and tiny primates in tree holes are killed as their homes are sent crashing to the ground and dragged along the forest floor.

Forests' Retreat: Page 7

Kitt Chubb, a Canadian wildlife rescuer, recounted the trauma that one family of owls endured as a result of a mechanical logging operation. Tiny Screech Owl (*Otus asia*) chicks, still downy and being fed in their treehole nest by the parents, suddenly found themselves slammed to the ground when the tree was cut. A giant logskidder machine roared through the woods gathering up the cut trees, including the one containing the owl chicks (Chubb 1995). The machine proceeded through the woods, bouncing and violently rocking over rocks and ruts. This cacophony must have terrified the owl chicks. Finally, the driver dumped the trees with a crash onto a pasture (Chubb 1995). Soon after, an employee with a chain saw began to cut up the trunks, and as he cut into a big knothole, he jerked the saw back when he saw three fuzzy grey owl chicks with their eyes closed tight (Chubb 1995). Amazingly, they had not been injured or killed after being knocked and bounced about. The loggers decided to save the little Screech Owls, bringing them to Chubb's wildlife rescue center. She placed them in a wooden box and returned with the box the next day to the spot where their nest tree had stood. The forest where the owls had lived had been obliterated, and not a single tree remained. Finding a hollow beech stump in the clearcut not too far away, she and fellow rescuers placed the box in the stump, covering the top with leafy branches for shade, hoping the parents would return to feed the chicks (Chubb 1995). The next day, Chubb was surprised to find a frog leg in the box with the chicks, left by a parent owl. The chicks were lively and vocalizing, and 10 days later, they were still healthy and ready to be banded (Chubb 1995). Unfortunately, few baby birds and other animals survive logging operations or are lucky enough to be rescued if found alive.

Even animals as large as bears are frequently killed when they den in large tree holes. If their cubs survive, they will die of starvation if not rescued. Numerous cases of logging operations orphaning or causing mothers to abandon bear cubs are documented each year. A National Geographic Society film, fiMother Bear Man,fl shown in 1998 on "National Geographic Explorer," told the story of three bear cubs found after logging operations and their long return to the wild under the care of a kind and experienced wildlife rehabilitator in New England. Turtles, rodents, snakes and ground birds sheltering in burrows can be crushed to death by heavy logging machines. The soil, no longer held in place by root systems, breaks loose when saturated by heavy rains. Severe erosion on hillsides can cause mud slides that swallow up houses and the forest below, leaving a virtual moonscape, devoid of life. On level areas, rain washes soil into streams and rivers, clogging them, which kills fish and other aquatic lifeforms. Beautiful tropical forests with 300 or more species of trees per acre, a typical diversity, and myriad species of birds, mammals, reptiles, amphibians and invertebrates inhabiting them, become denuded patches of bare soil interspersed with stumps and broken limbs after clearcutting.

Even in remote wildernesses, the heavy machines that are now used to harvest and transport trees create such havoc and noise that wildlife flees. Many species of rare primates and birds disappear from logged forests, unable to adapt to any logging activities. A recent study in Gabon found that selective logging operations so traumatized Chimpanzees (*Pan troglodytes*) that their population in one 2,000-square-mile reserve fell by 80 percent after logging, even though only 10 percent of the trees were cut (Stevens 1997a). Dr. Lee White, a biologist with the Wildlife Conservation Society in New York, who was studying these Chimpanzees, made the following observation when loggers were in the forest: "I had whole chimpanzee communities charging to about five meters and screaming at me, and that's very unusual behavior" (Stevens 1997a). They were observed in logging areas in extremely agitated states, drumming on trees and calling to each other. The tremendous noise and disturbance by large machines apparently caused them to flee into the territory of neighboring Chimpanzees, where they fought to the death (Stevens 1997a). Both the Chimpanzee and Bonobo, or Pygmy Chimpanzee (*Pan paniscus*), are endangered species, and the latter is unlikely to survive much longer in the wild as a result of logging. Its tiny population inhabits a restricted portion of

forest in the Democratic Republic of the Congo, the former Zaire. Both are also killed in large numbers for meat markets by loggers and hunters, who use logging roads to enter forests. The traumatized orphaned young are sold as pets and to others who exploit them commercially.

Forests' Retreat: Page 8

Many of the last old-growth forests have been cut for throwaway products such as shipping crates, concrete forms, plywood, chopsticks and newsprint. Virgin rainforests in southeast Asia, Australia, Alaska, Russia and British Columbia are being logged to supply the enormous demand for such products, destroying entire ecosystems in the process. The United States and Japan have played major roles in the logging and trading of lumber at extremely low prices for industrial uses (Yates 1992). When one country's forests are stripped, loggers move on to another. In this way, the great Philippine forests of Pliocene trees and Central American forests were cut in the mid-20th century, followed by the teak forests of Thailand and the hardwoods of Indonesia and West Africa. These areas have lost 80 percent or more of their forest cover, and loggers have now moved on to Central Africa, Burma, Belize and Amazonian South America. Brazil's beautiful rosewood trees have already been logged to near extinction. The World Conservation Monitoring Centre of Cambridge, UK, conducted a study on commercial logging and found that 304 tree species from Asia and Africa were threatened with extinction by trade (Bohan *et al.* 1996). Fifteen species of commercially logged trees are listed by the Convention on International Trade in Endangered Species (CITES) in the most endangered category.

In response to criticism about clearcutting, some logging companies and conservation organizations endorse selective cutting, or cutting only certain species of trees or trees of a certain age. Yet such logging is also destructive. One United Nations (UN) Food and Agriculture Organization (FAO) study found that selective cutting destroyed as much as 70 percent of forest cover when conducted totally irresponsibly and, on average, destroyed 30 to 40 percent of the trees (Bohan *et al*. 1996). Destruction of non-target trees occurs with the construction of logging roads and use of heavy equipment to extract trees; when tree canopies and vines entangle one another, many trees are brought down, although only one may be cut. A study in French Guiana found that an average of 57 trees are killed for every tree extracted by selective logging (Bohan *et al*. 1996). Research on logging in Sarawak, a Malaysian state on Borneo, found that of every 26 old-growth trees cut, 33 others were destroyed or damaged, and canopies were broken, isolating animals who will not cross open spaces (Yates 1992). The thin tropical soil was also compacted and exposed, preventing natural regeneration of the forest (Yates 1992).

Many logging companies claim that by cutting mature trees selectively on 30- to 70-year rotations, they are conserving forests (Collins 1990). By definition, no tree older than 70 years can exist in such a forest. Such logging will end in destruction of the ancient and diverse forests, with trees 1,000 or more years old harboring a wealth of species that can only grow and prosper in old-growth forests. The more diverse a forest, the more stable ecologically, and logging tends to impoverish diversity by selectively removing certain commercially valuable species.

Thousands--and perhaps millions--of species depend on primary, virgin forests and cannot adjust to second-growth or logged forests. How many, and which species they are, however, is only partially known. Even scientists specializing in forest wildlife have not determined all the species that fall into this category, especially in complex tropical forest ecosystems. Unfortunately, this knowledge is often acquired too late, after logging has taken place and endemic species have disappeared. Logging operations are proceeding with such speed, and the scientists chronicling the damage are so few in number, that in terms of threats to plants and wildlife, only the tip of the iceberg is being documented.

Forests' Retreat: Page 9

Until the 1970s, no one knew what the effects of clearcutting forests would be on various species of rainforest wildlife. The US government's Smithsonian Institution, with ornithologist Dr. Thomas Lovejoy supervising, conducted the first scientific studies of the effects of forest destruction in the Amazon on a wide range of wildlife. Blocks of interior forest of various sizes were inventoried by teams of biologists with mist nets and live animal traps. After each inventory was completed, the blocks were isolated by clearcutting the forests surrounding them. Then, after a period, they were inventoried again to discover the effects of clearcutting on the wildlife in the newly isolated forest patches. This type of research aims to discover how large reserves must be to preserve the diversity of ecosystems.

The results of Lovejoy's research in Amazonian primary forest indicated that small reserves of 2.5 acres or less lose a large percentage of their wildlife, and the larger the reserve, the fewer the number of species that disappear (Lovejoy *et al.* 1984). Certain species are dependent on large areas of primary, old-growth forest and are quick to disappear as soon as forests are disturbed or fragmented. Bird populations tended to decline in most reserve sizes, and species composition changed. In the smallest plot, 39 species of birds dwindled to 18 species after three years, and in the larger plot of 25 acres, 48 species declined to 38 (Lovejoy *et al.* 1984). The understory species were censused, as opposed to the canopy birds which seem less vulnerable to fragmentation of forest. Ecological dependencies caused some extinctions. For example, army ants thrive in large areas but disappear from smaller ones, and birds that feed on these ants, such as antbirds which are diverse and numerous in primary forests, disappeared within a short period from smaller plots (Lovejoy *et al*. 1984).

In another chain reaction, the White-lipped Peccary (*Tayassu albirostris*) proved to be a keystone forest species. It digs small waterholes to wallow in when ponds dry up, providing habitat for other wildlife. Peccaries travel in large groups seeking their diet of fruits, especially palm fruits, and act as seed dispersers. The key to their survival is territory size: a herd of 100 animals requires a territory of 97 square miles (Fragoso and Silvius 1995). They disappear from smaller forests causing the local extinction of frogs, who lay their eggs in these waterholes. In the Amazon study, four species of frogs disappeared from areas where peccaries had insufficient habitat to survive (Lovejoy *et al*. 1984).

Many other mammals are affected by forest fragmentation. Twenty species of mammals occupied a large, undisturbed forest plot, while only five were left in an isolated 25-acre-forest; a mere three mammal species remained in a 2.5-acre-forest (Lovejoy *et al*. 1984).

Theoretically, extinctions also can be caused when species have limited distributions which are destroyed by logging. A number of birds and mammals, including several newly discovered marmoset species in the upper Amazon forests, inhabit extremely restricted ranges of only a few square miles. Some species of primates will refuse to cross a road, such as a logging road, or an open clearing. Should a road be built in the middle of their tiny ranges, they would face extinction. Since tropical forests have not been thoroughly inventoried, the endemic species at risk most probably number in the tens of thousands.

Butterflies that live only in deep, virgin rainforest are so intolerant of fragmented forest that they disappear from areas less than 250 acres and, even there, survive only in the central core area (Laurance and Bierregaard 1997, Lovejoy *et al.* 1984). Forest butterflies, which exist in amazing diversity, are highly sensitive to the disappearance of their host plants, upon which they lay their eggs, and thrive in greatest number when vegetation is highly diverse. Some cannot tolerate the penetration of light into forests, and others require such large territories to feed that they disappear from small reserves, according to research by Keith Brown and Roger Hutchings (Laurance and Bierregaard

1997).

In small forest blocks, trees on the forest edge become vulnerable to the effects of wind and fire, fall in far greater numbers than those in the center and succumb to fires that spread from neighboring grasslands. Fires consumed large areas of rainforest in the Amazon during the late 1990s as a result of fragmentation. This was the first record of rainforest fires in this region. Storms blow down trees adjacent to the edges of fragmented forests and, over a period, will destroy the inner primary forest (Lovejoy *et al.* 1984).

Research on forest fragmentation is now taking place in Africa, Asia, Australia, the Indian Ocean islands and elsewhere in the world. Numerous scientific papers on the subject were gathered in a book entitled *Tropical Forest Remnants. Ecology, Management, and Conservation of Fragmented Communities* (Laurance and Bierregaard 1997). Many of these studies paint a grim picture of the effects of forest fragmentation on biodiversity.

Bats are important forest pollinators but are extremely vulnerable to extinction. They are rarely protected and often persecuted. The valuable Durian fruit of Asia is one such plant pollinated by a declining species of rainforest bat. Other food plants pollinated by bats include wild bananas, breadfruit, mangoes, guavas, avocados, almonds, cashews and cloves, according to Bat Conservation International, which is dedicated to changing the negative image of bats and preserving wild populations (see Organizations list for address).

Forests' Retreat: Page 10

Throughout the world, biologically diverse natural forests are being replaced with tree farms of fast-growing pine or eucalyptus. In Japan, cedar is planted over millions of acres for harvesting. The goal of these farms is to replace old-growth forests that take hundreds of years to mature with trees that can be harvested in 30 to 50 years. Large amounts of herbicides and pesticides are applied to prevent the growth of "undesirable" plants and to control insects. These tree farms have contaminated water tables, destroyed natural diversity, and eliminated countless life forms crucial to maintaining the ecological balance of the planet. Moreover, many are now failing even in their goal of producing fast-growing, healthy trees because of a lack of understanding of ecological systems and natural forest functioning. Tree farms are frequently swept by disease and, in the case of Japan's cedar plantations, which cover 10 million acres, shallow roots have resulted in trees blown over in windstorms and landslides after heavy rains. A healthy forest has many species of trees. This diversity discourages insect pests, which tend to specialize in individual species, from spreading and sweeping through the forest, killing all the trees. The variety of trees in a natural forest also means that many are deep-rooted or have root mats that anchor the soil from erosion.

An added environmental threat posed by tree farms is the use of genetically engineered seedlings, whose effects on ecosystems are not yet known. By transplanting genes from other species of trees--and even animals-- into these unnatural trees, the possibility that their seeds could spread to the wild and contaminate natural trees and plants is very real.

Major disruptions in pollination occur in fragmented forests. Natural tropical forests, with hundreds or even thousands of species of trees, have evolved complex systems of reproduction. Because other trees of the same species might be miles away, trees send their pollen far and wide. Insect pollinators travel great distances to find trees of the same species. Biologists have found that even in selectively logged forests, trees were not being pollinated naturally because others of their kind were removed or became too distant; some species self-pollinated, causing in-breeding, while others simply died out (Yoon 1995b). These biologists concluded, "Even the forests that appear the healthiest but are being selectively logged or otherwise thinned may be endangered in the long run by an increase in less desirable inbred seed" (Yoon 1995). Inbred stock usually loses vigor and ability to reproduce over the long run. This is an ominous finding considering that many conservation organizations and international logging companies have

endorsed certain "sustainable" logging programs, urging the public to purchase products identified as such. Moreover, many of these ancient trees tower 200 or more feet, with wide buttresses at ground level to anchor them in the thin tropical soil. Such trees may have stood on the forest floor for 1,000 years and are living monuments, treasures to be preserved, not raw material for packing cartons, furniture or paper pulp.

Preserving Forests

A 10-year mapping project by the World Conservation Monitoring Centre ending in 1996 found that only about 6 percent of the world's remaining forests are protected against logging and development. Because of the rate of destruction and the potential loss of biological diversity, this is an extremely critical situation.

Preserving Forests: Page 1

Much of the logging in the world is a result of markets provided in the United States, Japan and Europe for wood and wood products. Because paper pulp is cheap, there is little effort to find substitutes or even to recycle the millions of tons of paper thrown into landfills each year. The use of trees for making paper is government-subsidized, encouraging waste and destruction of forests. Tree farms have failed to meet the enormous demand for paper. Financial incentives to recycle or use other materials should be made by consuming countries. Finding substitutes for lumber and raw material for paper will be crucial in protecting entire forests. The United States imports 800 million pounds of paper from Brazil every year, to the detriment of that country's forests. In spite of computers and Internet communications, total amounts of paper used in the United States have not decreased; 4.3 million tons of paper are used in US offices alone each year, and millions more tons are used in newsprint, magazines and other paper products. Because of a lack of economic incentive, only a small portion of this paper is being recycled into new paper. In fact, studies of landfills have shown that 40 percent of material in these dumps consists of unrecycled newspapers.

Innovative approaches are needed to encourage recycling and to end subsidies and the importation of wood chips and newsprint from forests around the world. Some of the alternatives to paper made from wood are already in use. Thousands of years ago, Egyptians produced paper from papyrus reeds, and rice is still used to make paper in parts of East Asia. Cotton and flax are the raw materials of fine quality paper used for currency and other purposes.

Many other plant species are now seen as substitutes for wood pulp in making paper. In *A Wealth of Wild Species, Storehouse for Human Welfare*, Norman Myers (1983) mentions one of these, a plant called kenaf, that is a distant relative of cotton and okra. This plant has been cultivated for centuries in Asia for making burlap bags. A fast-growing, reed-like plant, kenaf shows great potential in the manufacture of paper. Its straight, slender stem has no side-stems, nor does it produce the kind of resins that must be eliminated when wood pulp is processed for paper. Planted like corn, it is ready for harvesting in four months and produces five times more pulp per acre than a pine tree plantation (Myers 1983). In research conducted by the US Department of Agriculture, kenaf has proven an excellent substitute for paper in newspapers and even bank notes (Myers 1983). A few kenaf farms have been established

without government sponsorship in Texas and other southern states, and already many organizations are printing newsletters using kenaf instead of wood-based paper. Processing kenaf does not involve the serious water pollution caused when cellulose is removed from wood and pulp is bleached with chlorine. Air pollution from wood pulp processing plants has been injurious to human health (Verhovek 2000).

Earth Island Institute of San Francisco, California, has published a report, *Forest Friendly Paper Guide*, giving more information on kenaf and other non-tree substitutes for paper, including a new paper product by Arboken of Canada that is made from wheat straw, recycled corrugated cardboard and calcium carbonate filler. A publication called *Guide to Environmentally Sound Papers*, issued by an organization called Conservatree, lists more than 400 types of "green" paper. Among these are recycled, kenaf-based, hemp, sugarbeet and corn, grass and crop waste paper. (These can be obtained from Earth Island Institute. See the list of organizations in this book for the address.)

Preserving Forests: Page 2

Most homes are constructed of wood. An average of 40 to 50 trees are needed to build a 2,000-square-foot wood-framed house (Bielski 1996). Building with stronger materials, such as steel, concrete, brick and stone, would spare millions of trees. Moreover, these materials are not vulnerable to infestations by termites, which destroy entire foundations and frameworks of buildings made of wood. To control these insects, pest control companies apply large quantities of extremely toxic pesticides that can leach into the soil and water table, killing wildlife, and pose hazards to the occupants of the house. The Institute of Ecolonomics in Ridgeway, Colorado, reports that a new tree-free "wood" has been developed for use as building material. Called BioComp, it contains half recycled plastic and half agricultural residue and, according to the Institute, is twice as strong as Douglas Fir, termite-proof, impervious to water, and can be made fire retardant. BioComp resembles wood and is easily molded, sawed and nailed. Some alternatives to wood are also less expensive. Steel is being used in New England homes for major support beams with a metal roof for less money than the same home would cost made of wood (Hotton 2001).

The Wood Reduction Clearinghouse has been formed in San Francisco to address the failure of considering consumption as a driving force in deforestation (Bielski 1996). A group of leading environmentalists issued a statement in 1995 calling for a 75 percent reduction in wood and paper use by 2025, and strategies for eliminating the need for wood altogether are being explored (Bielski 1996). The use of timber for shipping crates and concrete molds--especially tropical hardwoods--should be phased out and substitutes, such as plastics, phased in that would be more economical because they could be reused. Some stores are already using substitutes for the millions of cardboard cartons used to ship goods.

Preserving Forests: Page 3

At the 1992 "Earth Summit" in Rio de Janeiro, Brazil, convened by the United Nations Conference on Environment and Development, world leaders agreed on the importance of slowing the rate of global forest destruction. Conservationists have pressed for a new, legally binding Global Forest Agreement to conserve and manage the world's forests. In spite of the urgent need for such an international treaty, no agreement has been reached in the intervening years. Numerous meetings and conferences between nations have failed to draft a policy that would curtail the uncontrolled commercial logging that is ravaging forests around the world.

Several organizations, including the Environmental Investigation Agency (EIA), headquartered in London, and the World Resources Institute (WRI) of Washington, DC, have issued reports that chronicle the damage being done and

the need for such a treaty. EIA's report, *Corporate Power, Corruption & The Destruction of the World's Forests, The Case for a New Global Forest Agreement*, argues for the need for international agreements to control commercial logging (Bohan et al. 1996). This report gives detailed information on the companies doing the most environmental damage to the world's forests and the methods used by these corporations to bribe and otherwise corrupt the leaders of poor nations to obtain logging contracts. Other organizations, such as the Rainforest Action Network, agree that international logging corporations must be regulated. This $100-billion-a-year trade operates with generous tax breaks from the countries where companies are based and the granting of logging concessions that often cover millions of acres through special arrangements made behind closed doors with government officials (Bohan *et al.* 1996). Logging concessions almost always ignore or overrule strict legislation already existing in many countries protecting the environment and wildlife, including endangered species (Bohan *et al.* 1996).

At present, cutting of forests is "regulated" only by the timber industry itself through the Tropical Timber Agreement, signed in 1983 by various international lumber companies. This agreement does not protect wildlife and the environment. In spite of renegotiation in the mid-1990s, the agreement still does not address ecological concerns or species preservation. Pressure from multi-national companies, primarily Japanese, to supply this lucrative market have overwhelmed the voices of conservationists throughout the world.

Logging in Central Africa is in the process of destroying the once vast and unspoiled forests. A conference in 1999 was convened by the World Wildlife Fund (WWF) to reach an agreement about the fate of these large tracts of tropical rainforest in Africa, located in Cameroon, Central African Republic, Gabon, the new Democratic Republic of the Congo, Equatorial Guinea and the Congo. In this region, 40,000 square kilometers of forest are being destroyed a year, endangering hundreds of wildlife species and opening up the forest to a devastating trade in bushmeat. Prince Philip, in speaking on behalf of WWF, stated that the organization hoped to protect 10 percent of this vast forest, an area too small to prevent extinctions and great biodiversity loss. The Democratic Republic of the Congo, which is in a state of political chaos, did not attend the conference, and no pact was signed.

Preserving Forests: Page 4

The forests of the Democratic Republic of the Congo are among the wildest and least explored in the world, but this wilderness is being invaded by loggers and meat hunters. Michael Fay, a biologist with the Wildlife Conservation Society in New York, has been on a mission to cross this vast area on foot, accompanied by some natives and correspondents, describing the amazing sights along the way. He is trying to draw attention to this region and the urgency of saving it while most of it is still in pristine condition. He has already succeeded in having a sizeable national park established. His trek is dangerous, with poisonous snakes, leeches, tropical diseases and other threats, but he is a dedicated conservationist and scoffs at the dangers. The National Geographic Society is helping to sponsor his trip and publishes regular articles in their magazine on his progress, and their website gives more information. Several short films have also been made for the National Geographic fiExplorerfl program. His mission is extremely important and has the potential of preserving entire ecosystems of threatened animals and plants.

A growing awareness of the problem, along with creative solutions, give hope that in at least some parts of the world, large tracts of tropical forests and their wildlife will be spared. Two enormous parks were established in Suriname and Bolivia in the 1990s, mainly as a result of the work of Conservation International, a US organization that successfully convinced the governments of these countries that such protection will be far more beneficial for the country than short-term exploitation and forest clearance. Other organizations are working effectively in central Africa, Peru, Brazil, Burma, Laos, Vietnam, and the Philippines to protect these species-rich forests.

New approaches to deriving funds from forests without logging and destroying diversity include regulated extraction of non-wood products, such as seeds, fruits and plants, for food and medicinal purposes. Ecotourism is one

of the most lucrative and growing industries in the world, with revenues in the billions of dollars and rising.

Old-growth forests are being cut not because they provide raw material that cannot be found elsewhere, but because they provide a high profit margin to European, North American and Asian logging companies. Decisions made about the fate of these forests, upon which the survival of so many species depends, are not being made by the people where logging takes place, nor by conservationists. These precious and irreplaceable resources, habitat of the majority of the world's threatened species, are being sold to logging companies for pittances. The United Nations has recently endorsed the concept that forest diversity must be maintained, joining the ranks of many other international organizations. In time, society may learn to preserve these storehouses of evolution with the same zeal that great works of art are protected.

Preserving Forests: Page 5

One project has greatly improved the standard of living for villagers in India, while taking steps toward protecting the forest habitat of the highly endangered Bengal Tiger. Many thousands of residents were forced to move when Ranthambhore National Park was established decades ago, causing much resentment. At first, they were banned from gathering firewood and grazing livestock within the park. This had an extremely positive effect on the forests, which regenerated, and Tigers, deer and other wildlife prospered. Gradually, however, park authorities became more tolerant of the incursions of local people and their livestock into the forests. During the 1980s, large areas became deforested, and poaching endangered Tigers and deer within the park.

To reverse this trend and preserve the habitat of this park's wildlife, a Tiger conservationist and author, Valmik Thapar, established the Ranthambhore Foundation. This Foundation sponsored a nursery which propagated 500,000 tree seedlings, employing villagers to replant the national park. It set up a farm with domestic buffalo which had been bred with milk cows and kept in stalls and enclosures away from the forests. These animals yield far more milk than the emaciated Indian cows overgrazing the forests; fuel for cooking and heating is provided by a bio-gas plant producing methane from the buffalo's dung; a new crafts industry employs women in the village (Ward and Ward 1993). In the first four years of the project, 6,000 school children from local areas were taken into Ranthambhore National Park for education programs (Currey 1996).

A Cable News Network (CNN) reporter, Gary Streiker, visited one of these farms outside Ranthambhore National Park in mid-1997. The villagers were economically better off and appreciated having the bio-gas fuel, which saved them the effort of scouring the landscape for firewood, often a full-day's activity. This allowed them to devote time to crafts and other small businesses. Unfortunately, some of the other villagers around the park were still gathering wood, denuding the park. These age-old customs will be difficult to change. Eco-development and conservation projects in 60 villages surrounding Ranthambhore National Park have been launched. Conservation education on the importance of saving the forests will help to change attitudes and protect the park's wildlife and trees. This will bring tourists and new sources of income.

Preserving Forests: Page 6

Several remarkable successes have proved a positive contrast to the otherwise gloomy trends of forest destruction. In South America, large expanses of undisturbed tropical forest remain, but they are fast disappearing. The Amazon Basin and its forests once covered 2.3 million square miles, comprising three•fourths of the world's tropical forests, but forest clearing has destroyed some 20 percent of the original forests and damaged far more. Amazonian forests contain 14,000 endemic species of plants (Harcourt and Sayer 1996).

Parque Nacional Madidi, Bolivia's newest national park, covers 4.7 million acres, protecting a variety of threatened habitats and species. Avian diversity for this park is estimated at 1,088 species of birds, or 11 percent of the world's birds, the highest in any protected area in the world; among these are many threatened species and others with small ranges (Remsen and Parker 1995). This park, watered by numerous rivers, borders eastern Peru and includes a variety of threatened environments. Humid lowland forests, grasslands and montane cloud forests are among these. Resident birds include the threatened Yellow-rumped Antwren (*Terenura sharpei*) and various species of tinamous and curassows (Remsen and Parker 1995). The latter birds are among the first species to disappear from areas as a result of hunting and habitat destruction. A proposed hydroelectric dam, which would drown large sections of rich lowland forests., is a major threat to the park. It may have been stopped as a result of publicity by *National Geographic* magazine, which featured a cover story in 1999 on the importance of saving this park. Public opinion and the potential tourist trade may compensate this country for lost revenues from the dam. An even larger park of 8.6 million acres along the border with Paraguay, the Kaa-Iya del Gran Chaco National Park, protects the most sizeable block of endangered dry tropical forest in the world (Seve 1996). These two parks will preserve more than 20,000 square miles, and native tribespeople will play a role in administering them (Seve 1996).

Another positive development is the trend in a growing number of countries to share the profits from national park fees with local people and involve them in the decision-making processes of managing the park and the local wildlife. Madagascar has been successful at this, combining income from park fees with international grants to build schools, libraries and clinics for the local people. Patricia Wright, a primatologist, helped establish Ranomafana National Park to protect endangered lemurs as well as to protect the watershed from floods. In the recent past, deforestation carried out by local villagers had caused landslides that inundated their homes and caused water sources to dry up. They have become convinced of the importance of preserving the forests for their own survival. This new approach of educating local people on the benefits that would accrue to them as a result of conservation, as well as payment from park fees and profits from ecotourism, is the future of forest preservation.

Another trend that will prove important is the involvement of biologists studying wildlife with local people, learning from their observations and sharing the knowledge they uncover. Biologists in Madagascar who rediscovered an owl thought extinct, brought local students to see it and raised money for needed school supplies from birdwatchers who came from around the world to see the bird. This creates a positive impression on the local people and instills natural history curiosity and a realization of the uniqueness of their own wildlife. In the future, this may be expanded by showing them films about the natural world that surrounds them and opening up new worlds with books and publications about the subject. Very few people are aware of the endemic wildlife and plants in the environments in which they live, whether in the United States or the Cameroon. When people learn of the flora and fauna in their neighborhood that exists nowhere else, or is of biological importance, they are far more likely to protect it. Even in the United States, where Natural Heritage Programs chronicle the endemic and declining species of every state, the information has not always been made available to the public in the form of state publications or television or newspaper publicity that could have a major effect on whether forests and other habitats are protected.

A recent campaign to alert the public to the ecological advantages of choosing shade-grown, organic coffee has helped preserve rainforests in many parts of the world. A trend toward planting coffee plants in open fields rather than in the traditional way, as an understory to tall trees, has been devastating to tropical forests, home to both tropical birds and other animals, and to migratory birds from North America who spend the winter in Latin America and the Caribbean. Smithsonian biologists began this campaign in 1990 when they saw bird species decline with the planting of sun-grown coffee plants, and patented the logo "Bird Friendly" coffee. Such coffee is now commonly sold in health food and specialty stores and may become more popular as the public is educated about the problem. With the enormous popularity of coffee, this could make a major difference to birds and other wildlife.

North America™s Forests

The history of the destruction of all but 5 percent of the 850 million acres of old-growth forests in North America has been recounted in Chapter One. Second-growth forests now dominate the East, forests far different in species composition from the original virgin forests. The great chestnuts, elms and beeches are gone, and woodlands are now young, mixed pine and hardwood. Moreover, these forests are fragmented by roads and development. Only a few roadless areas remain. A few remnants of old-growth forests have been located in the East, primarily on steep slopes and areas that loggers found difficult to reach. In southern Maine, for example**,** a biologist recently located a stand of Black Gum trees, some 9 feet in circumference. One stump had 450 rings, and another, larger one was still thriving. It was estimated to be more than 500 years old, dating back to the time of Columbus. Unfortunately**,** this area is in the path of development (BG 2000). The Great Smoky Mountains National Park is a large block of forest totaling 500,000 acres in the southern Appalachians of eastern Tennessee and western North Carolina. This national park harbors some virgin old-growth and a wealth of rare native trees, plants and wildlife, including a great diversity of salamanders that inhabit its damp, mossy forest floors and fast-flowing streams. It sits atop a mountain range that is a meeting place of northern and southern species, an important area to the endangered Appalachian forest ecosystems and a primary migratory stopover and nesting area for threatened wood warblers and songbirds. This area recently has been designated an International Biosphere Preserve, and its diversity is being inventoried by a team of biologists and other earth scientists.

North America™s Forests: Page 1

Migratory songbirds of eastern forests have declined by at least 45 percent in the past 50 years. These dazzling migrants--wood warblers, vireos, tanagers, orioles, grosbeaks and thrushes--suffer from a variety of threats. Deforestation of tropical forests where many of these birds spend the winter has been a major factor. Species requiring mature, undisturbed forest have declined to the greatest degree, some losing up to 90 percent of their populations. Clearcut logging and fragmentation of their breeding forests by housing, malls, roads and other

development have consumed millions of acres, displacing these songbirds. Many birds returning from tropical wintering grounds find their breeding forests destroyed or too small for successful breeding. A small patch of woods large enough for only one male songbird, surrounded by agriculture or development, will be abandoned if the male is unable to hear the songs of neighboring males (Line 1995). Many birds establish territories and maintain them by singing and challenging other males.

Another effect of forest fragmentation has been the proliferation of forest edge species that prey on songbirds and their eggs (Terborgh 1992). The Brown•headed Cowbird (*Molothus ater*), a parasitic species, was once seen only in grasslands. In the past, when huge herds of American Bison roamed the prairies of the Midwest, cowbirds accompanied them, laying their eggs in the nests of grassland birds, who raised them as their own. With the disappearance of the Bison, cowbirds entered the forests bordering agricultural and pasture land, laying their eggs in songbird nests. Some cowbirds now remain close to domestic cattle and fly into the nearest woodland to lay their eggs. Their eggs usually outnumber those of the host species, and the large chicks instinctively nudge the small songbird nestlings out of the nest. Because of the increase in forest openings, the net result of these losses has been a 90 percent decline in the number of songbirds recorded in the 1940s in many eastern forests (Terborgh 1992).

A campaign to declare a large section of the forests in northern New England a reserve began in the mid-1990s. To add urgency to the need for a national park in Maine, New Hampshire and Vermont, a new species of thrush, native only to this region, has been discovered. Once considered a subspecies of the wide-ranging Gray-cheeked Thrush (*Catharus minimus*), Bicknell's Thrush (*Catharus aliciae*) was found to be a totally distinct species in 1995, smaller and with a unique song. A bird of high altitude forests, it has already disappeared from its only nesting area in Massachusetts, Mt. Greylock. The major breeding area for Bicknell's Thrushes is now Vermont, whose forests are under pressure from ski developments and proposed wind turbines. Additional populations of fewer than 3,000 birds inhabit neighboring southern Canada, but the traditional practice there of thinning forests renders these forests unsuitable. Its habitat of spruce-fir forests is dying out from acid rain and global warming (BI 2000). This threatened bird is also losing habitat in its West Indian wintering grounds, especially Hispaniola, where forests are being cleared (BI 2000).

Another member of the thrush family is declining toward extinction. Known for its melodious, fluted song, which many find more intricate and beautiful than the Nightingale's, the Wood Thrush (*Hylocichla mustelina*) has declined precipitously in recent years. Native to undisturbed hardwood and mixed forests in eastern North America, the Wood Thrush winters in Central America, from southern Mexico to southern Panama (Rappole *et al.* 1983). In August, these birds begin their southerly migration, often gathering in groups where the chorus of 50 or more Wood Thrushes may echo like a cantata in the tall trees. One research project studied these birds in one of their tropical wintering areas in the Tuxtla Mountain region of southern Veracruz, Mexico, on the Gulf of Mexico. Studies of this population of birds began in the mid-1970s when the wintering habitat consisted of primary rainforest. (Rappole *et al.* 1989). This forest has declined by 85 percent, a far higher percentage than elsewhere in Central America, leaving mere fragments of the once rich tropical rainforest (Rappole *et al.* 1989). In 1980, the two researchers returned to find that their 12-acre rainforest study plot had been converted to a patchwork of fields and forest fragments; less than 5 acres remained of the original forest (Terborgh 1989). Using radio•tracking and mist netting, researchers discovered that Wood Thrushes do not adapt to forests without tall trees, even as a wintering area, preferring undisturbed rainforest. Year after year the same individual birds returned to the same sites. In rainforest, they tended to survive the winter, while Wood Thrushes forced to winter in neighboring second-growth or disturbed forest had a high mortality rate from predators and other causes (Rappole *et al.* 1989).

Throughout their winter range, the forests that once harbored tens or perhaps hundreds of thousands of Wood Thrushes in Mexico and Central America have been turned to pastureland or tilled for agriculture. Between 50 and 70 percent have been destroyed (Collins 1990). Fewer and fewer Wood Thrushes return to nest in Eastern forests, even when they have not been fragmented or cleared (Terborgh 1989). Their nests have also been vulnerable to parasitism by Brown-headed Cowbirds (Terborgh 1989). In Illinois, for example, where Brown•headed Cowbird populations have skyrocketed in past decades, one study found that 29 of 30 Wood Thrush nests had been parasitized by

Brown-headed Cowbirds, who laid eggs that crowded out those laid by the thrushes; the conclusion of the study: "Wood Thrushes are doing nothing but raising cowbirds" (Terborgh 1989). In the few areas where forests are unbroken and extensive, Wood Thrushes have been successful breeders (Robinson 1996).

Unfortunately, the combined effects of habitat destruction in both its breeding and wintering grounds, and parasitism of its nests by cowbirds, may result in the extinction of the Wood Thrush. A recent study in several Midwestern states found that birds from large stretches of forest that are holding their own may be having young that disperse to neighboring forest fragments, only to be crowded out by cowbirds (Robinson 1996). The melodic Wood Thrushes are disappearing throughout their range, along with many other beautiful songbirds.*

---

*See Video section. fiOn a Wing and a Song,fl a Canadian Broadcasting Co. film produced in 1994 for The Nature of Things series, explores the decline in songbirds. Another excellent film on the same subject with a similar title, fiOn a Wing and a Prayer,fl produced in 1995 by Kurtis Productions and WTTW for the PBS series New Explorers, concentrates on the decline in breeding songbirds of Illinois and their migrations.

Other changes in environments also contribute to songbirds' declines. Recent research has found that high levels of noise from highways, airports and other man-made activities have interfered with the ability of birds to sing breeding songs and breed successfully. Birds that migrate to the Caribbean and Latin America suffer high mortality from collisions with television and cellphone towers and tall buildings. For many years, one scientist at Chicago's Field Museum has collected migrating songbirds that died from flying into a single building near the museum**.** His collection now totals 20,000 birds. He estimates that total mortality from building collisions may be 60 million songbirds a year, an enormous loss.

A great concentration of breeding songbirds is found in Belt Woods, a 500-acre-forest near Bowie, Maryland. Trees that were growing when Columbus discovered America survive here. Perhaps the largest tract of old-growth forest in the region, it has a variety of habitats from swamp forest to dry hardwood stands. More than 40 species of migrant birds nest here, including Wood Thrushes, Rose-breasted Grosbeaks, Baltimore (Northern) Orioles, Scarlet Tanagers, Prairie Warblers and Ovenbirds. These are species that have disappeared from woodlands that have become fragmented, or contain few tall trees. This wealth of breeding birds underlines the importance of protecting old-growth forests. Privately owned, Belt Woods was willed by the late owner, William Seton Belts, to the Episcopal Church to be kept intact in perpetuity. The church, however, went to court in the 1990s to change the will to allow sale to developers, claiming that it had more important works to accomplish with the funds than saving the forest.

After conservationists had decided it was a hopeless cause, a local resident, Pam Cooper, decided to spearhead a rescue of these precious woodlands. By conducting publicity campaigns and fund-raising efforts, she and the Western Shore Conservancy raised money. A Maryland author and illustrator of children's books, Lynn Cherry, organized The Friends of the Woods to enlist children to help influence their parents and public opinion to place the preservation of this threatened woodland above that of sheer materialism and to champion the need to take on local conservation problems as a community. Her children's book, *Flute's Journey, the Life of a Wood Thrush*, chronicled the life of a Wood Thrush born in Belt Woods, its migration to Costa Rica and its uncertain future. The plight of Belt Woods was given national attention in April 1996 on a CBS program, "Sunday Morning," which may have been a crucial turning point in the preservation of this forest. Within months, an arrangement was finalized with conservation organizations that would turn Belt Woods into a reserve, ending the possibility that it would be sold to developers.

At a time when losses in the numbers of North America's beautiful songbirds may have become irreversible, scientific research is revealing that they play a crucial role in controlling insects in forests (Yoon 1994). In a controlled experiment, birds were excluded from a section of forest with netting cages that allowed insects to enter. It was found that trees and plants incurred twice the damage to foliage where birds were excluded (Yoon 1994). The

study concludes that songbirds constitute a major and important form of natural pest management, superior to pesticides (Yoon 1994). Keeping songbirds from nesting in a stand of White Oaks, other researchers found that caterpillars consumed so much foliage that the trees grew significantly more slowly than White Oaks with nesting songbirds (Robinson 1996).

North America™s Forests: Page 2

It would probably shock most residents of suburban New York City to know that 150 years ago, wild Gray Wolves preyed on White•tailed Deer, Eastern Bison and Elk in the dense virgin forests now occupied by their neatly clipped green lawns, while overhead the flight of millions of Passenger Pigeons darkened the sky. The Eastern United States is undergoing a "Europeanization" in which natural forest is being lost to housing tracts, highways and urbanization. This sprawl consumes the second-growth forests, some of which had become excellent wildlife habitat, and the new residents often contaminate the water and soil with pesticides and herbicides to maintain green lawns. The natural world and its fauna and flora are fast disappearing.

Just as they are disappearing, discoveries about the medical potential of eastern forest trees are being made. Recently a fungus was discovered that is a missing link in the life cycle of a mold that produces the billion-dollar drug cyclosporin, used to prevent the rejection of transplanted organs (Yoon 1996). The forest of the Finger Lakes Land Trust in Ithaca, New York, where Cornell University students found the fungus, has established the nation's first reserve set aside specifically for chemical prospecting outside the tropics (Yoon 1996).

Most of the Great Lakes region was originally covered in ancient pines. During the logging boom of the late 1800s, mills of one Great Lakes port alone, Ashland, Wisconsin, cut 500 million board feet of lumber a year (a board foot is equal to wood 1 foot square and 1 inch thick), enough for 50,000 houses (Johnson 1997). Timber barons shipped the lumber to rebuild Chicago after the great fire of 1871, and the logged-over area, covered in broken branches, stumps and discarded trees, ignited a series of fires, one of which killed 1,152 people in the town of Peshtigo, Wisconsin (Johnson 1997). These fires charred millions of acres, leaving a wasteland (Jonas 1993). By the end of the 19th century, the majority of these forests had been clearcut by commercial loggers (Jonas 1993). There remains a scarcity of timber, and in 1996 a treasure trove of 20,000 to 30,000 old-growth tree trunks was found by divers on the bottom of Lake Superior; they had sunk more than a century after being cut and floated to mills (Johnson 1997). Old-growth timber is extremely valuable. It has tight grain resulting from slow growth, unlike the grain in the trees grown on tree farms. These logs are worth many millions of dollars, and a company is bringing the logs to the surface, selling them for ten times the price of new wood (Johnson 1997). These are the last remnants of a once vast forest.

Early in the 20th century, Weyerhauser, the German timber magnate, having logged out the old growth of the Great Lakes area, turned to the forests of the Southeast. Forests dominated by Longleaf (*Pinus palustris*) and Shortleaf Pines (*Pinus echinata*), which have the world's greatest diversity of forest floor plants, dominated northern Florida west to Louisiana and north to central Georgia. Longleaf Pine forest once covered 90 million acres from Virginia to Texas. These forests also harbored Loblolly (*Pinus taeda*), Virginia (*Pinus virginiana*), Pond (*Pinus serotina*) and Pitch Pines (*Pinus rigida*), which grew in various types of soil and climatic conditions. Loggers decimated this ecosystem, cutting millions of board feet, and by the 1930s, these forests had been reduced to a fraction of their original extent. Today, only about 2 percent of the Longleaf Pine forests remain, making them the most endangered forest ecosystem in North America. For the most part, these forests have been replanted with other species, predominantly commercial tree farm monocultures.

Much of the remaining virgin pine forests of the Southeast lie on national forest land, and they are being heavily logged. On December 15, 1995, this destruction was fought by the Biodiversity Legal Foundation and the Alabama Wilderness Alliance, which filed suit in Federal District Court against the US Forest Service challenging the legality

of the Forest Service decision to open a series of massive salvage timber sales of trees blown down by a hurricane, along with some healthy standing trees, on 15,000 acres of the Conecuh National Forest in Alabama. The Biodiversity Legal Foundation hired biologists and other experts, who testified that Forest Service management of the forest violated its own environmental regulation relating to logging near waterways and had planted non-native trees instead of the native species that are preferred by the Red•cockaded Woodpecker (*Dendrocopus borealis*), an endangered resident of this forest. This lawsuit was settled in favor of the conservation organizations.

North America™s Forests: Page 3

A victim of this logging, the Red-cockaded Woodpecker is a small bird marked in black and white and named for the male's tiny streak of red on each side of the nape. These birds have very specific habitat needs. For nesting trees they usually choose old-growth pines stricken with red heart disease whose soft wood permits easy excavation of nesting holes; the sap running down the trunk deters snakes and other predators (McFarlane 1992). Red-cockaded Woodpeckers nest in small groups or clans, requiring large areas of undisturbed forest. Each clan has "helpers," non-breeding birds that aid in feeding the nestlings (McFarlane 1992). These woodpeckers were the primary control of the southern Pine Beetle, a major pest in pine forests; after destruction of old-growth pine forests, which endangered these birds, Pine Beetles proliferated and destroyed other types of pines (McFarlane 1992).

Prior to the commercial logging of the early 20th century, these woodpeckers may have numbered in the hundreds of thousands. Nineteenth century records exist of Red-cockaded Woodpeckers as far north as northern New Jersey and southeastern Pennsylvania, and west to Missouri (Jackson 1994). Gradually, their range shrank as pine forests were destroyed; by 1946 the species was gone from Missouri, and by 1976 from Maryland (Jackson 1994). Populations in Tennessee declined to a single bird by 1992, and they disappeared from northern Mississippi in 1977; Kentucky and Virginia have only a few family groups (Jackson 1994). In the Southeast, clans became rare and widely separated from one another as millions of acres of old-growth pine were logged. When listed on the Endangered Species Act in 1968, programs to prevent its extinction were launched. Inbreeding of Red-cockaded Woodpeckers is apparently occurring in populations isolated by forest fragmentation (Jackson 1994). Some females have been physically translocated to isolated groups without females to counteract this problem (Jackson 1994). Nest holes have been artificially created, and existing nest holes have been modified with steel plates, restricting the size of the opening to prevent predators and larger birds from entering the nest hole (Jackson 1994).

The problem of declining habitat remains, however, and some conservation organizations, including the Biodiversity Legal Foundation, have successfully taken the Forest Service to court concerning their replanting policies, obtaining court orders mandating replanting with Longleaf Pine to benefit the Red-cockaded Woodpecker. At present, only about 30 known clans remain, with South Carolina and Florida having the largest numbers; the entire population of the Red-cockaded Woodpecker may not exceed 7,400 birds (Collar *et al.* 1994).

One haven for the Red-cockaded Woodpecker is Eglin Air Force base, located on the Florida panhandle. This 460,000-acre base preserves the world's largest remnant of Longleaf Pine forest, which occupies 320,000 acres of the base (Stevens 1996); 10,000 acres of this forest are the largest remaining old-growth Longleaf Pine in the world, with many 400-year-old trees (Biondo 1997). The Nature Conservancy has spent years conducting biological surveys and has discovered that more than 90 rare or imperiled species, including a salamander new to science, inhabit the base (Biondo 1997). Eglin protects 1,200 plant species, with numerous threatened species among these. Military activities are carried out as carefully as possible, and the base employs a full-time chief of natural resources with a staff of 25 (Biondo 1997).

North America™s Forests: Page 4

The military conducts munitions tests on Eglin Air Force Base, causing fires that have inadvertently benefited the ecosystem. The piney woods of the Southeast need fire, without which shade-tolerant hardwoods begin to intrude on Longleaf and other native pine stands (Jonas 1993). At present, Eglin officials conduct controlled burns to maintain this habitat (Stevens 1996) and are removing non-native and overabundant plants and trees (Biondo 1997). To return the Longleaf Pines to former abundance, more than 3 million seedlings have been planted, restoring 200,000 acres over the past five years (Biondo 1997).

The Gulf Coastal Plain Ecosystem Partnership, a plan to link populations of Longleaf Pine forests, was formed in 1996 to protect 840,000 acres of contiguous forest held by seven major landowners in northern Florida and southern Alabama (Biondo 1997). The partnership has signed a memorandum of understanding that encourages cooperation between the diverse owners, from private logging companies to state forest departments and water management districts (Biondo 1997). More than 160 rare or imperiled plants and animals reside in these lands, and Eglin Air Force Base's land has been the best preserved of any because of limited human intrusion and very little logging. It also protects a sizeable population of threatened Gopher Tortoises (*Gopherus polyphemus*). This keystone reptile excavates deep tunnels and cavities which provide habitat and shelter during fires for hundreds of animals, including threatened species.

Southern Bald Cypress (*Taxodium distichum*) swamp forests were once found in many low-lying areas of the South, but today, the Okefenokee Swamp is the largest remaining tract. Plans to clearcut this huge forest were abandoned early in the century after logging proved unprofitable. Later, the Okefenokee was declared a National Wildlife Refuge, and it is one of the most important examples of this ecosystem, home to River Otters (*Lutra canadensis*), Alligators (*Alligator mississippiensis*) and abundant water birds.

Massive stands of ancient Live Oaks (*Quercus virginianus*) draped in Spanish moss evoke the very essence of the South. Although the majority of these huge trees have been logged, many survive that are 10 to 12 feet in diameter. They have a dense wood that was used in the construction of ships such as the USS Constitution. This ship was called "Old Ironsides" because this hardwood was impervious to cannonballs. The last sizeable stands of these picturesque trees are disappearing, however. Companies are buying wood lots with Live Oaks, cutting and replacing them with tree farms of fast-growing pine. As an added threat, a fungus first identified in the 1940s as "oak wilt," has been killing many Live Oaks. The disease chokes the flow of water into the tree and gradually kills it from the inside out, spreading through root connections which link Live Oaks growing in close proximity. In Texas, where this disease has killed many of these oaks, the Texas Forest Service has been successful in injecting chemicals that kill the fungus and digging trenches that break connections between these oaks.

North America™s Forests: Page 5

Predators of the Southeastern forests declined or disappeared after European settlement as a result of overhunting and persecution, leaving an imbalance in which White-tailed Deer proliferated without Grey Wolves or Mountain Lions to limit their numbers. Both the latter predators remain absent in the eastern United States, although there are unsubstantiated sightings of Mountain Lions in Maine and elsewhere. A few Grey Wolves have entered northern Maine in recent years, and some conservation organizations have proposed reintroductions of the species into Adirondack Park in New York state or in northern New England. Red Wolves (*Canis rufus*) were totally eliminated by predator control programs and hybridization with the Coyote, reaching extinction in the wild by 1973 when the last

wild members of the species were taken into captivity. This uniquely American species, which until recently was considered to have been native to only the southeastern United States, is now thought to have been distributed throughout eastern North America, based on DNA testing showing close relationships between the Red Wolf and wolves of eastern Canada, which have managed to persist to the present. The species was larger in northern states and preyed on deer and elk. Red Wolves survive today as a result of the 14 animals that formed the nucleus of the Fish and Wildlife Service's breeding colony. By 1993, more than 233 animals resided in 31 breeding facilities. Several successful releases have taken place in North Carolina and other eastern states, and about 100 Red Wolves survive from these releases.

West of the Mississippi River, pine forests in the mountainous regions of the Southwest were also heavily logged. A resident of these forests, the southern Mexican Spotted Owl (*Strix occidentalis lucida*), a race of the Spotted Owl, whose northern race inhabits old-growth forests of the Pacific Northwest, has become very rare. This owl, like its northern relative, requires undisturbed forests. The dominant tree of the southwestern forests is the Ponderosa Pine (*Pinus ponderosa*), which towers 180 feet tall and can live 500 years (Jonas 1993). Originally, these trees covered hundreds of thousands of acres in northern Arizona, New Mexico, and neighboring states; old-growth pine forests also stretched south into northern Mexico. Beautifully adapted to the dry, mountainous habitat, Ponderosa Pines often grow in large, pure stands. These forests have very little old growth left today, and Mexican Spotted Owls have disappeared from national forests in Arizona and New Mexico after the oldest trees were logged (Johnson 1995).

Many unusual and endemic species live in pine and juniper forests of the Kaibab Plateau on the north rim of the Grand Canyon. The Kaibab Squirrel (*Sciurus aberti kaibabensis*) is confined to this plateau. This beautiful squirrel is considered by most authorities to be a subspecies of Abert's or Tassel-eared Squirrel, but some zoologists treat it as a separate species. One of the most dramatic looking of all squirrels, the Kaibab is dark brown, with long tassels on its ears, and a snow-white bushy tail. Its close relative, Abert's Squirrel, is dark, grizzled gray on its back and tail. Feeding mainly on conifer seeds, these squirrels suffer high mortality from hunting, road kills and natural predation by hawks (Whitaker 1980). Their habitat is restricted, and they are considered a rare and endemic animal. Ecologically, these squirrels are important in helping the Ponderosa Pine reproduce. They dig for truffles and absorb their spores, which enter their feces. When their feces are deposited near Ponderosa Pines, they spread the spores to the tree's roots, which grow into a fungus, triggering the tree's reproductive biology. In the spring of 2000, wildfires raged through their habitat, undoubtedly causing the squirrels high mortality.

North America™s Forests: Page 6

The problem of illegal logging is growing in the national forests, and a recent threat is the invasion of forests by drug growers. These people have entered roadless federal lands in the West and are seldom detected because of the remoteness and size of many of these tracts. In Los Padres National Forest, they destroyed large sections of forest in 1995 and 1996 to plant marijuana. After cutting trees, they cleared brush with herbicides which killed native plants, many of which are rare and protected. They also diverted scarce water from streams to irrigate their plants, which eliminated native plants dependent on that water. The drug growers put out poison to kill animals, such as deer, they feared might eat the marijuana. This situation presents a major threat to many species of wildlife, and especially to California Condors, who have been reintroduced to Los Padres National Forest and feed on carrion.

Ancient old-growth pine forests covered much of northern Mexico until a few decades ago. Large-scale logging has been felling these great trees, and what reserves have been set aside to protect the remaining patches of old growth are not carefully patrolled to guard against illegal logging. The Imperial Woodpecker (*Campephilus imperialis*), the world's largest woodpecker and one of the most beautiful, declined to extinction as a result of failure by both the Mexican government and private conservation organizations to preserve its habitat. Its decline began from hunting, and logging removed its feeding and nesting habitat during the first half of the 20th century. Several of these birds

were sighted in the 1990s, but because no emergency action took place to preserve these birds in their last retreat, they disappeared. Each pair of Imperial Woodpeckers required a habitat of at least 25 square kilometers, and no area of old-growth forest this large now remains in the Sierra Madre Occidental (Lammertink 1996). Only a few fragments of old growth survive in this huge area, and even these are in imminent danger of being logged.

Mexican logging companies offered local people $2,000 per household for permission to log, and this may have been the deciding factor that led to the end of Mexico's old-growth forests. All that remains of the Imperial Woodpecker are museum specimens. A photograph of three specimens was recently published in the article, "The Lost Empire of the Imperial Woodpecker," in *World Birdwatch* (Lammertink 1996). Martjan Lammertink concluded after his field survey that if the Imperial Woodpecker still exists, no breeding habitat remains and, at most, one or two solitary birds may be left who must fly over huge areas to find food (Lammertink 1996).

A courageous defender of the Sierra Madre forests, Mexican activist Edwin Bustillos has risked his life to fight the drug lords who have taken over large areas in these forests for cultivation of drug plants. In several incidents, Bustillos had five ribs and his arm broken and spent a month in the hospital from injuries sustained when attacked by drug dealers. In 1996, he received the Goldman Environmental Award for his long-term efforts on behalf of these endangered forests.

A beautiful parrot also inhabits these same pine forests. The Thick-billed Parrot (*Rhynchopsitta pachyrhyncha*) once flew in large flocks in search of pine seeds, but its populations have declined from loss of old-growth forests and illegal shooting. The species is listed on the US Endangered Species Act, as endangered by the *2000 IUCN Red List Species*, and on CITES Appendix I, which bans all commercial trade. These large green parrots have red feathers on their foreheads, shoulders and thighs, and bare skin surrounding their yellow eyes. Their large hooked beaks aid them in prying open pine cones. Native to Sierra Madre Occidental of eastern Mexico and, originally, pine forests in Arizona, Thick-billed Parrots live mainly above 2,000 meters. Heavy logging of old-growth pine forests has destroyed 99 percent of its habitat and removed the huge, old trees it needed for nesting (BI 2000, Collar *et al.* 1994). A field survey in 1994 in southern Chihuahua uncovered massive forest destruction and the penetration into its habitat of drug-growers, cattle and loggers (Collar *et al.* 1994). Populations have declined from flocks of thousands seen in the 1950s (Lammertink 1996) to about 5,000 in 1992 and only 1,000 to 4,000 in 1995 (BI 2000). Reintroductions into Arizona of captive-bred birds have not been successful because the birds did not know how to avoid predators or forage for pine seeds (BI 2000).

North America™s Forests: Page 7

Some highly threatened birds persist in unlogged portions of northern Mexico. The beautiful, iridescent Eared Quetzal (*Euptilotis neoxenus*), for example, was formerly common but is now confined to corridors of unlogged trees along rivers. These bits of forest are, at the present at least, inaccessible to loggers (Lammertink 1996). These quetzals require large trees for nesting and lay their eggs in cavities created when large tree snags fall off. Such trees, however, are rare and may disappear altogether in the future, since loggers cut them down as a general rule. It is considered Near-threatened, and close to qualifying as Vulnerable by BirdLife International (BI 2000). The Tufted Jay (*Cyanocorax dickeyi*) is another striking bird with a stiff, bristly, black fan crest on his head and forehead, unlike any other jay. This species is endemic to a limited area in the southern Sierra Madre Occidental, in mixed forested hillsides of oak, dense evergreen and deciduous forest near watercourses. Although a Near-threatened species (BI 2000), it has, nevertheless, no protected reserve.

Pine forests extend south to central Mexico, and up to 30 million Monarch Butterflies (*Danaus plexippus*) from the eastern United States and Canada migrate up to 2,000 miles to several groves of fir trees where they spend the winter clinging to branches in a semi-torpor. These butterflies constitute 90 percent of the species' population, and scientists

believe that they have wintered here for more than 10,000 years (Aridjis and Brower 1996). Their migration is a biological mystery and unique among butterflies. Until the fir groves, where they festoon the tall trees like dazzling orange and black ornaments, were discovered, no one knew where they spent the winter. Even now, their method of locating this particular forest remains unknown. The butterflies that fly south are third generation ancestors of the ones who wintered in Mexico the previous year. On warm days, they wake from their torpor and venture out to take nectar, and in the spring, they head north, breeding along the way (Pyle 1981).

Entirely dependent on these groves of firs, which shelter them from the freezing rains that fall in this high-altitude forest, the Monarchs are threatened by logging. In spite of a 1986 order by Mexican President Miguel de la Madrid to protect the five wintering populations, all located in close proximity, the surrounding trees were not given protection. Local people cut trees for fuel and building materials, and cattle trample fir seedlings (Aridjis and Brower 1996). They have logged up to the very limits of the groves, and without the protection of bordering trees, the butterflies are more vulnerable to cold spells, dying in unprecedented numbers. Snowstorms and cold weather killed millions of these fragile butterflies in 1991 and 1995.

Ann Swengel and Dr. Paul Opler, who coordinate nationwide butterfly counts for the Xerces Society, a butterfly conservation organization, began noticing declines in Monarch populations in the United States, and scientists have seen many declines in areas where they were previously abundant.
Conservation of the precious fir trees upon which the species winters is a key to saving this species. Dr. Lincoln P. Brower, professor of zoology at the University of Florida and a leading authority on the species, and Homero Aridjis, President of the Group of 100, a Mexican environmental organization, made a public appeal for the protection of the Monarchs' winter habitat in an Op-ed article for *The New York Times* in January 1996 (Aridjis and Brower 1996). They maintained that all three countries--the United States, Canada and Mexico--should cooperate to purchase the forests in keeping with the North American Free Trade Agreement (NAFTA) (Aridjis and Brower 1996). A comparison of forest cover in the Monarch groves based on aerial photographs taken in 2000 and in the 1950s, shows great losses in these protected trees from illegal logging over the past 40 years. The situation has reached crisis proportions, according to scientists. In response, the Mexican government has promised to protect the remaining groves and enlarge the reserve. Local people have expressed opposition, however, as they have traditionally logged the forests and have not profited from the tourists who come to see the butterflies. If this situation is not resolved in favor of the butterflies, these beautiful jewels that brighten fields and gardens may disappear from their breeding grounds in the United States.

North America™s Forests: Page 8

The ancient forests of the West Coast once stretched from northern California nearly unbroken through coastal Canada to southeastern Alaska, covering 70,000 square miles. Logging by Europeans began in the 19th century, and as the forests fell, a few voices were raised in protest. Even Horace Greeley, a promoter of "progress" and settlement of the West, exhorted Americans in 1851 to "spare, preserve and cherish some portion of your primitive forest" (Peck 1990). It was the fiery Scottish wilderness advocate John Muir who finally succeeded in convincing the US government to protect some of these ancient forests. He settled near California's Yosemite wilderness in the 1860s and began passionately denouncing the destroyers of nature, from loggers to livestock operators. Muir pointed to the political influences that allowed destruction to occur. During the 19th century, livestock swarmed in great numbers over wilderness areas. Muir described sheep as "hoofed locusts" and, in trying to get them removed from Yosemite, said, "As sheep advance, flowers, vegetation, grass, soil, plenty, and poetry vanish" (Peck 1990). When he saw the ancient Sequoias being cut, Muir was outraged:

Through all the wonderful, eventful centuries since Christ's time--and long before that--God has cared for these trees, saved them from drought, disease, avalanches, and a thousand straining, leveling tempests and floods; but He cannot save them from fools--only Uncle Sam can do that.

Muir proved to be an adept politician, making friends with influential magazine editors and railroad magnates; President Theodore Roosevelt camped out with Muir in Yosemite in 1903 (Peck 1990). Through Muir™s influence, Yosemite became a national park in 1906, followed by Sequoia, Mt. Rainier, Crater Lake, Glacier and Mesa Verde National Parks (Peck 1990). In 1892, Muir established The Sierra Club conservation organization. If not for Muir's courageous and effective work on behalf of these forests, it is likely that very little old-growth forest land would remain today.

North America™s Forests: Page 9

These centuries-old trees, often covered in epiphytes, plants that get nutrients from moisture and air, and lichens, including one species that drapes over branches in delicate, lacy strands, exude a lushness reminiscent of tropical rainforests. More than 140 inches of rain per year produce luxuriant tree growth and a verdant understory of ferns and hardwoods. Bright green mosses and masses of ferns carpet the ground, and a great variety of mushrooms and lichens flourish in the damp environment. In the spring, the forest floor is carpeted with beautiful white trilliums and other flowers that contrast with the deep greens of the forest. Mist and fog enshroud the giant trees, which intercept the moisture from the atmosphere, supplying the trees and the entire environment with water throughout the year (Ellis and Kane 1991).* The southern portion of these forests is dominated by Coast Redwoods, with the record tree reaching more than 365 feet in height. Its upper branches are more than 50 feet in length. They are among the most ancient as well, some over 2,000 years old (Middleton 1992). The great Redwoods of northern California gradually melt into a forest of mixed pines, fir, cedars and hemlock.

---

*Along with the fine book by D. Middleton (1992), cited frequently here, *North America's Rain Forest. The Endangered Paradise*, by Gerry Ellis and Karen Kane (NorthWord Press, 1991), is an excellent resource, beautifully illustrated with the trees, plants and wildlife of these forests, and shows the devastating clearcuts contrasted with living forests. *Western Forests*, a book in the *National Audubon Society Nature Guides* series illustrates most wildlife and plant species, as well as discussing forest ecosystems.

Douglas Firs (*Pseudotsuga menziesii*) grow to ages of 700 to 1,000 years old in climax growth, veterans of hundreds of periodic fires; they may reach 325 feet in height (Jonas 1993). A tree 250 years old is considered young in an old-growth forest, while middle age is 400•500 years, and old age is more than 700 years (Middleton 1992). Recent research conducted in these forests indicates that rich diversity does not develop until forests are at least 200 years old (Moffet 1997).

Ancient Red Cedars (*Thuja plicata*) grew in abundance in these old-growth forests and were among the first to be cut by loggers. Old specimens are very rare at present, and activists recently saved one area with many exceptionally old and massive cedars from being logged. This forest, in Upper Priest Lake, northern Idaho, has cedars 1,500 years old. The largest trees are 20 stories tall, with trunks 10 feet in diameter. The ground beneath is carpeted with ferns, including the largest population of Braun's Holly Fern in the West. Old-growth cottonwoods also grow here. Endangered Woodland Caribou (*Rangifer tarandus caribou*), threatened Grizzly Bears, Fishers and Wolverines, rare Cutthroat Trout, endemic salamanders, and Harlequin Ducks are resident in the forest and wetlands. This forest covers 520 acres, worth at least $9 million to the lumber company that owns it. The US Forest Service was unable to

obtain federal money to purchase it in 1996, and not until October 1997 was the grove preserved through a trade of land worth $8.7 million between the owner and the Forest Service.

More than 1,000 plant and animal species depend on old-growth forests (Egan 1994a). Invertebrate animals of the soil are highly diverse: an area 1 meter by 1 meter shelters 200,000 mites of 75 species (Middleton 1992). Fallen logs may take 500 years to rot, and this decaying wood is fed upon by the most diverse fungal network in the world (Middleton 1992). The hollow logs are used as nest holes by Red•backed Voles and other small species. The young of these voles feed on truffles that grow in the rich soil. At least 300 insect species have been described from the rotting•log community of organisms (Middleton 1992). A host of other insect species of the forest canopy have yet to be described.

Many vertebrates depend on the old-growth forests of the Pacific Northwest for their survival, and some of these live nowhere else. The Sitka Black•tailed Deer and Roosevelt Elk and a unique bluish strain of American Black Bear from southeastern Alaska are among these. Bats of several species--Long•eared, Hoary and Silver•haired--are major pollinators and insect-predators in forests of the Pacific Northwest. Roosting in the hollow trunks of ancient trees, these bats have declined in many areas because of logging. A great diversity of amphibians lives in the moist environments of these temperate rainforests. Among them are the Slender, Olympic, Pacific Giant and Del Norte Salamanders, Pacific Tree Frog and Tailed Frog.

North America™s Forests: page 10

The Northern Spotted Owl (*Strix occidentalis caurina*) may be the most famous resident of these forests. The struggle over old-growth forests became a bitter controversy focused on the fate of this bird, which was declared a Threatened species under the Endangered Species Act in June 1990. This owl is native to old-growth forests in northern California, Oregon and Washington, and each pair of owls requires up to 3,200 acres as territory, making it a naturally rare species (Middleton 1992). Northern Spotted Owls nest in natural tree cavities or holes created when great branches from living trees fall to the ground. The canopy above shields owlet chicks from the view of large birds of prey that fly above. These owls feed on the Red Voles, Dusky-footed Wood Rats and Northern Flying Squirrels that are abundant in old-growth forests. When these forests are cut and young second-growth forest takes over, Spotted Owls disappear (Seideman 1997). In spite of the protection of portions of their habitat, these owls have not recovered their numbers since listing on the US Endangered Species Act, and they continue to decline. The US Forest Service released extensive data compiled on the populations of these birds between 1985 and 1993, which showed a drop of 4.5 percent a year, with an accelerating rate of decline (Seideman 1997). Another threat to these owls is the recent invasion of their habitat by the larger and more adaptable Barred Owl, which is displacing the Spotted Owl in some areas. Even more ominously, interbreeding has taken place between the two species (Seideman 1997).

When the Northern Spotted Owl was listed as Threatened on the Endangered Species Act and large sections of its habitat protected, it became a focal point, polarizing pro-logging and anti-logging advocates. Owl haters urged others to kill these birds, who were blamed for ending the logging industry. Their cars sported bumper stickers such as "Kill an Owl, Save a Job." Such venom totally obscured the fact that the forests were being overcut and that logging jobs were destined to be eliminated anyway, as the last old-growth forests disappeared under the saw. A state in the heart of this owl's range, Oregon, found that reducing logging ended up helping its economy; an influx of technology businesses provided better salaries than those paid for logging jobs (Egan 1994b, Verhovek 2000). The Governor of the state supported the logging restrictions as helping to maintain the overall quality of life in the state, preventing

floods and attracting tourists, which are supplying another large segment of the state's revenues.

Habitat Conservation Plans (HCPs), authorized under the Endangered Species Act may be contributing to the Spotted Owl's decline. Under these plans, agreements are negotiated with landowners which include a provision known as "no surprises." This gives landowners assurances that once the regulations on their properties have been agreed to, they are exempt from further restrictions. Should new populations of an endangered species be discovered on their property, they have no obligation to protect them. Habitats of Spotted Owls in old-growth forests in Washington State have been bartered away in HCPs that, in the view of Eric Hanson, biologist for the Yakima Indian Nation in Washington state, will end in reducing the state's populations of this species by 35 percent, from 880 breeding pairs to 550 (Seideman 1997). These HCPs allow habitat destruction and other actions that can result in deaths of Spotted Owls. The Forest Service collected population data on these owls for the years between 1994 and 1996 but failed to issue the results (Seideman 1997).

The Clinton Administration sponsored a series of local meetings to resolve differences. These resulted in plans to federally fund job•training for loggers who might become unemployed by logging cutbacks. Even so, logging interests sued the federal government to nullify the stricter quotas, and the California Forest Products Association unsuccessfully petitioned the Fish and Wildlife Service in October 1993 to remove the Northern Spotted Owl from the Endangered Species Act, claiming the species was mistakenly placed on the list. This case was argued all the way to the US Supreme Court which, in the summer of 1995, made a historic decision upholding the Endangered Species Act and its protection of endangered species' habitats.

The Timber Salvage Act of 1995 made a mockery of previous attempts to mediate between loggers and conservationists, allowing a year and a half of totally unregulated logging in the habitat of the Northern Spotted Owl and other threatened species. This law had the stated purpose of taking only fallen and dead trees, but in practice, tens of thousands of old-growth, healthy trees were logged. In its quarterly report on the Timber Salvage Act, issued February 29, 1996, the Forest Service reported that an astounding 2.1 *billion* board feet had been cut since passage of the law. The Forest Service's stated objective was to sell 4.5 billion board feet by the end of 1996. By August 1996, some 2.9 billion board feet, the equivalent of 580,000 logging trucks full, had been cut under the Timber Salvage Act (Bass 1996). National forest lands to be logged totaled at least 50 million acres. Major habitat areas for many endangered and threatened species were among these lands. Fortunately, this law expired at the end of 1996.

North America™s Forests: Page 11

The Marbled Murrelet (*Brachyramphus marmoratus*) is also dependent on old-growth forests and has been seriously impacted by the logging that, since the 19th century, has destroyed 95 percent of its old-growth habitat in the US Pacific Northwest. This small, black-and-white seabird is a Threatened species on the US Endangered Species Act and is listed as Vulnerable by BirdLife International. Unlike any other seabird, this Murrelet nests high in the branches of 200- and 300•foot trees. Sometimes seen in offshore waters of the Pacific Northwest and Alaska, their nests are rarely found. In fact, only about 30 nests have ever been located in the Pacific Northwest--all high in the

crowns of old-growth forest trees.

A researcher who was studying the ecology of old-growth tree canopies made an exciting discovery of a Marbled Murrelet nest. He photographed the adult on its nest, made of lichens, with a small fish in its mouth for its chick for *National Geographic* magazine (Moffett 1997). Despite surveys up and down the Pacific coast, this was one of the few nests found in 1996, and plans for logging near the nest site were stopped (Moffett 1997). A prime area for Marbled Murrelets is the Olympic National Forest in Washington state where large tracts were sold for clearcutting in 1996 under the Timber Salvage Act. In Umpqua National Forest, Oregon, over the weekend of March 23-24, 1996, several thousand-year-old Douglas Firs were cut; their age was determined by coring and ring counts. The Umpqua River has endangered populations of Coho Salmon (*Oncorhynchus kisutch*) and sea-run Cutthroat Trout, and logging may eliminate them. The Marbled Murrelet's nesting trees are being logged throughout the species' range. A few areas have been protected in Alaska, but they are declining rapidly, at a rate of 31 to 48 percent per decade, with little hope that sizeable areas of old-growth forest will be protected (BI 2000).

North America™s Forests: Page 12

The Pacific Yew (*Taxus brevifolia*)**,** found only in these forests of the Pacific Northwest, is considered a "trash species" by foresters who clear it away to make room for more valuable species. This plant grows in the undergrowth of old-growth forests from California to southeastern Alaska (Jonas 1993). It has recently been shown to contain a chemical substance, Taxol, that has proven effective in treating ovarian and other cancers (Middleton 1992). A rush to cut these trees and strip their bark to obtain Taxol threatened them with extinction until the chemical was successfully produced synthetically. Taxol will be a major new tool in treating cancers and will result in sales totaling many millions of dollars for the pharmaceutical industry.

These discoveries have taken place as the fate of the last stands of old-growth forests is hanging in the balance. Ninety-five percent of these forests in the United States, and more than 60 percent in Canada, have already been cut. Opposition to clearcutting is increasing, however. Lewis H. Nash is a member of an organization known as the "Environmental Air Force," which chronicles illegal cutting of Coastal Redwoods. Members pilot small planes over clearcuts and document the damage with photographs. Nash's work enabled an environmental lawyer to obtain an injunction in 1995 stopping logging the same day (Goldberg 1996a). In 1996, flying over the devastated forests of northern California, Nash remarked: "When I first started flying here 10 or 15 years ago, this was all the same, all primeval forest. All this has been pretty well hacked over" (Goldberg 1996a).

North America™s Forests: Page 13

One of the most heated debates over these forests involves the last privately-owned large tracts of redwoods. Commercial exploitation began in 1900 when Frederick Weyerhauser purchased 900,000 acres for $6.00 per acre, a ludicrously low price even in those days (Dietrich 1992). Almost all privately owned old-growth forests became depleted by the 1960s. One exception was a large tract of old-growth Coastal Redwoods and Douglas Firs in California's Humboldt County, in the northern part of the state, owned by the Pacific Lumber Company. This family-operated company had left most of its 200,000 acres intact and had been particularly protective of the most ancient trees in the 55,000-acre Headwaters Forest. In 1986, however, Houston financier Charles Hurwitz took over Pacific Lumber, using junk bonds. Hurwitz's United Savings Association of Texas failed, costing US taxpayers $1.6 billion, part of the savings-and-loan collapse (Brown and Stark 1995).

To pay his debts, Hurwitz began clearcutting the old-growth Coast Redwood and Douglas Firs. By 1995, he had

cut 40,000 acres of the Headwaters Forest and nearby old-growth trees, leaving only 5,500 acres of virgin Coastal Redwood and 5,000 acres of virgin Douglas Fir (Brown and Stark 1995). This is one of the most extreme cases of abuse of private land in the history of this country. Two-thousand-year-old trees were turned into picnic tables, lawn furniture and patio decks. Logging was delayed by several lawsuits, and to protect nesting sites of Marbled Murrelets, the California Forestry Department recommended in 1995 that Hurwitz be refused permission to build a logging road into the 4,400-acre grove of the most ancient trees (Brown and Stark 1995). Two California Congressmen, George Brown and Pete Stark, proposed that the federal government engage in a debt-for-nature swap, in which the Federal Deposit Insurance Corporation, which has sued Hurwitz for his role in the failure of his bank, would, through a special arrangement set up by the President, exchange the redwoods for his debt (Brown and Stark 1995). Hurwitz rejected the idea, calling it a "so-called fantasy of debt for nature" and threatened lawsuits against the government for excessively limiting the use of his land (Goldberg 1996b).

The value of the Headwaters Grove is estimated at between $100 and $500 million, with many giant trees several thousand years old and 12 feet in diameter; individual trees are worth more than $100,000 each (Goldberg 1996b). The ecological and esthetic values, however, are inestimable. Hurwitz called environmentalists who blocked sale of these trees "extremists" and insisted that he expected to be paid "fair market value for these trees" (Goldberg 1996b). Acrimonious negotiations for the grove continued in 1996 and 1997, with environmentalists demonstrating against an agreement negotiated that would protect only 7,500 acres, instead of the 100,000 they wanted saved. Early in 1997, Hurwitz demanded that he be paid in cash rather than land that was offered by the state of California, land which many environmentalists thought should be protected (Golden 1997). The deal arranged with Hurwitz allowed extensive cutting of the remaining 100,000 acres of old-growth forest without regard for endangered species' habitat.

Members of Earth First! began protests, entering the land and attempting to block logging trucks, and a young conservationist, Julia Hill, who became known as Julia "Butterfly" Hill, climbed up near the top of an ancient redwood tree she called Luna and refused to come down. She stayed up in this tree for two entire years, until the spring of 2000, while trees were cut in the surrounding area, until a sum of $50,000 was paid to the Hurwitz lumber company for Luna and 2.9 acres of surrounding forest, which were donated to Humboldt State University. She came down from the tree at last, a symbol of the extreme devotion and zeal that have been expended in attempts to preserve these ancient trees. The forest will continue to be cut, however, which will be a permanent loss to the environment and a stain on state and federal governments for not taking a stronger role to preserve the entire forest.

In a sad footnote, in November 2000, a vandal sawed a cut 32 inches deep and stretching 19 feet, or half the circumference, across the base of Julia Hill's tree, Luna. It appeared to have been done by a professional logger, judging from the precision of the cut. A team of specialists--an arborist, an engineer and a forester--was convened to try to save the tree (Quinn 2000). Metal braces were drilled into the tree spanning the cut. All efforts are being made to save this ancient tree from falling in winter storms. Visitors are being asked to stay away because the soil and hillside are being deeply eroded. It is a symbol of the senseless destruction of ancient forests.

Only 4 percent of the once vast and magnificent Coastal Redwood forests remain. These trees covered at least 2 million acres prior to logging, but only about 84,000 acres of virgin redwoods have been protected in state parks and the Redwood National Park; another 66,000 acres of logged and second-growth redwoods have been set aside (DiSilvestro 1990).

North America™s Forests: Page 14

Another major conservation struggle involves the magnificent Tongass National Forest in southeastern Alaska. This forest, covering 17 million acres, is the country's largest national forest--a mosaic of glaciers, mountains, fjords and islands covered by ancient trees. It makes up half of one of the largest remaining temperate rainforests on Earth,

which extends 1,000 miles in an arc along the southeastern coast. At least 6 million acres of Tongass are--or were--old-growth rainforest (DiSilvestro 1990). Sitka Spruce, Western Hemlock, and Red and Yellow Cedar many hundreds of years old dominate the forest.

The Tongass is home to a number of rare animals. Approximately 10,000 Bald Eagles nest in the tops of trees (DiSilvestro 1990). More Grizzly Bears live in the Tongass than in the entire lower 48 states, denning in the holes of towering old trees. A race of the Grey Wolf known as the Alexander Archipelago Wolf (*Canis lupus ligoni*) inhabits the Tongass; numbering only about 1,000 animals, its population is in decline (Williams 1995). Logging threatens these wolves and rare wildlife, including the Queen Charlotte Goshawk (*Accipiter gentilis laingi*) and the Marbled Murrelet (FWS 1994). The Wolf and the Goshawk are candidates for listing on the Endangered Species Act. These and other species of this beautiful area cannot survive in clearcuts and logged-over forests. The American Rivers organization has listed Tongass's Thorne River as one of the 10 most endangered in the United States, having become silted and its banks eroded from logging (Williams 1995).

The cutting of the Tongass's giant trees began in 1833, and by 1926, six sawmills were operating; by 1930, most of the lowland and easily accessible timber and giant old trees had been cut (DiSilvestro 1990). In the 1950s the Forest Service allowed cutting of ancient trees in rugged, steep areas and opened the way for a wood pulp industry to be fed by clearcutting. The Service offered two 50-year contracts at bargain-basement prices, instead of the usual three- to five-year contracts (DiSilvestro 1990). It signed an exclusive contract with the Ketchikan Pulp Corporation and, unlike other national forests where contracts are open to bidding, this contract was awarded during secret meetings from which the public and conservation organizations were excluded. From this time onward, 200 million board feet or more of old-growth forest were logged annually from the Tongass National Forest (DiSilvestro 1990).

The Alaska National Interest Lands Conservation Act of 1980 divided most of the state among federal, state and native interests. Within the law was a provision requiring maximum logging levels in the Tongass National Forest, with the quota of 4.5 *billion* board feet to be logged every decade, with annual subsidies of $40 million from the federal government for logging roads and other aid to timber companies (DiSilvestro 1990). In the 15 years that followed, billions of board feet were logged in this magnificent rainforest, at a financial loss to the taxpayer.

National organizations, including the Taxpayers for Common Sense based in Washington, DC, criticized the clearcutting of this and other national forests which provide no income to the federal treasury and are entirely subsidized by public funds (Schmitz 1996). A 1995 General Accounting Office report found that Tongass's Timber Program was the biggest money loser in the National Forest system, with a negative net return of $102 million to the US Treasury between 1990 and 1994 (Schmitz 1996). More recently, a study by the John Muir Project found that in the years 1997 through 1999, the National Forest Service Timber Sale Program operated at a net loss to taxpayers of more than $3.3 billion (Hanson 2000). This research found that less than 3 percent of the country's total annual wood consumption, and less than 4 percent of the sawtimber used for construction, comes from national forests (Hanson 2000). A nationwide poll in 1998 found that 69 percent of Americans oppose allowing timber companies to log the national forests (Hanson 2000).

The fight to save these forests is being waged in the courts, with public criticism and legal actions brought by conservation organizations. A 1987 book, *The Tongass. Alaska's Vanishing Rainforest*, dramatically illustrated the great beauty of this forest and the ravaging effects of logging, including clearcuts on steep, erodable slopes. This publication served as a catalyst for the passage of the Tongass Timber Reform Act of 1990 that stopped the $40 million subsidy to loggers and set aside 1 million acres to be closed to logging (Ketchum and Ketchum 1994). It did not stop or appreciably slow logging elsewhere in Tongass, however, and called for 150 million board feet a year to be cut. The book was updated in 1994 and described the continuing bitter battle being waged to protect this vast area (Ketchum and Ketchum 1994). In 1997, the heavily polluting Ketchikan pulp mill was finally closed. The Forest Service's 10-year plan for Tongass National Forest, finalized in May 1997, opened up 670,000 acres to logging, authorizing the cutting of 220 million to 267 million board feet of timber annually (this is enough to load 50,000 logging trucks or build more than 20,000 houses a year) (Cushman 1997). The Forest Service stated that the portion

of land that would be set aside would make it unnecessary to list the Alexander Archipelago Wolf and the Queen Charlotte Goshawk on the Endangered Species Act. Conservation organizations criticized the plan and the failure to support listing of these species. The Alaskan Congressional delegation expressed its disappointment that more timber had not been open to logging (Cushman 1997). The 100- to 125-year cycle of cutting by the Forest Service assured that old-growth forests and their complex and diverse ecosystems will disappear.

The Forest Service held nationwide hearings during the summer of 2000 regarding a proposal that some 50 million acres of national forests be protected from road-building. This proposal specifically exempted the Tongass National Forest. The Forest Service plan would allow massive road construction and logging in the Tongass's remaining pristine forests. In a surprise decision prior to leaving office, President Bill Clinton authorized the inclusion of 9.3 million acres of the Tongass National Forest in the final plan; although delayed until 2004, this was an extremely important event, condemned by the Alaskan Congressional delegation (Hughes 2000). The plan calls for $13 to $20 million to be spent in Alaska creating jobs lost in the timber industry. The plan had drawn more than 1.5 million letters and e-mail messages, the overwhelming majority in favor of banning road-building. In spite of opposition to the designation of wilderness in this vast national forest, conservationists succeeded in obtaining a moratorium on logging of 9 million acres, pending the results of studies on whether they qualify for permanent protection under the Wilderness Act (Earthjustice Legal Defense Fund 2001).

Another huge national forest in Alaska, the Chugach, located at the headwaters of the salmon-rich Kenai River, has received far less attention than the Tongass, in spite of being the second largest of all US National Forests. In 1996, the Forest Service cut nearly 16 million board feet in this old-growth forest.

North America™s Forests: Page 15

The future of forests in the United States is at a dramatic turning point. During the summer of 2000, devastating wildfires broke out in the Western United States, primarily in national forests. More than 6.7 million acres burned, along with hundreds of private homes (Janofsky 2000). Within months, the Clinton Administration proposed a major new approach to the national forests, dictating extensive thinning of millions of trees and the removal of brush to prevent future wildfires (Jehl 2000). This plan was based on the theory that the fires were caused by too little logging, resulting in dense forests with underbrush that caught fire and spread uncontrollably. Pro-logging Members of Congress, western Governors and logging companies immediately endorsed the plan (Janofsky 2000, Jehl 2000). Some Governors wanted even more money for the program (Janofsky 2000). The proposed thinning would cost taxpayers $12 billion over 15 years (Jehl 2000). This was challenged by a report issued by the Congressional Research Service soon after the fires were extinguished, which concluded that there was no connection between the level of logging and wildfires (Egan 2000). Other critics included the Forest Guardians of New Mexico, who contended that the fires were the result of decades of industrial logging in which the largest trees were taken; it suggested that instead of thinning, logging subsidies be directed at badly needed projects to control soil erosion, protect water quality and enhance wildlife habitat (Hitt 2000). Environmental groups opposed the logging portion of the proposal as a tool for fire prevention (Janofsky 2000).

As the ideal example of how national forests should be managed, the Clinton Administration proposal pointed to an Arizona Ponderosa forest that had been thinned and did not burn. Ponderosa forests are not typical, however, of all forests, tending to be open with little understory. Other types of forests, such as old-growth temperate rainforests, are not open, and drastic thinning of their undergrowth would result in more, not fewer fires. Moreover, nutrients would be lost, erosion encouraged and wildlife habitat destroyed by such thinning. Dr. Paul R. Epstein (2000), a scientist with Harvard's Medical School Center for Health and Global Environment, concluded that the wildfires were precipitated by global warming, which caused the drought that dried out these forests, making them vulnerable to wildfires. Epstein proposed that the most important reaction to these fires would be to control global warming and

restabilize the climate system.

An extremely important policy statement was made by Forest Service chief Mike Dombeck in January 2001, when he ordered the protection of the largest and oldest trees on Forest Service land (Jehl 2001a). In explaining his decision, Dombeck said, "In the future, we will celebrate the fact that national forests serve as a reservoir for our last remaining old-growth forests and their associated ecological and social values" (Jehl 2001a). Only about 3 percent of national forests is old-growth forest, yet these forests are among the most important refuges for rare and endangered species. Dombeck's statement and the philosophy behind it are reminiscent of John Muir or Henry David Thoreau, an extraordinary reversal from the utilitarian view of forests as tree farms that has held sway since the beginning of the Forest Service. In fact, it had been Forest Service policy that the oldest and biggest trees be cut first (Jehl 2001b). The new Republican Administration and the Senate panel overseeing the Forest Service announced that hearings would be held on the new policy, which runs counter to the one backed by President George W. Bush (Jehl 2001b). Dombeck was asked to leave his job soon after President Bush took office. Logging in national forests has declined from 1989, when 12 billion board feet were cut, to about 3 billion board feet in 2000 (Jehl 2001b). Loggers are expected to lobby hard to cut these last old-growth trees because of the huge amount of dense wood they contain.

North America™s Forests: Page 16

Although Canada's forests are far more extensive, with greater amounts of old-growth, they are being logged at an extremely rapid pace. The 1980s and early 1990s witnessed the clearcutting of millions of acres of Canadian forests, from boreal coniferous woodlands to deciduous and mixed forests in the east to the ancient temperate rainforests of British Columbia's coast. The logging that has removed vast tracts of Canada's forests is a major factor in the decline of the continent's colorful and ecologically important wood warblers and other songbirds. British Columbia's mountainous terrain is not conducive to clearcutting because of erosion, but this has been the method used to raze hundreds of thousands of acres. Wilderness valleys with forested slopes have been denuded and the soil and debris washed into salmon streams and rivers, clogging and destroying them. The Bowron Valley in central British Columbia was turned into a moonscape in 1992 when 1,600 square kilometers were clearcut; efforts to replant this huge area have not been successful (Devall 1993). Habitat of the Grizzly Bear in British Columbia's high-altitude forests has been devastated along with its forest wilderness home elsewhere in Canada (Devall 1993).

Research on Sitka Spruce (*Picea sutchensis*) canopies on Vancouver Island, along the British Columbia coast, has produced 300 new species of insects, and scientists state that this environment will reveal hundreds more. According to one biologist, "We have a virtually unexplored biological frontier in our own backyard" (Moffett 1997). A highly unusual Sitka Spruce, called "Golden Spruce" (*P.s. aurea*), grows on Graham Island in the Queen Charlotte Islands to the north of Vancouver Island (DePalma 1997). This extremely rare color phase had only one known adult specimen in the wild, the result of a genetic quirk that causes chlorophyll to break down, giving the needles a golden yellow hue when exposed to sunlight (Comeau 1997). Standing 160 feet tall, and 300 years old, the Golden Spruce was known to the native Haida tribe, who revered it, as "kiidk'yaas," or ancient tree (DePalma 1997). (A color photograph of this dazzling tree was published in the *Canadian Geographic* magazine in May/June 1997.) The Haida believed that the tree would be admired until their last generation and that it held the spirit of a young Haida boy who survived, along with his grandfather, the demise of their village, which was destroyed by an angry Creator (Comeau 1997). As they walked away, the elder warned the boy not to look back, but the boy disobeyed and was turned into a tree that came to be venerated as the embodiment of the tribe's spirit (Comeau 1997).

In January 1997, a mentally unbalanced man swam across the sound to the island and cut the tree down. This caused shock and dismay among the Haida, who felt they had failed in protecting this most important part of their traditions and believed that its death predicted their own demise (Comeau 1997). Fortunately, a few cuttings had been

taken from this tree in 1986 by a horticulturist, who brought them to the Botanical Garden at the University of British Columbia and propagated them. Two 5-feet-tall, scrawny trees were produced, and they are all that remain of the magnificent Golden Spruce (DePalma 1997). The Haida took about 100 cuttings from the top of the felled tree and asked the scientific community to help save it. They accepted one of the two propagated specimens from the university (Comeau 1997).

Vancouver Island, just north of Washington state, is one of the most magnificent scenic areas in the world. The struggle to stop clearcutting of its ancient forests has become pitched. One highly endangered species resident on this island is the endemic Vancouver Island Marmot (*Marmota vancouverensis*), one of 11 species of marmots in the world, all native to the Northern Hemisphere (Nowak 1999). Much of the Vancouver Island Marmot's habitat has been destroyed by development for ski slopes and logging, which apparently removed important migration corridors between colonies. This exposed the marmots to predation and prevented the establishment of new colonies (Thornback and Jenkins 1982). Colony sites became isolated, and vacant areas were not reoccupied, causing inbreeding (Thornback and Jenkins 1982). The Federation of British Columbian Naturalists formed a Vancouver Island Marmot Preservation Committee to conduct surveys and publicize the need to protect the Vancouver Island Marmot (Thornback and Jenkins 1982), yet in spite of long-term studies, logging continued. Surveys in 1979 and 1980 found only 11 colonies with 50 to 100 individuals (Thornback and Jenkins 1982). A 1984 survey found 231 animals, and some captive breeding has been successful (Nowak 1999).

The *2000 IUCN Red List Species* lists the Vancouver Island Marmot as Endangered (Hilton-Taylor 2000). It is also listed as Endangered by the US Endangered Species Act, and as Critically Endangered by the British Columbia Conservation Data Center of the province's Ministry of Environment. The Vancouver Island Marmot has been ranked in the most endangered category by the Center, as having few remaining individuals, and since this remnant population is continuing to decline, its extinction has become likely. By 1995, 11 colonies had declined to only eight, and the 1984 population of 231 animals had declined to only 150 animals. Biologist Andrew Bryant, chief scientist of the Marmot Recovery Foundation, conducted his Master's Thesis on the species and has continued to monitor it, according to the British Columbia Conservation Data Center. The population declined to a critical level in the late 1990s, and there are plans to take more animals into captivity to attempt captive breeding for future releases into protected habitat. In 1999, researchers found only 62 marmots left in the wild (NGS 2000). They took 27 into captivity for breeding programs. Bryant stated that the major threat to these animals was clearcutting, which greatly reduced their food supply; they are also vulnerable to predators (NGS 2000). The long-term plan is to reestablish these marmots in three separate sites and build populations up to 400-600 animals (NGS 200).

Vancouver Island's panoramic beauty is displayed in the 1994 film, fiRainforest of the Pacific Northwestfl (see Video, North America section). Aerial views of undisturbed forest and the majestic Clayoquot Sound contrast with large stretches of clearcut forest. Trees up to 270 feet tall and more than 1,000 years old grow on Vancouver Island, but less than one-third of the old-growth forest remains; at the making of the film only 4.5 percent of the forest was protected. The British Columbian government appointed a panel to recommend revisions to the logging plan for Clayoquot Sound and, to the delight of conservationists, issued recommendations in 1995 banning clearcutting and proposing strong streamside protections and so many safeguards that very little logging will be allowed (SCLDF 1995). In 1995, the British Columbian government announced that it would adopt all the recommendations made by the blue ribbon Science Panel. All commercial logging in pristine areas has been deferred until biological inventories are completed, according to the Rainforest Action Network (RAN). This does not mean a permanent end to logging in this beautiful Sound, and conservationists will need to continue the fight. The native-run Clayoquot Sound First Nations leaders are apprehensive that they may be pressured into joint logging ventures with timber companies, and they issued an unequivocal declaration calling for an end to commercial logging in all old-growth forests (Rosmarin 1995).

Forty miles north of Vancouver, old-growth coastal forests are being destroyed by commercial loggers to make way for urban and suburban growth. The Squamish River cuts through these forests and provides one of the great wildlife spectacles in North America. When salmon disappeared from almost every river of the Northwest and

pollution killed off fish in many northern states, Bald Eagles migrated north to the Squamish River (Nickerson 1995). Almost 4,000 Bald Eagles from as far away as Wisconsin and the Rocky Mountains winter along the river, feeding on spawning salmon (Nickerson 1995). "Americans are strange," a Squamish Native American remarked, "They revere the eagle as the pride of their country, then ruin his home and make him so hungry he flees to Canada" (Nickerson 1995). Yet this sanctuary is now threatened. A 600-acre industrial park at the heart of the winter roosting grounds is planned by local officials, and logging has removed much of the forest already (Nickerson 1995). The Nature Conservancy began acquiring parcels of land for the establishment of Canada's first sanctuary for Bald Eagles (Nickerson 1995). The goal of conservationists is a preserve of 2,700 acres to protect this important feeding area (Nickerson 1995).

North America™s Forests: Page 17

The white bears of Canada live along 1,000 square miles of rainforest on the British Columbian coast and off islands. Their main breeding island, Princess Royal Island, harbors the largest number of these bears, which are a rare color phase of the Black Bear. The percentage is even lower on other islands (Russell 1994). The world population of these bears is estimated at only about 400 (NRDC 2001). A delightful book, *Spirit Bear. Encounters with the White Bear of the Western Rainforest*, by naturalist Charles Russell, recounted his visits to the island with two filmmakers, Jeff and Sue Turner, who were working on "Island of the Ghost Bear." Russell, who has been studying and helping bears of many species throughout his life, wanted to write a book about the spirit bear to obtain sanctuary status for this island and its bears. The white bears on the island have been protected for thousands of years, first by the Native Americans, and now by the British Columbian government. They are so tame that Russell was amazed, having never encountered such friendly bears of any species. A young white bear came to inspect Russell and the filmmakers soon after they arrived, peering into their camera lens, leaving nose prints on the lens (Russell 1994). This bear would sit down near them, sometimes seeking their protection when larger Black Bears tried to take away salmon he had caught (Russell 1994). On one occasion, Russell followed the bear back into the forest to see where he went. After a long walk through the rainforest, the bear found a soft area covered in bright green moss and decided to take a nap. He was so trusting that he went to sleep with Russell watching him only a few feet away. While asleep, the bear seemed to be dreaming, his eyes moving, legs twitching, and sometimes grunting (Russell 1994). Russell's book is illustrated with many photos of the bear fishing, sprawled on his back in the forest, and climbing about the rocks. This bear let himself be scratched with a stick and even tried to wrestle with Russell and Jeff Turner. Russell and the Turners left the island but returned after a year, and the bear came to greet them, sitting down a few feet away as if they had not been gone at all (Russell 1994).

The entire range of this bear is slated for logging. The Black Bears living on these islands, which carry white bear genes and are only a bit less tame than the white bears, are hunted under British Columbian law, which allows two bears per hunter each season. When they were filming the bears, some Swiss, German and Austrian hunters had arranged a bear hunt (Russell 2000).

The film, fiGhost Bear,fl shown on PBS's Nature series in 1994, captured an island little changed for 10,000 years, never logged and teeming with wildlife. Black wolves, mergansers, Beavers, salmon and Bald Eagles live in this mossy, verdant forest with towering trees. The filmmakers urged protection for the bears and the forest. Other defenders of this bear and its forest are the members of the Kitasoo and Gitga™at Indian tribes of British Columbia, who believe that the white bears were created by a raven who came from heaven and decreed, "The white bears will live here forever in peace." The tribe wants to create a park of the entire area to protect the bears and the rainforest. Logging proceeded, however, within the proposed park, and a logging company cut a road through one island's ancient rainforest and the ancestral Kitasoo deer-hunting grounds. The Rainforest Action Network (RAN) began in the mid-1990s to help create a sanctuary, which is opposed by the British Columbian government. Twenty million acres of rainforest in the province may be cut, and RAN is campaigning to convince US customers to cancel contracts

and refuse to buy products from these ancient forests (Rosmarin 1995).

A Canadian couple, Ian and Karen McAllister, have formed an organization, Rainforest Conservation Society, to preserve the habitat of the Ghost Bears and the Great Bear Rainforest. Their book, *The Great Bear Rainforest, Canada's Forgotten Coast*, published in 1997 by Sierra Club Press, eloquently describes this magnificent region and their work to help preserve it. The Natural Resources Defense Council (NRDC), headquartered in New York, took on the cause in 2000, urging a consumer and commercial boycott of International Forest Products (Interfor), a logging company that is cutting the old-growth forests in the heart of 18 untouched rainforest valleys in the Great Bear Rainforest. As the company was about to clearcut East Creek on one island, it was stopped by construction of a tribal longhouse by the Gita™at Tribe at the mouth of the creek, aided by NRDC, which forced the company to suspend its plans (NRDC 2001). Negotiations between conservation groups and six logging companies, including Interfor, had appeared to achieve protection of the Great Bear Rainforest, but Interfor pulled out of the agreement and recently began logging within the habitat of the white bears. This devastation of a magnificent environment does not even make economic sense, as there could be a sizeable market for videocam views linked to a satellite of these enchanting bears and their mossy, green forests, paid for by viewers around the world for a long-term profit far exceeding that which will accrue to the loggers. The Giant Panda is also a charismatic species, and conservation donations from zoos now total $10 million a year or more to preserve the species™ habitat. The white and black bears of this wilderness deserve no less.

North America™s Forests: Page 18

Further inland, the Wood Buffalo National Park, bordering Alberta and the Northwest Territories, is the sole breeding ground of the endangered Whooping Crane (*Grus canadensis*). This enormous park, designated a United Nations World Heritage site, was logged in large clearcuts from the end of World War II until 1992, a tragic loss of old-growth boreal forest (Devall 1993). The logging was stopped by a lawsuit brought by the Sierra Club Legal Defense Fund (now Earthjustice Legal Defense Fund) in conjunction with the Canadian Parks and The Wilderness Society. The suit was based on the Canadian National Parks Act, which states, "The National Parks shall be maintained and made use of so as to leave them unimpaired for the enjoyment of future generations" (Devall 1993). The Peace River, flowing through Wood Buffalo, is so contaminated by dioxin from the Daihowa pulp mill upstream that natives no longer eat the fish, their major food staple, from the river (Devall 1993).

By the end of 1988, one-third of the land surface of Alberta, Canada-- 221,000 square kilometers--had been logged. Much of Saskatchewan's former forested land--more than one million hectares--has been clearcut and not replanted, nor has it regenerated naturally (Devall 1993). Manitoba, south of Hudson Bay, protects less than 2 percent of its territory from development and logging. In 1989, the Manitoba government opened up an area the size of Ohio, 108,000 square kilometers, to logging (Devall 1993). Logging in Manitoba, Saskatchewan and Alberta fueled $10 billion in new pulp mills, major water and air pollution sources (Devall 1993).

Eurasian Temperate Forests

The Siberian Tiger's Domain
Land of the Giant Panda
Lost Forests of the Mediterranean and Europe

Eurasian Temperate Forests: The Siberian Tiger's Domain

Russia's coniferous forests form the major part of the Eurasian taiga, a mixture of spruce, birch and other evergreens, covering 3 million square miles, two•thirds of the country's land surface (Sparks 1992). It is the world's largest forest of any type, more than twice the size of the Amazon rainforest (Stewart 1992). Russia's taiga makes up half of the world's total area of coniferous forest and about one-quarter of the entire forested area of the world; the Siberian portion alone is one•third larger than the whole of the United States (Sparks 1992). The forested land east of the Ural Mountains covers 5 million square miles (Linden 1995). Further south, deciduous trees mix with aspen, birch and alder (Sparks 1992). This entire, vast forest may once have been the domain of the Siberian Tiger (*Panthera tigris altaica*), as its fossilized bones have been found on Lyakhov Island off the north coast of Siberia (Matthiessen 2000).

The vast expanses of taiga forests were opened up to international logging after the dissolution of the USSRF. By the early 1990s, about 304 million acres, two•and•one•half times the size of France, had been clearcut (Stewart 1992). Each year an additional 12 million acres are logged (Lean and Hinrichsen 1992). Commercial exports of Siberia's logs to the United States have been encouraged by various corporations and the US Department of Commerce. Logging has also been intense in Russia's Far East, an area of great biological diversity, with many resident endangered species.

A nearly pristine and stunningly beautiful part of Russia is the Kamchatka Peninsula in the Far East, jutting into the Pacific Ocean. This area has 29 active volcanoes, wild rivers, hot springs, and beautiful forests. An endemic tree, the Kamchatka Fir (*Abies gracilis*), grows only on this peninsula. A relict of pre-Ice Age coniferous forests, it is a silvery fir with soft needles, which grows to about 70 feet in height; this once widespread tree is now restricted in range (Sparks 1992). The forests of Kamchatka are being heavily logged (Meulenaer and Vaisman 1996). Another threat is gold mining, as $10 billion worth of gold is thought to lie under the forests and lakes of the Peninsula (Specter 1997).

The Kamchatka Sable (*Martes zibellina*) is larger than sables in other parts of Russia and was nearly trapped to extinction in the 19th century (Stewart 1992). The Sable's habitat is dominated by Stone Birch (*Betula ermani*) forests with thick, grassy undergrowth covering the mountain slopes; some of these trees grow to be 600 years old (Stewart 1992). Mountain Ash provide berries which, along with an occasional fish, supplement the Sable's diet of voles (Stewart 1992). Unfortunately, anti-trapping restrictions are not being enforced in Russia's Far East, even in nature reserves. The Kronotsky Nature Reserve, covering 3,860 square miles on the peninsula's east coast, shelters 700 species of tundra, taiga and mountain plants, with a number of unusual endemic plants, including the beautiful Kamchatka Rhododendron (*Rhododendron kamchatkensis*), which has miniature red blooms (Sparks 1992).

The magnificent Siberian or Amur Tiger is the largest of all wild cats. Only a few hundred years ago, its realm extended from northern Manchuria west to Lake Baikal and south to North Korea and northeastern China (Matthiessen 2000). Its range shrank over the centuries as a result of hunting, persecution, loss of prey species and habitat. Today it is restricted to the extreme southeastern Maritime Region in the Amur River basin east of Manchuria, west of Sakhalin Island (Miquelle *et al.* 1999). During the 1980s, the Soviet government established a series of reserves for the Tiger, but heavy logging and hunting in the region caused declines in its major prey species, boar and deer. Only 5 percent of the Siberian Tiger's habitat is protected in reserves, according to Evgeny Smirnov, a Russian biologist who studies Tigers (Gourevitch 1995). Moreover, a trade in Tiger bones and other body parts for Traditional Medicine has resulted in the killing, often brutal, of thousands of Tigers throughout their range from India east and south to Indonesia (see Trade chapter).

Siberian Tigers require very large territories. In Sikhote-Alin, their major protected reserve, there are only 10 to 15

resident adults on 400,000 hectares (988,400 acres) (Smirnov and Miquelle 1999). Such large home ranges make them extremely vulnerable to habitat loss, especially the fragmentation of forests by logging. This region™s volcanic peaks rise 5,000 feet from the sea, and forests are crisscrossed by rivers and dotted by lakes. Northern and southern forests meet here, harboring a myriad of tree species. Tall Korean Pines (*Pinus koreansis*) mingle with oaks, maples, walnuts and birches, and unlike the typical Siberian taiga, shrubs and undergrowth are luxuriant (Stewart 1992). These trees reach heights of nearly 150 feet and produce a great volume of cones, providing food for Wild Boar, Brown Bear, Manchurian Moose, and the endemic Ussurian Asiatic Black Bear (*Selenarctos thibetanus ussuricus*). Korean Pines have been so heavily logged outside the reserve that the species is now threatened; although it is protected, illegal logging still occurs (Bohan *et al.* 1996).

A highly unusual type of dark•barked, slow•growing birch grows here. Known as the "Iron Birch" (*Betula schmidtii*), its wood is reputedly so heavy that it sinks in water (Stewart 1992). The Primoryi Province, in which this preserve is located, harbors more than 150 species of trees and shrubs. The meeting of northern and southern forests in this region has resulted in a rich diversity of wildlife. The Ussuri Sika deer (*Cervus nippon hortulorum*) lives alongside the endangered Goral (*Naemorhaedus goral*), a goat•like ungulate native to mountains west to the Himalayas. This is the northern edge of the Leopard's range. The Amur Leopard (*Panthera pardus orientalis*) is a highly endangered subspecies, threatened by both habitat loss and poaching. Lynx and Common Otter are also native. The Dhole (*Cuon alpinus*), a threatened wild dog native to more southerly regions west to India, may also be native to the Sikhote•Alin Preserve. This extraordinarily rich diversity of predators and prey is at great risk from overhunting and logging, however.

As many as 340 species of birds have been recorded in Sikhote•Alin (Stewart 1992), including two endangered waterbirds, the Red-crowned Crane (*Grus japonensis*) and the Oriental White Stork (*Ciconia boyciana*) (Collar *et al.* 1994). A species of ginseng (*Panax ginseng*) grows in the undergrowth and is valued by the indigenous Udege people and others as an invigorating tonic, making it the "root of life" in their folklore. They believe that the ginseng is guarded by the great Siberian Tiger, and shrines are erected to the Tiger, who is believed to possess near•magical powers (Stewart 1992).

In 1991, the Hyundai Corporation of South Korea signed a 30•year contract to cut 500,000 acres of virgin forest on the Pacific slope of the Sikhote•Alin range (Schafer and Hill 1993). By the end of 1992, the area had been clearcut, and Hyundai began logging in the Bikin River Basin, the last pristine river valley in the region (Schafer and Hill 1993). In the Bikin, a small population of Udege live along the river's forested banks, as they have for hundreds of years, subsisting on local wildlife (Schafer and Hill 1993). These people have opposed the entry of the loggers, filing suit to stop the logging, threatening to shoot at logging trucks and removing markers from trees slated for cutting (Schafer and Hill 1993). Their protests succeeded in stopping the logging, negating the original agreement; Hyundai continues, however, to try to gain access to the Bikin forests (Bohan *et al.* 1996). This 600,000-acre watershed of the Bikin River is among the last virgin forests in Ussuria (Matthiessen 2000). A plan by the US Weyerhauser Corporation to cut an area of virgin forests the size of Delaware was thwarted by conservationists, and this forest has been declared a nature preserve (Nunn 1996).

Some 10 million acres of Tiger habitat are being clearcut every year, and members of the Siberian Tiger Project, composed of US and Russian biologists, are proposing alternate methods of timber harvest for the region (Quigley and Hornocker 1994). The native deer and boar, upon which the Tiger depends, are being hunted out of many areas by local villagers and professional poachers, who sell their bones and antlers for the Chinese Traditional Medicine trade. In 1995, the Russian government issued a decree "On Saving the Amur Tiger," which called for a specific plan and schedule to implement Tiger protection efforts (Galster 1996). In response, the Russian-American scientific team formulated a plan the same year to protect all existing Tiger habitat with connected reserves, new national parks, multiple use zones and ecological corridors linking them. It would be the world's largest sanctuary, preserving old-growth Korean Pine and designating various zones in this immense area, which extends from north of Khabarovsk south to Vladivostok in a mosaic of connected land (Galster 1996). The plan also called for a new national Tiger census, which was carried out in early 1996 and found more Tigers than previously assumed, an estimated 330 to 371

animals. The proposed protection plan, when combined with the Bikin traditional reserve and a large region a US government agency is helping to protect through multiple use, would preserve about 26 percent of existing habitat of the 156,000 square kilometers used by Siberian Tigers in Russia (Miquelle *et al.* 1999). The remaining area is either scheduled for logging or agricultural development. The Tiger biologists are urging that all Tiger habitat be included in a national protection plan, as signs of Tigers have been seen in 90 percent of the habitat (Miquelle *et al.* 1999). Coexistence between Tigers and people is essential. This would mean easing human hunting pressure on its prey, primarily Elk and Wild Boar, which have become rare, a major cause for the Tiger™s need of such large territories. Moreover, Tiger poaching needs to be stopped, and Tigers need access to river valleys, which they use for hunting and movements. Most of these have been taken over for human use.

The Siberian Tiger Project was the subject of a 1995 National Geographic film, "Tigers of the Snow," which included the first filming of a baby Siberian Tiger being weighed and examined by biologists in its wild den. The magnificent scenery of this coastal region was filmed from an aircraft, and areas of clearcutting were in stark contrast to the unbroken forests. The film also noted the sad end to a young Tiger hit by a logging truck. These trucks, loaded with giant tree trunks, thunder through the beautiful valleys. The Siberian Tiger Project is the first research study involving radio-tracking ever undertaken of the Siberian Tiger, and it is revealing new information on its range, behavior and habitat needs. Should the reserves be set aside, Siberian Tigers will be the first race or population of Tigers to become stabilized and perhaps increase at a time when all other populations are in drastic decline.

An eloquent book by Peter Matthiessen (2000), *Tigers in the Snow*, focuses on this research and the future of all Tigers. Anti-poaching work is helping to stem the decline of both the Tiger and its prey, but until its habitat is secure, this once proud cat, master of its domain, will remain beleaguered and under constant threat. Its world has become a battleground, filled with the screeching of power saws destroying the forests it needs to survive, and the constant threat of poachers. As a keystone species at the top of its food chain, the survival of the Tiger is "the best indicator of the health of the ecosystem as a whole" (Matthiessen 2000). Without the Tiger, the deer and boar will become slow, small and overpopulated, destroying their habitat as they have in Europe, where most predators have been eliminated. This is a crucial turning point for the species, whose tropical populations may not survive long. The Siberian Tiger inhabits a world without high human populations, a still-extensive forest habitat, and is the subject of a strong conservation program. The many people who are dedicated to saving it may succeed. In the words of Maurice Hornocker, an overseer of this research project, "One day it will be culturally unacceptable to kill Tigers anywhere for any reason" (Matthiessen 2000).

Eurasian Temperate Forests: Land of the Giant Panda

China's once extensive forests have declined over the centuries as human population increased. In south-central China, temperate forests of many types are watered by the five great rivers of Southeast Asia: the Mekong, Irrawaddy, Yellow, Yangtze and Salween (Mittermeier 1999). This is botanically the richest temperate region in the world, twice the size of California with half of China's plants--12,000 species, of which 3,500 are endemic (Mittermeier 1999). This is the home of the Giant Panda (*Ailuropoda melanoleuca*). Fewer than 1,000 of these black-and-white bears remain in small, scattered populations. When climates were cooler during the Ice Ages 12,000 years ago, Giant Pandas had a far larger distribution, covering much of central and southern China and bordering areas of Burma. As climates warmed and human populations took over much of their habitat, they declined in numbers, and their bamboo forests retreated. Today, Giant Pandas remain only in three provinces, with the largest number in Sichuan. Between 1974 and 1989, their habitat was halved as a result of logging and settlements, from 20,000 square kilometers to 10,000 square kilometers (Mittermeier *et al.* 1999). Satellite studies of their major reserve, Wolong Nature Reserve, found a dramatic decline in forest cover from 1965 to 1997 as growing numbers of people living in the reserve cut deciduous trees and bamboo for firewood (Revkin 2001). During the last decades, with international attention focused on this extremely charismatic animal, reserves have been set aside. Twenty reserves have been established in the

remnants of the Giant Panda's habitat, but the species has continued to decline as destruction of forests turn the reserves into islands surrounded by clearcut hillsides. Many Pandas have starved to death when their bamboo forests were cut or underwent a cyclical die-off. Prior to this deforestation, when local bamboo forests died off, Giant Pandas were able to wander widely in search of other bamboo. Their habitat has decreased so much that they are now at the mercy of local conditions within each reserve (Mittermeier 1999 *et al.* 1999).

A long•term study of this species by Dr. George Schaller, of the New York-based Wildlife Conservation Society, arrived at the pessimistic conclusion that the Giant Panda was headed inexorably toward extinction (Schaller 1993). In his 1993 book, *The Last Panda*, Schaller wrote a scathing and unflinching analysis of the failure of existing conservation programs. Among his conclusions was that almost all of the millions of dollars raised around the world to preserve this most popular of all animals had been wasted while wild Giant Panda populations dwindled. His research revealed that Pandas were readily taken into captivity during bamboo die•offs when, in fact, enough bamboo still remained to supply their needs (Schaller 1993). Most of the funds were spent on building dungeon-like breeding and holding compounds rather than on saving its ever•dwindling habitat or hiring wardens to prevent poaching (Schaller 1993). The Wolong Reserve, which covers 780 square miles, was the location of his research area. Wolong had 4,200 people living within its borders in 1989, who were cutting trees and setting snares to kill wildlife for meat, musk and skins (Schaller 1993). In eight years alone, 14 square miles of the Wolong forest were destroyed, and an unknown number of Pandas died in cruel wire snares (Schaller 1993).

Only time will tell whether the urgent habitat and anti•poaching needs of the Giant Panda will be met, or whether funds meant for its conservation will continue to be spent on breeding compounds. Seventeen forest corridors are planned to link fragmented habitat, but breeding and holding compounds continue to be built, with a goal of 32 stations (Williams 1994). A dedicated Chinese scientist, Pan Wenshi, who has studied these animals for decades, helped save the habitat of some 80 Pandas in these mountains when the high•pitched whining of chain saws was within earshot (Wenshi 1995). The National Geographic Society filmed the mother Panda that Pan Wenshi had studied throughout her life, Jiao Jiao, and her tiny mouse•sized cub when only a few days old (see Video section). This cub, a female he named Xi Wang, meaning Hope, grew into a healthy young Panda and, when four months old, took her first shaky steps out of the warm den (Wenshi 1995). As she grew older, Xi Wang took naps lying on her back in the tops of pine trees, watching her mother as she fed in the forest (Wenshi 1995).

If forest corridors are not soon set aside linking the reserves to one another to allow free movement of Pandas, the species will probably fade gradually to extinction from inbreeding (Lean and Hinrichsen 1992). One source of funding to preserve habitat is the Chinese government loan program, under which Giant Pandas are sent to foreign zoos for periods of up to 10 years. Various zoos in the United States have arranged such loans, paying the Chinese government $1 million per year per zoo, and these funds must be applied to conserving the species in the wild under supervision of the US Fish and Wildlife Service. A pair in the San Diego Zoo produced a healthy female cub in 1999 through artificial insemination. Other pairs were acquired by Zoo Atlanta and the National Zoo in Washington, DC, in 2000. Few Giant Pandas breed naturally in zoos. This funding and the new attention directed at conserving these highly endangered and endearing animals may turn the tide in China to protecting their habitat. If successful, it will also spell survival for thousands of rare Chinese plants and animals that inhabit the Pandas™ forests.

Xi Wang, the Giant Panda studied by Wenshi, inhabits the Qin Ling Mountains, haven for a wide diversity of rare plants. One mountain alone, the 12,359-foot Taibai Mountain, has 150 endemic species of plants, among them the Qin Ling Mountain Fir (*Abies chenensis*) (Ji 1990). Two varieties of this species are listed by the *1997 IUCN Red List Plants* (Walter and Gillett 1998). A neighboring mountain, the Shennongjia, is known as a "Treasure House of Plants" because of the many unusual and ancient species here (Ji 1990). In Hubei Province in the same region is the Dawn Redwood, a deciduous tree which is a close relative of the North American Coast Redwood and Sequoia but far more ancient in lineage (Ji 1990). Until 1941 when a few groves were discovered by Chinese botanists, the Dawn Redwood was known only from Jurassic fossils (MacKinnon 1996). Small populations survive in Sichuan, Hubei and Hunan provinces, but the species is considered Endangered by the International Union for the Conservation of Nature (IUCN) (Walter and Gillett 1998) and only about 1,000 trees may survive in the wild (Dyer 2000). This tree grows to

a height of about 115 feet, its delicate pinnate leaves turning golden in the fall. As the sole member of its genus, and a living example of trees that grew in the age of dinosaurs, it is considered a great botanical treasure.

Its seeds have been planted in many parks and botanical gardens around the world. John Williams, the award-winning composer, became fascinated with a Dawn Redwood growing in Boston's Public Garden (Dyer 2000). "It not only looked lovely, but it seemed animate, even intelligent," he said (Dyer 2000). By chance, he met a retired Harvard University botanist, Dr. Siu-Ying Hu, and praised the tree on a walk through the Public Garden. Hu pointed out that he had planted this very tree back in the 1940s, having brought a bag of seeds to America when he arrived from China (Dyer 2000). The Dawn Redwood inspired Williams to compose a musical piece entitled "Tree Song" for harps, keyboards, flutes and delicate percussion. It was performed by the Boston Symphony Orchestra at the opening of the summer concert series at Tanglewood, Massachusetts, in July 2000 and recorded on CD (Dyer 2000).

The extraordinary Dove Tree (*Davidia involucrata*) was named after its discoverer, Pere Armand David, a French missionary who traveled in China in the 19th century and named hundreds of animals and plants. Its white leaves are up to 6 inches long and 3 inches wide, resembling a flock of doves taking flight (Schaller 1993). These trees are quite rare in China, after centuries of deforestation (Walter and Gillett 1998). Even in 1900, when American botanist E.H. Wilson went to China to find seeds from this tree, he traveled six months before he even met someone who had ever seen one (Stocker 1997). When Wilson finally found a Dove Tree, only a stump remained: it had been cut and the wood used to build a house. He later found 10 wild specimens and brought back seed to Harvard University's Arnold Arboretum (Stocker 1997). This species, too, has ancient origins and once dominated prehistoric forests (MacKinnon 1996). Like the Dawn Redwood, it was rescued from extinction and is now cultivated in nurseries and botanical gardens (Stocker 1997).

Many of these plants and trees share the habitat of the Giant Panda, and forest reserves would ensure their survival. A number of endangered mammals that have disappeared from other regions as a result of hunting and habitat loss can be found in Wolong and other Giant Panda Reserves. The Red Panda (*Ailurus fulgens*), thought to be a relative of the Giant Panda, is a rare native, as are the Golden Monkey (*Pygathrix roxellanae*) and the Takin (*Budorcas taxicolor*), a goat•like ungulate. All three are endangered species and declining as the forests are cut. An endangered bird, the Sichuan Partridge (*Arborophila rufipectus*), is restricted to an area of less than 100 square kilometers in south-central Sichuan, where fewer than 2,000 birds survive (BI 2000, Collar *et al.* 1994). Its old-growth broadleaf forest is being felled at a rapid rate, and people enter its habitat to collect bamboo shoots in its breeding season, disturbances that are driving these birds toward extinction (BI 2000). Twenty-six other species of pheasants inhabit this part of south-central China, including the most iridescent birds in the world, the monals. The threatened Chinese Monal (*Lophophorus lhuysii*) inhabits rhododendron and high-altitude coniferous forests and is in decline as a result of logging and hunting, which have been facilitated by the construction of logging roads (BI 2000). The male Chinese Monal has dazzling plumage in an array of emerald green, purple, coppery-golden, purplish-green and white, while the female is more subdued in gray and rufous-brown. The creation of reserves for the Giant Panda have aided this bird's survival, as
several are within this bird's range (BI 2000).

China's 25,000 native plant species make up 11.4 percent of the world's plants, including many ancient ones (MacKinnon 1996). The Ginkgo (*Ginkgo biloba*) has been on Earth for 200 million years; this tree grows wild in scattered locations in China, indicating that it was once far more widespread and was eliminated by logging over the centuries (MacKinnon 1996). In prehistoric times, Ginkgoes grew throughout the world but were thought extinct until a few trees were found in remote forests (MacKinnon 1996). Its unusual wide, lobed leaves turn yellow in the fall before falling. This tree has been considered sacred by the Chinese for centuries and is grown in temple gardens and other religious sites. Extracts are sold around the world as an herbal stimulant. In the Himalayas, giant cypresses (*Cupressus*) grow to immense size when protected by Buddhist temples; one specimen measures almost 20 feet in diameter and is estimated to be 2,000 years old (MacKinnon 1996). Entire forests of these giant trees also grew on Taiwan, where only massive stumps remain (MacKinnon 1996). Stephen Spongberg, Curator at the Arnold Arboretum, has studied China's native trees and found numerous species to be extinct in the wild (Stocker 1997).

Antique Chinese furniture sought by collectors is often made from the wood of trees that are now extinct, and some trees are so rare that most Chinese botanists have never seen them in the wild (Stocker 1997).

China has more forest types than any country in the world. In the far north, taiga dominates. Conifers, birches and oaks blend into temperate coniferous forests in the northeast. Further south, the Giant Panda's habitat is temperate, evergreen forest. Himalayan forests occur in the west, and in the south, tropical monsoon rainforest prevails (Ji 1990). Unfortunately, very little virgin forests remain in the country, other than in high altitude and remote areas (Ji 1990). In the Giant Panda's highly diverse habitat of south-central China, less than 10 percent of the forests remain in pristine condition (Mittermeier *et al.* 1999). The destruction of these forests has been going on for centuries. During the 19th century, Pere Armand David lamented its destruction:

> *From one year's end to another, one hears the hatchet and the axe cutting the most beautiful trees. The destruction of these primitive forests, of which there are only fragments in all of China, progresses with unfortunate speed. They will never be replaced. With the great trees will disappear a multitude of shrubs and other plants which cannot survive except in their shade; also all the animals, small and large, which need the forest in order to live and perpetuate their species . . . They have the right to life and we annihilate them and brutally make existence impossible for them*
>
> Pere Armand David, 1875

In many parts of China, virtually no natural habitat remains, as centuries of human habitation and agriculture have replaced native vegetation and wildlife. One can travel for 1,500 miles in east•central China, for example, and see a landscape covered entirely with agricultural fields and villages, devoid of wildlife (Schaller 1993). Deforestation caused massive floods in the summer of 1995, when the Yangtze River, the country's longest, flowing from central China east to Shanghai, overflowed its banks. More than l.3 million people were displaced by the flooding, 900,000 houses collapsed, 2.7 million acres of crops were destroyed and 1,200 lives were lost (AP 1995). The economic losses were estimated at $4.4 billion. Each year these floods worsen as development covers the region, removing all natural flood controls (AP 1995). The last forests of any extent in China can be found in the northeast, and in 1987, fires destroyed 18 million acres (an area the size of Scotland) as well as 12 million acres in adjacent Russia (Schaller 1993).

Pere David's Deer (*Elaphurus davidianus*), named for its discoverer, and was once common in the northern forests and marshes. Hunting nearly eliminated the species, and to prevent its extinction, Chinese emperors kept the surviving population in a walled imperial hunting park near Beijing for more than 1,000 years. Even this population was killed by soldiers and villagers in the 1900 Boxer Rebellion, however; fortunately, some had been taken to England and kept by the Duke of Bedford on his estate (Schaller 1993). In 1985, 22 of these deer were returned from captive populations to the same walled park in China, now reduced from 150 square miles to 440 acres (Schaller 1993). Several other herds have been reintroduced elsewhere in China, numbering some 600 animals (MacKinnon 1996).

Reverence for nature in China dates back many thousands of years and is an integral part of the culture of this ancient country. It may now be reemerging. The 1979 Forest Law contained strict regulations on logging and required 40 percent forest cover in the mountains and 30 percent nationwide. This was strengthened in 1988 with a ban on logging in Yunnan and Sichuan, and legal protection was accorded to 389 plant and 206 animal species (Geatz 1999, Mittermeier *et al.* 1999). Reserves are being set aside throughout the country, increasing from 44 in 1956 to 600 in 1991, with a goal of 800 reserves protecting 5 percent of the country (Schaller 1993). This is indeed laudable in the most populous country on earth, and this eleventh-hour commitment is preserving many remnants of the once diverse and abundant natural heritage.

In practice, however, logging and firewood cutting tend to far exceed reforestation or preservation of forests in reserves or parks. Heavy livestock grazing by herders, who also clear forests for pasture, is devastating delicate forest

habitats (Mittermeier *et al.* 1999). Logging trucks carrying the trunks of the last remaining stands of old-growth forest can be seen in many areas. These deforested areas do not tend to regenerate because fires and grazing by goats kill the saplings (Mittermeier *et al.* 1999). During the late 1990s, The Nature Conservancy began a major project to study the biodiversity of the southern province of Yunnan, whose ecosystems range from alpine to subtropical forest (Geatz 1999). Certain tribes of this region have a strong tradition of conservation, and the provincial government has welcomed the help of this organization in helping to protect their natural heritage. Its 2000 report, "Conservation and Development Master Plan for Northwest Yunnan," includes recommendations for the protection of biodiversity, regional planning and resource development to provide ideas for non-destructive economic projects, such as growing plants for medicinal and ornamental purposes as an export commodity and developing ecotourism for this spectacular region (Geatz 1999, The Nature Conservancy 2000).

The future of China's forests and its tremendous biological diversity are greatly affected by its enormous human population of more than 1.2 billion people, whose growing needs encourage heavy hunting of its depleted deer and ungulate populations and large livestock herds, as well as excessive tree cutting for firewood (Mittermeier *et al.* 1999). Various international conservation organizations are working to help China in assessing its diversity and the threats to it, and to encourage enforcement of its 1982 Constitution, which states that the nation must protect and improve its environment and ecosystems, prevent pollution and protect precious animals and plants (Mittermeier *et al.* 1999).

Asia's beautiful pheasants and partridges are disappearing rapidly as their forests are cut and many are hunted for meat. Partridges and pheasants are found from the Himalayas to sea level tropical forests throughout most of Asia. They have declined dramatically, however. Of 22 species of Asian partridges, 15 species, or 68 percent, are listed by BirdLife International in *Birds to Watch 2: The World List of Threatened Birds* (Collar *et al.* 1994). An even higher degree of threat is suffered by the many spectacular pheasants. Of the 52 species of Asian pheasants, 38 species, or 73 percent, are threatened by the destruction of forests and hunting by the same authorities (Collar *et al.* 1994). Some endangered Himalayan pheasants include the Tibetan Eared Pheasant (*Crossoptilon harmani*), White Eared-pheasant (*Crossoptilon crossoptilon*), Cheer Pheasant (*Catreus wallichi*) and Elliot's Pheasant (*Syrmaticus ellioti*) (Collar *et al.* 1994). They show a great variety in their colorful and iridescent plumages, rivaling birds-of-paradise in beauty. Their relatively large size and brilliant plumage make them vulnerable to hunters, and they have not been studied intensively in the wild to determine habitat size and other requirements for their survival. Very few species have been protected in parks and reserves.

The mixed hardwood forests that once cloaked the Himalayas, studded in many areas by native rhododendrons, have been decimated during this century. Some 57 Asian rhododendrons are listed by the *1997 IUCN Red List Plants*. The deforested steep slopes are now prone to erosion by the monsoon rains that arrive annually. Heavy rains bring huge landslides and floods. Tree cutting, primarily by people gathering firewood or clearing land for agriculture, has been particularly severe in the Indian, Pakistani and Nepalese Himalayas. The once unbroken stands of oak and pine have become fragmented and totally absent in many areas. Human populations have risen over the past century to levels far above carrying capacity of this delicate region.

The Ganges River, which flooded only once every 50 years prior to deforestation, now floods every few years since the Himalayan forests that retained the water throughout the years have been logged (Lean and Hinrichsen 1992). Only Bhutan has preserved the majority of its forests, which are crucial to the survival of many species extinct elsewhere in the Himalayas. Tigers, Asian Black Bears, Himalayan Tahr (*Hemitragus hemlahicus*), Red Pandas, Golden Leaf Monkeys (*Trachypithecus geei*), and Tibetan Macaques (*Macaca thibetana*) are among the many mammals endangered by the loss of Himalayan forests. The Woolly Flying Squirrel (*Eupetaurus cinereus*), the largest squirrel species in the world, has just been rediscovered in northern Pakistan after being thought extinct for 70 years (Walters 1995). Four feet from its nose to the end of its tail, this squirrel may be able to glide distances of up to 1,000 feet (Walters 1995). Peter Zahler, a Cornell University zoologist, traveled to Pakistan in 1994. In a remote valley where this squirrel was rumored to exist, a local villager, who found one in a mountain cave, supplied a live animal in a bag. Zahler studied it for a short time, photographed and measured it, and then hiked 3 hours up the

mountain and released the squirrel at its capture site (Walters 1995). This squirrel has been designated Endangered by the *1996 IUCN Red List Animals*. This exciting rediscovery is tempered by the threats from deforestation and overgrazing in its mountain habitat. Local people report that it is solitary and active throughout the year, climbing conifer trees to feed (Nowak 1999). The Woolly Flying Squirrel is not hunted, but the conifers on which it depends are being cut at a great rate, causing it to decline over the past decade (Nowak 1999). Its total population is estimated at fewer than 2,500 and falling as a result of habitat loss (Nowak 1999). (Photos of this squirrel appear in Nowak 1999.)

Eurasian Temperate Forests: Lost Forests of the Mediterranean and Europe

Forests of towering cedars, oaks, firs, pine and beech once blanketed the region surrounding the Mediterranean Sea. Wildlife abounded in these primeval forests. Some 8,000 years ago, forest cutting began (Mittermeier *et al.* 1999a). Livestock gradually replaced wildlife, stripping the vegetation. In 3,000 B.C., Phoenicians logged the great forests of Cedars of Lebanon (*Cedrus libani*) for ship and building construction to trade with Egyptians and other cultures (Mittermeier *et al.* 1999). These massive trees reach 130 feet in height and are among the most majestic and stately of all trees. On the island of Cyprus, an endemic cedar, the Cyprian Cedar (*Cedrus brevifolia*), covered the island. Centuries of tree cutting and livestock overgrazing have reduced this tree to a relict population. Other forests on the Mediterranean's eastern shores were felled for building and to clear land for agriculture and grazing. The Greeks cut their forests in spite of warnings by the philosopher Plato as early as 4,000 B.C. that water supplies and wildlife would disappear (Pontiff 1991). The country's climate grew dryer and its topsoil washed into the sea (Runnels 1995).

Italy's southern forests were cut in Roman times, but north of the Adriatic Ocean, large expanses of beech and oak forests remained intact until the 16th century when they became the raw material for ships and galleys that sailed the Mediterranean waging battles and trading. Enormous amounts of lumber were needed to build these ships. When an exact replica of a galley was reconstructed a few years ago, 650 mature trees were required: 50 beech trees were needed for oars, 300 pines and firs for planks and spars, and 300 mature oaks for hull timbers (Attenborough 1987). In 1571, Venetian fleets battled the Turkish fleet which had been attacking and looting their ships. The 500 vessels in the Venetian and Turkish fleets had required the felling of more than a quarter-million mature trees (Attenborough 1987). Soon thereafter, the building of Venetian galleys came to an end for lack of trees, and shipbuilding moved elsewhere in Europe where trees were still abundant (Attenborough 1987). A single forest resembling the original beech and evergreen forest remains intact near the Adriatic in the former Yugoslavia. Its beauty was filmed for the series, fiThe First Eden. The Mediterranean World and Manfl (see Video section, Regional, Mediterranean).

Hardwood forests covered much of Spain until the early 16th century when, by royal decree, it was decided that the economy of the country could be expanded by developing a Spanish monopoly on the breeding of Merino sheep for their valuable wool (Attenborough 1987). Sheep herds became larger and larger, and forests were cut to provide grazing land. Within decades, the forests that had covered central Spain were gone, and topsoil had eroded, leaving shrubland (Attenborough 1987). These forests have not regenerated. Some oak forests have survived in parts of Spain, but intact ecosystems with native ungulates and predators have disappeared. Livestock grazes in all but the most remote areas. The few remaining Gray Wolves, as well as the endemic Iberian Lynx (*Felis pardina*), are critically endangered due to loss of forests and persecution. As an indication of the degradation of habitat, many species of Spanish wildlife are threatened with extinction. Worldwide, about 11 percent of the world's birds are threatened with extinction (Collar *et al.* 1994), but 37 percent of Spain's birds are threatened, 53 percent of its mammals, 41 percent of its reptiles, and 45 percent of its amphibians (Peters and Lovejoy 1990).

Forests of pine, cedars and oaks blanketed the slopes of the Atlas Mountains of Algeria and Morocco prior to the

Roman conquest. Logging by the Romans and people in the intervening centuries has destroyed all but fragments of these forests. The Atlas Bear (*Ursus arctos crowtheri*) originally ranged in these forests but was gradually pushed toward extinction by loss of its forest habitat, hunting and capture. The last of these bears was killed in the late 19th century (Day 1981). The endemic Atlas Cedar (*Cedrus atlantica*) has wide girths and grows to heights of more than 125 feet. They are often covered in moss and lichens in the cool altitudes (color photo, see Mittermeier *et al.* 1999a). Unfortunately, they are fast being depleted by timber cutters in Morocco and Algeria (Mittermeier *et al.* 1999a). North Africa's forests have become fragmented by centuries of logging and heavy grazing by cattle, sheep, and goats. The native Wild Boar (*Sus scrofa*) have also been extremely destructive to the few forests that remain, endangering many birds (Collar and Stuart 1985).

Surprisingly, a bird species native to the Atlas Mountain forests remained unknown until 1975. The Algerian Nuthatch (*Sitta ledanti*), a small, buffy songbird with white eyebrows, was discovered in a national park on Mont Babor (Collar and Stuart 1985). Even in national parks in this region, however, livestock are permitted to graze, consuming young trees and other vegetation. After conservationists protested that this little bird's entire habitat would be eliminated if livestock were not excluded, sheep and goats-- but not cattle--were banned from the park in 1981. To prevent forest cutting by the local people, propane gas has been supplied to use as fuel for cooking and heat (Collar and Stuart 1985). The forest on Mont Babor consists of mixed Atlas oak, Atlas Cedar and the Algerian Fir (*Abies numidica*), a threatened species which grows only on this mountain (Walter and Gillett 1998). The Algerian Nuthatch uses cedars, oaks and, especially, the Algerian Fir for seeds and nesting (Harrap and Quinn 1995). The population of about 80 pairs of Algerian Nuthatches censused in Mont Babor National Park in the early 1980s remained constant, and in 1989, a second population of about 350 birds was discovered in a nearby oak forest within the Taza National Park (Collar *et al.* 1994). Even though the Taza has National Park status, conservation of the forest has been hindered by cattle grazing that prevents tree regeneration. Also, wood-cutting is allowed that removes potential nest sites, and fires are set, killing many types of animals (Harrap and Quinn 1995). These birds also survive in two small isolated tracts of unprotected, degenerating forest 30 kilometers away, but the total population probably does not exceed 1,000 birds (BI 2000).

Another rare animal, the Barbary Deer (*Cervus elaphus barbarus*), barely clings to life in the disappearing Algerian forests. It is now extinct in Morocco and survives only in a small forest of cork oak and pine on the border between Tunisia and Algeria. They number only a few hundred, including a captive population, and are declining each year. This subspecies of the European Red Deer is listed as Endangered onthe US Endangered Species Act.

Israel has reintroduced related subspecies of some wildlife that have become extinct, bringing in closely related races of gazelles, wild goats, wild asses and Ostriches. The forests, however, are unlikely to return. The vegetation surrounding the Mediterranean today is dominated by shrubland that can regenerate after frequent burning (Mittermeier *et al.* 1999a). Livestock in vast numbers consume tree saplings and pull plants out by the roots. Goats are able to climb low bushes and graze their tops. The soil structure is very loose and alkaline, and the nutrients have been leached out by thousands of years of cultivation, overgrazing and erosion. Only plants that survive in arid climates on poor soil, such as succulents, annuals and those that regenerate from roots, can grow here (Peters and Lovejoy 1990). In many areas, exotic species, such as American prickly pears and Australian eucalyptus, have taken over as a result of the impoverished soil. The remaining bits of forest in southeastern Spain, Morocco, Algeria, Syria and Israel are being cut for fuel at a rate of 14 percent per year (Peters and Lovejoy 1990). The net result of the widespread loss of forests in the Mediterranean is that only about 1 to 2 percent of pristine, original forest remained at the end of the 20th century, all in small fragments surrounded by farmed and developed land (Mittermeier *et al.* 1999a).

The transitions that brought about the present state of affairs occurred over many centuries. So gradual was the environmental deterioration that one generation of people was usually unaware of the ecological changes wrought by previous generations. Once the forests were lost, succeeding generations may have been unaware that they had ever existed. Whether any progress can be made in regenerating forests by bringing in topsoil and replanting in protected areas will depend on the concerns and will of the people of the Mediterranean, who number more than 300 million

(Peters and Lovejoy 1990).

North of the Mediterranean, vast forests covering most of Western Europe remained until a few hundred years ago. Deciduous and mixed pine forests were logged over the centuries near towns and cites, and the forests retreated, replaced by agriculture and grazing land. By the 18th century, 90 percent of the forests had disappeared. In Scandinavia, Germany, Austria and Switzerland, tree farms have taken the place of natural forests. Man-made hallmarks of civilization now cover northern Europe except for a few isolated pockets of original virgin forest. Along with these forests, went the Auroch (*Bos primagenius*), an immense wild cow that became extinct in the 17th century. The large predators, Gray Wolves, Lynx and Brown Bears, that preyed on deer, elk and European Bison (*Bison bonasus*) were persecuted to near extinction and remain very rare. The largest remnant of these once vast forests is Bialowieza, on the Polish-Belarus border. It harbors the last herd of free-ranging European Bison and a small number of Gray Wolves.

An organization to protect these wolves, The Association for Nature "Wolf" is also concerned about the cutting of the old-growth trees in Bialowieza Primitive Forest, of which only 22 percent is protected in Poland (Nowak and Myslajek 1999). The "Wolf" organization is working to stop logging and protect this forest for future generations by the creation of a transnational park with Belarus (Nowak and Myslajek 1999). As the top predator in this and other forests of Poland and other European countries, the Grey Wolf helps maintain the health of the forest and cull overpopulations of hoofed animals such as deer. *Wolfnet*, the bulletin published by The Association for Nature "Wolf," is helping to educate the public about this maligned animal, which is often killed on sight in Europe. The organization is also sponsoring studies of the estimated 500 wolves in Poland and training livestock owners in the use of guard dogs to protect sheep (Nowak and Myslajek 1999).

Eurasia's northern boreal forests, or taiga, are far more extensive than North America's, stretching 6,000 miles from the Atlantic coast of Norway east to the Sea of Okhotsk on the Pacific rim (Sparks 1992). The western section in Scandinavia is almost gone: more than 90 percent of the taiga in the Scandinavian peninsula has been replaced by tree farms, which support almost no wildlife (Walsh 1995). Norway has lost 100 percent of its natural forests, and Sweden and Finland nearly all of theirs (Walsh 1995). The result of this destruction has been a crash in forest biodiversity and declines in many forest species. Seventy•three species of birds are declining or vulnerable in this region, including the Siberian Jay (*Perisoreus infaustus*) and White•backed Woodpecker (*Dendrocopos leucotos*) (Walsh 1995). Sweden's tree farms have replaced more than 200 species of plants and animals, and 800 species are rare or declining, as reported in *Taiga News: Newsletter on Boreal Forests* in 1992. The same publication noted that 805 species are endangered from clearcutting old-growth forests in Finland, and conservation groups have formed to try to save them from corporate logging. The Russian portion of taiga forest, which makes up the majority of these forests, has been less damaged, but with the fall of the Soviet Union, forests are now open to international lumber companies. Much of this forest is so remote that it may never be logged, but millions of acres are likely to be leveled over the next century.

Temperate Rainforests of the Southern Hemisphere

South of the Equator, in widely separated areas, are remnants of forests with species of trees older than the dinosaurs. These temperate rainforests grow in southern Chile and Argentina and, far to the west, in New Zealand, eastern Australia and the islands of Norfolk and New Caledonia. They have been growing nearly undisturbed for more than 100 million years, and many species of animals native to them have ancient lineages as well. Giant beeches grow in southern South America as well as far away in southern New Zealand and Australia. All these trees once grew on the southern supercontinent, Gondwana, some 160 million years ago. New Zealand, Australia and South America were joined and these trees were part of vast primitive forests. The continent gradually broke apart. Many species of trees survived on these new continents and islands as long as they could adapt to the new climates of the

different latitudes and longitudes, where they were pushed by continental drift through movements of the Earth's tectonic plates. In spite of eons of dramatic changes on Earth, geological and climatic, large fragments of these ancient forests have survived to the 21st century, only to face possible extinction. The wildlife now inhabiting them is predominated by more recently evolved species which coexist with species whose ancestors inhabited Gondwana. These fragile and unique ecosystems have undergone radical changes over the past few centuries, and many have been logged and cleared, with serious consequences for the native wild animals and plants.

South America

Only a century ago, South America's primitive forests blanketed the entire region from the southern tip of the continent north half the length of Chile's coast and eastward into Argentina's Patagonia. Beech trees of the genus *Nothofagus* covered most of the region, mixed with evergreen and various deciduous trees. Once extending more than 35 million acres, these forests comprised the largest stands of pristine temperate rainforest in the world (Nash 1994). *Nothofagus* beeches are among the most ancient species of trees and have been on Earth more than 150 million years. Soon after their arrival in the 16th century, European settlers began logging these forests, but not until the 20th century did widespread clearance begin. During the 1940s and 1950s, some 13,000 square miles, or 8.3 million acres, of these beech forests were cleared and burned for cattle ranching. Commercial logging continued, subsidized by the Chilean government, which spent comparatively little on forest conservation (Sims 1995). These beautiful forests have been cut mainly for wood chipping factories that produce paper pulp for export to Japan. Powerful commercial lobbyists have opposed legislation to protect the portions of these forests that remain, enabling logging companies to continue clearcutting, pushing some species to the brink of extinction. Once logged, the land is replanted with plantations of eucalyptus or pine, or turned into pastureland for livestock. The *1997 IUCN Red List Plants* lists four species of *Nothofagus* native to Chile and Argentina as vulnerable, indicating a decline toward Endangered status that, if not reversed, will result in their extinction (Walter and Gillett 1998).

Not all Chilean government officials are proponents of the logging. Carlos Ritter, head of the technical department for the National Forest Corporation, a government entity, complained: "Japan has fomented the cutting of our native forests, but they try not to assume responsibility. They say they are only buying the wood. But they have created so much demand the peasant farmer cannot resist cutting his forest" (Nash 1994). During the 1990s, an American logging firm, the Trillium Company, purchased 632,000 acres, or 987 square miles, of ancient forest in the southernmost region, Tierra del Fuego (Sims 1995). The Chilean government overruled opposition and gave permission to the company to begin logging in mid-1996.

An American conservationist, Douglas Tompkins, has preserved some of these forests. He purchased 741,000 acres in the southern province of Palena with more than $12 million from his clothing chain, Esprit. The cost of these beautiful forests, at $17 per acre, was miniscule in comparison to the cost of preserving temperate rainforests in the United States. Save•the•Redwoods League, an American conservation organization founded in 1918, recently celebrated its 75th anniversary, having spent $73 million to save 260,000 acres (about one•third of Tompkins™ acquisitions in Chile) of Coastal Redwoods at an average price of $280 per acre (National Geographic Society 1993). Most of the acreage of American old-growth redwoods that has been saved was purchased decades ago, and today it is worth hundreds of thousands of dollars per acre. The timber saved by the Save-the-Redwoods League is worth more than $5 billion (National Geographic Society 1993).

Tompkins' land includes South America's largest block of virgin temperate rainforest, protecting 78 percent of the remaining old-growth rainforest in Chile, including the country's largest remaining virgin stands of Chilean Larch or Alerce (*Fitzroya cuppressoides*) (Bowermaster 1995). This endemic and ancient tree grows to heights rivaling North American Coast Redwoods, with girths nearly as great as Sequoias (*Sequoia dendron*) (Dorst 1967, Walter and Gillett 1998). These majestic trees can live up to 4,000 years and take 500 years to reach commercial size. Extremely slow

to reproduce, Alerces do not produce seed until 200 years of age. Like redwoods, they are highly coveted for their lumber and have been cut with little regard to conservation. Highly endangered in Argentina and Chile (Walter and Gillett 1998), few groves of these trees remain, and although officially protected, they are sometimes illegally cut for the international timber market.

Tomkins came under attack by Chilean politicians and leaders of the Catholic Church who questioned his motives in purchasing such a large area and objected to his organization, the Foundation for Deep Ecology, for its statements about the importance of birth control to prevent human overpopulation (Sims 1995). Others falsely accused him of razing forests, setting up a nuclear dump, promoting abortion and even importing Israeli commandos. Many objected to private ownership of extensive areas of land by foreigners or disliked the idea of large-scale land preservation, but a Chilean conservation organization, the National Committee for the Defense of Fauna and Flora, rallied to his defense. After much contention, the Government of Chile accepted Tompkins' gift of 677,000 acres as a park in July 1997 (Grove 1999). It is known as Pumalin National Park and is considered one of the most ecologically important national parks in South America.

In an ominous note, part of the agreement with the Chilean government allowed access to the park by mining companies. The forest will not be logged, and there are plans for tourist accommodations and trails for hiking. This land is spectacularly beautiful, with glacial lakes and waterfalls, bisected by pristine rivers, its ancient forests teeming with wildlife. Covering the entire width of Chile, it borders a magnificent coastline with abundant marine mammals and sea birds. If preserved with care, the park will prevent the extinction of Chilean Larch and at least a portion of the magnificent southern beech forests which have been destroyed elsewhere. Ecotourism is being developed in the park area on a very small scale, with rustic accommodations, and tours from the United States and elsewhere are now visiting the park regularly. Not far to the north, the Parque Nacional Huerquehue preserves some of the magnificent scenery of this region. Known as the Lake District, portions of old-growth rainforest are protected in a landscape of crystalline lakes, waterfalls and churning rivers.

Another tree that survives from the Jurassic, the Monkey Puzzle Tree (*Araucaria imbricata*), has a somewhat larger range in South America. It is a member of a family of primitive conifers, the Araucaria, that grew on Gondwana. Monkey Puzzle Trees are being logged for timber and displaced by development, cattle ranches and mines. Named for their dense and interwoven crowns said to puzzle monkeys climbing them, the wide, unbranched trunk is covered in leathery bark in a knobby, diamond-shaped pattern. The nuts produced by these trees have been prized by the native Malpuche people for thousands of years. Malpuche means "People of the Monkey Puzzle Tree," and traditionally they did not overexploit these trees. Commercial exploitation of the nuts in local markets is threatening the species by leaving too few seeds for regeneration. Extracts from the Monkey Puzzle Trees have shown promise as a birth control drug, a traditional use by native peoples.

Like the Alerce, Monkey Puzzle Trees live to be very old, at least 1,300 years, and trees of the Araucaria family are considered the progenitor of all pines (Grove 1999). (See photographs in Grove 1999, and Dorst 1967.) When the Discovery Channel-BBC producers of the documentary film, fiWalking With Dinosaurs,fl searched for living landscapes in which to place their animated dinosaur models, an open forest of Araucaria trees in Chile was selected as an authentic backdrop, having changed little since dinosaurs fed on their crowns. The book based on this film has photographs of Araucaria forests from the movie (Haines 1999). Thirty-eight species of Araucaria survive, distributed in South America, New Zealand, Fiji, New Caledonia, Australia and Norfolk Island north to Malaysia. More than three-fourths of these, 30 species, are threatened with extinction, according to the *1997 IUCN Red List Plants* (Walter and Gillett 1998).

Another family of trees dating back to Gondwana, the podocarps, are also extremely primitive evergreens. Podocarps often have straight, unbranched trunks and clumps of dense needles near the trunk. Like the Araucaria, many of the species in the family are in decline: of 125 species worldwide, 70 are threatened (Walter and Gillett 1998). Two of these inhabit the southern rainforests of Chile and Argentina, and others survive in more tropical climates in Venezuela, Bolivia and Brazil, Madagascar, New Caledonia, Fiji, New Guinea and Malaysia. Australia

and New Zealand have more temperate climates and many native podocarps.

A threatened bird native to the old-growth forests of Chile and southern Argentina is the Slender-billed Parakeet (*Enicognathus leptorhynchus*), one of the few members of the parrot family that can survive cold climates. It has undergone steep declines in recent years as a result of forest clearance (Forshaw 1989). At least 22 bird species are restricted to Chilean *Nothofagus* forests, making this region a center of endemism (Cracraft 1985).

The most endangered denizen of southern rainforests may be the South Andean Huemul (*Hippocamelus bisulcus*), a short•legged, stocky deer that once lived throughout this habitat in Chile and Argentina. Driven from most of its haunts by the introduction of European deer, cattle ranching, logging and hunting, they now survive only in the extreme south of Chile, in tundra•like terrain with elfin woodlands. Low, gnarled trees are whipped by the strong ocean winds from Antarctic regions (Dorst 1967). No more than 1,300 South Andean Huemul are thought to remain (Nowak 1999), and a campaign has been launched to save these deer (Stutzin 1995). The National Committee for the Defense of Fauna and Flora and the Frankfurt Zoological Society are researching their status and raising money to purchase sufficient habitat for their survival (Stutzin 1995). Two reserves protect about 100 Huemul, but as the target of meat poachers throughout their range, they are found only in inaccessible areas. Researchers studying these deer, which had never had contact with humans, found them completely unafraid, grazing and bedding down within feet of their tents. This tameness makes them especially vulnerable to poachers.

Without immediate habitat protection and guarding of the remaining deer, the Huemul may not last long. Their status has declined even in national parks within the past few years. Alejandro Frid, a biologist who found these deer living in pristine habitat along a fjord in extreme southern Chile in a 1990 study, returned in 1995 to find near-disaster. Cattle had been set free in the Bernardo O'Higgins National Park, displacing the Huemul from their prime grassland habitat and forcing them into the sparse vegetation of the uplands (Frid 1997). He was told by a local ex-poacher that illegal hunting by local fishermen still occurred, and the lowland habitat was so trampled by the cattle that it was covered in muddy pits (Frid 1997). Ironically, the owners of the cattle did not eat beef but were adopting European cultural traditions, and since this harsh region did not provide good habitat, the cattle were not in good condition (Frid 1997). Conservationists are working to have the cattle removed from the national park, and international organizations are working to protect remnant populations of these deer. On the Straits of Magellan, where other South Andean Huemuls survive, commercial logging corporations are clearing forests (Frid 1997). The introduced Elk (*Cervus elaphus*) competes for habitat, and many Huemul are killed in attacks by domestic dogs (Nowak 1999). The South Andean Huemul and its close relative the North Andean Huemul (*Hippocamelus antisensis*) are both listed as Endangered on the US Endangered Species Act. This listing may not prevent their extinction, however.

The world's smallest deer, the Southern Pudu (*Pudu puda*), also inhabits southern temperate rainforests. This dog-sized deer is short-legged, with thick, buffy, reddish-brown fur and small, spike-like antlers. It is so diminutive, weighing only 5.8 to 13.4 kilos (Nowak 1999), that people have captured them as pets, which has contributed to their rarity. Its range within Chile was once far more extensive (Nowak 1999). The major threat to this species and its close relative, the Northern Pudu (*Pudu mephistophiles*) of the Andes of Peru through Colombia, is forest destruction. *Pudu puda* is listed as endangered on the US Endangered Species Act and on Appendix I of CITES, banning commercial trade, but hunting still threatens it.*

---

*Many trees of the southern beech forest, the South Andean Huemul and Pudu deer appeared in the 1997 film, fiChile, Land of Extremesfl (see Video, Central and South America section); the trees were photographed in *Living Planet, Preserving Edens of the Earth* (Grove 1999).

New Zealand

New Zealand was formed some 80 million years ago when it broke off from the tropical southern continent, Gondwana (Molloy 1994). The land mass moved away with resident pterosaurs, sauropod and carnosaur dinosaurs, along with primitive frogs, lizards, land snails, spiders and other insects and invertebrates. It is also possible that the ancestors of the flightless moas and kiwis were present on Gondwana (Heather and Robertson 1997).

Unlike South America, New Zealand remained uninhabited by humans until a thousand years ago, allowing an extraordinary fauna and flora to evolve. Giant trees of many types, some almost as massive as sequoias and others rivaling American Coast Redwood in height, thrived in primeval rainforests and swamps. The dinosaurs died off 65 million years ago simultaneous with their extinction elsewhere in the world. Over the eons, as the land moved southward, the climate cooled. Many tropical species, unable to adapt, died out, while others coexisted with immigrant species of plants, birds and insects that arrived by wind or ocean current. Geological and climatic events--from earthquakes and mountain uplifts caused by movements in the Earth's plates, to the weathering of wind, sun and rain--produced great changes in the topography over the millennia. The original land mass split into two main islands and many satellite islands, and snow-capped mountains rose on the southern island. Ice Age glaciations occurred during the Pleistocene between 2.4 million years and 10,000 years ago (Molloy 1994). These cold periods did not, however, eliminate the majority of ancient plant or animal species, another proof of their amazing adaptability.

When the Polynesian Maori people arrived about 1,000 A.D., temperate rainforests with understories of giant tree ferns grew throughout the island's swamps, lowlands and highlands, over 80 percent of the land. The Maori must have been stunned to see thousands of flightless birds of various sizes roaming the island. The moas had evolved from a single ancestor into some 11 species which grazed in herds or in small groups. Following the extinctions of the dinosaurs, moas evolved in a wide range of species able to browse vegetation in forest, shrubland and grassland habitats (Molloy 1994). The native plants developed thorns and other means of defense against the moas. These plant adaptations persist today, long after the disappearance of the moas, remnants of a bizarre and fascinating ecosystem. These emu-like birds ranged from chicken-sized to a species 10 feet or more in height, the tallest bird that ever lived. With heads disproportionately small and necks long and gangly, these down-covered birds walked about on thick, scaly legs. Also resident on the islands was a massive eagle, weighing up to 29 pounds (Molloy 1994). This giant bird of prey was the largest eagle to have ever lived on Earth and may have preyed on moas or soared about in search of moa carrion.

On the southern island, penguins lived on rocky coasts and in wet coastal rainforests; one species was a giant, standing more than 5 feet tall (Molloy 1994). No mammals other than bats were native. Lizards called tuataras, older than dinosaurs, lived in many habitats on the islands. Primitive and unusual frogs of types long extinct elsewhere were abundant, especially in mossy rainforests. Huge, cricket-like wetas, insects virtually unchanged for 200 million years, had evolved into 70 species. Compared to grasshoppers, wetas have heavy bodies, weighing as much as 2.5 ounces. Scurrying about at night, their diet and behavior are rodent-like. They are considered by zoologists to be among the most interesting animals on the islands (Molloy 1994).

The forests were dominated by trees very little changed since the age of the dinosaurs. Three major groups of trees, all evergreens, dominated New Zealand's forests, survivors of the Cretaceous Era 135 million years ago: araucaria, podocarps and southern beeches. All had close relatives in South America and other parts of the world.

A single species of the Araucaria family, to which the South American Monkey Puzzle Tree belongs, dominated forests on North Island. The enormous Kauri (*Agathis australis*) has a massive, wide trunk that rises to great heights

before branching in a wide canopy. Its gray, grainy bark forms deep, vertical ridges that curve upward, wrapping around the tree as it rises hundreds of feet into the air. Verdant tree ferns, with large, short trunks, and primitive club mosses form an understory beneath them.

Seventeen species of podocarp trees survive in New Zealand, some of which reach great heights. New Zealand's tallest tree is the Kahikatea (*Dacrycarpus dacrydioides*), or New Zealand Cedar, a type of podocarp which is nearly as tall as Coast Redwoods but with a slimmer trunk, often covered in epiphytic plants (Molloy 1994). Podocarp forests were once very widespread throughout both North and South Islands, each species in a slightly different habitat (Molloy 1994). At the other extreme is the world's smallest conifer, the ankle-high Pygmy Pine (*Lepidothamnus laxifolius*), a podocarp growing at high altitudes in a beautiful area known as the Southern Alps on South Island (Molloy 1994). Another podocarp type, the Celery Pines (*Phyllocladus spp*), are small trees whose leaves are actually flattened stems. One podocarp, *Halocarpus kirkii*, is listed as Threatened by the International Union for the Conservation of Nature (IUCN) (Walter and Gillett 1998), and all have declined dramatically in range.

Southern beeches of *Nothofagus*, the same genus as those in South America, once blanketed South Island in dense, canopied forests, often without an understory of plants other than low ferns (Molloy 1994). Today some forests remain, growing in association with broadleafed trees and hardwoods that arrived in New Zealand at a more recent time (Molloy 1994).

Some extremely primitive plants have also survived in New Zealand. The largest moss in the world (*Dawsonia superba*), giant liverworts, clubmosses and horsetails are among these (Molloy 1994). *Tmesipteris*, an epiphyte, is a relict of the earliest vascular plants, which evolved some 400 million years ago. This rootless plant clings to the branches of trees and hangs in vine-like, leafy strings. New Zealand's forest floor plants, a micro-world of species, most of which are less than an inch high, are beautifully photographed and described in *The Forest Carpet* by Bill and Nancy Malcolm (1989), a book devoted to New Zealand's mosses and related plants.

Other survivors from Gondwana include an extremely ancient family of spiders, Archaeidae. First described from a specimen frozen in amber several million years old, seven species have been found on Madagascar, also a part of Gondwana: one in South Africa, three in Australia, five in New Zealand and one at the tip of South America (Preston-Mafham 1991). The Archaeidae spiders have strange, grotesquely shaped bodies, visible only through a microscope since they are only 0.14 inches long; they live among leaf litter on the ground (Preston-Mafham 1991).

The beauty and primitive auras of many of the Kauri, beech, podocarp forests and pristine forest swamps evoke a "bygone era when dinosaurs still roamed the Earth" (Molloy 1994).* Beech and podocarpus forests cover South Island's Fiordland, a region along the southeastern coast resembling Norway's fiords, with inlets penetrating deep inland, lined by misty forests. The trees are buffeted by fierce winds from the west that bring rainfall of up to 20 feet a year. In this rugged wilderness, mosses and huge tree ferns thrive in the dampness.

---

*Many of the primitive landscapes that survive in New Zealand were captured in Gerald Cubitt's photos in *Wild New Zealand,* accompanied by natural history information in the text by Les Molloy (1994). Also, two films, fiLand of the Kiwifl and fiMountains of Water,fl described in the Video section, display these vistas.

The moas, which must have been very tame and unafraid, were hunted by the Maoris, who lived on their meat and eggs for centuries. The last of the moas, all smaller species, are said by some authorities to have survived until the 18th and 19th centuries (Greenway 1967), although this is disputed by others who assert that the moas were killed off well before the 15th century (BI 2000). Some Europeans claimed to have seen living moas, but no account was ever confirmed. Millions of their bones and eggs, and a few examples of skin, are all that now remain of these birds. The giant penguin, giant eagle and many flightless birds were also wiped out, apparently by hunting. European settlers eliminated many more species when they cleared forests and imported animals, such as dogs, cats, the weasel-like

stoat that preyed on native animals, and livestock that eliminated their habitats. Apart from the moas, nine birds, one reptile and one mammal are known to have become extinct in New Zealand since 1500. One of the birds, a beautiful forest songbird, the Huia (*Heteralocha acutirostris*), was truly unique: the male and female had different sized and shaped bills. Hunted for its plumes, and with its habitat destroyed, the Huia was last seen in the late 19th century. Others, including a flightless owl; a quail; two wrens, one of which was the only known flightless songbird; a bittern; a thrush; a storm-petrel; a flightless rail; and another songbird became extinct. A gecko and a native bat also disappeared (see Appendix for a chronological list of these species).

Although the Maoris cut and burned portions of the Kauri forests, not until the Europeans arrived in the 18th century did clearcut logging begin. Captain James Cook, the first European to visit New Zealand, noted some very tall trees that were probably Kauris while reconnoitering for lumber on his visit to New Zealand on November 21, 1769: "I judged that there was 356 solid feet of timber in this tree clear of branches." Millions of these great trees were felled for lumber or to clear land, leaving only fragments of the original forests. On the Coromandel Peninsula on North Island, isolated patches of mature Kauri forest are protected in several sanctuaries where old tramways, constructed to remove the logs, still scar the landscape (Molloy 1994).

Overall, approximately 75 percent of native forests in New Zealand have been cleared for agriculture and grazing land for 60 million sheep and other livestock. Fortunately, the Government of New Zealand has set aside many large parks and reserves to preserve landscapes, forests, endemic plants and animals. Thirty percent of the islands are protected, one of the highest rates of preservation in the world. In the majority of western Europe, for example, less than 5 percent of the land is protected, and villages and residences are allowed in many national parks. Not all New Zealand's ancient forests are safe from logging, however. A controlling interest in one of the last sizeable expanses of forest, 193,000 acres on the northern end of South Island owned by Fletcher Challenge Ltd., a logging company, was sold in 1997 to the US lumber company, Weyerhauser.

Many native animals of New Zealand's forests have been pushed to the edge of extinction by a combination of loss of habitat and the introduction of exotic species. Even the weta insects are in decline. Nine weta species are listed on the *1996 IUCN Red List Animals* (Baillie and Groombridge 1996). All four species of kiwis in New Zealand are rapidly approaching extinction, listed as Vulnerable or Endangered by *Threatened Birds of the World* (BI 2000). Authorities now recognize four, rather than three kinds of kiwi, and one, the Brown Kiwi (*Apteryx mantelli*), is endangered, its population having declined 90 percent since 1900 (BI 2000). Among the most ancient of bird species and possessing many unique physical and behavioral characteristics, their loss would represent as important a biological tragedy as the extinction of the moas. They have been placed in their own family, Apterygidae, an indication of their uniqueness. These flightless birds, which weigh from about 2 to 10 pounds, have small, stunted wings with claws on the end that are hidden beneath a cloak of shaggy, brown, hair-like plumage, giving them a mammalian appearance. Their long, pointed, ivory-colored bills are used to probe the leaf litter on the forest floor for earthworms and other invertebrates at night, and they can be heard snuffling as they forage. They have short, strong legs, and long, sharp claws on their toes, used for digging and fighting (Heather and Robertson 1997). Their food supply is ample: 200 species of earthworms live in New Zealand, with the largest species measuring an amazing 40 inches in length and 4 inches in diameter (Molloy 1994).

At the end of the kiwis' bills are nasal openings for their highly developed sense of smell, which aid them in detecting their prey. An acute sense of smell is a highly unusual trait in a bird. Kiwis also have sharp hearing but poor eyesight. Such characteristics are more common in mammals than birds (Hoyo *et al.,* 1992). Kiwis possess other mammal-like traits, such as two functionally alternating ovaries rather than one in the female (Feduccia 1996). In an interesting evolutionary phenomenon, where land mammals are absent, animals totally unrelated to them often develop mammal-like traits. Kiwis mate for life and live in large burrows. The single egg laid by the female is enormous in proportion to her size, weighing 20 to 25 percent of her weight. It is the largest egg, proportionally, of any bird and four times the size that would be expected for a bird her size (Hoyo *et al.* 1992). By comparison, a human mother weighing 125 pounds would have to bear a 25- to 30-pound baby. The hatching process is long and arduous, taking two to three days from the time the chick begins to break out; because the chick lacks an egg tooth, it

must kick its way out of the shell with its feet (Hoyo *et al.* 1992). Many chicks die during this process. When the chick emerges at last with damp feathers, its yolk sack is still connected and nourishes it for several days. A miniature version of its parents, it is able to follow them on their nocturnal feeding trips within a few days (Hoyo *et al.* 1992). (Rare footage of incubation and hatching of a kiwi in the wild can be seen in fiBirds of Paradox.fl See Video section F, Birds.)

Kiwis are totally unable to protect themselves against predators, such as dogs, cats, stoats and introduced Australian Brush-tailed Possums (*Trichosurus vulpecula*), who kill them or prey on their eggs (BI 2000). At least 94 percent of kiwis die before adulthood as a result of this predation (BI 2000). The possums also destroy rainforest vegetation by browsing on canopy leaves, epiphytic and ground plants; they have exterminated a native mistletoe (Molloy 1994). Non-indigenous animals have effectively eliminated kiwis from all but a few remote parts of their original ranges. At least one reserve, the 290-square-mile Coromandel Forest Park, has erected a fence within the Kauri forest to keep out possums, protecting kiwis and other native birds (Molloy 1994). Elsewhere, kiwis are being killed by predators; official government protection since 1908 has not stopped their continued decline. Feral dogs killed 500 Brown Kiwis in a population of 900 in less than two months in the early 1990s (Hoyo *et al.* 1992). Another cause of mortality has been steel-jaw leghold traps and poison set out to capture Brush-tailed Possums, although recently the use of traps has been regulated to prohibit any possible capture of kiwis (Hoyo *et al.* 1992). Dependence on humid rainforest habitat has also been a major factor in their disappearance, as this habitat has been destroyed by logging, fire and agriculture (Hoyo *et al.* 1992). Many kiwis are burned to death in the intentionally set fires that follow logging operations, as their shallow burrows do not protect them from the smoke, heat and flames. Often they are afield when fires are set and die in the fires. Those not killed lose their habitat when the humus and leaf litter essential for their feeding is consumed in the fires.

The Little Spotted Kiwi (*Apteryx ownii*) is the smallest and rarest kiwi, numbering only about 1,100 birds (BI 2000). A population of about 950 birds inhabits the 20-square-kilometer Kapiti Island off the southwest coast of North Island (Collar *et al.* 1994), where it was introduced from the mainland. Another introduced population on Tiritiri Matangi Island, a sanctuary of 543 acres off the northern coast of North Island, has adapted well (Molloy 1994). At one time, this kiwi was found throughout the main islands (Hoyo *et al.* 1992). In the summer of 2000, Little Spotted Kiwis were returned to a reserve on the mainland, a step toward their recovery. The Great Spotted Kiwi (*Apteryx haastii*), the largest species, is confined to forests in extreme northwestern South Island in the southern Alps (Heather and Robertson 1997). Although its habitat here is protected, its numbers are still declining from predation (Collar *et al.* 1994). At present, no Great Spotted Kiwis are living on a predator-free out-island (Heather and Robertson 1997), and only one small population is protected by controlling predators (BI 2000).

Another highly endangered bird, and a species almost as bizarre as the kiwi, is the Kakapo or Owl Parrot (*Strigops habroptilus*). The world's heaviest parrot, it weighs up to 3.5 kilograms and is the only living flightless member of the parrot family. It is also one of the rarest birds in the world. Once native to all but the highest mountain altitudes on North, South and Stewart Islands, Kakapos probably numbered in the tens of thousands (Collar *et al.* 1994, Forshaw 1989). They may have flown to the islands at a very early date, long before the land split into North and South Islands, and gradually lost their ability to fly. These 2-foot-long parrots have dull green plumage, mottled with brown, that blends into the vegetation of their rainforest habitat. Known as the Owl Parrot because of large eye discs and nocturnal habits, the Kakapo has another distinction in being the only member of the parrot family to gather in male groups near a bare area where "lek" displays are performed for females during breeding season. Males call females to the lek with loud, low-frequency, booming sounds emanating from their thoracic air sacs. These calls are audible to humans from as far as 3 miles away (Molloy 1994). They perform these booming calls for six to eight hours a night throughout the three- to five-month breeding season, which takes place only every three to five years under normal conditions (Heather and Robertson 1997). Very placid and slow-moving, they are unable to defend themselves against the rats, cats, stoats and dogs that Europeans brought to the main islands.

The range of the Kakapo began shrinking with the arrival of Maoris and their domestic animals, but in 1800 they were still common in central North Island and parts of South Island where their habitats had not been destroyed

(Heather and Robertson 1997). The European Stoat, introduced to the islands in the 1880s, proved an efficient predator of these parrots, eliminating them entirely from North Island and all but remote parts of South Island. In 1970, a survey revealed that only 18 Kakapos remained--all males--in Fiordland, South Island, and these last birds were gone by the early 1990s (Heather and Robertson 1997).

Fortunately, a previously unknown population of 100 birds was discovered in 1977 on Stewart Island, a fairly large island due south of South Island, but these birds were under attack from feral cats (Heather and Robertson 1997). After a decade of decline, all the remaining 61 Kakapos were transferred from Stewart Island by the New Zealand wildlife department to predator-free islets located off North and South Islands (Heather and Robertson 1997). In 1997, a lone female was discovered on Stewart Island and was removed (BI 2000). This rendered the species extinct throughout its original range. Unfortunately, many of the parrots starved to death in their new environments because these islets lacked sufficient food. Their natural diet of fruits, berries, nuts, fern fronds, roots, tubers, moss and fungi was abundant in the temperate rainforests and tussock grasslands of the main islands. A 1983 BBC documentary, fiBirds of Paradoxfl (see Video section), filmed a Kakapo chick being fed by its mother, who walked over steep terrain 3 miles each night to obtain seeds and other food for her offspring. Kakapos can live for as long as 70 years, and this longevity has prevented their extinction, since many years pass without any successful breeding. New Zealand wildlife officials finally provided supplemental feeding, which immediately resulted in the first surviving chicks in a decade in 1991. A population of 62 birds survived in 1999, of which 26 were females and 36 males, including six chicks (WC 2000). Although their numbers are slowly growing, many of the males appear to be sterile, and others have been filmed calling alone, rather than in male groups; some seem to be calling in vain, with no females responding (Hynum 1999). An Internet website has been established to monitor these extraordinary birds: www.kakapo.net.

Many other native songbirds, shorebirds, reptiles and amphibians are threatened in New Zealand, and some survive only on offshore islets where predators are absent or have been eliminated. New Zealand has had success in eliminating cats and possums from several sizeable islands off the main islands, but on North and South Islands, rats, cats and stoats, as well as European deer and goats, are uncontrolled (Molloy 1994). Some 70 million Brush-tailed Possums live throughout both islands, and they are now endangering forest birds by preying on eggs and chicks (Molloy 1994). Exotic plants have also invaded forests, smothering native plants and choking lakes (Molloy 1994). There is, however, a remarkable awareness in New Zealand of these conservation problems and its extraordinary natural heritage. Moreover, the government agencies dealing with wildlife and the environment, TV New Zealand Natural History (which makes superb wildlife films), and scientist-writers such as Les Molloy (1994) are educating the public about this natural legacy, much of which has endured for hundreds of millions of years. Contributions of funds and expertise from many nations and organizations might aid New Zealanders in their conservation work.

Australia

Australia's temperate rainforests are very similar to those in New Zealand, and fragments persist in portions of eastern and southeastern Australia. Relatives of the Kauri, the Nothofagus beeches, and podocarpus trees are native. An exciting botanical discovery was made in one of these forests in 1994. Named the Wollemia Tree (*Wollemia noblei*) after the national park where it was discovered, it is a member of the Araucaria family and somehow escaped attention until 1994. A species familiar to botanists through fossil records, it was thought to have become extinct 50 million years ago (Wilford 1994). A botanist noticed an unusual tree in Wollemi National Park in New South Wales, southeastern Australia and, when he investigated closely, found its fern-like leaves and other proof that it was indeed a living fossil (Wilford 1994). About 23 of these "living fossils" have been located in the park, the tallest towering 130 feet with a 10-foot girth and the species is being propagated by the Australian government. At a press conference soon after its discovery, Ken Hill, botanist at the Royal Botanic Gardens in Sydney, exhibited a fossil imprint of the Wollemia's fern-like leaves next to the living branches for news media, stating that it was one of the outstanding

biological discoveries of the century (Wilford 1994). Pictures of these trees were shown on television news programs around the world, an indication of the new appreciation being accorded such natural wonders. These massive pines have dense, waxy foliage and knobby, dark bark with strange-shaped branches growing from the trunk (Wilford 1994). They were found growing in a secluded area of little more than an acre, deep in the national park, where high humidity and moisture probably protected them from fire and provided ideal habitat (Wilford 1994). Had these priceless trees not survived in a national park, they might have been cut for firewood or commercial logs long ago. Wollemi National Park's protection was considered a great triumph for Australian conservationists. It contains the country's largest area of undisturbed forest--more than 486,400 hectares (1,201,894 acres) (Campbell 1989). The Colo River, the last unpolluted waterway in New South Wales, flows through the park. Other trees in this park include tall eucalyptus, which predominate; Snow Gums; Mallees; and pockets of rainforest in gullies (Campbell 1989).

Four species of Australian Podocarps are listed by the *1997 IUCN Red List Plants*. They range from Queensland's rainforests to temperate rainforests in New South Wales and Tasmania. Such forests, with their tall, evergreen trees and understories of tree ferns, are very rare today as a result of climatic change, a gradual drying of the continent and logging. Eucalyptus trees, which can withstand a dryer climate, gradually increased in range in Australia's temperate rainforests since they appeared in the Oligocene Epoch 35 million years ago (Vandenbeld 1988). They first colonized forest edges and flourished in open woodlands, then grew into entire forests growing from Queensland south to Tasmania, having radiated into 500 species (Vandenbeld 1988).

From New South Wales south to Tasmania, Nothofagus beech forests have been edged out by eucalyptus but remain in a few areas, a glimpse of the past. Mosses, ragworts, rotting logs, ferns and tree ferns carpet the forest floor, similar to those growing farther east in southern New Zealand (Vandenbeld 1988). European colonists logged these forests to clear the land for farms and grazing. The ancient eucalyptus, with their massive trunks, dwarfed the teams of oxen that dragged out the logs. This primeval forest is now almost gone. A 19th century artist, Isaac Whitehead, depicted a magnificent old-growth forest being logged in a dramatic painting showing trees that must have had circumferences of well over 50 feet. If not for the huge stumps that remain, one might have doubted that they actually existed (Vandenbeld 1988).

Forty percent of the country's forests have been cleared, including 75 percent of the rainforests in northern Queensland and 90 percent of both the dry mallee of the south and the eastern temperate woodlands (Parfit 2000). Logging had a devastating effect on the continent's woodland mammals who depended on the forests for survival. Of 144 marsupials inhabiting Australia 200 years ago, 21 are extinct, and a total of 88 Australian marsupials are listed in the *2000 IUCN Red List Species*. Many of these were forest species. Australia has had more mammals become extinct over the past few centuries than any other country in the world. The majority of forests in Australia did not revert to second-growth but became grazing land, plantations, agricultural fields, or tree farms of non-native pines for pulpwood (Vandenbeld 1988).

The eucalyptus forests that came to dominate many of Australia's woodlands are interspersed with savannah in the dryer north. In the south, they grow in dense, moist woodlands, with tree ferns and mosses as ground cover. Among the most characteristic trees of Australia, almost all the great old specimens are gone. Few Australians have ever seen a gigantic, 400-year-old eucalyptus tree, so massive that it takes 15 people to embrace its girth, but such trees were once common (Sharp 1995). It takes 200 to 300 years for a eucalyptus to form nesting holes that provide homes for possums, gliders, bats, snakes, birds, parrots and other creatures that were once prolific in Australia (Sharp 1995). The tallest trees in Australia, many eucalyptus stand more than 300 feet high (Attenborough 1995). In 1880, just before cutting it down, a surveyor measured a eucalyptus that stood 375 feet tall; another inspector around the same time told of a fallen trunk that was 435 feet long (Attenborough 1995). Had this been confirmed, it would have been the world record for the tallest tree ever measured (Attenborough 1995). Their straight, unlimbed trunks rise to great heights before branching. Settlers cut them for building materials and railroad ties, clearing vast areas and threatening many species. An astounding 175 species of the genus *Eucalyptus* are listed on the *1997 IUCN Red List Plants*.

In central Queensland, 5 billion eucalyptus trees were cut to create permanent grazing land for up to 2 million

cattle. Up to half of the trees in 100 million hectares in this Australian state have been cut (Arnold 1994). The last forests of Queensland are being cleared for livestock and agriculture at one of the highest rates of deforestation in the world, estimated at 840,000 acres a year (Parfit 2000).

Koalas (*Phascolarctus cinereus*), native to eastern Australia's eucalyptus forests, are entirely dependent on the leaves of these trees for their food. Most animals avoid eucalyptus because the leaves contain toxic oils, but Koalas have the ability to detoxify these oils, which also gives them a natural insect repellant (Berra 1998). They eat about 36 species of eucalyptus and obtain most of their moisture from dew and the leaves (Berra 1998). Forest clearing has had a disastrous effect on their populations. The last large population of Koalas in southeast Queensland was decimated by construction of an expressway, over vehement opposition from citizen groups (Arnold 1994). Likewise, in the state of Victoria in the southeast, Koalas have been reduced to a few remnant colonies as a result of hunting, development, tree cutting, highways, fires, droughts and predation by dogs and foxes. At least 4,000 Koalas are reported killed each year, and about 2,500 of these die after being struck by cars near urban areas (Berra 1998). They have also been victims of a variety of illnesses, including *Chlamydia*, which causes reproductive failure, pneumonia, blindness and other ailments (Berra 1998). They have declined so dramatically that in 2000 the species was listed as Threatened on the US Endangered Species Act.

Outside of protected areas, the last old-growth forests in New South Wales are being cut. The government accorded a giant multinational corporation, Boral, a contract to cut 500,000 tons of woodchips in the mid-1990s. (Arnold 1994). This logging will remove virtually every native forest not protected in national parks in northeast New South Wales, according to Sue Arnold, Coordinator of Australians for Animals (Arnold 1994).

Victoria still retains some old-growth forest, home to a host of rare animals. Old eucalyptus tower over tree ferns, sassafras, mountain pepper and mosses. In 1999 and 2000, loggers began cutting one of the last of these forests known as the Goolengook Forest (*EarthFirst! Journal* 2000). Aborigines have been able to stop logging in some traditional areas, including East Gippsland, Victoria, but the delicate and endangered native marsupials inhabiting most of these forests may not survive for long.

A strange mammal of Victoria's eucalyptus forests is Leadbeater's Possum (*Gymnobelideus leadbeateri*). Native to the Central Highlands, it lives in colonies in tall, old-growth eucalyptus trees (Strahan 1995). Thought extinct, this marsupial was rediscovered in 1961. With a tail almost twice the size of its body, huge black eyes and a stripe down its back, this possum looks like a cross between a squirrel and a skunk. Each night, it emerges from tree hollows to climb tall trees in search of insects. Forest clearing has destroyed much of its mountain forests (Nowak 1999). Only about 5,000 or fewer Leadbeater's Possums survive, and the species continues to decline as logging clears its habitat (Kennedy 1992). Its dependence on large trees, especially those 300 or more years old which have large tree holes for their nests, has made it very rare (Strahan 1995). Specializing in finding crickets, beetles, spiders and other arthropods beneath the shedding bark of eucalyptus and other trees, it may require, for an as yet unknown reason, a particular species of tree cricket which shelters under the bark of a certain type of eucalyptus (Strahan 1995). This possum also eats gum and tree sap. Less than 3 percent of its total range of 4,000 square kilometers is protected in nature reserves, and 75 percent is located in timber-production forests where tall, old trees are likely to be cut (Strahan 1995).

Tropical Forests

Tropical forests have, for the most part, evolved in stable environments over a period of millions of years, untouched by the recent Ice Ages. The oldest forests on Earth may be in Borneo where the same species of towering trees have been growing for 250 million years. Climates in tropical forests tend to be uniformly warm year-round, with half the year rainy, and the other half dryer but not without rain. Tropical trees generate enormous amounts of

moisture. In some parts of the world, the climate has changed over the ages, resulting in islands of forests surrounded by grassland or other habitats. Many scientists theorize that some forests, including the Amazon and African rainforests, went through such climatic changes during the Ice Ages (Collins 1990). Isolation might explain the evolution of a great number of endemic species in these regions, which today are continuous forest. These tropical forests are showcases of evolution.

Tropical forests vary greatly according to altitude, region and species of trees. Each has a different micro-climate, soil type, fauna and flora. They grow in tropical latitudes 30 degrees to the north and south of the Equator (Collins 1990). Among the many types of tropical forests are evergreen wet forests, deciduous dry forests, mountain cloud forests, and mixed lowland rainforests. In general, lowland rainforests are the most biologically diverse, as well as the most endangered. Covering only 7 percent of the Earth's surface, rainforests harbor half its species (Lean and Hinrichsen 1992). Biological research in tropical forests has consistently shown that this great diversity helps stabilize ecosystems and the very life support systems of the planet.

Some tropical forests have been characterized as "hotspots," having exceptionally high diversity of endemic species that are found nowhere else on Earth. All are threatened by deforestation. Two studies by ecologist Norman Myers in 1988 identified 10 highly endangered and biologically diverse tropical forest hotspots in the world; in 1990, he revised that number to 18 (Myers 1988, 1990; McNeely *et al.* 1990, Mittermeier *et al*. 1999a). Myers pointed out that the 10 hotspots named covered only 0.2 percent of the land surface of the world, but contained 27 percent of the plants and also a high percentage of endemic species. *Hotspots*, a book by Russell Mittermeier, President of Conservation International, and other biologists and ecologists, describes 15 tropical forest hotspots throughout the world among a total of 25 hotspots of all types of ecosystems. The high diversity in tropical forests is reflected in the fact that these hotspots covered 61 percent of the land area of all hotspots identified in the study. Many have lost 90 percent or more of their original forests and continue to decline. Originally, these extremely diverse tropical forests covered 10,635,513 square kilometers; at present, only 1,246,538 square kilometers remain, a loss of 86 percent (Mittermeier *et al.* 1999a). These tropical forest hotspots cover only 0.08 percent of Earth, but harbor 205,789 plant species and 21,903 vertebrate species other than fish (Mittermeier *et. al.* 1999a), a large percentage of the some 248,428 named vascular plants and 23,524 non-fish vertebrates (Wilson 1988). One can only wonder what diversity these areas had prior to their near-destruction. Such astounding facts should result in strong programs to preserve these regions, all of which are being degraded.

The tropical forest hotspots include the Caribbean, Central America, Brazil's Atlantic Rainforest, western Ecuador's Choco region, Andean tropical forests, Indo-Burma, the Philippines, Indonesia and Peninsular Malaysia, the Western Ghats of India, Madagascar, New Caledonia, Polynesia and Micronesia, Guinean Forests of West Africa, and mountains and coastal forests of Tanzania and Kenya (Mittermeier *et al.* 1999).

-

The richest and most diverse hotspot on Earth is found in the tropical Andes, stretching from western Venezuela to Chile and Argentina (Mittermeier *et al.* 1999a). This area has innumerable isolated valleys, slopes, and peaks in many altitudes, all physical characteristics that contribute to the evolution of a great array of plants and animals. Covering 1,258,000 square kilometers, these forests are interspersed with alpine vegetation and grassland. Between 45,000 and 50,000 kinds of plants are found here, 20,000 of which are found nowhere else (Mittermeier *et al.* 1999a). Birdlife is prolific, with 1,666 species, 41 percent of which are endemic. Andean Cock-of-the-Rocks (*Rupicola peruviana*), threatened Toucan Barbets (*Semnornis ramphastinus*), the giant Andean Condor (*Vultur gryphus*), also a threatened species, and the greatest variety of hummingbirds in the world are resident (Mittermeier *et al.* 1999a). The critically endangered Yellow-tailed Woolly Monkey (*Lagothrix flavicauda*) is native to a few Peruvian cloud forests, and the Spectacled Bear (*Tremarctos ornatus*) and Mountain Tapir (*Tapirus pinchaque*) are other endangered species of the region. Deforestation has destroyed much of the region through slash-and-burn farming and extensive cultivation of opium poppies, which are controlled with herbicides that poison rivers and streams, suspected to cause declines in frogs and toads (Mittermeier *et al.* 1999a). Several national parks have been set aside, including the Madidi and Tambopota National Parks on the Peru-Bolivia border, covering some 2,225,000 hectares.

-

The Atlantic forest of southeastern Brazil, another hotspot, has been reduced by 92 percent, yet it has been found to contain the greatest diversity of trees in the world: 476 species in a plot of only 2.5 acres, including 104 previously unknown tree species. By contrast, a plot of similar size in a North American temperate forest has only about 20 species of trees. A much larger plot, totaling 129 acres, in an old-growth forest in Malaysia's Lambir Hills National Park has an astounding 1,175 tree species (NGS 1997). This site is surrounded by farms, and nearby forests have been logged to the forest's boundaries. Both sites are tropical forest hotspots.

Africa's tropical forests once stretched in a wide band from Sierra Leone east through Zaire to Uganda and Kenya, and south to Angola. Of the original 3,620,000 square kilometers, less than half, or about 1,760,000 square kilometers, remained in the early 1990s (Martin 1991). The worst damage has occurred in West Africa where logging and clearance for plantations and villages have destroyed at least 85 percent of its rainforests (Collins 1990, Mittermeier *et al.* 1999a). Even the now-extensive forests of the Democratic Republic of the Congo and neighboring countries are being logged so rapidly that, outside reserves, they will have disappeared in 50 years, according to a 1997 study. A primate anthropologist, John F. Oates, researched the destruction of West African forests and the role played by international loan agencies such as the World Bank and the Ford Foundation. His book, *Myth and Reality in the Rain Forest. How Conservation Strategies Are Failing in West Africa* (Oates 1999), carefully documents the establishment of forest sanctuaries that did not protect forests and their wildlife, but encouraged logging, farming and bushmeat hunting. Almost no forest or sanctuary in West Africa is protected from logging, wildlife killing or capture, or other destruction. The rainforests stretching from Sierra Leone east to western Cameroon and the Gulf of Guinea islands of Equatorial Guinea comprise one of the world's most endangered hotspots for biological diversity (Mittermeier *et al.* 1999a). They covered 1,265,000 square kilometers a few hundred years ago, but have been reduced to only 182,348 square kilometers, or 14.4 percent of the original; of the remaining forests, only about 126,500 square kilometers are pristine forest, a scant 10 percent of the original (Mittermeier *et al*. 1999a). These forests are fragmented and largely unprotected. Some 9,000 species of plants exist in this region, of which 2,250 are endemic (Mittermeier *et al*. 1999a).

Some of the world's most fascinating and unusual wildlife species can be found here as well, including the world's largest frog, the threatened, 3.3 kilogram Goliath Frog (*Conraua goliath*), which inhabits mountain streams in Cameroon. The Western Chimpanzee (*Pan troglodytes verus*) of these forests is highly endangered by forest clearance and killing for the meat trade. Like the Chimpanzees of Kenya studied by Jane Goodall, they are tool-using, employing stones to crack open hard nuts on logs. They may be a completely different species of chimpanzee (Mittermeier *et al.* 1999a). Forest Elephants (*Loxodonta africana cyclotis*) are vital to forest ecosystems as seed dispersers and to open up forest glades for wildlife, such as the threatened White-breasted Guineafowl (*Agelastes meleagrides*) (Kingdon 1989). They also dig waterholes which provide a lifeline for a host of animals. Unfortunately, they are endangered as a result of deforestation and poaching. These forests also harbor many species of little forest antelope known as duikers, all less than 3 feet tall, which dart about the undergrowth in the Guinean forests. Sixteen of the 17 species are listed in the *2000 IUCN Red List Species*, declining from forest loss and intense hunting. The rarest is Jentink's Duiker (*Cephalophus jentinki*), of which only a few hundred remain. There are no individuals of this species in captivity, and no photo has ever been published of this little antelope (Martin 1991).

In spite of these extraordinary treasures, there are few national parks in the Guinean forests, and almost all remaining forests are being commercially logged. In Sierra Leone, the only protected area is Tiwai Island, a 12-square-kilometer, primate-rich area (Mittermeier *et al.* 1999a). The parks that have been set aside, such as the Tai National Park, an extremely important and biologically rich forest in the Ivory Coast, are under siege from illegal hunters, and farmers whittling away at the forest. Kakum National Park in Ghana has been aided by Conservation International in promoting ecotourism over the past six years; a new canopy walk and aid in tourist promotion helped attract 40,000 tourists in 1997 (Mittermeier *et al.* 1999a). Few of the existing preserves are large enough to preserve the diversity of wildlife and plants of the region. Unless dramatic action is taken, many extinctions will take place in the near future.

In Gabon, to the south of Cameroon, recent progress has been made in protecting a large block of forest in the

center of the country. Lope Reserve covers 1,900 square miles of Equatorial jungle coveted by loggers. An agreement signed in July 2000 between logging companies, the government and a variety of environmental organizations permanently prohibited logging in this sizeable area (Revkin 2000a). A compromise included the removal of 400 square miles of the reserve area with valuable Okoume Tree (*Aucoumea klaineana*) in order to add 200 square miles of extremely important habitat for primates, elephants and other wildlife (Revkin 2000a). Since 1957 when only a small percentage of Gabon's forests were open for logging, to the present when almost all the country is logged, wildlife has been driven from many areas by logging noise, roads that open up the forest to hunters and loss of habitat (Revkin 2000a). Dr. Lee J.T. White of the Wildlife Conservation Society has documented this phenomenon and has convinced the government to approve a country-wide forest inventory to identify other areas to protect for a network of national parks (Revkin 2000a).

The Lope Reserve, according to zoologist Jonathan Kingdon, does not include the Bee Forest, home to a very beautiful and rare primate, the Sun-tailed Guenon (*Cercopithecus solatus*), first classified and named in 1984. Dramatically patterned in dark gray with white facial markings and long reddish tails, these monkeys were photographed in the mid-1990s lying dead on tables at a market in Libreville, Gabon, offered for sale as meat (Bohan *et al.* 1996). Known only from this forest, this monkey is threatened by heavy logging in the forest by Isoroy, a French company acquired by Glunz Corporation of Germany (Bohan *et al.* 1996). The species is classified as Vulnerable in the *2000 IUCN Red List Species* (Hilton-Taylor 2000). Isoroy cuts about 140,000 cubic meters of logs per year from a 300,000-hectare (741,300-acre) concession in the Bee Forest, exporting logs to plywood factories in Europe (Bohan *et al.* 1996). The prime wood sought by the loggers is from the Okoume Tree, and a four-year study has found major damage being done to the forest in the process. On average, 8.5 trees were destroyed for every Okoume log harvested, and 49 percent of the forest canopy has been disrupted (Bohan *et al.* 1996).

The Sun-tailed Guenon is one of 26 species of guenons considered "refugia" species of African rainforests. During the Ice Ages, these forests shrank into islands, where many different primates evolved in isolation in these forest fragments. Each has brightly marked facial and body patterns (Kingdon 1989, 1997). These "masked monkeys," many of which were photographed in the spectacular PBS Nature film of that name, are often highly restricted in their ranges and considered threatened by the IUCN. Kingdon, who has studied these primates for decades, believes that they have brightly colored markings in order to see and identify one another in the dark forest foliage (Kingdon 1989).

A close relative of the Sun-tailed Guenon is the endangered Diana Monkey (*Cercopithecus roloway*), endemic to the Guinean region. This lovely primate's jet black face contrasts with its white chest and legs; its back is russet red and gray, and its long tail is black. Its fur seems to have been painted on, so silky and lustrous is its texture. The majority of Americans know little about this species and other endangered African monkeys. This was dramatically illustrated in the summer of 2000 when New York state authorities ordered the confiscation of a pet Diana Monkey kept by an immigrant family. This animal had been bought in a Long Island pet store in 1995, long after its listing on the US Endangered Species Act and New York's endangered species legislation, yet no one seemed to notice when it was offered for sale illegally. The new owners immediately had a veterinarian spay and remove the canine teeth from this female monkey, named her "Cookie" and dressed her in tutus as a family pet. They said they had no idea that she was an endangered species and refused to give her to the state, which planned to place her in the Detroit Zoo with a male of the species. She can never be part of a breeding program, however, and is a genetic loss to the species. Had the plight of these beautiful primates been better recognized and the species better known, this unfortunate incident would never have happened.

Another "masked monkey" native to Ghana and the Ivory Coast has recently been declared extinct, the first primate extinction in several centuries (Revkin 2000b). Known as Miss Waldron's Red Colobus (*Procolobus badius waldroni*), this monkey had colorful, reddish-brown legs and head, and charcoal body. Last seen in the 1970s, deforestation and hunting caused its extinction; thorough searches over seven years within its habitat proved fruitless (Revkin 2000b). Had it been protected in a forest reserve, this colorful monkey would have avoided extinction (Revkin 2000b). This extinction is likely to be followed in the near future by those of many other critically

endangered primates as a result of logging and hunting.

The deforestation of Central and West Africa also presents dangers for people. Many scientists warned that an inevitable consequence of opening up Africa's tropical rainforest through logging was the eruption of ebola virus and other diseases carried by native mammals. Such warnings went unheeded, and several outbreaks of the highly contagious and nearly always fatal ebola virus have occurred. Meat hunting of Chimpanzees in Gabon was a source of this virus, which has killed hundreds of people (French 1996).

The number of threatened vertebrates native to tropical forests of all types has grown astronomically in the past 20 years, concurrent with their widespread destruction. Indonesia, Brazil, Peru, Ecuador, India, Madagascar and Mexico are among the countries with the greatest number of endangered species, enormous diversity, and significant losses of tropical forest cover.

Among the hardest hit of tropical mammals are the primates. Ninety percent of all species inhabit tropical forests, and recent surveys have found that 204 species, or one-third of the world's 650 taxa (taxonomic listing including subspecies), are in high degrees of threat; 103 are critically endangered or endangered (Mittermeier *et al.* 1999b). In Southeast Asia, 90 percent of primates are either threatened or near-threatened, an amazingly high rate of endangerment. Primates are in rapid decline as a result of forest loss, killing for the pet trade, hunting for meat, and capture for zoos, the pet trade and research (Mittermeier *et al.* 1999b). The combination of all these factors has pushed some species so close to extinction that some primate species and subspecies have total world populations of fewer than 100 animals (Mittermeier *et al.* 1999).

Focus on Indonesia

Indonesia has the greatest biological diversity in Asia. A vast mosaic of 13,667 islands, Indonesia links two biogeographic regions known as the Sunda subregion, an area stretching from southern Burma and Thailand south to northern Indonesia and Borneo, with Oceania to the south and east. The political boundaries of Indonesia have little to do with ecosystems or ethnic cultures. The giant island of Borneo, for example, has been divided among several Asian countries. Indonesia claims the southern two•thirds, known as Kalimantan, while Malaysia rules two states in the north and west, Sabah and Sarawak, and the small independent country of Brunei lies on the northwestern coast. Likewise, New Guinea, whose Melanesian tribes have inhabited the island for thousands of years, has been divided between Indonesia, which rules with a strong military presence in the western half, Irian Jaya, and Papua New Guinea in the east, an independent nation. Politically, Indonesia has been in turmoil for decades, with a series of presidents who have grown rich on foreign aid and siphoning off profits from exploitation of timber, oil and minerals.

Focus on Indonesia: Page 1

The world's greatest variety of palm species grows in Indonesia along with 10,000 kinds of trees and 25,000 species of flowering plants (Collins *et al.* 1991). About 40 percent of its plants exist nowhere else, and its forests have a diversity of plants equaled only in Amazonia (Collins *et al.* 1991). One high-altitude forest on Borneo, Mount Kinabalu, has 70 species of oaks, and more than 100 grow on the island, along with 30 kinds of squirrels who feed on their acorns. Such trees are usually considered temperate forest species, but in these forests, which vary greatly in altitude and habitat type, an incredible variety grows. Two thousand species of orchids grow on Borneo (Mittermeier *et al.* 1999a). At high altitudes on Mount Kinabalu, the soggy ground is 90 percent covered in orchids, some with flowers as tiny as grains of rice (Lanting 2000).

Forests cover 85 percent of New Guinea (O'Neill 1996), the majority of which are humid, with very rich diversity in the lowlands. Above 750 meters, oaks and Araucaria trees related to those in South America's Atlantic Forest grow. Even higher, above 2,000 meters, tangles of bamboo and *Nothofagus* beech trees grow in great stands (Beehler *et al.* 1986). New Guinea's mountains rise above 4,200 meters, where alpine shrubbery and boggy grassland dominate. Mangrove forest fringes most coastal areas (Beehler *et al*. 1986).

Until the beginning of the 20th century, forests of many types covered most of Indonesia. The isolation of many of the islands from one another resulted in a radiation of evolution in all types of plants and animals. Many species of animals that had become extinct or rare on mainland Asia still thrived in Indonesia--rhinoceros, Asian Elephants, Tigers and Orangutans, for example. Other mammals, such as the extraordinary, long-nosed Proboscis Monkey (*Nasalis larvatus*), evolved among the mangrove swamps of Borneo. An unparalleled beauty and wealth of birds had evolved. Among these were birds-of-paradise, parrots, lories and cockatoos, colorful songbirds and hornbills. As the 21st century dawns, however, this diversity is in ruins, with many plants and animals close to extinction. The small original populations of many of the endemic species made them highly vulnerable to loss of habitat as the ancient trees were felled, and population growth consumed millions of acres for agriculture.

Of more than 1,500 species of birds native to the islands of Indonesia, or 17 percent of the world's avifauna, 430 are endemic to the country (Collins 1990). Indonesia has twice the number of breeding birds as North America in only one-fifth the land area. Many of these birds live on only one or two small islands. About 164 species are endemic to the Sunda subregion alone. The great loss of forest and other types of habitats in Indonesia is perhaps the most important cause threatening 319 species of native birds, of which 114 are extremely threatened (BI 2000). This is the largest number of threatened birds of any country in the world. Further field research may uncover even more species to add to this list, especially in view of the accelerating deforestation in Kalimantan**,** Sumatra and New Guinea.

Two hundred and one of Indonesia's 436 species of mammals--almost half-- are endemic, an amazingly high rate of endemism (Baillie and Groombridge 1996). Not surprisingly, Indonesia also leads the world in the number of threatened mammals--135 species, or 31 percent of all of its native mammals (Hilton-Taylor 2000). One thousand species of reptiles and amphibians live in Indonesia, 10 percent of the world's 10,484 herpetofauna (Collins 1990). Twenty-eight species of reptiles are considered threatened by the *2000 IUCN Red List Species*, along with at least 59 species of freshwater fish. Research on endangered amphibians, fish and invertebrates in tropical countries lags far behind that in temperate areas, and the endangered list of the latter species is likely to grow when further research is done.

Focus on Indonesia: Page 2

New Guinea has some of the largest expanses of ancient species of trees in the world, most of which grow in cool climates in highlands and mountains. One species of *Agathis* kauri from the highlands of Papua New Guinea is considered rare by the *1997 IUCN Red List Plants*, as are two more *Agathis* species in the Solomon Islands and Vanuatu to the southeast of New Guinea, also bits of Gondwana. The kauri pines (*Agathis macrophylla*) occur on both the latter island groups but have been logged over. Their close relatives on the island of Borneo are in steep decline from logging and land clearance. In New Guinea, logging and clearance for settlements or agriculture, and even native tribes, are destroying these giant trees. Known as "timber trees" in the IUCN-sponsored *Conservation Atlas of Tropical Forests. Asia and the Pacific* (Collins *et al.* 1991), the *Araucaria* pines, relatives of the Monkey Puzzle Tree, grow in groves in parts of New Guinea's highlands, and some tribes venerate them.

Zoologist Tim Flannery (1998) walked among these *Araucaria* trees near the highland village of Telefolip and reflected: "Around the edge of the grove they were saplings but, further in, the pines were soaring giants, mist swirling through their crowns. Their straight, clean boles carried patches of bright green moss, which contrasted with their walnut-colored bark . . . The most striking thing about the grove was the quality of the sound. It seemed as if, in an instant, we had left the noisy, muddy world of drizzle and people and entered a large, open-air cathedral." The grove was considered so sacred by the local tribe that not a single leaf, not even a mosquito, could be disturbed in it (Flannery 1998). They thought that all life had begun in the grove. In the middle of the grove, Flannery saw a rare bird of paradise displaying. The male Splendid Astrapia (*Astrapia splendidissima*) has iridescent colors on the breast and head, and long, dramatic tail feathers that are much desired by the native hunters. These birds are usually shy, but generations of Astrapias had learned that they could display in this sacred Araucaria grove without fear that they would be killed (Flannery 1998). Baptist missionaries worked to end what they called pagan beliefs and offered to purchase timber cut from this sacred grove; gradually they succeeded in ending the taboos. When Flannery visited the grove in 1992, a great fallen Araucaria lay near the path, its trunk hewn into segments with a chainsaw.

New Guinea's birds-of-paradise have been called the most spectacular birds in the world. They are confined to this island and its satellite islands, and extreme northern Queensland in Australia. Their dazzling plumage, showy courtship displays and haunting songs have inspired awe in all who see them. fiVoices in the Forest,fl a BBC film (see Video section, Birds), featuring these spectacular birds dramatically illustrates their conservation problems. Their feathers have been traditionally used for headdresses and costumes by natives, which has threatened some species. Commercial demand from outside the island for feathers, zoo and aviary birds and dried specimens poses additional threats to them. The entire family of these birds, Paradisaeidae, has been placed on CITES Appendix II to prevent illegal trade. Forest cutting poses an even more serious danger to birds-of-paradise populations. The majority of species inhabit primary rainforests, and many have extremely specialized habitat needs. As clearing continues, and logging roads open up more and more of New Guinea's forests, these birds lose their habitats and are more easily hunted. Four species of birds-of-paradise are listed as Vulnerable, and eight more as Near-threatened by BirdLife International; they comprise 28 percent of the 43 members of this avian family (BI 2000).

Less showy, but no less interesting, are New Guinea's bowerbirds. The constructions of bowerbirds are so elaborate that when explorers first encountered them, they were assumed to be man-made. Each species has variations on the construction, some building bowers with pass-through tunnels, others concentrating on accumulating a vast array of objects collected in piles of the same color to attract females. One very rare bowerbird, searched for in the wild on a dozen occasions, was finally found in the remote Foja Mountains by Dr. Jared M. Diamond of the University of California in 1979. This beautiful bird, the Golden-fronted Bowerbird (*Amblyornis flavifrons*), which may number only about 1,000 birds, is very restricted in range, limited to an area north of the Idenburg River between 1,000 and 2,000 meters (Beehler *et al.* 1986). The male of this species arranges sticks in a pile around a tree fern or sapling,

forming a tower up to 3.5 feet high on a circular moss platform with a raised rim. He clears the adjacent area of debris and places separate piles of blue, green and yellow fruits to attract the female. The blue fruit was also a newly discovered species. Making varied, loud calls even while holding a blue fruit in his beak, which contrasts boldly with his brilliant yellow head and back feathers, the Yellow-fronted Bowerbird perches near his elaborate bower performing for the drabber female.

An even more threatened bowerbird, Archbold's Bowerbird (*Archboldia papuensis*), ranges in the central mountain ranges of the island. The male has a long, forked tail and constructs a bower made of a large mat of ferns (Beehler *et al.* 1986). Inhabiting ancient *Nothofagus* beech forests, mixed with podocarps, bamboo and *Pandanus* at high altitudes between 2,300 and 2,900 meters, it has declined as a result of logging operations (BI 2000).

New Guinea's marsupials show great biological diversity, ranging from tree-kangaroos, an arboreal relative of the land kangaroos of Australia, to colorful cuscuses, tiny nocturnal possums and bandicoots. These fascinating mammals remained unknown to scientists until very recently as a result of the extremely rugged terrain, native tribes who were often unfriendly to outsiders, and the almost total lack of roads and other means of access. Many of these mammals are also secretive and nocturnal, hiding in the holes of giant trees covered in vines or inhabiting such restricted ranges that many have only recently been discovered after intensive searches in the wild. In 1865, for example, only 15 mammals had been named from New Guinea, and in 1875 that number had grown to 20 (Flannery 1995). By 1906, 126 mammals had been identified, including 50 marsupials and monotremes, but today it is known that at least 212 indigenous mammals inhabit New Guinea, many of which were discovered within the past decade (Flannery 1995). A surprising number of mammals inhabit a relatively small area and are threatened by forest loss and hunting.

Focus on Indonesia: Page 3

Thirty-eight marsupials and one monotreme (egg-laying mammal such as a platypus) are listed in the *2000 IUCN Red List Species*. One marsupial was previously unknown to scientists until 1994 when Tim Flannery (1998) discovered it in a remote mountainous area of Irian Jaya. This panda-like animal has long, fluffy black fur on its back and head, stripes of white on its belly and muzzle, and a white star on its forehead (see Flannery 1998 for color photo). It resembles no other tree-kangaroo and is also far more terrestrial than other species (Flannery 1998). The Moni tribe call it the "man of the forest," or Dingiso, because when threatened, it raises its arms above its head, exposing its white belly while letting out a whistle, which they consider a sign of recognition (Flannery 1998).

The Dingiso's scientific name, *Dendrolagus mbaiso*, means "forbidden" tree-kangaroo. The Moni believe it to be an ancestor and will not hunt it, but a neighboring tribe, the Dani, has no such taboo and kills the Dingisos for their fur, claws and tail tips. Weighing about 30 pounds and 30 inches tall, this fairly large tree-kangaroo lives in a dense, cloud pine forest up to 10,000 feet in altitude in the Maoke Mountain Range, an area where tree-kangaroos had never been seen. Within the territory of the Moni, this very tame tree-kangaroo is still common and can be easily approached by offering it some leaves; hunters take advantage of this trait by feeding it leaves and slipping a noose over its head (Flannery 1998). This beautiful animal is endangered, and should the protection of the Moni people end for some reason, it will likely become extinct, as it has already disappeared from the territory of the Dani tribe (Flannery 1998).

Focus on Indonesia: Page 4

Fig trees are among the most characteristic trees of Indonesia and other rainforests and are keystone species for wildlife. They are threatened by forest clearance and by loss of their seed dispersers. Some 800 species of fig trees

are found in tropical rainforests around the world. On Borneo alone, there are 140 species, 13 of which are endemic (Yates 1992). Among the tallest trees in these forests, they may attain a height of 150 feet. Strangler figs grow on the trunks of other trees, which they gradually kill by encircling them. All fig trees are dependent on wasps less than an inch long for pollination. (See "Borneo's Strangler Fig Trees," by Tim Laman in *National Geographic*, April 1997, which illustrates this pollination process in detail.)

A wide variety of birds and mammals feed on the abundant fig fruits, but few species actually disperse the seeds. Figs contain chemical compounds that have a laxative effect on the wildlife that eat them, a reproductive strategy designed to release seeds over a wide area. Animals as small as ants and as large as wild pigs, gibbons, and deer feed on the fruit (Laman 1997). Figs exist in such variety in unlogged, primary tropical forests that one species is always fruiting, supplying life-giving food to wildlife (Laman 1997). Hornbills may be more important than any other species in dispersing fig seeds because, rather than eating a portion of the fruit only, they eat the entire fruit, which is full of tiny fertile seeds, and then fly long distances, spreading the seeds in defecations. One ornithologist observed fruiting fig trees in Borneo with as many as 50 hornbills of eight species feeding together (Yates 1992).

Focus on Indonesia: Page 5

Hornbills also spread the seeds of other plants. In India, Great Pied Hornbills are vital to the dispersal of nutmeg seeds, since they are the only species with a beak large enough to open the seeds (Youth 1995). Ragupathy Kannan, a biologist studying this species in the Ghats region of southwestern India, discovered that the forestry department was intentionally cutting large fig trees in order to feed domestic Asian Elephants to haul lumber (Youth 1995). Kannan managed to convince them to ban fig tree cutting and, instead, to let Elephants browse freely in the forest (Youth 1995). If such conservation work took place throughout the ranges of hornbills, their future might be brighter.

The decline of hornbills throughout their Asian ranges highlights the loss of seed dispersers, as the forests themselves disappear or become logged over and fragmented. Hornbills are extraordinary birds, with their enormous beaks composed of horn-like material and, often, colorful facial markings. Some have a casque on top of the bill, giving the appearance of a double beak. The Rhinoceros Hornbill (*Buceros rhinoceros*), for example, has a typical downward-curving, white pointed beak, but atop it a bright orange-red casque curls upward at the tip like a rhinoceros horn. This species, native to Malaysia, Sumatra, Borneo and Java, has declined from trade and is listed on Appendix II of CITES. Averaging more than 4 feet long with 3-foot tails, hornbills make dramatic silhouettes as they fly over the forest canopy. Unfortunately, their size attracts hunters who kill them for sport or food, another factor in their rarity outside national parks. Their reproduction is highly unusual--unique, in fact--among birds. Courtship can involve spectacular head•on collisions between males, clashing their casques together. The hornbill pair, which mates for life, selects a nest hole high in a hollow tree, usually one that was created by a large limb falling off and the trunk area becoming rotted.

Since ideal nest sites are rare and found only in trees hundreds of years old, hornbills often use the same nest year after year. The female plasters the inside with droppings that harden, and the male plasters the outside, leaving a slit that effectively imprisons the female in the tree trunk hole for the next three months. She pokes her bill out to receive food from the male, who tips his beak into the female's open one and lets small round figs and other grape-sized fruits roll down. Other adults may help in feeding the chicks and female. Before the chicks are ready to fledge, the female breaks out and leaves the nest; the chick or chicks instinctively reseal themselves for another month, both parents continuing to feed them (Yates 1992). Finally, when ready, the chicks break out of the nest. It is thought that hornbills have evolved this method of reproduction to protect the female and young from tree•climbing predators, such as snakes and lizards. (The courtship behavior, nesting and feeding of the female and chick by the male Red-billed or Celebes Hornbill (*Penelopides exarhatus*) are beautifully photographed in the BBC film, fiCastaways of Sulawesi.fl See Video section.)

Hornbills, so important to fig trees and the host of species that feed on them, are themselves dependent on primary rainforest (Collins 1990). Their nest trees are often intentionally cut to obtain chicks for sale to zoos and in open wildlife markets. When these great trees crash down, they bring with them many adjoining trees, killing small mammals and birds in the process. The dual threats to hornbills of habitat loss and capture have resulted in dramatic declines in their populations. Should all the hornbill species that are threatened become extinct, the extinction of hundreds of other species may result, from the fig trees, whose seeds they spread, to many vertebrates and invertebrates. In 1980, only one species, the east Asian Helmeted Hornbill (*Buceros vigil*), was listed as Indeterminate by the International Council for Bird Preservation (ICBP) (now BirdLife International) as a result of killing to use their large casques for carving (King 1980). But by 1988, that organization listed seven Asian hornbills as threatened with extinction (Collar and Andrew 1988). In 2000, 18 of Asia's 30 species, or 60 percent, of hornbills were listed in *Threatened Birds of the World* (BI 2000). Seven of the 10 Philippine endemic hornbill species are threatened with extinction (BI 2000). The dramatic increase in threat to these keystone rainforest birds is a reflection of the destruction of Asia's rainforests.

Focus on Indonesia: Page 6

Other rare and declining inhabitants of Asia's rainforests play important roles in pollination. Many trees that produce important commercial products need to be pollinated by wild animals. An extremely valuable fruit is the Durian, which is almost unknown outside southeast Asia. In spite of a rank odor emanating from the outer fruit, the yellow core inside the rind is considered a great delicacy, worth more than $90 million a year in markets throughout Indonesia and Malaysia. What is less well known is the dependence of the Durian tree on a particular species of bat to pollinate it. The Cave Fruit Bat (*Eonycteris spelaea*) is the sole pollinator of these valuable trees, pollinating the flowers while feeding on the nectar of the flowering fruit. Yet this bat is unprotected from the persecution, hunting for food and destruction of its limestone caves that are causing its decline. The number of threatened bat species native to Asia has increased dramatically in recent years, according to the IUCN (Hilton-Taylor 2000). Throughout these rainforests, bats are disappearing, some before their ecological role was known.

Hundreds of tropical plants and trees have evolved for pollination by bats. Most flowers of such trees are found in the canopy, giving easy access to the nectar•feeding and fruit bats, either hanging on long stems, set clear of the surrounding foliage, or clustered on branch tips near twigs where bats can land (Mitchell 1986). These bat flowers open only at night, with odors quite unlike the day•blooming flowers that attract insects and birds; instead, they are musky and sour, which seem to attract the bats (Mitchell 1986). Evolved with shapes that conform to the muzzle of the bat in order to deposit pollen on the bat's face, some flowers have large, trumpet•like openings that almost engulf the bat's head. Others are brush•like with masses of stamens rich in pollen, while still others have numerous small flowers in a ball•like inflorescence producing both nectar and pollen (Mitchell 1986).

The trees that have evolved to be pollinated by bats, some even by a particular species of bat, while providing food for the bats, represent a classic example of mutual dependency. Current logging practices and the killing of many of these bats for food, or destruction of their caves, endanger both trees and bats. Many of Indonesia's threatened bats are fruit bats, and a large number are found only in Indonesia. The Pygmy Fruit Bat (*Aethalops alecto*), for example, is found only on Borneo; the Small•toothed Fruit Bat (*Neopteryx frosti*) is native to Sulawesi; the Javan Tail•less Fruit Bat (*Megaerops kusnotoi*) is restricted to Java; four others are confined to the island of New Guinea. Half of Borneo's 140 mammal species are bats, and more than 50 of these feed primarily on insects (Yates 1992), another major benefit of these poorly understood mammals.

Focus on Indonesia: Page 7

The threats to Indonesia's environment are strongly linked to the growth of its human populations. With the largest number of people on Sumatra, Java and Bali, lowland forests on these islands were cut for cities and farmland during the first half of the 20th century (Collins *et al.* 1991). Beginning in the 1960s, industrial, government-sponsored logging began on many islands for valuable timber. Uncontrolled logging and wildfires have consumed millions of acres for decades, destroying 44 percent of original habitats and nearly all the lowland rainforests in Indonesia (Mittermeier *et al.* 1999a). Java has become nearly denuded, due mainly to the massive growth in human population that totals more than 110 million, almost half the entire population of the United States (Mydans 1996a). The tiny satellite island of Bali has similar crowding problems, and very little forest remains. Between 65 and 80 percent of Sumatra's lowland forests have been cleared to make way for the ever-expanding human population (Collins *et al.* 1991). By June 2000, an estimated 224.8 million people inhabited Indonesia, the equivalent of 82 percent of the US population, living on 741,000 square miles, or 20 percent of the US land area (New York Times 2000).

Among the first casualties of this deforestation and population growth were Tigers, who numbered in the thousands on Sumatra, Java and Bali up until 1900. The populations of each island had been separated for at least 8,000 years (Matthiessen 2000), as each evolved into a separate race. The Javan (*Panthera tigris sondaica*) and Bali Tigers (*Panthera tigris balica*) were far smaller than other Tiger races, with males weighing only about 200 pounds, one•fourth the size of a male Siberian Tiger. Several Javan Tigers were kept in the Berlin Zoo in the early 1900s without any effort to breed them in captivity (see photo in Tilson and Christie 1999). After massive deforestation of these islands and heavy hunting pressure, their populations crashed (Simon and Geroudet 1970). Udjung Kulon, a large national park, was set aside for the Javan Tiger in 1921, but only 20 to 25 of the species survived by 1955, of which 10 were in this park (Simon and Geroudet 1970). By the 1970s, they had disappeared from Udjong Kulon, and only a few were left in Meru Betiri National Park in the far south. In 1980 a careful survey found tracks of at least three Javan Tigers, but there have been no signs since (Jackson 1990). Bali Tigers were once common in the western portion of the island, but not since 1952 has there been a confirmed report (Simon and Geroudet 1970). Both these races are now considered extinct in the wild, and none survives in zoos (Jackson 1990). These Tigers represented unique genetic strains that are now lost forever. They were the chief predators at the top of their food chain, and their loss impoverished these ecosystems.

The Sumatran Tiger (*Panthera tigris sumatrae*), the largest of the three, is the only surviving Indonesian Tiger. Highly endangered (Jackson 1990), its wild population may total only 500 or fewer animals (Nyhus *et al.* 1999). An intensive conservation program, begun in 1995, involves an international team of biologists who are attempting to determine just how many Tigers are left, whether they have sufficient prey species, how many are being killed by local people and the status of their habitat (Franklin *et al.* 1999). In Way Kambas National Park in the southeast, researchers, using cameras placed on trails, have photographed them. An estimated 36 Tigers inhabit the second-growth forest and degraded grassland habitat in this park of about 1,500 square kilometers. It is completely surrounded by villages, and nearly all its lowland primary rainforest has been cut (Franklin *et al.* 1999). Villagers resent the park's ban on using forest and grassland products, and when Tigers prey on livestock, often because of a lack of natural prey, the villagers put out poison. Sumatra's forest fires and rampant poaching of all large animals in Indonesia may extinguish the last of these Tigers, but the conservation research program intends to involve local villagers in saving the Sumatran Tiger and help address many of their needs in the process (Franklin *et al.* 1999). This race of Tiger is kept in many zoos around the world, unlike the Bali and Java Tigers, and has reproduced. The fragmentation of the forest range of Tigers throughout Asia to India has isolated populations, caused inbreeding, and exposed them to poaching, even in national parks.

The parks created for the Javan and Bali Tigers protect a great diversity of other wildlife and plants. Meru Betiri

National Park preserves the last remnants of lowland rainforest in Java (Whitten and Whitten 1992). A population of about 75 to 100 endangered wild cattle, or Banteng (*Bos javanicus*), and Leopards (*Panthera pardus*) are also resident (Whitten and Whitten 1992). Unfortunately, illegal cutting of trees and rattan within the Meru Betiri National Park has been extremely destructive (Whitten and Whitten 1992). Udjung Kulon National Park on the western tip of Java is home to a small population of Javan Rhinoceros (*Rhinoceros sondaicus*), the rarest of all rhinoceros, along with Sambar Deer (*Cervus unicolor*) and Barking Deer (*Muntiacus muntjak*) and Banteng (Whitten and Whitten 1992). Sumatra has several important national parks as well. Mount Leuser National Park's swamp forests protect the last Sumatran Rhinoceros (*Dicerorhinus sumatrensis*), second rarest of the rhinos. This extremely primitive and hairy rhinoceros has been captured for zoos, where most have died and none has been born in captivity. Researchers in the park have tried to prevent further captures of these highly aquatic rhinos in order to preserve the last wild members of the species. This park also has resident Orangutans (*Pongo pygmaeus*), Siamangs (*Hylobates syndactylus*) and endangered Sun Bears (*Helarctos malayanus*). Unfortunately, some of Sumatra's national parks have been overrun with people cutting trees, causing erosion, and replacing forest with agriculture. The Kerinci-Seblat National Park, located along a mountain range in southern Sumatra, encompasses 14,847 square kilometers of forest, but within the park is a virtual city of 273,000 people, growing at a rate of 3.6 percent a year, who denude the hillsides and convert forest to cinnamon, cloves and coffee. They are gradually destroying this entire forest and the watersheds of the island's two most important rivers (Collins *et al.* 1991).

Focus on Indonesia: Page 8

Until about 30 years ago, Borneo had extensive, unspoiled and magnificent forests. The third largest island in the world after Greenland and New Guinea, it covers 215,000 square miles (Smythies 1960). Prior to recent logging and forest fires, it was described as "one enormous forest" by Bertram E. Smythies, author of *The Birds of Borneo* (1960); 75 percent of the island was primary forest, and 10 to 15 percent, secondary forest (Smythies 1960). Mangrove forests grew abundantly along the southern and southeastern coasts, extending far inland, lining major rivers and blending into vast swamp•forests (Yates 1992).

By the late 1970s, an estimated 66 million acres of the country's forests had been classified as denuded (Allen 1980). Forest clearance on Borneo and in Sumatra took a dramatic turn in the early 1980s when landowners and settlers set fire to forests felled for commercial timber, palm oil and tree plantations and homesteads to destroy stumps and brush. This was done in spite of a law banning the setting of fires. The largest forest fire ever recorded on Earth took place in the old-growth forests of Borneo during 1982-83 and lasted for 18 months (Collins *et al.* 1991). More than 9 million acres, or 33,000 square kilometers, were destroyed in east Kalimantan, including 8,000 square kilometers of unlogged dryland primary rainforest and 5,500 square kilometers of peat swamp forest; the rest was selectively logged forest and settlement areas (Collins *et al.* 1991). This was the first time that living rainforest had been seen to burn. Half the new Kutai National Park was destroyed, and another 2.5 million acres burned in Sabah in the northwest of Borneo (Yates 1992). Wildlife was seriously affected, and some burned land was later converted to tree plantations (Collins *et al.* 1991).

During the 1990s, more fires erupted, spreading to adjoining forests. Logging practices involved the removal of the largest trees, leaving leaf litter, small trees and broken branches that dry out (Paul 1998). The logging opened up the canopy, allowing further drying-out of the forest floor, and humidity dropped (Paul 1998). Fires set in clearcuts entered logged rainforest through these logging openings, setting the entire forest afire (Paul 1998). In 1991, another 190 square miles of East Kalimantan burned, and in 1995, massive fires broke out in Kalimantan and Sumtra (Paul 1998). Two years later, an estimated 750,000 to 1.5 million acres of forest burned in Sumatra and Kalimantan (Howe 1997), including a devastating fire in Tanjung Puting National Park, a prime refuge for Orangutans (Paul 1998). So immense were these wildfires that the smoke spread to neighboring countries, causing severe air pollution in cities and towns, and the fires were seen clearly from satellites orbiting the Earth. A Canadian observer from a vessel in the

China Sea during these fires wrote to *National Geographic* (December 1998): "Even at 250 kilometers [155 miles] distance from the coast of Kalimantan, the air was thick with smoke. For nearly three weeks we could not see the sun's disk, only smoke-diffused light. The most astonishing and sad event we witnessed happened one night when we were surveying . . . Our ship was engulfed by an ever increasing flock of exhausted birds and bats, all fleeing the fires of Sumatra. Dozens of birds landed all over the deck, where, too fatigued to move, they could easily be approached and handled. In the morning we found several tired bats dangling from overhead steel gratings. I sincerely hope that a new and more benign Indonesian government will prevent such awful, and needless, environmental calamities from happening again" (Christopher Woodworth).

In Borneo and Sumatra alone, 14.8 million acres are estimated to have been destroyed prior to 1998, still charred and black years afterward (Paul 1998). A zoology student and his girlfriend traveled across Kalimantan in the late 1990s, seeing no green except along roads--small farms and banana trees (Paul 1998). In parts of the region, underground fires burn for years, igniting deep beds of peat and coal seams. The Indonesian government's reforestation funds were rerouted, first by President Suharto, then by his successor, President Habibie, to develop industrial oil palm and timber estates (Paul 1998).

After worldwide publicity and protests from other countries about the fires, and condemnation of Indonesia's failure to act against those responsible, in early October 1997, the government revoked the operating permits of 29 companies that had set illegal fires. This had little effect on fire-setting, as more fires broke out in the following year. In 1998, another million acres burned, and in 1999, an area the size of Vermont and New Hampshire burned on Borneo. In the summer of 2000, smoke from Indonesia's illegal forest fires again blanketed nearby Malaysia's capital, Kuala Lumpur, and Singapore (Mydans 2000). After the fires, floods made the forest loss in Kalimantan permanent by washing away soil, leaf litter and nutrients from the fires ashes (Kaplan and Rogers 2000). Exotic Imperata grasses took hold in many areas, poisoning the ground with substances that inhibit the growth of trees, signaling the end of the rainforest (Kaplan and Rogers 2000). Some 80 percent of the forests in the southeast of Borneo are now gone.

During these fires, wildlife, including such critically endangered species as Sumatran Tigers, Orangutans (*Pongo pygmaeus*) and Asian Elephants (*Elaphus maximus*), fled the fires into villages, where many were killed or captured for sale as meat or pets. Stephanie Fried, a scientist with the Environmental Defense Fund in Washington, DC, who has studied the timber trade in Indonesia, described these fires as the result of "appalling forestry practices and rapacious greed" (Howe 1997).

The fires destroyed most of Borneo's lowland rainforests, where 267 of the world's 600 dipterocarp trees, or trees with "two•winged fruits," dominate; 150 of these exist nowhere else (Whitten and Whitten 1992). This family of trees, Dipterocarpaceae, has species from the Seychelles to New Guinea, but Borneo has by far the most species (Whitten and Whitten 1992). Many reach heights of 250 feet or more and are pollinated by tiny thrip insects. They are extremely important to wildlife, producing fruits, flowers and digestible leaves that are fed on by birds, gibbons and a variety of other animals (Whitten and Whitten 1992). Each year, 2,500 square kilometers of dipterocarp forest are logged in Sarawak, and these old-growth forests are often replaced with tree plantations (Collins *et al.* 1991). Elsewhere in Indonesia, these are the preferred trees to be logged, with their unbranched, wide trunks used in furniture, plywood, resins and camphor (Whitten and Whitten 1992). It was almost inevitable that many of these trees became extinct. The *1997 IUCN Red List Plants* lists a dipterocarp trees native to west Sumatra as Extinct. Another species is extinct on Sumatra but still survives in Peninsular Malaysia, along with 95 other members of the family listed as Threatened or Extinct on the island of Borneo and the rest of Indonesia. Four species of the giant kauri *Agathis* that grow in Borneo's higher altitude forests are also threatened with extinction (Walter and Gillett 1998).

Focus on Indonesia: Page 9

Orangutans once ranged in mainland southeast Asia as well as Indonesia, but hunting and forest cutting eliminated them from 98 percent of their original territory, leaving populations only on Sumatra and Borneo. These islands were home to tens of thousands of Orangutans at the turn of the century, but since then, these intelligent apes have been pushed into pockets of shrinking rainforest. Orangutans are unable to adjust to second-growth forest and depend on very large ranges within primary rainforest, where they feed on ripe fruit and flowers. Their populations have become scattered from loss of old-growth forest, and even national parks are no longer safe havens for them, as poaching and illegal logging increased in the late 1990s. Orangutan populations decline between 60 percent and 95 percent in selectively logged forests (Newman *et al.* 2000). The logging scares them out of their territories, and they often die of starvation or accidents (Newman *et al*. 2000).

One of their former strongholds was the Tanjung Puting National Park, 741,000 acres on a peninsula on the south coast of Borneo. It was upgraded to national park status in 1982, primarily to protect the Orangutan. This is the largest swamp forest in southeast Asia, with a mosaic of habitats, including primary rainforests. The Environmental Investigation Agency (EIA) of London conducted an in-depth study of illegal logging in this park, publishing a report, *The Final Cut*, in 1999 (Newman *et al.* 1999). Illegal loggers were so blatant that they built a wooden railway to slide out the giant logs. When government officials were notified, they did nothing, as they had apparently been corrupted by bribes from the loggers (Newman *et al*. 1999). In December 1999, biologists in the park found themselves ordered by armed loggers to leave. Similar illegal logging took place in other parks and reserves crucial to the survival of the Orangutan, leaving few areas not seriously degraded (Newman *et al*. 1999). EIA turned over to Indonesian government authorities, including the Governor of the Province, copies of its detailed report on illegal logging, which had uncovered the fact that 70 percent of the timber being processed in Indonesia came from illegal logging (Newman *et al*. 2000).

The World Bank in Jakarta estimated that between 1985 and 1997, Indonesia lost an average of 1.5 million hectares of forest cover every year, with dry tropical forest, an endangered ecosystem, suffering the greatest losses. Sulawesi has been logged out, and this forest type could disappear from Sumatra and Kalimantan in the near future (Newman *et al.* 2000). Logging supplies 2 million cubic meters of timber to its many pulp mills (Mittermeier *et al.* 1999a). The lack of strong government control has allowed corrupt timber barons to emerge and control the rampant illegal logging that is leaving little of the country untouched (Newman *et al.* 2000). In spite of international publicity about this disastrous state of affairs, and pressure from international donor agencies, the Indonesian Government stated that it would stop the illegal logging, but did not take action. The bribery scandal apparently reaches into high levels within the government (Newman *et al.* 2000). In May 2000, student activists, frustrated by the government complicity in the looting of their national heritage, held four government officials at a port in West Kalimantan after Customs and other officials failed to halt the shipment of an illegal consignment of timber to Singapore. This shipment, with 70 containers of logs, was forced to return to port and its cargo seized (Newman *et al.* 2000). China and the European Union import more than half the timber exported from Indonesia, and to date, no action has taken place by importing countries to confiscate illegal shipments of timber (Newman *et al.* 2000).

The status of Orangutans has gone from endangered to critical. Decades of logging, clearing and forest fires have destroyed the majority of their primary, old-growth forests on Borneo and Sumatra. Thousands were killed during these fires and hundreds that fled burning forests and entered open areas near villages were killed by villagers wielding machetes. Mothers were hacked to death to obtain their babies, who were often wounded in the process. Hundreds of orphaned Orangutans, pitiful, sickly and malnourished, were confiscated during this period and placed in rehabilitation centers. Many died, and the traumatized survivors clung to one another in crowded pens and crates, mass fed by volunteers and workers of these centers. The Leakey Research and Rehabilitation Center for Orangutans in southern Borneo, and two other centers on the island, have cared for hundreds of these orphans. In 1997, the Wanariset Orangutan Reintroduction Project in East Kalimantan received 118 baby Orangutans, and in 1998, 60 more arrived (Paul 1998). In August, 1998, the station held 171 refugee and injured Orangutans, most very young (Kaplan and Rogers 2000). Many mother Orangutans died of starvation, trying to sustain themselves on acacia bark, and their young were so weak they could hold on no longer and fell to the ground. Some mothers were eaten by the starving

local people, and others succumbed to disease (Kaplan and Rogers 2000). Even those saved and rehabilitated have a low rate of survival. Fewer than half survive in the wild, according to Martinus de Kam, site manager of the Wanariset Forestry Research Project (Paul 1998).

Birute Galdikas, a renowned primatologist and the world's foremost expert on the species, runs the Leakey center and was almost overwhelmed by the numbers of orphans to care for. Moreover, quite a few Orangutans that had been rehabilitated over the past decade and returned to the rainforest came back to the Leakey center for food as their forests were burned or fruit trees cut. In the early 1990s, Orangutan populations were estimated at more than 22,000, with 9,200 on Sumatra and up to 15,546 on Borneo (Nowak 1999). Few believe that more than 15,000 survived the forest destruction and fires of the late 20th century. Galdikas has stated that the species may be doomed to extinction, left with too little habitat to survive. Two primatologists, Gisela Kaplan and Lesley J. Rogers (2000), who have studied Orangutans for many years, conclude that these fires may have been enough to set the final scene for their extinction in Borneo before too many years. Wild populations are unable to sustain the removal of so many female Orangutans. Their reproduction is among the slowest of any mammal. Males are solitary, and females live with their single young for eight to nine years before having another baby (Kuznik 1997). A loss rate of only five Orangutan females out of 1,000 per year can cause a stable population to decline, according to Mark Leighton, a Harvard ecologist conducting research in Borneo's rainforests (Kaplan and Rogers 2000). This rate was surpassed many times during the 1990s. This picture has been further complicated by the recent genetic analysis of Orangutan DNA, which has revealed that there are two, not one species: the Sumatran has been renamed (*Pongo abelii*) and the Bornean retains the original scientific name, *Pongo pygmaeus*. These two primates have been long separated from one another and developed changes in their genes that warrant separating them as species (Kaplan and Rogers 2000; Hilton-Taylor 2000). There are physical differences as well. The Bornean Orangutan is far larger than the Sumatran, perhaps because it has not had to be agile to flee from Tigers, since the species is absent on Borneo. Both species are listed in the *2000 IUCN Red List Species*, the Sumatran as Critical and the Bornean as Endangered.

Focus on Indonesia: Page 10

Many islands, including Borneo (Kalimantan), Sulawesi and western New Guinea have had to absorb millions of people relocated from overpopulated Java under a government program. Beginning in 1978 with partial funding from the World Bank, more than 100,000 people per year were relocated to these and other out-islands costing $2 billion by 1992 (Durrell 1992). By 1996, 6 million people had been relocated from Java; Sumatra received the greatest number of people, followed by Kalimantan, Sulawesi and Irian Jaya (Mydans 1996a).

Irian Jaya™s 350,000 square kilometers of forests are still largely intact, but they are rapidly being destroyed by settlers. More than 250,000 people have been sent here, pushing aside the native New Guinea tribes who have witnessed their pristine rainforests cleared, even on steep slopes, for subsistence farming (O'Neill 1996). One tribesman said, "While we believe we are descended from the forest, most Indonesians believe that devils live in the forest and that the forest must be destroyed" (O'Neill 1996). The Indonesian government clearcuts 5 acres of forest for each family and supplies tin shacks, seeds and tools (O'Neill 1996); these shacks are lined up in rows on the remnants of the rainforest that once rang with the calls of birds-of-paradise. Villagers are encouraged to cut trees and are paid $1.30 for each tree by the government (O'Neill 1996). Roads, schools, clinics and other modernizations are planned, and towns of up to 250,000 people are being carved out of the virgin rainforest (Flannery 1998). New Guinea tribespeople are resentful about the forest cutting and have documented many instances of killing and cruel treatment they have received from the Indonesian military (Flannery 1998). They believe that Indonesia has invaded their lands, and they have organized a resistance movement, demanding that the land be returned to them (Flannery 1998).

The relocation program has been a dismal failure, not only for the people who were unable to farm the thin,

infertile soil of cleared rainforests, but for the devastated environment and wildlife (Durrell 1992, Flannery 1998). The rainforest is not the only ecosystem that has been destroyed by these settlers. On heath and sandstone ridges on Borneo, stands of Ironwood (*Eusideroxylon zwangeri*) grow. These are very unusual trees for tropical areas (Mittermeier *et al.* 1999a). Many of the Javan immigrants are unhappy with the conditions of their new lives and return home (Mydans 1996a). Irian Jaya is expected to remain a center for relocation, however, since only 4 million people live here, and the giant Freeport mine that has removed entire forests employs large numbers of people who come from abroad to work in the mines, living in air-conditioned, newly built homes. Family planning over the past decade reduced the rate of growth on Java from 2.1 percent to 1.5 percent, or half a million fewer births every year (Durrell 1992), but an influx of as many as 1 million people a year still flood into Java from elsewhere in Indonesia and Southeast Asia (Mydans 1996a). Had Indonesia devoted more of its financial resources to family planning a generation ago, as did Singapore, which now has a stable population with a low birth rate, the highly expensive relocation program would not even have been considered.

Focus on Indonesia: Page 11

The future of Indonesia's forests and their wildlife may be as bleak as that of other tropical forests in the Philippines, Thailand, West Africa and many parts of Latin America and the Caribbean. The disappearance and endangerment of large, wide-ranging mammals, followed by fragmentation and loss of the fauna and flora of entire regions, is a pattern that is being repeated here. The government has set aside many national parks, but as in other parts of the world, they are rarely given a high priority for protection, and local people are allowed to log and even establish agriculture plantings and villages within them. The native tribes of Papua and Kalimantan may force a change in the attitude of the government toward the forests and even end in a return of the land to the people who have lived there for thousands of years and have a strong bond with the native trees and animals. Violence has broken out between natives and immigrants on both islands, leading to the forced departure of hundreds of people in Kalimantan after many were killed by Dyak tribesmen in 2001. In Papua New Guinea, international rainforest organizations have become allied with native tribes in fighting corporate loggers from Australia, and they have been successful in taking legal actions that negated corrupt agreements made between their own leaders and the loggers.

The potential for ecotourism in Indonesia is great. The islands are already a major draw for tourists, spending more than $1 billion per year. A powerful movement for democracy is making strides in the country, and with more help from the United States and other democracies of the world, this would become a reality. With a radical change in Indonesia's government, priorities might change to benefit the Indonesian people and their environment instead of making the rich richer at the expense of biodiversity. If that happened, more and more people would learn the value of preserving forests and the country's extraordinary biodiversity for their own benefit as well as that of the entire world. The thin, tropical soils of the country have proven to be best for growing trees, and when this is better appreciated, the tide may turn.

Strong and immediate action is required, however, to prevent biological diversity losses that will dwarf those of any other area on Earth. Stabilizing the human population would be a major step in the right direction. By 2025, it is projected that Indonesia's population will exceed 275 million (Mittermeier *et al.* 1999a). If the government does not stop the disastrous and unsuccessful resettlement program, there will be no wilderness forests left, and the remotest national parks will be invaded for tree and rattan cutting and other destructive uses that will inevitably cause massive animal and plant extinctions.

The participation of international conservation organizations in programs to educate Indonesians to live in harmony with nature and to protect biodiversity is in its early stages. Several of these groups have helped produce field guides, books, posters, pamphlets and textbooks, and the series *Ecology of Indonesia*, in Indonesian (Mittermeier *et al.* 1999a). Protected areas total about 110,000 square kilometers, and the important work of protecting them from

encroachment and destruction is being aided by projects such as The Nature Conservancy (TNC) work in a huge, 231,000-hectare national park in southern Sulawesi, Lore Lindu National Park (Mittermeier *et al.* 1999a). In cooperation with the government conservation agency and local groups, TNC is conducting a comprehensive education program that also encourages butterfly farming and ecotourism to stem forest clearing and rattan collection (Mittermeier *et al.* 1999a). Other programs to encourage ecotourism and create sustainable models for local economies have been launched. In some cases, international programs have failed. In the 1980s, the World Bank funded a program to protect a 300,000-hectare national park in northern Sulawesi and help local farmers irrigate rice fields while protecting the watershed. These worked at first, but enforcement lagged and gold miners have entered the park and poisoned rivers with mercury. Forest clearing, hunting and rattan collection have also occurred within the park (Mittermeier *et al.* 1999a). Emergency programs to stop incursions into national parks are needed.

A new and potentially major source of income to benefit wildlife and the environment involves the placement of videocameras connected to the Internet in wilderness areas. These cameras can be solar-powered and placed in tree tops, animal dens, waterfalls or other attractions. Such videocameras, using satellites to beam live pictures or web pages to Internet users around the world for a small fee, are helping to finance the conservation work of national parks in South Africa and Central America. Internet users have increased exponentially in the past decade and are expected to continue to grow in number. Many "surf" the Internet for amusement, while others seek wilderness views or natural history information. If the funds were managed so as to be devoted entirely to protection of the environment and related programs, many millions of dollars could accrue. A conservation organization could publicize the fate of a particular species, group of species or region to raise funds for its protection. Certainly Indonesia has hundreds of appealing animals. Orangutans, Sumatran Tigers, Proboscis Monkeys, gibbons, Babirusa, tiny deer, cockatoos and parrots (some as small as sparrows), birds-of-paradise, bower birds and Komodo Dragons are among animals that could appeal to millions of people around the world. Spectacular and magnificent coral reefs, ancient forests, giant flowers, carnivorous plants, mangroves and wild rivers could also be filmed for the Internet. An Internet site could have biodiversity data for students and the general public and lists of projects that need financial aid. Ecotourism opportunities could also be part of this site.

On behalf of American consumers and those in Japan and countries importing plywood and concrete forms from Indonesia, conservationists could approach importers, building companies, stores and builders to propose substitutes. In many cases, users of these products have little idea where they came from or the effect their purchase has on forests half a world away. The key to saving Indonesia's wild heritage lies in making it more profitable to conserve it than destroy it, and educating these already highly literate people to preserve their own future in the process.

Forest

Introduction

In an Ecuadorian rainforest, great towering trees festooned with orchids whir with hummingbirds. Primitive mammals skitter up massive Australian trees of species older than the dinosaurs. The world's tallest trees grow in northern California; at the forest floor beneath them grows an intricate diversity of emerald green mosses and ferns inhabited by tiny creatures. At the southern end of the South American continent, a forest of small gnarled trees buffeted by sea winds shelters herds of short-legged Huemul deer. Kiwis, in their downy cloaks of brown feathers, probe the forest litter among giant tree ferns in New Zealand's dark rainforests, pushing their long, pointed bills into the soil to extract earthworms. Monkeys with elaborate facial patterns, in blues, reds and blacks, chatter in treetops above a plodding West African elephant herd. New Guinea's dazzling birdwing butterflies, measuring 1 foot across, flutter near moss-hung trees where iridescent birds-of-paradise display and utter resounding, eerie calls. Thousands of insects and hundreds of other life forms may inhabit a single tree, whose fruits and flowers feed countless other animals, each the

product of eons of evolution and geological history. These irreplaceable forests are in imminent danger of disappearing. The most biologically diverse of these are the untouched, old-growth forests of the world, of which only 20 percent remain, largely unprotected from destruction.

Benefits of Forests

The great beauty and inspirational qualities of forests belie their important biological tasks. By producing vast amounts of oxygen and water vapor, and absorbing carbon dioxide, they help support all life on Earth. A single mature oak tree produces enough oxygen to keep eight people alive for a year. In 1995, an international team of ecologists working in Brazil documented that each hectare (2.47 acres) of undisturbed tropical rainforests absorbs 1 ton of carbon dioxide per year. The world's rainforests are thus absorbing a billion tons of carbon dioxide a year, one-sixth the amount produced by burning fossil fuels such as oil and coal, according to the National Oceanic and Atmospheric Administration (NOAA). Cutting and burning of forests around the world releases carbon dioxide into the air. The high levels of carbon dioxide in the world's atmosphere have caused increases in average global temperatures. The value of tropical forests in trapping carbon dioxide is so significant that four US utility companies have sponsored a pilot program in Belize to protect large areas of forest and plant trees; energy companies will contribute $2.6 million to a 120,000-acre reserve that will absorb 5.2 million tons of carbon dioxide gas over 40 years (Geatz 1996). The Clean Air Act allows such "pollution credits" to compensate for pollution released elsewhere. In 2000, the US government proposed a massive program of tree planting and protection of forests to compensate for the effects of global warming caused by the release of carbon dioxide and other pollutants.

The cooling effect of forests results from leaf transpiration generating moisture that rises to the atmosphere, forming clouds which release water as rain or other precipitation. When forests are cut, the climate dries as rainfall decreases and soils lose moisture. Tree roots absorb about one•half of the rain that falls, releasing the water gradually during the year (Schreiber *et al*. 1989). In countries with wet and dry seasons, water retention by trees makes the difference between deadly floods that kill thousands of people and sweep away their homes and precious topsoil, and river levels that remain stable, preserving soil and the environment. Forests stabilize the soil, preventing erosion and landslides and allowing streams and rivers to flow clear.

The leaves, bark and wood of trees have been found to contain hundreds of compounds valuable to medicine and industry. Forests produce a wealth of useful species: oils, gums, resins, tannins, waxes, edible oils, dyes, cosmetics, spices, fruits, nuts and life•saving compounds used in medicine. Spices alone are worth more than $1 billion per year (Schreiber *et al*. 1989). Medications derived from wild plants are worth $40 billion annually (Lean and Hinrichsen 1994). Painkillers, birth•control agents and malaria drugs, as well as quinine, digitalis and morphine, are all derived from tropical forest plants. According to one study, more than 40 percent of all prescriptions in the United States still depend on natural plant sources (Swaminathan 1990). Only a small percentage of wild plants have been tested for medicinal value. In some cases, plants that might have disappeared altogether were found to be medical treasures. The Madagascar periwinkle, native to an island which has lost 80 percent of its forests to deforestation, has been the source of two potent compounds that have proven effective in the treatment of Hodgkin's disease and produce a 99 percent remission in patients with acute lymphocytic leukemia (Myers 1983). Global sales of these two drugs now exceed $180 million a year (Wilson 1992). Taxol, a compound from the Pacific Yew found in the last of North America's old-growth forests, has proven effective against ovarian and other cancers.

In the long run, forests left standing are of greater benefit than those cut and destroyed. The dollar value of natural ecological systems, of which forests make up a large part, in performing services for human society has been estimated at as much as $54 trillion, as seen in Chapter 1 ("Earth's Worth" section). Along with their role in flood prevention and climate regulation, forests provide fruits and flowers to be pollinated by wild insects and birds, and

clear rivers as habitat for valuable salmon and trout fisheries (Stevens 1997b). The World Resources Institute in Washington, DC, has calculated that the loss of value from deforestation is four times as high as the value of the timber extracted and the depletion of soils, forests and fisheries amounted to an average reduction of 25 to 30 percent in potential economic growth (Stevens 1997b).

The ways in which forests function are only beginning to be understood. Great fig trees are dependent on tiny wasps to complete their reproduction, and fungi in the roots of trees play intrinsic roles in their survival. Pollinators are key to the health of forests, but for many species of trees and plants, only fragmentary information has been acquired about how they are pollinated and the conservation status of these pollinators. Understanding the interrelationships of plants and animals within these ecosystems is key to their preservation, yet forest ecology is in its infancy.

While logic would seem to mandate that such awesome and useful ecosystems be accorded great respect and legal protection, the opposite is true. They are being destroyed so rapidly by logging, dams, climatic changes caused by human activity, and pollution that the last pristine forests may soon be gone. Even minor alterations in their environments have interfered with their healthy functioning.

Cutting forests for financial gain or to resettle people from overpopulated cities provides developing countries with short-term solutions to problems and one-time profits. Neither the extremely important ecological roles that forests play, nor their value as species storehouses, are appreciated by the majority of the world's nations. The recent spate of massive landslides and floods after periods of heavy rains in countries around the world has, in most cases, been traced to logging that left hillsides and entire regions open to erosion. Millions of people have been left homeless around the world in recent years, and thousands have lost their lives to such floods. These floods may be only a prelude to far more serious and long-lasting consequences of forest destruction. Global warming will increase as forests vanish, especially with the cutting of old-growth trees, which have immense canopies for absorbing carbon dioxide and cooling the atmosphere. Higher temperatures have already brought droughts, increased desertification and caused rivers and streams to lose volume and even dry up. The loss of potential disease cures is another byproduct of destroying forests, and the destruction of these beautiful environments, with their multitude of life forms, may result in collapsed ecosystems that cannot be restored.

Forests' Retreat

As recently as 1960, forests covered one•fourth of the Earth's land surface (CEQ 1980). With continued logging and clearance, two decades later, in 1980, only one•fifth remained forested (CEQ 1980). Since then, forests have continued their decline, losing more than 5 million square miles since 1960. During the last quarter-century alone, the world's forests have shrunk the equivalent of one-half the land area of the United States.

This destruction has threatened thousands of animals and plants with extinction. In fact, forests have the greatest number of endangered species of any ecosystem. Of all types of forests, primary, old-growth forests, especially tropical rainforests, harbor the greatest wildlife and plant diversity and the greatest number of endangered species (Collar *et al*. 1994, Collins 1990, Mittermeier *et al.* 1999a). Second-growth and mixed types of forests are also key habitats for many species, and clearing these forests has threatened thousands of plants and animals.

Forests' Retreat: Page 1

Forest destruction is often gradual, a whittling away by settlers and farmers who destroy portions of forest to grow crops using fislash-and-burn,fl in which trees are cut, set afire, and the ashes are used as fertilizer for subsistence agriculture. In tropical forests, the thin soil is fertile for only a few years, and farmers move on to clear more forests. When human populations are very small, as in the case of the native peoples of many tropical forests, their effects are not severe or permanent, as the forest grows back. Non-indigenous people, however, often remove forest cover permanently**.** They do not think of the forest as a source of life, providing food and protection, as native peoples do. The entire center of the 1,000-mile-long island of Madagascar, once a verdant paradise with giant trees and teeming with wildlife, is now a moonscape as a result of such misuse of the land. Millions of rural people in developing countries now depend on wood cut in local forests for fuel. This has been another major factor in deforestation because of the growth of human populations spreading into new regions, cutting trees and clearing away vegetation.

In the Caribbean, Europe, eastern North America, North Africa and West Asia, most of the original forest cover was destroyed prior to modern times. These forests will not return once cut, nor will their diversity. The ecology and diversity of the forests that once covered much of Europe and the eastern United States will remain unknown because they were cut prior to any biological studies. We have only descriptions of giant trees and the wildlife that inhabited these forests. In the temperate rainforests of the Pacific Northwest, however, biologists are studying the last 5 percent that survives of these magnificent**,** old-growth forests. Working in the canopies hundreds of feet above the forest floor, they are making new discoveries about these ecosystems. They have learned that lichens colonize only the oldest forests and are key to fixing nitrogen (Moffett 1997), or converting this essential gas into compounds that can be used in forming life-sustaining amino acids and proteins (Franck and Brownstone 1992). One forestry student who climbed a 2,000-year-old Sequoia found cones growing only on the outer branches, which can remain on the tree for as long as two decades**;** a rich variety of lichens grow**s** on trunks and branches (Moffett 1997). Such discoveries illustrate the importance of preserving these ancient forests.

Only a little more than a century ago, rainforest and temperate old- growth forest covered millions of square miles in West Africa, Central and South America, Southeast Asia, Australia and the western United States. Early settlers, followed by commercial loggers and large-scale livestock and agricultural interests, permanently destroyed these complex ecosystems. In some areas, second-growth forest or shrub has replaced them. Only in Amazonia, Central Africa, Russia and northern Canada do large tracts of virgin forest remain, and these are now being logged by international corporations.

Forests' Retreat: Page 2

A major use of timber is newsprint. Every Sunday edition of *The New York Times* consumes 75,000 trees (Bohan *et al*. 1996). Each issue of *Audubon* magazine, published by the National Audubon Society bimonthly, consumes 1,500 trees to make the 150 tons of glossy paper used to print 500,000 copies, according to its own research (Webster 2001). The trees used in the making of this paper were cut after 12 years by a mechanical harvesting machine that periodically clearcuts and replants with only one type of tree, creating an unnatural monoculture (Webster 2001). To

remove the cellulose, chlorine is used, which releases .004 pounds of chlorine and chlorine gases into the air (Webster 2001), less than in the past but still an environmental threat. This organization, like many using large amounts of non-recycled paper, claims that the monocultures are teeming with wildlife (Webster 2001) and, by all appearances, does not consider other alternatives for the manufacture of its magazine. Other magazines, such as *National Geographic*, also use unrecycled, glossy paper. By contrast, The Nature Conservancy decided in the 1990s to abandon use of virgin paper for their magazine, even if it meant a less glossy finish, and now prints on recycled paper. Many other conservation organizations have followed suit.

Tropical woods are also used to manufacture paper. With conservation and recycling by consumers in North America, Europe and Japan, no tropical forest trees would need to be cut for paper. The majority of newspaper used in the United States, which is the world™s largest consumer of paper, is thrown into landfills or burned (Bohan *et al.* 1996). Many tree-based products, from shipping crates to plywood and paper, could be made from other materials, both non-wood and re-used wood. Corporations feed a market hungry for inexpensive raw material. The trees are sold for almost nothing by the countries of origin, resulting in high profit margins for logging companies.

Forests' Retreat: Page 3

In the year 1500, tropical forests covered continental and island areas totaling 5.5 million square miles (Collins 1990). Today, only a fraction of this extraordinarily rich ecosystem remains. The estimates of loss vary. Some scientists count only the acreage of untouched pristine rainforest in their estimates, while others include various types of tropical forests, second-growth and disturbed forests. Satellite images, combined with aerial photography and ground surveys, are giving an ever more detailed and accurate picture of the decline of these irreplaceable forests. One reference, *The Last Rainforests*, edited by Mark Collins (1990), calculated that in 1990, only 3.3 million square miles of tropical forest remained in the world. It estimated that about 54,000 square miles were being cleared worldwide every year (Collins 1990). This authority concluded that 50 percent of all tropical forests had been lost since 1900 (Collins 1990). In the disastrous decade of the 1990s, as much as half of the remaining tropical forests were cut or burned. Although estimates of loss vary, there is general agreement that dramatic losses occurred in many parts of the world during the 20th century.

This destruction is taking place at a catastrophic rate. According to Dr. Edward O. Wilson of Harvard University, an expert in biodiversity and tropical forests, the surviving tropical forests equal the lower 48 US states in area, and a region the size of Florida is disappearing each year. The Nature Conservancy (2000) estimates that 40 million acres of tropical forests disappear every year. Settlers in many tropical forests have traditionally practiced slash-and-burn. The soil is so thin that it becomes sterile after a few years of farming, and the farmers move on, cutting more forest. Such practices whittle away at forests, but when carried out only by small bands of natives, these cut-over acres tend to recover in time. In many areas, however, European settlers have cleared land in this manner and fertilized the soil, maintaining it as agricultural land or depleting it so severely that the forest can never grow back.

Forests' Retreat: Page 4

Cambodia's last expanses of tropical forest are being lost in a pattern typical of many countries. Intensive logging during the past 50 years has reduced forest cover in this country from 70 percent to only 35 percent (Mydans 1996b). In spite of a logging ban instituted in January 1996 and a ban on exporting logs set in place in April 1995, the country's two Prime Ministers signed secret concessions to sell off virtually all of Cambodia's remaining forests (Mydans 1996b). The ancient teak forests are being openly felled, with logs exported to neighboring countries for profits of $10 to $20 million per month and in spite of official pledges to stop this logging (Mydans 1996b).

Elephants are used to haul the logs across rough terrain, and many are abused with drugs to keep them working and overloaded, causing serious injuries or death. Some have been maimed or killed by stepping on land mines. Armed guards protect these loggers and sawmill operators; regional forestry officials, who oppose the cutting, are unequipped to confront them (Mydans 1996b). Already, siltation, erosion, flooding, and destruction of agricultural fields have resulted, and Cambodia's King Norodom Sihanouk, who appears helpless to stop this situation, commented, "If this deforestation does not stop, Cambodia will be, alas, a desert country in the 21st century" (Mydans 1996b).

Asian logging companies have now turned to the pristine forests of Belize, the only sizeable forests remaining in Central America. In 1997, the government of Belize sold logging rights to Atlantic Industries, a Malaysian company, for $60 an acre to clearcut in primary, old-growth rainforest**,** principally for mahogany (Hecker 1997). The company logged in areas outside the agreed-upon area and leveled large numbers of Sapodilla trees, the source of chicle that can be tapped sustainably (Hecker 1997). The deforestation of Central America has been most extreme in El Salvador, Nicaragua and Costa Rica (Collins 1990, Harcourt and Sayer 1996). Fires set by settlers and business interests creating plantations for palm oil and tree farms, burned out of control in the late 1990s in Borneo, Sumatra, Bolivia and Brazil, destroying many ancient forests, including some in national parks.

Secret agreements between various government leaders and international logging corporations or with friends and relatives, for logging rights over large sections of forest are commonplace in many countries. Indonesia and Malaysia, for example, encourage destructive clearcuts in which conservation is not a concern, and fast-paced logging is carried out because the agreements may be negated by a change in government officials (Yates 1992). The largest remaining rainforest in West Africa, a 2.5-million-acre swath in Liberia, is being logged by a Hong Kong timber company as a result of a large bribe paid to the brother of Charles Taylor, the newly elected President of the country (Farah 2001). Such bartering away of the world's greatest treasure-houses of biological diversity is a travesty that will adversely affect the Earth's stability and the lives of many generations of people in the future. Lost will be magnificent ecosystems containing plants and animals not even discovered.

Corporate logging has emerged as the major cause of tropical forest destruction, greater even than the losses to settlers and agriculture. This logging is carried on without international controls and with inadequate national controls. This industry grows each year, and the international trade in wood, pulp and paper is now worth about $100 billion per year, making timber the third most valuable natural resource (Bohan *et al*. 1996). Of this total, a large percentage is timber from tropical forests. By the mid-1990s, scientists estimated that some 80 percent of Southeast Asia's--and a similar percentage of West African and Madagascar's--forests had been destroyed. An in-depth study of corporate logging by the Environmental Investigation Agency (EIA) estimated total sales of one of the largest corporations, Mitsubishi, at $5.3 billion in 1995, controlling a total land area of 9 million hectares (22.2 million acres) (Bohan *et al*. 1996). Mitsubishi's plywood mill in the Brazilian Amazon consumes 130,000 cubic meters of logs every year through the intensive and unregulated harvest of virola trees (Bohan *et al*. 1996). About 75 percent of all tropical forest trees is turned into plywood for disposable packing crates, construction and furniture, according to the Rainforest Action Network (RAN) of San Francisco, California (RAN 1993). The United States alone imports several hundred million pallets of tropical hardwood each year and throws them away after a single use (Revkin 1997).

Forests' Retreat: Page 5

The promotion of a commercial approach to old-growth tropical rainforests, even "sustainable yield," is based on fragmentary and inadequate knowledge of these ecosystems. It is not known with certainty that their trees can be harvested without harm. Sustained yield forestry concerns prevention of the extinction of various tree species by controlling harvest and, to a lesser extent, protecting of watershed and soil, but not necessarily ecosystem protection. Maintaining the complex web of plants and animals that form a forest should be the prime consideration in conservation. To this end, protection from harm is the logical approach until these ecosystems are properly

understood. Their ecological value will only be measurable as knowledge about their functioning and their role in the world's climate are explored in the future. In economic terms, they have great potential as tourist attractions, and the new videocam Internet business, as described in the Focus on Indonesia section below, will likely far outproduce short-term income from timber or conversion to agriculture.

An indication of the effects of this destruction is the fact that 76 percent of the 1,186 birds in higher categories of threat, or 902 species, are forest•dwellers, according to *Threatened Birds of the World*, a comprehensive report by BirdLife International, which examines bird status for the *Red Lists of Threatened Species* published by the International Union for the Conservation of Nature (IUCN) (BI 2000). All these birds are in danger of extinction. Some, such as the 182 Critical species, are in imminent danger of becoming extinct. Of the 902 forest birds, 93 percent are native to tropical forests; of these, 41 percent are found in lowland forests and 36 percent in montane moist forests, such as cloud forests (BI 2000). Three-fourths of threatened forest birds are dependent on a particular type of forest, and almost half require near-pristine habitat, with little or no disturbance, or habitat degradation (BI 2000). Only 3 percent of threatened forest birds can tolerate habitat modification. Unsustainable selective logging affects 367 forest bird species, while other threats include clearing forests for small farms (24 percent), tree plantations, clearcutting forest, livestock grazing, cutting trees for firewood, mining in forests and human settlements (BI 2000). An additional 727 bird species are classified as Near-threatened or close to qualifying as Threatened.

Likewise, forests are the major habitat for threatened mammals. The IUCN assigned habitat types to 515 (46 percent) of threatened mammals, finding that about 75 percent inhabited tropical rainforest; of these species, 35 percent in lowland and about 22 percent in montane (Hilton-Taylor 2000). (Some mammals may occupy more than one habitat). Tropical dry forest accounts for another 15 percent; tropical degraded forest, 4 percent; and tropical savannah woodland about 5 percent of threatened mammal habitats. By comparison, temperate broadleaf forest is the habitat for some 4 percent; and coniferous forests, 5 percent of threatened mammals (Hilton-Taylor 2000). The vast majority of threatened frogs and toads are also native to tropical forests.

Many species of tropical trees have been driven to extinction by habitat destruction and the exotic wood trade. The majority of Caribbean islands, which were covered in tropical rainforests when Europeans first saw them in the late 15th century, are now barren. A species of mahogany native to the Caribbean (*Swietenia mahogani*) has been so heavily exploited that no unstunted specimen remains. Elsewhere, once common species of forest plants and animals have been eliminated or endangered. Where habitats were limited on islands such as Hawaii and Mauritius, fragrant sandalwoods and other trees were cleared, and few--if any--specimens remain of the trees that once made up these forests.

Forests' Retreat: Page 6

The Rainforest Action Network has documented that 140,000 mahogany trees are being logged annually, with each tree worth about $1,500 wholesale in the United States, where most are marketed (Line 1996). RAN states that most of the mahogany trees in trade have been illegally logged from parks, conservation areas or other protected lands, causing ecological damage on a large scale.

Mahogany takes 40 years to reach harvestable size, and the majority of this wood that is traded internationally comes from wild harvested trees. Many tropical species have reached commercial extinction, and Honduran Mahogany, which grows to 130 feet with a massive canopy, is the major target of the logging industry in Central America. By having a market for mahogany, especially a lucrative one, loggers seek out these trees, even in protected national parks. Once in commerce, distinguishing legal from illegal becomes impossible.

Trees that are commercially valuable are often the very ones most important to wildlife for food sources or shelter.

The largest and oldest trees produce the greatest profits and are the first to be cut. These trees provide nest holes for owls, toucans, hornbills, parrots, tiny monkeys, lorises and galagos, rare lemurs, and countless other wildlife species. Many species of wildlife use tree holes for shelter year-round. Although some birds, such as woodpeckers, can excavate nest holes, the majority of animals who shelter and nest in tree holes depend on natural cavities. These holes form when tree limbs fall off or from rotting within tree trunks. Research on wild macaws has determined that a lack of trees with nest holes plays a major role in limiting their populations. Macaws nest only in large cavities very high, usually 100 feet or more, in tall tropical trees. Only the oldest and largest trees have tree holes for the more sizeable animals, such as hornbills, macaws and families of small primates who den together.

The Harpy Eagle (*Harpia harpyja*), the world's largest eagle, is endangered in its neotropical rainforests. Its range once extended unbroken from southern Mexico through the Amazon but today it is rare or absent throughout the remaining forests. A major factor in its decline is logging of the tall, old trees it requires for nesting. These eagles need a high vantage point overlooking the treetops to spot prey and to prevent predation on their nests. Harpy Eagle chicks have a long period of fledging, and prior to their independence, they must strengthen their leg and wing muscles. Eagle parents always make their massive nests near the top of giant trees with wide branches near the nest where the chicks can exercise by running across the branches, flapping their wings. As the strongest avian predators in these forests, they must be able to kill animals as large as sloths and carry them off in their talons. Loggers spot these giant trees rising over the forest canopy and cut them for the enormous amount of wood they contain. In much of Central America, selective logging and clearcutting have destroyed many of the former haunts of this magnificent bird.

Dead trees still standing are also prime wildlife nests and shelters, but because they are considered fire hazards, they are cut routinely. Hollow limbs and fallen logs are used by many types of animals for shelter or nesting, and these are usually trimmed off by loggers. Rotting tree trunks and cavities in both standing and fallen trees support entire communities of insects and invertebrates, upon which many vertebrates depend for food, and which contribute to the forest's health.

Modern loggers use mechanized tools and machines to clearcut forests. Chainsaws can cut through the massive trunk of a thousand-year-old tree in minutes. For smaller trees, saws mounted on trucks slice their trunks like matchsticks, and machines lift the trunks onto logging trucks for transport, trimming off side limbs in the process. Every tree in a forest, ancient or young, commercially valuable or cut only to be discarded, is logged. Forests covering 1,000 square kilometers have been completely denuded in a single clearcut. Huge processing trucks sweep through the forests, creating deep ruts in the forest floor. Roads are bulldozed for this logging, opening up forests, causing erosion to soils and flattening fragile plants. Baby birds, squirrels, bats and tiny primates in tree holes are killed as their homes are sent crashing to the ground and dragged along the forest floor.

Forests' Retreat: Page 7

Kitt Chubb, a Canadian wildlife rescuer, recounted the trauma that one family of owls endured as a result of a mechanical logging operation. Tiny Screech Owl (*Otus asia*) chicks, still downy and being fed in their treehole nest by the parents, suddenly found themselves slammed to the ground when the tree was cut. A giant logskidder machine roared through the woods gathering up the cut trees, including the one containing the owl chicks (Chubb 1995). The machine proceeded through the woods, bouncing and violently rocking over rocks and ruts. This cacophony must have terrified the owl chicks. Finally, the driver dumped the trees with a crash onto a pasture (Chubb 1995). Soon after, an employee with a chain saw began to cut up the trunks, and as he cut into a big knothole, he jerked the saw back when he saw three fuzzy grey owl chicks with their eyes closed tight (Chubb 1995). Amazingly, they had not been injured or killed after being knocked and bounced about. The loggers decided to save the little Screech Owls, bringing them to Chubb's wildlife rescue center. She placed them in a wooden box and returned with the box the next

day to the spot where their nest tree had stood. The forest where the owls had lived had been obliterated, and not a single tree remained. Finding a hollow beech stump in the clearcut not too far away, she and fellow rescuers placed the box in the stump, covering the top with leafy branches for shade, hoping the parents would return to feed the chicks (Chubb 1995). The next day, Chubb was surprised to find a frog leg in the box with the chicks, left by a parent owl. The chicks were lively and vocalizing, and 10 days later, they were still healthy and ready to be banded (Chubb 1995). Unfortunately, few baby birds and other animals survive logging operations or are lucky enough to be rescued if found alive.

Even animals as large as bears are frequently killed when they den in large tree holes. If their cubs survive, they will die of starvation if not rescued. Numerous cases of logging operations orphaning or causing mothers to abandon bear cubs are documented each year. A National Geographic Society film, fiMother Bear Man,fl shown in 1998 on "National Geographic Explorer," told the story of three bear cubs found after logging operations and their long return to the wild under the care of a kind and experienced wildlife rehabilitator in New England. Turtles, rodents, snakes and ground birds sheltering in burrows can be crushed to death by heavy logging machines. The soil, no longer held in place by root systems, breaks loose when saturated by heavy rains. Severe erosion on hillsides can cause mud slides that swallow up houses and the forest below, leaving a virtual moonscape, devoid of life. On level areas, rain washes soil into streams and rivers, clogging them, which kills fish and other aquatic lifeforms. Beautiful tropical forests with 300 or more species of trees per acre, a typical diversity, and myriad species of birds, mammals, reptiles, amphibians and invertebrates inhabiting them, become denuded patches of bare soil interspersed with stumps and broken limbs after clearcutting.

Even in remote wildernesses, the heavy machines that are now used to harvest and transport trees create such havoc and noise that wildlife flees. Many species of rare primates and birds disappear from logged forests, unable to adapt to any logging activities. A recent study in Gabon found that selective logging operations so traumatized Chimpanzees (*Pan troglodytes*) that their population in one 2,000-square-mile reserve fell by 80 percent after logging, even though only 10 percent of the trees were cut (Stevens 1997a). Dr. Lee White, a biologist with the Wildlife Conservation Society in New York, who was studying these Chimpanzees, made the following observation when loggers were in the forest: "I had whole chimpanzee communities charging to about five meters and screaming at me, and that's very unusual behavior" (Stevens 1997a). They were observed in logging areas in extremely agitated states, drumming on trees and calling to each other. The tremendous noise and disturbance by large machines apparently caused them to flee into the territory of neighboring Chimpanzees, where they fought to the death (Stevens 1997a). Both the Chimpanzee and Bonobo, or Pygmy Chimpanzee (*Pan paniscus*), are endangered species, and the latter is unlikely to survive much longer in the wild as a result of logging. Its tiny population inhabits a restricted portion of forest in the Democratic Republic of the Congo, the former Zaire. Both are also killed in large numbers for meat markets by loggers and hunters, who use logging roads to enter forests. The traumatized orphaned young are sold as pets and to others who exploit them commercially.

Forests' Retreat: Page 8

Many of the last old-growth forests have been cut for throwaway products such as shipping crates, concrete forms, plywood, chopsticks and newsprint. Virgin rainforests in southeast Asia, Australia, Alaska, Russia and British Columbia are being logged to supply the enormous demand for such products, destroying entire ecosystems in the process. The United States and Japan have played major roles in the logging and trading of lumber at extremely low prices for industrial uses (Yates 1992). When one country's forests are stripped, loggers move on to another. In this way, the great Philippine forests of Pliocene trees and Central American forests were cut in the mid-20th century, followed by the teak forests of Thailand and the hardwoods of Indonesia and West Africa. These areas have lost 80 percent or more of their forest cover, and loggers have now moved on to Central Africa, Burma, Belize and Amazonian South America. Brazil's beautiful rosewood trees have already been logged to near extinction. The World

Conservation Monitoring Centre of Cambridge, UK, conducted a study on commercial logging and found that 304 tree species from Asia and Africa were threatened with extinction by trade (Bohan *et al.* 1996). Fifteen species of commercially logged trees are listed by the Convention on International Trade in Endangered Species (CITES) in the most endangered category.

In response to criticism about clearcutting, some logging companies and conservation organizations endorse selective cutting, or cutting only certain species of trees or trees of a certain age. Yet such logging is also destructive. One United Nations (UN) Food and Agriculture Organization (FAO) study found that selective cutting destroyed as much as 70 percent of forest cover when conducted totally irresponsibly and, on average, destroyed 30 to 40 percent of the trees (Bohan *et al*. 1996). Destruction of non-target trees occurs with the construction of logging roads and use of heavy equipment to extract trees; when tree canopies and vines entangle one another, many trees are brought down, although only one may be cut. A study in French Guiana found that an average of 57 trees are killed for every tree extracted by selective logging (Bohan *et al*. 1996). Research on logging in Sarawak, a Malaysian state on Borneo, found that of every 26 old-growth trees cut, 33 others were destroyed or damaged, and canopies were broken, isolating animals who will not cross open spaces (Yates 1992). The thin tropical soil was also compacted and exposed, preventing natural regeneration of the forest (Yates 1992).

Many logging companies claim that by cutting mature trees selectively on 30- to 70-year rotations, they are conserving forests (Collins 1990). By definition, no tree older than 70 years can exist in such a forest. Such logging will end in destruction of the ancient and diverse forests, with trees 1,000 or more years old harboring a wealth of species that can only grow and prosper in old-growth forests. The more diverse a forest, the more stable ecologically, and logging tends to impoverish diversity by selectively removing certain commercially valuable species.

Thousands--and perhaps millions--of species depend on primary, virgin forests and cannot adjust to second-growth or logged forests. How many, and which species they are, however, is only partially known. Even scientists specializing in forest wildlife have not determined all the species that fall into this category, especially in complex tropical forest ecosystems. Unfortunately, this knowledge is often acquired too late, after logging has taken place and endemic species have disappeared. Logging operations are proceeding with such speed, and the scientists chronicling the damage are so few in number, that in terms of threats to plants and wildlife, only the tip of the iceberg is being documented.

Forests' Retreat: Page 9

Until the 1970s, no one knew what the effects of clearcutting forests would be on various species of rainforest wildlife. The US government's Smithsonian Institution, with ornithologist Dr. Thomas Lovejoy supervising, conducted the first scientific studies of the effects of forest destruction in the Amazon on a wide range of wildlife. Blocks of interior forest of various sizes were inventoried by teams of biologists with mist nets and live animal traps. After each inventory was completed, the blocks were isolated by clearcutting the forests surrounding them. Then, after a period, they were inventoried again to discover the effects of clearcutting on the wildlife in the newly isolated forest patches. This type of research aims to discover how large reserves must be to preserve the diversity of ecosystems.

The results of Lovejoy's research in Amazonian primary forest indicated that small reserves of 2.5 acres or less lose a large percentage of their wildlife, and the larger the reserve, the fewer the number of species that disappear (Lovejoy *et al.* 1984). Certain species are dependent on large areas of primary, old-growth forest and are quick to disappear as soon as forests are disturbed or fragmented. Bird populations tended to decline in most reserve sizes, and species composition changed. In the smallest plot, 39 species of birds dwindled to 18 species after three years, and in the larger plot of 25 acres, 48 species declined to 38 (Lovejoy *et al.* 1984). The understory species were censused, as

opposed to the canopy birds which seem less vulnerable to fragmentation of forest. Ecological dependencies caused some extinctions. For example, army ants thrive in large areas but disappear from smaller ones, and birds that feed on these ants, such as antbirds which are diverse and numerous in primary forests, disappeared within a short period from smaller plots (Lovejoy *et al*. 1984).

In another chain reaction, the White-lipped Peccary (*Tayassu albirostris*) proved to be a keystone forest species. It digs small waterholes to wallow in when ponds dry up, providing habitat for other wildlife. Peccaries travel in large groups seeking their diet of fruits, especially palm fruits, and act as seed dispersers. The key to their survival is territory size: a herd of 100 animals requires a territory of 97 square miles (Fragoso and Silvius 1995). They disappear from smaller forests causing the local extinction of frogs, who lay their eggs in these waterholes. In the Amazon study, four species of frogs disappeared from areas where peccaries had insufficient habitat to survive (Lovejoy *et al*. 1984).

Many other mammals are affected by forest fragmentation. Twenty species of mammals occupied a large, undisturbed forest plot, while only five were left in an isolated 25-acre-forest; a mere three mammal species remained in a 2.5-acre-forest (Lovejoy *et al*. 1984).

Theoretically, extinctions also can be caused when species have limited distributions which are destroyed by logging. A number of birds and mammals, including several newly discovered marmoset species in the upper Amazon forests, inhabit extremely restricted ranges of only a few square miles. Some species of primates will refuse to cross a road, such as a logging road, or an open clearing. Should a road be built in the middle of their tiny ranges, they would face extinction. Since tropical forests have not been thoroughly inventoried, the endemic species at risk most probably number in the tens of thousands.

Butterflies that live only in deep, virgin rainforest are so intolerant of fragmented forest that they disappear from areas less than 250 acres and, even there, survive only in the central core area (Laurance and Bierregaard 1997, Lovejoy *et al.* 1984). Forest butterflies, which exist in amazing diversity, are highly sensitive to the disappearance of their host plants, upon which they lay their eggs, and thrive in greatest number when vegetation is highly diverse. Some cannot tolerate the penetration of light into forests, and others require such large territories to feed that they disappear from small reserves, according to research by Keith Brown and Roger Hutchings (Laurance and Bierregaard 1997).

In small forest blocks, trees on the forest edge become vulnerable to the effects of wind and fire, fall in far greater numbers than those in the center and succumb to fires that spread from neighboring grasslands. Fires consumed large areas of rainforest in the Amazon during the late 1990s as a result of fragmentation. This was the first record of rainforest fires in this region. Storms blow down trees adjacent to the edges of fragmented forests and, over a period, will destroy the inner primary forest (Lovejoy *et al.* 1984).

Research on forest fragmentation is now taking place in Africa, Asia, Australia, the Indian Ocean islands and elsewhere in the world. Numerous scientific papers on the subject were gathered in a book entitled *Tropical Forest Remnants. Ecology, Management, and Conservation of Fragmented Communities* (Laurance and Bierregaard 1997). Many of these studies paint a grim picture of the effects of forest fragmentation on biodiversity.

Bats are important forest pollinators but are extremely vulnerable to extinction. They are rarely protected and often persecuted. The valuable Durian fruit of Asia is one such plant pollinated by a declining species of rainforest bat. Other food plants pollinated by bats include wild bananas, breadfruit, mangoes, guavas, avocados, almonds, cashews and cloves, according to Bat Conservation International, which is dedicated to changing the negative image of bats and preserving wild populations (see Organizations list for address).

Forests' Retreat: Page 10

Throughout the world, biologically diverse natural forests are being replaced with tree farms of fast-growing pine or eucalyptus. In Japan, cedar is planted over millions of acres for harvesting. The goal of these farms is to replace old-growth forests that take hundreds of years to mature with trees that can be harvested in 30 to 50 years. Large amounts of herbicides and pesticides are applied to prevent the growth of "undesirable" plants and to control insects. These tree farms have contaminated water tables, destroyed natural diversity, and eliminated countless life forms crucial to maintaining the ecological balance of the planet. Moreover, many are now failing even in their goal of producing fast-growing, healthy trees because of a lack of understanding of ecological systems and natural forest functioning. Tree farms are frequently swept by disease and, in the case of Japan's cedar plantations, which cover 10 million acres, shallow roots have resulted in trees blown over in windstorms and landslides after heavy rains. A healthy forest has many species of trees. This diversity discourages insect pests, which tend to specialize in individual species, from spreading and sweeping through the forest, killing all the trees. The variety of trees in a natural forest also means that many are deep-rooted or have root mats that anchor the soil from erosion.

An added environmental threat posed by tree farms is the use of genetically engineered seedlings, whose effects on ecosystems are not yet known. By transplanting genes from other species of trees--and even animals-- into these unnatural trees, the possibility that their seeds could spread to the wild and contaminate natural trees and plants is very real.

Major disruptions in pollination occur in fragmented forests. Natural tropical forests, with hundreds or even thousands of species of trees, have evolved complex systems of reproduction. Because other trees of the same species might be miles away, trees send their pollen far and wide. Insect pollinators travel great distances to find trees of the same species. Biologists have found that even in selectively logged forests, trees were not being pollinated naturally because others of their kind were removed or became too distant; some species self-pollinated, causing in-breeding, while others simply died out (Yoon 1995b). These biologists concluded, "Even the forests that appear the healthiest but are being selectively logged or otherwise thinned may be endangered in the long run by an increase in less desirable inbred seed" (Yoon 1995). Inbred stock usually loses vigor and ability to reproduce over the long run. This is an ominous finding considering that many conservation organizations and international logging companies have endorsed certain "sustainable" logging programs, urging the public to purchase products identified as such. Moreover, many of these ancient trees tower 200 or more feet, with wide buttresses at ground level to anchor them in the thin tropical soil. Such trees may have stood on the forest floor for 1,000 years and are living monuments, treasures to be preserved, not raw material for packing cartons, furniture or paper pulp.

Preserving Forests

A 10-year mapping project by the World Conservation Monitoring Centre ending in 1996 found that only about 6 percent of the world's remaining forests are protected against logging and development. Because of the rate of destruction and the potential loss of biological diversity, this is an extremely critical situation.

Page 1 (Recycling and Substitutions)

Preserving Forests: Page 1

Much of the logging in the world is a result of markets provided in the United States, Japan and Europe for wood and wood products. Because paper pulp is cheap, there is little effort to find substitutes or even to recycle the millions of tons of paper thrown into landfills each year. The use of trees for making paper is government-subsidized, encouraging waste and destruction of forests. Tree farms have failed to meet the enormous demand for paper. Financial incentives to recycle or use other materials should be made by consuming countries. Finding substitutes for lumber and raw material for paper will be crucial in protecting entire forests. The United States imports 800 million pounds of paper from Brazil every year, to the detriment of that country's forests. In spite of computers and Internet communications, total amounts of paper used in the United States have not decreased; 4.3 million tons of paper are used in US offices alone each year, and millions more tons are used in newsprint, magazines and other paper products. Because of a lack of economic incentive, only a small portion of this paper is being recycled into new paper. In fact, studies of landfills have shown that 40 percent of material in these dumps consists of unrecycled newspapers.

Innovative approaches are needed to encourage recycling and to end subsidies and the importation of wood chips and newsprint from forests around the world. Some of the alternatives to paper made from wood are already in use. Thousands of years ago, Egyptians produced paper from papyrus reeds, and rice is still used to make paper in parts of East Asia. Cotton and flax are the raw materials of fine quality paper used for currency and other purposes.

Many other plant species are now seen as substitutes for wood pulp in making paper. In *A Wealth of Wild Species, Storehouse for Human Welfare*, Norman Myers (1983) mentions one of these, a plant called kenaf, that is a distant relative of cotton and okra. This plant has been cultivated for centuries in Asia for making burlap bags. A fast-growing, reed-like plant, kenaf shows great potential in the manufacture of paper. Its straight, slender stem has no side-stems, nor does it produce the kind of resins that must be eliminated when wood pulp is processed for paper. Planted like corn, it is ready for harvesting in four months and produces five times more pulp per acre than a pine tree plantation (Myers 1983). In research conducted by the US Department of Agriculture, kenaf has proven an excellent substitute for paper in newspapers and even bank notes (Myers 1983). A few kenaf farms have been established without government sponsorship in Texas and other southern states, and already many organizations are printing newsletters using kenaf instead of wood-based paper. Processing kenaf does not involve the serious water pollution caused when cellulose is removed from wood and pulp is bleached with chlorine. Air pollution from wood pulp processing plants has been injurious to human health (Verhovek 2000).

Earth Island Institute of San Francisco, California, has published a report, *Forest Friendly Paper Guide*, giving more information on kenaf and other non-tree substitutes for paper, including a new paper product by Arboken of Canada that is made from wheat straw, recycled corrugated cardboard and calcium carbonate filler. A publication called *Guide to Environmentally Sound Papers*, issued by an organization called Conservatree, lists more than 400 types of "green" paper. Among these are recycled, kenaf-based, hemp, sugarbeet and corn, grass and crop waste paper. (These can be obtained from Earth Island Institute. See the list of organizations in this book for the address.)

Preserving Forests: Page 2

Most homes are constructed of wood. An average of 40 to 50 trees are needed to build a 2,000-square-foot

wood-framed house (Bielski 1996). Building with stronger materials, such as steel, concrete, brick and stone, would spare millions of trees. Moreover, these materials are not vulnerable to infestations by termites, which destroy entire foundations and frameworks of buildings made of wood. To control these insects, pest control companies apply large quantities of extremely toxic pesticides that can leach into the soil and water table, killing wildlife, and pose hazards to the occupants of the house. The Institute of Ecolonomics in Ridgeway, Colorado, reports that a new tree-free "wood" has been developed for use as building material. Called BioComp, it contains half recycled plastic and half agricultural residue and, according to the Institute, is twice as strong as Douglas Fir, termite-proof, impervious to water, and can be made fire retardant. BioComp resembles wood and is easily molded, sawed and nailed. Some alternatives to wood are also less expensive. Steel is being used in New England homes for major support beams with a metal roof for less money than the same home would cost made of wood (Hotton 2001).

The Wood Reduction Clearinghouse has been formed in San Francisco to address the failure of considering consumption as a driving force in deforestation (Bielski 1996). A group of leading environmentalists issued a statement in 1995 calling for a 75 percent reduction in wood and paper use by 2025, and strategies for eliminating the need for wood altogether are being explored (Bielski 1996). The use of timber for shipping crates and concrete molds--especially tropical hardwoods--should be phased out and substitutes, such as plastics, phased in that would be more economical because they could be reused. Some stores are already using substitutes for the millions of cardboard cartons used to ship goods.

Preserving Forests: Page 3

At the 1992 "Earth Summit" in Rio de Janeiro, Brazil, convened by the United Nations Conference on Environment and Development, world leaders agreed on the importance of slowing the rate of global forest destruction. Conservationists have pressed for a new, legally binding Global Forest Agreement to conserve and manage the world's forests. In spite of the urgent need for such an international treaty, no agreement has been reached in the intervening years. Numerous meetings and conferences between nations have failed to draft a policy that would curtail the uncontrolled commercial logging that is ravaging forests around the world.

Several organizations, including the Environmental Investigation Agency (EIA), headquartered in London, and the World Resources Institute (WRI) of Washington, DC, have issued reports that chronicle the damage being done and the need for such a treaty. EIA's report, *Corporate Power, Corruption & The Destruction of the World's Forests, The Case for a New Global Forest Agreement*, argues for the need for international agreements to control commercial logging (Bohan et al. 1996). This report gives detailed information on the companies doing the most environmental damage to the world's forests and the methods used by these corporations to bribe and otherwise corrupt the leaders of poor nations to obtain logging contracts. Other organizations, such as the Rainforest Action Network, agree that international logging corporations must be regulated. This $100-billion-a-year trade operates with generous tax breaks from the countries where companies are based and the granting of logging concessions that often cover millions of acres through special arrangements made behind closed doors with government officials (Bohan *et al.* 1996). Logging concessions almost always ignore or overrule strict legislation already existing in many countries protecting the environment and wildlife, including endangered species (Bohan *et al.* 1996).

At present, cutting of forests is "regulated" only by the timber industry itself through the Tropical Timber Agreement, signed in 1983 by various international lumber companies. This agreement does not protect wildlife and the environment. In spite of renegotiation in the mid-1990s, the agreement still does not address ecological concerns or species preservation. Pressure from multi-national companies, primarily Japanese, to supply this lucrative market have overwhelmed the voices of conservationists throughout the world.

Logging in Central Africa is in the process of destroying the once vast and unspoiled forests. A conference in 1999

was convened by the World Wildlife Fund (WWF) to reach an agreement about the fate of these large tracts of tropical rainforest in Africa, located in Cameroon, Central African Republic, Gabon, the new Democratic Republic of the Congo, Equatorial Guinea and the Congo. In this region, 40,000 square kilometers of forest are being destroyed a year, endangering hundreds of wildlife species and opening up the forest to a devastating trade in bushmeat. Prince Philip, in speaking on behalf of WWF, stated that the organization hoped to protect 10 percent of this vast forest, an area too small to prevent extinctions and great biodiversity loss. The Democratic Republic of the Congo, which is in a state of political chaos, did not attend the conference, and no pact was signed.

Preserving Forests: Page 4

The forests of the Democratic Republic of the Congo are among the wildest and least explored in the world, but this wilderness is being invaded by loggers and meat hunters. Michael Fay, a biologist with the Wildlife Conservation Society in New York, has been on a mission to cross this vast area on foot, accompanied by some natives and correspondents, describing the amazing sights along the way. He is trying to draw attention to this region and the urgency of saving it while most of it is still in pristine condition. He has already succeeded in having a sizeable national park established. His trek is dangerous, with poisonous snakes, leeches, tropical diseases and other threats, but he is a dedicated conservationist and scoffs at the dangers. The National Geographic Society is helping to sponsor his trip and publishes regular articles in their magazine on his progress, and their website gives more information. Several short films have also been made for the National Geographic fiExplorerfl program. His mission is extremely important and has the potential of preserving entire ecosystems of threatened animals and plants.

A growing awareness of the problem, along with creative solutions, give hope that in at least some parts of the world, large tracts of tropical forests and their wildlife will be spared. Two enormous parks were established in Suriname and Bolivia in the 1990s, mainly as a result of the work of Conservation International, a US organization that successfully convinced the governments of these countries that such protection will be far more beneficial for the country than short-term exploitation and forest clearance. Other organizations are working effectively in central Africa, Peru, Brazil, Burma, Laos, Vietnam, and the Philippines to protect these species-rich forests.

New approaches to deriving funds from forests without logging and destroying diversity include regulated extraction of non-wood products, such as seeds, fruits and plants, for food and medicinal purposes. Ecotourism is one of the most lucrative and growing industries in the world, with revenues in the billions of dollars and rising.

Old-growth forests are being cut not because they provide raw material that cannot be found elsewhere, but because they provide a high profit margin to European, North American and Asian logging companies. Decisions made about the fate of these forests, upon which the survival of so many species depends, are not being made by the people where logging takes place, nor by conservationists. These precious and irreplaceable resources, habitat of the majority of the world's threatened species, are being sold to logging companies for pittances. The United Nations has recently endorsed the concept that forest diversity must be maintained, joining the ranks of many other international organizations. In time, society may learn to preserve these storehouses of evolution with the same zeal that great works of art are protected.

Preserving Forests: Page 5

One project has greatly improved the standard of living for villagers in India, while taking steps toward protecting the forest habitat of the highly endangered Bengal Tiger. Many thousands of residents were forced to move when Ranthambhore National Park was established decades ago, causing much resentment. At first, they were banned from

gathering firewood and grazing livestock within the park. This had an extremely positive effect on the forests, which regenerated, and Tigers, deer and other wildlife prospered. Gradually, however, park authorities became more tolerant of the incursions of local people and their livestock into the forests. During the 1980s, large areas became deforested, and poaching endangered Tigers and deer within the park.

To reverse this trend and preserve the habitat of this park's wildlife, a Tiger conservationist and author, Valmik Thapar, established the Ranthambhore Foundation. This Foundation sponsored a nursery which propagated 500,000 tree seedlings, employing villagers to replant the national park. It set up a farm with domestic buffalo which had been bred with milk cows and kept in stalls and enclosures away from the forests. These animals yield far more milk than the emaciated Indian cows overgrazing the forests; fuel for cooking and heating is provided by a bio-gas plant producing methane from the buffalo's dung; a new crafts industry employs women in the village (Ward and Ward 1993). In the first four years of the project, 6,000 school children from local areas were taken into Ranthambhore National Park for education programs (Currey 1996).

A Cable News Network (CNN) reporter, Gary Streiker, visited one of these farms outside Ranthambhore National Park in mid-1997. The villagers were economically better off and appreciated having the bio-gas fuel, which saved them the effort of scouring the landscape for firewood, often a full-day's activity. This allowed them to devote time to crafts and other small businesses. Unfortunately, some of the other villagers around the park were still gathering wood, denuding the park. These age-old customs will be difficult to change. Eco-development and conservation projects in 60 villages surrounding Ranthambhore National Park have been launched. Conservation education on the importance of saving the forests will help to change attitudes and protect the park's wildlife and trees. This will bring tourists and new sources of income.

Preserving Forests: Page 6

Several remarkable successes have proved a positive contrast to the otherwise gloomy trends of forest destruction. In South America, large expanses of undisturbed tropical forest remain, but they are fast disappearing. The Amazon Basin and its forests once covered 2.3 million square miles, comprising three•fourths of the world's tropical forests, but forest clearing has destroyed some 20 percent of the original forests and damaged far more. Amazonian forests contain 14,000 endemic species of plants (Harcourt and Sayer 1996).

Parque Nacional Madidi, Bolivia's newest national park, covers 4.7 million acres, protecting a variety of threatened habitats and species. Avian diversity for this park is estimated at 1,088 species of birds, or 11 percent of the world's birds, the highest in any protected area in the world; among these are many threatened species and others with small ranges (Remsen and Parker 1995). This park, watered by numerous rivers, borders eastern Peru and includes a variety of threatened environments. Humid lowland forests, grasslands and montane cloud forests are among these. Resident birds include the threatened Yellow-rumped Antwren (*Terenura sharpei*) and various species of tinamous and curassows (Remsen and Parker 1995). The latter birds are among the first species to disappear from areas as a result of hunting and habitat destruction. A proposed hydroelectric dam, which would drown large sections of rich lowland forests., is a major threat to the park. It may have been stopped as a result of publicity by *National Geographic* magazine, which featured a cover story in 1999 on the importance of saving this park. Public opinion and the potential tourist trade may compensate this country for lost revenues from the dam. An even larger park of 8.6 million acres along the border with Paraguay, the Kaa-Iya del Gran Chaco National Park, protects the most sizeable block of endangered dry tropical forest in the world (Seve 1996). These two parks will preserve more than 20,000 square miles, and native tribespeople will play a role in administering them (Seve 1996).

Another positive development is the trend in a growing number of countries to share the profits from national park fees with local people and involve them in the decision-making processes of managing the park and the local wildlife.

Madagascar has been successful at this, combining income from park fees with international grants to build schools, libraries and clinics for the local people. Patricia Wright, a primatologist, helped establish Ranomafana National Park to protect endangered lemurs as well as to protect the watershed from floods. In the recent past, deforestation carried out by local villagers had caused landslides that inundated their homes and caused water sources to dry up. They have become convinced of the importance of preserving the forests for their own survival. This new approach of educating local people on the benefits that would accrue to them as a result of conservation, as well as payment from park fees and profits from ecotourism, is the future of forest preservation.

Another trend that will prove important is the involvement of biologists studying wildlife with local people, learning from their observations and sharing the knowledge they uncover. Biologists in Madagascar who rediscovered an owl thought extinct, brought local students to see it and raised money for needed school supplies from birdwatchers who came from around the world to see the bird. This creates a positive impression on the local people and instills natural history curiosity and a realization of the uniqueness of their own wildlife. In the future, this may be expanded by showing them films about the natural world that surrounds them and opening up new worlds with books and publications about the subject. Very few people are aware of the endemic wildlife and plants in the environments in which they live, whether in the United States or the Cameroon. When people learn of the flora and fauna in their neighborhood that exists nowhere else, or is of biological importance, they are far more likely to protect it. Even in the United States, where Natural Heritage Programs chronicle the endemic and declining species of every state, the information has not always been made available to the public in the form of state publications or television or newspaper publicity that could have a major effect on whether forests and other habitats are protected.

A recent campaign to alert the public to the ecological advantages of choosing shade-grown, organic coffee has helped preserve rainforests in many parts of the world. A trend toward planting coffee plants in open fields rather than in the traditional way, as an understory to tall trees, has been devastating to tropical forests, home to both tropical birds and other animals, and to migratory birds from North America who spend the winter in Latin America and the Caribbean. Smithsonian biologists began this campaign in 1990 when they saw bird species decline with the planting of sun-grown coffee plants, and patented the logo "Bird Friendly" coffee. Such coffee is now commonly sold in health food and specialty stores and may become more popular as the public is educated about the problem. With the enormous popularity of coffee, this could make a major difference to birds and other wildlife.

North America™s Forests

The history of the destruction of all but 5 percent of the 850 million acres of old-growth forests in North America has been recounted in Chapter One. Second-growth forests now dominate the East, forests far different in species composition from the original virgin forests. The great chestnuts, elms and beeches are gone, and woodlands are now young, mixed pine and hardwood. Moreover, these forests are fragmented by roads and development. Only a few roadless areas remain. A few remnants of old-growth forests have been located in the East, primarily on steep slopes and areas that loggers found difficult to reach. In southern Maine, for example**,** a biologist recently located a stand of Black Gum trees, some 9 feet in circumference. One stump had 450 rings, and another, larger one was still thriving. It was estimated to be more than 500 years old, dating back to the time of Columbus. Unfortunately**,** this area is in the path of development (BG 2000). The Great Smoky Mountains National Park is a large block of forest totaling 500,000 acres in the southern Appalachians of eastern Tennessee and western North Carolina. This national park harbors some virgin old-growth and a wealth of rare native trees, plants and wildlife, including a great diversity of salamanders that inhabit its damp, mossy forest floors and fast-flowing streams. It sits atop a mountain range that is a meeting place of northern and southern species, an important area to the endangered Appalachian forest ecosystems and a primary migratory stopover and nesting area for threatened wood warblers and songbirds. This area recently has been designated an International Biosphere Preserve, and its diversity is being inventoried by a team of biologists and other earth scientists.

North America™s Forests: Page 1

Migratory songbirds of eastern forests have declined by at least 45 percent in the past 50 years. These dazzling migrants--wood warblers, vireos, tanagers, orioles, grosbeaks and thrushes--suffer from a variety of threats. Deforestation of tropical forests where many of these birds spend the winter has been a major factor. Species requiring mature, undisturbed forest have declined to the greatest degree, some losing up to 90 percent of their populations. Clearcut logging and fragmentation of their breeding forests by housing, malls, roads and other development have consumed millions of acres, displacing these songbirds. Many birds returning from tropical wintering grounds find their breeding forests destroyed or too small for successful breeding. A small patch of woods large enough for only one male songbird, surrounded by agriculture or development, will be abandoned if the male is unable to hear the songs of neighboring males (Line 1995). Many birds establish territories and maintain them by singing and challenging other males.

Another effect of forest fragmentation has been the proliferation of forest edge species that prey on songbirds and their eggs (Terborgh 1992). The Brown•headed Cowbird (*Molothus ater*), a parasitic species, was once seen only in grasslands. In the past, when huge herds of American Bison roamed the prairies of the Midwest, cowbirds accompanied them, laying their eggs in the nests of grassland birds, who raised them as their own. With the disappearance of the Bison, cowbirds entered the forests bordering agricultural and pasture land, laying their eggs in songbird nests. Some cowbirds now remain close to domestic cattle and fly into the nearest woodland to lay their eggs. Their eggs usually outnumber those of the host species, and the large chicks instinctively nudge the small songbird nestlings out of the nest. Because of the increase in forest openings, the net result of these losses has been a 90 percent decline in the number of songbirds recorded in the 1940s in many eastern forests (Terborgh 1992).

A campaign to declare a large section of the forests in northern New England a reserve began in the mid-1990s. To add urgency to the need for a national park in Maine, New Hampshire and Vermont, a new species of thrush, native only to this region, has been discovered. Once considered a subspecies of the wide-ranging Gray-cheeked Thrush (*Catharus minimus*), Bicknell's Thrush (*Catharus aliciae*) was found to be a totally distinct species in 1995, smaller and with a unique song. A bird of high altitude forests, it has already disappeared from its only nesting area in

Massachusetts, Mt. Greylock. The major breeding area for Bicknell's Thrushes is now Vermont, whose forests are under pressure from ski developments and proposed wind turbines. Additional populations of fewer than 3,000 birds inhabit neighboring southern Canada, but the traditional practice there of thinning forests renders these forests unsuitable. Its habitat of spruce-fir forests is dying out from acid rain and global warming (BI 2000). This threatened bird is also losing habitat in its West Indian wintering grounds, especially Hispaniola, where forests are being cleared (BI 2000).

Another member of the thrush family is declining toward extinction. Known for its melodious, fluted song, which many find more intricate and beautiful than the Nightingale's, the Wood Thrush (*Hylocichla mustelina*) has declined precipitously in recent years. Native to undisturbed hardwood and mixed forests in eastern North America, the Wood Thrush winters in Central America, from southern Mexico to southern Panama (Rappole *et al.* 1983). In August, these birds begin their southerly migration, often gathering in groups where the chorus of 50 or more Wood Thrushes may echo like a cantata in the tall trees. One research project studied these birds in one of their tropical wintering areas in the Tuxtla Mountain region of southern Veracruz, Mexico, on the Gulf of Mexico. Studies of this population of birds began in the mid-1970s when the wintering habitat consisted of primary rainforest. (Rappole *et al.* 1989). This forest has declined by 85 percent, a far higher percentage than elsewhere in Central America, leaving mere fragments of the once rich tropical rainforest (Rappole *et al.* 1989). In 1980, the two researchers returned to find that their 12-acre rainforest study plot had been converted to a patchwork of fields and forest fragments; less than 5 acres remained of the original forest (Terborgh 1989). Using radio•tracking and mist netting, researchers discovered that Wood Thrushes do not adapt to forests without tall trees, even as a wintering area, preferring undisturbed rainforest. Year after year the same individual birds returned to the same sites. In rainforest, they tended to survive the winter, while Wood Thrushes forced to winter in neighboring second-growth or disturbed forest had a high mortality rate from predators and other causes (Rappole *et al.* 1989).

Throughout their winter range, the forests that once harbored tens or perhaps hundreds of thousands of Wood Thrushes in Mexico and Central America have been turned to pastureland or tilled for agriculture. Between 50 and 70 percent have been destroyed (Collins 1990). Fewer and fewer Wood Thrushes return to nest in Eastern forests, even when they have not been fragmented or cleared (Terborgh 1989). Their nests have also been vulnerable to parasitism by Brown-headed Cowbirds (Terborgh 1989). In Illinois, for example, where Brown•headed Cowbird populations have skyrocketed in past decades, one study found that 29 of 30 Wood Thrush nests had been parasitized by Brown-headed Cowbirds, who laid eggs that crowded out those laid by the thrushes; the conclusion of the study: "Wood Thrushes are doing nothing but raising cowbirds" (Terborgh 1989). In the few areas where forests are unbroken and extensive, Wood Thrushes have been successful breeders (Robinson 1996).

Unfortunately, the combined effects of habitat destruction in both its breeding and wintering grounds, and parasitism of its nests by cowbirds, may result in the extinction of the Wood Thrush. A recent study in several Midwestern states found that birds from large stretches of forest that are holding their own may be having young that disperse to neighboring forest fragments, only to be crowded out by cowbirds (Robinson 1996). The melodic Wood Thrushes are disappearing throughout their range, along with many other beautiful songbirds.*

---

*See Video section. fiOn a Wing and a Song,fl a Canadian Broadcasting Co. film produced in 1994 for The Nature of Things series, explores the decline in songbirds. Another excellent film on the same subject with a similar title, fiOn a Wing and a Prayer,fl produced in 1995 by Kurtis Productions and WTTW for the PBS series New Explorers, concentrates on the decline in breeding songbirds of Illinois and their migrations.

Other changes in environments also contribute to songbirds' declines. Recent research has found that high levels of noise from highways, airports and other man-made activities have interfered with the ability of birds to sing breeding songs and breed successfully. Birds that migrate to the Caribbean and Latin America suffer high mortality from

collisions with television and cellphone towers and tall buildings. For many years, one scientist at Chicago's Field Museum has collected migrating songbirds that died from flying into a single building near the museum**.** His collection now totals 20,000 birds. He estimates that total mortality from building collisions may be 60 million songbirds a year, an enormous loss.

A great concentration of breeding songbirds is found in Belt Woods, a 500-acre-forest near Bowie, Maryland. Trees that were growing when Columbus discovered America survive here. Perhaps the largest tract of old-growth forest in the region, it has a variety of habitats from swamp forest to dry hardwood stands. More than 40 species of migrant birds nest here, including Wood Thrushes, Rose-breasted Grosbeaks, Baltimore (Northern) Orioles, Scarlet Tanagers, Prairie Warblers and Ovenbirds. These are species that have disappeared from woodlands that have become fragmented, or contain few tall trees. This wealth of breeding birds underlines the importance of protecting old-growth forests. Privately owned, Belt Woods was willed by the late owner, William Seton Belts, to the Episcopal Church to be kept intact in perpetuity. The church, however, went to court in the 1990s to change the will to allow sale to developers, claiming that it had more important works to accomplish with the funds than saving the forest.

After conservationists had decided it was a hopeless cause, a local resident, Pam Cooper, decided to spearhead a rescue of these precious woodlands. By conducting publicity campaigns and fund-raising efforts, she and the Western Shore Conservancy raised money. A Maryland author and illustrator of children's books, Lynn Cherry, organized The Friends of the Woods to enlist children to help influence their parents and public opinion to place the preservation of this threatened woodland above that of sheer materialism and to champion the need to take on local conservation problems as a community. Her children's book, *Flute's Journey, the Life of a Wood Thrush*, chronicled the life of a Wood Thrush born in Belt Woods, its migration to Costa Rica and its uncertain future. The plight of Belt Woods was given national attention in April 1996 on a CBS program, "Sunday Morning," which may have been a crucial turning point in the preservation of this forest. Within months, an arrangement was finalized with conservation organizations that would turn Belt Woods into a reserve, ending the possibility that it would be sold to developers.

At a time when losses in the numbers of North America's beautiful songbirds may have become irreversible, scientific research is revealing that they play a crucial role in controlling insects in forests (Yoon 1994). In a controlled experiment, birds were excluded from a section of forest with netting cages that allowed insects to enter. It was found that trees and plants incurred twice the damage to foliage where birds were excluded (Yoon 1994). The study concludes that songbirds constitute a major and important form of natural pest management, superior to pesticides (Yoon 1994). Keeping songbirds from nesting in a stand of White Oaks, other researchers found that caterpillars consumed so much foliage that the trees grew significantly more slowly than White Oaks with nesting songbirds (Robinson 1996).

North America™s Forests: Page 2

It would probably shock most residents of suburban New York City to know that 150 years ago, wild Gray Wolves preyed on White•tailed Deer, Eastern Bison and Elk in the dense virgin forests now occupied by their neatly clipped green lawns, while overhead the flight of millions of Passenger Pigeons darkened the sky. The Eastern United States is undergoing a "Europeanization" in which natural forest is being lost to housing tracts, highways and urbanization. This sprawl consumes the second-growth forests, some of which had become excellent wildlife habitat, and the new residents often contaminate the water and soil with pesticides and herbicides to maintain green lawns. The natural world and its fauna and flora are fast disappearing.

Just as they are disappearing, discoveries about the medical potential of eastern forest trees are being made. Recently a fungus was discovered that is a missing link in the life cycle of a mold that produces the billion-dollar drug cyclosporin, used to prevent the rejection of transplanted organs (Yoon 1996). The forest of the Finger Lakes Land

Trust in Ithaca, New York, where Cornell University students found the fungus, has established the nation's first reserve set aside specifically for chemical prospecting outside the tropics (Yoon 1996).

Most of the Great Lakes region was originally covered in ancient pines. During the logging boom of the late 1800s, mills of one Great Lakes port alone, Ashland, Wisconsin, cut 500 million board feet of lumber a year (a board foot is equal to wood 1 foot square and 1 inch thick), enough for 50,000 houses (Johnson 1997). Timber barons shipped the lumber to rebuild Chicago after the great fire of 1871, and the logged-over area, covered in broken branches, stumps and discarded trees, ignited a series of fires, one of which killed 1,152 people in the town of Peshtigo, Wisconsin (Johnson 1997). These fires charred millions of acres, leaving a wasteland (Jonas 1993). By the end of the 19th century, the majority of these forests had been clearcut by commercial loggers (Jonas 1993). There remains a scarcity of timber, and in 1996 a treasure trove of 20,000 to 30,000 old-growth tree trunks was found by divers on the bottom of Lake Superior; they had sunk more than a century after being cut and floated to mills (Johnson 1997). Old-growth timber is extremely valuable. It has tight grain resulting from slow growth, unlike the grain in the trees grown on tree farms. These logs are worth many millions of dollars, and a company is bringing the logs to the surface, selling them for ten times the price of new wood (Johnson 1997). These are the last remnants of a once vast forest.

Early in the 20th century, Weyerhauser, the German timber magnate, having logged out the old growth of the Great Lakes area, turned to the forests of the Southeast. Forests dominated by Longleaf (*Pinus palustris*) and Shortleaf Pines (*Pinus echinata*), which have the world's greatest diversity of forest floor plants, dominated northern Florida west to Louisiana and north to central Georgia. Longleaf Pine forest once covered 90 million acres from Virginia to Texas. These forests also harbored Loblolly (*Pinus taeda*), Virginia (*Pinus virginiana*), Pond (*Pinus serotina*) and Pitch Pines (*Pinus rigida*), which grew in various types of soil and climatic conditions. Loggers decimated this ecosystem, cutting millions of board feet, and by the 1930s, these forests had been reduced to a fraction of their original extent. Today, only about 2 percent of the Longleaf Pine forests remain, making them the most endangered forest ecosystem in North America. For the most part, these forests have been replanted with other species, predominantly commercial tree farm monocultures.

Much of the remaining virgin pine forests of the Southeast lie on national forest land, and they are being heavily logged. On December 15, 1995, this destruction was fought by the Biodiversity Legal Foundation and the Alabama Wilderness Alliance, which filed suit in Federal District Court against the US Forest Service challenging the legality of the Forest Service decision to open a series of massive salvage timber sales of trees blown down by a hurricane, along with some healthy standing trees, on 15,000 acres of the Conecuh National Forest in Alabama. The Biodiversity Legal Foundation hired biologists and other experts, who testified that Forest Service management of the forest violated its own environmental regulation relating to logging near waterways and had planted non-native trees instead of the native species that are preferred by the Red•cockaded Woodpecker (*Dendrocopus borealis*), an endangered resident of this forest. This lawsuit was settled in favor of the conservation organizations.

North America™s Forests: Page 3

A victim of this logging, the Red-cockaded Woodpecker is a small bird marked in black and white and named for the male's tiny streak of red on each side of the nape. These birds have very specific habitat needs. For nesting trees they usually choose old-growth pines stricken with red heart disease whose soft wood permits easy excavation of nesting holes; the sap running down the trunk deters snakes and other predators (McFarlane 1992). Red-cockaded Woodpeckers nest in small groups or clans, requiring large areas of undisturbed forest. Each clan has "helpers," non-breeding birds that aid in feeding the nestlings (McFarlane 1992). These woodpeckers were the primary control of the southern Pine Beetle, a major pest in pine forests; after destruction of old-growth pine forests, which endangered these birds, Pine Beetles proliferated and destroyed other types of pines (McFarlane 1992).

Prior to the commercial logging of the early 20th century, these woodpeckers may have numbered in the hundreds of thousands. Nineteenth century records exist of Red-cockaded Woodpeckers as far north as northern New Jersey and southeastern Pennsylvania, and west to Missouri (Jackson 1994). Gradually, their range shrank as pine forests were destroyed; by 1946 the species was gone from Missouri, and by 1976 from Maryland (Jackson 1994). Populations in Tennessee declined to a single bird by 1992, and they disappeared from northern Mississippi in 1977; Kentucky and Virginia have only a few family groups (Jackson 1994). In the Southeast, clans became rare and widely separated from one another as millions of acres of old-growth pine were logged. When listed on the Endangered Species Act in 1968, programs to prevent its extinction were launched. Inbreeding of Red-cockaded Woodpeckers is apparently occurring in populations isolated by forest fragmentation (Jackson 1994). Some females have been physically translocated to isolated groups without females to counteract this problem (Jackson 1994). Nest holes have been artificially created, and existing nest holes have been modified with steel plates, restricting the size of the opening to prevent predators and larger birds from entering the nest hole (Jackson 1994).

The problem of declining habitat remains, however, and some conservation organizations, including the Biodiversity Legal Foundation, have successfully taken the Forest Service to court concerning their replanting policies, obtaining court orders mandating replanting with Longleaf Pine to benefit the Red-cockaded Woodpecker. At present, only about 30 known clans remain, with South Carolina and Florida having the largest numbers; the entire population of the Red-cockaded Woodpecker may not exceed 7,400 birds (Collar *et al.* 1994).

One haven for the Red-cockaded Woodpecker is Eglin Air Force base, located on the Florida panhandle. This 460,000-acre base preserves the world's largest remnant of Longleaf Pine forest, which occupies 320,000 acres of the base (Stevens 1996); 10,000 acres of this forest are the largest remaining old-growth Longleaf Pine in the world, with many 400-year-old trees (Biondo 1997). The Nature Conservancy has spent years conducting biological surveys and has discovered that more than 90 rare or imperiled species, including a salamander new to science, inhabit the base (Biondo 1997). Eglin protects 1,200 plant species, with numerous threatened species among these. Military activities are carried out as carefully as possible, and the base employs a full-time chief of natural resources with a staff of 25 (Biondo 1997).

North America™s Forests: Page 4

The military conducts munitions tests on Eglin Air Force Base, causing fires that have inadvertently benefited the ecosystem. The piney woods of the Southeast need fire, without which shade-tolerant hardwoods begin to intrude on Longleaf and other native pine stands (Jonas 1993). At present, Eglin officials conduct controlled burns to maintain this habitat (Stevens 1996) and are removing non-native and overabundant plants and trees (Biondo 1997). To return the Longleaf Pines to former abundance, more than 3 million seedlings have been planted, restoring 200,000 acres over the past five years (Biondo 1997).

The Gulf Coastal Plain Ecosystem Partnership, a plan to link populations of Longleaf Pine forests, was formed in 1996 to protect 840,000 acres of contiguous forest held by seven major landowners in northern Florida and southern Alabama (Biondo 1997). The partnership has signed a memorandum of understanding that encourages cooperation between the diverse owners, from private logging companies to state forest departments and water management districts (Biondo 1997). More than 160 rare or imperiled plants and animals reside in these lands, and Eglin Air Force Base's land has been the best preserved of any because of limited human intrusion and very little logging. It also protects a sizeable population of threatened Gopher Tortoises (*Gopherus polyphemus*). This keystone reptile excavates deep tunnels and cavities which provide habitat and shelter during fires for hundreds of animals, including threatened species.

Southern Bald Cypress (*Taxodium distichum*) swamp forests were once found in many low-lying areas of the

South, but today, the Okefenokee Swamp is the largest remaining tract. Plans to clearcut this huge forest were abandoned early in the century after logging proved unprofitable. Later, the Okefenokee was declared a National Wildlife Refuge, and it is one of the most important examples of this ecosystem, home to River Otters (*Lutra canadensis*), Alligators (*Alligator mississippiensis*) and abundant water birds.

Massive stands of ancient Live Oaks (*Quercus virginianus*) draped in Spanish moss evoke the very essence of the South. Although the majority of these huge trees have been logged, many survive that are 10 to 12 feet in diameter. They have a dense wood that was used in the construction of ships such as the USS Constitution. This ship was called "Old Ironsides" because this hardwood was impervious to cannonballs. The last sizeable stands of these picturesque trees are disappearing, however. Companies are buying wood lots with Live Oaks, cutting and replacing them with tree farms of fast-growing pine. As an added threat, a fungus first identified in the 1940s as "oak wilt," has been killing many Live Oaks. The disease chokes the flow of water into the tree and gradually kills it from the inside out, spreading through root connections which link Live Oaks growing in close proximity. In Texas, where this disease has killed many of these oaks, the Texas Forest Service has been successful in injecting chemicals that kill the fungus and digging trenches that break connections between these oaks.

North America™s Forests: Page 5

Predators of the Southeastern forests declined or disappeared after European settlement as a result of overhunting and persecution, leaving an imbalance in which White-tailed Deer proliferated without Grey Wolves or Mountain Lions to limit their numbers. Both the latter predators remain absent in the eastern United States, although there are unsubstantiated sightings of Mountain Lions in Maine and elsewhere. A few Grey Wolves have entered northern Maine in recent years, and some conservation organizations have proposed reintroductions of the species into Adirondack Park in New York state or in northern New England. Red Wolves (*Canis rufus*) were totally eliminated by predator control programs and hybridization with the Coyote, reaching extinction in the wild by 1973 when the last wild members of the species were taken into captivity. This uniquely American species, which until recently was considered to have been native to only the southeastern United States, is now thought to have been distributed throughout eastern North America, based on DNA testing showing close relationships between the Red Wolf and wolves of eastern Canada, which have managed to persist to the present. The species was larger in northern states and preyed on deer and elk. Red Wolves survive today as a result of the 14 animals that formed the nucleus of the Fish and Wildlife Service's breeding colony. By 1993, more than 233 animals resided in 31 breeding facilities. Several successful releases have taken place in North Carolina and other eastern states, and about 100 Red Wolves survive from these releases.

West of the Mississippi River, pine forests in the mountainous regions of the Southwest were also heavily logged. A resident of these forests, the southern Mexican Spotted Owl (*Strix occidentalis lucida*), a race of the Spotted Owl, whose northern race inhabits old-growth forests of the Pacific Northwest, has become very rare. This owl, like its northern relative, requires undisturbed forests. The dominant tree of the southwestern forests is the Ponderosa Pine (*Pinus ponderosa*), which towers 180 feet tall and can live 500 years (Jonas 1993). Originally, these trees covered hundreds of thousands of acres in northern Arizona, New Mexico, and neighboring states; old-growth pine forests also stretched south into northern Mexico. Beautifully adapted to the dry, mountainous habitat, Ponderosa Pines often grow in large, pure stands. These forests have very little old growth left today, and Mexican Spotted Owls have disappeared from national forests in Arizona and New Mexico after the oldest trees were logged (Johnson 1995).

Many unusual and endemic species live in pine and juniper forests of the Kaibab Plateau on the north rim of the Grand Canyon. The Kaibab Squirrel (*Sciurus aberti kaibabensis*) is confined to this plateau. This beautiful squirrel is considered by most authorities to be a subspecies of Abert's or Tassel-eared Squirrel, but some zoologists treat it as a separate species. One of the most dramatic looking of all squirrels, the Kaibab is dark brown, with long tassels on its

ears, and a snow-white bushy tail. Its close relative, Abert's Squirrel, is dark, grizzled gray on its back and tail. Feeding mainly on conifer seeds, these squirrels suffer high mortality from hunting, road kills and natural predation by hawks (Whitaker 1980). Their habitat is restricted, and they are considered a rare and endemic animal. Ecologically, these squirrels are important in helping the Ponderosa Pine reproduce. They dig for truffles and absorb their spores, which enter their feces. When their feces are deposited near Ponderosa Pines, they spread the spores to the tree's roots, which grow into a fungus, triggering the tree's reproductive biology. In the spring of 2000, wildfires raged through their habitat, undoubtedly causing the squirrels high mortality.

North America™s Forests: Page 6

The problem of illegal logging is growing in the national forests, and a recent threat is the invasion of forests by drug growers. These people have entered roadless federal lands in the West and are seldom detected because of the remoteness and size of many of these tracts. In Los Padres National Forest, they destroyed large sections of forest in 1995 and 1996 to plant marijuana. After cutting trees, they cleared brush with herbicides which killed native plants, many of which are rare and protected. They also diverted scarce water from streams to irrigate their plants, which eliminated native plants dependent on that water. The drug growers put out poison to kill animals, such as deer, they feared might eat the marijuana. This situation presents a major threat to many species of wildlife, and especially to California Condors, who have been reintroduced to Los Padres National Forest and feed on carrion.

Ancient old-growth pine forests covered much of northern Mexico until a few decades ago. Large-scale logging has been felling these great trees, and what reserves have been set aside to protect the remaining patches of old growth are not carefully patrolled to guard against illegal logging. The Imperial Woodpecker (*Campephilus imperialis*), the world's largest woodpecker and one of the most beautiful, declined to extinction as a result of failure by both the Mexican government and private conservation organizations to preserve its habitat. Its decline began from hunting, and logging removed its feeding and nesting habitat during the first half of the 20th century. Several of these birds were sighted in the 1990s, but because no emergency action took place to preserve these birds in their last retreat, they disappeared. Each pair of Imperial Woodpeckers required a habitat of at least 25 square kilometers, and no area of old-growth forest this large now remains in the Sierra Madre Occidental (Lammertink 1996). Only a few fragments of old growth survive in this huge area, and even these are in imminent danger of being logged.

Mexican logging companies offered local people $2,000 per household for permission to log, and this may have been the deciding factor that led to the end of Mexico's old-growth forests. All that remains of the Imperial Woodpecker are museum specimens. A photograph of three specimens was recently published in the article, "The Lost Empire of the Imperial Woodpecker," in *World Birdwatch* (Lammertink 1996). Martjan Lammertink concluded after his field survey that if the Imperial Woodpecker still exists, no breeding habitat remains and, at most, one or two solitary birds may be left who must fly over huge areas to find food (Lammertink 1996).

A courageous defender of the Sierra Madre forests, Mexican activist Edwin Bustillos has risked his life to fight the drug lords who have taken over large areas in these forests for cultivation of drug plants. In several incidents, Bustillos had five ribs and his arm broken and spent a month in the hospital from injuries sustained when attacked by drug dealers. In 1996, he received the Goldman Environmental Award for his long-term efforts on behalf of these endangered forests.

A beautiful parrot also inhabits these same pine forests. The Thick-billed Parrot (*Rhynchopsitta pachyrhyncha*) once flew in large flocks in search of pine seeds, but its populations have declined from loss of old-growth forests and illegal shooting. The species is listed on the US Endangered Species Act, as endangered by the *2000 IUCN Red List Species*, and on CITES Appendix I, which bans all commercial trade. These large green parrots have red feathers on their foreheads, shoulders and thighs, and bare skin surrounding their yellow eyes. Their large hooked beaks aid them

in prying open pine cones. Native to Sierra Madre Occidental of eastern Mexico and, originally, pine forests in Arizona, Thick-billed Parrots live mainly above 2,000 meters. Heavy logging of old-growth pine forests has destroyed 99 percent of its habitat and removed the huge, old trees it needed for nesting (BI 2000, Collar *et al.* 1994). A field survey in 1994 in southern Chihuahua uncovered massive forest destruction and the penetration into its habitat of drug-growers, cattle and loggers (Collar *et al.* 1994). Populations have declined from flocks of thousands seen in the 1950s (Lammertink 1996) to about 5,000 in 1992 and only 1,000 to 4,000 in 1995 (BI 2000). Reintroductions into Arizona of captive-bred birds have not been successful because the birds did not know how to avoid predators or forage for pine seeds (BI 2000).

North America™s Forests: Page 7

Some highly threatened birds persist in unlogged portions of northern Mexico. The beautiful, iridescent Eared Quetzal (*Euptilotis neoxenus*), for example, was formerly common but is now confined to corridors of unlogged trees along rivers. These bits of forest are, at the present at least, inaccessible to loggers (Lammertink 1996). These quetzals require large trees for nesting and lay their eggs in cavities created when large tree snags fall off. Such trees, however, are rare and may disappear altogether in the future, since loggers cut them down as a general rule. It is considered Near-threatened, and close to qualifying as Vulnerable by BirdLife International (BI 2000). The Tufted Jay (*Cyanocorax dickeyi*) is another striking bird with a stiff, bristly, black fan crest on his head and forehead, unlike any other jay. This species is endemic to a limited area in the southern Sierra Madre Occidental, in mixed forested hillsides of oak, dense evergreen and deciduous forest near watercourses. Although a Near-threatened species (BI 2000), it has, nevertheless, no protected reserve.

Pine forests extend south to central Mexico, and up to 30 million Monarch Butterflies (*Danaus plexippus*) from the eastern United States and Canada migrate up to 2,000 miles to several groves of fir trees where they spend the winter clinging to branches in a semi-torpor. These butterflies constitute 90 percent of the species' population, and scientists believe that they have wintered here for more than 10,000 years (Aridjis and Brower 1996). Their migration is a biological mystery and unique among butterflies. Until the fir groves, where they festoon the tall trees like dazzling orange and black ornaments, were discovered, no one knew where they spent the winter. Even now, their method of locating this particular forest remains unknown. The butterflies that fly south are third generation ancestors of the ones who wintered in Mexico the previous year. On warm days, they wake from their torpor and venture out to take nectar, and in the spring, they head north, breeding along the way (Pyle 1981).

Entirely dependent on these groves of firs, which shelter them from the freezing rains that fall in this high-altitude forest, the Monarchs are threatened by logging. In spite of a 1986 order by Mexican President Miguel de la Madrid to protect the five wintering populations, all located in close proximity, the surrounding trees were not given protection. Local people cut trees for fuel and building materials, and cattle trample fir seedlings (Aridjis and Brower 1996). They have logged up to the very limits of the groves, and without the protection of bordering trees, the butterflies are more vulnerable to cold spells, dying in unprecedented numbers. Snowstorms and cold weather killed millions of these fragile butterflies in 1991 and 1995.

Ann Swengel and Dr. Paul Opler, who coordinate nationwide butterfly counts for the Xerces Society, a butterfly conservation organization, began noticing declines in Monarch populations in the United States, and scientists have seen many declines in areas where they were previously abundant.
Conservation of the precious fir trees upon which the species winters is a key to saving this species. Dr. Lincoln P. Brower, professor of zoology at the University of Florida and a leading authority on the species, and Homero Aridjis, President of the Group of 100, a Mexican environmental organization, made a public appeal for the protection of the Monarchs' winter habitat in an Op-ed article for *The New York Times* in January 1996 (Aridjis and Brower 1996). They maintained that all three countries--the United States, Canada and Mexico--should cooperate to purchase the

forests in keeping with the North American Free Trade Agreement (NAFTA) (Aridjis and Brower 1996). A comparison of forest cover in the Monarch groves based on aerial photographs taken in 2000 and in the 1950s, shows great losses in these protected trees from illegal logging over the past 40 years. The situation has reached crisis proportions, according to scientists. In response, the Mexican government has promised to protect the remaining groves and enlarge the reserve. Local people have expressed opposition, however, as they have traditionally logged the forests and have not profited from the tourists who come to see the butterflies. If this situation is not resolved in favor of the butterflies, these beautiful jewels that brighten fields and gardens may disappear from their breeding grounds in the United States.

North America™s Forests: Page 8

The ancient forests of the West Coast once stretched from northern California nearly unbroken through coastal Canada to southeastern Alaska, covering 70,000 square miles. Logging by Europeans began in the 19th century, and as the forests fell, a few voices were raised in protest. Even Horace Greeley, a promoter of "progress" and settlement of the West, exhorted Americans in 1851 to "spare, preserve and cherish some portion of your primitive forest" (Peck 1990). It was the fiery Scottish wilderness advocate John Muir who finally succeeded in convincing the US government to protect some of these ancient forests. He settled near California's Yosemite wilderness in the 1860s and began passionately denouncing the destroyers of nature, from loggers to livestock operators. Muir pointed to the political influences that allowed destruction to occur. During the 19th century, livestock swarmed in great numbers over wilderness areas. Muir described sheep as "hoofed locusts" and, in trying to get them removed from Yosemite, said, "As sheep advance, flowers, vegetation, grass, soil, plenty, and poetry vanish" (Peck 1990). When he saw the ancient Sequoias being cut, Muir was outraged:

> *Through all the wonderful, eventful centuries since Christ's time--and long before that--God has cared for these trees, saved them from drought, disease, avalanches, and a thousand straining, leveling tempests and floods; but He cannot save them from fools--only Uncle Sam can do that.*

Muir proved to be an adept politician, making friends with influential magazine editors and railroad magnates; President Theodore Roosevelt camped out with Muir in Yosemite in 1903 (Peck 1990). Through Muir™s influence, Yosemite became a national park in 1906, followed by Sequoia, Mt. Rainier, Crater Lake, Glacier and Mesa Verde National Parks (Peck 1990). In 1892, Muir established The Sierra Club conservation organization. If not for Muir's courageous and effective work on behalf of these forests, it is likely that very little old-growth forest land would remain today.

North America™s Forests: Page 9

These centuries-old trees, often covered in epiphytes, plants that get nutrients from moisture and air, and lichens, including one species that drapes over branches in delicate, lacy strands, exude a lushness reminiscent of tropical rainforests. More than 140 inches of rain per year produce luxuriant tree growth and a verdant understory of ferns and hardwoods. Bright green mosses and masses of ferns carpet the ground, and a great variety of mushrooms and lichens flourish in the damp environment. In the spring, the forest floor is carpeted with beautiful white trilliums and other flowers that contrast with the deep greens of the forest. Mist and fog enshroud the giant trees, which intercept the moisture from the atmosphere, supplying the trees and the entire environment with water throughout the year (Ellis and Kane 1991).* The southern portion of these forests is dominated by Coast Redwoods, with the record tree

reaching more than 365 feet in height. Its upper branches are more than 50 feet in length. They are among the most ancient as well, some over 2,000 years old (Middleton 1992). The great Redwoods of northern California gradually melt into a forest of mixed pines, fir, cedars and hemlock.

---

*Along with the fine book by D. Middleton (1992), cited frequently here, *North America's Rain Forest. The Endangered Paradise*, by Gerry Ellis and Karen Kane (NorthWord Press, 1991), is an excellent resource, beautifully illustrated with the trees, plants and wildlife of these forests, and shows the devastating clearcuts contrasted with living forests. *Western Forests*, a book in the *National Audubon Society Nature Guides* series illustrates most wildlife and plant species, as well as discussing forest ecosystems.

Douglas Firs (*Pseudotsuga menziesii*) grow to ages of 700 to 1,000 years old in climax growth, veterans of hundreds of periodic fires; they may reach 325 feet in height (Jonas 1993). A tree 250 years old is considered young in an old-growth forest, while middle age is 400•500 years, and old age is more than 700 years (Middleton 1992). Recent research conducted in these forests indicates that rich diversity does not develop until forests are at least 200 years old (Moffet 1997).

Ancient Red Cedars (*Thuja plicata*) grew in abundance in these old-growth forests and were among the first to be cut by loggers. Old specimens are very rare at present, and activists recently saved one area with many exceptionally old and massive cedars from being logged. This forest, in Upper Priest Lake, northern Idaho, has cedars 1,500 years old. The largest trees are 20 stories tall, with trunks 10 feet in diameter. The ground beneath is carpeted with ferns, including the largest population of Braun's Holly Fern in the West. Old-growth cottonwoods also grow here. Endangered Woodland Caribou (*Rangifer tarandus caribou*), threatened Grizzly Bears, Fishers and Wolverines, rare Cutthroat Trout, endemic salamanders, and Harlequin Ducks are resident in the forest and wetlands. This forest covers 520 acres, worth at least $9 million to the lumber company that owns it. The US Forest Service was unable to obtain federal money to purchase it in 1996, and not until October 1997 was the grove preserved through a trade of land worth $8.7 million between the owner and the Forest Service.

More than 1,000 plant and animal species depend on old-growth forests (Egan 1994a). Invertebrate animals of the soil are highly diverse: an area 1 meter by 1 meter shelters 200,000 mites of 75 species (Middleton 1992). Fallen logs may take 500 years to rot, and this decaying wood is fed upon by the most diverse fungal network in the world (Middleton 1992). The hollow logs are used as nest holes by Red•backed Voles and other small species. The young of these voles feed on truffles that grow in the rich soil. At least 300 insect species have been described from the rotting•log community of organisms (Middleton 1992). A host of other insect species of the forest canopy have yet to be described.

Many vertebrates depend on the old-growth forests of the Pacific Northwest for their survival, and some of these live nowhere else. The Sitka Black•tailed Deer and Roosevelt Elk and a unique bluish strain of American Black Bear from southeastern Alaska are among these. Bats of several species--Long•eared, Hoary and Silver•haired--are major pollinators and insect-predators in forests of the Pacific Northwest. Roosting in the hollow trunks of ancient trees, these bats have declined in many areas because of logging. A great diversity of amphibians lives in the moist environments of these temperate rainforests. Among them are the Slender, Olympic, Pacific Giant and Del Norte Salamanders, Pacific Tree Frog and Tailed Frog.

The Northern Spotted Owl (*Strix occidentalis caurina*) may be the most famous resident of these forests. The struggle over old-growth forests became a bitter controversy focused on the fate of this bird, which was declared a Threatened species under the Endangered Species Act in June 1990. This owl is native to old-growth forests in northern California, Oregon and Washington, and each pair of owls requires up to 3,200 acres as territory, making it a naturally rare species (Middleton 1992). Northern Spotted Owls nest in natural tree cavities or holes created when great branches from living trees fall to the ground. The canopy above shields owlet chicks from the view of large birds of prey that fly above. These owls feed on the Red Voles, Dusky-footed Wood Rats and Northern Flying Squirrels that are abundant in old-growth forests. When these forests are cut and young second-growth forest takes over, Spotted Owls disappear (Seideman 1997). In spite of the protection of portions of their habitat, these owls have not recovered their numbers since listing on the US Endangered Species Act, and they continue to decline. The US Forest Service released extensive data compiled on the populations of these birds between 1985 and 1993, which showed a drop of 4.5 percent a year, with an accelerating rate of decline (Seideman 1997). Another threat to these owls is the recent invasion of their habitat by the larger and more adaptable Barred Owl, which is displacing the Spotted Owl in some areas. Even more ominously, interbreeding has taken place between the two species (Seideman 1997).

When the Northern Spotted Owl was listed as Threatened on the Endangered Species Act and large sections of its habitat protected, it became a focal point, polarizing pro-logging and anti-logging advocates. Owl haters urged others to kill these birds, who were blamed for ending the logging industry. Their cars sported bumper stickers such as "Kill an Owl, Save a Job." Such venom totally obscured the fact that the forests were being overcut and that logging jobs were destined to be eliminated anyway, as the last old-growth forests disappeared under the saw. A state in the heart of this owl's range, Oregon, found that reducing logging ended up helping its economy; an influx of technology businesses provided better salaries than those paid for logging jobs (Egan 1994b, Verhovek 2000). The Governor of the state supported the logging restrictions as helping to maintain the overall quality of life in the state, preventing floods and attracting tourists, which are supplying another large segment of the state's revenues.

Habitat Conservation Plans (HCPs), authorized under the Endangered Species Act may be contributing to the Spotted Owl's decline. Under these plans, agreements are negotiated with landowners which include a provision known as "no surprises." This gives landowners assurances that once the regulations on their properties have been agreed to, they are exempt from further restrictions. Should new populations of an endangered species be discovered on their property, they have no obligation to protect them. Habitats of Spotted Owls in old-growth forests in Washington State have been bartered away in HCPs that, in the view of Eric Hanson, biologist for the Yakima Indian Nation in Washington state, will end in reducing the state's populations of this species by 35 percent, from 880 breeding pairs to 550 (Seideman 1997). These HCPs allow habitat destruction and other actions that can result in deaths of Spotted Owls. The Forest Service collected population data on these owls for the years between 1994 and 1996 but failed to issue the results (Seideman 1997).

The Clinton Administration sponsored a series of local meetings to resolve differences. These resulted in plans to federally fund job•training for loggers who might become unemployed by logging cutbacks. Even so, logging interests sued the federal government to nullify the stricter quotas, and the California Forest Products Association unsuccessfully petitioned the Fish and Wildlife Service in October 1993 to remove the Northern Spotted Owl from the Endangered Species Act, claiming the species was mistakenly placed on the list. This case was argued all the way to the US Supreme Court which, in the summer of 1995, made a historic decision upholding the Endangered Species Act and its protection of endangered species' habitats.

The Timber Salvage Act of 1995 made a mockery of previous attempts to mediate between loggers and conservationists, allowing a year and a half of totally unregulated logging in the habitat of the Northern Spotted Owl and other threatened species. This law had the stated purpose of taking only fallen and dead trees, but in practice, tens of thousands of old-growth, healthy trees were logged. In its quarterly report on the Timber Salvage Act, issued February 29, 1996, the Forest Service reported that an astounding 2.1 *billion* board feet had been cut since passage of the law. The Forest Service's stated objective was to sell 4.5 billion board feet by the end of 1996. By August 1996, some 2.9 billion board feet, the equivalent of 580,000 logging trucks full, had been cut under the Timber Salvage Act (Bass 1996). National forest lands to be logged totaled at least 50 million acres. Major habitat areas for many endangered and threatened species were among these lands. Fortunately, this law expired at the end of 1996.

North America™s Forests: Page 11

The Marbled Murrelet (*Brachyramphus marmoratus*) is also dependent on old-growth forests and has been seriously impacted by the logging that, since the 19th century, has destroyed 95 percent of its old-growth habitat in the US Pacific Northwest. This small, black-and-white seabird is a Threatened species on the US Endangered Species Act and is listed as Vulnerable by BirdLife International. Unlike any other seabird, this Murrelet nests high in the branches of 200- and 300•foot trees. Sometimes seen in offshore waters of the Pacific Northwest and Alaska, their nests are rarely found. In fact, only about 30 nests have ever been located in the Pacific Northwest--all high in the crowns of old-growth forest trees.

A researcher who was studying the ecology of old-growth tree canopies made an exciting discovery of a Marbled Murrelet nest. He photographed the adult on its nest, made of lichens, with a small fish in its mouth for its chick for *National Geographic* magazine (Moffett 1997). Despite surveys up and down the Pacific coast, this was one of the few nests found in 1996, and plans for logging near the nest site were stopped (Moffett 1997). A prime area for Marbled Murrelets is the Olympic National Forest in Washington state where large tracts were sold for clearcutting in 1996 under the Timber Salvage Act. In Umpqua National Forest, Oregon, over the weekend of March 23-24, 1996, several thousand-year-old Douglas Firs were cut; their age was determined by coring and ring counts. The Umpqua River has endangered populations of Coho Salmon (*Oncorhynchus kisutch*) and sea-run Cutthroat Trout, and logging may eliminate them. The Marbled Murrelet's nesting trees are being logged throughout the species' range. A few areas have been protected in Alaska, but they are declining rapidly, at a rate of 31 to 48 percent per decade, with little hope that sizeable areas of old-growth forest will be protected (BI 2000).

North America™s Forests: Page 12

The Pacific Yew (*Taxus brevifolia*)**,** found only in these forests of the Pacific Northwest, is considered a "trash species" by foresters who clear it away to make room for more valuable species. This plant grows in the undergrowth of old-growth forests from California to southeastern Alaska (Jonas 1993). It has recently been shown to contain a chemical substance, Taxol, that has proven effective in treating ovarian and other cancers (Middleton 1992). A rush to cut these trees and strip their bark to obtain Taxol threatened them with extinction until the chemical was successfully produced synthetically. Taxol will be a major new tool in treating cancers and will result in sales totaling many millions of dollars for the pharmaceutical industry.

These discoveries have taken place as the fate of the last stands of old-growth forests is hanging in the balance. Ninety-five percent of these forests in the United States, and more than 60 percent in Canada, have already been cut. Opposition to clearcutting is increasing, however. Lewis H. Nash is a member of an organization known as the "Environmental Air Force," which chronicles illegal cutting of Coastal Redwoods. Members pilot small planes over clearcuts and document the damage with photographs. Nash's work enabled an environmental lawyer to obtain an injunction in 1995 stopping logging the same day (Goldberg 1996a). In 1996, flying over the devastated forests of northern California, Nash remarked: "When I first started flying here 10 or 15 years ago, this was all the same, all primeval forest. All this has been pretty well hacked over" (Goldberg 1996a).

North America™s Forests: Page 13

One of the most heated debates over these forests involves the last privately-owned large tracts of redwoods. Commercial exploitation began in 1900 when Frederick Weyerhauser purchased 900,000 acres for $6.00 per acre, a ludicrously low price even in those days (Dietrich 1992). Almost all privately owned old-growth forests became depleted by the 1960s. One exception was a large tract of old-growth Coastal Redwoods and Douglas Firs in California's Humboldt County, in the northern part of the state, owned by the Pacific Lumber Company. This family-operated company had left most of its 200,000 acres intact and had been particularly protective of the most ancient trees in the 55,000-acre Headwaters Forest. In 1986, however, Houston financier Charles Hurwitz took over Pacific Lumber, using junk bonds. Hurwitz's United Savings Association of Texas failed, costing US taxpayers $1.6 billion, part of the savings-and-loan collapse (Brown and Stark 1995).

To pay his debts, Hurwitz began clearcutting the old-growth Coast Redwood and Douglas Firs. By 1995, he had cut 40,000 acres of the Headwaters Forest and nearby old-growth trees, leaving only 5,500 acres of virgin Coastal Redwood and 5,000 acres of virgin Douglas Fir (Brown and Stark 1995). This is one of the most extreme cases of abuse of private land in the history of this country. Two-thousand-year-old trees were turned into picnic tables, lawn furniture and patio decks. Logging was delayed by several lawsuits, and to protect nesting sites of Marbled Murrelets, the California Forestry Department recommended in 1995 that Hurwitz be refused permission to build a logging road into the 4,400-acre grove of the most ancient trees (Brown and Stark 1995). Two California Congressmen, George Brown and Pete Stark, proposed that the federal government engage in a debt-for-nature swap, in which the Federal Deposit Insurance Corporation, which has sued Hurwitz for his role in the failure of his bank, would, through a special arrangement set up by the President, exchange the redwoods for his debt (Brown and Stark 1995). Hurwitz rejected the idea, calling it a "so-called fantasy of debt for nature" and threatened lawsuits against the government for excessively limiting the use of his land (Goldberg 1996b).

The value of the Headwaters Grove is estimated at between $100 and $500 million, with many giant trees several thousand years old and 12 feet in diameter; individual trees are worth more than $100,000 each (Goldberg 1996b). The ecological and esthetic values, however, are inestimable. Hurwitz called environmentalists who blocked sale of these trees "extremists" and insisted that he expected to be paid "fair market value for these trees" (Goldberg 1996b). Acrimonious negotiations for the grove continued in 1996 and 1997, with environmentalists demonstrating against an agreement negotiated that would protect only 7,500 acres, instead of the 100,000 they wanted saved. Early in 1997, Hurwitz demanded that he be paid in cash rather than land that was offered by the state of California, land which many environmentalists thought should be protected (Golden 1997). The deal arranged with Hurwitz allowed extensive cutting of the remaining 100,000 acres of old-growth forest without regard for endangered species' habitat.

Members of Earth First! began protests, entering the land and attempting to block logging trucks, and a young conservationist, Julia Hill, who became known as Julia "Butterfly" Hill, climbed up near the top of an ancient redwood tree she called Luna and refused to come down. She stayed up in this tree for two entire years, until the

spring of 2000, while trees were cut in the surrounding area, until a sum of $50,000 was paid to the Hurwitz lumber company for Luna and 2.9 acres of surrounding forest, which were donated to Humboldt State University. She came down from the tree at last, a symbol of the extreme devotion and zeal that have been expended in attempts to preserve these ancient trees. The forest will continue to be cut, however, which will be a permanent loss to the environment and a stain on state and federal governments for not taking a stronger role to preserve the entire forest.

In a sad footnote, in November 2000, a vandal sawed a cut 32 inches deep and stretching 19 feet, or half the circumference, across the base of Julia Hill's tree, Luna. It appeared to have been done by a professional logger, judging from the precision of the cut. A team of specialists--an arborist, an engineer and a forester--was convened to try to save the tree (Quinn 2000). Metal braces were drilled into the tree spanning the cut. All efforts are being made to save this ancient tree from falling in winter storms. Visitors are being asked to stay away because the soil and hillside are being deeply eroded. It is a symbol of the senseless destruction of ancient forests.

Only 4 percent of the once vast and magnificent Coastal Redwood forests remain. These trees covered at least 2 million acres prior to logging, but only about 84,000 acres of virgin redwoods have been protected in state parks and the Redwood National Park; another 66,000 acres of logged and second-growth redwoods have been set aside (DiSilvestro 1990).

North America™s Forests: Page 14

Another major conservation struggle involves the magnificent Tongass National Forest in southeastern Alaska. This forest, covering 17 million acres, is the country's largest national forest--a mosaic of glaciers, mountains, fjords and islands covered by ancient trees. It makes up half of one of the largest remaining temperate rainforests on Earth, which extends 1,000 miles in an arc along the southeastern coast. At least 6 million acres of Tongass are--or were--old-growth rainforest (DiSilvestro 1990). Sitka Spruce, Western Hemlock, and Red and Yellow Cedar many hundreds of years old dominate the forest.

The Tongass is home to a number of rare animals. Approximately 10,000 Bald Eagles nest in the tops of trees (DiSilvestro 1990). More Grizzly Bears live in the Tongass than in the entire lower 48 states, denning in the holes of towering old trees. A race of the Grey Wolf known as the Alexander Archipelago Wolf (*Canis lupus ligoni*) inhabits the Tongass; numbering only about 1,000 animals, its population is in decline (Williams 1995). Logging threatens these wolves and rare wildlife, including the Queen Charlotte Goshawk (*Accipiter gentilis laingi*) and the Marbled Murrelet (FWS 1994). The Wolf and the Goshawk are candidates for listing on the Endangered Species Act. These and other species of this beautiful area cannot survive in clearcuts and logged-over forests. The American Rivers organization has listed Tongass's Thorne River as one of the 10 most endangered in the United States, having become silted and its banks eroded from logging (Williams 1995).

The cutting of the Tongass's giant trees began in 1833, and by 1926, six sawmills were operating; by 1930, most of the lowland and easily accessible timber and giant old trees had been cut (DiSilvestro 1990). In the 1950s the Forest Service allowed cutting of ancient trees in rugged, steep areas and opened the way for a wood pulp industry to be fed by clearcutting. The Service offered two 50-year contracts at bargain-basement prices, instead of the usual three- to five-year contracts (DiSilvestro 1990). It signed an exclusive contract with the Ketchikan Pulp Corporation and, unlike other national forests where contracts are open to bidding, this contract was awarded during secret meetings from which the public and conservation organizations were excluded. From this time onward, 200 million board feet or more of old-growth forest were logged annually from the Tongass National Forest (DiSilvestro 1990).

The Alaska National Interest Lands Conservation Act of 1980 divided most of the state among federal, state and native interests. Within the law was a provision requiring maximum logging levels in the Tongass National Forest,

with the quota of 4.5 *billion* board feet to be logged every decade, with annual subsidies of $40 million from the federal government for logging roads and other aid to timber companies (DiSilvestro 1990). In the 15 years that followed, billions of board feet were logged in this magnificent rainforest, at a financial loss to the taxpayer.

National organizations, including the Taxpayers for Common Sense based in Washington, DC, criticized the clearcutting of this and other national forests which provide no income to the federal treasury and are entirely subsidized by public funds (Schmitz 1996). A 1995 General Accounting Office report found that Tongass's Timber Program was the biggest money loser in the National Forest system, with a negative net return of $102 million to the US Treasury between 1990 and 1994 (Schmitz 1996). More recently, a study by the John Muir Project found that in the years 1997 through 1999, the National Forest Service Timber Sale Program operated at a net loss to taxpayers of more than $3.3 billion (Hanson 2000). This research found that less than 3 percent of the country's total annual wood consumption, and less than 4 percent of the sawtimber used for construction, comes from national forests (Hanson 2000). A nationwide poll in 1998 found that 69 percent of Americans oppose allowing timber companies to log the national forests (Hanson 2000).

The fight to save these forests is being waged in the courts, with public criticism and legal actions brought by conservation organizations. A 1987 book, *The Tongass. Alaska's Vanishing Rainforest*, dramatically illustrated the great beauty of this forest and the ravaging effects of logging, including clearcuts on steep, erodable slopes. This publication served as a catalyst for the passage of the Tongass Timber Reform Act of 1990 that stopped the $40 million subsidy to loggers and set aside 1 million acres to be closed to logging (Ketchum and Ketchum 1994). It did not stop or appreciably slow logging elsewhere in Tongass, however, and called for 150 million board feet a year to be cut. The book was updated in 1994 and described the continuing bitter battle being waged to protect this vast area (Ketchum and Ketchum 1994). In 1997, the heavily polluting Ketchikan pulp mill was finally closed. The Forest Service's 10-year plan for Tongass National Forest, finalized in May 1997, opened up 670,000 acres to logging, authorizing the cutting of 220 million to 267 million board feet of timber annually (this is enough to load 50,000 logging trucks or build more than 20,000 houses a year) (Cushman 1997). The Forest Service stated that the portion of land that would be set aside would make it unnecessary to list the Alexander Archipelago Wolf and the Queen Charlotte Goshawk on the Endangered Species Act. Conservation organizations criticized the plan and the failure to support listing of these species. The Alaskan Congressional delegation expressed its disappointment that more timber had not been open to logging (Cushman 1997). The 100- to 125-year cycle of cutting by the Forest Service assured that old-growth forests and their complex and diverse ecosystems will disappear.

The Forest Service held nationwide hearings during the summer of 2000 regarding a proposal that some 50 million acres of national forests be protected from road-building. This proposal specifically exempted the Tongass National Forest. The Forest Service plan would allow massive road construction and logging in the Tongass's remaining pristine forests. In a surprise decision prior to leaving office, President Bill Clinton authorized the inclusion of 9.3 million acres of the Tongass National Forest in the final plan; although delayed until 2004, this was an extremely important event, condemned by the Alaskan Congressional delegation (Hughes 2000). The plan calls for $13 to $20 million to be spent in Alaska creating jobs lost in the timber industry. The plan had drawn more than 1.5 million letters and e-mail messages, the overwhelming majority in favor of banning road-building. In spite of opposition to the designation of wilderness in this vast national forest, conservationists succeeded in obtaining a moratorium on logging of 9 million acres, pending the results of studies on whether they qualify for permanent protection under the Wilderness Act (Earthjustice Legal Defense Fund 2001).

Another huge national forest in Alaska, the Chugach, located at the headwaters of the salmon-rich Kenai River, has received far less attention than the Tongass, in spite of being the second largest of all US National Forests. In 1996, the Forest Service cut nearly 16 million board feet in this old-growth forest.

North America™s Forests: Page 15

The future of forests in the United States is at a dramatic turning point. During the summer of 2000, devastating wildfires broke out in the Western United States, primarily in national forests. More than 6.7 million acres burned, along with hundreds of private homes (Janofsky 2000). Within months, the Clinton Administration proposed a major new approach to the national forests, dictating extensive thinning of millions of trees and the removal of brush to prevent future wildfires (Jehl 2000). This plan was based on the theory that the fires were caused by too little logging, resulting in dense forests with underbrush that caught fire and spread uncontrollably. Pro-logging Members of Congress, western Governors and logging companies immediately endorsed the plan (Janofsky 2000, Jehl 2000). Some Governors wanted even more money for the program (Janofsky 2000). The proposed thinning would cost taxpayers $12 billion over 15 years (Jehl 2000). This was challenged by a report issued by the Congressional Research Service soon after the fires were extinguished, which concluded that there was no connection between the level of logging and wildfires (Egan 2000). Other critics included the Forest Guardians of New Mexico, who contended that the fires were the result of decades of industrial logging in which the largest trees were taken; it suggested that instead of thinning, logging subsidies be directed at badly needed projects to control soil erosion, protect water quality and enhance wildlife habitat (Hitt 2000). Environmental groups opposed the logging portion of the proposal as a tool for fire prevention (Janofsky 2000).

As the ideal example of how national forests should be managed, the Clinton Administration proposal pointed to an Arizona Ponderosa forest that had been thinned and did not burn. Ponderosa forests are not typical, however, of all forests, tending to be open with little understory. Other types of forests, such as old-growth temperate rainforests, are not open, and drastic thinning of their undergrowth would result in more, not fewer fires. Moreover, nutrients would be lost, erosion encouraged and wildlife habitat destroyed by such thinning. Dr. Paul R. Epstein (2000), a scientist with Harvard's Medical School Center for Health and Global Environment, concluded that the wildfires were precipitated by global warming, which caused the drought that dried out these forests, making them vulnerable to wildfires. Epstein proposed that the most important reaction to these fires would be to control global warming and restabilize the climate system.

An extremely important policy statement was made by Forest Service chief Mike Dombeck in January 2001, when he ordered the protection of the largest and oldest trees on Forest Service land (Jehl 2001a). In explaining his decision, Dombeck said, "In the future, we will celebrate the fact that national forests serve as a reservoir for our last remaining old-growth forests and their associated ecological and social values" (Jehl 2001a). Only about 3 percent of national forests is old-growth forest, yet these forests are among the most important refuges for rare and endangered species. Dombeck's statement and the philosophy behind it are reminiscent of John Muir or Henry David Thoreau, an extraordinary reversal from the utilitarian view of forests as tree farms that has held sway since the beginning of the Forest Service. In fact, it had been Forest Service policy that the oldest and biggest trees be cut first (Jehl 2001b). The new Republican Administration and the Senate panel overseeing the Forest Service announced that hearings would be held on the new policy, which runs counter to the one backed by President George W. Bush (Jehl 2001b). Dombeck was asked to leave his job soon after President Bush took office. Logging in national forests has declined from 1989, when 12 billion board feet were cut, to about 3 billion board feet in 2000 (Jehl 2001b). Loggers are expected to lobby hard to cut these last old-growth trees because of the huge amount of dense wood they contain.

Although Canada's forests are far more extensive, with greater amounts of old-growth, they are being logged at an extremely rapid pace. The 1980s and early 1990s witnessed the clearcutting of millions of acres of Canadian forests, from boreal coniferous woodlands to deciduous and mixed forests in the east to the ancient temperate rainforests of British Columbia's coast. The logging that has removed vast tracts of Canada's forests is a major factor in the decline of the continent's colorful and ecologically important wood warblers and other songbirds. British Columbia's mountainous terrain is not conducive to clearcutting because of erosion, but this has been the method used to raze hundreds of thousands of acres. Wilderness valleys with forested slopes have been denuded and the soil and debris washed into salmon streams and rivers, clogging and destroying them. The Bowron Valley in central British Columbia was turned into a moonscape in 1992 when 1,600 square kilometers were clearcut; efforts to replant this huge area have not been successful (Devall 1993). Habitat of the Grizzly Bear in British Columbia's high-altitude forests has been devastated along with its forest wilderness home elsewhere in Canada (Devall 1993).

Research on Sitka Spruce (*Picea sutchensis*) canopies on Vancouver Island, along the British Columbia coast, has produced 300 new species of insects, and scientists state that this environment will reveal hundreds more. According to one biologist, "We have a virtually unexplored biological frontier in our own backyard" (Moffett 1997). A highly unusual Sitka Spruce, called "Golden Spruce" (*P.s. aurea*), grows on Graham Island in the Queen Charlotte Islands to the north of Vancouver Island (DePalma 1997). This extremely rare color phase had only one known adult specimen in the wild, the result of a genetic quirk that causes chlorophyll to break down, giving the needles a golden yellow hue when exposed to sunlight (Comeau 1997). Standing 160 feet tall, and 300 years old, the Golden Spruce was known to the native Haida tribe, who revered it, as "kiidk'yaas," or ancient tree (DePalma 1997). (A color photograph of this dazzling tree was published in the *Canadian Geographic* magazine in May/June 1997.) The Haida believed that the tree would be admired until their last generation and that it held the spirit of a young Haida boy who survived, along with his grandfather, the demise of their village, which was destroyed by an angry Creator (Comeau 1997). As they walked away, the elder warned the boy not to look back, but the boy disobeyed and was turned into a tree that came to be venerated as the embodiment of the tribe's spirit (Comeau 1997).

In January 1997, a mentally unbalanced man swam across the sound to the island and cut the tree down. This caused shock and dismay among the Haida, who felt they had failed in protecting this most important part of their traditions and believed that its death predicted their own demise (Comeau 1997). Fortunately, a few cuttings had been taken from this tree in 1986 by a horticulturist, who brought them to the Botanical Garden at the University of British Columbia and propagated them. Two 5-feet-tall, scrawny trees were produced, and they are all that remain of the magnificent Golden Spruce (DePalma 1997). The Haida took about 100 cuttings from the top of the felled tree and asked the scientific community to help save it. They accepted one of the two propagated specimens from the university (Comeau 1997).

Vancouver Island, just north of Washington state, is one of the most magnificent scenic areas in the world. The struggle to stop clearcutting of its ancient forests has become pitched. One highly endangered species resident on this island is the endemic Vancouver Island Marmot (*Marmota vancouverensis*), one of 11 species of marmots in the world, all native to the Northern Hemisphere (Nowak 1999). Much of the Vancouver Island Marmot's habitat has been destroyed by development for ski slopes and logging, which apparently removed important migration corridors between colonies. This exposed the marmots to predation and prevented the establishment of new colonies (Thornback and Jenkins 1982). Colony sites became isolated, and vacant areas were not reoccupied, causing inbreeding (Thornback and Jenkins 1982). The Federation of British Columbian Naturalists formed a Vancouver Island Marmot Preservation Committee to conduct surveys and publicize the need to protect the Vancouver Island Marmot (Thornback and Jenkins 1982), yet in spite of long-term studies, logging continued. Surveys in 1979 and 1980 found only 11 colonies with 50 to 100 individuals (Thornback and Jenkins 1982). A 1984 survey found 231 animals, and some captive breeding has been successful (Nowak 1999).

The *2000 IUCN Red List Species* lists the Vancouver Island Marmot as Endangered (Hilton-Taylor 2000). It is also listed as Endangered by the US Endangered Species Act, and as Critically Endangered by the British Columbia

Conservation Data Center of the province's Ministry of Environment. The Vancouver Island Marmot has been ranked in the most endangered category by the Center, as having few remaining individuals, and since this remnant population is continuing to decline, its extinction has become likely. By 1995, 11 colonies had declined to only eight, and the 1984 population of 231 animals had declined to only 150 animals. Biologist Andrew Bryant, chief scientist of the Marmot Recovery Foundation, conducted his Master's Thesis on the species and has continued to monitor it, according to the British Columbia Conservation Data Center. The population declined to a critical level in the late 1990s, and there are plans to take more animals into captivity to attempt captive breeding for future releases into protected habitat. In 1999, researchers found only 62 marmots left in the wild (NGS 2000). They took 27 into captivity for breeding programs. Bryant stated that the major threat to these animals was clearcutting, which greatly reduced their food supply; they are also vulnerable to predators (NGS 2000). The long-term plan is to reestablish these marmots in three separate sites and build populations up to 400-600 animals (NGS 200).

Vancouver Island's panoramic beauty is displayed in the 1994 film, fiRainforest of the Pacific Northwestfl (see Video, North America section). Aerial views of undisturbed forest and the majestic Clayoquot Sound contrast with large stretches of clearcut forest. Trees up to 270 feet tall and more than 1,000 years old grow on Vancouver Island, but less than one-third of the old-growth forest remains; at the making of the film only 4.5 percent of the forest was protected. The British Columbian government appointed a panel to recommend revisions to the logging plan for Clayoquot Sound and, to the delight of conservationists, issued recommendations in 1995 banning clearcutting and proposing strong streamside protections and so many safeguards that very little logging will be allowed (SCLDF 1995). In 1995, the British Columbian government announced that it would adopt all the recommendations made by the blue ribbon Science Panel. All commercial logging in pristine areas has been deferred until biological inventories are completed, according to the Rainforest Action Network (RAN). This does not mean a permanent end to logging in this beautiful Sound, and conservationists will need to continue the fight. The native-run Clayoquot Sound First Nations leaders are apprehensive that they may be pressured into joint logging ventures with timber companies, and they issued an unequivocal declaration calling for an end to commercial logging in all old-growth forests (Rosmarin 1995).

Forty miles north of Vancouver, old-growth coastal forests are being destroyed by commercial loggers to make way for urban and suburban growth. The Squamish River cuts through these forests and provides one of the great wildlife spectacles in North America. When salmon disappeared from almost every river of the Northwest and pollution killed off fish in many northern states, Bald Eagles migrated north to the Squamish River (Nickerson 1995). Almost 4,000 Bald Eagles from as far away as Wisconsin and the Rocky Mountains winter along the river, feeding on spawning salmon (Nickerson 1995). "Americans are strange," a Squamish Native American remarked, "They revere the eagle as the pride of their country, then ruin his home and make him so hungry he flees to Canada" (Nickerson 1995). Yet this sanctuary is now threatened. A 600-acre industrial park at the heart of the winter roosting grounds is planned by local officials, and logging has removed much of the forest already (Nickerson 1995). The Nature Conservancy began acquiring parcels of land for the establishment of Canada's first sanctuary for Bald Eagles (Nickerson 1995). The goal of conservationists is a preserve of 2,700 acres to protect this important feeding area (Nickerson 1995).

North America™s Forests: Page 17

The white bears of Canada live along 1,000 square miles of rainforest on the British Columbian coast and off islands. Their main breeding island, Princess Royal Island, harbors the largest number of these bears, which are a rare color phase of the Black Bear. The percentage is even lower on other islands (Russell 1994). The world population of these bears is estimated at only about 400 (NRDC 2001). A delightful book, *Spirit Bear. Encounters with the White Bear of the Western Rainforest*, by naturalist Charles Russell, recounted his visits to the island with two filmmakers, Jeff and Sue Turner, who were working on "Island of the Ghost Bear." Russell, who has been studying and helping

bears of many species throughout his life, wanted to write a book about the spirit bear to obtain sanctuary status for this island and its bears. The white bears on the island have been protected for thousands of years, first by the Native Americans, and now by the British Columbian government. They are so tame that Russell was amazed, having never encountered such friendly bears of any species. A young white bear came to inspect Russell and the filmmakers soon after they arrived, peering into their camera lens, leaving nose prints on the lens (Russell 1994). This bear would sit down near them, sometimes seeking their protection when larger Black Bears tried to take away salmon he had caught (Russell 1994). On one occasion, Russell followed the bear back into the forest to see where he went. After a long walk through the rainforest, the bear found a soft area covered in bright green moss and decided to take a nap. He was so trusting that he went to sleep with Russell watching him only a few feet away. While asleep, the bear seemed to be dreaming, his eyes moving, legs twitching, and sometimes grunting (Russell 1994). Russell's book is illustrated with many photos of the bear fishing, sprawled on his back in the forest, and climbing about the rocks. This bear let himself be scratched with a stick and even tried to wrestle with Russell and Jeff Turner. Russell and the Turners left the island but returned after a year, and the bear came to greet them, sitting down a few feet away as if they had not been gone at all (Russell 1994).

The entire range of this bear is slated for logging. The Black Bears living on these islands, which carry white bear genes and are only a bit less tame than the white bears, are hunted under British Columbian law, which allows two bears per hunter each season. When they were filming the bears, some Swiss, German and Austrian hunters had arranged a bear hunt (Russell 2000).

The film, fiGhost Bear,fl shown on PBS's Nature series in 1994, captured an island little changed for 10,000 years, never logged and teeming with wildlife. Black wolves, mergansers, Beavers, salmon and Bald Eagles live in this mossy, verdant forest with towering trees. The filmmakers urged protection for the bears and the forest. Other defenders of this bear and its forest are the members of the Kitasoo and Gitga™at Indian tribes of British Columbia, who believe that the white bears were created by a raven who came from heaven and decreed, "The white bears will live here forever in peace." The tribe wants to create a park of the entire area to protect the bears and the rainforest. Logging proceeded, however, within the proposed park, and a logging company cut a road through one island's ancient rainforest and the ancestral Kitasoo deer-hunting grounds. The Rainforest Action Network (RAN) began in the mid-1990s to help create a sanctuary, which is opposed by the British Columbian government. Twenty million acres of rainforest in the province may be cut, and RAN is campaigning to convince US customers to cancel contracts and refuse to buy products from these ancient forests (Rosmarin 1995).

A Canadian couple, Ian and Karen McAllister, have formed an organization, Rainforest Conservation Society, to preserve the habitat of the Ghost Bears and the Great Bear Rainforest. Their book, *The Great Bear Rainforest, Canada's Forgotten Coast*, published in 1997 by Sierra Club Press, eloquently describes this magnificent region and their work to help preserve it. The Natural Resources Defense Council (NRDC), headquartered in New York, took on the cause in 2000, urging a consumer and commercial boycott of International Forest Products (Interfor), a logging company that is cutting the old-growth forests in the heart of 18 untouched rainforest valleys in the Great Bear Rainforest. As the company was about to clearcut East Creek on one island, it was stopped by construction of a tribal longhouse by the Gita™at Tribe at the mouth of the creek, aided by NRDC, which forced the company to suspend its plans (NRDC 2001). Negotiations between conservation groups and six logging companies, including Interfor, had appeared to achieve protection of the Great Bear Rainforest, but Interfor pulled out of the agreement and recently began logging within the habitat of the white bears. This devastation of a magnificent environment does not even make economic sense, as there could be a sizeable market for videocam views linked to a satellite of these enchanting bears and their mossy, green forests, paid for by viewers around the world for a long-term profit far exceeding that which will accrue to the loggers. The Giant Panda is also a charismatic species, and conservation donations from zoos now total $10 million a year or more to preserve the species™ habitat. The white and black bears of this wilderness deserve no less.

North America™s Forests: Page 18

Further inland, the Wood Buffalo National Park, bordering Alberta and the Northwest Territories, is the sole breeding ground of the endangered Whooping Crane (*Grus canadensis*). This enormous park, designated a United Nations World Heritage site, was logged in large clearcuts from the end of World War II until 1992, a tragic loss of old-growth boreal forest (Devall 1993). The logging was stopped by a lawsuit brought by the Sierra Club Legal Defense Fund (now Earthjustice Legal Defense Fund) in conjunction with the Canadian Parks and The Wilderness Society. The suit was based on the Canadian National Parks Act, which states, "The National Parks shall be maintained and made use of so as to leave them unimpaired for the enjoyment of future generations" (Devall 1993). The Peace River, flowing through Wood Buffalo, is so contaminated by dioxin from the Daihowa pulp mill upstream that natives no longer eat the fish, their major food staple, from the river (Devall 1993).

By the end of 1988, one-third of the land surface of Alberta, Canada-- 221,000 square kilometers--had been logged. Much of Saskatchewan's former forested land--more than one million hectares--has been clearcut and not replanted, nor has it regenerated naturally (Devall 1993). Manitoba, south of Hudson Bay, protects less than 2 percent of its territory from development and logging. In 1989, the Manitoba government opened up an area the size of Ohio, 108,000 square kilometers, to logging (Devall 1993). Logging in Manitoba, Saskatchewan and Alberta fueled $10 billion in new pulp mills, major water and air pollution sources (Devall 1993).

Eurasian Temperate Forests

Eurasian Temperate Forests: The Siberian Tiger's Domain

Russia's coniferous forests form the major part of the Eurasian taiga, a mixture of spruce, birch and other evergreens, covering 3 million square miles, two•thirds of the country's land surface (Sparks 1992). It is the world's largest forest of any type, more than twice the size of the Amazon rainforest (Stewart 1992). Russia's taiga makes up half of the world's total area of coniferous forest and about one-quarter of the entire forested area of the world; the Siberian portion alone is one•third larger than the whole of the United States (Sparks 1992). The forested land east of the Ural Mountains covers 5 million square miles (Linden 1995). Further south, deciduous trees mix with aspen, birch and alder (Sparks 1992). This entire, vast forest may once have been the domain of the Siberian Tiger (*Panthera tigris altaica*), as its fossilized bones have been found on Lyakhov Island off the north coast of Siberia (Matthiessen 2000).

The vast expanses of taiga forests were opened up to international logging after the dissolution of the USSRF. By the early 1990s, about 304 million acres, two•and•one•half times the size of France, had been clearcut (Stewart 1992). Each year an additional 12 million acres are logged (Lean and Hinrichsen 1992). Commercial exports of Siberia's logs to the United States have been encouraged by various corporations and the US Department of

Commerce. Logging has also been intense in Russia's Far East, an area of great biological diversity, with many resident endangered species.

A nearly pristine and stunningly beautiful part of Russia is the Kamchatka Peninsula in the Far East, jutting into the Pacific Ocean. This area has 29 active volcanoes, wild rivers, hot springs, and beautiful forests. An endemic tree, the Kamchatka Fir (*Abies gracilis*), grows only on this peninsula. A relict of pre-Ice Age coniferous forests, it is a silvery fir with soft needles, which grows to about 70 feet in height; this once widespread tree is now restricted in range (Sparks 1992). The forests of Kamchatka are being heavily logged (Meulenaer and Vaisman 1996). Another threat is gold mining, as $10 billion worth of gold is thought to lie under the forests and lakes of the Peninsula (Specter 1997).

The Kamchatka Sable (*Martes zibellina*) is larger than sables in other parts of Russia and was nearly trapped to extinction in the 19th century (Stewart 1992). The Sable's habitat is dominated by Stone Birch (*Betula ermani*) forests with thick, grassy undergrowth covering the mountain slopes; some of these trees grow to be 600 years old (Stewart 1992). Mountain Ash provide berries which, along with an occasional fish, supplement the Sable's diet of voles (Stewart 1992). Unfortunately, anti-trapping restrictions are not being enforced in Russia's Far East, even in nature reserves. The Kronotsky Nature Reserve, covering 3,860 square miles on the peninsula's east coast, shelters 700 species of tundra, taiga and mountain plants, with a number of unusual endemic plants, including the beautiful Kamchatka Rhododendron (*Rhododendron kamchatkensis*), which has miniature red blooms (Sparks 1992).

The magnificent Siberian or Amur Tiger is the largest of all wild cats. Only a few hundred years ago, its realm extended from northern Manchuria west to Lake Baikal and south to North Korea and northeastern China (Matthiessen 2000). Its range shrank over the centuries as a result of hunting, persecution, loss of prey species and habitat. Today it is restricted to the extreme southeastern Maritime Region in the Amur River basin east of Manchuria, west of Sakhalin Island (Miquelle *et al.* 1999). During the 1980s, the Soviet government established a series of reserves for the Tiger, but heavy logging and hunting in the region caused declines in its major prey species, boar and deer. Only 5 percent of the Siberian Tiger's habitat is protected in reserves, according to Evgeny Smirnov, a Russian biologist who studies Tigers (Gourevitch 1995). Moreover, a trade in Tiger bones and other body parts for Traditional Medicine has resulted in the killing, often brutal, of thousands of Tigers throughout their range from India east and south to Indonesia (see Trade chapter).

Siberian Tigers require very large territories. In Sikhote-Alin, their major protected reserve, there are only 10 to 15 resident adults on 400,000 hectares (988,400 acres) (Smirnov and Miquelle 1999). Such large home ranges make them extremely vulnerable to habitat loss, especially the fragmentation of forests by logging. This region™s volcanic peaks rise 5,000 feet from the sea, and forests are crisscrossed by rivers and dotted by lakes. Northern and southern forests meet here, harboring a myriad of tree species. Tall Korean Pines (*Pinus koreansis*) mingle with oaks, maples, walnuts and birches, and unlike the typical Siberian taiga, shrubs and undergrowth are luxuriant (Stewart 1992). These trees reach heights of nearly 150 feet and produce a great volume of cones, providing food for Wild Boar, Brown Bear, Manchurian Moose, and the endemic Ussurian Asiatic Black Bear (*Selenarctos thibetanus ussuricus*). Korean Pines have been so heavily logged outside the reserve that the species is now threatened; although it is protected, illegal logging still occurs (Bohan *et al.* 1996).

A highly unusual type of dark•barked, slow•growing birch grows here. Known as the "Iron Birch" (*Betula schmidtii*), its wood is reputedly so heavy that it sinks in water (Stewart 1992). The Primoryi Province, in which this preserve is located, harbors more than 150 species of trees and shrubs. The meeting of northern and southern forests in this region has resulted in a rich diversity of wildlife. The Ussuri Sika deer (*Cervus nippon hortulorum*) lives alongside the endangered Goral (*Naemorhaedus goral*), a goat•like ungulate native to mountains west to the Himalayas. This is the northern edge of the Leopard's range. The Amur Leopard (*Panthera pardus orientalis*) is a highly endangered subspecies, threatened by both habitat loss and poaching. Lynx and Common Otter are also native. The Dhole (*Cuon alpinus*), a threatened wild dog native to more southerly regions west to India, may also be native to the Sikhote•Alin Preserve. This extraordinarily rich diversity of predators and prey is at great risk from overhunting and logging, however.

As many as 340 species of birds have been recorded in Sikhote•Alin (Stewart 1992), including two endangered waterbirds, the Red-crowned Crane (*Grus japonensis*) and the Oriental White Stork (*Ciconia boyciana*) (Collar *et al.* 1994). A species of ginseng (*Panax ginseng*) grows in the undergrowth and is valued by the indigenous Udege people and others as an invigorating tonic, making it the "root of life" in their folklore. They believe that the ginseng is guarded by the great Siberian Tiger, and shrines are erected to the Tiger, who is believed to possess near•magical powers (Stewart 1992).

In 1991, the Hyundai Corporation of South Korea signed a 30•year contract to cut 500,000 acres of virgin forest on the Pacific slope of the Sikhote•Alin range (Schafer and Hill 1993). By the end of 1992, the area had been clearcut, and Hyundai began logging in the Bikin River Basin, the last pristine river valley in the region (Schafer and Hill 1993). In the Bikin, a small population of Udege live along the river's forested banks, as they have for hundreds of years, subsisting on local wildlife (Schafer and Hill 1993). These people have opposed the entry of the loggers, filing suit to stop the logging, threatening to shoot at logging trucks and removing markers from trees slated for cutting (Schafer and Hill 1993). Their protests succeeded in stopping the logging, negating the original agreement; Hyundai continues, however, to try to gain access to the Bikin forests (Bohan *et al.* 1996). This 600,000-acre watershed of the Bikin River is among the last virgin forests in Ussuria (Matthiessen 2000). A plan by the US Weyerhauser Corporation to cut an area of virgin forests the size of Delaware was thwarted by conservationists, and this forest has been declared a nature preserve (Nunn 1996).

Some 10 million acres of Tiger habitat are being clearcut every year, and members of the Siberian Tiger Project, composed of US and Russian biologists, are proposing alternate methods of timber harvest for the region (Quigley and Hornocker 1994). The native deer and boar, upon which the Tiger depends, are being hunted out of many areas by local villagers and professional poachers, who sell their bones and antlers for the Chinese Traditional Medicine trade. In 1995, the Russian government issued a decree "On Saving the Amur Tiger," which called for a specific plan and schedule to implement Tiger protection efforts (Galster 1996). In response, the Russian-American scientific team formulated a plan the same year to protect all existing Tiger habitat with connected reserves, new national parks, multiple use zones and ecological corridors linking them. It would be the world's largest sanctuary, preserving old-growth Korean Pine and designating various zones in this immense area, which extends from north of Khabarovsk south to Vladivostok in a mosaic of connected land (Galster 1996). The plan also called for a new national Tiger census, which was carried out in early 1996 and found more Tigers than previously assumed, an estimated 330 to 371 animals. The proposed protection plan, when combined with the Bikin traditional reserve and a large region a US government agency is helping to protect through multiple use, would preserve about 26 percent of existing habitat of the 156,000 square kilometers used by Siberian Tigers in Russia (Miquelle *et al.* 1999). The remaining area is either scheduled for logging or agricultural development. The Tiger biologists are urging that all Tiger habitat be included in a national protection plan, as signs of Tigers have been seen in 90 percent of the habitat (Miquelle *et al.* 1999). Coexistence between Tigers and people is essential. This would mean easing human hunting pressure on its prey, primarily Elk and Wild Boar, which have become rare, a major cause for the Tiger™s need of such large territories. Moreover, Tiger poaching needs to be stopped, and Tigers need access to river valleys, which they use for hunting and movements. Most of these have been taken over for human use.

The Siberian Tiger Project was the subject of a 1995 National Geographic film, "Tigers of the Snow," which included the first filming of a baby Siberian Tiger being weighed and examined by biologists in its wild den. The magnificent scenery of this coastal region was filmed from an aircraft, and areas of clearcutting were in stark contrast to the unbroken forests. The film also noted the sad end to a young Tiger hit by a logging truck. These trucks, loaded with giant tree trunks, thunder through the beautiful valleys. The Siberian Tiger Project is the first research study involving radio-tracking ever undertaken of the Siberian Tiger, and it is revealing new information on its range, behavior and habitat needs. Should the reserves be set aside, Siberian Tigers will be the first race or population of Tigers to become stabilized and perhaps increase at a time when all other populations are in drastic decline.

An eloquent book by Peter Matthiessen (2000), *Tigers in the Snow*, focuses on this research and the future of all

Tigers. Anti-poaching work is helping to stem the decline of both the Tiger and its prey, but until its habitat is secure, this once proud cat, master of its domain, will remain beleaguered and under constant threat. Its world has become a battleground, filled with the screeching of power saws destroying the forests it needs to survive, and the constant threat of poachers. As a keystone species at the top of its food chain, the survival of the Tiger is "the best indicator of the health of the ecosystem as a whole" (Matthiessen 2000). Without the Tiger, the deer and boar will become slow, small and overpopulated, destroying their habitat as they have in Europe, where most predators have been eliminated. This is a crucial turning point for the species, whose tropical populations may not survive long. The Siberian Tiger inhabits a world without high human populations, a still-extensive forest habitat, and is the subject of a strong conservation program. The many people who are dedicated to saving it may succeed. In the words of Maurice Hornocker, an overseer of this research project, "One day it will be culturally unacceptable to kill Tigers anywhere for any reason" (Matthiessen 2000).

Eurasian Temperate Forests: Land of the Giant Panda

China's once extensive forests have declined over the centuries as human population increased. In south-central China, temperate forests of many types are watered by the five great rivers of Southeast Asia: the Mekong, Irrawaddy, Yellow, Yangtze and Salween (Mittermeier 1999). This is botanically the richest temperate region in the world, twice the size of California with half of China's plants--12,000 species, of which 3,500 are endemic (Mittermeier 1999). This is the home of the Giant Panda (*Ailuropoda melanoleuca*). Fewer than 1,000 of these black-and-white bears remain in small, scattered populations. When climates were cooler during the Ice Ages 12,000 years ago, Giant Pandas had a far larger distribution, covering much of central and southern China and bordering areas of Burma. As climates warmed and human populations took over much of their habitat, they declined in numbers, and their bamboo forests retreated. Today, Giant Pandas remain only in three provinces, with the largest number in Sichuan. Between 1974 and 1989, their habitat was halved as a result of logging and settlements, from 20,000 square kilometers to 10,000 square kilometers (Mittermeier *et al.* 1999). Satellite studies of their major reserve, Wolong Nature Reserve, found a dramatic decline in forest cover from 1965 to 1997 as growing numbers of people living in the reserve cut deciduous trees and bamboo for firewood (Revkin 2001). During the last decades, with international attention focused on this extremely charismatic animal, reserves have been set aside. Twenty reserves have been established in the remnants of the Giant Panda's habitat, but the species has continued to decline as destruction of forests turn the reserves into islands surrounded by clearcut hillsides. Many Pandas have starved to death when their bamboo forests were cut or underwent a cyclical die-off. Prior to this deforestation, when local bamboo forests died off, Giant Pandas were able to wander widely in search of other bamboo. Their habitat has decreased so much that they are now at the mercy of local conditions within each reserve (Mittermeier 1999 *et al.* 1999).

A long•term study of this species by Dr. George Schaller, of the New York-based Wildlife Conservation Society, arrived at the pessimistic conclusion that the Giant Panda was headed inexorably toward extinction (Schaller 1993). In his 1993 book, *The Last Panda*, Schaller wrote a scathing and unflinching analysis of the failure of existing conservation programs. Among his conclusions was that almost all of the millions of dollars raised around the world to preserve this most popular of all animals had been wasted while wild Giant Panda populations dwindled. His research revealed that Pandas were readily taken into captivity during bamboo die•offs when, in fact, enough bamboo still remained to supply their needs (Schaller 1993). Most of the funds were spent on building dungeon-like breeding and holding compounds rather than on saving its ever•dwindling habitat or hiring wardens to prevent poaching (Schaller 1993). The Wolong Reserve, which covers 780 square miles, was the location of his research area. Wolong had 4,200 people living within its borders in 1989, who were cutting trees and setting snares to kill wildlife for meat, musk and skins (Schaller 1993). In eight years alone, 14 square miles of the Wolong forest were destroyed, and an unknown number of Pandas died in cruel wire snares (Schaller 1993).

Only time will tell whether the urgent habitat and anti•poaching needs of the Giant Panda will be met, or whether

funds meant for its conservation will continue to be spent on breeding compounds. Seventeen forest corridors are planned to link fragmented habitat, but breeding and holding compounds continue to be built, with a goal of 32 stations (Williams 1994). A dedicated Chinese scientist, Pan Wenshi, who has studied these animals for decades, helped save the habitat of some 80 Pandas in these mountains when the high•pitched whining of chain saws was within earshot (Wenshi 1995). The National Geographic Society filmed the mother Panda that Pan Wenshi had studied throughout her life, Jiao Jiao, and her tiny mouse•sized cub when only a few days old (see Video section). This cub, a female he named Xi Wang, meaning Hope, grew into a healthy young Panda and, when four months old, took her first shaky steps out of the warm den (Wenshi 1995). As she grew older, Xi Wang took naps lying on her back in the tops of pine trees, watching her mother as she fed in the forest (Wenshi 1995).

If forest corridors are not soon set aside linking the reserves to one another to allow free movement of Pandas, the species will probably fade gradually to extinction from inbreeding (Lean and Hinrichsen 1992). One source of funding to preserve habitat is the Chinese government loan program, under which Giant Pandas are sent to foreign zoos for periods of up to 10 years. Various zoos in the United States have arranged such loans, paying the Chinese government $1 million per year per zoo, and these funds must be applied to conserving the species in the wild under supervision of the US Fish and Wildlife Service. A pair in the San Diego Zoo produced a healthy female cub in 1999 through artificial insemination. Other pairs were acquired by Zoo Atlanta and the National Zoo in Washington, DC, in 2000. Few Giant Pandas breed naturally in zoos. This funding and the new attention directed at conserving these highly endangered and endearing animals may turn the tide in China to protecting their habitat. If successful, it will also spell survival for thousands of rare Chinese plants and animals that inhabit the Pandas™ forests.

Xi Wang, the Giant Panda studied by Wenshi, inhabits the Qin Ling Mountains, haven for a wide diversity of rare plants. One mountain alone, the 12,359-foot Taibai Mountain, has 150 endemic species of plants, among them the Qin Ling Mountain Fir (*Abies chenensis*) (Ji 1990). Two varieties of this species are listed by the *1997 IUCN Red List Plants* (Walter and Gillett 1998). A neighboring mountain, the Shennongjia, is known as a "Treasure House of Plants" because of the many unusual and ancient species here (Ji 1990). In Hubei Province in the same region is the Dawn Redwood, a deciduous tree which is a close relative of the North American Coast Redwood and Sequoia but far more ancient in lineage (Ji 1990). Until 1941 when a few groves were discovered by Chinese botanists, the Dawn Redwood was known only from Jurassic fossils (MacKinnon 1996). Small populations survive in Sichuan, Hubei and Hunan provinces, but the species is considered Endangered by the International Union for the Conservation of Nature (IUCN) (Walter and Gillett 1998) and only about 1,000 trees may survive in the wild (Dyer 2000). This tree grows to a height of about 115 feet, its delicate pinnate leaves turning golden in the fall. As the sole member of its genus, and a living example of trees that grew in the age of dinosaurs, it is considered a great botanical treasure.

Its seeds have been planted in many parks and botanical gardens around the world. John Williams, the award-winning composer, became fascinated with a Dawn Redwood growing in Boston's Public Garden (Dyer 2000). "It not only looked lovely, but it seemed animate, even intelligent," he said (Dyer 2000). By chance, he met a retired Harvard University botanist, Dr. Siu-Ying Hu, and praised the tree on a walk through the Public Garden. Hu pointed out that he had planted this very tree back in the 1940s, having brought a bag of seeds to America when he arrived from China (Dyer 2000). The Dawn Redwood inspired Williams to compose a musical piece entitled "Tree Song" for harps, keyboards, flutes and delicate percussion. It was performed by the Boston Symphony Orchestra at the opening of the summer concert series at Tanglewood, Massachusetts, in July 2000 and recorded on CD (Dyer 2000).

The extraordinary Dove Tree (*Davidia involucrata*) was named after its discoverer, Pere Armand David, a French missionary who traveled in China in the 19th century and named hundreds of animals and plants. Its white leaves are up to 6 inches long and 3 inches wide, resembling a flock of doves taking flight (Schaller 1993). These trees are quite rare in China, after centuries of deforestation (Walter and Gillett 1998). Even in 1900, when American botanist E.H. Wilson went to China to find seeds from this tree, he traveled six months before he even met someone who had ever seen one (Stocker 1997). When Wilson finally found a Dove Tree, only a stump remained: it had been cut and the wood used to build a house. He later found 10 wild specimens and brought back seed to Harvard University's Arnold Arboretum (Stocker 1997). This species, too, has ancient origins and once dominated prehistoric forests (MacKinnon

1996). Like the Dawn Redwood, it was rescued from extinction and is now cultivated in nurseries and botanical gardens (Stocker 1997).

Many of these plants and trees share the habitat of the Giant Panda, and forest reserves would ensure their survival. A number of endangered mammals that have disappeared from other regions as a result of hunting and habitat loss can be found in Wolong and other Giant Panda Reserves. The Red Panda (*Ailurus fulgens*), thought to be a relative of the Giant Panda, is a rare native, as are the Golden Monkey (*Pygathrix roxellanae*) and the Takin (*Budorcas taxicolor*), a goat•like ungulate. All three are endangered species and declining as the forests are cut. An endangered bird, the Sichuan Partridge (*Arborophila rufipectus*), is restricted to an area of less than 100 square kilometers in south-central Sichuan, where fewer than 2,000 birds survive (BI 2000, Collar *et al.* 1994). Its old-growth broadleaf forest is being felled at a rapid rate, and people enter its habitat to collect bamboo shoots in its breeding season, disturbances that are driving these birds toward extinction (BI 2000). Twenty-six other species of pheasants inhabit this part of south-central China, including the most iridescent birds in the world, the monals. The threatened Chinese Monal (*Lophophorus lhuysii*) inhabits rhododendron and high-altitude coniferous forests and is in decline as a result of logging and hunting, which have been facilitated by the construction of logging roads (BI 2000). The male Chinese Monal has dazzling plumage in an array of emerald green, purple, coppery-golden, purplish-green and white, while the female is more subdued in gray and rufous-brown. The creation of reserves for the Giant Panda have aided this bird's survival, as several are within this bird's range (BI 2000).

China's 25,000 native plant species make up 11.4 percent of the world's plants, including many ancient ones (MacKinnon 1996). The Ginkgo (*Ginkgo biloba*) has been on Earth for 200 million years; this tree grows wild in scattered locations in China, indicating that it was once far more widespread and was eliminated by logging over the centuries (MacKinnon 1996). In prehistoric times, Ginkgoes grew throughout the world but were thought extinct until a few trees were found in remote forests (MacKinnon 1996). Its unusual wide, lobed leaves turn yellow in the fall before falling. This tree has been considered sacred by the Chinese for centuries and is grown in temple gardens and other religious sites. Extracts are sold around the world as an herbal stimulant. In the Himalayas, giant cypresses (*Cupressus*) grow to immense size when protected by Buddhist temples; one specimen measures almost 20 feet in diameter and is estimated to be 2,000 years old (MacKinnon 1996). Entire forests of these giant trees also grew on Taiwan, where only massive stumps remain (MacKinnon 1996). Stephen Spongberg, Curator at the Arnold Arboretum, has studied China's native trees and found numerous species to be extinct in the wild (Stocker 1997). Antique Chinese furniture sought by collectors is often made from the wood of trees that are now extinct, and some trees are so rare that most Chinese botanists have never seen them in the wild (Stocker 1997).

China has more forest types than any country in the world. In the far north, taiga dominates. Conifers, birches and oaks blend into temperate coniferous forests in the northeast. Further south, the Giant Panda's habitat is temperate, evergreen forest. Himalayan forests occur in the west, and in the south, tropical monsoon rainforest prevails (Ji 1990). Unfortunately, very little virgin forests remain in the country, other than in high altitude and remote areas (Ji 1990). In the Giant Panda's highly diverse habitat of south-central China, less than 10 percent of the forests remain in pristine condition (Mittermeier *et al.* 1999). The destruction of these forests has been going on for centuries. During the 19th century, Pere Armand David lamented its destruction:

> *From one year's end to another, one hears the hatchet and the axe cutting the most beautiful trees. The destruction of these primitive forests, of which there are only fragments in all of China, progresses with unfortunate speed. They will never be replaced. With the great trees will disappear a multitude of shrubs and other plants which cannot survive except in their shade; also all the animals, small and large, which need the forest in order to live and perpetuate their species . . . They have the right to life and we annihilate them and brutally make existence impossible for them*
>
> Pere Armand David, 1875

In many parts of China, virtually no natural habitat remains, as centuries of human habitation and agriculture have replaced native vegetation and wildlife. One can travel for 1,500 miles in east•central China, for example, and see a landscape covered entirely with agricultural fields and villages, devoid of wildlife (Schaller 1993). Deforestation caused massive floods in the summer of 1995, when the Yangtze River, the country's longest, flowing from central China east to Shanghai, overflowed its banks. More than l.3 million people were displaced by the flooding, 900,000 houses collapsed, 2.7 million acres of crops were destroyed and 1,200 lives were lost (AP 1995). The economic losses were estimated at $4.4 billion. Each year these floods worsen as development covers the region, removing all natural flood controls (AP 1995). The last forests of any extent in China can be found in the northeast, and in 1987, fires destroyed 18 million acres (an area the size of Scotland) as well as 12 million acres in adjacent Russia (Schaller 1993).

Pere David's Deer (*Elaphurus davidianus*), named for its discoverer, and was once common in the northern forests and marshes. Hunting nearly eliminated the species, and to prevent its extinction, Chinese emperors kept the surviving population in a walled imperial hunting park near Beijing for more than 1,000 years. Even this population was killed by soldiers and villagers in the 1900 Boxer Rebellion, however; fortunately, some had been taken to England and kept by the Duke of Bedford on his estate (Schaller 1993). In 1985, 22 of these deer were returned from captive populations to the same walled park in China, now reduced from 150 square miles to 440 acres (Schaller 1993). Several other herds have been reintroduced elsewhere in China, numbering some 600 animals (MacKinnon 1996).

Reverence for nature in China dates back many thousands of years and is an integral part of the culture of this ancient country. It may now be reemerging. The 1979 Forest Law contained strict regulations on logging and required 40 percent forest cover in the mountains and 30 percent nationwide. This was strengthened in 1988 with a ban on logging in Yunnan and Sichuan, and legal protection was accorded to 389 plant and 206 animal species (Geatz 1999, Mittermeier *et al.* 1999). Reserves are being set aside throughout the country, increasing from 44 in 1956 to 600 in 1991, with a goal of 800 reserves protecting 5 percent of the country (Schaller 1993). This is indeed laudable in the most populous country on earth, and this eleventh-hour commitment is preserving many remnants of the once diverse and abundant natural heritage.

In practice, however, logging and firewood cutting tend to far exceed reforestation or preservation of forests in reserves or parks. Heavy livestock grazing by herders, who also clear forests for pasture, is devastating delicate forest habitats (Mittermeier *et al.* 1999). Logging trucks carrying the trunks of the last remaining stands of old-growth forest can be seen in many areas. These deforested areas do not tend to regenerate because fires and grazing by goats kill the saplings (Mittermeier *et al.* 1999). During the late 1990s, The Nature Conservancy began a major project to study the biodiversity of the southern province of Yunnan, whose ecosystems range from alpine to subtropical forest (Geatz 1999). Certain tribes of this region have a strong tradition of conservation, and the provincial government has welcomed the help of this organization in helping to protect their natural heritage. Its 2000 report, "Conservation and Development Master Plan for Northwest Yunnan," includes recommendations for the protection of biodiversity, regional planning and resource development to provide ideas for non-destructive economic projects, such as growing plants for medicinal and ornamental purposes as an export commodity and developing ecotourism for this spectacular region (Geatz 1999, The Nature Conservancy 2000).

The future of China's forests and its tremendous biological diversity are greatly affected by its enormous human population of more than 1.2 billion people, whose growing needs encourage heavy hunting of its depleted deer and ungulate populations and large livestock herds, as well as excessive tree cutting for firewood (Mittermeier *et al.* 1999). Various international conservation organizations are working to help China in assessing its diversity and the threats to it, and to encourage enforcement of its 1982 Constitution, which states that the nation must protect and improve its environment and ecosystems, prevent pollution and protect precious animals and plants (Mittermeier *et al.* 1999).

Asia's beautiful pheasants and partridges are disappearing rapidly as their forests are cut and many are hunted for

meat. Partridges and pheasants are found from the Himalayas to sea level tropical forests throughout most of Asia. They have declined dramatically, however. Of 22 species of Asian partridges, 15 species, or 68 percent, are listed by BirdLife International in *Birds to Watch 2: The World List of Threatened Birds* (Collar *et al.* 1994). An even higher degree of threat is suffered by the many spectacular pheasants. Of the 52 species of Asian pheasants, 38 species, or 73 percent, are threatened by the destruction of forests and hunting by the same authorities (Collar *et al.* 1994). Some endangered Himalayan pheasants include the Tibetan Eared Pheasant (*Crossoptilon harmani*), White Eared-pheasant (*Crossoptilon crossoptilon*), Cheer Pheasant (*Catreus wallichi*) and Elliot's Pheasant (*Syrmaticus ellioti*) (Collar *et al.* 1994). They show a great variety in their colorful and iridescent plumages, rivaling birds-of-paradise in beauty. Their relatively large size and brilliant plumage make them vulnerable to hunters, and they have not been studied intensively in the wild to determine habitat size and other requirements for their survival. Very few species have been protected in parks and reserves.

The mixed hardwood forests that once cloaked the Himalayas, studded in many areas by native rhododendrons, have been decimated during this century. Some 57 Asian rhododendrons are listed by the *1997 IUCN Red List Plants*. The deforested steep slopes are now prone to erosion by the monsoon rains that arrive annually. Heavy rains bring huge landslides and floods. Tree cutting, primarily by people gathering firewood or clearing land for agriculture, has been particularly severe in the Indian, Pakistani and Nepalese Himalayas. The once unbroken stands of oak and pine have become fragmented and totally absent in many areas. Human populations have risen over the past century to levels far above carrying capacity of this delicate region.

The Ganges River, which flooded only once every 50 years prior to deforestation, now floods every few years since the Himalayan forests that retained the water throughout the years have been logged (Lean and Hinrichsen 1992). Only Bhutan has preserved the majority of its forests, which are crucial to the survival of many species extinct elsewhere in the Himalayas. Tigers, Asian Black Bears, Himalayan Tahr (*Hemitragus hemlahicus*), Red Pandas, Golden Leaf Monkeys (*Trachypithecus geei*), and Tibetan Macaques (*Macaca thibetana*) are among the many mammals endangered by the loss of Himalayan forests. The Woolly Flying Squirrel (*Eupetaurus cinereus*), the largest squirrel species in the world, has just been rediscovered in northern Pakistan after being thought extinct for 70 years (Walters 1995). Four feet from its nose to the end of its tail, this squirrel may be able to glide distances of up to 1,000 feet (Walters 1995). Peter Zahler, a Cornell University zoologist, traveled to Pakistan in 1994. In a remote valley where this squirrel was rumored to exist, a local villager, who found one in a mountain cave, supplied a live animal in a bag. Zahler studied it for a short time, photographed and measured it, and then hiked 3 hours up the mountain and released the squirrel at its capture site (Walters 1995). This squirrel has been designated Endangered by the *1996 IUCN Red List Animals*. This exciting rediscovery is tempered by the threats from deforestation and overgrazing in its mountain habitat. Local people report that it is solitary and active throughout the year, climbing conifer trees to feed (Nowak 1999). The Woolly Flying Squirrel is not hunted, but the conifers on which it depends are being cut at a great rate, causing it to decline over the past decade (Nowak 1999). Its total population is estimated at fewer than 2,500 and falling as a result of habitat loss (Nowak 1999). (Photos of this squirrel appear in Nowak 1999.)

Eurasian Temperate Forests: Lost Forests of the Mediterranean and Europe

Forests of towering cedars, oaks, firs, pine and beech once blanketed the region surrounding the Mediterranean Sea. Wildlife abounded in these primeval forests. Some 8,000 years ago, forest cutting began (Mittermeier *et al.* 1999a). Livestock gradually replaced wildlife, stripping the vegetation. In 3,000 B.C., Phoenicians logged the great forests of Cedars of Lebanon (*Cedrus libani*) for ship and building construction to trade with Egyptians and other cultures (Mittermeier *et al.* 1999). These massive trees reach 130 feet in height and are among the most majestic and stately of all trees. On the island of Cyprus, an endemic cedar, the Cyprian Cedar (*Cedrus brevifolia*), covered the

island. Centuries of tree cutting and livestock overgrazing have reduced this tree to a relict population. Other forests on the Mediterranean's eastern shores were felled for building and to clear land for agriculture and grazing. The Greeks cut their forests in spite of warnings by the philosopher Plato as early as 4,000 B.C. that water supplies and wildlife would disappear (Pontiff 1991). The country's climate grew dryer and its topsoil washed into the sea (Runnels 1995).

Italy's southern forests were cut in Roman times, but north of the Adriatic Ocean, large expanses of beech and oak forests remained intact until the 16th century when they became the raw material for ships and galleys that sailed the Mediterranean waging battles and trading. Enormous amounts of lumber were needed to build these ships. When an exact replica of a galley was reconstructed a few years ago, 650 mature trees were required: 50 beech trees were needed for oars, 300 pines and firs for planks and spars, and 300 mature oaks for hull timbers (Attenborough 1987). In 1571, Venetian fleets battled the Turkish fleet which had been attacking and looting their ships. The 500 vessels in the Venetian and Turkish fleets had required the felling of more than a quarter-million mature trees (Attenborough 1987). Soon thereafter, the building of Venetian galleys came to an end for lack of trees, and shipbuilding moved elsewhere in Europe where trees were still abundant (Attenborough 1987). A single forest resembling the original beech and evergreen forest remains intact near the Adriatic in the former Yugoslavia. Its beauty was filmed for the series, fiThe First Eden. The Mediterranean World and Manfl (see Video section, Regional, Mediterranean).

Hardwood forests covered much of Spain until the early 16th century when, by royal decree, it was decided that the economy of the country could be expanded by developing a Spanish monopoly on the breeding of Merino sheep for their valuable wool (Attenborough 1987). Sheep herds became larger and larger, and forests were cut to provide grazing land. Within decades, the forests that had covered central Spain were gone, and topsoil had eroded, leaving shrubland (Attenborough 1987). These forests have not regenerated. Some oak forests have survived in parts of Spain, but intact ecosystems with native ungulates and predators have disappeared. Livestock grazes in all but the most remote areas. The few remaining Gray Wolves, as well as the endemic Iberian Lynx (*Felis pardina*), are critically endangered due to loss of forests and persecution. As an indication of the degradation of habitat, many species of Spanish wildlife are threatened with extinction. Worldwide, about 11 percent of the world's birds are threatened with extinction (Collar *et al.* 1994), but 37 percent of Spain's birds are threatened, 53 percent of its mammals, 41 percent of its reptiles, and 45 percent of its amphibians (Peters and Lovejoy 1990).

Forests of pine, cedars and oaks blanketed the slopes of the Atlas Mountains of Algeria and Morocco prior to the Roman conquest. Logging by the Romans and people in the intervening centuries has destroyed all but fragments of these forests. The Atlas Bear (*Ursus arctos crowtheri*) originally ranged in these forests but was gradually pushed toward extinction by loss of its forest habitat, hunting and capture. The last of these bears was killed in the late 19th century (Day 1981). The endemic Atlas Cedar (*Cedrus atlantica*) has wide girths and grows to heights of more than 125 feet. They are often covered in moss and lichens in the cool altitudes (color photo, see Mittermeier *et al.* 1999a). Unfortunately, they are fast being depleted by timber cutters in Morocco and Algeria (Mittermeier *et al.* 1999a). North Africa's forests have become fragmented by centuries of logging and heavy grazing by cattle, sheep, and goats. The native Wild Boar (*Sus scrofa*) have also been extremely destructive to the few forests that remain, endangering many birds (Collar and Stuart 1985).

Surprisingly, a bird species native to the Atlas Mountain forests remained unknown until 1975. The Algerian Nuthatch (*Sitta ledanti*), a small, buffy songbird with white eyebrows, was discovered in a national park on Mont Babor (Collar and Stuart 1985). Even in national parks in this region, however, livestock are permitted to graze, consuming young trees and other vegetation. After conservationists protested that this little bird's entire habitat would be eliminated if livestock were not excluded, sheep and goats-- but not cattle--were banned from the park in 1981. To prevent forest cutting by the local people, propane gas has been supplied to use as fuel for cooking and heat (Collar and Stuart 1985). The forest on Mont Babor consists of mixed Atlas oak, Atlas Cedar and the Algerian Fir (*Abies numidica*), a threatened species which grows only on this mountain (Walter and Gillett 1998). The Algerian Nuthatch uses cedars, oaks and, especially, the Algerian Fir for seeds and nesting (Harrap and Quinn 1995). The population of about 80 pairs of Algerian Nuthatches censused in Mont Babor National Park in the early 1980s remained constant,

and in 1989, a second population of about 350 birds was discovered in a nearby oak forest within the Taza National Park (Collar *et al.* 1994). Even though the Taza has National Park status, conservation of the forest has been hindered by cattle grazing that prevents tree regeneration. Also, wood-cutting is allowed that removes potential nest sites, and fires are set, killing many types of animals (Harrap and Quinn 1995). These birds also survive in two small isolated tracts of unprotected, degenerating forest 30 kilometers away, but the total population probably does not exceed 1,000 birds (BI 2000).

Another rare animal, the Barbary Deer (*Cervus elaphus barbarus*), barely clings to life in the disappearing Algerian forests. It is now extinct in Morocco and survives only in a small forest of cork oak and pine on the border between Tunisia and Algeria. They number only a few hundred, including a captive population, and are declining each year. This subspecies of the European Red Deer is listed as Endangered onthe US Endangered Species Act.

Israel has reintroduced related subspecies of some wildlife that have become extinct, bringing in closely related races of gazelles, wild goats, wild asses and Ostriches. The forests, however, are unlikely to return. The vegetation surrounding the Mediterranean today is dominated by shrubland that can regenerate after frequent burning (Mittermeier *et al.* 1999a). Livestock in vast numbers consume tree saplings and pull plants out by the roots. Goats are able to climb low bushes and graze their tops. The soil structure is very loose and alkaline, and the nutrients have been leached out by thousands of years of cultivation, overgrazing and erosion. Only plants that survive in arid climates on poor soil, such as succulents, annuals and those that regenerate from roots, can grow here (Peters and Lovejoy 1990). In many areas, exotic species, such as American prickly pears and Australian eucalyptus, have taken over as a result of the impoverished soil. The remaining bits of forest in southeastern Spain, Morocco, Algeria, Syria and Israel are being cut for fuel at a rate of 14 percent per year (Peters and Lovejoy 1990). The net result of the widespread loss of forests in the Mediterranean is that only about 1 to 2 percent of pristine, original forest remained at the end of the 20th century, all in small fragments surrounded by farmed and developed land (Mittermeier *et al.* 1999a).

The transitions that brought about the present state of affairs occurred over many centuries. So gradual was the environmental deterioration that one generation of people was usually unaware of the ecological changes wrought by previous generations. Once the forests were lost, succeeding generations may have been unaware that they had ever existed. Whether any progress can be made in regenerating forests by bringing in topsoil and replanting in protected areas will depend on the concerns and will of the people of the Mediterranean, who number more than 300 million (Peters and Lovejoy 1990).

North of the Mediterranean, vast forests covering most of Western Europe remained until a few hundred years ago. Deciduous and mixed pine forests were logged over the centuries near towns and cites, and the forests retreated, replaced by agriculture and grazing land. By the 18th century, 90 percent of the forests had disappeared. In Scandinavia, Germany, Austria and Switzerland, tree farms have taken the place of natural forests. Man-made hallmarks of civilization now cover northern Europe except for a few isolated pockets of original virgin forest. Along with these forests, went the Auroch (*Bos primagenius*), an immense wild cow that became extinct in the 17th century. The large predators, Gray Wolves, Lynx and Brown Bears, that preyed on deer, elk and European Bison (*Bison bonasus*) were persecuted to near extinction and remain very rare. The largest remnant of these once vast forests is Bialowieza, on the Polish-Belarus border. It harbors the last herd of free-ranging European Bison and a small number of Gray Wolves.

An organization to protect these wolves, The Association for Nature "Wolf" is also concerned about the cutting of the old-growth trees in Bialowieza Primitive Forest, of which only 22 percent is protected in Poland (Nowak and Myslajek 1999). The "Wolf" organization is working to stop logging and protect this forest for future generations by the creation of a transnational park with Belarus (Nowak and Myslajek 1999). As the top predator in this and other forests of Poland and other European countries, the Grey Wolf helps maintain the health of the forest and cull overpopulations of hoofed animals such as deer. *Wolfnet*, the bulletin published by The Association for Nature "Wolf," is helping to educate the public about this maligned animal, which is often killed on sight in Europe. The

organization is also sponsoring studies of the estimated 500 wolves in Poland and training livestock owners in the use of guard dogs to protect sheep (Nowak and Myslajek 1999).

Eurasia's northern boreal forests, or taiga, are far more extensive than North America's, stretching 6,000 miles from the Atlantic coast of Norway east to the Sea of Okhotsk on the Pacific rim (Sparks 1992). The western section in Scandinavia is almost gone: more than 90 percent of the taiga in the Scandinavian peninsula has been replaced by tree farms, which support almost no wildlife (Walsh 1995). Norway has lost 100 percent of its natural forests, and Sweden and Finland nearly all of theirs (Walsh 1995). The result of this destruction has been a crash in forest biodiversity and declines in many forest species. Seventy•three species of birds are declining or vulnerable in this region, including the Siberian Jay (*Perisoreus infaustus*) and White•backed Woodpecker (*Dendrocopos leucotos*) (Walsh 1995). Sweden's tree farms have replaced more than 200 species of plants and animals, and 800 species are rare or declining, as reported in *Taiga News: Newsletter on Boreal Forests* in 1992. The same publication noted that 805 species are endangered from clearcutting old-growth forests in Finland, and conservation groups have formed to try to save them from corporate logging. The Russian portion of taiga forest, which makes up the majority of these forests, has been less damaged, but with the fall of the Soviet Union, forests are now open to international lumber companies. Much of this forest is so remote that it may never be logged, but millions of acres are likely to be leveled over the next century.

Temperate Rainforests of the Southern Hemisphere

South of the Equator, in widely separated areas, are remnants of forests with species of trees older than the dinosaurs. These temperate rainforests grow in southern Chile and Argentina and, far to the west, in New Zealand, eastern Australia and the islands of Norfolk and New Caledonia. They have been growing nearly undisturbed for more than 100 million years, and many species of animals native to them have ancient lineages as well. Giant beeches grow in southern South America as well as far away in southern New Zealand and Australia. All these trees once grew on the southern supercontinent, Gondwana, some 160 million years ago. New Zealand, Australia and South America were joined and these trees were part of vast primitive forests. The continent gradually broke apart. Many species of trees survived on these new continents and islands as long as they could adapt to the new climates of the different latitudes and longitudes, where they were pushed by continental drift through movements of the Earth's tectonic plates. In spite of eons of dramatic changes on Earth, geological and climatic, large fragments of these ancient forests have survived to the 21st century, only to face possible extinction. The wildlife now inhabiting them is predominated by more recently evolved species which coexist with species whose ancestors inhabited Gondwana. These fragile and unique ecosystems have undergone radical changes over the past few centuries, and many have been logged and cleared, with serious consequences for the native wild animals and plants.

South America

Only a century ago, South America's primitive forests blanketed the entire region from the southern tip of the continent north half the length of Chile's coast and eastward into Argentina's Patagonia. Beech trees of the genus *Nothofagus* covered most of the region, mixed with evergreen and various deciduous trees. Once extending more than 35 million acres, these forests comprised the largest stands of pristine temperate rainforest in the world (Nash 1994). *Nothofagus* beeches are among the most ancient species of trees and have been on Earth more than 150 million years. Soon after their arrival in the 16th century, European settlers began logging these forests, but not until the 20th century did widespread clearance begin. During the 1940s and 1950s, some 13,000 square miles, or 8.3 million acres, of these beech forests were cleared and burned for cattle ranching. Commercial logging continued, subsidized by the Chilean government, which spent comparatively little on forest conservation (Sims 1995). These beautiful forests

have been cut mainly for wood chipping factories that produce paper pulp for export to Japan. Powerful commercial lobbyists have opposed legislation to protect the portions of these forests that remain, enabling logging companies to continue clearcutting, pushing some species to the brink of extinction. Once logged, the land is replanted with plantations of eucalyptus or pine, or turned into pastureland for livestock. The *1997 IUCN Red List Plants* lists four species of *Nothofagus* native to Chile and Argentina as vulnerable, indicating a decline toward Endangered status that, if not reversed, will result in their extinction (Walter and Gillett 1998).

Not all Chilean government officials are proponents of the logging. Carlos Ritter, head of the technical department for the National Forest Corporation, a government entity, complained: "Japan has fomented the cutting of our native forests, but they try not to assume responsibility. They say they are only buying the wood. But they have created so much demand the peasant farmer cannot resist cutting his forest" (Nash 1994). During the 1990s, an American logging firm, the Trillium Company, purchased 632,000 acres, or 987 square miles, of ancient forest in the southernmost region, Tierra del Fuego (Sims 1995). The Chilean government overruled opposition and gave permission to the company to begin logging in mid-1996.

An American conservationist, Douglas Tompkins, has preserved some of these forests. He purchased 741,000 acres in the southern province of Palena with more than $12 million from his clothing chain, Esprit. The cost of these beautiful forests, at $17 per acre, was miniscule in comparison to the cost of preserving temperate rainforests in the United States. Save•the•Redwoods League, an American conservation organization founded in 1918, recently celebrated its 75th anniversary, having spent $73 million to save 260,000 acres (about one•third of Tompkins™ acquisitions in Chile) of Coastal Redwoods at an average price of $280 per acre (National Geographic Society 1993). Most of the acreage of American old-growth redwoods that has been saved was purchased decades ago, and today it is worth hundreds of thousands of dollars per acre. The timber saved by the Save-the-Redwoods League is worth more than $5 billion (National Geographic Society 1993).

Tompkins' land includes South America's largest block of virgin temperate rainforest, protecting 78 percent of the remaining old-growth rainforest in Chile, including the country's largest remaining virgin stands of Chilean Larch or Alerce (*Fitzroya cuppressoides*) (Bowermaster 1995). This endemic and ancient tree grows to heights rivaling North American Coast Redwoods, with girths nearly as great as Sequoias (*Sequoia dendron*) (Dorst 1967, Walter and Gillett 1998). These majestic trees can live up to 4,000 years and take 500 years to reach commercial size. Extremely slow to reproduce, Alerces do not produce seed until 200 years of age. Like redwoods, they are highly coveted for their lumber and have been cut with little regard to conservation. Highly endangered in Argentina and Chile (Walter and Gillett 1998), few groves of these trees remain, and although officially protected, they are sometimes illegally cut for the international timber market.

Tomkins came under attack by Chilean politicians and leaders of the Catholic Church who questioned his motives in purchasing such a large area and objected to his organization, the Foundation for Deep Ecology, for its statements about the importance of birth control to prevent human overpopulation (Sims 1995). Others falsely accused him of razing forests, setting up a nuclear dump, promoting abortion and even importing Israeli commandos. Many objected to private ownership of extensive areas of land by foreigners or disliked the idea of large-scale land preservation, but a Chilean conservation organization, the National Committee for the Defense of Fauna and Flora, rallied to his defense. After much contention, the Government of Chile accepted Tompkins' gift of 677,000 acres as a park in July 1997 (Grove 1999). It is known as Pumalin National Park and is considered one of the most ecologically important national parks in South America.

In an ominous note, part of the agreement with the Chilean government allowed access to the park by mining companies. The forest will not be logged, and there are plans for tourist accommodations and trails for hiking. This land is spectacularly beautiful, with glacial lakes and waterfalls, bisected by pristine rivers, its ancient forests teeming with wildlife. Covering the entire width of Chile, it borders a magnificent coastline with abundant marine mammals and sea birds. If preserved with care, the park will prevent the extinction of Chilean Larch and at least a portion of the magnificent southern beech forests which have been destroyed elsewhere. Ecotourism is being developed in the park

area on a very small scale, with rustic accommodations, and tours from the United States and elsewhere are now visiting the park regularly. Not far to the north, the Parque Nacional Huerquehue preserves some of the magnificent scenery of this region. Known as the Lake District, portions of old-growth rainforest are protected in a landscape of crystalline lakes, waterfalls and churning rivers.

Another tree that survives from the Jurassic, the Monkey Puzzle Tree (*Araucaria imbricata*), has a somewhat larger range in South America. It is a member of a family of primitive conifers, the Araucaria, that grew on Gondwana. Monkey Puzzle Trees are being logged for timber and displaced by development, cattle ranches and mines. Named for their dense and interwoven crowns said to puzzle monkeys climbing them, the wide, unbranched trunk is covered in leathery bark in a knobby, diamond-shaped pattern. The nuts produced by these trees have been prized by the native Malpuche people for thousands of years. Malpuche means "People of the Monkey Puzzle Tree," and traditionally they did not overexploit these trees. Commercial exploitation of the nuts in local markets is threatening the species by leaving too few seeds for regeneration. Extracts from the Monkey Puzzle Trees have shown promise as a birth control drug, a traditional use by native peoples.

Like the Alerce, Monkey Puzzle Trees live to be very old, at least 1,300 years, and trees of the Araucaria family are considered the progenitor of all pines (Grove 1999). (See photographs in Grove 1999, and Dorst 1967.) When the Discovery Channel-BBC producers of the documentary film, fiWalking With Dinosaurs,fl searched for living landscapes in which to place their animated dinosaur models, an open forest of Araucaria trees in Chile was selected as an authentic backdrop, having changed little since dinosaurs fed on their crowns. The book based on this film has photographs of Araucaria forests from the movie (Haines 1999). Thirty-eight species of Araucaria survive, distributed in South America, New Zealand, Fiji, New Caledonia, Australia and Norfolk Island north to Malaysia. More than three-fourths of these, 30 species, are threatened with extinction, according to the *1997 IUCN Red List Plants* (Walter and Gillett 1998).

Another family of trees dating back to Gondwana, the podocarps, are also extremely primitive evergreens. Podocarps often have straight, unbranched trunks and clumps of dense needles near the trunk. Like the Araucaria, many of the species in the family are in decline: of 125 species worldwide, 70 are threatened (Walter and Gillett 1998). Two of these inhabit the southern rainforests of Chile and Argentina, and others survive in more tropical climates in Venezuela, Bolivia and Brazil, Madagascar, New Caledonia, Fiji, New Guinea and Malaysia. Australia and New Zealand have more temperate climates and many native podocarps.

A threatened bird native to the old-growth forests of Chile and southern Argentina is the Slender-billed Parakeet (*Enicognathus leptorhynchus*), one of the few members of the parrot family that can survive cold climates. It has undergone steep declines in recent years as a result of forest clearance (Forshaw 1989). At least 22 bird species are restricted to Chilean *Nothofagus* forests, making this region a center of endemism (Cracraft 1985).

The most endangered denizen of southern rainforests may be the South Andean Huemul (*Hippocamelus bisulcus*), a short•legged, stocky deer that once lived throughout this habitat in Chile and Argentina. Driven from most of its haunts by the introduction of European deer, cattle ranching, logging and hunting, they now survive only in the extreme south of Chile, in tundra•like terrain with elfin woodlands. Low, gnarled trees are whipped by the strong ocean winds from Antarctic regions (Dorst 1967). No more than 1,300 South Andean Huemul are thought to remain (Nowak 1999), and a campaign has been launched to save these deer (Stutzin 1995). The National Committee for the Defense of Fauna and Flora and the Frankfurt Zoological Society are researching their status and raising money to purchase sufficient habitat for their survival (Stutzin 1995). Two reserves protect about 100 Huemul, but as the target of meat poachers throughout their range, they are found only in inaccessible areas. Researchers studying these deer, which had never had contact with humans, found them completely unafraid, grazing and bedding down within feet of their tents. This tameness makes them especially vulnerable to poachers.

Without immediate habitat protection and guarding of the remaining deer, the Huemul may not last long. Their status has declined even in national parks within the past few years. Alejandro Frid, a biologist who found these deer

living in pristine habitat along a fjord in extreme southern Chile in a 1990 study, returned in 1995 to find near-disaster. Cattle had been set free in the Bernardo O'Higgins National Park, displacing the Huemul from their prime grassland habitat and forcing them into the sparse vegetation of the uplands (Frid 1997). He was told by a local ex-poacher that illegal hunting by local fishermen still occurred, and the lowland habitat was so trampled by the cattle that it was covered in muddy pits (Frid 1997). Ironically, the owners of the cattle did not eat beef but were adopting European cultural traditions, and since this harsh region did not provide good habitat, the cattle were not in good condition (Frid 1997). Conservationists are working to have the cattle removed from the national park, and international organizations are working to protect remnant populations of these deer. On the Straits of Magellan, where other South Andean Huemuls survive, commercial logging corporations are clearing forests (Frid 1997). The introduced Elk (*Cervus elaphus*) competes for habitat, and many Huemul are killed in attacks by domestic dogs (Nowak 1999). The South Andean Huemul and its close relative the North Andean Huemul (*Hippocamelus antisensis*) are both listed as Endangered on the US Endangered Species Act. This listing may not prevent their extinction, however.

The world's smallest deer, the Southern Pudu (*Pudu puda*), also inhabits southern temperate rainforests. This dog-sized deer is short-legged, with thick, buffy, reddish-brown fur and small, spike-like antlers. It is so diminutive, weighing only 5.8 to 13.4 kilos (Nowak 1999), that people have captured them as pets, which has contributed to their rarity. Its range within Chile was once far more extensive (Nowak 1999). The major threat to this species and its close relative, the Northern Pudu (*Pudu mephistophiles*) of the Andes of Peru through Colombia, is forest destruction. *Pudu puda* is listed as endangered on the US Endangered Species Act and on Appendix I of CITES, banning commercial trade, but hunting still threatens it.*

---

*Many trees of the southern beech forest, the South Andean Huemul and Pudu deer appeared in the 1997 film, fiChile, Land of Extremesfl (see Video, Central and South America section); the trees were photographed in *Living Planet, Preserving Edens of the Earth* (Grove 1999).

New Zealand

New Zealand was formed some 80 million years ago when it broke off from the tropical southern continent, Gondwana (Molloy 1994). The land mass moved away with resident pterosaurs, sauropod and carnosaur dinosaurs, along with primitive frogs, lizards, land snails, spiders and other insects and invertebrates. It is also possible that the ancestors of the flightless moas and kiwis were present on Gondwana (Heather and Robertson 1997).

Unlike South America, New Zealand remained uninhabited by humans until a thousand years ago, allowing an extraordinary fauna and flora to evolve. Giant trees of many types, some almost as massive as sequoias and others rivaling American Coast Redwood in height, thrived in primeval rainforests and swamps. The dinosaurs died off 65 million years ago simultaneous with their extinction elsewhere in the world. Over the eons, as the land moved southward, the climate cooled. Many tropical species, unable to adapt, died out, while others coexisted with immigrant species of plants, birds and insects that arrived by wind or ocean current. Geological and climatic events--from earthquakes and mountain uplifts caused by movements in the Earth's plates, to the weathering of wind, sun and rain--produced great changes in the topography over the millennia. The original land mass split into two main islands and many satellite islands, and snow-capped mountains rose on the southern island. Ice Age glaciations occurred during the Pleistocene between 2.4 million years and 10,000 years ago (Molloy 1994). These cold periods did not, however, eliminate the majority of ancient plant or animal species, another proof of their amazing adaptability.

When the Polynesian Maori people arrived about 1,000 A.D., temperate rainforests with understories of giant tree ferns grew throughout the island's swamps, lowlands and highlands, over 80 percent of the land. The Maori must have been stunned to see thousands of flightless birds of various sizes roaming the island. The moas had evolved from a single ancestor into some 11 species which grazed in herds or in small groups. Following the extinctions of the dinosaurs, moas evolved in a wide range of species able to browse vegetation in forest, shrubland and grassland habitats (Molloy 1994). The native plants developed thorns and other means of defense against the moas. These plant adaptations persist today, long after the disappearance of the moas, remnants of a bizarre and fascinating ecosystem. These emu-like birds ranged from chicken-sized to a species 10 feet or more in height, the tallest bird that ever lived. With heads disproportionately small and necks long and gangly, these down-covered birds walked about on thick, scaly legs. Also resident on the islands was a massive eagle, weighing up to 29 pounds (Molloy 1994). This giant bird of prey was the largest eagle to have ever lived on Earth and may have preyed on moas or soared about in search of moa carrion.

On the southern island, penguins lived on rocky coasts and in wet coastal rainforests; one species was a giant, standing more than 5 feet tall (Molloy 1994). No mammals other than bats were native. Lizards called tuataras, older than dinosaurs, lived in many habitats on the islands. Primitive and unusual frogs of types long extinct elsewhere were abundant, especially in mossy rainforests. Huge, cricket-like wetas, insects virtually unchanged for 200 million years, had evolved into 70 species. Compared to grasshoppers, wetas have heavy bodies, weighing as much as 2.5 ounces. Scurrying about at night, their diet and behavior are rodent-like. They are considered by zoologists to be among the most interesting animals on the islands (Molloy 1994).

The forests were dominated by trees very little changed since the age of the dinosaurs. Three major groups of trees, all evergreens, dominated New Zealand's forests, survivors of the Cretaceous Era 135 million years ago: araucaria, podocarps and southern beeches. All had close relatives in South America and other parts of the world.

A single species of the Araucaria family, to which the South American Monkey Puzzle Tree belongs, dominated forests on North Island. The enormous Kauri (*Agathis australis*) has a massive, wide trunk that rises to great heights before branching in a wide canopy. Its gray, grainy bark forms deep, vertical ridges that curve upward, wrapping around the tree as it rises hundreds of feet into the air. Verdant tree ferns, with large, short trunks, and primitive club mosses form an understory beneath them.

Seventeen species of podocarp trees survive in New Zealand, some of which reach great heights. New Zealand's tallest tree is the Kahikatea (*Dacrycarpus dacrydioides*), or New Zealand Cedar, a type of podocarp which is nearly as tall as Coast Redwoods but with a slimmer trunk, often covered in epiphytic plants (Molloy 1994). Podocarp forests were once very widespread throughout both North and South Islands, each species in a slightly different habitat (Molloy 1994). At the other extreme is the world's smallest conifer, the ankle-high Pygmy Pine (*Lepidothamnus laxifolius*), a podocarp growing at high altitudes in a beautiful area known as the Southern Alps on South Island (Molloy 1994). Another podocarp type, the Celery Pines (*Phyllocladus spp*), are small trees whose leaves are actually flattened stems. One podocarp, *Halocarpus kirkii*, is listed as Threatened by the International Union for the Conservation of Nature (IUCN) (Walter and Gillett 1998), and all have declined dramatically in range.

Southern beeches of *Nothofagus*, the same genus as those in South America, once blanketed South Island in dense, canopied forests, often without an understory of plants other than low ferns (Molloy 1994). Today some forests remain, growing in association with broadleafed trees and hardwoods that arrived in New Zealand at a more recent time (Molloy 1994).

Some extremely primitive plants have also survived in New Zealand. The largest moss in the world (*Dawsonia superba*), giant liverworts, clubmosses and horsetails are among these (Molloy 1994). *Tmesipteris*, an epiphyte, is a relict of the earliest vascular plants, which evolved some 400 million years ago. This rootless plant clings to the branches of trees and hangs in vine-like, leafy strings. New Zealand's forest floor plants, a micro-world of species, most of which are less than an inch high, are beautifully photographed and described in *The Forest Carpet* by Bill and

Nancy Malcolm (1989), a book devoted to New Zealand's mosses and related plants.

Other survivors from Gondwana include an extremely ancient family of spiders, Archaeidae. First described from a specimen frozen in amber several million years old, seven species have been found on Madagascar, also a part of Gondwana: one in South Africa, three in Australia, five in New Zealand and one at the tip of South America (Preston-Mafham 1991). The Archaeidae spiders have strange, grotesquely shaped bodies, visible only through a microscope since they are only 0.14 inches long; they live among leaf litter on the ground (Preston-Mafham 1991).

The beauty and primitive auras of many of the Kauri, beech, podocarp forests and pristine forest swamps evoke a "bygone era when dinosaurs still roamed the Earth" (Molloy 1994).* Beech and podocarpus forests cover South Island's Fiordland, a region along the southeastern coast resembling Norway's fiords, with inlets penetrating deep inland, lined by misty forests. The trees are buffeted by fierce winds from the west that bring rainfall of up to 20 feet a year. In this rugged wilderness, mosses and huge tree ferns thrive in the dampness.

---

*Many of the primitive landscapes that survive in New Zealand were captured in Gerald Cubitt's photos in *Wild New Zealand,* accompanied by natural history information in the text by Les Molloy (1994). Also, two films, fiLand of the Kiwifl and fiMountains of Water,fl described in the Video section, display these vistas.

The moas, which must have been very tame and unafraid, were hunted by the Maoris, who lived on their meat and eggs for centuries. The last of the moas, all smaller species, are said by some authorities to have survived until the 18th and 19th centuries (Greenway 1967), although this is disputed by others who assert that the moas were killed off well before the 15th century (BI 2000). Some Europeans claimed to have seen living moas, but no account was ever confirmed. Millions of their bones and eggs, and a few examples of skin, are all that now remain of these birds. The giant penguin, giant eagle and many flightless birds were also wiped out, apparently by hunting. European settlers eliminated many more species when they cleared forests and imported animals, such as dogs, cats, the weasel-like stoat that preyed on native animals, and livestock that eliminated their habitats. Apart from the moas, nine birds, one reptile and one mammal are known to have become extinct in New Zealand since 1500. One of the birds, a beautiful forest songbird, the Huia (*Heteralocha acutirostris*), was truly unique: the male and female had different sized and shaped bills. Hunted for its plumes, and with its habitat destroyed, the Huia was last seen in the late 19th century. Others, including a flightless owl; a quail; two wrens, one of which was the only known flightless songbird; a bittern; a thrush; a storm-petrel; a flightless rail; and another songbird became extinct. A gecko and a native bat also disappeared (see Appendix for a chronological list of these species).

Although the Maoris cut and burned portions of the Kauri forests, not until the Europeans arrived in the 18th century did clearcut logging begin. Captain James Cook, the first European to visit New Zealand, noted some very tall trees that were probably Kauris while reconnoitering for lumber on his visit to New Zealand on November 21, 1769: "I judged that there was 356 solid feet of timber in this tree clear of branches." Millions of these great trees were felled for lumber or to clear land, leaving only fragments of the original forests. On the Coromandel Peninsula on North Island, isolated patches of mature Kauri forest are protected in several sanctuaries where old tramways, constructed to remove the logs, still scar the landscape (Molloy 1994).

Overall, approximately 75 percent of native forests in New Zealand have been cleared for agriculture and grazing land for 60 million sheep and other livestock. Fortunately, the Government of New Zealand has set aside many large parks and reserves to preserve landscapes, forests, endemic plants and animals. Thirty percent of the islands are protected, one of the highest rates of preservation in the world. In the majority of western Europe, for example, less than 5 percent of the land is protected, and villages and residences are allowed in many national parks. Not all New Zealand's ancient forests are safe from logging, however. A controlling interest in one of the last sizeable expanses of forest, 193,000 acres on the northern end of South Island owned by Fletcher Challenge Ltd., a logging company, was sold in 1997 to the US lumber company, Weyerhauser.

Many native animals of New Zealand's forests have been pushed to the edge of extinction by a combination of loss of habitat and the introduction of exotic species. Even the weta insects are in decline. Nine weta species are listed on the *1996 IUCN Red List Animals* (Baillie and Groombridge 1996). All four species of kiwis in New Zealand are rapidly approaching extinction, listed as Vulnerable or Endangered by *Threatened Birds of the World* (BI 2000). Authorities now recognize four, rather than three kinds of kiwi, and one, the Brown Kiwi (*Apteryx mantelli*), is endangered, its population having declined 90 percent since 1900 (BI 2000). Among the most ancient of bird species and possessing many unique physical and behavioral characteristics, their loss would represent as important a biological tragedy as the extinction of the moas. They have been placed in their own family, Apterygidae, an indication of their uniqueness. These flightless birds, which weigh from about 2 to 10 pounds, have small, stunted wings with claws on the end that are hidden beneath a cloak of shaggy, brown, hair-like plumage, giving them a mammalian appearance. Their long, pointed, ivory-colored bills are used to probe the leaf litter on the forest floor for earthworms and other invertebrates at night, and they can be heard snuffling as they forage. They have short, strong legs, and long, sharp claws on their toes, used for digging and fighting (Heather and Robertson 1997). Their food supply is ample: 200 species of earthworms live in New Zealand, with the largest species measuring an amazing 40 inches in length and 4 inches in diameter (Molloy 1994).

At the end of the kiwis' bills are nasal openings for their highly developed sense of smell, which aid them in detecting their prey. An acute sense of smell is a highly unusual trait in a bird. Kiwis also have sharp hearing but poor eyesight. Such characteristics are more common in mammals than birds (Hoyo *et al.,* 1992). Kiwis possess other mammal-like traits, such as two functionally alternating ovaries rather than one in the female (Feduccia 1996). In an interesting evolutionary phenomenon, where land mammals are absent, animals totally unrelated to them often develop mammal-like traits. Kiwis mate for life and live in large burrows. The single egg laid by the female is enormous in proportion to her size, weighing 20 to 25 percent of her weight. It is the largest egg, proportionally, of any bird and four times the size that would be expected for a bird her size (Hoyo *et al.* 1992). By comparison, a human mother weighing 125 pounds would have to bear a 25- to 30-pound baby. The hatching process is long and arduous, taking two to three days from the time the chick begins to break out; because the chick lacks an egg tooth, it must kick its way out of the shell with its feet (Hoyo *et al.* 1992). Many chicks die during this process. When the chick emerges at last with damp feathers, its yolk sack is still connected and nourishes it for several days. A miniature version of its parents, it is able to follow them on their nocturnal feeding trips within a few days (Hoyo *et al.* 1992). (Rare footage of incubation and hatching of a kiwi in the wild can be seen in fiBirds of Paradox.fl See Video section F, Birds.)

Kiwis are totally unable to protect themselves against predators, such as dogs, cats, stoats and introduced Australian Brush-tailed Possums (*Trichosurus vulpecula*), who kill them or prey on their eggs (BI 2000). At least 94 percent of kiwis die before adulthood as a result of this predation (BI 2000). The possums also destroy rainforest vegetation by browsing on canopy leaves, epiphytic and ground plants; they have exterminated a native mistletoe (Molloy 1994). Non-indigenous animals have effectively eliminated kiwis from all but a few remote parts of their original ranges. At least one reserve, the 290-square-mile Coromandel Forest Park, has erected a fence within the Kauri forest to keep out possums, protecting kiwis and other native birds (Molloy 1994). Elsewhere, kiwis are being killed by predators; official government protection since 1908 has not stopped their continued decline. Feral dogs killed 500 Brown Kiwis in a population of 900 in less than two months in the early 1990s (Hoyo *et al.* 1992). Another cause of mortality has been steel-jaw leghold traps and poison set out to capture Brush-tailed Possums, although recently the use of traps has been regulated to prohibit any possible capture of kiwis (Hoyo *et al.* 1992). Dependence on humid rainforest habitat has also been a major factor in their disappearance, as this habitat has been destroyed by logging, fire and agriculture (Hoyo *et al.* 1992). Many kiwis are burned to death in the intentionally set fires that follow logging operations, as their shallow burrows do not protect them from the smoke, heat and flames. Often they are afield when fires are set and die in the fires. Those not killed lose their habitat when the humus and leaf litter essential for their feeding is consumed in the fires.

The Little Spotted Kiwi (*Apteryx ownii*) is the smallest and rarest kiwi, numbering only about 1,100 birds (BI

2000). A population of about 950 birds inhabits the 20-square-kilometer Kapiti Island off the southwest coast of North Island (Collar *et al.* 1994), where it was introduced from the mainland. Another introduced population on Tiritiri Matangi Island, a sanctuary of 543 acres off the northern coast of North Island, has adapted well (Molloy 1994). At one time, this kiwi was found throughout the main islands (Hoyo *et al.* 1992). In the summer of 2000, Little Spotted Kiwis were returned to a reserve on the mainland, a step toward their recovery. The Great Spotted Kiwi (*Apteryx haastii*), the largest species, is confined to forests in extreme northwestern South Island in the southern Alps (Heather and Robertson 1997). Although its habitat here is protected, its numbers are still declining from predation (Collar *et al.* 1994). At present, no Great Spotted Kiwis are living on a predator-free out-island (Heather and Robertson 1997), and only one small population is protected by controlling predators (BI 2000).

Another highly endangered bird, and a species almost as bizarre as the kiwi, is the Kakapo or Owl Parrot (*Strigops habroptilus*). The world's heaviest parrot, it weighs up to 3.5 kilograms and is the only living flightless member of the parrot family. It is also one of the rarest birds in the world. Once native to all but the highest mountain altitudes on North, South and Stewart Islands, Kakapos probably numbered in the tens of thousands (Collar *et al.* 1994, Forshaw 1989). They may have flown to the islands at a very early date, long before the land split into North and South Islands, and gradually lost their ability to fly. These 2-foot-long parrots have dull green plumage, mottled with brown, that blends into the vegetation of their rainforest habitat. Known as the Owl Parrot because of large eye discs and nocturnal habits, the Kakapo has another distinction in being the only member of the parrot family to gather in male groups near a bare area where "lek" displays are performed for females during breeding season. Males call females to the lek with loud, low-frequency, booming sounds emanating from their thoracic air sacs. These calls are audible to humans from as far as 3 miles away (Molloy 1994). They perform these booming calls for six to eight hours a night throughout the three- to five-month breeding season, which takes place only every three to five years under normal conditions (Heather and Robertson 1997). Very placid and slow-moving, they are unable to defend themselves against the rats, cats, stoats and dogs that Europeans brought to the main islands.

The range of the Kakapo began shrinking with the arrival of Maoris and their domestic animals, but in 1800 they were still common in central North Island and parts of South Island where their habitats had not been destroyed (Heather and Robertson 1997). The European Stoat, introduced to the islands in the 1880s, proved an efficient predator of these parrots, eliminating them entirely from North Island and all but remote parts of South Island. In 1970, a survey revealed that only 18 Kakapos remained--all males--in Fiordland, South Island, and these last birds were gone by the early 1990s (Heather and Robertson 1997).

Fortunately, a previously unknown population of 100 birds was discovered in 1977 on Stewart Island, a fairly large island due south of South Island, but these birds were under attack from feral cats (Heather and Robertson 1997). After a decade of decline, all the remaining 61 Kakapos were transferred from Stewart Island by the New Zealand wildlife department to predator-free islets located off North and South Islands (Heather and Robertson 1997). In 1997, a lone female was discovered on Stewart Island and was removed (BI 2000). This rendered the species extinct throughout its original range. Unfortunately, many of the parrots starved to death in their new environments because these islets lacked sufficient food. Their natural diet of fruits, berries, nuts, fern fronds, roots, tubers, moss and fungi was abundant in the temperate rainforests and tussock grasslands of the main islands. A 1983 BBC documentary, fiBirds of Paradoxfl (see Video section), filmed a Kakapo chick being fed by its mother, who walked over steep terrain 3 miles each night to obtain seeds and other food for her offspring. Kakapos can live for as long as 70 years, and this longevity has prevented their extinction, since many years pass without any successful breeding. New Zealand wildlife officials finally provided supplemental feeding, which immediately resulted in the first surviving chicks in a decade in 1991. A population of 62 birds survived in 1999, of which 26 were females and 36 males, including six chicks (WC 2000). Although their numbers are slowly growing, many of the males appear to be sterile, and others have been filmed calling alone, rather than in male groups; some seem to be calling in vain, with no females responding (Hynum 1999). An Internet website has been established to monitor these extraordinary birds: www.kakapo.net.

Many other native songbirds, shorebirds, reptiles and amphibians are threatened in New Zealand, and some survive

only on offshore islets where predators are absent or have been eliminated. New Zealand has had success in eliminating cats and possums from several sizeable islands off the main islands, but on North and South Islands, rats, cats and stoats, as well as European deer and goats, are uncontrolled (Molloy 1994). Some 70 million Brush-tailed Possums live throughout both islands, and they are now endangering forest birds by preying on eggs and chicks (Molloy 1994). Exotic plants have also invaded forests, smothering native plants and choking lakes (Molloy 1994). There is, however, a remarkable awareness in New Zealand of these conservation problems and its extraordinary natural heritage. Moreover, the government agencies dealing with wildlife and the environment, TV New Zealand Natural History (which makes superb wildlife films), and scientist-writers such as Les Molloy (1994) are educating the public about this natural legacy, much of which has endured for hundreds of millions of years. Contributions of funds and expertise from many nations and organizations might aid New Zealanders in their conservation work.

Australia

Australia's temperate rainforests are very similar to those in New Zealand, and fragments persist in portions of eastern and southeastern Australia. Relatives of the Kauri, the Nothofagus beeches, and podocarpus trees are native. An exciting botanical discovery was made in one of these forests in 1994. Named the Wollemia Tree (*Wollemia noblei*) after the national park where it was discovered, it is a member of the Araucaria family and somehow escaped attention until 1994. A species familiar to botanists through fossil records, it was thought to have become extinct 50 million years ago (Wilford 1994). A botanist noticed an unusual tree in Wollemi National Park in New South Wales, southeastern Australia and, when he investigated closely, found its fern-like leaves and other proof that it was indeed a living fossil (Wilford 1994). About 23 of these "living fossils" have been located in the park, the tallest towering 130 feet with a 10-foot girth and the species is being propagated by the Australian government. At a press conference soon after its discovery, Ken Hill, botanist at the Royal Botanic Gardens in Sydney, exhibited a fossil imprint of the Wollemia's fern-like leaves next to the living branches for news media, stating that it was one of the outstanding biological discoveries of the century (Wilford 1994). Pictures of these trees were shown on television news programs around the world, an indication of the new appreciation being accorded such natural wonders. These massive pines have dense, waxy foliage and knobby, dark bark with strange-shaped branches growing from the trunk (Wilford 1994). They were found growing in a secluded area of little more than an acre, deep in the national park, where high humidity and moisture probably protected them from fire and provided ideal habitat (Wilford 1994). Had these priceless trees not survived in a national park, they might have been cut for firewood or commercial logs long ago. Wollemi National Park's protection was considered a great triumph for Australian conservationists. It contains the country's largest area of undisturbed forest--more than 486,400 hectares (1,201,894 acres) (Campbell 1989). The Colo River, the last unpolluted waterway in New South Wales, flows through the park. Other trees in this park include tall eucalyptus, which predominate; Snow Gums; Mallees; and pockets of rainforest in gullies (Campbell 1989).

Four species of Australian Podocarps are listed by the *1997 IUCN Red List Plants*. They range from Queensland's rainforests to temperate rainforests in New South Wales and Tasmania. Such forests, with their tall, evergreen trees and understories of tree ferns, are very rare today as a result of climatic change, a gradual drying of the continent and logging. Eucalyptus trees, which can withstand a dryer climate, gradually increased in range in Australia's temperate rainforests since they appeared in the Oligocene Epoch 35 million years ago (Vandenbeld 1988). They first colonized forest edges and flourished in open woodlands, then grew into entire forests growing from Queensland south to Tasmania, having radiated into 500 species (Vandenbeld 1988).

From New South Wales south to Tasmania, Nothofagus beech forests have been edged out by eucalyptus but remain in a few areas, a glimpse of the past. Mosses, ragworts, rotting logs, ferns and tree ferns carpet the forest floor, similar to those growing farther east in southern New Zealand (Vandenbeld 1988). European colonists logged these forests to clear the land for farms and grazing. The ancient eucalyptus, with their massive trunks, dwarfed the teams of oxen that dragged out the logs. This primeval forest is now almost gone. A 19th century artist, Isaac Whitehead,

depicted a magnificent old-growth forest being logged in a dramatic painting showing trees that must have had circumferences of well over 50 feet. If not for the huge stumps that remain, one might have doubted that they actually existed (Vandenbeld 1988).

Forty percent of the country's forests have been cleared, including 75 percent of the rainforests in northern Queensland and 90 percent of both the dry mallee of the south and the eastern temperate woodlands (Parfit 2000). Logging had a devastating effect on the continent's woodland mammals who depended on the forests for survival. Of 144 marsupials inhabiting Australia 200 years ago, 21 are extinct, and a total of 88 Australian marsupials are listed in the *2000 IUCN Red List Species*. Many of these were forest species. Australia has had more mammals become extinct over the past few centuries than any other country in the world. The majority of forests in Australia did not revert to second-growth but became grazing land, plantations, agricultural fields, or tree farms of non-native pines for pulpwood (Vandenbeld 1988).

The eucalyptus forests that came to dominate many of Australia's woodlands are interspersed with savannah in the dryer north. In the south, they grow in dense, moist woodlands, with tree ferns and mosses as ground cover. Among the most characteristic trees of Australia, almost all the great old specimens are gone. Few Australians have ever seen a gigantic, 400-year-old eucalyptus tree, so massive that it takes 15 people to embrace its girth, but such trees were once common (Sharp 1995). It takes 200 to 300 years for a eucalyptus to form nesting holes that provide homes for possums, gliders, bats, snakes, birds, parrots and other creatures that were once prolific in Australia (Sharp 1995). The tallest trees in Australia, many eucalyptus stand more than 300 feet high (Attenborough 1995). In 1880, just before cutting it down, a surveyor measured a eucalyptus that stood 375 feet tall; another inspector around the same time told of a fallen trunk that was 435 feet long (Attenborough 1995). Had this been confirmed, it would have been the world record for the tallest tree ever measured (Attenborough 1995). Their straight, unlimbed trunks rise to great heights before branching. Settlers cut them for building materials and railroad ties, clearing vast areas and threatening many species. An astounding 175 species of the genus *Eucalyptus* are listed on the *1997 IUCN Red List Plants*.

In central Queensland, 5 billion eucalyptus trees were cut to create permanent grazing land for up to 2 million cattle. Up to half of the trees in 100 million hectares in this Australian state have been cut (Arnold 1994). The last forests of Queensland are being cleared for livestock and agriculture at one of the highest rates of deforestation in the world, estimated at 840,000 acres a year (Parfit 2000).

Koalas (*Phascolarctus cinereus*), native to eastern Australia's eucalyptus forests, are entirely dependent on the leaves of these trees for their food. Most animals avoid eucalyptus because the leaves contain toxic oils, but Koalas have the ability to detoxify these oils, which also gives them a natural insect repellant (Berra 1998). They eat about 36 species of eucalyptus and obtain most of their moisture from dew and the leaves (Berra 1998). Forest clearing has had a disastrous effect on their populations. The last large population of Koalas in southeast Queensland was decimated by construction of an expressway, over vehement opposition from citizen groups (Arnold 1994). Likewise, in the state of Victoria in the southeast, Koalas have been reduced to a few remnant colonies as a result of hunting, development, tree cutting, highways, fires, droughts and predation by dogs and foxes. At least 4,000 Koalas are reported killed each year, and about 2,500 of these die after being struck by cars near urban areas (Berra 1998). They have also been victims of a variety of illnesses, including *Chlamydia*, which causes reproductive failure, pneumonia, blindness and other ailments (Berra 1998). They have declined so dramatically that in 2000 the species was listed as Threatened on the US Endangered Species Act.

Outside of protected areas, the last old-growth forests in New South Wales are being cut. The government accorded a giant multinational corporation, Boral, a contract to cut 500,000 tons of woodchips in the mid-1990s. (Arnold 1994). This logging will remove virtually every native forest not protected in national parks in northeast New South Wales, according to Sue Arnold, Coordinator of Australians for Animals (Arnold 1994).

Victoria still retains some old-growth forest, home to a host of rare animals. Old eucalyptus tower over tree ferns, sassafras, mountain pepper and mosses. In 1999 and 2000, loggers began cutting one of the last of these forests

known as the Goolengook Forest (*EarthFirst! Journal* 2000). Aborigines have been able to stop logging in some traditional areas, including East Gippsland, Victoria, but the delicate and endangered native marsupials inhabiting most of these forests may not survive for long.

A strange mammal of Victoria's eucalyptus forests is Leadbeater's Possum (*Gymnobelideus leadbeateri*). Native to the Central Highlands, it lives in colonies in tall, old-growth eucalyptus trees (Strahan 1995). Thought extinct, this marsupial was rediscovered in 1961. With a tail almost twice the size of its body, huge black eyes and a stripe down its back, this possum looks like a cross between a squirrel and a skunk. Each night, it emerges from tree hollows to climb tall trees in search of insects. Forest clearing has destroyed much of its mountain forests (Nowak 1999). Only about 5,000 or fewer Leadbeater's Possums survive, and the species continues to decline as logging clears its habitat (Kennedy 1992). Its dependence on large trees, especially those 300 or more years old which have large tree holes for their nests, has made it very rare (Strahan 1995). Specializing in finding crickets, beetles, spiders and other arthropods beneath the shedding bark of eucalyptus and other trees, it may require, for an as yet unknown reason, a particular species of tree cricket which shelters under the bark of a certain type of eucalyptus (Strahan 1995). This possum also eats gum and tree sap. Less than 3 percent of its total range of 4,000 square kilometers is protected in nature reserves, and 75 percent is located in timber-production forests where tall, old trees are likely to be cut (Strahan 1995).

Tropical Forests

Tropical forests have, for the most part, evolved in stable environments over a period of millions of years, untouched by the recent Ice Ages. The oldest forests on Earth may be in Borneo where the same species of towering trees have been growing for 250 million years. Climates in tropical forests tend to be uniformly warm year-round, with half the year rainy, and the other half dryer but not without rain. Tropical trees generate enormous amounts of moisture. In some parts of the world, the climate has changed over the ages, resulting in islands of forests surrounded by grassland or other habitats. Many scientists theorize that some forests, including the Amazon and African rainforests, went through such climatic changes during the Ice Ages (Collins 1990). Isolation might explain the evolution of a great number of endemic species in these regions, which today are continuous forest. These tropical forests are showcases of evolution.

Tropical forests vary greatly according to altitude, region and species of trees. Each has a different micro-climate, soil type, fauna and flora. They grow in tropical latitudes 30 degrees to the north and south of the Equator (Collins 1990). Among the many types of tropical forests are evergreen wet forests, deciduous dry forests, mountain cloud forests, and mixed lowland rainforests. In general, lowland rainforests are the most biologically diverse, as well as the most endangered. Covering only 7 percent of the Earth's surface, rainforests harbor half its species (Lean and Hinrichsen 1992). Biological research in tropical forests has consistently shown that this great diversity helps stabilize ecosystems and the very life support systems of the planet.

Some tropical forests have been characterized as "hotspots," having exceptionally high diversity of endemic species that are found nowhere else on Earth. All are threatened by deforestation. Two studies by ecologist Norman Myers in 1988 identified 10 highly endangered and biologically diverse tropical forest hotspots in the world; in 1990, he revised that number to 18 (Myers 1988, 1990; McNeely *et al.* 1990, Mittermeier *et al*. 1999a). Myers pointed out that the 10 hotspots named covered only 0.2 percent of the land surface of the world, but contained 27 percent of the plants and also a high percentage of endemic species. *Hotspots*, a book by Russell Mittermeier, President of Conservation International, and other biologists and ecologists, describes 15 tropical forest hotspots throughout the world among a total of 25 hotspots of all types of ecosystems. The high diversity in tropical forests is reflected in the fact that these hotspots covered 61 percent of the land area of all hotspots identified in the study. Many have lost 90 percent or more of their original forests and continue to decline. Originally, these extremely diverse tropical forests

covered 10,635,513 square kilometers; at present, only 1,246,538 square kilometers remain, a loss of 86 percent (Mittermeier *et al.* 1999a). These tropical forest hotspots cover only 0.08 percent of Earth, but harbor 205,789 plant species and 21,903 vertebrate species other than fish (Mittermeier *et. al.* 1999a), a large percentage of the some 248,428 named vascular plants and 23,524 non-fish vertebrates (Wilson 1988). One can only wonder what diversity these areas had prior to their near-destruction. Such astounding facts should result in strong programs to preserve these regions, all of which are being degraded.

The tropical forest hotspots include the Caribbean, Central America, Brazil's Atlantic Rainforest, western Ecuador's Choco region, Andean tropical forests, Indo-Burma, the Philippines, Indonesia and Peninsular Malaysia, the Western Ghats of India, Madagascar, New Caledonia, Polynesia and Micronesia, Guinean Forests of West Africa, and mountains and coastal forests of Tanzania and Kenya (Mittermeier *et al.* 1999).

The richest and most diverse hotspot on Earth is found in the tropical Andes, stretching from western Venezuela to Chile and Argentina (Mittermeier *et al.* 1999a). This area has innumerable isolated valleys, slopes, and peaks in many altitudes, all physical characteristics that contribute to the evolution of a great array of plants and animals. Covering 1,258,000 square kilometers, these forests are interspersed with alpine vegetation and grassland. Between 45,000 and 50,000 kinds of plants are found here, 20,000 of which are found nowhere else (Mittermeier *et al.* 1999a). Birdlife is prolific, with 1,666 species, 41 percent of which are endemic. Andean Cock-of-the-Rocks (*Rupicola peruviana*), threatened Toucan Barbets (*Semnornis ramphastinus*), the giant Andean Condor (*Vultur gryphus*), also a threatened species, and the greatest variety of hummingbirds in the world are resident (Mittermeier *et al.* 1999a). The critically endangered Yellow-tailed Woolly Monkey (*Lagothrix flavicauda*) is native to a few Peruvian cloud forests, and the Spectacled Bear (*Tremarctos ornatus*) and Mountain Tapir (*Tapirus pinchaque*) are other endangered species of the region. Deforestation has destroyed much of the region through slash-and-burn farming and extensive cultivation of opium poppies, which are controlled with herbicides that poison rivers and streams, suspected to cause declines in frogs and toads (Mittermeier *et al.* 1999a). Several national parks have been set aside, including the Madidi and Tambopota National Parks on the Peru-Bolivia border, covering some 2,225,000 hectares.

The Atlantic forest of southeastern Brazil, another hotspot, has been reduced by 92 percent, yet it has been found to contain the greatest diversity of trees in the world: 476 species in a plot of only 2.5 acres, including 104 previously unknown tree species. By contrast, a plot of similar size in a North American temperate forest has only about 20 species of trees. A much larger plot, totaling 129 acres, in an old-growth forest in Malaysia's Lambir Hills National Park has an astounding 1,175 tree species (NGS 1997). This site is surrounded by farms, and nearby forests have been logged to the forest's boundaries. Both sites are tropical forest hotspots.

Africa's tropical forests once stretched in a wide band from Sierra Leone east through Zaire to Uganda and Kenya, and south to Angola. Of the original 3,620,000 square kilometers, less than half, or about 1,760,000 square kilometers, remained in the early 1990s (Martin 1991). The worst damage has occurred in West Africa where logging and clearance for plantations and villages have destroyed at least 85 percent of its rainforests (Collins 1990, Mittermeier *et al.* 1999a). Even the now-extensive forests of the Democratic Republic of the Congo and neighboring countries are being logged so rapidly that, outside reserves, they will have disappeared in 50 years, according to a 1997 study. A primate anthropologist, John F. Oates, researched the destruction of West African forests and the role played by international loan agencies such as the World Bank and the Ford Foundation. His book, *Myth and Reality in the Rain Forest. How Conservation Strategies Are Failing in West Africa* (Oates 1999), carefully documents the establishment of forest sanctuaries that did not protect forests and their wildlife, but encouraged logging, farming and bushmeat hunting. Almost no forest or sanctuary in West Africa is protected from logging, wildlife killing or capture, or other destruction. The rainforests stretching from Sierra Leone east to western Cameroon and the Gulf of Guinea islands of Equatorial Guinea comprise one of the world's most endangered hotspots for biological diversity (Mittermeier *et al.* 1999a). They covered 1,265,000 square kilometers a few hundred years ago, but have been reduced to only 182,348 square kilometers, or 14.4 percent of the original; of the remaining forests, only about 126,500 square kilometers are pristine forest, a scant 10 percent of the original (Mittermeier *et al*. 1999a). These forests are fragmented and largely unprotected. Some 9,000 species of plants exist in this region, of which 2,250 are

endemic (Mittermeier *et al*. 1999a).

Some of the world's most fascinating and unusual wildlife species can be found here as well, including the world's largest frog, the threatened, 3.3 kilogram Goliath Frog (*Conraua goliath*), which inhabits mountain streams in Cameroon. The Western Chimpanzee (*Pan troglodytes verus*) of these forests is highly endangered by forest clearance and killing for the meat trade. Like the Chimpanzees of Kenya studied by Jane Goodall, they are tool-using, employing stones to crack open hard nuts on logs. They may be a completely different species of chimpanzee (Mittermeier *et al.* 1999a). Forest Elephants (*Loxodonta africana cyclotis*) are vital to forest ecosystems as seed dispersers and to open up forest glades for wildlife, such as the threatened White-breasted Guineafowl (*Agelastes meleagrides*) (Kingdon 1989). They also dig waterholes which provide a lifeline for a host of animals. Unfortunately, they are endangered as a result of deforestation and poaching. These forests also harbor many species of little forest antelope known as duikers, all less than 3 feet tall, which dart about the undergrowth in the Guinean forests. Sixteen of the 17 species are listed in the *2000 IUCN Red List Species*, declining from forest loss and intense hunting. The rarest is Jentink's Duiker (*Cephalophus jentinki*), of which only a few hundred remain. There are no individuals of this species in captivity, and no photo has ever been published of this little antelope (Martin 1991).

In spite of these extraordinary treasures, there are few national parks in the Guinean forests, and almost all remaining forests are being commercially logged. In Sierra Leone, the only protected area is Tiwai Island, a 12-square-kilometer, primate-rich area (Mittermeier *et al.* 1999a). The parks that have been set aside, such as the Tai National Park, an extremely important and biologically rich forest in the Ivory Coast, are under siege from illegal hunters, and farmers whittling away at the forest. Kakum National Park in Ghana has been aided by Conservation International in promoting ecotourism over the past six years; a new canopy walk and aid in tourist promotion helped attract 40,000 tourists in 1997 (Mittermeier *et al.* 1999a). Few of the existing preserves are large enough to preserve the diversity of wildlife and plants of the region. Unless dramatic action is taken, many extinctions will take place in the near future.

In Gabon, to the south of Cameroon, recent progress has been made in protecting a large block of forest in the center of the country. Lope Reserve covers 1,900 square miles of Equatorial jungle coveted by loggers. An agreement signed in July 2000 between logging companies, the government and a variety of environmental organizations permanently prohibited logging in this sizeable area (Revkin 2000a). A compromise included the removal of 400 square miles of the reserve area with valuable Okoume Tree (*Aucoumea klaineana*) in order to add 200 square miles of extremely important habitat for primates, elephants and other wildlife (Revkin 2000a). Since 1957 when only a small percentage of Gabon's forests were open for logging, to the present when almost all the country is logged, wildlife has been driven from many areas by logging noise, roads that open up the forest to hunters and loss of habitat (Revkin 2000a). Dr. Lee J.T. White of the Wildlife Conservation Society has documented this phenomenon and has convinced the government to approve a country-wide forest inventory to identify other areas to protect for a network of national parks (Revkin 2000a).

The Lope Reserve, according to zoologist Jonathan Kingdon, does not include the Bee Forest, home to a very beautiful and rare primate, the Sun-tailed Guenon (*Cercopithecus solatus*), first classified and named in 1984. Dramatically patterned in dark gray with white facial markings and long reddish tails, these monkeys were photographed in the mid-1990s lying dead on tables at a market in Libreville, Gabon, offered for sale as meat (Bohan *et al.* 1996). Known only from this forest, this monkey is threatened by heavy logging in the forest by Isoroy, a French company acquired by Glunz Corporation of Germany (Bohan *et al.* 1996). The species is classified as Vulnerable in the *2000 IUCN Red List Species* (Hilton-Taylor 2000). Isoroy cuts about 140,000 cubic meters of logs per year from a 300,000-hectare (741,300-acre) concession in the Bee Forest, exporting logs to plywood factories in Europe (Bohan *et al.* 1996). The prime wood sought by the loggers is from the Okoume Tree, and a four-year study has found major damage being done to the forest in the process. On average, 8.5 trees were destroyed for every Okoume log harvested, and 49 percent of the forest canopy has been disrupted (Bohan *et al.* 1996).

The Sun-tailed Guenon is one of 26 species of guenons considered "refugia" species of African rainforests. During

the Ice Ages, these forests shrank into islands, where many different primates evolved in isolation in these forest fragments. Each has brightly marked facial and body patterns (Kingdon 1989, 1997). These "masked monkeys," many of which were photographed in the spectacular PBS Nature film of that name, are often highly restricted in their ranges and considered threatened by the IUCN. Kingdon, who has studied these primates for decades, believes that they have brightly colored markings in order to see and identify one another in the dark forest foliage (Kingdon 1989).

A close relative of the Sun-tailed Guenon is the endangered Diana Monkey (*Cercopithecus roloway*), endemic to the Guinean region. This lovely primate's jet black face contrasts with its white chest and legs; its back is russet red and gray, and its long tail is black. Its fur seems to have been painted on, so silky and lustrous is its texture. The majority of Americans know little about this species and other endangered African monkeys. This was dramatically illustrated in the summer of 2000 when New York state authorities ordered the confiscation of a pet Diana Monkey kept by an immigrant family. This animal had been bought in a Long Island pet store in 1995, long after its listing on the US Endangered Species Act and New York's endangered species legislation, yet no one seemed to notice when it was offered for sale illegally. The new owners immediately had a veterinarian spay and remove the canine teeth from this female monkey, named her "Cookie" and dressed her in tutus as a family pet. They said they had no idea that she was an endangered species and refused to give her to the state, which planned to place her in the Detroit Zoo with a male of the species. She can never be part of a breeding program, however, and is a genetic loss to the species. Had the plight of these beautiful primates been better recognized and the species better known, this unfortunate incident would never have happened.

Another "masked monkey" native to Ghana and the Ivory Coast has recently been declared extinct, the first primate extinction in several centuries (Revkin 2000b). Known as Miss Waldron's Red Colobus (*Procolobus badius waldroni*), this monkey had colorful, reddish-brown legs and head, and charcoal body. Last seen in the 1970s, deforestation and hunting caused its extinction; thorough searches over seven years within its habitat proved fruitless (Revkin 2000b). Had it been protected in a forest reserve, this colorful monkey would have avoided extinction (Revkin 2000b). This extinction is likely to be followed in the near future by those of many other critically endangered primates as a result of logging and hunting.

The deforestation of Central and West Africa also presents dangers for people. Many scientists warned that an inevitable consequence of opening up Africa's tropical rainforest through logging was the eruption of ebola virus and other diseases carried by native mammals. Such warnings went unheeded, and several outbreaks of the highly contagious and nearly always fatal ebola virus have occurred. Meat hunting of Chimpanzees in Gabon was a source of this virus, which has killed hundreds of people (French 1996).

The number of threatened vertebrates native to tropical forests of all types has grown astronomically in the past 20 years, concurrent with their widespread destruction. Indonesia, Brazil, Peru, Ecuador, India, Madagascar and Mexico are among the countries with the greatest number of endangered species, enormous diversity, and significant losses of tropical forest cover.

Among the hardest hit of tropical mammals are the primates. Ninety percent of all species inhabit tropical forests, and recent surveys have found that 204 species, or one-third of the world's 650 taxa (taxonomic listing including subspecies), are in high degrees of threat; 103 are critically endangered or endangered (Mittermeier *et al.* 1999b). In Southeast Asia, 90 percent of primates are either threatened or near-threatened, an amazingly high rate of endangerment. Primates are in rapid decline as a result of forest loss, killing for the pet trade, hunting for meat, and capture for zoos, the pet trade and research (Mittermeier *et al.* 1999b). The combination of all these factors has pushed some species so close to extinction that some primate species and subspecies have total world populations of fewer than 100 animals (Mittermeier *et al.* 1999).

Focus on Indonesia

Indonesia has the greatest biological diversity in Asia. A vast mosaic of 13,667 islands, Indonesia links two biogeographic regions known as the Sunda subregion, an area stretching from southern Burma and Thailand south to northern Indonesia and Borneo, with Oceania to the south and east. The political boundaries of Indonesia have little to do with ecosystems or ethnic cultures. The giant island of Borneo, for example, has been divided among several Asian countries. Indonesia claims the southern two•thirds, known as Kalimantan, while Malaysia rules two states in the north and west, Sabah and Sarawak, and the small independent country of Brunei lies on the northwestern coast. Likewise, New Guinea, whose Melanesian tribes have inhabited the island for thousands of years, has been divided between Indonesia, which rules with a strong military presence in the western half, Irian Jaya, and Papua New Guinea in the east, an independent nation. Politically, Indonesia has been in turmoil for decades, with a series of presidents who have grown rich on foreign aid and siphoning off profits from exploitation of timber, oil and minerals.

Focus on Indonesia: Page 1

The world's greatest variety of palm species grows in Indonesia along with 10,000 kinds of trees and 25,000 species of flowering plants (Collins *et al.* 1991). About 40 percent of its plants exist nowhere else, and its forests have a diversity of plants equaled only in Amazonia (Collins *et al.* 1991). One high-altitude forest on Borneo, Mount Kinabalu, has 70 species of oaks, and more than 100 grow on the island, along with 30 kinds of squirrels who feed on their acorns. Such trees are usually considered temperate forest species, but in these forests, which vary greatly in altitude and habitat type, an incredible variety grows. Two thousand species of orchids grow on Borneo (Mittermeier *et al.* 1999a). At high altitudes on Mount Kinabalu, the soggy ground is 90 percent covered in orchids, some with flowers as tiny as grains of rice (Lanting 2000).

Forests cover 85 percent of New Guinea (O'Neill 1996), the majority of which are humid, with very rich diversity in the lowlands. Above 750 meters, oaks and Araucaria trees related to those in South America's Atlantic Forest grow. Even higher, above 2,000 meters, tangles of bamboo and *Nothofagus* beech trees grow in great stands (Beehler *et al.* 1986). New Guinea's mountains rise above 4,200 meters, where alpine shrubbery and boggy grassland dominate. Mangrove forest fringes most coastal areas (Beehler *et al*. 1986).

Until the beginning of the 20th century, forests of many types covered most of Indonesia. The isolation of many of the islands from one another resulted in a radiation of evolution in all types of plants and animals. Many species of animals that had become extinct or rare on mainland Asia still thrived in Indonesia--rhinoceros, Asian Elephants,

Tigers and Orangutans, for example. Other mammals, such as the extraordinary, long-nosed Proboscis Monkey (*Nasalis larvatus*), evolved among the mangrove swamps of Borneo. An unparalleled beauty and wealth of birds had evolved. Among these were birds-of-paradise, parrots, lories and cockatoos, colorful songbirds and hornbills. As the 21st century dawns, however, this diversity is in ruins, with many plants and animals close to extinction. The small original populations of many of the endemic species made them highly vulnerable to loss of habitat as the ancient trees were felled, and population growth consumed millions of acres for agriculture.

Of more than 1,500 species of birds native to the islands of Indonesia, or 17 percent of the world's avifauna, 430 are endemic to the country (Collins 1990). Indonesia has twice the number of breeding birds as North America in only one-fifth the land area. Many of these birds live on only one or two small islands. About 164 species are endemic to the Sunda subregion alone. The great loss of forest and other types of habitats in Indonesia is perhaps the most important cause threatening 319 species of native birds, of which 114 are extremely threatened (BI 2000). This is the largest number of threatened birds of any country in the world. Further field research may uncover even more species to add to this list, especially in view of the accelerating deforestation in Kalimantan**,** Sumatra and New Guinea.

Two hundred and one of Indonesia's 436 species of mammals--almost half-- are endemic, an amazingly high rate of endemism (Baillie and Groombridge 1996). Not surprisingly, Indonesia also leads the world in the number of threatened mammals--135 species, or 31 percent of all of its native mammals (Hilton-Taylor 2000). One thousand species of reptiles and amphibians live in Indonesia, 10 percent of the world's 10,484 herpetofauna (Collins 1990). Twenty-eight species of reptiles are considered threatened by the *2000 IUCN Red List Species*, along with at least 59 species of freshwater fish. Research on endangered amphibians, fish and invertebrates in tropical countries lags far behind that in temperate areas, and the endangered list of the latter species is likely to grow when further research is done.

Focus on Indonesia: Page 2

New Guinea has some of the largest expanses of ancient species of trees in the world, most of which grow in cool climates in highlands and mountains. One species of *Agathis* kauri from the highlands of Papua New Guinea is considered rare by the *1997 IUCN Red List Plants*, as are two more *Agathis* species in the Solomon Islands and Vanuatu to the southeast of New Guinea, also bits of Gondwana. The kauri pines (*Agathis macrophylla*) occur on both the latter island groups but have been logged over. Their close relatives on the island of Borneo are in steep decline from logging and land clearance. In New Guinea, logging and clearance for settlements or agriculture, and even native tribes, are destroying these giant trees. Known as "timber trees" in the IUCN-sponsored *Conservation Atlas of Tropical Forests. Asia and the Pacific* (Collins *et al.* 1991), the *Araucaria* pines, relatives of the Monkey Puzzle Tree, grow in groves in parts of New Guinea's highlands, and some tribes venerate them.

Zoologist Tim Flannery (1998) walked among these *Araucaria* trees near the highland village of Telefolip and reflected: "Around the edge of the grove they were saplings but, further in, the pines were soaring giants, mist swirling through their crowns. Their straight, clean boles carried patches of bright green moss, which contrasted with their walnut-colored bark . . . The most striking thing about the grove was the quality of the sound. It seemed as if, in an instant, we had left the noisy, muddy world of drizzle and people and entered a large, open-air cathedral." The grove was considered so sacred by the local tribe that not a single leaf, not even a mosquito, could be disturbed in it (Flannery 1998). They thought that all life had begun in the grove. In the middle of the grove, Flannery saw a rare bird of paradise displaying. The male Splendid Astrapia (*Astrapia splendidissima*) has iridescent colors on the breast and head, and long, dramatic tail feathers that are much desired by the native hunters. These birds are usually shy, but generations of Astrapias had learned that they could display in this sacred Araucaria grove without fear that they would be killed (Flannery 1998). Baptist missionaries worked to end what they called pagan beliefs and offered to

purchase timber cut from this sacred grove; gradually they succeeded in ending the taboos. When Flannery visited the grove in 1992, a great fallen Araucaria lay near the path, its trunk hewn into segments with a chainsaw.

New Guinea's birds-of-paradise have been called the most spectacular birds in the world. They are confined to this island and its satellite islands, and extreme northern Queensland in Australia. Their dazzling plumage, showy courtship displays and haunting songs have inspired awe in all who see them. fiVoices in the Forest,fl a BBC film (see Video section, Birds), featuring these spectacular birds dramatically illustrates their conservation problems. Their feathers have been traditionally used for headdresses and costumes by natives, which has threatened some species. Commercial demand from outside the island for feathers, zoo and aviary birds and dried specimens poses additional threats to them. The entire family of these birds, Paradisaeidae, has been placed on CITES Appendix II to prevent illegal trade. Forest cutting poses an even more serious danger to birds-of-paradise populations. The majority of species inhabit primary rainforests, and many have extremely specialized habitat needs. As clearing continues, and logging roads open up more and more of New Guinea's forests, these birds lose their habitats and are more easily hunted. Four species of birds-of-paradise are listed as Vulnerable, and eight more as Near-threatened by BirdLife International; they comprise 28 percent of the 43 members of this avian family (BI 2000).

Less showy, but no less interesting, are New Guinea's bowerbirds. The constructions of bowerbirds are so elaborate that when explorers first encountered them, they were assumed to be man-made. Each species has variations on the construction, some building bowers with pass-through tunnels, others concentrating on accumulating a vast array of objects collected in piles of the same color to attract females. One very rare bowerbird, searched for in the wild on a dozen occasions, was finally found in the remote Foja Mountains by Dr. Jared M. Diamond of the University of California in 1979. This beautiful bird, the Golden-fronted Bowerbird (*Amblyornis flavifrons*), which may number only about 1,000 birds, is very restricted in range, limited to an area north of the Idenburg River between 1,000 and 2,000 meters (Beehler *et al.* 1986). The male of this species arranges sticks in a pile around a tree fern or sapling, forming a tower up to 3.5 feet high on a circular moss platform with a raised rim. He clears the adjacent area of debris and places separate piles of blue, green and yellow fruits to attract the female. The blue fruit was also a newly discovered species. Making varied, loud calls even while holding a blue fruit in his beak, which contrasts boldly with his brilliant yellow head and back feathers, the Yellow-fronted Bowerbird perches near his elaborate bower performing for the drabber female.

An even more threatened bowerbird, Archbold's Bowerbird (*Archboldia papuensis*), ranges in the central mountain ranges of the island. The male has a long, forked tail and constructs a bower made of a large mat of ferns (Beehler *et al.* 1986). Inhabiting ancient *Nothofagus* beech forests, mixed with podocarps, bamboo and *Pandanus* at high altitudes between 2,300 and 2,900 meters, it has declined as a result of logging operations (BI 2000).

New Guinea's marsupials show great biological diversity, ranging from tree-kangaroos, an arboreal relative of the land kangaroos of Australia, to colorful cuscuses, tiny nocturnal possums and bandicoots. These fascinating mammals remained unknown to scientists until very recently as a result of the extremely rugged terrain, native tribes who were often unfriendly to outsiders, and the almost total lack of roads and other means of access. Many of these mammals are also secretive and nocturnal, hiding in the holes of giant trees covered in vines or inhabiting such restricted ranges that many have only recently been discovered after intensive searches in the wild. In 1865, for example, only 15 mammals had been named from New Guinea, and in 1875 that number had grown to 20 (Flannery 1995). By 1906, 126 mammals had been identified, including 50 marsupials and monotremes, but today it is known that at least 212 indigenous mammals inhabit New Guinea, many of which were discovered within the past decade (Flannery 1995). A surprising number of mammals inhabit a relatively small area and are threatened by forest loss and hunting.

Focus on Indonesia: Page 3

Thirty-eight marsupials and one monotreme (egg-laying mammal such as a platypus) are listed in the *2000 IUCN Red List Species*. One marsupial was previously unknown to scientists until 1994 when Tim Flannery (1998) discovered it in a remote mountainous area of Irian Jaya. This panda-like animal has long, fluffy black fur on its back and head, stripes of white on its belly and muzzle, and a white star on its forehead (see Flannery 1998 for color photo). It resembles no other tree-kangaroo and is also far more terrestrial than other species (Flannery 1998). The Moni tribe call it the "man of the forest," or Dingiso, because when threatened, it raises its arms above its head, exposing its white belly while letting out a whistle, which they consider a sign of recognition (Flannery 1998).

The Dingiso's scientific name, *Dendrolagus mbaiso*, means "forbidden" tree-kangaroo. The Moni believe it to be an ancestor and will not hunt it, but a neighboring tribe, the Dani, has no such taboo and kills the Dingisos for their fur, claws and tail tips. Weighing about 30 pounds and 30 inches tall, this fairly large tree-kangaroo lives in a dense, cloud pine forest up to 10,000 feet in altitude in the Maoke Mountain Range, an area where tree-kangaroos had never been seen. Within the territory of the Moni, this very tame tree-kangaroo is still common and can be easily approached by offering it some leaves; hunters take advantage of this trait by feeding it leaves and slipping a noose over its head (Flannery 1998). This beautiful animal is endangered, and should the protection of the Moni people end for some reason, it will likely become extinct, as it has already disappeared from the territory of the Dani tribe (Flannery 1998).

Focus on Indonesia: Page 4

Fig trees are among the most characteristic trees of Indonesia and other rainforests and are keystone species for wildlife. They are threatened by forest clearance and by loss of their seed dispersers. Some 800 species of fig trees are found in tropical rainforests around the world. On Borneo alone, there are 140 species, 13 of which are endemic (Yates 1992). Among the tallest trees in these forests, they may attain a height of 150 feet. Strangler figs grow on the trunks of other trees, which they gradually kill by encircling them. All fig trees are dependent on wasps less than an inch long for pollination. (See "Borneo's Strangler Fig Trees," by Tim Laman in *National Geographic*, April 1997, which illustrates this pollination process in detail.)

A wide variety of birds and mammals feed on the abundant fig fruits, but few species actually disperse the seeds. Figs contain chemical compounds that have a laxative effect on the wildlife that eat them, a reproductive strategy designed to release seeds over a wide area. Animals as small as ants and as large as wild pigs, gibbons, and deer feed on the fruit (Laman 1997). Figs exist in such variety in unlogged, primary tropical forests that one species is always fruiting, supplying life-giving food to wildlife (Laman 1997). Hornbills may be more important than any other species in dispersing fig seeds because, rather than eating a portion of the fruit only, they eat the entire fruit, which is full of tiny fertile seeds, and then fly long distances, spreading the seeds in defecations. One ornithologist observed fruiting fig trees in Borneo with as many as 50 hornbills of eight species feeding together (Yates 1992).

Focus on Indonesia: Page 5

Hornbills also spread the seeds of other plants. In India, Great Pied Hornbills are vital to the dispersal of nutmeg seeds, since they are the only species with a beak large enough to open the seeds (Youth 1995). Ragupathy Kannan, a biologist studying this species in the Ghats region of southwestern India, discovered that the forestry department was intentionally cutting large fig trees in order to feed domestic Asian Elephants to haul lumber (Youth 1995). Kannan managed to convince them to ban fig tree cutting and, instead, to let Elephants browse freely in the forest (Youth 1995). If such conservation work took place throughout the ranges of hornbills, their future might be brighter.

The decline of hornbills throughout their Asian ranges highlights the loss of seed dispersers, as the forests themselves disappear or become logged over and fragmented. Hornbills are extraordinary birds, with their enormous beaks composed of horn-like material and, often, colorful facial markings. Some have a casque on top of the bill, giving the appearance of a double beak. The Rhinoceros Hornbill (*Buceros rhinoceros*), for example, has a typical downward-curving, white pointed beak, but atop it a bright orange-red casque curls upward at the tip like a rhinoceros horn. This species, native to Malaysia, Sumatra, Borneo and Java, has declined from trade and is listed on Appendix II of CITES. Averaging more than 4 feet long with 3-foot tails, hornbills make dramatic silhouettes as they fly over the forest canopy. Unfortunately, their size attracts hunters who kill them for sport or food, another factor in their rarity outside national parks. Their reproduction is highly unusual--unique, in fact--among birds. Courtship can involve spectacular head•on collisions between males, clashing their casques together. The hornbill pair, which mates for life, selects a nest hole high in a hollow tree, usually one that was created by a large limb falling off and the trunk area becoming rotted.

Since ideal nest sites are rare and found only in trees hundreds of years old, hornbills often use the same nest year after year. The female plasters the inside with droppings that harden, and the male plasters the outside, leaving a slit that effectively imprisons the female in the tree trunk hole for the next three months. She pokes her bill out to receive food from the male, who tips his beak into the female's open one and lets small round figs and other grape-sized fruits roll down. Other adults may help in feeding the chicks and female. Before the chicks are ready to fledge, the female breaks out and leaves the nest; the chick or chicks instinctively reseal themselves for another month, both parents continuing to feed them (Yates 1992). Finally, when ready, the chicks break out of the nest. It is thought that hornbills have evolved this method of reproduction to protect the female and young from tree•climbing predators, such as snakes and lizards. (The courtship behavior, nesting and feeding of the female and chick by the male Red-billed or Celebes Hornbill (*Penelopides exarhatus*) are beautifully photographed in the BBC film, fiCastaways of Sulawesi.fl See Video section.)

Hornbills, so important to fig trees and the host of species that feed on them, are themselves dependent on primary rainforest (Collins 1990). Their nest trees are often intentionally cut to obtain chicks for sale to zoos and in open wildlife markets. When these great trees crash down, they bring with them many adjoining trees, killing small mammals and birds in the process. The dual threats to hornbills of habitat loss and capture have resulted in dramatic declines in their populations. Should all the hornbill species that are threatened become extinct, the extinction of hundreds of other species may result, from the fig trees, whose seeds they spread, to many vertebrates and invertebrates. In 1980, only one species, the east Asian Helmeted Hornbill (*Buceros vigil*), was listed as Indeterminate by the International Council for Bird Preservation (ICBP) (now BirdLife International) as a result of killing to use their large casques for carving (King 1980). But by 1988, that organization listed seven Asian hornbills as threatened with extinction (Collar and Andrew 1988). In 2000, 18 of Asia's 30 species, or 60 percent, of hornbills were listed in *Threatened Birds of the World* (BI 2000). Seven of the 10 Philippine endemic hornbill species are threatened with extinction (BI 2000). The dramatic increase in threat to these keystone rainforest birds is a reflection of the destruction of Asia's rainforests.

Focus on Indonesia: Page 6

Other rare and declining inhabitants of Asia's rainforests play important roles in pollination. Many trees that produce important commercial products need to be pollinated by wild animals. An extremely valuable fruit is the Durian, which is almost unknown outside southeast Asia. In spite of a rank odor emanating from the outer fruit, the yellow core inside the rind is considered a great delicacy, worth more than $90 million a year in markets throughout Indonesia and Malaysia. What is less well known is the dependence of the Durian tree on a particular species of bat to pollinate it. The Cave Fruit Bat (*Eonycteris spelaea*) is the sole pollinator of these valuable trees, pollinating the

flowers while feeding on the nectar of the flowering fruit. Yet this bat is unprotected from the persecution, hunting for food and destruction of its limestone caves that are causing its decline. The number of threatened bat species native to Asia has increased dramatically in recent years, according to the IUCN (Hilton-Taylor 2000). Throughout these rainforests, bats are disappearing, some before their ecological role was known.

Hundreds of tropical plants and trees have evolved for pollination by bats. Most flowers of such trees are found in the canopy, giving easy access to the nectar•feeding and fruit bats, either hanging on long stems, set clear of the surrounding foliage, or clustered on branch tips near twigs where bats can land (Mitchell 1986). These bat flowers open only at night, with odors quite unlike the day•blooming flowers that attract insects and birds; instead, they are musky and sour, which seem to attract the bats (Mitchell 1986). Evolved with shapes that conform to the muzzle of the bat in order to deposit pollen on the bat's face, some flowers have large, trumpet•like openings that almost engulf the bat's head. Others are brush•like with masses of stamens rich in pollen, while still others have numerous small flowers in a ball•like inflorescence producing both nectar and pollen (Mitchell 1986).

The trees that have evolved to be pollinated by bats, some even by a particular species of bat, while providing food for the bats, represent a classic example of mutual dependency. Current logging practices and the killing of many of these bats for food, or destruction of their caves, endanger both trees and bats. Many of Indonesia's threatened bats are fruit bats, and a large number are found only in Indonesia. The Pygmy Fruit Bat (*Aethalops alecto*), for example, is found only on Borneo; the Small•toothed Fruit Bat (*Neopteryx frosti*) is native to Sulawesi; the Javan Tail•less Fruit Bat (*Megaerops kusnotoi*) is restricted to Java; four others are confined to the island of New Guinea. Half of Borneo's 140 mammal species are bats, and more than 50 of these feed primarily on insects (Yates 1992), another major benefit of these poorly understood mammals.

Focus on Indonesia: Page 7

The threats to Indonesia's environment are strongly linked to the growth of its human populations. With the largest number of people on Sumatra, Java and Bali, lowland forests on these islands were cut for cities and farmland during the first half of the 20th century (Collins *et al.* 1991). Beginning in the 1960s, industrial, government-sponsored logging began on many islands for valuable timber. Uncontrolled logging and wildfires have consumed millions of acres for decades, destroying 44 percent of original habitats and nearly all the lowland rainforests in Indonesia (Mittermeier *et al.* 1999a). Java has become nearly denuded, due mainly to the massive growth in human population that totals more than 110 million, almost half the entire population of the United States (Mydans 1996a). The tiny satellite island of Bali has similar crowding problems, and very little forest remains. Between 65 and 80 percent of Sumatra's lowland forests have been cleared to make way for the ever-expanding human population (Collins *et al.* 1991). By June 2000, an estimated 224.8 million people inhabited Indonesia, the equivalent of 82 percent of the US population, living on 741,000 square miles, or 20 percent of the US land area (New York Times 2000).

Among the first casualties of this deforestation and population growth were Tigers, who numbered in the thousands on Sumatra, Java and Bali up until 1900. The populations of each island had been separated for at least 8,000 years (Matthiessen 2000), as each evolved into a separate race. The Javan (*Panthera tigris sondaica*) and Bali Tigers (*Panthera tigris balica*) were far smaller than other Tiger races, with males weighing only about 200 pounds, one•fourth the size of a male Siberian Tiger. Several Javan Tigers were kept in the Berlin Zoo in the early 1900s without any effort to breed them in captivity (see photo in Tilson and Christie 1999). After massive deforestation of these islands and heavy hunting pressure, their populations crashed (Simon and Geroudet 1970). Udjung Kulon, a large national park, was set aside for the Javan Tiger in 1921, but only 20 to 25 of the species survived by 1955, of which 10 were in this park (Simon and Geroudet 1970). By the 1970s, they had disappeared from Udjong Kulon, and only a few were left in Meru Betiri National Park in the far south. In 1980 a careful survey found tracks of at least three Javan Tigers, but there have been no signs since (Jackson 1990). Bali Tigers were once common in the western

portion of the island, but not since 1952 has there been a confirmed report (Simon and Geroudet 1970). Both these races are now considered extinct in the wild, and none survives in zoos (Jackson 1990). These Tigers represented unique genetic strains that are now lost forever. They were the chief predators at the top of their food chain, and their loss impoverished these ecosystems.

The Sumatran Tiger (*Panthera tigris sumatrae*), the largest of the three, is the only surviving Indonesian Tiger. Highly endangered (Jackson 1990), its wild population may total only 500 or fewer animals (Nyhus *et al.* 1999). An intensive conservation program, begun in 1995, involves an international team of biologists who are attempting to determine just how many Tigers are left, whether they have sufficient prey species, how many are being killed by local people and the status of their habitat (Franklin *et al.* 1999). In Way Kambas National Park in the southeast, researchers, using cameras placed on trails, have photographed them. An estimated 36 Tigers inhabit the second-growth forest and degraded grassland habitat in this park of about 1,500 square kilometers. It is completely surrounded by villages, and nearly all its lowland primary rainforest has been cut (Franklin *et al.* 1999). Villagers resent the park's ban on using forest and grassland products, and when Tigers prey on livestock, often because of a lack of natural prey, the villagers put out poison. Sumatra's forest fires and rampant poaching of all large animals in Indonesia may extinguish the last of these Tigers, but the conservation research program intends to involve local villagers in saving the Sumatran Tiger and help address many of their needs in the process (Franklin *et al.* 1999). This race of Tiger is kept in many zoos around the world, unlike the Bali and Java Tigers, and has reproduced. The fragmentation of the forest range of Tigers throughout Asia to India has isolated populations, caused inbreeding, and exposed them to poaching, even in national parks.

The parks created for the Javan and Bali Tigers protect a great diversity of other wildlife and plants. Meru Betiri National Park preserves the last remnants of lowland rainforest in Java (Whitten and Whitten 1992). A population of about 75 to 100 endangered wild cattle, or Banteng (*Bos javanicus*), and Leopards (*Panthera pardus*) are also resident (Whitten and Whitten 1992). Unfortunately, illegal cutting of trees and rattan within the Meru Betiri National Park has been extremely destructive (Whitten and Whitten 1992). Udjung Kulon National Park on the western tip of Java is home to a small population of Javan Rhinoceros (*Rhinoceros sondaicus*), the rarest of all rhinoceros, along with Sambar Deer (*Cervus unicolor*) and Barking Deer (*Muntiacus muntjak*) and Banteng (Whitten and Whitten 1992). Sumatra has several important national parks as well. Mount Leuser National Park's swamp forests protect the last Sumatran Rhinoceros (*Dicerorhinus sumatrensis*), second rarest of the rhinos. This extremely primitive and hairy rhinoceros has been captured for zoos, where most have died and none has been born in captivity. Researchers in the park have tried to prevent further captures of these highly aquatic rhinos in order to preserve the last wild members of the species. This park also has resident Orangutans (*Pongo pygmaeus*), Siamangs (*Hylobates syndactylus*) and endangered Sun Bears (*Helarctos malayanus*). Unfortunately, some of Sumatra's national parks have been overrun with people cutting trees, causing erosion, and replacing forest with agriculture. The Kerinci-Seblat National Park, located along a mountain range in southern Sumatra, encompasses 14,847 square kilometers of forest, but within the park is a virtual city of 273,000 people, growing at a rate of 3.6 percent a year, who denude the hillsides and convert forest to cinnamon, cloves and coffee. They are gradually destroying this entire forest and the watersheds of the island's two most important rivers (Collins *et al.* 1991).

Focus on Indonesia: Page 8

Until about 30 years ago, Borneo had extensive, unspoiled and magnificent forests. The third largest island in the world after Greenland and New Guinea, it covers 215,000 square miles (Smythies 1960). Prior to recent logging and forest fires, it was described as "one enormous forest" by Bertram E. Smythies, author of *The Birds of Borneo* (1960); 75 percent of the island was primary forest, and 10 to 15 percent, secondary forest (Smythies 1960). Mangrove forests grew abundantly along the southern and southeastern coasts, extending far inland, lining major rivers and blending into vast swamp•forests (Yates 1992).

By the late 1970s, an estimated 66 million acres of the country's forests had been classified as denuded (Allen 1980). Forest clearance on Borneo and in Sumatra took a dramatic turn in the early 1980s when landowners and settlers set fire to forests felled for commercial timber, palm oil and tree plantations and homesteads to destroy stumps and brush. This was done in spite of a law banning the setting of fires. The largest forest fire ever recorded on Earth took place in the old-growth forests of Borneo during 1982-83 and lasted for 18 months (Collins *et al.* 1991). More than 9 million acres, or 33,000 square kilometers, were destroyed in east Kalimantan, including 8,000 square kilometers of unlogged dryland primary rainforest and 5,500 square kilometers of peat swamp forest; the rest was selectively logged forest and settlement areas (Collins *et al.* 1991). This was the first time that living rainforest had been seen to burn. Half the new Kutai National Park was destroyed, and another 2.5 million acres burned in Sabah in the northwest of Borneo (Yates 1992). Wildlife was seriously affected, and some burned land was later converted to tree plantations (Collins *et al.* 1991).

During the 1990s, more fires erupted, spreading to adjoining forests. Logging practices involved the removal of the largest trees, leaving leaf litter, small trees and broken branches that dry out (Paul 1998). The logging opened up the canopy, allowing further drying-out of the forest floor, and humidity dropped (Paul 1998). Fires set in clearcuts entered logged rainforest through these logging openings, setting the entire forest afire (Paul 1998). In 1991, another 190 square miles of East Kalimantan burned, and in 1995, massive fires broke out in Kalimantan and Sumtra (Paul 1998). Two years later, an estimated 750,000 to 1.5 million acres of forest burned in Sumatra and Kalimantan (Howe 1997), including a devastating fire in Tanjung Puting National Park, a prime refuge for Orangutans (Paul 1998). So immense were these wildfires that the smoke spread to neighboring countries, causing severe air pollution in cities and towns, and the fires were seen clearly from satellites orbiting the Earth. A Canadian observer from a vessel in the China Sea during these fires wrote to *National Geographic* (December 1998): "Even at 250 kilometers [155 miles] distance from the coast of Kalimantan, the air was thick with smoke. For nearly three weeks we could not see the sun's disk, only smoke-diffused light. The most astonishing and sad event we witnessed happened one night when we were surveying . . . Our ship was engulfed by an ever increasing flock of exhausted birds and bats, all fleeing the fires of Sumatra. Dozens of birds landed all over the deck, where, too fatigued to move, they could easily be approached and handled. In the morning we found several tired bats dangling from overhead steel gratings. I sincerely hope that a new and more benign Indonesian government will prevent such awful, and needless, environmental calamities from happening again" (Christopher Woodworth).

In Borneo and Sumatra alone, 14.8 million acres are estimated to have been destroyed prior to 1998, still charred and black years afterward (Paul 1998). A zoology student and his girlfriend traveled across Kalimantan in the late 1990s, seeing no green except along roads--small farms and banana trees (Paul 1998). In parts of the region, underground fires burn for years, igniting deep beds of peat and coal seams. The Indonesian government's reforestation funds were rerouted, first by President Suharto, then by his successor, President Habibie, to develop industrial oil palm and timber estates (Paul 1998).

After worldwide publicity and protests from other countries about the fires, and condemnation of Indonesia's failure to act against those responsible, in early October 1997, the government revoked the operating permits of 29 companies that had set illegal fires. This had little effect on fire-setting, as more fires broke out in the following year. In 1998, another million acres burned, and in 1999, an area the size of Vermont and New Hampshire burned on Borneo. In the summer of 2000, smoke from Indonesia's illegal forest fires again blanketed nearby Malaysia's capital, Kuala Lumpur, and Singapore (Mydans 2000). After the fires, floods made the forest loss in Kalimantan permanent by washing away soil, leaf litter and nutrients from the fires ashes (Kaplan and Rogers 2000). Exotic Imperata grasses took hold in many areas, poisoning the ground with substances that inhibit the growth of trees, signaling the end of the rainforest (Kaplan and Rogers 2000). Some 80 percent of the forests in the southeast of Borneo are now gone.

During these fires, wildlife, including such critically endangered species as Sumatran Tigers, Orangutans (*Pongo pygmaeus*) and Asian Elephants (*Elaphus maximus*), fled the fires into villages, where many were killed or captured for sale as meat or pets. Stephanie Fried, a scientist with the Environmental Defense Fund in Washington, DC, who

has studied the timber trade in Indonesia, described these fires as the result of "appalling forestry practices and rapacious greed" (Howe 1997).

The fires destroyed most of Borneo's lowland rainforests, where 267 of the world's 600 dipterocarp trees, or trees with "two•winged fruits," dominate; 150 of these exist nowhere else (Whitten and Whitten 1992). This family of trees, Dipterocarpaceae, has species from the Seychelles to New Guinea, but Borneo has by far the most species (Whitten and Whitten 1992). Many reach heights of 250 feet or more and are pollinated by tiny thrip insects. They are extremely important to wildlife, producing fruits, flowers and digestible leaves that are fed on by birds, gibbons and a variety of other animals (Whitten and Whitten 1992). Each year, 2,500 square kilometers of dipterocarp forest are logged in Sarawak, and these old-growth forests are often replaced with tree plantations (Collins *et al.* 1991). Elsewhere in Indonesia, these are the preferred trees to be logged, with their unbranched, wide trunks used in furniture, plywood, resins and camphor (Whitten and Whitten 1992). It was almost inevitable that many of these trees became extinct. The *1997 IUCN Red List Plants* lists a dipterocarp trees native to west Sumatra as Extinct. Another species is extinct on Sumatra but still survives in Peninsular Malaysia, along with 95 other members of the family listed as Threatened or Extinct on the island of Borneo and the rest of Indonesia. Four species of the giant kauri *Agathis* that grow in Borneo's higher altitude forests are also threatened with extinction (Walter and Gillett 1998).

Focus on Indonesia: Page 9

Orangutans once ranged in mainland southeast Asia as well as Indonesia, but hunting and forest cutting eliminated them from 98 percent of their original territory, leaving populations only on Sumatra and Borneo. These islands were home to tens of thousands of Orangutans at the turn of the century, but since then, these intelligent apes have been pushed into pockets of shrinking rainforest. Orangutans are unable to adjust to second-growth forest and depend on very large ranges within primary rainforest, where they feed on ripe fruit and flowers. Their populations have become scattered from loss of old-growth forest, and even national parks are no longer safe havens for them, as poaching and illegal logging increased in the late 1990s. Orangutan populations decline between 60 percent and 95 percent in selectively logged forests (Newman *et al.* 2000). The logging scares them out of their territories, and they often die of starvation or accidents (Newman *et al*. 2000).

One of their former strongholds was the Tanjung Puting National Park, 741,000 acres on a peninsula on the south coast of Borneo. It was upgraded to national park status in 1982, primarily to protect the Orangutan. This is the largest swamp forest in southeast Asia, with a mosaic of habitats, including primary rainforests. The Environmental Investigation Agency (EIA) of London conducted an in-depth study of illegal logging in this park, publishing a report, *The Final Cut*, in 1999 (Newman *et al.* 1999). Illegal loggers were so blatant that they built a wooden railway to slide out the giant logs. When government officials were notified, they did nothing, as they had apparently been corrupted by bribes from the loggers (Newman *et al*. 1999). In December 1999, biologists in the park found themselves ordered by armed loggers to leave. Similar illegal logging took place in other parks and reserves crucial to the survival of the Orangutan, leaving few areas not seriously degraded (Newman *et al*. 1999). EIA turned over to Indonesian government authorities, including the Governor of the Province, copies of its detailed report on illegal logging, which had uncovered the fact that 70 percent of the timber being processed in Indonesia came from illegal logging (Newman *et al*. 2000).

The World Bank in Jakarta estimated that between 1985 and 1997, Indonesia lost an average of 1.5 million hectares of forest cover every year, with dry tropical forest, an endangered ecosystem, suffering the greatest losses. Sulawesi has been logged out, and this forest type could disappear from Sumatra and Kalimantan in the near future (Newman *et al.* 2000). Logging supplies 2 million cubic meters of timber to its many pulp mills (Mittermeier *et al.* 1999a). The lack of strong government control has allowed corrupt timber barons to emerge and control the rampant

illegal logging that is leaving little of the country untouched (Newman *et al.* 2000). In spite of international publicity about this disastrous state of affairs, and pressure from international donor agencies, the Indonesian Government stated that it would stop the illegal logging, but did not take action. The bribery scandal apparently reaches into high levels within the government (Newman *et al.* 2000). In May 2000, student activists, frustrated by the government complicity in the looting of their national heritage, held four government officials at a port in West Kalimantan after Customs and other officials failed to halt the shipment of an illegal consignment of timber to Singapore. This shipment, with 70 containers of logs, was forced to return to port and its cargo seized (Newman *et al.* 2000). China and the European Union import more than half the timber exported from Indonesia, and to date, no action has taken place by importing countries to confiscate illegal shipments of timber (Newman *et al.* 2000).

The status of Orangutans has gone from endangered to critical. Decades of logging, clearing and forest fires have destroyed the majority of their primary, old-growth forests on Borneo and Sumatra. Thousands were killed during these fires and hundreds that fled burning forests and entered open areas near villages were killed by villagers wielding machetes. Mothers were hacked to death to obtain their babies, who were often wounded in the process. Hundreds of orphaned Orangutans, pitiful, sickly and malnourished, were confiscated during this period and placed in rehabilitation centers. Many died, and the traumatized survivors clung to one another in crowded pens and crates, mass fed by volunteers and workers of these centers. The Leakey Research and Rehabilitation Center for Orangutans in southern Borneo, and two other centers on the island, have cared for hundreds of these orphans. In 1997, the Wanariset Orangutan Reintroduction Project in East Kalimantan received 118 baby Orangutans, and in 1998, 60 more arrived (Paul 1998). In August, 1998, the station held 171 refugee and injured Orangutans, most very young (Kaplan and Rogers 2000). Many mother Orangutans died of starvation, trying to sustain themselves on acacia bark, and their young were so weak they could hold on no longer and fell to the ground. Some mothers were eaten by the starving local people, and others succumbed to disease (Kaplan and Rogers 2000). Even those saved and rehabilitated have a low rate of survival. Fewer than half survive in the wild, according to Martinus de Kam, site manager of the Wanariset Forestry Research Project (Paul 1998).

Birute Galdikas, a renowned primatologist and the world's foremost expert on the species, runs the Leakey center and was almost overwhelmed by the numbers of orphans to care for. Moreover, quite a few Orangutans that had been rehabilitated over the past decade and returned to the rainforest came back to the Leakey center for food as their forests were burned or fruit trees cut. In the early 1990s, Orangutan populations were estimated at more than 22,000, with 9,200 on Sumatra and up to 15,546 on Borneo (Nowak 1999). Few believe that more than 15,000 survived the forest destruction and fires of the late 20th century. Galdikas has stated that the species may be doomed to extinction, left with too little habitat to survive. Two primatologists, Gisela Kaplan and Lesley J. Rogers (2000), who have studied Orangutans for many years, conclude that these fires may have been enough to set the final scene for their extinction in Borneo before too many years. Wild populations are unable to sustain the removal of so many female Orangutans. Their reproduction is among the slowest of any mammal. Males are solitary, and females live with their single young for eight to nine years before having another baby (Kuznik 1997). A loss rate of only five Orangutan females out of 1,000 per year can cause a stable population to decline, according to Mark Leighton, a Harvard ecologist conducting research in Borneo's rainforests (Kaplan and Rogers 2000). This rate was surpassed many times during the 1990s. This picture has been further complicated by the recent genetic analysis of Orangutan DNA, which has revealed that there are two, not one species: the Sumatran has been renamed (*Pongo abelii*) and the Bornean retains the original scientific name, *Pongo pygmaeus*. These two primates have been long separated from one another and developed changes in their genes that warrant separating them as species (Kaplan and Rogers 2000; Hilton-Taylor 2000). There are physical differences as well. The Bornean Orangutan is far larger than the Sumatran, perhaps because it has not had to be agile to flee from Tigers, since the species is absent on Borneo. Both species are listed in the *2000 IUCN Red List Species*, the Sumatran as Critical and the Bornean as Endangered.

Focus on Indonesia: Page 10

Many islands, including Borneo (Kalimantan), Sulawesi and western New Guinea have had to absorb millions of people relocated from overpopulated Java under a government program. Beginning in 1978 with partial funding from the World Bank, more than 100,000 people per year were relocated to these and other out-islands costing $2 billion by 1992 (Durrell 1992). By 1996, 6 million people had been relocated from Java; Sumatra received the greatest number of people, followed by Kalimantan, Sulawesi and Irian Jaya (Mydans 1996a).

Irian Jaya™s 350,000 square kilometers of forests are still largely intact, but they are rapidly being destroyed by settlers. More than 250,000 people have been sent here, pushing aside the native New Guinea tribes who have witnessed their pristine rainforests cleared, even on steep slopes, for subsistence farming (O'Neill 1996). One tribesman said, "While we believe we are descended from the forest, most Indonesians believe that devils live in the forest and that the forest must be destroyed" (O'Neill 1996). The Indonesian government clearcuts 5 acres of forest for each family and supplies tin shacks, seeds and tools (O'Neill 1996); these shacks are lined up in rows on the remnants of the rainforest that once rang with the calls of birds-of-paradise. Villagers are encouraged to cut trees and are paid $1.30 for each tree by the government (O'Neill 1996). Roads, schools, clinics and other modernizations are planned, and towns of up to 250,000 people are being carved out of the virgin rainforest (Flannery 1998). New Guinea tribespeople are resentful about the forest cutting and have documented many instances of killing and cruel treatment they have received from the Indonesian military (Flannery 1998). They believe that Indonesia has invaded their lands, and they have organized a resistance movement, demanding that the land be returned to them (Flannery 1998).

The relocation program has been a dismal failure, not only for the people who were unable to farm the thin, infertile soil of cleared rainforests, but for the devastated environment and wildlife (Durrell 1992, Flannery 1998). The rainforest is not the only ecosystem that has been destroyed by these settlers. On heath and sandstone ridges on Borneo, stands of Ironwood (*Eusideroxylon zwangeri*) grow. These are very unusual trees for tropical areas (Mittermeier *et al.* 1999a). Many of the Javan immigrants are unhappy with the conditions of their new lives and return home (Mydans 1996a). Irian Jaya is expected to remain a center for relocation, however, since only 4 million people live here, and the giant Freeport mine that has removed entire forests employs large numbers of people who come from abroad to work in the mines, living in air-conditioned, newly built homes. Family planning over the past decade reduced the rate of growth on Java from 2.1 percent to 1.5 percent, or half a million fewer births every year (Durrell 1992), but an influx of as many as 1 million people a year still flood into Java from elsewhere in Indonesia and Southeast Asia (Mydans 1996a). Had Indonesia devoted more of its financial resources to family planning a generation ago, as did Singapore, which now has a stable population with a low birth rate, the highly expensive relocation program would not even have been considered.

Focus on Indonesia: Page 11

The future of Indonesia's forests and their wildlife may be as bleak as that of other tropical forests in the Philippines, Thailand, West Africa and many parts of Latin America and the Caribbean. The disappearance and endangerment of large, wide-ranging mammals, followed by fragmentation and loss of the fauna and flora of entire regions, is a pattern that is being repeated here. The government has set aside many national parks, but as in other parts of the world, they are rarely given a high priority for protection, and local people are allowed to log and even establish agriculture plantings and villages within them. The native tribes of Papua and Kalimantan may force a change in the attitude of the government toward the forests and even end in a return of the land to the people who have lived there for thousands of years and have a strong bond with the native trees and animals. Violence has broken out between natives and immigrants on both islands, leading to the forced departure of hundreds of people in Kalimantan after many were killed by Dyak tribesmen in 2001. In Papua New Guinea, international rainforest organizations have become allied with native tribes in fighting corporate loggers from Australia, and they have been successful in taking

legal actions that negated corrupt agreements made between their own leaders and the loggers.

The potential for ecotourism in Indonesia is great. The islands are already a major draw for tourists, spending more than $1 billion per year. A powerful movement for democracy is making strides in the country, and with more help from the United States and other democracies of the world, this would become a reality. With a radical change in Indonesia's government, priorities might change to benefit the Indonesian people and their environment instead of making the rich richer at the expense of biodiversity. If that happened, more and more people would learn the value of preserving forests and the country's extraordinary biodiversity for their own benefit as well as that of the entire world. The thin, tropical soils of the country have proven to be best for growing trees, and when this is better appreciated, the tide may turn.

Strong and immediate action is required, however, to prevent biological diversity losses that will dwarf those of any other area on Earth. Stabilizing the human population would be a major step in the right direction. By 2025, it is projected that Indonesia's population will exceed 275 million (Mittermeier *et al.* 1999a). If the government does not stop the disastrous and unsuccessful resettlement program, there will be no wilderness forests left, and the remotest national parks will be invaded for tree and rattan cutting and other destructive uses that will inevitably cause massive animal and plant extinctions.

The participation of international conservation organizations in programs to educate Indonesians to live in harmony with nature and to protect biodiversity is in its early stages. Several of these groups have helped produce field guides, books, posters, pamphlets and textbooks, and the series *Ecology of Indonesia*, in Indonesian (Mittermeier *et al.* 1999a). Protected areas total about 110,000 square kilometers, and the important work of protecting them from encroachment and destruction is being aided by projects such as The Nature Conservancy (TNC) work in a huge, 231,000-hectare national park in southern Sulawesi, Lore Lindu National Park (Mittermeier *et al.* 1999a). In cooperation with the government conservation agency and local groups, TNC is conducting a comprehensive education program that also encourages butterfly farming and ecotourism to stem forest clearing and rattan collection (Mittermeier *et al.* 1999a). Other programs to encourage ecotourism and create sustainable models for local economies have been launched. In some cases, international programs have failed. In the 1980s, the World Bank funded a program to protect a 300,000-hectare national park in northern Sulawesi and help local farmers irrigate rice fields while protecting the watershed. These worked at first, but enforcement lagged and gold miners have entered the park and poisoned rivers with mercury. Forest clearing, hunting and rattan collection have also occurred within the park (Mittermeier *et al.* 1999a). Emergency programs to stop incursions into national parks are needed.

A new and potentially major source of income to benefit wildlife and the environment involves the placement of videocameras connected to the Internet in wilderness areas. These cameras can be solar-powered and placed in tree tops, animal dens, waterfalls or other attractions. Such videocameras, using satellites to beam live pictures or web pages to Internet users around the world for a small fee, are helping to finance the conservation work of national parks in South Africa and Central America. Internet users have increased exponentially in the past decade and are expected to continue to grow in number. Many "surf" the Internet for amusement, while others seek wilderness views or natural history information. If the funds were managed so as to be devoted entirely to protection of the environment and related programs, many millions of dollars could accrue. A conservation organization could publicize the fate of a particular species, group of species or region to raise funds for its protection. Certainly Indonesia has hundreds of appealing animals. Orangutans, Sumatran Tigers, Proboscis Monkeys, gibbons, Babirusa, tiny deer, cockatoos and parrots (some as small as sparrows), birds-of-paradise, bower birds and Komodo Dragons are among animals that could appeal to millions of people around the world. Spectacular and magnificent coral reefs, ancient forests, giant flowers, carnivorous plants, mangroves and wild rivers could also be filmed for the Internet. An Internet site could have biodiversity data for students and the general public and lists of projects that need financial aid. Ecotourism opportunities could also be part of this site.

On behalf of American consumers and those in Japan and countries importing plywood and concrete forms from Indonesia, conservationists could approach importers, building companies, stores and builders to propose substitutes.

In many cases, users of these products have little idea where they came from or the effect their purchase has on forests half a world away. The key to saving Indonesia's wild heritage lies in making it more profitable to conserve it than destroy it, and educating these already highly literate people to preserve their own future in the process.

Forest

http://www.endangeredspecieshandbook.org/forest_indonesia.php

Introduction

In an Ecuadorian rainforest, great towering trees festooned with orchids whir with hummingbirds. Primitive mammals skitter up massive Australian trees of species older than the dinosaurs. The world's tallest trees grow in northern California; at the forest floor beneath them grows an intricate diversity of emerald green mosses and ferns inhabited by tiny creatures. At the southern end of the South American continent, a forest of small gnarled trees buffeted by sea winds shelters herds of short-legged Huemul deer. Kiwis, in their downy cloaks of brown feathers, probe the forest litter among giant tree ferns in New Zealand's dark rainforests, pushing their long, pointed bills into the soil to extract earthworms. Monkeys with elaborate facial patterns, in blues, reds and blacks, chatter in treetops above a plodding West African elephant herd. New Guinea's dazzling birdwing butterflies, measuring 1 foot across, flutter near moss-hung trees where iridescent birds-of-paradise display and utter resounding, eerie calls. Thousands of insects and hundreds of other life forms may inhabit a single tree, whose fruits and flowers feed countless other animals, each the product of eons of evolution and geological history. These irreplaceable forests are in imminent danger of disappearing. The most biologically diverse of these are the untouched, old-growth forests of the world, of which only 20 percent remain, largely unprotected from destruction.

Benefits of Forests

The great beauty and inspirational qualities of forests belie their important biological tasks. By producing vast amounts of oxygen and water vapor, and absorbing carbon dioxide, they help support all life on Earth. A single mature oak tree produces enough oxygen to keep eight people alive for a year. In 1995, an international team of ecologists working in Brazil documented that each hectare (2.47 acres) of undisturbed tropical rainforests absorbs 1 ton of carbon dioxide per year. The world's rainforests are thus absorbing a billion tons of carbon dioxide a year, one-sixth the amount produced by burning fossil fuels such as oil and coal, according to the National Oceanic and Atmospheric Administration (NOAA). Cutting and burning of forests around the world releases carbon dioxide into the air. The high levels of carbon dioxide in the world's atmosphere have caused increases in average global temperatures. The value of tropical forests in trapping carbon dioxide is so significant that four US utility companies have sponsored a pilot program in Belize to protect large areas of forest and plant trees; energy companies will contribute $2.6 million to a 120,000-acre reserve that will absorb 5.2 million tons of carbon dioxide gas over 40 years (Geatz 1996). The Clean Air Act allows such "pollution credits" to compensate for pollution released elsewhere. In 2000, the US government proposed a massive program of tree planting and protection of forests to compensate for the effects of global warming caused by the release of carbon dioxide and other pollutants.

The cooling effect of forests results from leaf transpiration generating moisture that rises to the atmosphere, forming clouds which release water as rain or other precipitation. When forests are cut, the climate dries as rainfall decreases and soils lose moisture. Tree roots absorb about one•half of the rain that falls, releasing the water gradually during the year (Schreiber *et al*. 1989). In countries with wet and dry seasons, water retention by trees makes the

difference between deadly floods that kill thousands of people and sweep away their homes and precious topsoil, and river levels that remain stable, preserving soil and the environment. Forests stabilize the soil, preventing erosion and landslides and allowing streams and rivers to flow clear.

The leaves, bark and wood of trees have been found to contain hundreds of compounds valuable to medicine and industry. Forests produce a wealth of useful species: oils, gums, resins, tannins, waxes, edible oils, dyes, cosmetics, spices, fruits, nuts and life•saving compounds used in medicine. Spices alone are worth more than $1 billion per year (Schreiber *et al*. 1989). Medications derived from wild plants are worth $40 billion annually (Lean and Hinrichsen 1994). Painkillers, birth•control agents and malaria drugs, as well as quinine, digitalis and morphine, are all derived from tropical forest plants. According to one study, more than 40 percent of all prescriptions in the United States still depend on natural plant sources (Swaminathan 1990). Only a small percentage of wild plants have been tested for medicinal value. In some cases, plants that might have disappeared altogether were found to be medical treasures. The Madagascar periwinkle, native to an island which has lost 80 percent of its forests to deforestation, has been the source of two potent compounds that have proven effective in the treatment of Hodgkin's disease and produce a 99 percent remission in patients with acute lymphocytic leukemia (Myers 1983). Global sales of these two drugs now exceed $180 million a year (Wilson 1992). Taxol, a compound from the Pacific Yew found in the last of North America's old-growth forests, has proven effective against ovarian and other cancers.

In the long run, forests left standing are of greater benefit than those cut and destroyed. The dollar value of natural ecological systems, of which forests make up a large part, in performing services for human society has been estimated at as much as $54 trillion, as seen in Chapter 1 ("Earth's Worth" section). Along with their role in flood prevention and climate regulation, forests provide fruits and flowers to be pollinated by wild insects and birds, and clear rivers as habitat for valuable salmon and trout fisheries (Stevens 1997b). The World Resources Institute in Washington, DC, has calculated that the loss of value from deforestation is four times as high as the value of the timber extracted and the depletion of soils, forests and fisheries amounted to an average reduction of 25 to 30 percent in potential economic growth (Stevens 1997b).

The ways in which forests function are only beginning to be understood. Great fig trees are dependent on tiny wasps to complete their reproduction, and fungi in the roots of trees play intrinsic roles in their survival. Pollinators are key to the health of forests, but for many species of trees and plants, only fragmentary information has been acquired about how they are pollinated and the conservation status of these pollinators. Understanding the interrelationships of plants and animals within these ecosystems is key to their preservation, yet forest ecology is in its infancy.

While logic would seem to mandate that such awesome and useful ecosystems be accorded great respect and legal protection, the opposite is true. They are being destroyed so rapidly by logging, dams, climatic changes caused by human activity, and pollution that the last pristine forests may soon be gone. Even minor alterations in their environments have interfered with their healthy functioning.

Cutting forests for financial gain or to resettle people from overpopulated cities provides developing countries with short-term solutions to problems and one-time profits. Neither the extremely important ecological roles that forests play, nor their value as species storehouses, are appreciated by the majority of the world's nations. The recent spate of massive landslides and floods after periods of heavy rains in countries around the world has, in most cases, been traced to logging that left hillsides and entire regions open to erosion. Millions of people have been left homeless around the world in recent years, and thousands have lost their lives to such floods. These floods may be only a prelude to far more serious and long-lasting consequences of forest destruction. Global warming will increase as forests vanish, especially with the cutting of old-growth trees, which have immense canopies for absorbing carbon dioxide and cooling the atmosphere. Higher temperatures have already brought droughts, increased desertification and caused rivers and streams to lose volume and even dry up. The loss of potential disease cures is another byproduct of destroying forests, and the destruction of these beautiful environments, with their multitude of life forms, may result in collapsed ecosystems that cannot be restored.

Forests' Retreat

As recently as 1960, forests covered one•fourth of the Earth's land surface (CEQ 1980). With continued logging and clearance, two decades later, in 1980, only one•fifth remained forested (CEQ 1980). Since then, forests have continued their decline, losing more than 5 million square miles since 1960. During the last quarter-century alone, the world's forests have shrunk the equivalent of one-half the land area of the United States.

This destruction has threatened thousands of animals and plants with extinction. In fact, forests have the greatest number of endangered species of any ecosystem. Of all types of forests, primary, old-growth forests, especially tropical rainforests, harbor the greatest wildlife and plant diversity and the greatest number of endangered species (Collar *et al*. 1994, Collins 1990, Mittermeier *et al.* 1999a). Second-growth and mixed types of forests are also key habitats for many species, and clearing these forests has threatened thousands of plants and animals.

Forests' Retreat: Page 1

Forest destruction is often gradual, a whittling away by settlers and farmers who destroy portions of forest to grow crops using fislash-and-burn,fl in which trees are cut, set afire, and the ashes are used as fertilizer for subsistence agriculture. In tropical forests, the thin soil is fertile for only a few years, and farmers move on to clear more forests. When human populations are very small, as in the case of the native peoples of many tropical forests, their effects are not severe or permanent, as the forest grows back. Non-indigenous people, however, often remove forest cover permanently**.** They do not think of the forest as a source of life, providing food and protection, as native peoples do. The entire center of the 1,000-mile-long island of Madagascar, once a verdant paradise with giant trees and teeming with wildlife, is now a moonscape as a result of such misuse of the land. Millions of rural people in developing countries now depend on wood cut in local forests for fuel. This has been another major factor in deforestation because of the growth of human populations spreading into new regions, cutting trees and clearing away vegetation.

In the Caribbean, Europe, eastern North America, North Africa and West Asia, most of the original forest cover was destroyed prior to modern times. These forests will not return once cut, nor will their diversity. The ecology and diversity of the forests that once covered much of Europe and the eastern United States will remain unknown because they were cut prior to any biological studies. We have only descriptions of giant trees and the wildlife that inhabited these forests. In the temperate rainforests of the Pacific Northwest, however, biologists are studying the last 5 percent that survives of these magnificent**,** old-growth forests. Working in the canopies hundreds of feet above the forest floor, they are making new discoveries about these ecosystems. They have learned that lichens colonize only the oldest forests and are key to fixing nitrogen (Moffett 1997), or converting this essential gas into compounds that can

be used in forming life-sustaining amino acids and proteins (Franck and Brownstone 1992). One forestry student who climbed a 2,000-year-old Sequoia found cones growing only on the outer branches, which can remain on the tree for as long as two decades**;** a rich variety of lichens grow**s** on trunks and branches (Moffett 1997). Such discoveries illustrate the importance of preserving these ancient forests.

Only a little more than a century ago, rainforest and temperate old- growth forest covered millions of square miles in West Africa, Central and South America, Southeast Asia, Australia and the western United States. Early settlers, followed by commercial loggers and large-scale livestock and agricultural interests, permanently destroyed these complex ecosystems. In some areas, second-growth forest or shrub has replaced them. Only in Amazonia, Central Africa, Russia and northern Canada do large tracts of virgin forest remain, and these are now being logged by international corporations.

Forests' Retreat: Page 2

A major use of timber is newsprint. Every Sunday edition of *The New York Times* consumes 75,000 trees (Bohan *et al*. 1996). Each issue of *Audubon* magazine, published by the National Audubon Society bimonthly, consumes 1,500 trees to make the 150 tons of glossy paper used to print 500,000 copies, according to its own research (Webster 2001). The trees used in the making of this paper were cut after 12 years by a mechanical harvesting machine that periodically clearcuts and replants with only one type of tree, creating an unnatural monoculture (Webster 2001). To remove the cellulose, chlorine is used, which releases .004 pounds of chlorine and chlorine gases into the air (Webster 2001), less than in the past but still an environmental threat. This organization, like many using large amounts of non-recycled paper, claims that the monocultures are teeming with wildlife (Webster 2001) and, by all appearances, does not consider other alternatives for the manufacture of its magazine. Other magazines, such as *National Geographic*, also use unrecycled, glossy paper. By contrast, The Nature Conservancy decided in the 1990s to abandon use of virgin paper for their magazine, even if it meant a less glossy finish, and now prints on recycled paper. Many other conservation organizations have followed suit.

Tropical woods are also used to manufacture paper. With conservation and recycling by consumers in North America, Europe and Japan, no tropical forest trees would need to be cut for paper. The majority of newspaper used in the United States, which is the world™s largest consumer of paper, is thrown into landfills or burned (Bohan *et al.* 1996). Many tree-based products, from shipping crates to plywood and paper, could be made from other materials, both non-wood and re-used wood. Corporations feed a market hungry for inexpensive raw material. The trees are sold for almost nothing by the countries of origin, resulting in high profit margins for logging companies.

Forests' Retreat: Page 3

In the year 1500, tropical forests covered continental and island areas totaling 5.5 million square miles (Collins 1990). Today, only a fraction of this extraordinarily rich ecosystem remains. The estimates of loss vary. Some scientists count only the acreage of untouched pristine rainforest in their estimates, while others include various types of tropical forests, second-growth and disturbed forests. Satellite images, combined with aerial photography and ground surveys, are giving an ever more detailed and accurate picture of the decline of these irreplaceable forests. One reference, *The Last Rainforests*, edited by Mark Collins (1990), calculated that in 1990, only 3.3 million square miles of tropical forest remained in the world. It estimated that about 54,000 square miles were being cleared worldwide every year (Collins 1990). This authority concluded that 50 percent of all tropical forests had been lost since 1900 (Collins 1990). In the disastrous decade of the 1990s, as much as half of the remaining tropical forests were cut or burned. Although estimates of loss vary, there is general agreement that dramatic losses occurred in many

parts of the world during the 20th century.

This destruction is taking place at a catastrophic rate. According to Dr. Edward O. Wilson of Harvard University, an expert in biodiversity and tropical forests, the surviving tropical forests equal the lower 48 US states in area, and a region the size of Florida is disappearing each year. The Nature Conservancy (2000) estimates that 40 million acres of tropical forests disappear every year. Settlers in many tropical forests have traditionally practiced slash-and-burn. The soil is so thin that it becomes sterile after a few years of farming, and the farmers move on, cutting more forest. Such practices whittle away at forests, but when carried out only by small bands of natives, these cut-over acres tend to recover in time. In many areas, however, European settlers have cleared land in this manner and fertilized the soil, maintaining it as agricultural land or depleting it so severely that the forest can never grow back.

Forests' Retreat: Page 4

Cambodia's last expanses of tropical forest are being lost in a pattern typical of many countries. Intensive logging during the past 50 years has reduced forest cover in this country from 70 percent to only 35 percent (Mydans 1996b). In spite of a logging ban instituted in January 1996 and a ban on exporting logs set in place in April 1995, the country's two Prime Ministers signed secret concessions to sell off virtually all of Cambodia's remaining forests (Mydans 1996b). The ancient teak forests are being openly felled, with logs exported to neighboring countries for profits of $10 to $20 million per month and in spite of official pledges to stop this logging (Mydans 1996b). Elephants are used to haul the logs across rough terrain, and many are abused with drugs to keep them working and overloaded, causing serious injuries or death. Some have been maimed or killed by stepping on land mines. Armed guards protect these loggers and sawmill operators; regional forestry officials, who oppose the cutting, are unequipped to confront them (Mydans 1996b). Already, siltation, erosion, flooding, and destruction of agricultural fields have resulted, and Cambodia's King Norodom Sihanouk, who appears helpless to stop this situation, commented, "If this deforestation does not stop, Cambodia will be, alas, a desert country in the 21st century" (Mydans 1996b).

Asian logging companies have now turned to the pristine forests of Belize, the only sizeable forests remaining in Central America. In 1997, the government of Belize sold logging rights to Atlantic Industries, a Malaysian company, for $60 an acre to clearcut in primary, old-growth rainforest**,** principally for mahogany (Hecker 1997). The company logged in areas outside the agreed-upon area and leveled large numbers of Sapodilla trees, the source of chicle that can be tapped sustainably (Hecker 1997). The deforestation of Central America has been most extreme in El Salvador, Nicaragua and Costa Rica (Collins 1990, Harcourt and Sayer 1996). Fires set by settlers and business interests creating plantations for palm oil and tree farms, burned out of control in the late 1990s in Borneo, Sumatra, Bolivia and Brazil, destroying many ancient forests, including some in national parks.

Secret agreements between various government leaders and international logging corporations or with friends and relatives, for logging rights over large sections of forest are commonplace in many countries. Indonesia and Malaysia, for example, encourage destructive clearcuts in which conservation is not a concern, and fast-paced logging is carried out because the agreements may be negated by a change in government officials (Yates 1992). The largest remaining rainforest in West Africa, a 2.5-million-acre swath in Liberia, is being logged by a Hong Kong timber company as a result of a large bribe paid to the brother of Charles Taylor, the newly elected President of the country (Farah 2001). Such bartering away of the world's greatest treasure-houses of biological diversity is a travesty that will adversely affect the Earth's stability and the lives of many generations of people in the future. Lost will be magnificent ecosystems containing plants and animals not even discovered.

Corporate logging has emerged as the major cause of tropical forest destruction, greater even than the losses to settlers and agriculture. This logging is carried on without international controls and with inadequate national controls. This industry grows each year, and the international trade in wood, pulp and paper is now worth about $100

billion per year, making timber the third most valuable natural resource (Bohan *et al*. 1996). Of this total, a large percentage is timber from tropical forests. By the mid-1990s, scientists estimated that some 80 percent of Southeast Asia's--and a similar percentage of West African and Madagascar's--forests had been destroyed. An in-depth study of corporate logging by the Environmental Investigation Agency (EIA) estimated total sales of one of the largest corporations, Mitsubishi, at $5.3 billion in 1995, controlling a total land area of 9 million hectares (22.2 million acres) (Bohan *et al*. 1996). Mitsubishi's plywood mill in the Brazilian Amazon consumes 130,000 cubic meters of logs every year through the intensive and unregulated harvest of virola trees (Bohan *et al*. 1996). About 75 percent of all tropical forest trees is turned into plywood for disposable packing crates, construction and furniture, according to the Rainforest Action Network (RAN) of San Francisco, California (RAN 1993). The United States alone imports several hundred million pallets of tropical hardwood each year and throws them away after a single use (Revkin 1997).

Forests' Retreat: Page 5

The promotion of a commercial approach to old-growth tropical rainforests, even "sustainable yield," is based on fragmentary and inadequate knowledge of these ecosystems. It is not known with certainty that their trees can be harvested without harm. Sustained yield forestry concerns prevention of the extinction of various tree species by controlling harvest and, to a lesser extent, protecting of watershed and soil, but not necessarily ecosystem protection. Maintaining the complex web of plants and animals that form a forest should be the prime consideration in conservation. To this end, protection from harm is the logical approach until these ecosystems are properly understood. Their ecological value will only be measurable as knowledge about their functioning and their role in the world's climate are explored in the future. In economic terms, they have great potential as tourist attractions, and the new videocam Internet business, as described in the Focus on Indonesia section below, will likely far outproduce short-term income from timber or conversion to agriculture.

An indication of the effects of this destruction is the fact that 76 percent of the 1,186 birds in higher categories of threat, or 902 species, are forest•dwellers, according to *Threatened Birds of the World*, a comprehensive report by BirdLife International, which examines bird status for the *Red Lists of Threatened Species* published by the International Union for the Conservation of Nature (IUCN) (BI 2000). All these birds are in danger of extinction. Some, such as the 182 Critical species, are in imminent danger of becoming extinct. Of the 902 forest birds, 93 percent are native to tropical forests; of these, 41 percent are found in lowland forests and 36 percent in montane moist forests, such as cloud forests (BI 2000). Three-fourths of threatened forest birds are dependent on a particular type of forest, and almost half require near-pristine habitat, with little or no disturbance, or habitat degradation (BI 2000). Only 3 percent of threatened forest birds can tolerate habitat modification. Unsustainable selective logging affects 367 forest bird species, while other threats include clearing forests for small farms (24 percent), tree plantations, clearcutting forest, livestock grazing, cutting trees for firewood, mining in forests and human settlements (BI 2000). An additional 727 bird species are classified as Near-threatened or close to qualifying as Threatened.

Likewise, forests are the major habitat for threatened mammals. The IUCN assigned habitat types to 515 (46 percent) of threatened mammals, finding that about 75 percent inhabited tropical rainforest; of these species, 35 percent in lowland and about 22 percent in montane (Hilton-Taylor 2000). (Some mammals may occupy more than one habitat). Tropical dry forest accounts for another 15 percent; tropical degraded forest, 4 percent; and tropical savannah woodland about 5 percent of threatened mammal habitats. By comparison, temperate broadleaf forest is the habitat for some 4 percent; and coniferous forests, 5 percent of threatened mammals (Hilton-Taylor 2000). The vast majority of threatened frogs and toads are also native to tropical forests.

Many species of tropical trees have been driven to extinction by habitat destruction and the exotic wood trade. The majority of Caribbean islands, which were covered in tropical rainforests when Europeans first saw them in the late 15th century, are now barren. A species of mahogany native to the Caribbean (*Swietenia mahogani*) has been so

heavily exploited that no unstunted specimen remains. Elsewhere, once common species of forest plants and animals have been eliminated or endangered. Where habitats were limited on islands such as Hawaii and Mauritius, fragrant sandalwoods and other trees were cleared, and few--if any--specimens remain of the trees that once made up these forests.

Forests' Retreat: Page 6

The Rainforest Action Network has documented that 140,000 mahogany trees are being logged annually, with each tree worth about $1,500 wholesale in the United States, where most are marketed (Line 1996). RAN states that most of the mahogany trees in trade have been illegally logged from parks, conservation areas or other protected lands, causing ecological damage on a large scale.

Mahogany takes 40 years to reach harvestable size, and the majority of this wood that is traded internationally comes from wild harvested trees. Many tropical species have reached commercial extinction, and Honduran Mahogany, which grows to 130 feet with a massive canopy, is the major target of the logging industry in Central America. By having a market for mahogany, especially a lucrative one, loggers seek out these trees, even in protected national parks. Once in commerce, distinguishing legal from illegal becomes impossible.

Trees that are commercially valuable are often the very ones most important to wildlife for food sources or shelter. The largest and oldest trees produce the greatest profits and are the first to be cut. These trees provide nest holes for owls, toucans, hornbills, parrots, tiny monkeys, lorises and galagos, rare lemurs, and countless other wildlife species. Many species of wildlife use tree holes for shelter year-round. Although some birds, such as woodpeckers, can excavate nest holes, the majority of animals who shelter and nest in tree holes depend on natural cavities. These holes form when tree limbs fall off or from rotting within tree trunks. Research on wild macaws has determined that a lack of trees with nest holes plays a major role in limiting their populations. Macaws nest only in large cavities very high, usually 100 feet or more, in tall tropical trees. Only the oldest and largest trees have tree holes for the more sizeable animals, such as hornbills, macaws and families of small primates who den together.

The Harpy Eagle (*Harpia harpyja*), the world's largest eagle, is endangered in its neotropical rainforests. Its range once extended unbroken from southern Mexico through the Amazon but today it is rare or absent throughout the remaining forests. A major factor in its decline is logging of the tall, old trees it requires for nesting. These eagles need a high vantage point overlooking the treetops to spot prey and to prevent predation on their nests. Harpy Eagle chicks have a long period of fledging, and prior to their independence, they must strengthen their leg and wing muscles. Eagle parents always make their massive nests near the top of giant trees with wide branches near the nest where the chicks can exercise by running across the branches, flapping their wings. As the strongest avian predators in these forests, they must be able to kill animals as large as sloths and carry them off in their talons. Loggers spot these giant trees rising over the forest canopy and cut them for the enormous amount of wood they contain. In much of Central America, selective logging and clearcutting have destroyed many of the former haunts of this magnificent bird.

Dead trees still standing are also prime wildlife nests and shelters, but because they are considered fire hazards, they are cut routinely. Hollow limbs and fallen logs are used by many types of animals for shelter or nesting, and these are usually trimmed off by loggers. Rotting tree trunks and cavities in both standing and fallen trees support entire communities of insects and invertebrates, upon which many vertebrates depend for food, and which contribute to the forest's health.

Modern loggers use mechanized tools and machines to clearcut forests. Chainsaws can cut through the massive trunk of a thousand-year-old tree in minutes. For smaller trees, saws mounted on trucks slice their trunks like

matchsticks, and machines lift the trunks onto logging trucks for transport, trimming off side limbs in the process. Every tree in a forest, ancient or young, commercially valuable or cut only to be discarded, is logged. Forests covering 1,000 square kilometers have been completely denuded in a single clearcut. Huge processing trucks sweep through the forests, creating deep ruts in the forest floor. Roads are bulldozed for this logging, opening up forests, causing erosion to soils and flattening fragile plants. Baby birds, squirrels, bats and tiny primates in tree holes are killed as their homes are sent crashing to the ground and dragged along the forest floor.

Forests' Retreat: Page 7

Kitt Chubb, a Canadian wildlife rescuer, recounted the trauma that one family of owls endured as a result of a mechanical logging operation. Tiny Screech Owl (*Otus asia*) chicks, still downy and being fed in their treehole nest by the parents, suddenly found themselves slammed to the ground when the tree was cut. A giant logskidder machine roared through the woods gathering up the cut trees, including the one containing the owl chicks (Chubb 1995). The machine proceeded through the woods, bouncing and violently rocking over rocks and ruts. This cacophony must have terrified the owl chicks. Finally, the driver dumped the trees with a crash onto a pasture (Chubb 1995). Soon after, an employee with a chain saw began to cut up the trunks, and as he cut into a big knothole, he jerked the saw back when he saw three fuzzy grey owl chicks with their eyes closed tight (Chubb 1995). Amazingly, they had not been injured or killed after being knocked and bounced about. The loggers decided to save the little Screech Owls, bringing them to Chubb's wildlife rescue center. She placed them in a wooden box and returned with the box the next day to the spot where their nest tree had stood. The forest where the owls had lived had been obliterated, and not a single tree remained. Finding a hollow beech stump in the clearcut not too far away, she and fellow rescuers placed the box in the stump, covering the top with leafy branches for shade, hoping the parents would return to feed the chicks (Chubb 1995). The next day, Chubb was surprised to find a frog leg in the box with the chicks, left by a parent owl. The chicks were lively and vocalizing, and 10 days later, they were still healthy and ready to be banded (Chubb 1995). Unfortunately, few baby birds and other animals survive logging operations or are lucky enough to be rescued if found alive.

Even animals as large as bears are frequently killed when they den in large tree holes. If their cubs survive, they will die of starvation if not rescued. Numerous cases of logging operations orphaning or causing mothers to abandon bear cubs are documented each year. A National Geographic Society film, fiMother Bear Man,fl shown in 1998 on "National Geographic Explorer," told the story of three bear cubs found after logging operations and their long return to the wild under the care of a kind and experienced wildlife rehabilitator in New England. Turtles, rodents, snakes and ground birds sheltering in burrows can be crushed to death by heavy logging machines. The soil, no longer held in place by root systems, breaks loose when saturated by heavy rains. Severe erosion on hillsides can cause mud slides that swallow up houses and the forest below, leaving a virtual moonscape, devoid of life. On level areas, rain washes soil into streams and rivers, clogging them, which kills fish and other aquatic lifeforms. Beautiful tropical forests with 300 or more species of trees per acre, a typical diversity, and myriad species of birds, mammals, reptiles, amphibians and invertebrates inhabiting them, become denuded patches of bare soil interspersed with stumps and broken limbs after clearcutting.

Even in remote wildernesses, the heavy machines that are now used to harvest and transport trees create such havoc and noise that wildlife flees. Many species of rare primates and birds disappear from logged forests, unable to adapt to any logging activities. A recent study in Gabon found that selective logging operations so traumatized Chimpanzees (*Pan troglodytes*) that their population in one 2,000-square-mile reserve fell by 80 percent after logging, even though only 10 percent of the trees were cut (Stevens 1997a). Dr. Lee White, a biologist with the Wildlife Conservation Society in New York, who was studying these Chimpanzees, made the following observation when loggers were in the forest: "I had whole chimpanzee communities charging to about five meters and screaming at me, and that's very unusual behavior" (Stevens 1997a). They were observed in logging areas in extremely agitated states,

drumming on trees and calling to each other. The tremendous noise and disturbance by large machines apparently caused them to flee into the territory of neighboring Chimpanzees, where they fought to the death (Stevens 1997a). Both the Chimpanzee and Bonobo, or Pygmy Chimpanzee (*Pan paniscus*), are endangered species, and the latter is unlikely to survive much longer in the wild as a result of logging. Its tiny population inhabits a restricted portion of forest in the Democratic Republic of the Congo, the former Zaire. Both are also killed in large numbers for meat markets by loggers and hunters, who use logging roads to enter forests. The traumatized orphaned young are sold as pets and to others who exploit them commercially.

Forests' Retreat: Page 8

Many of the last old-growth forests have been cut for throwaway products such as shipping crates, concrete forms, plywood, chopsticks and newsprint. Virgin rainforests in southeast Asia, Australia, Alaska, Russia and British Columbia are being logged to supply the enormous demand for such products, destroying entire ecosystems in the process. The United States and Japan have played major roles in the logging and trading of lumber at extremely low prices for industrial uses (Yates 1992). When one country's forests are stripped, loggers move on to another. In this way, the great Philippine forests of Pliocene trees and Central American forests were cut in the mid-20th century, followed by the teak forests of Thailand and the hardwoods of Indonesia and West Africa. These areas have lost 80 percent or more of their forest cover, and loggers have now moved on to Central Africa, Burma, Belize and Amazonian South America. Brazil's beautiful rosewood trees have already been logged to near extinction. The World Conservation Monitoring Centre of Cambridge, UK, conducted a study on commercial logging and found that 304 tree species from Asia and Africa were threatened with extinction by trade (Bohan *et al.* 1996). Fifteen species of commercially logged trees are listed by the Convention on International Trade in Endangered Species (CITES) in the most endangered category.

In response to criticism about clearcutting, some logging companies and conservation organizations endorse selective cutting, or cutting only certain species of trees or trees of a certain age. Yet such logging is also destructive. One United Nations (UN) Food and Agriculture Organization (FAO) study found that selective cutting destroyed as much as 70 percent of forest cover when conducted totally irresponsibly and, on average, destroyed 30 to 40 percent of the trees (Bohan *et al*. 1996). Destruction of non-target trees occurs with the construction of logging roads and use of heavy equipment to extract trees; when tree canopies and vines entangle one another, many trees are brought down, although only one may be cut. A study in French Guiana found that an average of 57 trees are killed for every tree extracted by selective logging (Bohan *et al*. 1996). Research on logging in Sarawak, a Malaysian state on Borneo, found that of every 26 old-growth trees cut, 33 others were destroyed or damaged, and canopies were broken, isolating animals who will not cross open spaces (Yates 1992). The thin tropical soil was also compacted and exposed, preventing natural regeneration of the forest (Yates 1992).

Many logging companies claim that by cutting mature trees selectively on 30- to 70-year rotations, they are conserving forests (Collins 1990). By definition, no tree older than 70 years can exist in such a forest. Such logging will end in destruction of the ancient and diverse forests, with trees 1,000 or more years old harboring a wealth of species that can only grow and prosper in old-growth forests. The more diverse a forest, the more stable ecologically, and logging tends to impoverish diversity by selectively removing certain commercially valuable species.

Thousands--and perhaps millions--of species depend on primary, virgin forests and cannot adjust to second-growth or logged forests. How many, and which species they are, however, is only partially known. Even scientists specializing in forest wildlife have not determined all the species that fall into this category, especially in complex tropical forest ecosystems. Unfortunately, this knowledge is often acquired too late, after logging has taken place and endemic species have disappeared. Logging operations are proceeding with such speed, and the scientists chronicling the damage are so few in number, that in terms of threats to plants and wildlife, only the tip of the iceberg is being

documented.

Forests' Retreat: Page 9

Until the 1970s, no one knew what the effects of clearcutting forests would be on various species of rainforest wildlife. The US government's Smithsonian Institution, with ornithologist Dr. Thomas Lovejoy supervising, conducted the first scientific studies of the effects of forest destruction in the Amazon on a wide range of wildlife. Blocks of interior forest of various sizes were inventoried by teams of biologists with mist nets and live animal traps. After each inventory was completed, the blocks were isolated by clearcutting the forests surrounding them. Then, after a period, they were inventoried again to discover the effects of clearcutting on the wildlife in the newly isolated forest patches. This type of research aims to discover how large reserves must be to preserve the diversity of ecosystems.

The results of Lovejoy's research in Amazonian primary forest indicated that small reserves of 2.5 acres or less lose a large percentage of their wildlife, and the larger the reserve, the fewer the number of species that disappear (Lovejoy *et al.* 1984). Certain species are dependent on large areas of primary, old-growth forest and are quick to disappear as soon as forests are disturbed or fragmented. Bird populations tended to decline in most reserve sizes, and species composition changed. In the smallest plot, 39 species of birds dwindled to 18 species after three years, and in the larger plot of 25 acres, 48 species declined to 38 (Lovejoy *et al.* 1984). The understory species were censused, as opposed to the canopy birds which seem less vulnerable to fragmentation of forest. Ecological dependencies caused some extinctions. For example, army ants thrive in large areas but disappear from smaller ones, and birds that feed on these ants, such as antbirds which are diverse and numerous in primary forests, disappeared within a short period from smaller plots (Lovejoy *et al*. 1984).

In another chain reaction, the White-lipped Peccary (*Tayassu albirostris*) proved to be a keystone forest species. It digs small waterholes to wallow in when ponds dry up, providing habitat for other wildlife. Peccaries travel in large groups seeking their diet of fruits, especially palm fruits, and act as seed dispersers. The key to their survival is territory size: a herd of 100 animals requires a territory of 97 square miles (Fragoso and Silvius 1995). They disappear from smaller forests causing the local extinction of frogs, who lay their eggs in these waterholes. In the Amazon study, four species of frogs disappeared from areas where peccaries had insufficient habitat to survive (Lovejoy *et al*. 1984).

Many other mammals are affected by forest fragmentation. Twenty species of mammals occupied a large, undisturbed forest plot, while only five were left in an isolated 25-acre-forest; a mere three mammal species remained in a 2.5-acre-forest (Lovejoy *et al*. 1984).

Theoretically, extinctions also can be caused when species have limited distributions which are destroyed by logging. A number of birds and mammals, including several newly discovered marmoset species in the upper Amazon forests, inhabit extremely restricted ranges of only a few square miles. Some species of primates will refuse to cross a road, such as a logging road, or an open clearing. Should a road be built in the middle of their tiny ranges, they would face extinction. Since tropical forests have not been thoroughly inventoried, the endemic species at risk most probably number in the tens of thousands.

Butterflies that live only in deep, virgin rainforest are so intolerant of fragmented forest that they disappear from areas less than 250 acres and, even there, survive only in the central core area (Laurance and Bierregaard 1997, Lovejoy *et al.* 1984). Forest butterflies, which exist in amazing diversity, are highly sensitive to the disappearance of their host plants, upon which they lay their eggs, and thrive in greatest number when vegetation is highly diverse. Some cannot tolerate the penetration of light into forests, and others require such large territories to feed that they

disappear from small reserves, according to research by Keith Brown and Roger Hutchings (Laurance and Bierregaard 1997).

In small forest blocks, trees on the forest edge become vulnerable to the effects of wind and fire, fall in far greater numbers than those in the center and succumb to fires that spread from neighboring grasslands. Fires consumed large areas of rainforest in the Amazon during the late 1990s as a result of fragmentation. This was the first record of rainforest fires in this region. Storms blow down trees adjacent to the edges of fragmented forests and, over a period, will destroy the inner primary forest (Lovejoy *et al.* 1984).

Research on forest fragmentation is now taking place in Africa, Asia, Australia, the Indian Ocean islands and elsewhere in the world. Numerous scientific papers on the subject were gathered in a book entitled *Tropical Forest Remnants. Ecology, Management, and Conservation of Fragmented Communities* (Laurance and Bierregaard 1997). Many of these studies paint a grim picture of the effects of forest fragmentation on biodiversity.

Bats are important forest pollinators but are extremely vulnerable to extinction. They are rarely protected and often persecuted. The valuable Durian fruit of Asia is one such plant pollinated by a declining species of rainforest bat. Other food plants pollinated by bats include wild bananas, breadfruit, mangoes, guavas, avocados, almonds, cashews and cloves, according to Bat Conservation International, which is dedicated to changing the negative image of bats and preserving wild populations (see Organizations list for address).

Forests' Retreat: Page 10

Throughout the world, biologically diverse natural forests are being replaced with tree farms of fast-growing pine or eucalyptus. In Japan, cedar is planted over millions of acres for harvesting. The goal of these farms is to replace old-growth forests that take hundreds of years to mature with trees that can be harvested in 30 to 50 years. Large amounts of herbicides and pesticides are applied to prevent the growth of "undesirable" plants and to control insects. These tree farms have contaminated water tables, destroyed natural diversity, and eliminated countless life forms crucial to maintaining the ecological balance of the planet. Moreover, many are now failing even in their goal of producing fast-growing, healthy trees because of a lack of understanding of ecological systems and natural forest functioning. Tree farms are frequently swept by disease and, in the case of Japan's cedar plantations, which cover 10 million acres, shallow roots have resulted in trees blown over in windstorms and landslides after heavy rains. A healthy forest has many species of trees. This diversity discourages insect pests, which tend to specialize in individual species, from spreading and sweeping through the forest, killing all the trees. The variety of trees in a natural forest also means that many are deep-rooted or have root mats that anchor the soil from erosion.

An added environmental threat posed by tree farms is the use of genetically engineered seedlings, whose effects on ecosystems are not yet known. By transplanting genes from other species of trees--and even animals-- into these unnatural trees, the possibility that their seeds could spread to the wild and contaminate natural trees and plants is very real.

Major disruptions in pollination occur in fragmented forests. Natural tropical forests, with hundreds or even thousands of species of trees, have evolved complex systems of reproduction. Because other trees of the same species might be miles away, trees send their pollen far and wide. Insect pollinators travel great distances to find trees of the same species. Biologists have found that even in selectively logged forests, trees were not being pollinated naturally because others of their kind were removed or became too distant; some species self-pollinated, causing in-breeding, while others simply died out (Yoon 1995b). These biologists concluded, "Even the forests that appear the healthiest but are being selectively logged or otherwise thinned may be endangered in the long run by an increase in less desirable inbred seed" (Yoon 1995). Inbred stock usually loses vigor and ability to reproduce over the long run. This

is an ominous finding considering that many conservation organizations and international logging companies have endorsed certain "sustainable" logging programs, urging the public to purchase products identified as such. Moreover, many of these ancient trees tower 200 or more feet, with wide buttresses at ground level to anchor them in the thin tropical soil. Such trees may have stood on the forest floor for 1,000 years and are living monuments, treasures to be preserved, not raw material for packing cartons, furniture or paper pulp.

Preserving Forests

A 10-year mapping project by the World Conservation Monitoring Centre ending in 1996 found that only about 6 percent of the world's remaining forests are protected against logging and development. Because of the rate of destruction and the potential loss of biological diversity, this is an extremely critical situation.

Preserving Forests: Page 1

Much of the logging in the world is a result of markets provided in the United States, Japan and Europe for wood and wood products. Because paper pulp is cheap, there is little effort to find substitutes or even to recycle the millions of tons of paper thrown into landfills each year. The use of trees for making paper is government-subsidized, encouraging waste and destruction of forests. Tree farms have failed to meet the enormous demand for paper. Financial incentives to recycle or use other materials should be made by consuming countries. Finding substitutes for lumber and raw material for paper will be crucial in protecting entire forests. The United States imports 800 million pounds of paper from Brazil every year, to the detriment of that country's forests. In spite of computers and Internet communications, total amounts of paper used in the United States have not decreased; 4.3 million tons of paper are used in US offices alone each year, and millions more tons are used in newsprint, magazines and other paper products. Because of a lack of economic incentive, only a small portion of this paper is being recycled into new paper. In fact, studies of landfills have shown that 40 percent of material in these dumps consists of unrecycled newspapers.

Innovative approaches are needed to encourage recycling and to end subsidies and the importation of wood chips and newsprint from forests around the world. Some of the alternatives to paper made from wood are already in use. Thousands of years ago, Egyptians produced paper from papyrus reeds, and rice is still used to make paper in parts of East Asia. Cotton and flax are the raw materials of fine quality paper used for currency and other purposes.

Many other plant species are now seen as substitutes for wood pulp in making paper. In *A Wealth of Wild Species, Storehouse for Human Welfare*, Norman Myers (1983) mentions one of these, a plant called kenaf, that is a distant relative of cotton and okra. This plant has been cultivated for centuries in Asia for making burlap bags. A fast-growing, reed-like plant, kenaf shows great potential in the manufacture of paper. Its straight, slender stem has no side-stems, nor does it produce the kind of resins that must be eliminated when wood pulp is processed for paper. Planted like corn, it is ready for harvesting in four months and produces five times more pulp per acre than a pine tree plantation (Myers 1983). In research conducted by the US Department of Agriculture, kenaf has proven an excellent

substitute for paper in newspapers and even bank notes (Myers 1983). A few kenaf farms have been established without government sponsorship in Texas and other southern states, and already many organizations are printing newsletters using kenaf instead of wood-based paper. Processing kenaf does not involve the serious water pollution caused when cellulose is removed from wood and pulp is bleached with chlorine. Air pollution from wood pulp processing plants has been injurious to human health (Verhovek 2000).

Earth Island Institute of San Francisco, California, has published a report, *Forest Friendly Paper Guide*, giving more information on kenaf and other non-tree substitutes for paper, including a new paper product by Arboken of Canada that is made from wheat straw, recycled corrugated cardboard and calcium carbonate filler. A publication called *Guide to Environmentally Sound Papers*, issued by an organization called Conservatree, lists more than 400 types of "green" paper. Among these are recycled, kenaf-based, hemp, sugarbeet and corn, grass and crop waste paper. (These can be obtained from Earth Island Institute. See the list of organizations in this book for the address.)

Preserving Forests: Page 2

Most homes are constructed of wood. An average of 40 to 50 trees are needed to build a 2,000-square-foot wood-framed house (Bielski 1996). Building with stronger materials, such as steel, concrete, brick and stone, would spare millions of trees. Moreover, these materials are not vulnerable to infestations by termites, which destroy entire foundations and frameworks of buildings made of wood. To control these insects, pest control companies apply large quantities of extremely toxic pesticides that can leach into the soil and water table, killing wildlife, and pose hazards to the occupants of the house. The Institute of Ecolonomics in Ridgeway, Colorado, reports that a new tree-free "wood" has been developed for use as building material. Called BioComp, it contains half recycled plastic and half agricultural residue and, according to the Institute, is twice as strong as Douglas Fir, termite-proof, impervious to water, and can be made fire retardant. BioComp resembles wood and is easily molded, sawed and nailed. Some alternatives to wood are also less expensive. Steel is being used in New England homes for major support beams with a metal roof for less money than the same home would cost made of wood (Hotton 2001).

The Wood Reduction Clearinghouse has been formed in San Francisco to address the failure of considering consumption as a driving force in deforestation (Bielski 1996). A group of leading environmentalists issued a statement in 1995 calling for a 75 percent reduction in wood and paper use by 2025, and strategies for eliminating the need for wood altogether are being explored (Bielski 1996). The use of timber for shipping crates and concrete molds--especially tropical hardwoods--should be phased out and substitutes, such as plastics, phased in that would be more economical because they could be reused. Some stores are already using substitutes for the millions of cardboard cartons used to ship goods.

Preserving Forests: Page 3

At the 1992 "Earth Summit" in Rio de Janeiro, Brazil, convened by the United Nations Conference on Environment and Development, world leaders agreed on the importance of slowing the rate of global forest destruction. Conservationists have pressed for a new, legally binding Global Forest Agreement to conserve and manage the world's forests. In spite of the urgent need for such an international treaty, no agreement has been reached in the intervening years. Numerous meetings and conferences between nations have failed to draft a policy that would curtail the uncontrolled commercial logging that is ravaging forests around the world.

Several organizations, including the Environmental Investigation Agency (EIA), headquartered in London, and the

World Resources Institute (WRI) of Washington, DC, have issued reports that chronicle the damage being done and the need for such a treaty. EIA's report, *Corporate Power, Corruption & The Destruction of the World's Forests, The Case for a New Global Forest Agreement*, argues for the need for international agreements to control commercial logging (Bohan et al. 1996). This report gives detailed information on the companies doing the most environmental damage to the world's forests and the methods used by these corporations to bribe and otherwise corrupt the leaders of poor nations to obtain logging contracts. Other organizations, such as the Rainforest Action Network, agree that international logging corporations must be regulated. This $100-billion-a-year trade operates with generous tax breaks from the countries where companies are based and the granting of logging concessions that often cover millions of acres through special arrangements made behind closed doors with government officials (Bohan *et al.* 1996). Logging concessions almost always ignore or overrule strict legislation already existing in many countries protecting the environment and wildlife, including endangered species (Bohan *et al.* 1996).

At present, cutting of forests is "regulated" only by the timber industry itself through the Tropical Timber Agreement, signed in 1983 by various international lumber companies. This agreement does not protect wildlife and the environment. In spite of renegotiation in the mid-1990s, the agreement still does not address ecological concerns or species preservation. Pressure from multi-national companies, primarily Japanese, to supply this lucrative market have overwhelmed the voices of conservationists throughout the world.

Logging in Central Africa is in the process of destroying the once vast and unspoiled forests. A conference in 1999 was convened by the World Wildlife Fund (WWF) to reach an agreement about the fate of these large tracts of tropical rainforest in Africa, located in Cameroon, Central African Republic, Gabon, the new Democratic Republic of the Congo, Equatorial Guinea and the Congo. In this region, 40,000 square kilometers of forest are being destroyed a year, endangering hundreds of wildlife species and opening up the forest to a devastating trade in bushmeat. Prince Philip, in speaking on behalf of WWF, stated that the organization hoped to protect 10 percent of this vast forest, an area too small to prevent extinctions and great biodiversity loss. The Democratic Republic of the Congo, which is in a state of political chaos, did not attend the conference, and no pact was signed.

Preserving Forests: Page 4

The forests of the Democratic Republic of the Congo are among the wildest and least explored in the world, but this wilderness is being invaded by loggers and meat hunters. Michael Fay, a biologist with the Wildlife Conservation Society in New York, has been on a mission to cross this vast area on foot, accompanied by some natives and correspondents, describing the amazing sights along the way. He is trying to draw attention to this region and the urgency of saving it while most of it is still in pristine condition. He has already succeeded in having a sizeable national park established. His trek is dangerous, with poisonous snakes, leeches, tropical diseases and other threats, but he is a dedicated conservationist and scoffs at the dangers. The National Geographic Society is helping to sponsor his trip and publishes regular articles in their magazine on his progress, and their website gives more information. Several short films have also been made for the National Geographic fiExplorerfl program. His mission is extremely important and has the potential of preserving entire ecosystems of threatened animals and plants.

A growing awareness of the problem, along with creative solutions, give hope that in at least some parts of the world, large tracts of tropical forests and their wildlife will be spared. Two enormous parks were established in Suriname and Bolivia in the 1990s, mainly as a result of the work of Conservation International, a US organization that successfully convinced the governments of these countries that such protection will be far more beneficial for the country than short-term exploitation and forest clearance. Other organizations are working effectively in central Africa, Peru, Brazil, Burma, Laos, Vietnam, and the Philippines to protect these species-rich forests.

New approaches to deriving funds from forests without logging and destroying diversity include regulated

extraction of non-wood products, such as seeds, fruits and plants, for food and medicinal purposes. Ecotourism is one of the most lucrative and growing industries in the world, with revenues in the billions of dollars and rising.

Old-growth forests are being cut not because they provide raw material that cannot be found elsewhere, but because they provide a high profit margin to European, North American and Asian logging companies. Decisions made about the fate of these forests, upon which the survival of so many species depends, are not being made by the people where logging takes place, nor by conservationists. These precious and irreplaceable resources, habitat of the majority of the world's threatened species, are being sold to logging companies for pittances. The United Nations has recently endorsed the concept that forest diversity must be maintained, joining the ranks of many other international organizations. In time, society may learn to preserve these storehouses of evolution with the same zeal that great works of art are protected.

Preserving Forests: Page 5

One project has greatly improved the standard of living for villagers in India, while taking steps toward protecting the forest habitat of the highly endangered Bengal Tiger. Many thousands of residents were forced to move when Ranthambhore National Park was established decades ago, causing much resentment. At first, they were banned from gathering firewood and grazing livestock within the park. This had an extremely positive effect on the forests, which regenerated, and Tigers, deer and other wildlife prospered. Gradually, however, park authorities became more tolerant of the incursions of local people and their livestock into the forests. During the 1980s, large areas became deforested, and poaching endangered Tigers and deer within the park.

To reverse this trend and preserve the habitat of this park's wildlife, a Tiger conservationist and author, Valmik Thapar, established the Ranthambhore Foundation. This Foundation sponsored a nursery which propagated 500,000 tree seedlings, employing villagers to replant the national park. It set up a farm with domestic buffalo which had been bred with milk cows and kept in stalls and enclosures away from the forests. These animals yield far more milk than the emaciated Indian cows overgrazing the forests; fuel for cooking and heating is provided by a bio-gas plant producing methane from the buffalo's dung; a new crafts industry employs women in the village (Ward and Ward 1993). In the first four years of the project, 6,000 school children from local areas were taken into Ranthambhore National Park for education programs (Currey 1996).

A Cable News Network (CNN) reporter, Gary Streiker, visited one of these farms outside Ranthambhore National Park in mid-1997. The villagers were economically better off and appreciated having the bio-gas fuel, which saved them the effort of scouring the landscape for firewood, often a full-day's activity. This allowed them to devote time to crafts and other small businesses. Unfortunately, some of the other villagers around the park were still gathering wood, denuding the park. These age-old customs will be difficult to change. Eco-development and conservation projects in 60 villages surrounding Ranthambhore National Park have been launched. Conservation education on the importance of saving the forests will help to change attitudes and protect the park's wildlife and trees. This will bring tourists and new sources of income.

Preserving Forests: Page 6

Several remarkable successes have proved a positive contrast to the otherwise gloomy trends of forest destruction. In South America, large expanses of undisturbed tropical forest remain, but they are fast disappearing. The Amazon Basin and its forests once covered 2.3 million square miles, comprising three•fourths of the world's tropical forests, but forest clearing has destroyed some 20 percent of the original forests and damaged far more. Amazonian forests

contain 14,000 endemic species of plants (Harcourt and Sayer 1996).

Parque Nacional Madidi, Bolivia's newest national park, covers 4.7 million acres, protecting a variety of threatened habitats and species. Avian diversity for this park is estimated at 1,088 species of birds, or 11 percent of the world's birds, the highest in any protected area in the world; among these are many threatened species and others with small ranges (Remsen and Parker 1995). This park, watered by numerous rivers, borders eastern Peru and includes a variety of threatened environments. Humid lowland forests, grasslands and montane cloud forests are among these. Resident birds include the threatened Yellow-rumped Antwren (*Terenura sharpei*) and various species of tinamous and curassows (Remsen and Parker 1995). The latter birds are among the first species to disappear from areas as a result of hunting and habitat destruction. A proposed hydroelectric dam, which would drown large sections of rich lowland forests., is a major threat to the park. It may have been stopped as a result of publicity by *National Geographic* magazine, which featured a cover story in 1999 on the importance of saving this park. Public opinion and the potential tourist trade may compensate this country for lost revenues from the dam. An even larger park of 8.6 million acres along the border with Paraguay, the Kaa-Iya del Gran Chaco National Park, protects the most sizeable block of endangered dry tropical forest in the world (Seve 1996). These two parks will preserve more than 20,000 square miles, and native tribespeople will play a role in administering them (Seve 1996).

Another positive development is the trend in a growing number of countries to share the profits from national park fees with local people and involve them in the decision-making processes of managing the park and the local wildlife. Madagascar has been successful at this, combining income from park fees with international grants to build schools, libraries and clinics for the local people. Patricia Wright, a primatologist, helped establish Ranomafana National Park to protect endangered lemurs as well as to protect the watershed from floods. In the recent past, deforestation carried out by local villagers had caused landslides that inundated their homes and caused water sources to dry up. They have become convinced of the importance of preserving the forests for their own survival. This new approach of educating local people on the benefits that would accrue to them as a result of conservation, as well as payment from park fees and profits from ecotourism, is the future of forest preservation.

Another trend that will prove important is the involvement of biologists studying wildlife with local people, learning from their observations and sharing the knowledge they uncover. Biologists in Madagascar who rediscovered an owl thought extinct, brought local students to see it and raised money for needed school supplies from birdwatchers who came from around the world to see the bird. This creates a positive impression on the local people and instills natural history curiosity and a realization of the uniqueness of their own wildlife. In the future, this may be expanded by showing them films about the natural world that surrounds them and opening up new worlds with books and publications about the subject. Very few people are aware of the endemic wildlife and plants in the environments in which they live, whether in the United States or the Cameroon. When people learn of the flora and fauna in their neighborhood that exists nowhere else, or is of biological importance, they are far more likely to protect it. Even in the United States, where Natural Heritage Programs chronicle the endemic and declining species of every state, the information has not always been made available to the public in the form of state publications or television or newspaper publicity that could have a major effect on whether forests and other habitats are protected.

A recent campaign to alert the public to the ecological advantages of choosing shade-grown, organic coffee has helped preserve rainforests in many parts of the world. A trend toward planting coffee plants in open fields rather than in the traditional way, as an understory to tall trees, has been devastating to tropical forests, home to both tropical birds and other animals, and to migratory birds from North America who spend the winter in Latin America and the Caribbean. Smithsonian biologists began this campaign in 1990 when they saw bird species decline with the planting of sun-grown coffee plants, and patented the logo "Bird Friendly" coffee. Such coffee is now commonly sold in health food and specialty stores and may become more popular as the public is educated about the problem. With the enormous popularity of coffee, this could make a major difference to birds and other wildlife.

North America™s Forests

The history of the destruction of all but 5 percent of the 850 million acres of old-growth forests in North America has been recounted in Chapter One. Second-growth forests now dominate the East, forests far different in species composition from the original virgin forests. The great chestnuts, elms and beeches are gone, and woodlands are now young, mixed pine and hardwood. Moreover, these forests are fragmented by roads and development. Only a few roadless areas remain. A few remnants of old-growth forests have been located in the East, primarily on steep slopes and areas that loggers found difficult to reach. In southern Maine, for example**,** a biologist recently located a stand of Black Gum trees, some 9 feet in circumference. One stump had 450 rings, and another, larger one was still thriving. It was estimated to be more than 500 years old, dating back to the time of Columbus. Unfortunately**,** this area is in the path of development (BG 2000). The Great Smoky Mountains National Park is a large block of forest totaling 500,000 acres in the southern Appalachians of eastern Tennessee and western North Carolina. This national park harbors some virgin old-growth and a wealth of rare native trees, plants and wildlife, including a great diversity of salamanders that inhabit its damp, mossy forest floors and fast-flowing streams. It sits atop a mountain range that is a meeting place of northern and southern species, an important area to the endangered Appalachian forest ecosystems and a primary migratory stopover and nesting area for threatened wood warblers and songbirds. This area recently has been designated an International Biosphere Preserve, and its diversity is being inventoried by a team of biologists and other earth scientists.

North America™s Forests: Page 1

Migratory songbirds of eastern forests have declined by at least 45 percent in the past 50 years. These dazzling migrants--wood warblers, vireos, tanagers, orioles, grosbeaks and thrushes--suffer from a variety of threats. Deforestation of tropical forests where many of these birds spend the winter has been a major factor. Species requiring mature, undisturbed forest have declined to the greatest degree, some losing up to 90 percent of their populations. Clearcut logging and fragmentation of their breeding forests by housing, malls, roads and other

development have consumed millions of acres, displacing these songbirds. Many birds returning from tropical wintering grounds find their breeding forests destroyed or too small for successful breeding. A small patch of woods large enough for only one male songbird, surrounded by agriculture or development, will be abandoned if the male is unable to hear the songs of neighboring males (Line 1995). Many birds establish territories and maintain them by singing and challenging other males.

Another effect of forest fragmentation has been the proliferation of forest edge species that prey on songbirds and their eggs (Terborgh 1992). The Brown•headed Cowbird (*Molothus ater*), a parasitic species, was once seen only in grasslands. In the past, when huge herds of American Bison roamed the prairies of the Midwest, cowbirds accompanied them, laying their eggs in the nests of grassland birds, who raised them as their own. With the disappearance of the Bison, cowbirds entered the forests bordering agricultural and pasture land, laying their eggs in songbird nests. Some cowbirds now remain close to domestic cattle and fly into the nearest woodland to lay their eggs. Their eggs usually outnumber those of the host species, and the large chicks instinctively nudge the small songbird nestlings out of the nest. Because of the increase in forest openings, the net result of these losses has been a 90 percent decline in the number of songbirds recorded in the 1940s in many eastern forests (Terborgh 1992).

A campaign to declare a large section of the forests in northern New England a reserve began in the mid-1990s. To add urgency to the need for a national park in Maine, New Hampshire and Vermont, a new species of thrush, native only to this region, has been discovered. Once considered a subspecies of the wide-ranging Gray-cheeked Thrush (*Catharus minimus*), Bicknell's Thrush (*Catharus aliciae*) was found to be a totally distinct species in 1995, smaller and with a unique song. A bird of high altitude forests, it has already disappeared from its only nesting area in Massachusetts, Mt. Greylock. The major breeding area for Bicknell's Thrushes is now Vermont, whose forests are under pressure from ski developments and proposed wind turbines. Additional populations of fewer than 3,000 birds inhabit neighboring southern Canada, but the traditional practice there of thinning forests renders these forests unsuitable. Its habitat of spruce-fir forests is dying out from acid rain and global warming (BI 2000). This threatened bird is also losing habitat in its West Indian wintering grounds, especially Hispaniola, where forests are being cleared (BI 2000).

Another member of the thrush family is declining toward extinction. Known for its melodious, fluted song, which many find more intricate and beautiful than the Nightingale's, the Wood Thrush (*Hylocichla mustelina*) has declined precipitously in recent years. Native to undisturbed hardwood and mixed forests in eastern North America, the Wood Thrush winters in Central America, from southern Mexico to southern Panama (Rappole *et al.* 1983). In August, these birds begin their southerly migration, often gathering in groups where the chorus of 50 or more Wood Thrushes may echo like a cantata in the tall trees. One research project studied these birds in one of their tropical wintering areas in the Tuxtla Mountain region of southern Veracruz, Mexico, on the Gulf of Mexico. Studies of this population of birds began in the mid-1970s when the wintering habitat consisted of primary rainforest. (Rappole *et al.* 1989). This forest has declined by 85 percent, a far higher percentage than elsewhere in Central America, leaving mere fragments of the once rich tropical rainforest (Rappole *et al.* 1989). In 1980, the two researchers returned to find that their 12-acre rainforest study plot had been converted to a patchwork of fields and forest fragments; less than 5 acres remained of the original forest (Terborgh 1989). Using radio•tracking and mist netting, researchers discovered that Wood Thrushes do not adapt to forests without tall trees, even as a wintering area, preferring undisturbed rainforest. Year after year the same individual birds returned to the same sites. In rainforest, they tended to survive the winter, while Wood Thrushes forced to winter in neighboring second-growth or disturbed forest had a high mortality rate from predators and other causes (Rappole *et al.* 1989).

Throughout their winter range, the forests that once harbored tens or perhaps hundreds of thousands of Wood Thrushes in Mexico and Central America have been turned to pastureland or tilled for agriculture. Between 50 and 70 percent have been destroyed (Collins 1990). Fewer and fewer Wood Thrushes return to nest in Eastern forests, even when they have not been fragmented or cleared (Terborgh 1989). Their nests have also been vulnerable to parasitism by Brown-headed Cowbirds (Terborgh 1989). In Illinois, for example, where Brown•headed Cowbird populations have skyrocketed in past decades, one study found that 29 of 30 Wood Thrush nests had been parasitized by

Brown-headed Cowbirds, who laid eggs that crowded out those laid by the thrushes; the conclusion of the study: "Wood Thrushes are doing nothing but raising cowbirds" (Terborgh 1989). In the few areas where forests are unbroken and extensive, Wood Thrushes have been successful breeders (Robinson 1996).

Unfortunately, the combined effects of habitat destruction in both its breeding and wintering grounds, and parasitism of its nests by cowbirds, may result in the extinction of the Wood Thrush. A recent study in several Midwestern states found that birds from large stretches of forest that are holding their own may be having young that disperse to neighboring forest fragments, only to be crowded out by cowbirds (Robinson 1996). The melodic Wood Thrushes are disappearing throughout their range, along with many other beautiful songbirds.*

---

*See Video section. fiOn a Wing and a Song,fl a Canadian Broadcasting Co. film produced in 1994 for The Nature of Things series, explores the decline in songbirds. Another excellent film on the same subject with a similar title, fiOn a Wing and a Prayer,fl produced in 1995 by Kurtis Productions and WTTW for the PBS series New Explorers, concentrates on the decline in breeding songbirds of Illinois and their migrations.

Other changes in environments also contribute to songbirds' declines. Recent research has found that high levels of noise from highways, airports and other man-made activities have interfered with the ability of birds to sing breeding songs and breed successfully. Birds that migrate to the Caribbean and Latin America suffer high mortality from collisions with television and cellphone towers and tall buildings. For many years, one scientist at Chicago's Field Museum has collected migrating songbirds that died from flying into a single building near the museum**.** His collection now totals 20,000 birds. He estimates that total mortality from building collisions may be 60 million songbirds a year, an enormous loss.

A great concentration of breeding songbirds is found in Belt Woods, a 500-acre-forest near Bowie, Maryland. Trees that were growing when Columbus discovered America survive here. Perhaps the largest tract of old-growth forest in the region, it has a variety of habitats from swamp forest to dry hardwood stands. More than 40 species of migrant birds nest here, including Wood Thrushes, Rose-breasted Grosbeaks, Baltimore (Northern) Orioles, Scarlet Tanagers, Prairie Warblers and Ovenbirds. These are species that have disappeared from woodlands that have become fragmented, or contain few tall trees. This wealth of breeding birds underlines the importance of protecting old-growth forests. Privately owned, Belt Woods was willed by the late owner, William Seton Belts, to the Episcopal Church to be kept intact in perpetuity. The church, however, went to court in the 1990s to change the will to allow sale to developers, claiming that it had more important works to accomplish with the funds than saving the forest.

After conservationists had decided it was a hopeless cause, a local resident, Pam Cooper, decided to spearhead a rescue of these precious woodlands. By conducting publicity campaigns and fund-raising efforts, she and the Western Shore Conservancy raised money. A Maryland author and illustrator of children's books, Lynn Cherry, organized The Friends of the Woods to enlist children to help influence their parents and public opinion to place the preservation of this threatened woodland above that of sheer materialism and to champion the need to take on local conservation problems as a community. Her children's book, *Flute's Journey, the Life of a Wood Thrush*, chronicled the life of a Wood Thrush born in Belt Woods, its migration to Costa Rica and its uncertain future. The plight of Belt Woods was given national attention in April 1996 on a CBS program, "Sunday Morning," which may have been a crucial turning point in the preservation of this forest. Within months, an arrangement was finalized with conservation organizations that would turn Belt Woods into a reserve, ending the possibility that it would be sold to developers.

At a time when losses in the numbers of North America's beautiful songbirds may have become irreversible, scientific research is revealing that they play a crucial role in controlling insects in forests (Yoon 1994). In a controlled experiment, birds were excluded from a section of forest with netting cages that allowed insects to enter. It was found that trees and plants incurred twice the damage to foliage where birds were excluded (Yoon 1994). The

study concludes that songbirds constitute a major and important form of natural pest management, superior to pesticides (Yoon 1994). Keeping songbirds from nesting in a stand of White Oaks, other researchers found that caterpillars consumed so much foliage that the trees grew significantly more slowly than White Oaks with nesting songbirds (Robinson 1996).

North America™s Forests: Page 2

It would probably shock most residents of suburban New York City to know that 150 years ago, wild Gray Wolves preyed on White•tailed Deer, Eastern Bison and Elk in the dense virgin forests now occupied by their neatly clipped green lawns, while overhead the flight of millions of Passenger Pigeons darkened the sky. The Eastern United States is undergoing a "Europeanization" in which natural forest is being lost to housing tracts, highways and urbanization. This sprawl consumes the second-growth forests, some of which had become excellent wildlife habitat, and the new residents often contaminate the water and soil with pesticides and herbicides to maintain green lawns. The natural world and its fauna and flora are fast disappearing.

Just as they are disappearing, discoveries about the medical potential of eastern forest trees are being made. Recently a fungus was discovered that is a missing link in the life cycle of a mold that produces the billion-dollar drug cyclosporin, used to prevent the rejection of transplanted organs (Yoon 1996). The forest of the Finger Lakes Land Trust in Ithaca, New York, where Cornell University students found the fungus, has established the nation's first reserve set aside specifically for chemical prospecting outside the tropics (Yoon 1996).

Most of the Great Lakes region was originally covered in ancient pines. During the logging boom of the late 1800s, mills of one Great Lakes port alone, Ashland, Wisconsin, cut 500 million board feet of lumber a year (a board foot is equal to wood 1 foot square and 1 inch thick), enough for 50,000 houses (Johnson 1997). Timber barons shipped the lumber to rebuild Chicago after the great fire of 1871, and the logged-over area, covered in broken branches, stumps and discarded trees, ignited a series of fires, one of which killed 1,152 people in the town of Peshtigo, Wisconsin (Johnson 1997). These fires charred millions of acres, leaving a wasteland (Jonas 1993). By the end of the 19th century, the majority of these forests had been clearcut by commercial loggers (Jonas 1993). There remains a scarcity of timber, and in 1996 a treasure trove of 20,000 to 30,000 old-growth tree trunks was found by divers on the bottom of Lake Superior; they had sunk more than a century after being cut and floated to mills (Johnson 1997). Old-growth timber is extremely valuable. It has tight grain resulting from slow growth, unlike the grain in the trees grown on tree farms. These logs are worth many millions of dollars, and a company is bringing the logs to the surface, selling them for ten times the price of new wood (Johnson 1997). These are the last remnants of a once vast forest.

Early in the 20th century, Weyerhauser, the German timber magnate, having logged out the old growth of the Great Lakes area, turned to the forests of the Southeast. Forests dominated by Longleaf (*Pinus palustris*) and Shortleaf Pines (*Pinus echinata*), which have the world's greatest diversity of forest floor plants, dominated northern Florida west to Louisiana and north to central Georgia. Longleaf Pine forest once covered 90 million acres from Virginia to Texas. These forests also harbored Loblolly (*Pinus taeda*), Virginia (*Pinus virginiana*), Pond (*Pinus serotina*) and Pitch Pines (*Pinus rigida*), which grew in various types of soil and climatic conditions. Loggers decimated this ecosystem, cutting millions of board feet, and by the 1930s, these forests had been reduced to a fraction of their original extent. Today, only about 2 percent of the Longleaf Pine forests remain, making them the most endangered forest ecosystem in North America. For the most part, these forests have been replanted with other species, predominantly commercial tree farm monocultures.

Much of the remaining virgin pine forests of the Southeast lie on national forest land, and they are being heavily logged. On December 15, 1995, this destruction was fought by the Biodiversity Legal Foundation and the Alabama Wilderness Alliance, which filed suit in Federal District Court against the US Forest Service challenging the legality

of the Forest Service decision to open a series of massive salvage timber sales of trees blown down by a hurricane, along with some healthy standing trees, on 15,000 acres of the Conecuh National Forest in Alabama. The Biodiversity Legal Foundation hired biologists and other experts, who testified that Forest Service management of the forest violated its own environmental regulation relating to logging near waterways and had planted non-native trees instead of the native species that are preferred by the Red•cockaded Woodpecker (*Dendrocopus borealis*), an endangered resident of this forest. This lawsuit was settled in favor of the conservation organizations.

North America™s Forests: Page 3

A victim of this logging, the Red-cockaded Woodpecker is a small bird marked in black and white and named for the male's tiny streak of red on each side of the nape. These birds have very specific habitat needs. For nesting trees they usually choose old-growth pines stricken with red heart disease whose soft wood permits easy excavation of nesting holes; the sap running down the trunk deters snakes and other predators (McFarlane 1992). Red-cockaded Woodpeckers nest in small groups or clans, requiring large areas of undisturbed forest. Each clan has "helpers," non-breeding birds that aid in feeding the nestlings (McFarlane 1992). These woodpeckers were the primary control of the southern Pine Beetle, a major pest in pine forests; after destruction of old-growth pine forests, which endangered these birds, Pine Beetles proliferated and destroyed other types of pines (McFarlane 1992).

Prior to the commercial logging of the early 20th century, these woodpeckers may have numbered in the hundreds of thousands. Nineteenth century records exist of Red-cockaded Woodpeckers as far north as northern New Jersey and southeastern Pennsylvania, and west to Missouri (Jackson 1994). Gradually, their range shrank as pine forests were destroyed; by 1946 the species was gone from Missouri, and by 1976 from Maryland (Jackson 1994). Populations in Tennessee declined to a single bird by 1992, and they disappeared from northern Mississippi in 1977; Kentucky and Virginia have only a few family groups (Jackson 1994). In the Southeast, clans became rare and widely separated from one another as millions of acres of old-growth pine were logged. When listed on the Endangered Species Act in 1968, programs to prevent its extinction were launched. Inbreeding of Red-cockaded Woodpeckers is apparently occurring in populations isolated by forest fragmentation (Jackson 1994). Some females have been physically translocated to isolated groups without females to counteract this problem (Jackson 1994). Nest holes have been artificially created, and existing nest holes have been modified with steel plates, restricting the size of the opening to prevent predators and larger birds from entering the nest hole (Jackson 1994).

The problem of declining habitat remains, however, and some conservation organizations, including the Biodiversity Legal Foundation, have successfully taken the Forest Service to court concerning their replanting policies, obtaining court orders mandating replanting with Longleaf Pine to benefit the Red-cockaded Woodpecker. At present, only about 30 known clans remain, with South Carolina and Florida having the largest numbers; the entire population of the Red-cockaded Woodpecker may not exceed 7,400 birds (Collar *et al.* 1994).

One haven for the Red-cockaded Woodpecker is Eglin Air Force base, located on the Florida panhandle. This 460,000-acre base preserves the world's largest remnant of Longleaf Pine forest, which occupies 320,000 acres of the base (Stevens 1996); 10,000 acres of this forest are the largest remaining old-growth Longleaf Pine in the world, with many 400-year-old trees (Biondo 1997). The Nature Conservancy has spent years conducting biological surveys and has discovered that more than 90 rare or imperiled species, including a salamander new to science, inhabit the base (Biondo 1997). Eglin protects 1,200 plant species, with numerous threatened species among these. Military activities are carried out as carefully as possible, and the base employs a full-time chief of natural resources with a staff of 25 (Biondo 1997).

North America™s Forests: Page 4

The military conducts munitions tests on Eglin Air Force Base, causing fires that have inadvertently benefited the ecosystem. The piney woods of the Southeast need fire, without which shade-tolerant hardwoods begin to intrude on Longleaf and other native pine stands (Jonas 1993). At present, Eglin officials conduct controlled burns to maintain this habitat (Stevens 1996) and are removing non-native and overabundant plants and trees (Biondo 1997). To return the Longleaf Pines to former abundance, more than 3 million seedlings have been planted, restoring 200,000 acres over the past five years (Biondo 1997).

The Gulf Coastal Plain Ecosystem Partnership, a plan to link populations of Longleaf Pine forests, was formed in 1996 to protect 840,000 acres of contiguous forest held by seven major landowners in northern Florida and southern Alabama (Biondo 1997). The partnership has signed a memorandum of understanding that encourages cooperation between the diverse owners, from private logging companies to state forest departments and water management districts (Biondo 1997). More than 160 rare or imperiled plants and animals reside in these lands, and Eglin Air Force Base's land has been the best preserved of any because of limited human intrusion and very little logging. It also protects a sizeable population of threatened Gopher Tortoises (*Gopherus polyphemus*). This keystone reptile excavates deep tunnels and cavities which provide habitat and shelter during fires for hundreds of animals, including threatened species.

Southern Bald Cypress (*Taxodium distichum*) swamp forests were once found in many low-lying areas of the South, but today, the Okefenokee Swamp is the largest remaining tract. Plans to clearcut this huge forest were abandoned early in the century after logging proved unprofitable. Later, the Okefenokee was declared a National Wildlife Refuge, and it is one of the most important examples of this ecosystem, home to River Otters (*Lutra canadensis*), Alligators (*Alligator mississippiensis*) and abundant water birds.

Massive stands of ancient Live Oaks (*Quercus virginianus*) draped in Spanish moss evoke the very essence of the South. Although the majority of these huge trees have been logged, many survive that are 10 to 12 feet in diameter. They have a dense wood that was used in the construction of ships such as the USS Constitution. This ship was called "Old Ironsides" because this hardwood was impervious to cannonballs. The last sizeable stands of these picturesque trees are disappearing, however. Companies are buying wood lots with Live Oaks, cutting and replacing them with tree farms of fast-growing pine. As an added threat, a fungus first identified in the 1940s as "oak wilt," has been killing many Live Oaks. The disease chokes the flow of water into the tree and gradually kills it from the inside out, spreading through root connections which link Live Oaks growing in close proximity. In Texas, where this disease has killed many of these oaks, the Texas Forest Service has been successful in injecting chemicals that kill the fungus and digging trenches that break connections between these oaks.

North America™s Forests: Page 5

Predators of the Southeastern forests declined or disappeared after European settlement as a result of overhunting and persecution, leaving an imbalance in which White-tailed Deer proliferated without Grey Wolves or Mountain Lions to limit their numbers. Both the latter predators remain absent in the eastern United States, although there are unsubstantiated sightings of Mountain Lions in Maine and elsewhere. A few Grey Wolves have entered northern Maine in recent years, and some conservation organizations have proposed reintroductions of the species into Adirondack Park in New York state or in northern New England. Red Wolves (*Canis rufus*) were totally eliminated by predator control programs and hybridization with the Coyote, reaching extinction in the wild by 1973 when the last

wild members of the species were taken into captivity. This uniquely American species, which until recently was considered to have been native to only the southeastern United States, is now thought to have been distributed throughout eastern North America, based on DNA testing showing close relationships between the Red Wolf and wolves of eastern Canada, which have managed to persist to the present. The species was larger in northern states and preyed on deer and elk. Red Wolves survive today as a result of the 14 animals that formed the nucleus of the Fish and Wildlife Service's breeding colony. By 1993, more than 233 animals resided in 31 breeding facilities. Several successful releases have taken place in North Carolina and other eastern states, and about 100 Red Wolves survive from these releases.

West of the Mississippi River, pine forests in the mountainous regions of the Southwest were also heavily logged. A resident of these forests, the southern Mexican Spotted Owl (*Strix occidentalis lucida*), a race of the Spotted Owl, whose northern race inhabits old-growth forests of the Pacific Northwest, has become very rare. This owl, like its northern relative, requires undisturbed forests. The dominant tree of the southwestern forests is the Ponderosa Pine (*Pinus ponderosa*), which towers 180 feet tall and can live 500 years (Jonas 1993). Originally, these trees covered hundreds of thousands of acres in northern Arizona, New Mexico, and neighboring states; old-growth pine forests also stretched south into northern Mexico. Beautifully adapted to the dry, mountainous habitat, Ponderosa Pines often grow in large, pure stands. These forests have very little old growth left today, and Mexican Spotted Owls have disappeared from national forests in Arizona and New Mexico after the oldest trees were logged (Johnson 1995).

Many unusual and endemic species live in pine and juniper forests of the Kaibab Plateau on the north rim of the Grand Canyon. The Kaibab Squirrel (*Sciurus aberti kaibabensis*) is confined to this plateau. This beautiful squirrel is considered by most authorities to be a subspecies of Abert's or Tassel-eared Squirrel, but some zoologists treat it as a separate species. One of the most dramatic looking of all squirrels, the Kaibab is dark brown, with long tassels on its ears, and a snow-white bushy tail. Its close relative, Abert's Squirrel, is dark, grizzled gray on its back and tail. Feeding mainly on conifer seeds, these squirrels suffer high mortality from hunting, road kills and natural predation by hawks (Whitaker 1980). Their habitat is restricted, and they are considered a rare and endemic animal. Ecologically, these squirrels are important in helping the Ponderosa Pine reproduce. They dig for truffles and absorb their spores, which enter their feces. When their feces are deposited near Ponderosa Pines, they spread the spores to the tree's roots, which grow into a fungus, triggering the tree's reproductive biology. In the spring of 2000, wildfires raged through their habitat, undoubtedly causing the squirrels high mortality.

North America™s Forests: Page 6

The problem of illegal logging is growing in the national forests, and a recent threat is the invasion of forests by drug growers. These people have entered roadless federal lands in the West and are seldom detected because of the remoteness and size of many of these tracts. In Los Padres National Forest, they destroyed large sections of forest in 1995 and 1996 to plant marijuana. After cutting trees, they cleared brush with herbicides which killed native plants, many of which are rare and protected. They also diverted scarce water from streams to irrigate their plants, which eliminated native plants dependent on that water. The drug growers put out poison to kill animals, such as deer, they feared might eat the marijuana. This situation presents a major threat to many species of wildlife, and especially to California Condors, who have been reintroduced to Los Padres National Forest and feed on carrion.

Ancient old-growth pine forests covered much of northern Mexico until a few decades ago. Large-scale logging has been felling these great trees, and what reserves have been set aside to protect the remaining patches of old growth are not carefully patrolled to guard against illegal logging. The Imperial Woodpecker (*Campephilus imperialis*), the world's largest woodpecker and one of the most beautiful, declined to extinction as a result of failure by both the Mexican government and private conservation organizations to preserve its habitat. Its decline began from hunting, and logging removed its feeding and nesting habitat during the first half of the 20th century. Several of these birds

were sighted in the 1990s, but because no emergency action took place to preserve these birds in their last retreat, they disappeared. Each pair of Imperial Woodpeckers required a habitat of at least 25 square kilometers, and no area of old-growth forest this large now remains in the Sierra Madre Occidental (Lammertink 1996). Only a few fragments of old growth survive in this huge area, and even these are in imminent danger of being logged.

Mexican logging companies offered local people $2,000 per household for permission to log, and this may have been the deciding factor that led to the end of Mexico's old-growth forests. All that remains of the Imperial Woodpecker are museum specimens. A photograph of three specimens was recently published in the article, "The Lost Empire of the Imperial Woodpecker," in *World Birdwatch* (Lammertink 1996). Martjan Lammertink concluded after his field survey that if the Imperial Woodpecker still exists, no breeding habitat remains and, at most, one or two solitary birds may be left who must fly over huge areas to find food (Lammertink 1996).

A courageous defender of the Sierra Madre forests, Mexican activist Edwin Bustillos has risked his life to fight the drug lords who have taken over large areas in these forests for cultivation of drug plants. In several incidents, Bustillos had five ribs and his arm broken and spent a month in the hospital from injuries sustained when attacked by drug dealers. In 1996, he received the Goldman Environmental Award for his long-term efforts on behalf of these endangered forests.

A beautiful parrot also inhabits these same pine forests. The Thick-billed Parrot (*Rhynchopsitta pachyrhyncha*) once flew in large flocks in search of pine seeds, but its populations have declined from loss of old-growth forests and illegal shooting. The species is listed on the US Endangered Species Act, as endangered by the *2000 IUCN Red List Species*, and on CITES Appendix I, which bans all commercial trade. These large green parrots have red feathers on their foreheads, shoulders and thighs, and bare skin surrounding their yellow eyes. Their large hooked beaks aid them in prying open pine cones. Native to Sierra Madre Occidental of eastern Mexico and, originally, pine forests in Arizona, Thick-billed Parrots live mainly above 2,000 meters. Heavy logging of old-growth pine forests has destroyed 99 percent of its habitat and removed the huge, old trees it needed for nesting (BI 2000, Collar *et al.* 1994). A field survey in 1994 in southern Chihuahua uncovered massive forest destruction and the penetration into its habitat of drug-growers, cattle and loggers (Collar *et al.* 1994). Populations have declined from flocks of thousands seen in the 1950s (Lammertink 1996) to about 5,000 in 1992 and only 1,000 to 4,000 in 1995 (BI 2000). Reintroductions into Arizona of captive-bred birds have not been successful because the birds did not know how to avoid predators or forage for pine seeds (BI 2000).

North America™s Forests: Page 7

Some highly threatened birds persist in unlogged portions of northern Mexico. The beautiful, iridescent Eared Quetzal (*Euptilotis neoxenus*), for example, was formerly common but is now confined to corridors of unlogged trees along rivers. These bits of forest are, at the present at least, inaccessible to loggers (Lammertink 1996). These quetzals require large trees for nesting and lay their eggs in cavities created when large tree snags fall off. Such trees, however, are rare and may disappear altogether in the future, since loggers cut them down as a general rule. It is considered Near-threatened, and close to qualifying as Vulnerable by BirdLife International (BI 2000). The Tufted Jay (*Cyanocorax dickeyi*) is another striking bird with a stiff, bristly, black fan crest on his head and forehead, unlike any other jay. This species is endemic to a limited area in the southern Sierra Madre Occidental, in mixed forested hillsides of oak, dense evergreen and deciduous forest near watercourses. Although a Near-threatened species (BI 2000), it has, nevertheless, no protected reserve.

Pine forests extend south to central Mexico, and up to 30 million Monarch Butterflies (*Danaus plexippus*) from the eastern United States and Canada migrate up to 2,000 miles to several groves of fir trees where they spend the winter clinging to branches in a semi-torpor. These butterflies constitute 90 percent of the species' population, and scientists

believe that they have wintered here for more than 10,000 years (Aridjis and Brower 1996). Their migration is a biological mystery and unique among butterflies. Until the fir groves, where they festoon the tall trees like dazzling orange and black ornaments, were discovered, no one knew where they spent the winter. Even now, their method of locating this particular forest remains unknown. The butterflies that fly south are third generation ancestors of the ones who wintered in Mexico the previous year. On warm days, they wake from their torpor and venture out to take nectar, and in the spring, they head north, breeding along the way (Pyle 1981).

Entirely dependent on these groves of firs, which shelter them from the freezing rains that fall in this high-altitude forest, the Monarchs are threatened by logging. In spite of a 1986 order by Mexican President Miguel de la Madrid to protect the five wintering populations, all located in close proximity, the surrounding trees were not given protection. Local people cut trees for fuel and building materials, and cattle trample fir seedlings (Aridjis and Brower 1996). They have logged up to the very limits of the groves, and without the protection of bordering trees, the butterflies are more vulnerable to cold spells, dying in unprecedented numbers. Snowstorms and cold weather killed millions of these fragile butterflies in 1991 and 1995.

Ann Swengel and Dr. Paul Opler, who coordinate nationwide butterfly counts for the Xerces Society, a butterfly conservation organization, began noticing declines in Monarch populations in the United States, and scientists have seen many declines in areas where they were previously abundant.
Conservation of the precious fir trees upon which the species winters is a key to saving this species. Dr. Lincoln P. Brower, professor of zoology at the University of Florida and a leading authority on the species, and Homero Aridjis, President of the Group of 100, a Mexican environmental organization, made a public appeal for the protection of the Monarchs' winter habitat in an Op-ed article for *The New York Times* in January 1996 (Aridjis and Brower 1996). They maintained that all three countries--the United States, Canada and Mexico--should cooperate to purchase the forests in keeping with the North American Free Trade Agreement (NAFTA) (Aridjis and Brower 1996). A comparison of forest cover in the Monarch groves based on aerial photographs taken in 2000 and in the 1950s, shows great losses in these protected trees from illegal logging over the past 40 years. The situation has reached crisis proportions, according to scientists. In response, the Mexican government has promised to protect the remaining groves and enlarge the reserve. Local people have expressed opposition, however, as they have traditionally logged the forests and have not profited from the tourists who come to see the butterflies. If this situation is not resolved in favor of the butterflies, these beautiful jewels that brighten fields and gardens may disappear from their breeding grounds in the United States.

North America™s Forests: Page 8

The ancient forests of the West Coast once stretched from northern California nearly unbroken through coastal Canada to southeastern Alaska, covering 70,000 square miles. Logging by Europeans began in the 19th century, and as the forests fell, a few voices were raised in protest. Even Horace Greeley, a promoter of "progress" and settlement of the West, exhorted Americans in 1851 to "spare, preserve and cherish some portion of your primitive forest" (Peck 1990). It was the fiery Scottish wilderness advocate John Muir who finally succeeded in convincing the US government to protect some of these ancient forests. He settled near California's Yosemite wilderness in the 1860s and began passionately denouncing the destroyers of nature, from loggers to livestock operators. Muir pointed to the political influences that allowed destruction to occur. During the 19th century, livestock swarmed in great numbers over wilderness areas. Muir described sheep as "hoofed locusts" and, in trying to get them removed from Yosemite, said, "As sheep advance, flowers, vegetation, grass, soil, plenty, and poetry vanish" (Peck 1990). When he saw the ancient Sequoias being cut, Muir was outraged:

Through all the wonderful, eventful centuries since Christ's time--and long before that--God has cared for these trees, saved them from drought, disease, avalanches, and a thousand straining, leveling tempests and floods; but He cannot save them from fools--only Uncle Sam can do that.

Muir proved to be an adept politician, making friends with influential magazine editors and railroad magnates; President Theodore Roosevelt camped out with Muir in Yosemite in 1903 (Peck 1990). Through Muir™s influence, Yosemite became a national park in 1906, followed by Sequoia, Mt. Rainier, Crater Lake, Glacier and Mesa Verde National Parks (Peck 1990). In 1892, Muir established The Sierra Club conservation organization. If not for Muir's courageous and effective work on behalf of these forests, it is likely that very little old-growth forest land would remain today.

North America™s Forests: Page 9

These centuries-old trees, often covered in epiphytes, plants that get nutrients from moisture and air, and lichens, including one species that drapes over branches in delicate, lacy strands, exude a lushness reminiscent of tropical rainforests. More than 140 inches of rain per year produce luxuriant tree growth and a verdant understory of ferns and hardwoods. Bright green mosses and masses of ferns carpet the ground, and a great variety of mushrooms and lichens flourish in the damp environment. In the spring, the forest floor is carpeted with beautiful white trilliums and other flowers that contrast with the deep greens of the forest. Mist and fog enshroud the giant trees, which intercept the moisture from the atmosphere, supplying the trees and the entire environment with water throughout the year (Ellis and Kane 1991).* The southern portion of these forests is dominated by Coast Redwoods, with the record tree reaching more than 365 feet in height. Its upper branches are more than 50 feet in length. They are among the most ancient as well, some over 2,000 years old (Middleton 1992). The great Redwoods of northern California gradually melt into a forest of mixed pines, fir, cedars and hemlock.

---

*Along with the fine book by D. Middleton (1992), cited frequently here, *North America's Rain Forest. The Endangered Paradise*, by Gerry Ellis and Karen Kane (NorthWord Press, 1991), is an excellent resource, beautifully illustrated with the trees, plants and wildlife of these forests, and shows the devastating clearcuts contrasted with living forests. *Western Forests*, a book in the *National Audubon Society Nature Guides* series illustrates most wildlife and plant species, as well as discussing forest ecosystems.

Douglas Firs (*Pseudotsuga menziesii*) grow to ages of 700 to 1,000 years old in climax growth, veterans of hundreds of periodic fires; they may reach 325 feet in height (Jonas 1993). A tree 250 years old is considered young in an old-growth forest, while middle age is 400•500 years, and old age is more than 700 years (Middleton 1992). Recent research conducted in these forests indicates that rich diversity does not develop until forests are at least 200 years old (Moffet 1997).

Ancient Red Cedars (*Thuja plicata*) grew in abundance in these old-growth forests and were among the first to be cut by loggers. Old specimens are very rare at present, and activists recently saved one area with many exceptionally old and massive cedars from being logged. This forest, in Upper Priest Lake, northern Idaho, has cedars 1,500 years old. The largest trees are 20 stories tall, with trunks 10 feet in diameter. The ground beneath is carpeted with ferns, including the largest population of Braun's Holly Fern in the West. Old-growth cottonwoods also grow here. Endangered Woodland Caribou (*Rangifer tarandus caribou*), threatened Grizzly Bears, Fishers and Wolverines, rare Cutthroat Trout, endemic salamanders, and Harlequin Ducks are resident in the forest and wetlands. This forest covers 520 acres, worth at least $9 million to the lumber company that owns it. The US Forest Service was unable to

obtain federal money to purchase it in 1996, and not until October 1997 was the grove preserved through a trade of land worth $8.7 million between the owner and the Forest Service.

More than 1,000 plant and animal species depend on old-growth forests (Egan 1994a). Invertebrate animals of the soil are highly diverse: an area 1 meter by 1 meter shelters 200,000 mites of 75 species (Middleton 1992). Fallen logs may take 500 years to rot, and this decaying wood is fed upon by the most diverse fungal network in the world (Middleton 1992). The hollow logs are used as nest holes by Red•backed Voles and other small species. The young of these voles feed on truffles that grow in the rich soil. At least 300 insect species have been described from the rotting•log community of organisms (Middleton 1992). A host of other insect species of the forest canopy have yet to be described.

Many vertebrates depend on the old-growth forests of the Pacific Northwest for their survival, and some of these live nowhere else. The Sitka Black•tailed Deer and Roosevelt Elk and a unique bluish strain of American Black Bear from southeastern Alaska are among these. Bats of several species--Long•eared, Hoary and Silver•haired--are major pollinators and insect-predators in forests of the Pacific Northwest. Roosting in the hollow trunks of ancient trees, these bats have declined in many areas because of logging. A great diversity of amphibians lives in the moist environments of these temperate rainforests. Among them are the Slender, Olympic, Pacific Giant and Del Norte Salamanders, Pacific Tree Frog and Tailed Frog.

North America™s Forests: page 10

The Northern Spotted Owl (*Strix occidentalis caurina*) may be the most famous resident of these forests. The struggle over old-growth forests became a bitter controversy focused on the fate of this bird, which was declared a Threatened species under the Endangered Species Act in June 1990. This owl is native to old-growth forests in northern California, Oregon and Washington, and each pair of owls requires up to 3,200 acres as territory, making it a naturally rare species (Middleton 1992). Northern Spotted Owls nest in natural tree cavities or holes created when great branches from living trees fall to the ground. The canopy above shields owlet chicks from the view of large birds of prey that fly above. These owls feed on the Red Voles, Dusky-footed Wood Rats and Northern Flying Squirrels that are abundant in old-growth forests. When these forests are cut and young second-growth forest takes over, Spotted Owls disappear (Seideman 1997). In spite of the protection of portions of their habitat, these owls have not recovered their numbers since listing on the US Endangered Species Act, and they continue to decline. The US Forest Service released extensive data compiled on the populations of these birds between 1985 and 1993, which showed a drop of 4.5 percent a year, with an accelerating rate of decline (Seideman 1997). Another threat to these owls is the recent invasion of their habitat by the larger and more adaptable Barred Owl, which is displacing the Spotted Owl in some areas. Even more ominously, interbreeding has taken place between the two species (Seideman 1997).

When the Northern Spotted Owl was listed as Threatened on the Endangered Species Act and large sections of its habitat protected, it became a focal point, polarizing pro-logging and anti-logging advocates. Owl haters urged others to kill these birds, who were blamed for ending the logging industry. Their cars sported bumper stickers such as "Kill an Owl, Save a Job." Such venom totally obscured the fact that the forests were being overcut and that logging jobs were destined to be eliminated anyway, as the last old-growth forests disappeared under the saw. A state in the heart of this owl's range, Oregon, found that reducing logging ended up helping its economy; an influx of technology businesses provided better salaries than those paid for logging jobs (Egan 1994b, Verhovek 2000). The Governor of the state supported the logging restrictions as helping to maintain the overall quality of life in the state, preventing

floods and attracting tourists, which are supplying another large segment of the state's revenues.

Habitat Conservation Plans (HCPs), authorized under the Endangered Species Act may be contributing to the Spotted Owl's decline. Under these plans, agreements are negotiated with landowners which include a provision known as "no surprises." This gives landowners assurances that once the regulations on their properties have been agreed to, they are exempt from further restrictions. Should new populations of an endangered species be discovered on their property, they have no obligation to protect them. Habitats of Spotted Owls in old-growth forests in Washington State have been bartered away in HCPs that, in the view of Eric Hanson, biologist for the Yakima Indian Nation in Washington state, will end in reducing the state's populations of this species by 35 percent, from 880 breeding pairs to 550 (Seideman 1997). These HCPs allow habitat destruction and other actions that can result in deaths of Spotted Owls. The Forest Service collected population data on these owls for the years between 1994 and 1996 but failed to issue the results (Seideman 1997).

The Clinton Administration sponsored a series of local meetings to resolve differences. These resulted in plans to federally fund job•training for loggers who might become unemployed by logging cutbacks. Even so, logging interests sued the federal government to nullify the stricter quotas, and the California Forest Products Association unsuccessfully petitioned the Fish and Wildlife Service in October 1993 to remove the Northern Spotted Owl from the Endangered Species Act, claiming the species was mistakenly placed on the list. This case was argued all the way to the US Supreme Court which, in the summer of 1995, made a historic decision upholding the Endangered Species Act and its protection of endangered species' habitats.

The Timber Salvage Act of 1995 made a mockery of previous attempts to mediate between loggers and conservationists, allowing a year and a half of totally unregulated logging in the habitat of the Northern Spotted Owl and other threatened species. This law had the stated purpose of taking only fallen and dead trees, but in practice, tens of thousands of old-growth, healthy trees were logged. In its quarterly report on the Timber Salvage Act, issued February 29, 1996, the Forest Service reported that an astounding 2.1 *billion* board feet had been cut since passage of the law. The Forest Service's stated objective was to sell 4.5 billion board feet by the end of 1996. By August 1996, some 2.9 billion board feet, the equivalent of 580,000 logging trucks full, had been cut under the Timber Salvage Act (Bass 1996). National forest lands to be logged totaled at least 50 million acres. Major habitat areas for many endangered and threatened species were among these lands. Fortunately, this law expired at the end of 1996.

North America™s Forests: Page 11

The Marbled Murrelet (*Brachyramphus marmoratus*) is also dependent on old-growth forests and has been seriously impacted by the logging that, since the 19th century, has destroyed 95 percent of its old-growth habitat in the US Pacific Northwest. This small, black-and-white seabird is a Threatened species on the US Endangered Species Act and is listed as Vulnerable by BirdLife International. Unlike any other seabird, this Murrelet nests high in the branches of 200- and 300•foot trees. Sometimes seen in offshore waters of the Pacific Northwest and Alaska, their nests are rarely found. In fact, only about 30 nests have ever been located in the Pacific Northwest--all high in the

crowns of old-growth forest trees.

A researcher who was studying the ecology of old-growth tree canopies made an exciting discovery of a Marbled Murrelet nest. He photographed the adult on its nest, made of lichens, with a small fish in its mouth for its chick for *National Geographic* magazine (Moffett 1997). Despite surveys up and down the Pacific coast, this was one of the few nests found in 1996, and plans for logging near the nest site were stopped (Moffett 1997). A prime area for Marbled Murrelets is the Olympic National Forest in Washington state where large tracts were sold for clearcutting in 1996 under the Timber Salvage Act. In Umpqua National Forest, Oregon, over the weekend of March 23-24, 1996, several thousand-year-old Douglas Firs were cut; their age was determined by coring and ring counts. The Umpqua River has endangered populations of Coho Salmon (*Oncorhynchus kisutch*) and sea-run Cutthroat Trout, and logging may eliminate them. The Marbled Murrelet's nesting trees are being logged throughout the species' range. A few areas have been protected in Alaska, but they are declining rapidly, at a rate of 31 to 48 percent per decade, with little hope that sizeable areas of old-growth forest will be protected (BI 2000).

North America™s Forests: Page 12

The Pacific Yew (*Taxus brevifolia*)**,** found only in these forests of the Pacific Northwest, is considered a "trash species" by foresters who clear it away to make room for more valuable species. This plant grows in the undergrowth of old-growth forests from California to southeastern Alaska (Jonas 1993). It has recently been shown to contain a chemical substance, Taxol, that has proven effective in treating ovarian and other cancers (Middleton 1992). A rush to cut these trees and strip their bark to obtain Taxol threatened them with extinction until the chemical was successfully produced synthetically. Taxol will be a major new tool in treating cancers and will result in sales totaling many millions of dollars for the pharmaceutical industry.

These discoveries have taken place as the fate of the last stands of old-growth forests is hanging in the balance. Ninety-five percent of these forests in the United States, and more than 60 percent in Canada, have already been cut. Opposition to clearcutting is increasing, however. Lewis H. Nash is a member of an organization known as the "Environmental Air Force," which chronicles illegal cutting of Coastal Redwoods. Members pilot small planes over clearcuts and document the damage with photographs. Nash's work enabled an environmental lawyer to obtain an injunction in 1995 stopping logging the same day (Goldberg 1996a). In 1996, flying over the devastated forests of northern California, Nash remarked: "When I first started flying here 10 or 15 years ago, this was all the same, all primeval forest. All this has been pretty well hacked over" (Goldberg 1996a).

North America™s Forests: Page 13

One of the most heated debates over these forests involves the last privately-owned large tracts of redwoods. Commercial exploitation began in 1900 when Frederick Weyerhauser purchased 900,000 acres for $6.00 per acre, a ludicrously low price even in those days (Dietrich 1992). Almost all privately owned old-growth forests became depleted by the 1960s. One exception was a large tract of old-growth Coastal Redwoods and Douglas Firs in California's Humboldt County, in the northern part of the state, owned by the Pacific Lumber Company. This family-operated company had left most of its 200,000 acres intact and had been particularly protective of the most ancient trees in the 55,000-acre Headwaters Forest. In 1986, however, Houston financier Charles Hurwitz took over Pacific Lumber, using junk bonds. Hurwitz's United Savings Association of Texas failed, costing US taxpayers $1.6 billion, part of the savings-and-loan collapse (Brown and Stark 1995).

To pay his debts, Hurwitz began clearcutting the old-growth Coast Redwood and Douglas Firs. By 1995, he had

cut 40,000 acres of the Headwaters Forest and nearby old-growth trees, leaving only 5,500 acres of virgin Coastal Redwood and 5,000 acres of virgin Douglas Fir (Brown and Stark 1995). This is one of the most extreme cases of abuse of private land in the history of this country. Two-thousand-year-old trees were turned into picnic tables, lawn furniture and patio decks. Logging was delayed by several lawsuits, and to protect nesting sites of Marbled Murrelets, the California Forestry Department recommended in 1995 that Hurwitz be refused permission to build a logging road into the 4,400-acre grove of the most ancient trees (Brown and Stark 1995). Two California Congressmen, George Brown and Pete Stark, proposed that the federal government engage in a debt-for-nature swap, in which the Federal Deposit Insurance Corporation, which has sued Hurwitz for his role in the failure of his bank, would, through a special arrangement set up by the President, exchange the redwoods for his debt (Brown and Stark 1995). Hurwitz rejected the idea, calling it a "so-called fantasy of debt for nature" and threatened lawsuits against the government for excessively limiting the use of his land (Goldberg 1996b).

The value of the Headwaters Grove is estimated at between $100 and $500 million, with many giant trees several thousand years old and 12 feet in diameter; individual trees are worth more than $100,000 each (Goldberg 1996b). The ecological and esthetic values, however, are inestimable. Hurwitz called environmentalists who blocked sale of these trees "extremists" and insisted that he expected to be paid "fair market value for these trees" (Goldberg 1996b). Acrimonious negotiations for the grove continued in 1996 and 1997, with environmentalists demonstrating against an agreement negotiated that would protect only 7,500 acres, instead of the 100,000 they wanted saved. Early in 1997, Hurwitz demanded that he be paid in cash rather than land that was offered by the state of California, land which many environmentalists thought should be protected (Golden 1997). The deal arranged with Hurwitz allowed extensive cutting of the remaining 100,000 acres of old-growth forest without regard for endangered species' habitat.

Members of Earth First! began protests, entering the land and attempting to block logging trucks, and a young conservationist, Julia Hill, who became known as Julia "Butterfly" Hill, climbed up near the top of an ancient redwood tree she called Luna and refused to come down. She stayed up in this tree for two entire years, until the spring of 2000, while trees were cut in the surrounding area, until a sum of $50,000 was paid to the Hurwitz lumber company for Luna and 2.9 acres of surrounding forest, which were donated to Humboldt State University. She came down from the tree at last, a symbol of the extreme devotion and zeal that have been expended in attempts to preserve these ancient trees. The forest will continue to be cut, however, which will be a permanent loss to the environment and a stain on state and federal governments for not taking a stronger role to preserve the entire forest.

In a sad footnote, in November 2000, a vandal sawed a cut 32 inches deep and stretching 19 feet, or half the circumference, across the base of Julia Hill's tree, Luna. It appeared to have been done by a professional logger, judging from the precision of the cut. A team of specialists--an arborist, an engineer and a forester--was convened to try to save the tree (Quinn 2000). Metal braces were drilled into the tree spanning the cut. All efforts are being made to save this ancient tree from falling in winter storms. Visitors are being asked to stay away because the soil and hillside are being deeply eroded. It is a symbol of the senseless destruction of ancient forests.

Only 4 percent of the once vast and magnificent Coastal Redwood forests remain. These trees covered at least 2 million acres prior to logging, but only about 84,000 acres of virgin redwoods have been protected in state parks and the Redwood National Park; another 66,000 acres of logged and second-growth redwoods have been set aside (DiSilvestro 1990).

North America™s Forests: Page 14

Another major conservation struggle involves the magnificent Tongass National Forest in southeastern Alaska. This forest, covering 17 million acres, is the country's largest national forest--a mosaic of glaciers, mountains, fjords and islands covered by ancient trees. It makes up half of one of the largest remaining temperate rainforests on Earth,

which extends 1,000 miles in an arc along the southeastern coast. At least 6 million acres of Tongass are--or were--old-growth rainforest (DiSilvestro 1990). Sitka Spruce, Western Hemlock, and Red and Yellow Cedar many hundreds of years old dominate the forest.

The Tongass is home to a number of rare animals. Approximately 10,000 Bald Eagles nest in the tops of trees (DiSilvestro 1990). More Grizzly Bears live in the Tongass than in the entire lower 48 states, denning in the holes of towering old trees. A race of the Grey Wolf known as the Alexander Archipelago Wolf (*Canis lupus ligoni*) inhabits the Tongass; numbering only about 1,000 animals, its population is in decline (Williams 1995). Logging threatens these wolves and rare wildlife, including the Queen Charlotte Goshawk (*Accipiter gentilis laingi*) and the Marbled Murrelet (FWS 1994). The Wolf and the Goshawk are candidates for listing on the Endangered Species Act. These and other species of this beautiful area cannot survive in clearcuts and logged-over forests. The American Rivers organization has listed Tongass's Thorne River as one of the 10 most endangered in the United States, having become silted and its banks eroded from logging (Williams 1995).

The cutting of the Tongass's giant trees began in 1833, and by 1926, six sawmills were operating; by 1930, most of the lowland and easily accessible timber and giant old trees had been cut (DiSilvestro 1990). In the 1950s the Forest Service allowed cutting of ancient trees in rugged, steep areas and opened the way for a wood pulp industry to be fed by clearcutting. The Service offered two 50-year contracts at bargain-basement prices, instead of the usual three- to five-year contracts (DiSilvestro 1990). It signed an exclusive contract with the Ketchikan Pulp Corporation and, unlike other national forests where contracts are open to bidding, this contract was awarded during secret meetings from which the public and conservation organizations were excluded. From this time onward, 200 million board feet or more of old-growth forest were logged annually from the Tongass National Forest (DiSilvestro 1990).

The Alaska National Interest Lands Conservation Act of 1980 divided most of the state among federal, state and native interests. Within the law was a provision requiring maximum logging levels in the Tongass National Forest, with the quota of 4.5 *billion* board feet to be logged every decade, with annual subsidies of $40 million from the federal government for logging roads and other aid to timber companies (DiSilvestro 1990). In the 15 years that followed, billions of board feet were logged in this magnificent rainforest, at a financial loss to the taxpayer.

National organizations, including the Taxpayers for Common Sense based in Washington, DC, criticized the clearcutting of this and other national forests which provide no income to the federal treasury and are entirely subsidized by public funds (Schmitz 1996). A 1995 General Accounting Office report found that Tongass's Timber Program was the biggest money loser in the National Forest system, with a negative net return of $102 million to the US Treasury between 1990 and 1994 (Schmitz 1996). More recently, a study by the John Muir Project found that in the years 1997 through 1999, the National Forest Service Timber Sale Program operated at a net loss to taxpayers of more than $3.3 billion (Hanson 2000). This research found that less than 3 percent of the country's total annual wood consumption, and less than 4 percent of the sawtimber used for construction, comes from national forests (Hanson 2000). A nationwide poll in 1998 found that 69 percent of Americans oppose allowing timber companies to log the national forests (Hanson 2000).

The fight to save these forests is being waged in the courts, with public criticism and legal actions brought by conservation organizations. A 1987 book, *The Tongass. Alaska's Vanishing Rainforest*, dramatically illustrated the great beauty of this forest and the ravaging effects of logging, including clearcuts on steep, erodable slopes. This publication served as a catalyst for the passage of the Tongass Timber Reform Act of 1990 that stopped the $40 million subsidy to loggers and set aside 1 million acres to be closed to logging (Ketchum and Ketchum 1994). It did not stop or appreciably slow logging elsewhere in Tongass, however, and called for 150 million board feet a year to be cut. The book was updated in 1994 and described the continuing bitter battle being waged to protect this vast area (Ketchum and Ketchum 1994). In 1997, the heavily polluting Ketchikan pulp mill was finally closed. The Forest Service's 10-year plan for Tongass National Forest, finalized in May 1997, opened up 670,000 acres to logging, authorizing the cutting of 220 million to 267 million board feet of timber annually (this is enough to load 50,000 logging trucks or build more than 20,000 houses a year) (Cushman 1997). The Forest Service stated that the portion

of land that would be set aside would make it unnecessary to list the Alexander Archipelago Wolf and the Queen Charlotte Goshawk on the Endangered Species Act. Conservation organizations criticized the plan and the failure to support listing of these species. The Alaskan Congressional delegation expressed its disappointment that more timber had not been open to logging (Cushman 1997). The 100- to 125-year cycle of cutting by the Forest Service assured that old-growth forests and their complex and diverse ecosystems will disappear.

The Forest Service held nationwide hearings during the summer of 2000 regarding a proposal that some 50 million acres of national forests be protected from road-building. This proposal specifically exempted the Tongass National Forest. The Forest Service plan would allow massive road construction and logging in the Tongass's remaining pristine forests. In a surprise decision prior to leaving office, President Bill Clinton authorized the inclusion of 9.3 million acres of the Tongass National Forest in the final plan; although delayed until 2004, this was an extremely important event, condemned by the Alaskan Congressional delegation (Hughes 2000). The plan calls for $13 to $20 million to be spent in Alaska creating jobs lost in the timber industry. The plan had drawn more than 1.5 million letters and e-mail messages, the overwhelming majority in favor of banning road-building. In spite of opposition to the designation of wilderness in this vast national forest, conservationists succeeded in obtaining a moratorium on logging of 9 million acres, pending the results of studies on whether they qualify for permanent protection under the Wilderness Act (Earthjustice Legal Defense Fund 2001).

Another huge national forest in Alaska, the Chugach, located at the headwaters of the salmon-rich Kenai River, has received far less attention than the Tongass, in spite of being the second largest of all US National Forests. In 1996, the Forest Service cut nearly 16 million board feet in this old-growth forest.

North America™s Forests: Page 15

The future of forests in the United States is at a dramatic turning point. During the summer of 2000, devastating wildfires broke out in the Western United States, primarily in national forests. More than 6.7 million acres burned, along with hundreds of private homes (Janofsky 2000). Within months, the Clinton Administration proposed a major new approach to the national forests, dictating extensive thinning of millions of trees and the removal of brush to prevent future wildfires (Jehl 2000). This plan was based on the theory that the fires were caused by too little logging, resulting in dense forests with underbrush that caught fire and spread uncontrollably. Pro-logging Members of Congress, western Governors and logging companies immediately endorsed the plan (Janofsky 2000, Jehl 2000). Some Governors wanted even more money for the program (Janofsky 2000). The proposed thinning would cost taxpayers $12 billion over 15 years (Jehl 2000). This was challenged by a report issued by the Congressional Research Service soon after the fires were extinguished, which concluded that there was no connection between the level of logging and wildfires (Egan 2000). Other critics included the Forest Guardians of New Mexico, who contended that the fires were the result of decades of industrial logging in which the largest trees were taken; it suggested that instead of thinning, logging subsidies be directed at badly needed projects to control soil erosion, protect water quality and enhance wildlife habitat (Hitt 2000). Environmental groups opposed the logging portion of the proposal as a tool for fire prevention (Janofsky 2000).

As the ideal example of how national forests should be managed, the Clinton Administration proposal pointed to an Arizona Ponderosa forest that had been thinned and did not burn. Ponderosa forests are not typical, however, of all forests, tending to be open with little understory. Other types of forests, such as old-growth temperate rainforests, are not open, and drastic thinning of their undergrowth would result in more, not fewer fires. Moreover, nutrients would be lost, erosion encouraged and wildlife habitat destroyed by such thinning. Dr. Paul R. Epstein (2000), a scientist with Harvard's Medical School Center for Health and Global Environment, concluded that the wildfires were precipitated by global warming, which caused the drought that dried out these forests, making them vulnerable to wildfires. Epstein proposed that the most important reaction to these fires would be to control global warming and

restabilize the climate system.

An extremely important policy statement was made by Forest Service chief Mike Dombeck in January 2001, when he ordered the protection of the largest and oldest trees on Forest Service land (Jehl 2001a). In explaining his decision, Dombeck said, "In the future, we will celebrate the fact that national forests serve as a reservoir for our last remaining old-growth forests and their associated ecological and social values" (Jehl 2001a). Only about 3 percent of national forests is old-growth forest, yet these forests are among the most important refuges for rare and endangered species. Dombeck's statement and the philosophy behind it are reminiscent of John Muir or Henry David Thoreau, an extraordinary reversal from the utilitarian view of forests as tree farms that has held sway since the beginning of the Forest Service. In fact, it had been Forest Service policy that the oldest and biggest trees be cut first (Jehl 2001b). The new Republican Administration and the Senate panel overseeing the Forest Service announced that hearings would be held on the new policy, which runs counter to the one backed by President George W. Bush (Jehl 2001b). Dombeck was asked to leave his job soon after President Bush took office. Logging in national forests has declined from 1989, when 12 billion board feet were cut, to about 3 billion board feet in 2000 (Jehl 2001b). Loggers are expected to lobby hard to cut these last old-growth trees because of the huge amount of dense wood they contain.

North America™s Forests: Page 16

Although Canada's forests are far more extensive, with greater amounts of old-growth, they are being logged at an extremely rapid pace. The 1980s and early 1990s witnessed the clearcutting of millions of acres of Canadian forests, from boreal coniferous woodlands to deciduous and mixed forests in the east to the ancient temperate rainforests of British Columbia's coast. The logging that has removed vast tracts of Canada's forests is a major factor in the decline of the continent's colorful and ecologically important wood warblers and other songbirds. British Columbia's mountainous terrain is not conducive to clearcutting because of erosion, but this has been the method used to raze hundreds of thousands of acres. Wilderness valleys with forested slopes have been denuded and the soil and debris washed into salmon streams and rivers, clogging and destroying them. The Bowron Valley in central British Columbia was turned into a moonscape in 1992 when 1,600 square kilometers were clearcut; efforts to replant this huge area have not been successful (Devall 1993). Habitat of the Grizzly Bear in British Columbia's high-altitude forests has been devastated along with its forest wilderness home elsewhere in Canada (Devall 1993).

Research on Sitka Spruce (*Picea sutchensis*) canopies on Vancouver Island, along the British Columbia coast, has produced 300 new species of insects, and scientists state that this environment will reveal hundreds more. According to one biologist, "We have a virtually unexplored biological frontier in our own backyard" (Moffett 1997). A highly unusual Sitka Spruce, called "Golden Spruce" (*P.s. aurea*), grows on Graham Island in the Queen Charlotte Islands to the north of Vancouver Island (DePalma 1997). This extremely rare color phase had only one known adult specimen in the wild, the result of a genetic quirk that causes chlorophyll to break down, giving the needles a golden yellow hue when exposed to sunlight (Comeau 1997). Standing 160 feet tall, and 300 years old, the Golden Spruce was known to the native Haida tribe, who revered it, as "kiidk'yaas," or ancient tree (DePalma 1997). (A color photograph of this dazzling tree was published in the *Canadian Geographic* magazine in May/June 1997.) The Haida believed that the tree would be admired until their last generation and that it held the spirit of a young Haida boy who survived, along with his grandfather, the demise of their village, which was destroyed by an angry Creator (Comeau 1997). As they walked away, the elder warned the boy not to look back, but the boy disobeyed and was turned into a tree that came to be venerated as the embodiment of the tribe's spirit (Comeau 1997).

In January 1997, a mentally unbalanced man swam across the sound to the island and cut the tree down. This caused shock and dismay among the Haida, who felt they had failed in protecting this most important part of their traditions and believed that its death predicted their own demise (Comeau 1997). Fortunately, a few cuttings had been

taken from this tree in 1986 by a horticulturist, who brought them to the Botanical Garden at the University of British Columbia and propagated them. Two 5-feet-tall, scrawny trees were produced, and they are all that remain of the magnificent Golden Spruce (DePalma 1997). The Haida took about 100 cuttings from the top of the felled tree and asked the scientific community to help save it. They accepted one of the two propagated specimens from the university (Comeau 1997).

Vancouver Island, just north of Washington state, is one of the most magnificent scenic areas in the world. The struggle to stop clearcutting of its ancient forests has become pitched. One highly endangered species resident on this island is the endemic Vancouver Island Marmot (*Marmota vancouverensis*), one of 11 species of marmots in the world, all native to the Northern Hemisphere (Nowak 1999). Much of the Vancouver Island Marmot's habitat has been destroyed by development for ski slopes and logging, which apparently removed important migration corridors between colonies. This exposed the marmots to predation and prevented the establishment of new colonies (Thornback and Jenkins 1982). Colony sites became isolated, and vacant areas were not reoccupied, causing inbreeding (Thornback and Jenkins 1982). The Federation of British Columbian Naturalists formed a Vancouver Island Marmot Preservation Committee to conduct surveys and publicize the need to protect the Vancouver Island Marmot (Thornback and Jenkins 1982), yet in spite of long-term studies, logging continued. Surveys in 1979 and 1980 found only 11 colonies with 50 to 100 individuals (Thornback and Jenkins 1982). A 1984 survey found 231 animals, and some captive breeding has been successful (Nowak 1999).

The *2000 IUCN Red List Species* lists the Vancouver Island Marmot as Endangered (Hilton-Taylor 2000). It is also listed as Endangered by the US Endangered Species Act, and as Critically Endangered by the British Columbia Conservation Data Center of the province's Ministry of Environment. The Vancouver Island Marmot has been ranked in the most endangered category by the Center, as having few remaining individuals, and since this remnant population is continuing to decline, its extinction has become likely. By 1995, 11 colonies had declined to only eight, and the 1984 population of 231 animals had declined to only 150 animals. Biologist Andrew Bryant, chief scientist of the Marmot Recovery Foundation, conducted his Master's Thesis on the species and has continued to monitor it, according to the British Columbia Conservation Data Center. The population declined to a critical level in the late 1990s, and there are plans to take more animals into captivity to attempt captive breeding for future releases into protected habitat. In 1999, researchers found only 62 marmots left in the wild (NGS 2000). They took 27 into captivity for breeding programs. Bryant stated that the major threat to these animals was clearcutting, which greatly reduced their food supply; they are also vulnerable to predators (NGS 2000). The long-term plan is to reestablish these marmots in three separate sites and build populations up to 400-600 animals (NGS 200).

Vancouver Island's panoramic beauty is displayed in the 1994 film, fiRainforest of the Pacific Northwestfl (see Video, North America section). Aerial views of undisturbed forest and the majestic Clayoquot Sound contrast with large stretches of clearcut forest. Trees up to 270 feet tall and more than 1,000 years old grow on Vancouver Island, but less than one-third of the old-growth forest remains; at the making of the film only 4.5 percent of the forest was protected. The British Columbian government appointed a panel to recommend revisions to the logging plan for Clayoquot Sound and, to the delight of conservationists, issued recommendations in 1995 banning clearcutting and proposing strong streamside protections and so many safeguards that very little logging will be allowed (SCLDF 1995). In 1995, the British Columbian government announced that it would adopt all the recommendations made by the blue ribbon Science Panel. All commercial logging in pristine areas has been deferred until biological inventories are completed, according to the Rainforest Action Network (RAN). This does not mean a permanent end to logging in this beautiful Sound, and conservationists will need to continue the fight. The native-run Clayoquot Sound First Nations leaders are apprehensive that they may be pressured into joint logging ventures with timber companies, and they issued an unequivocal declaration calling for an end to commercial logging in all old-growth forests (Rosmarin 1995).

Forty miles north of Vancouver, old-growth coastal forests are being destroyed by commercial loggers to make way for urban and suburban growth. The Squamish River cuts through these forests and provides one of the great wildlife spectacles in North America. When salmon disappeared from almost every river of the Northwest and

pollution killed off fish in many northern states, Bald Eagles migrated north to the Squamish River (Nickerson 1995). Almost 4,000 Bald Eagles from as far away as Wisconsin and the Rocky Mountains winter along the river, feeding on spawning salmon (Nickerson 1995). "Americans are strange," a Squamish Native American remarked, "They revere the eagle as the pride of their country, then ruin his home and make him so hungry he flees to Canada" (Nickerson 1995). Yet this sanctuary is now threatened. A 600-acre industrial park at the heart of the winter roosting grounds is planned by local officials, and logging has removed much of the forest already (Nickerson 1995). The Nature Conservancy began acquiring parcels of land for the establishment of Canada's first sanctuary for Bald Eagles (Nickerson 1995). The goal of conservationists is a preserve of 2,700 acres to protect this important feeding area (Nickerson 1995).

North America™s Forests: Page 17

The white bears of Canada live along 1,000 square miles of rainforest on the British Columbian coast and off islands. Their main breeding island, Princess Royal Island, harbors the largest number of these bears, which are a rare color phase of the Black Bear. The percentage is even lower on other islands (Russell 1994). The world population of these bears is estimated at only about 400 (NRDC 2001). A delightful book, *Spirit Bear. Encounters with the White Bear of the Western Rainforest*, by naturalist Charles Russell, recounted his visits to the island with two filmmakers, Jeff and Sue Turner, who were working on "Island of the Ghost Bear." Russell, who has been studying and helping bears of many species throughout his life, wanted to write a book about the spirit bear to obtain sanctuary status for this island and its bears. The white bears on the island have been protected for thousands of years, first by the Native Americans, and now by the British Columbian government. They are so tame that Russell was amazed, having never encountered such friendly bears of any species. A young white bear came to inspect Russell and the filmmakers soon after they arrived, peering into their camera lens, leaving nose prints on the lens (Russell 1994). This bear would sit down near them, sometimes seeking their protection when larger Black Bears tried to take away salmon he had caught (Russell 1994). On one occasion, Russell followed the bear back into the forest to see where he went. After a long walk through the rainforest, the bear found a soft area covered in bright green moss and decided to take a nap. He was so trusting that he went to sleep with Russell watching him only a few feet away. While asleep, the bear seemed to be dreaming, his eyes moving, legs twitching, and sometimes grunting (Russell 1994). Russell's book is illustrated with many photos of the bear fishing, sprawled on his back in the forest, and climbing about the rocks. This bear let himself be scratched with a stick and even tried to wrestle with Russell and Jeff Turner. Russell and the Turners left the island but returned after a year, and the bear came to greet them, sitting down a few feet away as if they had not been gone at all (Russell 1994).

The entire range of this bear is slated for logging. The Black Bears living on these islands, which carry white bear genes and are only a bit less tame than the white bears, are hunted under British Columbian law, which allows two bears per hunter each season. When they were filming the bears, some Swiss, German and Austrian hunters had arranged a bear hunt (Russell 2000).

The film, fiGhost Bear,fl shown on PBS's Nature series in 1994, captured an island little changed for 10,000 years, never logged and teeming with wildlife. Black wolves, mergansers, Beavers, salmon and Bald Eagles live in this mossy, verdant forest with towering trees. The filmmakers urged protection for the bears and the forest. Other defenders of this bear and its forest are the members of the Kitasoo and Gitga™at Indian tribes of British Columbia, who believe that the white bears were created by a raven who came from heaven and decreed, "The white bears will live here forever in peace." The tribe wants to create a park of the entire area to protect the bears and the rainforest. Logging proceeded, however, within the proposed park, and a logging company cut a road through one island's ancient rainforest and the ancestral Kitasoo deer-hunting grounds. The Rainforest Action Network (RAN) began in the mid-1990s to help create a sanctuary, which is opposed by the British Columbian government. Twenty million acres of rainforest in the province may be cut, and RAN is campaigning to convince US customers to cancel contracts

and refuse to buy products from these ancient forests (Rosmarin 1995).

A Canadian couple, Ian and Karen McAllister, have formed an organization, Rainforest Conservation Society, to preserve the habitat of the Ghost Bears and the Great Bear Rainforest. Their book, *The Great Bear Rainforest, Canada's Forgotten Coast*, published in 1997 by Sierra Club Press, eloquently describes this magnificent region and their work to help preserve it. The Natural Resources Defense Council (NRDC), headquartered in New York, took on the cause in 2000, urging a consumer and commercial boycott of International Forest Products (Interfor), a logging company that is cutting the old-growth forests in the heart of 18 untouched rainforest valleys in the Great Bear Rainforest. As the company was about to clearcut East Creek on one island, it was stopped by construction of a tribal longhouse by the Gita™at Tribe at the mouth of the creek, aided by NRDC, which forced the company to suspend its plans (NRDC 2001). Negotiations between conservation groups and six logging companies, including Interfor, had appeared to achieve protection of the Great Bear Rainforest, but Interfor pulled out of the agreement and recently began logging within the habitat of the white bears. This devastation of a magnificent environment does not even make economic sense, as there could be a sizeable market for videocam views linked to a satellite of these enchanting bears and their mossy, green forests, paid for by viewers around the world for a long-term profit far exceeding that which will accrue to the loggers. The Giant Panda is also a charismatic species, and conservation donations from zoos now total $10 million a year or more to preserve the species™ habitat. The white and black bears of this wilderness deserve no less.

North America™s Forests: Page 18

Further inland, the Wood Buffalo National Park, bordering Alberta and the Northwest Territories, is the sole breeding ground of the endangered Whooping Crane (*Grus canadensis*). This enormous park, designated a United Nations World Heritage site, was logged in large clearcuts from the end of World War II until 1992, a tragic loss of old-growth boreal forest (Devall 1993). The logging was stopped by a lawsuit brought by the Sierra Club Legal Defense Fund (now Earthjustice Legal Defense Fund) in conjunction with the Canadian Parks and The Wilderness Society. The suit was based on the Canadian National Parks Act, which states, "The National Parks shall be maintained and made use of so as to leave them unimpaired for the enjoyment of future generations" (Devall 1993). The Peace River, flowing through Wood Buffalo, is so contaminated by dioxin from the Daihowa pulp mill upstream that natives no longer eat the fish, their major food staple, from the river (Devall 1993).

By the end of 1988, one-third of the land surface of Alberta, Canada-- 221,000 square kilometers--had been logged. Much of Saskatchewan's former forested land--more than one million hectares--has been clearcut and not replanted, nor has it regenerated naturally (Devall 1993). Manitoba, south of Hudson Bay, protects less than 2 percent of its territory from development and logging. In 1989, the Manitoba government opened up an area the size of Ohio, 108,000 square kilometers, to logging (Devall 1993). Logging in Manitoba, Saskatchewan and Alberta fueled $10 billion in new pulp mills, major water and air pollution sources (Devall 1993).

Eurasian Temperate Forests

The Siberian Tiger's Domain
Land of the Giant Panda
Lost Forests of the Mediterranean and Europe

Eurasian Temperate Forests: The Siberian Tiger's Domain

Russia's coniferous forests form the major part of the Eurasian taiga, a mixture of spruce, birch and other evergreens, covering 3 million square miles, two•thirds of the country's land surface (Sparks 1992). It is the world's largest forest of any type, more than twice the size of the Amazon rainforest (Stewart 1992). Russia's taiga makes up half of the world's total area of coniferous forest and about one-quarter of the entire forested area of the world; the Siberian portion alone is one•third larger than the whole of the United States (Sparks 1992). The forested land east of the Ural Mountains covers 5 million square miles (Linden 1995). Further south, deciduous trees mix with aspen, birch and alder (Sparks 1992). This entire, vast forest may once have been the domain of the Siberian Tiger (*Panthera tigris altaica*), as its fossilized bones have been found on Lyakhov Island off the north coast of Siberia (Matthiessen 2000).

The vast expanses of taiga forests were opened up to international logging after the dissolution of the USSRF. By the early 1990s, about 304 million acres, two•and•one•half times the size of France, had been clearcut (Stewart 1992). Each year an additional 12 million acres are logged (Lean and Hinrichsen 1992). Commercial exports of Siberia's logs to the United States have been encouraged by various corporations and the US Department of Commerce. Logging has also been intense in Russia's Far East, an area of great biological diversity, with many resident endangered species.

A nearly pristine and stunningly beautiful part of Russia is the Kamchatka Peninsula in the Far East, jutting into the Pacific Ocean. This area has 29 active volcanoes, wild rivers, hot springs, and beautiful forests. An endemic tree, the Kamchatka Fir (*Abies gracilis*), grows only on this peninsula. A relict of pre-Ice Age coniferous forests, it is a silvery fir with soft needles, which grows to about 70 feet in height; this once widespread tree is now restricted in range (Sparks 1992). The forests of Kamchatka are being heavily logged (Meulenaer and Vaisman 1996). Another threat is gold mining, as $10 billion worth of gold is thought to lie under the forests and lakes of the Peninsula (Specter 1997).

The Kamchatka Sable (*Martes zibellina*) is larger than sables in other parts of Russia and was nearly trapped to extinction in the 19th century (Stewart 1992). The Sable's habitat is dominated by Stone Birch (*Betula ermani*) forests with thick, grassy undergrowth covering the mountain slopes; some of these trees grow to be 600 years old (Stewart 1992). Mountain Ash provide berries which, along with an occasional fish, supplement the Sable's diet of voles (Stewart 1992). Unfortunately, anti-trapping restrictions are not being enforced in Russia's Far East, even in nature reserves. The Kronotsky Nature Reserve, covering 3,860 square miles on the peninsula's east coast, shelters 700 species of tundra, taiga and mountain plants, with a number of unusual endemic plants, including the beautiful Kamchatka Rhododendron (*Rhododendron kamchatkensis*), which has miniature red blooms (Sparks 1992).

The magnificent Siberian or Amur Tiger is the largest of all wild cats. Only a few hundred years ago, its realm extended from northern Manchuria west to Lake Baikal and south to North Korea and northeastern China (Matthiessen 2000). Its range shrank over the centuries as a result of hunting, persecution, loss of prey species and habitat. Today it is restricted to the extreme southeastern Maritime Region in the Amur River basin east of Manchuria, west of Sakhalin Island (Miquelle *et al.* 1999). During the 1980s, the Soviet government established a series of reserves for the Tiger, but heavy logging and hunting in the region caused declines in its major prey species, boar and deer. Only 5 percent of the Siberian Tiger's habitat is protected in reserves, according to Evgeny Smirnov, a Russian biologist who studies Tigers (Gourevitch 1995). Moreover, a trade in Tiger bones and other body parts for Traditional Medicine has resulted in the killing, often brutal, of thousands of Tigers throughout their range from India east and south to Indonesia (see Trade chapter).

Siberian Tigers require very large territories. In Sikhote-Alin, their major protected reserve, there are only 10 to 15

resident adults on 400,000 hectares (988,400 acres) (Smirnov and Miquelle 1999). Such large home ranges make them extremely vulnerable to habitat loss, especially the fragmentation of forests by logging. This region™s volcanic peaks rise 5,000 feet from the sea, and forests are crisscrossed by rivers and dotted by lakes. Northern and southern forests meet here, harboring a myriad of tree species. Tall Korean Pines (*Pinus koreansis*) mingle with oaks, maples, walnuts and birches, and unlike the typical Siberian taiga, shrubs and undergrowth are luxuriant (Stewart 1992). These trees reach heights of nearly 150 feet and produce a great volume of cones, providing food for Wild Boar, Brown Bear, Manchurian Moose, and the endemic Ussurian Asiatic Black Bear (*Selenarctos thibetanus ussuricus*). Korean Pines have been so heavily logged outside the reserve that the species is now threatened; although it is protected, illegal logging still occurs (Bohan *et al.* 1996).

A highly unusual type of dark•barked, slow•growing birch grows here. Known as the "Iron Birch" (*Betula schmidtii*), its wood is reputedly so heavy that it sinks in water (Stewart 1992). The Primoryi Province, in which this preserve is located, harbors more than 150 species of trees and shrubs. The meeting of northern and southern forests in this region has resulted in a rich diversity of wildlife. The Ussuri Sika deer (*Cervus nippon hortulorum*) lives alongside the endangered Goral (*Naemorhaedus goral*), a goat•like ungulate native to mountains west to the Himalayas. This is the northern edge of the Leopard's range. The Amur Leopard (*Panthera pardus orientalis*) is a highly endangered subspecies, threatened by both habitat loss and poaching. Lynx and Common Otter are also native. The Dhole (*Cuon alpinus*), a threatened wild dog native to more southerly regions west to India, may also be native to the Sikhote•Alin Preserve. This extraordinarily rich diversity of predators and prey is at great risk from overhunting and logging, however.

As many as 340 species of birds have been recorded in Sikhote•Alin (Stewart 1992), including two endangered waterbirds, the Red-crowned Crane (*Grus japonensis*) and the Oriental White Stork (*Ciconia boyciana*) (Collar *et al.* 1994). A species of ginseng (*Panax ginseng*) grows in the undergrowth and is valued by the indigenous Udege people and others as an invigorating tonic, making it the "root of life" in their folklore. They believe that the ginseng is guarded by the great Siberian Tiger, and shrines are erected to the Tiger, who is believed to possess near•magical powers (Stewart 1992).

In 1991, the Hyundai Corporation of South Korea signed a 30•year contract to cut 500,000 acres of virgin forest on the Pacific slope of the Sikhote•Alin range (Schafer and Hill 1993). By the end of 1992, the area had been clearcut, and Hyundai began logging in the Bikin River Basin, the last pristine river valley in the region (Schafer and Hill 1993). In the Bikin, a small population of Udege live along the river's forested banks, as they have for hundreds of years, subsisting on local wildlife (Schafer and Hill 1993). These people have opposed the entry of the loggers, filing suit to stop the logging, threatening to shoot at logging trucks and removing markers from trees slated for cutting (Schafer and Hill 1993). Their protests succeeded in stopping the logging, negating the original agreement; Hyundai continues, however, to try to gain access to the Bikin forests (Bohan *et al.* 1996). This 600,000-acre watershed of the Bikin River is among the last virgin forests in Ussuria (Matthiessen 2000). A plan by the US Weyerhauser Corporation to cut an area of virgin forests the size of Delaware was thwarted by conservationists, and this forest has been declared a nature preserve (Nunn 1996).

Some 10 million acres of Tiger habitat are being clearcut every year, and members of the Siberian Tiger Project, composed of US and Russian biologists, are proposing alternate methods of timber harvest for the region (Quigley and Hornocker 1994). The native deer and boar, upon which the Tiger depends, are being hunted out of many areas by local villagers and professional poachers, who sell their bones and antlers for the Chinese Traditional Medicine trade. In 1995, the Russian government issued a decree "On Saving the Amur Tiger," which called for a specific plan and schedule to implement Tiger protection efforts (Galster 1996). In response, the Russian-American scientific team formulated a plan the same year to protect all existing Tiger habitat with connected reserves, new national parks, multiple use zones and ecological corridors linking them. It would be the world's largest sanctuary, preserving old-growth Korean Pine and designating various zones in this immense area, which extends from north of Khabarovsk south to Vladivostok in a mosaic of connected land (Galster 1996). The plan also called for a new national Tiger census, which was carried out in early 1996 and found more Tigers than previously assumed, an estimated 330 to 371

animals. The proposed protection plan, when combined with the Bikin traditional reserve and a large region a US government agency is helping to protect through multiple use, would preserve about 26 percent of existing habitat of the 156,000 square kilometers used by Siberian Tigers in Russia (Miquelle *et al.* 1999). The remaining area is either scheduled for logging or agricultural development. The Tiger biologists are urging that all Tiger habitat be included in a national protection plan, as signs of Tigers have been seen in 90 percent of the habitat (Miquelle *et al.* 1999). Coexistence between Tigers and people is essential. This would mean easing human hunting pressure on its prey, primarily Elk and Wild Boar, which have become rare, a major cause for the Tiger™s need of such large territories. Moreover, Tiger poaching needs to be stopped, and Tigers need access to river valleys, which they use for hunting and movements. Most of these have been taken over for human use.

The Siberian Tiger Project was the subject of a 1995 National Geographic film, "Tigers of the Snow," which included the first filming of a baby Siberian Tiger being weighed and examined by biologists in its wild den. The magnificent scenery of this coastal region was filmed from an aircraft, and areas of clearcutting were in stark contrast to the unbroken forests. The film also noted the sad end to a young Tiger hit by a logging truck. These trucks, loaded with giant tree trunks, thunder through the beautiful valleys. The Siberian Tiger Project is the first research study involving radio-tracking ever undertaken of the Siberian Tiger, and it is revealing new information on its range, behavior and habitat needs. Should the reserves be set aside, Siberian Tigers will be the first race or population of Tigers to become stabilized and perhaps increase at a time when all other populations are in drastic decline.

An eloquent book by Peter Matthiessen (2000), *Tigers in the Snow*, focuses on this research and the future of all Tigers. Anti-poaching work is helping to stem the decline of both the Tiger and its prey, but until its habitat is secure, this once proud cat, master of its domain, will remain beleaguered and under constant threat. Its world has become a battleground, filled with the screeching of power saws destroying the forests it needs to survive, and the constant threat of poachers. As a keystone species at the top of its food chain, the survival of the Tiger is "the best indicator of the health of the ecosystem as a whole" (Matthiessen 2000). Without the Tiger, the deer and boar will become slow, small and overpopulated, destroying their habitat as they have in Europe, where most predators have been eliminated. This is a crucial turning point for the species, whose tropical populations may not survive long. The Siberian Tiger inhabits a world without high human populations, a still-extensive forest habitat, and is the subject of a strong conservation program. The many people who are dedicated to saving it may succeed. In the words of Maurice Hornocker, an overseer of this research project, "One day it will be culturally unacceptable to kill Tigers anywhere for any reason" (Matthiessen 2000).

Eurasian Temperate Forests: Land of the Giant Panda

China's once extensive forests have declined over the centuries as human population increased. In south-central China, temperate forests of many types are watered by the five great rivers of Southeast Asia: the Mekong, Irrawaddy, Yellow, Yangtze and Salween (Mittermeier 1999). This is botanically the richest temperate region in the world, twice the size of California with half of China's plants--12,000 species, of which 3,500 are endemic (Mittermeier 1999). This is the home of the Giant Panda (*Ailuropoda melanoleuca*). Fewer than 1,000 of these black-and-white bears remain in small, scattered populations. When climates were cooler during the Ice Ages 12,000 years ago, Giant Pandas had a far larger distribution, covering much of central and southern China and bordering areas of Burma. As climates warmed and human populations took over much of their habitat, they declined in numbers, and their bamboo forests retreated. Today, Giant Pandas remain only in three provinces, with the largest number in Sichuan. Between 1974 and 1989, their habitat was halved as a result of logging and settlements, from 20,000 square kilometers to 10,000 square kilometers (Mittermeier *et al.* 1999). Satellite studies of their major reserve, Wolong Nature Reserve, found a dramatic decline in forest cover from 1965 to 1997 as growing numbers of people living in the reserve cut deciduous trees and bamboo for firewood (Revkin 2001). During the last decades, with international attention focused on this extremely charismatic animal, reserves have been set aside. Twenty reserves have been established in the

remnants of the Giant Panda's habitat, but the species has continued to decline as destruction of forests turn the reserves into islands surrounded by clearcut hillsides. Many Pandas have starved to death when their bamboo forests were cut or underwent a cyclical die-off. Prior to this deforestation, when local bamboo forests died off, Giant Pandas were able to wander widely in search of other bamboo. Their habitat has decreased so much that they are now at the mercy of local conditions within each reserve (Mittermeier 1999 *et al.* 1999).

A long•term study of this species by Dr. George Schaller, of the New York-based Wildlife Conservation Society, arrived at the pessimistic conclusion that the Giant Panda was headed inexorably toward extinction (Schaller 1993). In his 1993 book, *The Last Panda*, Schaller wrote a scathing and unflinching analysis of the failure of existing conservation programs. Among his conclusions was that almost all of the millions of dollars raised around the world to preserve this most popular of all animals had been wasted while wild Giant Panda populations dwindled. His research revealed that Pandas were readily taken into captivity during bamboo die•offs when, in fact, enough bamboo still remained to supply their needs (Schaller 1993). Most of the funds were spent on building dungeon-like breeding and holding compounds rather than on saving its ever•dwindling habitat or hiring wardens to prevent poaching (Schaller 1993). The Wolong Reserve, which covers 780 square miles, was the location of his research area. Wolong had 4,200 people living within its borders in 1989, who were cutting trees and setting snares to kill wildlife for meat, musk and skins (Schaller 1993). In eight years alone, 14 square miles of the Wolong forest were destroyed, and an unknown number of Pandas died in cruel wire snares (Schaller 1993).

Only time will tell whether the urgent habitat and anti•poaching needs of the Giant Panda will be met, or whether funds meant for its conservation will continue to be spent on breeding compounds. Seventeen forest corridors are planned to link fragmented habitat, but breeding and holding compounds continue to be built, with a goal of 32 stations (Williams 1994). A dedicated Chinese scientist, Pan Wenshi, who has studied these animals for decades, helped save the habitat of some 80 Pandas in these mountains when the high•pitched whining of chain saws was within earshot (Wenshi 1995). The National Geographic Society filmed the mother Panda that Pan Wenshi had studied throughout her life, Jiao Jiao, and her tiny mouse•sized cub when only a few days old (see Video section). This cub, a female he named Xi Wang, meaning Hope, grew into a healthy young Panda and, when four months old, took her first shaky steps out of the warm den (Wenshi 1995). As she grew older, Xi Wang took naps lying on her back in the tops of pine trees, watching her mother as she fed in the forest (Wenshi 1995).

If forest corridors are not soon set aside linking the reserves to one another to allow free movement of Pandas, the species will probably fade gradually to extinction from inbreeding (Lean and Hinrichsen 1992). One source of funding to preserve habitat is the Chinese government loan program, under which Giant Pandas are sent to foreign zoos for periods of up to 10 years. Various zoos in the United States have arranged such loans, paying the Chinese government $1 million per year per zoo, and these funds must be applied to conserving the species in the wild under supervision of the US Fish and Wildlife Service. A pair in the San Diego Zoo produced a healthy female cub in 1999 through artificial insemination. Other pairs were acquired by Zoo Atlanta and the National Zoo in Washington, DC, in 2000. Few Giant Pandas breed naturally in zoos. This funding and the new attention directed at conserving these highly endangered and endearing animals may turn the tide in China to protecting their habitat. If successful, it will also spell survival for thousands of rare Chinese plants and animals that inhabit the Pandas™ forests.

Xi Wang, the Giant Panda studied by Wenshi, inhabits the Qin Ling Mountains, haven for a wide diversity of rare plants. One mountain alone, the 12,359-foot Taibai Mountain, has 150 endemic species of plants, among them the Qin Ling Mountain Fir (*Abies chenensis*) (Ji 1990). Two varieties of this species are listed by the *1997 IUCN Red List Plants* (Walter and Gillett 1998). A neighboring mountain, the Shennongjia, is known as a "Treasure House of Plants" because of the many unusual and ancient species here (Ji 1990). In Hubei Province in the same region is the Dawn Redwood, a deciduous tree which is a close relative of the North American Coast Redwood and Sequoia but far more ancient in lineage (Ji 1990). Until 1941 when a few groves were discovered by Chinese botanists, the Dawn Redwood was known only from Jurassic fossils (MacKinnon 1996). Small populations survive in Sichuan, Hubei and Hunan provinces, but the species is considered Endangered by the International Union for the Conservation of Nature (IUCN) (Walter and Gillett 1998) and only about 1,000 trees may survive in the wild (Dyer 2000). This tree grows to

a height of about 115 feet, its delicate pinnate leaves turning golden in the fall. As the sole member of its genus, and a living example of trees that grew in the age of dinosaurs, it is considered a great botanical treasure.

Its seeds have been planted in many parks and botanical gardens around the world. John Williams, the award-winning composer, became fascinated with a Dawn Redwood growing in Boston's Public Garden (Dyer 2000). "It not only looked lovely, but it seemed animate, even intelligent," he said (Dyer 2000). By chance, he met a retired Harvard University botanist, Dr. Siu-Ying Hu, and praised the tree on a walk through the Public Garden. Hu pointed out that he had planted this very tree back in the 1940s, having brought a bag of seeds to America when he arrived from China (Dyer 2000). The Dawn Redwood inspired Williams to compose a musical piece entitled "Tree Song" for harps, keyboards, flutes and delicate percussion. It was performed by the Boston Symphony Orchestra at the opening of the summer concert series at Tanglewood, Massachusetts, in July 2000 and recorded on CD (Dyer 2000).

The extraordinary Dove Tree (*Davidia involucrata*) was named after its discoverer, Pere Armand David, a French missionary who traveled in China in the 19th century and named hundreds of animals and plants. Its white leaves are up to 6 inches long and 3 inches wide, resembling a flock of doves taking flight (Schaller 1993). These trees are quite rare in China, after centuries of deforestation (Walter and Gillett 1998). Even in 1900, when American botanist E.H. Wilson went to China to find seeds from this tree, he traveled six months before he even met someone who had ever seen one (Stocker 1997). When Wilson finally found a Dove Tree, only a stump remained: it had been cut and the wood used to build a house. He later found 10 wild specimens and brought back seed to Harvard University's Arnold Arboretum (Stocker 1997). This species, too, has ancient origins and once dominated prehistoric forests (MacKinnon 1996). Like the Dawn Redwood, it was rescued from extinction and is now cultivated in nurseries and botanical gardens (Stocker 1997).

Many of these plants and trees share the habitat of the Giant Panda, and forest reserves would ensure their survival. A number of endangered mammals that have disappeared from other regions as a result of hunting and habitat loss can be found in Wolong and other Giant Panda Reserves. The Red Panda (*Ailurus fulgens*), thought to be a relative of the Giant Panda, is a rare native, as are the Golden Monkey (*Pygathrix roxellanae*) and the Takin (*Budorcas taxicolor*), a goat•like ungulate. All three are endangered species and declining as the forests are cut. An endangered bird, the Sichuan Partridge (*Arborophila rufipectus*), is restricted to an area of less than 100 square kilometers in south-central Sichuan, where fewer than 2,000 birds survive (BI 2000, Collar *et al.* 1994). Its old-growth broadleaf forest is being felled at a rapid rate, and people enter its habitat to collect bamboo shoots in its breeding season, disturbances that are driving these birds toward extinction (BI 2000). Twenty-six other species of pheasants inhabit this part of south-central China, including the most iridescent birds in the world, the monals. The threatened Chinese Monal (*Lophophorus lhuysii*) inhabits rhododendron and high-altitude coniferous forests and is in decline as a result of logging and hunting, which have been facilitated by the construction of logging roads (BI 2000). The male Chinese Monal has dazzling plumage in an array of emerald green, purple, coppery-golden, purplish-green and white, while the female is more subdued in gray and rufous-brown. The creation of reserves for the Giant Panda have aided this bird's survival, as
several are within this bird's range (BI 2000).

China's 25,000 native plant species make up 11.4 percent of the world's plants, including many ancient ones (MacKinnon 1996). The Ginkgo (*Ginkgo biloba*) has been on Earth for 200 million years; this tree grows wild in scattered locations in China, indicating that it was once far more widespread and was eliminated by logging over the centuries (MacKinnon 1996). In prehistoric times, Ginkgoes grew throughout the world but were thought extinct until a few trees were found in remote forests (MacKinnon 1996). Its unusual wide, lobed leaves turn yellow in the fall before falling. This tree has been considered sacred by the Chinese for centuries and is grown in temple gardens and other religious sites. Extracts are sold around the world as an herbal stimulant. In the Himalayas, giant cypresses (*Cupressus*) grow to immense size when protected by Buddhist temples; one specimen measures almost 20 feet in diameter and is estimated to be 2,000 years old (MacKinnon 1996). Entire forests of these giant trees also grew on Taiwan, where only massive stumps remain (MacKinnon 1996). Stephen Spongberg, Curator at the Arnold Arboretum, has studied China's native trees and found numerous species to be extinct in the wild (Stocker 1997).

Antique Chinese furniture sought by collectors is often made from the wood of trees that are now extinct, and some trees are so rare that most Chinese botanists have never seen them in the wild (Stocker 1997).

China has more forest types than any country in the world. In the far north, taiga dominates. Conifers, birches and oaks blend into temperate coniferous forests in the northeast. Further south, the Giant Panda's habitat is temperate, evergreen forest. Himalayan forests occur in the west, and in the south, tropical monsoon rainforest prevails (Ji 1990). Unfortunately, very little virgin forests remain in the country, other than in high altitude and remote areas (Ji 1990). In the Giant Panda's highly diverse habitat of south-central China, less than 10 percent of the forests remain in pristine condition (Mittermeier *et al.* 1999). The destruction of these forests has been going on for centuries. During the 19th century, Pere Armand David lamented its destruction:

> *From one year's end to another, one hears the hatchet and the axe cutting the most beautiful trees. The destruction of these primitive forests, of which there are only fragments in all of China, progresses with unfortunate speed. They will never be replaced. With the great trees will disappear a multitude of shrubs and other plants which cannot survive except in their shade; also all the animals, small and large, which need the forest in order to live and perpetuate their species . . . They have the right to life and we annihilate them and brutally make existence impossible for them*
>
> Pere Armand David, 1875

In many parts of China, virtually no natural habitat remains, as centuries of human habitation and agriculture have replaced native vegetation and wildlife. One can travel for 1,500 miles in east•central China, for example, and see a landscape covered entirely with agricultural fields and villages, devoid of wildlife (Schaller 1993). Deforestation caused massive floods in the summer of 1995, when the Yangtze River, the country's longest, flowing from central China east to Shanghai, overflowed its banks. More than l.3 million people were displaced by the flooding, 900,000 houses collapsed, 2.7 million acres of crops were destroyed and 1,200 lives were lost (AP 1995). The economic losses were estimated at $4.4 billion. Each year these floods worsen as development covers the region, removing all natural flood controls (AP 1995). The last forests of any extent in China can be found in the northeast, and in 1987, fires destroyed 18 million acres (an area the size of Scotland) as well as 12 million acres in adjacent Russia (Schaller 1993).

Pere David's Deer (*Elaphurus davidianus*), named for its discoverer, and was once common in the northern forests and marshes. Hunting nearly eliminated the species, and to prevent its extinction, Chinese emperors kept the surviving population in a walled imperial hunting park near Beijing for more than 1,000 years. Even this population was killed by soldiers and villagers in the 1900 Boxer Rebellion, however; fortunately, some had been taken to England and kept by the Duke of Bedford on his estate (Schaller 1993). In 1985, 22 of these deer were returned from captive populations to the same walled park in China, now reduced from 150 square miles to 440 acres (Schaller 1993). Several other herds have been reintroduced elsewhere in China, numbering some 600 animals (MacKinnon 1996).

Reverence for nature in China dates back many thousands of years and is an integral part of the culture of this ancient country. It may now be reemerging. The 1979 Forest Law contained strict regulations on logging and required 40 percent forest cover in the mountains and 30 percent nationwide. This was strengthened in 1988 with a ban on logging in Yunnan and Sichuan, and legal protection was accorded to 389 plant and 206 animal species (Geatz 1999, Mittermeier *et al.* 1999). Reserves are being set aside throughout the country, increasing from 44 in 1956 to 600 in 1991, with a goal of 800 reserves protecting 5 percent of the country (Schaller 1993). This is indeed laudable in the most populous country on earth, and this eleventh-hour commitment is preserving many remnants of the once diverse and abundant natural heritage.

In practice, however, logging and firewood cutting tend to far exceed reforestation or preservation of forests in reserves or parks. Heavy livestock grazing by herders, who also clear forests for pasture, is devastating delicate forest

habitats (Mittermeier *et al.* 1999). Logging trucks carrying the trunks of the last remaining stands of old-growth forest can be seen in many areas. These deforested areas do not tend to regenerate because fires and grazing by goats kill the saplings (Mittermeier *et al.* 1999). During the late 1990s, The Nature Conservancy began a major project to study the biodiversity of the southern province of Yunnan, whose ecosystems range from alpine to subtropical forest (Geatz 1999). Certain tribes of this region have a strong tradition of conservation, and the provincial government has welcomed the help of this organization in helping to protect their natural heritage. Its 2000 report, "Conservation and Development Master Plan for Northwest Yunnan," includes recommendations for the protection of biodiversity, regional planning and resource development to provide ideas for non-destructive economic projects, such as growing plants for medicinal and ornamental purposes as an export commodity and developing ecotourism for this spectacular region (Geatz 1999, The Nature Conservancy 2000).

The future of China's forests and its tremendous biological diversity are greatly affected by its enormous human population of more than 1.2 billion people, whose growing needs encourage heavy hunting of its depleted deer and ungulate populations and large livestock herds, as well as excessive tree cutting for firewood (Mittermeier *et al.* 1999). Various international conservation organizations are working to help China in assessing its diversity and the threats to it, and to encourage enforcement of its 1982 Constitution, which states that the nation must protect and improve its environment and ecosystems, prevent pollution and protect precious animals and plants (Mittermeier *et al.* 1999).

Asia's beautiful pheasants and partridges are disappearing rapidly as their forests are cut and many are hunted for meat. Partridges and pheasants are found from the Himalayas to sea level tropical forests throughout most of Asia. They have declined dramatically, however. Of 22 species of Asian partridges, 15 species, or 68 percent, are listed by BirdLife International in *Birds to Watch 2: The World List of Threatened Birds* (Collar *et al.* 1994). An even higher degree of threat is suffered by the many spectacular pheasants. Of the 52 species of Asian pheasants, 38 species, or 73 percent, are threatened by the destruction of forests and hunting by the same authorities (Collar *et al.* 1994). Some endangered Himalayan pheasants include the Tibetan Eared Pheasant (*Crossoptilon harmani*), White Eared-pheasant (*Crossoptilon crossoptilon*), Cheer Pheasant (*Catreus wallichi*) and Elliot's Pheasant (*Syrmaticus ellioti*) (Collar *et al.* 1994). They show a great variety in their colorful and iridescent plumages, rivaling birds-of-paradise in beauty. Their relatively large size and brilliant plumage make them vulnerable to hunters, and they have not been studied intensively in the wild to determine habitat size and other requirements for their survival. Very few species have been protected in parks and reserves.

The mixed hardwood forests that once cloaked the Himalayas, studded in many areas by native rhododendrons, have been decimated during this century. Some 57 Asian rhododendrons are listed by the *1997 IUCN Red List Plants*. The deforested steep slopes are now prone to erosion by the monsoon rains that arrive annually. Heavy rains bring huge landslides and floods. Tree cutting, primarily by people gathering firewood or clearing land for agriculture, has been particularly severe in the Indian, Pakistani and Nepalese Himalayas. The once unbroken stands of oak and pine have become fragmented and totally absent in many areas. Human populations have risen over the past century to levels far above carrying capacity of this delicate region.

The Ganges River, which flooded only once every 50 years prior to deforestation, now floods every few years since the Himalayan forests that retained the water throughout the years have been logged (Lean and Hinrichsen 1992). Only Bhutan has preserved the majority of its forests, which are crucial to the survival of many species extinct elsewhere in the Himalayas. Tigers, Asian Black Bears, Himalayan Tahr (*Hemitragus hemlahicus*), Red Pandas, Golden Leaf Monkeys (*Trachypithecus geei*), and Tibetan Macaques (*Macaca thibetana*) are among the many mammals endangered by the loss of Himalayan forests. The Woolly Flying Squirrel (*Eupetaurus cinereus*), the largest squirrel species in the world, has just been rediscovered in northern Pakistan after being thought extinct for 70 years (Walters 1995). Four feet from its nose to the end of its tail, this squirrel may be able to glide distances of up to 1,000 feet (Walters 1995). Peter Zahler, a Cornell University zoologist, traveled to Pakistan in 1994. In a remote valley where this squirrel was rumored to exist, a local villager, who found one in a mountain cave, supplied a live animal in a bag. Zahler studied it for a short time, photographed and measured it, and then hiked 3 hours up the

mountain and released the squirrel at its capture site (Walters 1995). This squirrel has been designated Endangered by the *1996 IUCN Red List Animals*. This exciting rediscovery is tempered by the threats from deforestation and overgrazing in its mountain habitat. Local people report that it is solitary and active throughout the year, climbing conifer trees to feed (Nowak 1999). The Woolly Flying Squirrel is not hunted, but the conifers on which it depends are being cut at a great rate, causing it to decline over the past decade (Nowak 1999). Its total population is estimated at fewer than 2,500 and falling as a result of habitat loss (Nowak 1999). (Photos of this squirrel appear in Nowak 1999.)

Eurasian Temperate Forests: Lost Forests of the Mediterranean and Europe

Forests of towering cedars, oaks, firs, pine and beech once blanketed the region surrounding the Mediterranean Sea. Wildlife abounded in these primeval forests. Some 8,000 years ago, forest cutting began (Mittermeier *et al.* 1999a). Livestock gradually replaced wildlife, stripping the vegetation. In 3,000 B.C., Phoenicians logged the great forests of Cedars of Lebanon (*Cedrus libani*) for ship and building construction to trade with Egyptians and other cultures (Mittermeier *et al.* 1999). These massive trees reach 130 feet in height and are among the most majestic and stately of all trees. On the island of Cyprus, an endemic cedar, the Cyprian Cedar (*Cedrus brevifolia*), covered the island. Centuries of tree cutting and livestock overgrazing have reduced this tree to a relict population. Other forests on the Mediterranean's eastern shores were felled for building and to clear land for agriculture and grazing. The Greeks cut their forests in spite of warnings by the philosopher Plato as early as 4,000 B.C. that water supplies and wildlife would disappear (Pontiff 1991). The country's climate grew dryer and its topsoil washed into the sea (Runnels 1995).

Italy's southern forests were cut in Roman times, but north of the Adriatic Ocean, large expanses of beech and oak forests remained intact until the 16th century when they became the raw material for ships and galleys that sailed the Mediterranean waging battles and trading. Enormous amounts of lumber were needed to build these ships. When an exact replica of a galley was reconstructed a few years ago, 650 mature trees were required: 50 beech trees were needed for oars, 300 pines and firs for planks and spars, and 300 mature oaks for hull timbers (Attenborough 1987). In 1571, Venetian fleets battled the Turkish fleet which had been attacking and looting their ships. The 500 vessels in the Venetian and Turkish fleets had required the felling of more than a quarter-million mature trees (Attenborough 1987). Soon thereafter, the building of Venetian galleys came to an end for lack of trees, and shipbuilding moved elsewhere in Europe where trees were still abundant (Attenborough 1987). A single forest resembling the original beech and evergreen forest remains intact near the Adriatic in the former Yugoslavia. Its beauty was filmed for the series, fiThe First Eden. The Mediterranean World and Manfl (see Video section, Regional, Mediterranean).

Hardwood forests covered much of Spain until the early 16th century when, by royal decree, it was decided that the economy of the country could be expanded by developing a Spanish monopoly on the breeding of Merino sheep for their valuable wool (Attenborough 1987). Sheep herds became larger and larger, and forests were cut to provide grazing land. Within decades, the forests that had covered central Spain were gone, and topsoil had eroded, leaving shrubland (Attenborough 1987). These forests have not regenerated. Some oak forests have survived in parts of Spain, but intact ecosystems with native ungulates and predators have disappeared. Livestock grazes in all but the most remote areas. The few remaining Gray Wolves, as well as the endemic Iberian Lynx (*Felis pardina*), are critically endangered due to loss of forests and persecution. As an indication of the degradation of habitat, many species of Spanish wildlife are threatened with extinction. Worldwide, about 11 percent of the world's birds are threatened with extinction (Collar *et al.* 1994), but 37 percent of Spain's birds are threatened, 53 percent of its mammals, 41 percent of its reptiles, and 45 percent of its amphibians (Peters and Lovejoy 1990).

Forests of pine, cedars and oaks blanketed the slopes of the Atlas Mountains of Algeria and Morocco prior to the

Roman conquest. Logging by the Romans and people in the intervening centuries has destroyed all but fragments of these forests. The Atlas Bear (*Ursus arctos crowtheri*) originally ranged in these forests but was gradually pushed toward extinction by loss of its forest habitat, hunting and capture. The last of these bears was killed in the late 19th century (Day 1981). The endemic Atlas Cedar (*Cedrus atlantica*) has wide girths and grows to heights of more than 125 feet. They are often covered in moss and lichens in the cool altitudes (color photo, see Mittermeier *et al.* 1999a). Unfortunately, they are fast being depleted by timber cutters in Morocco and Algeria (Mittermeier *et al.* 1999a). North Africa's forests have become fragmented by centuries of logging and heavy grazing by cattle, sheep, and goats. The native Wild Boar (*Sus scrofa*) have also been extremely destructive to the few forests that remain, endangering many birds (Collar and Stuart 1985).

Surprisingly, a bird species native to the Atlas Mountain forests remained unknown until 1975. The Algerian Nuthatch (*Sitta ledanti*), a small, buffy songbird with white eyebrows, was discovered in a national park on Mont Babor (Collar and Stuart 1985). Even in national parks in this region, however, livestock are permitted to graze, consuming young trees and other vegetation. After conservationists protested that this little bird's entire habitat would be eliminated if livestock were not excluded, sheep and goats-- but not cattle--were banned from the park in 1981. To prevent forest cutting by the local people, propane gas has been supplied to use as fuel for cooking and heat (Collar and Stuart 1985). The forest on Mont Babor consists of mixed Atlas oak, Atlas Cedar and the Algerian Fir (*Abies numidica*), a threatened species which grows only on this mountain (Walter and Gillett 1998). The Algerian Nuthatch uses cedars, oaks and, especially, the Algerian Fir for seeds and nesting (Harrap and Quinn 1995). The population of about 80 pairs of Algerian Nuthatches censused in Mont Babor National Park in the early 1980s remained constant, and in 1989, a second population of about 350 birds was discovered in a nearby oak forest within the Taza National Park (Collar *et al.* 1994). Even though the Taza has National Park status, conservation of the forest has been hindered by cattle grazing that prevents tree regeneration. Also, wood-cutting is allowed that removes potential nest sites, and fires are set, killing many types of animals (Harrap and Quinn 1995). These birds also survive in two small isolated tracts of unprotected, degenerating forest 30 kilometers away, but the total population probably does not exceed 1,000 birds (BI 2000).

Another rare animal, the Barbary Deer (*Cervus elaphus barbarus*), barely clings to life in the disappearing Algerian forests. It is now extinct in Morocco and survives only in a small forest of cork oak and pine on the border between Tunisia and Algeria. They number only a few hundred, including a captive population, and are declining each year. This subspecies of the European Red Deer is listed as Endangered onthe US Endangered Species Act.

Israel has reintroduced related subspecies of some wildlife that have become extinct, bringing in closely related races of gazelles, wild goats, wild asses and Ostriches. The forests, however, are unlikely to return. The vegetation surrounding the Mediterranean today is dominated by shrubland that can regenerate after frequent burning (Mittermeier *et al.* 1999a). Livestock in vast numbers consume tree saplings and pull plants out by the roots. Goats are able to climb low bushes and graze their tops. The soil structure is very loose and alkaline, and the nutrients have been leached out by thousands of years of cultivation, overgrazing and erosion. Only plants that survive in arid climates on poor soil, such as succulents, annuals and those that regenerate from roots, can grow here (Peters and Lovejoy 1990). In many areas, exotic species, such as American prickly pears and Australian eucalyptus, have taken over as a result of the impoverished soil. The remaining bits of forest in southeastern Spain, Morocco, Algeria, Syria and Israel are being cut for fuel at a rate of 14 percent per year (Peters and Lovejoy 1990). The net result of the widespread loss of forests in the Mediterranean is that only about 1 to 2 percent of pristine, original forest remained at the end of the 20th century, all in small fragments surrounded by farmed and developed land (Mittermeier *et al.* 1999a).

The transitions that brought about the present state of affairs occurred over many centuries. So gradual was the environmental deterioration that one generation of people was usually unaware of the ecological changes wrought by previous generations. Once the forests were lost, succeeding generations may have been unaware that they had ever existed. Whether any progress can be made in regenerating forests by bringing in topsoil and replanting in protected areas will depend on the concerns and will of the people of the Mediterranean, who number more than 300 million

(Peters and Lovejoy 1990).

North of the Mediterranean, vast forests covering most of Western Europe remained until a few hundred years ago. Deciduous and mixed pine forests were logged over the centuries near towns and cites, and the forests retreated, replaced by agriculture and grazing land. By the 18th century, 90 percent of the forests had disappeared. In Scandinavia, Germany, Austria and Switzerland, tree farms have taken the place of natural forests. Man-made hallmarks of civilization now cover northern Europe except for a few isolated pockets of original virgin forest. Along with these forests, went the Auroch (*Bos primagenius*), an immense wild cow that became extinct in the 17th century. The large predators, Gray Wolves, Lynx and Brown Bears, that preyed on deer, elk and European Bison (*Bison bonasus*) were persecuted to near extinction and remain very rare. The largest remnant of these once vast forests is Bialowieza, on the Polish-Belarus border. It harbors the last herd of free-ranging European Bison and a small number of Gray Wolves.

An organization to protect these wolves, The Association for Nature "Wolf" is also concerned about the cutting of the old-growth trees in Bialowieza Primitive Forest, of which only 22 percent is protected in Poland (Nowak and Myslajek 1999). The "Wolf" organization is working to stop logging and protect this forest for future generations by the creation of a transnational park with Belarus (Nowak and Myslajek 1999). As the top predator in this and other forests of Poland and other European countries, the Grey Wolf helps maintain the health of the forest and cull overpopulations of hoofed animals such as deer. *Wolfnet*, the bulletin published by The Association for Nature "Wolf," is helping to educate the public about this maligned animal, which is often killed on sight in Europe. The organization is also sponsoring studies of the estimated 500 wolves in Poland and training livestock owners in the use of guard dogs to protect sheep (Nowak and Myslajek 1999).

Eurasia's northern boreal forests, or taiga, are far more extensive than North America's, stretching 6,000 miles from the Atlantic coast of Norway east to the Sea of Okhotsk on the Pacific rim (Sparks 1992). The western section in Scandinavia is almost gone: more than 90 percent of the taiga in the Scandinavian peninsula has been replaced by tree farms, which support almost no wildlife (Walsh 1995). Norway has lost 100 percent of its natural forests, and Sweden and Finland nearly all of theirs (Walsh 1995). The result of this destruction has been a crash in forest biodiversity and declines in many forest species. Seventy•three species of birds are declining or vulnerable in this region, including the Siberian Jay (*Perisoreus infaustus*) and White•backed Woodpecker (*Dendrocopos leucotos*) (Walsh 1995). Sweden's tree farms have replaced more than 200 species of plants and animals, and 800 species are rare or declining, as reported in *Taiga News: Newsletter on Boreal Forests* in 1992. The same publication noted that 805 species are endangered from clearcutting old-growth forests in Finland, and conservation groups have formed to try to save them from corporate logging. The Russian portion of taiga forest, which makes up the majority of these forests, has been less damaged, but with the fall of the Soviet Union, forests are now open to international lumber companies. Much of this forest is so remote that it may never be logged, but millions of acres are likely to be leveled over the next century.

Temperate Rainforests of the Southern Hemisphere

South of the Equator, in widely separated areas, are remnants of forests with species of trees older than the dinosaurs. These temperate rainforests grow in southern Chile and Argentina and, far to the west, in New Zealand, eastern Australia and the islands of Norfolk and New Caledonia. They have been growing nearly undisturbed for more than 100 million years, and many species of animals native to them have ancient lineages as well. Giant beeches grow in southern South America as well as far away in southern New Zealand and Australia. All these trees once grew on the southern supercontinent, Gondwana, some 160 million years ago. New Zealand, Australia and South America were joined and these trees were part of vast primitive forests. The continent gradually broke apart. Many species of trees survived on these new continents and islands as long as they could adapt to the new climates of the

different latitudes and longitudes, where they were pushed by continental drift through movements of the Earth's tectonic plates. In spite of eons of dramatic changes on Earth, geological and climatic, large fragments of these ancient forests have survived to the 21st century, only to face possible extinction. The wildlife now inhabiting them is predominated by more recently evolved species which coexist with species whose ancestors inhabited Gondwana. These fragile and unique ecosystems have undergone radical changes over the past few centuries, and many have been logged and cleared, with serious consequences for the native wild animals and plants.

South America

Only a century ago, South America's primitive forests blanketed the entire region from the southern tip of the continent north half the length of Chile's coast and eastward into Argentina's Patagonia. Beech trees of the genus *Nothofagus* covered most of the region, mixed with evergreen and various deciduous trees. Once extending more than 35 million acres, these forests comprised the largest stands of pristine temperate rainforest in the world (Nash 1994). *Nothofagus* beeches are among the most ancient species of trees and have been on Earth more than 150 million years. Soon after their arrival in the 16th century, European settlers began logging these forests, but not until the 20th century did widespread clearance begin. During the 1940s and 1950s, some 13,000 square miles, or 8.3 million acres, of these beech forests were cleared and burned for cattle ranching. Commercial logging continued, subsidized by the Chilean government, which spent comparatively little on forest conservation (Sims 1995). These beautiful forests have been cut mainly for wood chipping factories that produce paper pulp for export to Japan. Powerful commercial lobbyists have opposed legislation to protect the portions of these forests that remain, enabling logging companies to continue clearcutting, pushing some species to the brink of extinction. Once logged, the land is replanted with plantations of eucalyptus or pine, or turned into pastureland for livestock. The *1997 IUCN Red List Plants* lists four species of *Nothofagus* native to Chile and Argentina as vulnerable, indicating a decline toward Endangered status that, if not reversed, will result in their extinction (Walter and Gillett 1998).

Not all Chilean government officials are proponents of the logging. Carlos Ritter, head of the technical department for the National Forest Corporation, a government entity, complained: "Japan has fomented the cutting of our native forests, but they try not to assume responsibility. They say they are only buying the wood. But they have created so much demand the peasant farmer cannot resist cutting his forest" (Nash 1994). During the 1990s, an American logging firm, the Trillium Company, purchased 632,000 acres, or 987 square miles, of ancient forest in the southernmost region, Tierra del Fuego (Sims 1995). The Chilean government overruled opposition and gave permission to the company to begin logging in mid-1996.

An American conservationist, Douglas Tompkins, has preserved some of these forests. He purchased 741,000 acres in the southern province of Palena with more than $12 million from his clothing chain, Esprit. The cost of these beautiful forests, at $17 per acre, was miniscule in comparison to the cost of preserving temperate rainforests in the United States. Save•the•Redwoods League, an American conservation organization founded in 1918, recently celebrated its 75th anniversary, having spent $73 million to save 260,000 acres (about one•third of Tompkins™ acquisitions in Chile) of Coastal Redwoods at an average price of $280 per acre (National Geographic Society 1993). Most of the acreage of American old-growth redwoods that has been saved was purchased decades ago, and today it is worth hundreds of thousands of dollars per acre. The timber saved by the Save-the-Redwoods League is worth more than $5 billion (National Geographic Society 1993).

Tompkins' land includes South America's largest block of virgin temperate rainforest, protecting 78 percent of the remaining old-growth rainforest in Chile, including the country's largest remaining virgin stands of Chilean Larch or Alerce (*Fitzroya cuppressoides*) (Bowermaster 1995). This endemic and ancient tree grows to heights rivaling North American Coast Redwoods, with girths nearly as great as Sequoias (*Sequoia dendron*) (Dorst 1967, Walter and Gillett 1998). These majestic trees can live up to 4,000 years and take 500 years to reach commercial size. Extremely slow

to reproduce, Alerces do not produce seed until 200 years of age. Like redwoods, they are highly coveted for their lumber and have been cut with little regard to conservation. Highly endangered in Argentina and Chile (Walter and Gillett 1998), few groves of these trees remain, and although officially protected, they are sometimes illegally cut for the international timber market.

Tomkins came under attack by Chilean politicians and leaders of the Catholic Church who questioned his motives in purchasing such a large area and objected to his organization, the Foundation for Deep Ecology, for its statements about the importance of birth control to prevent human overpopulation (Sims 1995). Others falsely accused him of razing forests, setting up a nuclear dump, promoting abortion and even importing Israeli commandos. Many objected to private ownership of extensive areas of land by foreigners or disliked the idea of large-scale land preservation, but a Chilean conservation organization, the National Committee for the Defense of Fauna and Flora, rallied to his defense. After much contention, the Government of Chile accepted Tompkins' gift of 677,000 acres as a park in July 1997 (Grove 1999). It is known as Pumalin National Park and is considered one of the most ecologically important national parks in South America.

In an ominous note, part of the agreement with the Chilean government allowed access to the park by mining companies. The forest will not be logged, and there are plans for tourist accommodations and trails for hiking. This land is spectacularly beautiful, with glacial lakes and waterfalls, bisected by pristine rivers, its ancient forests teeming with wildlife. Covering the entire width of Chile, it borders a magnificent coastline with abundant marine mammals and sea birds. If preserved with care, the park will prevent the extinction of Chilean Larch and at least a portion of the magnificent southern beech forests which have been destroyed elsewhere. Ecotourism is being developed in the park area on a very small scale, with rustic accommodations, and tours from the United States and elsewhere are now visiting the park regularly. Not far to the north, the Parque Nacional Huerquehue preserves some of the magnificent scenery of this region. Known as the Lake District, portions of old-growth rainforest are protected in a landscape of crystalline lakes, waterfalls and churning rivers.

Another tree that survives from the Jurassic, the Monkey Puzzle Tree (*Araucaria imbricata*), has a somewhat larger range in South America. It is a member of a family of primitive conifers, the Araucaria, that grew on Gondwana. Monkey Puzzle Trees are being logged for timber and displaced by development, cattle ranches and mines. Named for their dense and interwoven crowns said to puzzle monkeys climbing them, the wide, unbranched trunk is covered in leathery bark in a knobby, diamond-shaped pattern. The nuts produced by these trees have been prized by the native Malpuche people for thousands of years. Malpuche means "People of the Monkey Puzzle Tree," and traditionally they did not overexploit these trees. Commercial exploitation of the nuts in local markets is threatening the species by leaving too few seeds for regeneration. Extracts from the Monkey Puzzle Trees have shown promise as a birth control drug, a traditional use by native peoples.

Like the Alerce, Monkey Puzzle Trees live to be very old, at least 1,300 years, and trees of the Araucaria family are considered the progenitor of all pines (Grove 1999). (See photographs in Grove 1999, and Dorst 1967.) When the Discovery Channel-BBC producers of the documentary film, fiWalking With Dinosaurs,fl searched for living landscapes in which to place their animated dinosaur models, an open forest of Araucaria trees in Chile was selected as an authentic backdrop, having changed little since dinosaurs fed on their crowns. The book based on this film has photographs of Araucaria forests from the movie (Haines 1999). Thirty-eight species of Araucaria survive, distributed in South America, New Zealand, Fiji, New Caledonia, Australia and Norfolk Island north to Malaysia. More than three-fourths of these, 30 species, are threatened with extinction, according to the *1997 IUCN Red List Plants* (Walter and Gillett 1998).

Another family of trees dating back to Gondwana, the podocarps, are also extremely primitive evergreens. Podocarps often have straight, unbranched trunks and clumps of dense needles near the trunk. Like the Araucaria, many of the species in the family are in decline: of 125 species worldwide, 70 are threatened (Walter and Gillett 1998). Two of these inhabit the southern rainforests of Chile and Argentina, and others survive in more tropical climates in Venezuela, Bolivia and Brazil, Madagascar, New Caledonia, Fiji, New Guinea and Malaysia. Australia

and New Zealand have more temperate climates and many native podocarps.

A threatened bird native to the old-growth forests of Chile and southern Argentina is the Slender-billed Parakeet (*Enicognathus leptorhynchus*), one of the few members of the parrot family that can survive cold climates. It has undergone steep declines in recent years as a result of forest clearance (Forshaw 1989). At least 22 bird species are restricted to Chilean *Nothofagus* forests, making this region a center of endemism (Cracraft 1985).

The most endangered denizen of southern rainforests may be the South Andean Huemul (*Hippocamelus bisulcus*), a short•legged, stocky deer that once lived throughout this habitat in Chile and Argentina. Driven from most of its haunts by the introduction of European deer, cattle ranching, logging and hunting, they now survive only in the extreme south of Chile, in tundra•like terrain with elfin woodlands. Low, gnarled trees are whipped by the strong ocean winds from Antarctic regions (Dorst 1967). No more than 1,300 South Andean Huemul are thought to remain (Nowak 1999), and a campaign has been launched to save these deer (Stutzin 1995). The National Committee for the Defense of Fauna and Flora and the Frankfurt Zoological Society are researching their status and raising money to purchase sufficient habitat for their survival (Stutzin 1995). Two reserves protect about 100 Huemul, but as the target of meat poachers throughout their range, they are found only in inaccessible areas. Researchers studying these deer, which had never had contact with humans, found them completely unafraid, grazing and bedding down within feet of their tents. This tameness makes them especially vulnerable to poachers.

Without immediate habitat protection and guarding of the remaining deer, the Huemul may not last long. Their status has declined even in national parks within the past few years. Alejandro Frid, a biologist who found these deer living in pristine habitat along a fjord in extreme southern Chile in a 1990 study, returned in 1995 to find near-disaster. Cattle had been set free in the Bernardo O'Higgins National Park, displacing the Huemul from their prime grassland habitat and forcing them into the sparse vegetation of the uplands (Frid 1997). He was told by a local ex-poacher that illegal hunting by local fishermen still occurred, and the lowland habitat was so trampled by the cattle that it was covered in muddy pits (Frid 1997). Ironically, the owners of the cattle did not eat beef but were adopting European cultural traditions, and since this harsh region did not provide good habitat, the cattle were not in good condition (Frid 1997). Conservationists are working to have the cattle removed from the national park, and international organizations are working to protect remnant populations of these deer. On the Straits of Magellan, where other South Andean Huemuls survive, commercial logging corporations are clearing forests (Frid 1997). The introduced Elk (*Cervus elaphus*) competes for habitat, and many Huemul are killed in attacks by domestic dogs (Nowak 1999). The South Andean Huemul and its close relative the North Andean Huemul (*Hippocamelus antisensis*) are both listed as Endangered on the US Endangered Species Act. This listing may not prevent their extinction, however.

The world's smallest deer, the Southern Pudu (*Pudu puda*), also inhabits southern temperate rainforests. This dog-sized deer is short-legged, with thick, buffy, reddish-brown fur and small, spike-like antlers. It is so diminutive, weighing only 5.8 to 13.4 kilos (Nowak 1999), that people have captured them as pets, which has contributed to their rarity. Its range within Chile was once far more extensive (Nowak 1999). The major threat to this species and its close relative, the Northern Pudu (*Pudu mephistophiles*) of the Andes of Peru through Colombia, is forest destruction. *Pudu puda* is listed as endangered on the US Endangered Species Act and on Appendix I of CITES, banning commercial trade, but hunting still threatens it.*

---

*Many trees of the southern beech forest, the South Andean Huemul and Pudu deer appeared in the 1997 film, fiChile, Land of Extremesfl (see Video, Central and South America section); the trees were photographed in *Living Planet, Preserving Edens of the Earth* (Grove 1999).

New Zealand

New Zealand was formed some 80 million years ago when it broke off from the tropical southern continent, Gondwana (Molloy 1994). The land mass moved away with resident pterosaurs, sauropod and carnosaur dinosaurs, along with primitive frogs, lizards, land snails, spiders and other insects and invertebrates. It is also possible that the ancestors of the flightless moas and kiwis were present on Gondwana (Heather and Robertson 1997).

Unlike South America, New Zealand remained uninhabited by humans until a thousand years ago, allowing an extraordinary fauna and flora to evolve. Giant trees of many types, some almost as massive as sequoias and others rivaling American Coast Redwood in height, thrived in primeval rainforests and swamps. The dinosaurs died off 65 million years ago simultaneous with their extinction elsewhere in the world. Over the eons, as the land moved southward, the climate cooled. Many tropical species, unable to adapt, died out, while others coexisted with immigrant species of plants, birds and insects that arrived by wind or ocean current. Geological and climatic events--from earthquakes and mountain uplifts caused by movements in the Earth's plates, to the weathering of wind, sun and rain--produced great changes in the topography over the millennia. The original land mass split into two main islands and many satellite islands, and snow-capped mountains rose on the southern island. Ice Age glaciations occurred during the Pleistocene between 2.4 million years and 10,000 years ago (Molloy 1994). These cold periods did not, however, eliminate the majority of ancient plant or animal species, another proof of their amazing adaptability.

When the Polynesian Maori people arrived about 1,000 A.D., temperate rainforests with understories of giant tree ferns grew throughout the island's swamps, lowlands and highlands, over 80 percent of the land. The Maori must have been stunned to see thousands of flightless birds of various sizes roaming the island. The moas had evolved from a single ancestor into some 11 species which grazed in herds or in small groups. Following the extinctions of the dinosaurs, moas evolved in a wide range of species able to browse vegetation in forest, shrubland and grassland habitats (Molloy 1994). The native plants developed thorns and other means of defense against the moas. These plant adaptations persist today, long after the disappearance of the moas, remnants of a bizarre and fascinating ecosystem. These emu-like birds ranged from chicken-sized to a species 10 feet or more in height, the tallest bird that ever lived. With heads disproportionately small and necks long and gangly, these down-covered birds walked about on thick, scaly legs. Also resident on the islands was a massive eagle, weighing up to 29 pounds (Molloy 1994). This giant bird of prey was the largest eagle to have ever lived on Earth and may have preyed on moas or soared about in search of moa carrion.

On the southern island, penguins lived on rocky coasts and in wet coastal rainforests; one species was a giant, standing more than 5 feet tall (Molloy 1994). No mammals other than bats were native. Lizards called tuataras, older than dinosaurs, lived in many habitats on the islands. Primitive and unusual frogs of types long extinct elsewhere were abundant, especially in mossy rainforests. Huge, cricket-like wetas, insects virtually unchanged for 200 million years, had evolved into 70 species. Compared to grasshoppers, wetas have heavy bodies, weighing as much as 2.5 ounces. Scurrying about at night, their diet and behavior are rodent-like. They are considered by zoologists to be among the most interesting animals on the islands (Molloy 1994).

The forests were dominated by trees very little changed since the age of the dinosaurs. Three major groups of trees, all evergreens, dominated New Zealand's forests, survivors of the Cretaceous Era 135 million years ago: araucaria, podocarps and southern beeches. All had close relatives in South America and other parts of the world.

A single species of the Araucaria family, to which the South American Monkey Puzzle Tree belongs, dominated forests on North Island. The enormous Kauri (*Agathis australis*) has a massive, wide trunk that rises to great heights

before branching in a wide canopy. Its gray, grainy bark forms deep, vertical ridges that curve upward, wrapping around the tree as it rises hundreds of feet into the air. Verdant tree ferns, with large, short trunks, and primitive club mosses form an understory beneath them.

Seventeen species of podocarp trees survive in New Zealand, some of which reach great heights. New Zealand's tallest tree is the Kahikatea (*Dacrycarpus dacrydioides*), or New Zealand Cedar, a type of podocarp which is nearly as tall as Coast Redwoods but with a slimmer trunk, often covered in epiphytic plants (Molloy 1994). Podocarp forests were once very widespread throughout both North and South Islands, each species in a slightly different habitat (Molloy 1994). At the other extreme is the world's smallest conifer, the ankle-high Pygmy Pine (*Lepidothamnus laxifolius*), a podocarp growing at high altitudes in a beautiful area known as the Southern Alps on South Island (Molloy 1994). Another podocarp type, the Celery Pines (*Phyllocladus spp*), are small trees whose leaves are actually flattened stems. One podocarp, *Halocarpus kirkii*, is listed as Threatened by the International Union for the Conservation of Nature (IUCN) (Walter and Gillett 1998), and all have declined dramatically in range.

Southern beeches of *Nothofagus*, the same genus as those in South America, once blanketed South Island in dense, canopied forests, often without an understory of plants other than low ferns (Molloy 1994). Today some forests remain, growing in association with broadleafed trees and hardwoods that arrived in New Zealand at a more recent time (Molloy 1994).

Some extremely primitive plants have also survived in New Zealand. The largest moss in the world (*Dawsonia superba*), giant liverworts, clubmosses and horsetails are among these (Molloy 1994). *Tmesipteris*, an epiphyte, is a relict of the earliest vascular plants, which evolved some 400 million years ago. This rootless plant clings to the branches of trees and hangs in vine-like, leafy strings. New Zealand's forest floor plants, a micro-world of species, most of which are less than an inch high, are beautifully photographed and described in *The Forest Carpet* by Bill and Nancy Malcolm (1989), a book devoted to New Zealand's mosses and related plants.

Other survivors from Gondwana include an extremely ancient family of spiders, Archaeidae. First described from a specimen frozen in amber several million years old, seven species have been found on Madagascar, also a part of Gondwana: one in South Africa, three in Australia, five in New Zealand and one at the tip of South America (Preston-Mafham 1991). The Archaeidae spiders have strange, grotesquely shaped bodies, visible only through a microscope since they are only 0.14 inches long; they live among leaf litter on the ground (Preston-Mafham 1991).

The beauty and primitive auras of many of the Kauri, beech, podocarp forests and pristine forest swamps evoke a "bygone era when dinosaurs still roamed the Earth" (Molloy 1994).* Beech and podocarpus forests cover South Island's Fiordland, a region along the southeastern coast resembling Norway's fiords, with inlets penetrating deep inland, lined by misty forests. The trees are buffeted by fierce winds from the west that bring rainfall of up to 20 feet a year. In this rugged wilderness, mosses and huge tree ferns thrive in the dampness.

---

*Many of the primitive landscapes that survive in New Zealand were captured in Gerald Cubitt's photos in *Wild New Zealand,* accompanied by natural history information in the text by Les Molloy (1994). Also, two films, fiLand of the Kiwifl and fiMountains of Water,fl described in the Video section, display these vistas.

The moas, which must have been very tame and unafraid, were hunted by the Maoris, who lived on their meat and eggs for centuries. The last of the moas, all smaller species, are said by some authorities to have survived until the 18th and 19th centuries (Greenway 1967), although this is disputed by others who assert that the moas were killed off well before the 15th century (BI 2000). Some Europeans claimed to have seen living moas, but no account was ever confirmed. Millions of their bones and eggs, and a few examples of skin, are all that now remain of these birds. The giant penguin, giant eagle and many flightless birds were also wiped out, apparently by hunting. European settlers eliminated many more species when they cleared forests and imported animals, such as dogs, cats, the weasel-like

stoat that preyed on native animals, and livestock that eliminated their habitats. Apart from the moas, nine birds, one reptile and one mammal are known to have become extinct in New Zealand since 1500. One of the birds, a beautiful forest songbird, the Huia (*Heteralocha acutirostris*), was truly unique: the male and female had different sized and shaped bills. Hunted for its plumes, and with its habitat destroyed, the Huia was last seen in the late 19th century. Others, including a flightless owl; a quail; two wrens, one of which was the only known flightless songbird; a bittern; a thrush; a storm-petrel; a flightless rail; and another songbird became extinct. A gecko and a native bat also disappeared (see Appendix for a chronological list of these species).

Although the Maoris cut and burned portions of the Kauri forests, not until the Europeans arrived in the 18th century did clearcut logging begin. Captain James Cook, the first European to visit New Zealand, noted some very tall trees that were probably Kauris while reconnoitering for lumber on his visit to New Zealand on November 21, 1769: "I judged that there was 356 solid feet of timber in this tree clear of branches." Millions of these great trees were felled for lumber or to clear land, leaving only fragments of the original forests. On the Coromandel Peninsula on North Island, isolated patches of mature Kauri forest are protected in several sanctuaries where old tramways, constructed to remove the logs, still scar the landscape (Molloy 1994).

Overall, approximately 75 percent of native forests in New Zealand have been cleared for agriculture and grazing land for 60 million sheep and other livestock. Fortunately, the Government of New Zealand has set aside many large parks and reserves to preserve landscapes, forests, endemic plants and animals. Thirty percent of the islands are protected, one of the highest rates of preservation in the world. In the majority of western Europe, for example, less than 5 percent of the land is protected, and villages and residences are allowed in many national parks. Not all New Zealand's ancient forests are safe from logging, however. A controlling interest in one of the last sizeable expanses of forest, 193,000 acres on the northern end of South Island owned by Fletcher Challenge Ltd., a logging company, was sold in 1997 to the US lumber company, Weyerhauser.

Many native animals of New Zealand's forests have been pushed to the edge of extinction by a combination of loss of habitat and the introduction of exotic species. Even the weta insects are in decline. Nine weta species are listed on the *1996 IUCN Red List Animals* (Baillie and Groombridge 1996). All four species of kiwis in New Zealand are rapidly approaching extinction, listed as Vulnerable or Endangered by *Threatened Birds of the World* (BI 2000). Authorities now recognize four, rather than three kinds of kiwi, and one, the Brown Kiwi (*Apteryx mantelli*), is endangered, its population having declined 90 percent since 1900 (BI 2000). Among the most ancient of bird species and possessing many unique physical and behavioral characteristics, their loss would represent as important a biological tragedy as the extinction of the moas. They have been placed in their own family, Apterygidae, an indication of their uniqueness. These flightless birds, which weigh from about 2 to 10 pounds, have small, stunted wings with claws on the end that are hidden beneath a cloak of shaggy, brown, hair-like plumage, giving them a mammalian appearance. Their long, pointed, ivory-colored bills are used to probe the leaf litter on the forest floor for earthworms and other invertebrates at night, and they can be heard snuffling as they forage. They have short, strong legs, and long, sharp claws on their toes, used for digging and fighting (Heather and Robertson 1997). Their food supply is ample: 200 species of earthworms live in New Zealand, with the largest species measuring an amazing 40 inches in length and 4 inches in diameter (Molloy 1994).

At the end of the kiwis' bills are nasal openings for their highly developed sense of smell, which aid them in detecting their prey. An acute sense of smell is a highly unusual trait in a bird. Kiwis also have sharp hearing but poor eyesight. Such characteristics are more common in mammals than birds (Hoyo *et al.,* 1992). Kiwis possess other mammal-like traits, such as two functionally alternating ovaries rather than one in the female (Feduccia 1996). In an interesting evolutionary phenomenon, where land mammals are absent, animals totally unrelated to them often develop mammal-like traits. Kiwis mate for life and live in large burrows. The single egg laid by the female is enormous in proportion to her size, weighing 20 to 25 percent of her weight. It is the largest egg, proportionally, of any bird and four times the size that would be expected for a bird her size (Hoyo *et al.* 1992). By comparison, a human mother weighing 125 pounds would have to bear a 25- to 30-pound baby. The hatching process is long and arduous, taking two to three days from the time the chick begins to break out; because the chick lacks an egg tooth, it

must kick its way out of the shell with its feet (Hoyo *et al.* 1992). Many chicks die during this process. When the chick emerges at last with damp feathers, its yolk sack is still connected and nourishes it for several days. A miniature version of its parents, it is able to follow them on their nocturnal feeding trips within a few days (Hoyo *et al.* 1992). (Rare footage of incubation and hatching of a kiwi in the wild can be seen in fiBirds of Paradox.fl See Video section F, Birds.)

Kiwis are totally unable to protect themselves against predators, such as dogs, cats, stoats and introduced Australian Brush-tailed Possums (*Trichosurus vulpecula*), who kill them or prey on their eggs (BI 2000). At least 94 percent of kiwis die before adulthood as a result of this predation (BI 2000). The possums also destroy rainforest vegetation by browsing on canopy leaves, epiphytic and ground plants; they have exterminated a native mistletoe (Molloy 1994). Non-indigenous animals have effectively eliminated kiwis from all but a few remote parts of their original ranges. At least one reserve, the 290-square-mile Coromandel Forest Park, has erected a fence within the Kauri forest to keep out possums, protecting kiwis and other native birds (Molloy 1994). Elsewhere, kiwis are being killed by predators; official government protection since 1908 has not stopped their continued decline. Feral dogs killed 500 Brown Kiwis in a population of 900 in less than two months in the early 1990s (Hoyo *et al.* 1992). Another cause of mortality has been steel-jaw leghold traps and poison set out to capture Brush-tailed Possums, although recently the use of traps has been regulated to prohibit any possible capture of kiwis (Hoyo *et al.* 1992). Dependence on humid rainforest habitat has also been a major factor in their disappearance, as this habitat has been destroyed by logging, fire and agriculture (Hoyo *et al.* 1992). Many kiwis are burned to death in the intentionally set fires that follow logging operations, as their shallow burrows do not protect them from the smoke, heat and flames. Often they are afield when fires are set and die in the fires. Those not killed lose their habitat when the humus and leaf litter essential for their feeding is consumed in the fires.

The Little Spotted Kiwi (*Apteryx ownii*) is the smallest and rarest kiwi, numbering only about 1,100 birds (BI 2000). A population of about 950 birds inhabits the 20-square-kilometer Kapiti Island off the southwest coast of North Island (Collar *et al.* 1994), where it was introduced from the mainland. Another introduced population on Tiritiri Matangi Island, a sanctuary of 543 acres off the northern coast of North Island, has adapted well (Molloy 1994). At one time, this kiwi was found throughout the main islands (Hoyo *et al.* 1992). In the summer of 2000, Little Spotted Kiwis were returned to a reserve on the mainland, a step toward their recovery. The Great Spotted Kiwi (*Apteryx haastii*), the largest species, is confined to forests in extreme northwestern South Island in the southern Alps (Heather and Robertson 1997). Although its habitat here is protected, its numbers are still declining from predation (Collar *et al.* 1994). At present, no Great Spotted Kiwis are living on a predator-free out-island (Heather and Robertson 1997), and only one small population is protected by controlling predators (BI 2000).

Another highly endangered bird, and a species almost as bizarre as the kiwi, is the Kakapo or Owl Parrot (*Strigops habroptilus*). The world's heaviest parrot, it weighs up to 3.5 kilograms and is the only living flightless member of the parrot family. It is also one of the rarest birds in the world. Once native to all but the highest mountain altitudes on North, South and Stewart Islands, Kakapos probably numbered in the tens of thousands (Collar *et al.* 1994, Forshaw 1989). They may have flown to the islands at a very early date, long before the land split into North and South Islands, and gradually lost their ability to fly. These 2-foot-long parrots have dull green plumage, mottled with brown, that blends into the vegetation of their rainforest habitat. Known as the Owl Parrot because of large eye discs and nocturnal habits, the Kakapo has another distinction in being the only member of the parrot family to gather in male groups near a bare area where "lek" displays are performed for females during breeding season. Males call females to the lek with loud, low-frequency, booming sounds emanating from their thoracic air sacs. These calls are audible to humans from as far as 3 miles away (Molloy 1994). They perform these booming calls for six to eight hours a night throughout the three- to five-month breeding season, which takes place only every three to five years under normal conditions (Heather and Robertson 1997). Very placid and slow-moving, they are unable to defend themselves against the rats, cats, stoats and dogs that Europeans brought to the main islands.

The range of the Kakapo began shrinking with the arrival of Maoris and their domestic animals, but in 1800 they were still common in central North Island and parts of South Island where their habitats had not been destroyed

(Heather and Robertson 1997). The European Stoat, introduced to the islands in the 1880s, proved an efficient predator of these parrots, eliminating them entirely from North Island and all but remote parts of South Island. In 1970, a survey revealed that only 18 Kakapos remained--all males--in Fiordland, South Island, and these last birds were gone by the early 1990s (Heather and Robertson 1997).

Fortunately, a previously unknown population of 100 birds was discovered in 1977 on Stewart Island, a fairly large island due south of South Island, but these birds were under attack from feral cats (Heather and Robertson 1997). After a decade of decline, all the remaining 61 Kakapos were transferred from Stewart Island by the New Zealand wildlife department to predator-free islets located off North and South Islands (Heather and Robertson 1997). In 1997, a lone female was discovered on Stewart Island and was removed (BI 2000). This rendered the species extinct throughout its original range. Unfortunately, many of the parrots starved to death in their new environments because these islets lacked sufficient food. Their natural diet of fruits, berries, nuts, fern fronds, roots, tubers, moss and fungi was abundant in the temperate rainforests and tussock grasslands of the main islands. A 1983 BBC documentary, fiBirds of Paradoxfl (see Video section), filmed a Kakapo chick being fed by its mother, who walked over steep terrain 3 miles each night to obtain seeds and other food for her offspring. Kakapos can live for as long as 70 years, and this longevity has prevented their extinction, since many years pass without any successful breeding. New Zealand wildlife officials finally provided supplemental feeding, which immediately resulted in the first surviving chicks in a decade in 1991. A population of 62 birds survived in 1999, of which 26 were females and 36 males, including six chicks (WC 2000). Although their numbers are slowly growing, many of the males appear to be sterile, and others have been filmed calling alone, rather than in male groups; some seem to be calling in vain, with no females responding (Hynum 1999). An Internet website has been established to monitor these extraordinary birds: www.kakapo.net.

Many other native songbirds, shorebirds, reptiles and amphibians are threatened in New Zealand, and some survive only on offshore islets where predators are absent or have been eliminated. New Zealand has had success in eliminating cats and possums from several sizeable islands off the main islands, but on North and South Islands, rats, cats and stoats, as well as European deer and goats, are uncontrolled (Molloy 1994). Some 70 million Brush-tailed Possums live throughout both islands, and they are now endangering forest birds by preying on eggs and chicks (Molloy 1994). Exotic plants have also invaded forests, smothering native plants and choking lakes (Molloy 1994). There is, however, a remarkable awareness in New Zealand of these conservation problems and its extraordinary natural heritage. Moreover, the government agencies dealing with wildlife and the environment, TV New Zealand Natural History (which makes superb wildlife films), and scientist-writers such as Les Molloy (1994) are educating the public about this natural legacy, much of which has endured for hundreds of millions of years. Contributions of funds and expertise from many nations and organizations might aid New Zealanders in their conservation work.

Australia

Australia's temperate rainforests are very similar to those in New Zealand, and fragments persist in portions of eastern and southeastern Australia. Relatives of the Kauri, the Nothofagus beeches, and podocarpus trees are native. An exciting botanical discovery was made in one of these forests in 1994. Named the Wollemia Tree (*Wollemia noblei*) after the national park where it was discovered, it is a member of the Araucaria family and somehow escaped attention until 1994. A species familiar to botanists through fossil records, it was thought to have become extinct 50 million years ago (Wilford 1994). A botanist noticed an unusual tree in Wollemi National Park in New South Wales, southeastern Australia and, when he investigated closely, found its fern-like leaves and other proof that it was indeed a living fossil (Wilford 1994). About 23 of these "living fossils" have been located in the park, the tallest towering 130 feet with a 10-foot girth and the species is being propagated by the Australian government. At a press conference soon after its discovery, Ken Hill, botanist at the Royal Botanic Gardens in Sydney, exhibited a fossil imprint of the Wollemia's fern-like leaves next to the living branches for news media, stating that it was one of the outstanding

biological discoveries of the century (Wilford 1994). Pictures of these trees were shown on television news programs around the world, an indication of the new appreciation being accorded such natural wonders. These massive pines have dense, waxy foliage and knobby, dark bark with strange-shaped branches growing from the trunk (Wilford 1994). They were found growing in a secluded area of little more than an acre, deep in the national park, where high humidity and moisture probably protected them from fire and provided ideal habitat (Wilford 1994). Had these priceless trees not survived in a national park, they might have been cut for firewood or commercial logs long ago. Wollemi National Park's protection was considered a great triumph for Australian conservationists. It contains the country's largest area of undisturbed forest--more than 486,400 hectares (1,201,894 acres) (Campbell 1989). The Colo River, the last unpolluted waterway in New South Wales, flows through the park. Other trees in this park include tall eucalyptus, which predominate; Snow Gums; Mallees; and pockets of rainforest in gullies (Campbell 1989).

Four species of Australian Podocarps are listed by the *1997 IUCN Red List Plants*. They range from Queensland's rainforests to temperate rainforests in New South Wales and Tasmania. Such forests, with their tall, evergreen trees and understories of tree ferns, are very rare today as a result of climatic change, a gradual drying of the continent and logging. Eucalyptus trees, which can withstand a dryer climate, gradually increased in range in Australia's temperate rainforests since they appeared in the Oligocene Epoch 35 million years ago (Vandenbeld 1988). They first colonized forest edges and flourished in open woodlands, then grew into entire forests growing from Queensland south to Tasmania, having radiated into 500 species (Vandenbeld 1988).

From New South Wales south to Tasmania, Nothofagus beech forests have been edged out by eucalyptus but remain in a few areas, a glimpse of the past. Mosses, ragworts, rotting logs, ferns and tree ferns carpet the forest floor, similar to those growing farther east in southern New Zealand (Vandenbeld 1988). European colonists logged these forests to clear the land for farms and grazing. The ancient eucalyptus, with their massive trunks, dwarfed the teams of oxen that dragged out the logs. This primeval forest is now almost gone. A 19th century artist, Isaac Whitehead, depicted a magnificent old-growth forest being logged in a dramatic painting showing trees that must have had circumferences of well over 50 feet. If not for the huge stumps that remain, one might have doubted that they actually existed (Vandenbeld 1988).

Forty percent of the country's forests have been cleared, including 75 percent of the rainforests in northern Queensland and 90 percent of both the dry mallee of the south and the eastern temperate woodlands (Parfit 2000). Logging had a devastating effect on the continent's woodland mammals who depended on the forests for survival. Of 144 marsupials inhabiting Australia 200 years ago, 21 are extinct, and a total of 88 Australian marsupials are listed in the *2000 IUCN Red List Species*. Many of these were forest species. Australia has had more mammals become extinct over the past few centuries than any other country in the world. The majority of forests in Australia did not revert to second-growth but became grazing land, plantations, agricultural fields, or tree farms of non-native pines for pulpwood (Vandenbeld 1988).

The eucalyptus forests that came to dominate many of Australia's woodlands are interspersed with savannah in the dryer north. In the south, they grow in dense, moist woodlands, with tree ferns and mosses as ground cover. Among the most characteristic trees of Australia, almost all the great old specimens are gone. Few Australians have ever seen a gigantic, 400-year-old eucalyptus tree, so massive that it takes 15 people to embrace its girth, but such trees were once common (Sharp 1995). It takes 200 to 300 years for a eucalyptus to form nesting holes that provide homes for possums, gliders, bats, snakes, birds, parrots and other creatures that were once prolific in Australia (Sharp 1995). The tallest trees in Australia, many eucalyptus stand more than 300 feet high (Attenborough 1995). In 1880, just before cutting it down, a surveyor measured a eucalyptus that stood 375 feet tall; another inspector around the same time told of a fallen trunk that was 435 feet long (Attenborough 1995). Had this been confirmed, it would have been the world record for the tallest tree ever measured (Attenborough 1995). Their straight, unlimbed trunks rise to great heights before branching. Settlers cut them for building materials and railroad ties, clearing vast areas and threatening many species. An astounding 175 species of the genus *Eucalyptus* are listed on the *1997 IUCN Red List Plants*.

In central Queensland, 5 billion eucalyptus trees were cut to create permanent grazing land for up to 2 million

cattle. Up to half of the trees in 100 million hectares in this Australian state have been cut (Arnold 1994). The last forests of Queensland are being cleared for livestock and agriculture at one of the highest rates of deforestation in the world, estimated at 840,000 acres a year (Parfit 2000).

Koalas (*Phascolarctus cinereus*), native to eastern Australia's eucalyptus forests, are entirely dependent on the leaves of these trees for their food. Most animals avoid eucalyptus because the leaves contain toxic oils, but Koalas have the ability to detoxify these oils, which also gives them a natural insect repellant (Berra 1998). They eat about 36 species of eucalyptus and obtain most of their moisture from dew and the leaves (Berra 1998). Forest clearing has had a disastrous effect on their populations. The last large population of Koalas in southeast Queensland was decimated by construction of an expressway, over vehement opposition from citizen groups (Arnold 1994). Likewise, in the state of Victoria in the southeast, Koalas have been reduced to a few remnant colonies as a result of hunting, development, tree cutting, highways, fires, droughts and predation by dogs and foxes. At least 4,000 Koalas are reported killed each year, and about 2,500 of these die after being struck by cars near urban areas (Berra 1998). They have also been victims of a variety of illnesses, including *Chlamydia*, which causes reproductive failure, pneumonia, blindness and other ailments (Berra 1998). They have declined so dramatically that in 2000 the species was listed as Threatened on the US Endangered Species Act.

Outside of protected areas, the last old-growth forests in New South Wales are being cut. The government accorded a giant multinational corporation, Boral, a contract to cut 500,000 tons of woodchips in the mid-1990s. (Arnold 1994). This logging will remove virtually every native forest not protected in national parks in northeast New South Wales, according to Sue Arnold, Coordinator of Australians for Animals (Arnold 1994).

Victoria still retains some old-growth forest, home to a host of rare animals. Old eucalyptus tower over tree ferns, sassafras, mountain pepper and mosses. In 1999 and 2000, loggers began cutting one of the last of these forests known as the Goolengook Forest (*EarthFirst! Journal* 2000). Aborigines have been able to stop logging in some traditional areas, including East Gippsland, Victoria, but the delicate and endangered native marsupials inhabiting most of these forests may not survive for long.

A strange mammal of Victoria's eucalyptus forests is Leadbeater's Possum (*Gymnobelideus leadbeateri*). Native to the Central Highlands, it lives in colonies in tall, old-growth eucalyptus trees (Strahan 1995). Thought extinct, this marsupial was rediscovered in 1961. With a tail almost twice the size of its body, huge black eyes and a stripe down its back, this possum looks like a cross between a squirrel and a skunk. Each night, it emerges from tree hollows to climb tall trees in search of insects. Forest clearing has destroyed much of its mountain forests (Nowak 1999). Only about 5,000 or fewer Leadbeater's Possums survive, and the species continues to decline as logging clears its habitat (Kennedy 1992). Its dependence on large trees, especially those 300 or more years old which have large tree holes for their nests, has made it very rare (Strahan 1995). Specializing in finding crickets, beetles, spiders and other arthropods beneath the shedding bark of eucalyptus and other trees, it may require, for an as yet unknown reason, a particular species of tree cricket which shelters under the bark of a certain type of eucalyptus (Strahan 1995). This possum also eats gum and tree sap. Less than 3 percent of its total range of 4,000 square kilometers is protected in nature reserves, and 75 percent is located in timber-production forests where tall, old trees are likely to be cut (Strahan 1995).

Tropical Forests

Tropical forests have, for the most part, evolved in stable environments over a period of millions of years, untouched by the recent Ice Ages. The oldest forests on Earth may be in Borneo where the same species of towering trees have been growing for 250 million years. Climates in tropical forests tend to be uniformly warm year-round, with half the year rainy, and the other half dryer but not without rain. Tropical trees generate enormous amounts of

moisture. In some parts of the world, the climate has changed over the ages, resulting in islands of forests surrounded by grassland or other habitats. Many scientists theorize that some forests, including the Amazon and African rainforests, went through such climatic changes during the Ice Ages (Collins 1990). Isolation might explain the evolution of a great number of endemic species in these regions, which today are continuous forest. These tropical forests are showcases of evolution.

Tropical forests vary greatly according to altitude, region and species of trees. Each has a different micro-climate, soil type, fauna and flora. They grow in tropical latitudes 30 degrees to the north and south of the Equator (Collins 1990). Among the many types of tropical forests are evergreen wet forests, deciduous dry forests, mountain cloud forests, and mixed lowland rainforests. In general, lowland rainforests are the most biologically diverse, as well as the most endangered. Covering only 7 percent of the Earth's surface, rainforests harbor half its species (Lean and Hinrichsen 1992). Biological research in tropical forests has consistently shown that this great diversity helps stabilize ecosystems and the very life support systems of the planet.

Some tropical forests have been characterized as "hotspots," having exceptionally high diversity of endemic species that are found nowhere else on Earth. All are threatened by deforestation. Two studies by ecologist Norman Myers in 1988 identified 10 highly endangered and biologically diverse tropical forest hotspots in the world; in 1990, he revised that number to 18 (Myers 1988, 1990; McNeely *et al.* 1990, Mittermeier *et al*. 1999a). Myers pointed out that the 10 hotspots named covered only 0.2 percent of the land surface of the world, but contained 27 percent of the plants and also a high percentage of endemic species. *Hotspots*, a book by Russell Mittermeier, President of Conservation International, and other biologists and ecologists, describes 15 tropical forest hotspots throughout the world among a total of 25 hotspots of all types of ecosystems. The high diversity in tropical forests is reflected in the fact that these hotspots covered 61 percent of the land area of all hotspots identified in the study. Many have lost 90 percent or more of their original forests and continue to decline. Originally, these extremely diverse tropical forests covered 10,635,513 square kilometers; at present, only 1,246,538 square kilometers remain, a loss of 86 percent (Mittermeier *et al.* 1999a). These tropical forest hotspots cover only 0.08 percent of Earth, but harbor 205,789 plant species and 21,903 vertebrate species other than fish (Mittermeier *et. al.* 1999a), a large percentage of the some 248,428 named vascular plants and 23,524 non-fish vertebrates (Wilson 1988). One can only wonder what diversity these areas had prior to their near-destruction. Such astounding facts should result in strong programs to preserve these regions, all of which are being degraded.

The tropical forest hotspots include the Caribbean, Central America, Brazil's Atlantic Rainforest, western Ecuador's Choco region, Andean tropical forests, Indo-Burma, the Philippines, Indonesia and Peninsular Malaysia, the Western Ghats of India, Madagascar, New Caledonia, Polynesia and Micronesia, Guinean Forests of West Africa, and mountains and coastal forests of Tanzania and Kenya (Mittermeier *et al.* 1999).

-

The richest and most diverse hotspot on Earth is found in the tropical Andes, stretching from western Venezuela to Chile and Argentina (Mittermeier *et al.* 1999a). This area has innumerable isolated valleys, slopes, and peaks in many altitudes, all physical characteristics that contribute to the evolution of a great array of plants and animals. Covering 1,258,000 square kilometers, these forests are interspersed with alpine vegetation and grassland. Between 45,000 and 50,000 kinds of plants are found here, 20,000 of which are found nowhere else (Mittermeier *et al.* 1999a). Birdlife is prolific, with 1,666 species, 41 percent of which are endemic. Andean Cock-of-the-Rocks (*Rupicola peruviana*), threatened Toucan Barbets (*Semnornis ramphastinus*), the giant Andean Condor (*Vultur gryphus*), also a threatened species, and the greatest variety of hummingbirds in the world are resident (Mittermeier *et al.* 1999a). The critically endangered Yellow-tailed Woolly Monkey (*Lagothrix flavicauda*) is native to a few Peruvian cloud forests, and the Spectacled Bear (*Tremarctos ornatus*) and Mountain Tapir (*Tapirus pinchaque*) are other endangered species of the region. Deforestation has destroyed much of the region through slash-and-burn farming and extensive cultivation of opium poppies, which are controlled with herbicides that poison rivers and streams, suspected to cause declines in frogs and toads (Mittermeier *et al.* 1999a). Several national parks have been set aside, including the Madidi and Tambopota National Parks on the Peru-Bolivia border, covering some 2,225,000 hectares.

-

The Atlantic forest of southeastern Brazil, another hotspot, has been reduced by 92 percent, yet it has been found to contain the greatest diversity of trees in the world: 476 species in a plot of only 2.5 acres, including 104 previously unknown tree species. By contrast, a plot of similar size in a North American temperate forest has only about 20 species of trees. A much larger plot, totaling 129 acres, in an old-growth forest in Malaysia's Lambir Hills National Park has an astounding 1,175 tree species (NGS 1997). This site is surrounded by farms, and nearby forests have been logged to the forest's boundaries. Both sites are tropical forest hotspots.

Africa's tropical forests once stretched in a wide band from Sierra Leone east through Zaire to Uganda and Kenya, and south to Angola. Of the original 3,620,000 square kilometers, less than half, or about 1,760,000 square kilometers, remained in the early 1990s (Martin 1991). The worst damage has occurred in West Africa where logging and clearance for plantations and villages have destroyed at least 85 percent of its rainforests (Collins 1990, Mittermeier *et al.* 1999a). Even the now-extensive forests of the Democratic Republic of the Congo and neighboring countries are being logged so rapidly that, outside reserves, they will have disappeared in 50 years, according to a 1997 study. A primate anthropologist, John F. Oates, researched the destruction of West African forests and the role played by international loan agencies such as the World Bank and the Ford Foundation. His book, *Myth and Reality in the Rain Forest. How Conservation Strategies Are Failing in West Africa* (Oates 1999), carefully documents the establishment of forest sanctuaries that did not protect forests and their wildlife, but encouraged logging, farming and bushmeat hunting. Almost no forest or sanctuary in West Africa is protected from logging, wildlife killing or capture, or other destruction. The rainforests stretching from Sierra Leone east to western Cameroon and the Gulf of Guinea islands of Equatorial Guinea comprise one of the world's most endangered hotspots for biological diversity (Mittermeier *et al.* 1999a). They covered 1,265,000 square kilometers a few hundred years ago, but have been reduced to only 182,348 square kilometers, or 14.4 percent of the original; of the remaining forests, only about 126,500 square kilometers are pristine forest, a scant 10 percent of the original (Mittermeier *et al*. 1999a). These forests are fragmented and largely unprotected. Some 9,000 species of plants exist in this region, of which 2,250 are endemic (Mittermeier *et al*. 1999a).

Some of the world's most fascinating and unusual wildlife species can be found here as well, including the world's largest frog, the threatened, 3.3 kilogram Goliath Frog (*Conraua goliath*), which inhabits mountain streams in Cameroon. The Western Chimpanzee (*Pan troglodytes verus*) of these forests is highly endangered by forest clearance and killing for the meat trade. Like the Chimpanzees of Kenya studied by Jane Goodall, they are tool-using, employing stones to crack open hard nuts on logs. They may be a completely different species of chimpanzee (Mittermeier *et al.* 1999a). Forest Elephants (*Loxodonta africana cyclotis*) are vital to forest ecosystems as seed dispersers and to open up forest glades for wildlife, such as the threatened White-breasted Guineafowl (*Agelastes meleagrides*) (Kingdon 1989). They also dig waterholes which provide a lifeline for a host of animals. Unfortunately, they are endangered as a result of deforestation and poaching. These forests also harbor many species of little forest antelope known as duikers, all less than 3 feet tall, which dart about the undergrowth in the Guinean forests. Sixteen of the 17 species are listed in the *2000 IUCN Red List Species*, declining from forest loss and intense hunting. The rarest is Jentink's Duiker (*Cephalophus jentinki*), of which only a few hundred remain. There are no individuals of this species in captivity, and no photo has ever been published of this little antelope (Martin 1991).

In spite of these extraordinary treasures, there are few national parks in the Guinean forests, and almost all remaining forests are being commercially logged. In Sierra Leone, the only protected area is Tiwai Island, a 12-square-kilometer, primate-rich area (Mittermeier *et al.* 1999a). The parks that have been set aside, such as the Tai National Park, an extremely important and biologically rich forest in the Ivory Coast, are under siege from illegal hunters, and farmers whittling away at the forest. Kakum National Park in Ghana has been aided by Conservation International in promoting ecotourism over the past six years; a new canopy walk and aid in tourist promotion helped attract 40,000 tourists in 1997 (Mittermeier *et al.* 1999a). Few of the existing preserves are large enough to preserve the diversity of wildlife and plants of the region. Unless dramatic action is taken, many extinctions will take place in the near future.

In Gabon, to the south of Cameroon, recent progress has been made in protecting a large block of forest in the

center of the country. Lope Reserve covers 1,900 square miles of Equatorial jungle coveted by loggers. An agreement signed in July 2000 between logging companies, the government and a variety of environmental organizations permanently prohibited logging in this sizeable area (Revkin 2000a). A compromise included the removal of 400 square miles of the reserve area with valuable Okoume Tree (*Aucoumea klaineana*) in order to add 200 square miles of extremely important habitat for primates, elephants and other wildlife (Revkin 2000a). Since 1957 when only a small percentage of Gabon's forests were open for logging, to the present when almost all the country is logged, wildlife has been driven from many areas by logging noise, roads that open up the forest to hunters and loss of habitat (Revkin 2000a). Dr. Lee J.T. White of the Wildlife Conservation Society has documented this phenomenon and has convinced the government to approve a country-wide forest inventory to identify other areas to protect for a network of national parks (Revkin 2000a).

The Lope Reserve, according to zoologist Jonathan Kingdon, does not include the Bee Forest, home to a very beautiful and rare primate, the Sun-tailed Guenon (*Cercopithecus solatus*), first classified and named in 1984. Dramatically patterned in dark gray with white facial markings and long reddish tails, these monkeys were photographed in the mid-1990s lying dead on tables at a market in Libreville, Gabon, offered for sale as meat (Bohan *et al.* 1996). Known only from this forest, this monkey is threatened by heavy logging in the forest by Isoroy, a French company acquired by Glunz Corporation of Germany (Bohan *et al.* 1996). The species is classified as Vulnerable in the *2000 IUCN Red List Species* (Hilton-Taylor 2000). Isoroy cuts about 140,000 cubic meters of logs per year from a 300,000-hectare (741,300-acre) concession in the Bee Forest, exporting logs to plywood factories in Europe (Bohan *et al.* 1996). The prime wood sought by the loggers is from the Okoume Tree, and a four-year study has found major damage being done to the forest in the process. On average, 8.5 trees were destroyed for every Okoume log harvested, and 49 percent of the forest canopy has been disrupted (Bohan *et al.* 1996).

The Sun-tailed Guenon is one of 26 species of guenons considered "refugia" species of African rainforests. During the Ice Ages, these forests shrank into islands, where many different primates evolved in isolation in these forest fragments. Each has brightly marked facial and body patterns (Kingdon 1989, 1997). These "masked monkeys," many of which were photographed in the spectacular PBS Nature film of that name, are often highly restricted in their ranges and considered threatened by the IUCN. Kingdon, who has studied these primates for decades, believes that they have brightly colored markings in order to see and identify one another in the dark forest foliage (Kingdon 1989).

A close relative of the Sun-tailed Guenon is the endangered Diana Monkey (*Cercopithecus roloway*), endemic to the Guinean region. This lovely primate's jet black face contrasts with its white chest and legs; its back is russet red and gray, and its long tail is black. Its fur seems to have been painted on, so silky and lustrous is its texture. The majority of Americans know little about this species and other endangered African monkeys. This was dramatically illustrated in the summer of 2000 when New York state authorities ordered the confiscation of a pet Diana Monkey kept by an immigrant family. This animal had been bought in a Long Island pet store in 1995, long after its listing on the US Endangered Species Act and New York's endangered species legislation, yet no one seemed to notice when it was offered for sale illegally. The new owners immediately had a veterinarian spay and remove the canine teeth from this female monkey, named her "Cookie" and dressed her in tutus as a family pet. They said they had no idea that she was an endangered species and refused to give her to the state, which planned to place her in the Detroit Zoo with a male of the species. She can never be part of a breeding program, however, and is a genetic loss to the species. Had the plight of these beautiful primates been better recognized and the species better known, this unfortunate incident would never have happened.

Another "masked monkey" native to Ghana and the Ivory Coast has recently been declared extinct, the first primate extinction in several centuries (Revkin 2000b). Known as Miss Waldron's Red Colobus (*Procolobus badius waldroni*), this monkey had colorful, reddish-brown legs and head, and charcoal body. Last seen in the 1970s, deforestation and hunting caused its extinction; thorough searches over seven years within its habitat proved fruitless (Revkin 2000b). Had it been protected in a forest reserve, this colorful monkey would have avoided extinction (Revkin 2000b). This extinction is likely to be followed in the near future by those of many other critically

endangered primates as a result of logging and hunting.

The deforestation of Central and West Africa also presents dangers for people. Many scientists warned that an inevitable consequence of opening up Africa's tropical rainforest through logging was the eruption of ebola virus and other diseases carried by native mammals. Such warnings went unheeded, and several outbreaks of the highly contagious and nearly always fatal ebola virus have occurred. Meat hunting of Chimpanzees in Gabon was a source of this virus, which has killed hundreds of people (French 1996).

The number of threatened vertebrates native to tropical forests of all types has grown astronomically in the past 20 years, concurrent with their widespread destruction. Indonesia, Brazil, Peru, Ecuador, India, Madagascar and Mexico are among the countries with the greatest number of endangered species, enormous diversity, and significant losses of tropical forest cover.

Among the hardest hit of tropical mammals are the primates. Ninety percent of all species inhabit tropical forests, and recent surveys have found that 204 species, or one-third of the world's 650 taxa (taxonomic listing including subspecies), are in high degrees of threat; 103 are critically endangered or endangered (Mittermeier *et al.* 1999b). In Southeast Asia, 90 percent of primates are either threatened or near-threatened, an amazingly high rate of endangerment. Primates are in rapid decline as a result of forest loss, killing for the pet trade, hunting for meat, and capture for zoos, the pet trade and research (Mittermeier *et al.* 1999b). The combination of all these factors has pushed some species so close to extinction that some primate species and subspecies have total world populations of fewer than 100 animals (Mittermeier *et al.* 1999).

Focus on Indonesia

Indonesia has the greatest biological diversity in Asia. A vast mosaic of 13,667 islands, Indonesia links two biogeographic regions known as the Sunda subregion, an area stretching from southern Burma and Thailand south to northern Indonesia and Borneo, with Oceania to the south and east. The political boundaries of Indonesia have little to do with ecosystems or ethnic cultures. The giant island of Borneo, for example, has been divided among several Asian countries. Indonesia claims the southern two•thirds, known as Kalimantan, while Malaysia rules two states in the north and west, Sabah and Sarawak, and the small independent country of Brunei lies on the northwestern coast. Likewise, New Guinea, whose Melanesian tribes have inhabited the island for thousands of years, has been divided between Indonesia, which rules with a strong military presence in the western half, Irian Jaya, and Papua New Guinea in the east, an independent nation. Politically, Indonesia has been in turmoil for decades, with a series of presidents who have grown rich on foreign aid and siphoning off profits from exploitation of timber, oil and minerals.

Focus on Indonesia: Page 1

The world's greatest variety of palm species grows in Indonesia along with 10,000 kinds of trees and 25,000 species of flowering plants (Collins *et al.* 1991). About 40 percent of its plants exist nowhere else, and its forests have a diversity of plants equaled only in Amazonia (Collins *et al.* 1991). One high-altitude forest on Borneo, Mount Kinabalu, has 70 species of oaks, and more than 100 grow on the island, along with 30 kinds of squirrels who feed on their acorns. Such trees are usually considered temperate forest species, but in these forests, which vary greatly in altitude and habitat type, an incredible variety grows. Two thousand species of orchids grow on Borneo (Mittermeier *et al.* 1999a). At high altitudes on Mount Kinabalu, the soggy ground is 90 percent covered in orchids, some with flowers as tiny as grains of rice (Lanting 2000).

Forests cover 85 percent of New Guinea (O'Neill 1996), the majority of which are humid, with very rich diversity in the lowlands. Above 750 meters, oaks and Araucaria trees related to those in South America's Atlantic Forest grow. Even higher, above 2,000 meters, tangles of bamboo and *Nothofagus* beech trees grow in great stands (Beehler *et al.* 1986). New Guinea's mountains rise above 4,200 meters, where alpine shrubbery and boggy grassland dominate. Mangrove forest fringes most coastal areas (Beehler *et al*. 1986).

Until the beginning of the 20th century, forests of many types covered most of Indonesia. The isolation of many of the islands from one another resulted in a radiation of evolution in all types of plants and animals. Many species of animals that had become extinct or rare on mainland Asia still thrived in Indonesia--rhinoceros, Asian Elephants, Tigers and Orangutans, for example. Other mammals, such as the extraordinary, long-nosed Proboscis Monkey (*Nasalis larvatus*), evolved among the mangrove swamps of Borneo. An unparalleled beauty and wealth of birds had evolved. Among these were birds-of-paradise, parrots, lories and cockatoos, colorful songbirds and hornbills. As the 21st century dawns, however, this diversity is in ruins, with many plants and animals close to extinction. The small original populations of many of the endemic species made them highly vulnerable to loss of habitat as the ancient trees were felled, and population growth consumed millions of acres for agriculture.

Of more than 1,500 species of birds native to the islands of Indonesia, or 17 percent of the world's avifauna, 430 are endemic to the country (Collins 1990). Indonesia has twice the number of breeding birds as North America in only one-fifth the land area. Many of these birds live on only one or two small islands. About 164 species are endemic to the Sunda subregion alone. The great loss of forest and other types of habitats in Indonesia is perhaps the most important cause threatening 319 species of native birds, of which 114 are extremely threatened (BI 2000). This is the largest number of threatened birds of any country in the world. Further field research may uncover even more species to add to this list, especially in view of the accelerating deforestation in Kalimantan**,** Sumatra and New Guinea.

Two hundred and one of Indonesia's 436 species of mammals--almost half-- are endemic, an amazingly high rate of endemism (Baillie and Groombridge 1996). Not surprisingly, Indonesia also leads the world in the number of threatened mammals--135 species, or 31 percent of all of its native mammals (Hilton-Taylor 2000). One thousand species of reptiles and amphibians live in Indonesia, 10 percent of the world's 10,484 herpetofauna (Collins 1990). Twenty-eight species of reptiles are considered threatened by the *2000 IUCN Red List Species*, along with at least 59 species of freshwater fish. Research on endangered amphibians, fish and invertebrates in tropical countries lags far behind that in temperate areas, and the endangered list of the latter species is likely to grow when further research is done.

Focus on Indonesia: Page 2

New Guinea has some of the largest expanses of ancient species of trees in the world, most of which grow in cool climates in highlands and mountains. One species of *Agathis* kauri from the highlands of Papua New Guinea is considered rare by the *1997 IUCN Red List Plants*, as are two more *Agathis* species in the Solomon Islands and Vanuatu to the southeast of New Guinea, also bits of Gondwana. The kauri pines (*Agathis macrophylla*) occur on both the latter island groups but have been logged over. Their close relatives on the island of Borneo are in steep decline from logging and land clearance. In New Guinea, logging and clearance for settlements or agriculture, and even native tribes, are destroying these giant trees. Known as "timber trees" in the IUCN-sponsored *Conservation Atlas of Tropical Forests. Asia and the Pacific* (Collins *et al.* 1991), the *Araucaria* pines, relatives of the Monkey Puzzle Tree, grow in groves in parts of New Guinea's highlands, and some tribes venerate them.

Zoologist Tim Flannery (1998) walked among these *Araucaria* trees near the highland village of Telefolip and reflected: "Around the edge of the grove they were saplings but, further in, the pines were soaring giants, mist swirling through their crowns. Their straight, clean boles carried patches of bright green moss, which contrasted with their walnut-colored bark . . . The most striking thing about the grove was the quality of the sound. It seemed as if, in an instant, we had left the noisy, muddy world of drizzle and people and entered a large, open-air cathedral." The grove was considered so sacred by the local tribe that not a single leaf, not even a mosquito, could be disturbed in it (Flannery 1998). They thought that all life had begun in the grove. In the middle of the grove, Flannery saw a rare bird of paradise displaying. The male Splendid Astrapia (*Astrapia splendidissima*) has iridescent colors on the breast and head, and long, dramatic tail feathers that are much desired by the native hunters. These birds are usually shy, but generations of Astrapias had learned that they could display in this sacred Araucaria grove without fear that they would be killed (Flannery 1998). Baptist missionaries worked to end what they called pagan beliefs and offered to purchase timber cut from this sacred grove; gradually they succeeded in ending the taboos. When Flannery visited the grove in 1992, a great fallen Araucaria lay near the path, its trunk hewn into segments with a chainsaw.

New Guinea's birds-of-paradise have been called the most spectacular birds in the world. They are confined to this island and its satellite islands, and extreme northern Queensland in Australia. Their dazzling plumage, showy courtship displays and haunting songs have inspired awe in all who see them. fiVoices in the Forest,fl a BBC film (see Video section, Birds), featuring these spectacular birds dramatically illustrates their conservation problems. Their feathers have been traditionally used for headdresses and costumes by natives, which has threatened some species. Commercial demand from outside the island for feathers, zoo and aviary birds and dried specimens poses additional threats to them. The entire family of these birds, Paradisaeidae, has been placed on CITES Appendix II to prevent illegal trade. Forest cutting poses an even more serious danger to birds-of-paradise populations. The majority of species inhabit primary rainforests, and many have extremely specialized habitat needs. As clearing continues, and logging roads open up more and more of New Guinea's forests, these birds lose their habitats and are more easily hunted. Four species of birds-of-paradise are listed as Vulnerable, and eight more as Near-threatened by BirdLife International; they comprise 28 percent of the 43 members of this avian family (BI 2000).

Less showy, but no less interesting, are New Guinea's bowerbirds. The constructions of bowerbirds are so elaborate that when explorers first encountered them, they were assumed to be man-made. Each species has variations on the construction, some building bowers with pass-through tunnels, others concentrating on accumulating a vast array of objects collected in piles of the same color to attract females. One very rare bowerbird, searched for in the wild on a dozen occasions, was finally found in the remote Foja Mountains by Dr. Jared M. Diamond of the University of California in 1979. This beautiful bird, the Golden-fronted Bowerbird (*Amblyornis flavifrons*), which may number only about 1,000 birds, is very restricted in range, limited to an area north of the Idenburg River between 1,000 and 2,000 meters (Beehler *et al.* 1986). The male of this species arranges sticks in a pile around a tree fern or sapling,

forming a tower up to 3.5 feet high on a circular moss platform with a raised rim. He clears the adjacent area of debris and places separate piles of blue, green and yellow fruits to attract the female. The blue fruit was also a newly discovered species. Making varied, loud calls even while holding a blue fruit in his beak, which contrasts boldly with his brilliant yellow head and back feathers, the Yellow-fronted Bowerbird perches near his elaborate bower performing for the drabber female.

An even more threatened bowerbird, Archbold's Bowerbird (*Archboldia papuensis*), ranges in the central mountain ranges of the island. The male has a long, forked tail and constructs a bower made of a large mat of ferns (Beehler *et al.* 1986). Inhabiting ancient *Nothofagus* beech forests, mixed with podocarps, bamboo and *Pandanus* at high altitudes between 2,300 and 2,900 meters, it has declined as a result of logging operations (BI 2000).

New Guinea's marsupials show great biological diversity, ranging from tree-kangaroos, an arboreal relative of the land kangaroos of Australia, to colorful cuscuses, tiny nocturnal possums and bandicoots. These fascinating mammals remained unknown to scientists until very recently as a result of the extremely rugged terrain, native tribes who were often unfriendly to outsiders, and the almost total lack of roads and other means of access. Many of these mammals are also secretive and nocturnal, hiding in the holes of giant trees covered in vines or inhabiting such restricted ranges that many have only recently been discovered after intensive searches in the wild. In 1865, for example, only 15 mammals had been named from New Guinea, and in 1875 that number had grown to 20 (Flannery 1995). By 1906, 126 mammals had been identified, including 50 marsupials and monotremes, but today it is known that at least 212 indigenous mammals inhabit New Guinea, many of which were discovered within the past decade (Flannery 1995). A surprising number of mammals inhabit a relatively small area and are threatened by forest loss and hunting.

Focus on Indonesia: Page 3

Thirty-eight marsupials and one monotreme (egg-laying mammal such as a platypus) are listed in the *2000 IUCN Red List Species*. One marsupial was previously unknown to scientists until 1994 when Tim Flannery (1998) discovered it in a remote mountainous area of Irian Jaya. This panda-like animal has long, fluffy black fur on its back and head, stripes of white on its belly and muzzle, and a white star on its forehead (see Flannery 1998 for color photo). It resembles no other tree-kangaroo and is also far more terrestrial than other species (Flannery 1998). The Moni tribe call it the "man of the forest," or Dingiso, because when threatened, it raises its arms above its head, exposing its white belly while letting out a whistle, which they consider a sign of recognition (Flannery 1998).

The Dingiso's scientific name, *Dendrolagus mbaiso*, means "forbidden" tree-kangaroo. The Moni believe it to be an ancestor and will not hunt it, but a neighboring tribe, the Dani, has no such taboo and kills the Dingisos for their fur, claws and tail tips. Weighing about 30 pounds and 30 inches tall, this fairly large tree-kangaroo lives in a dense, cloud pine forest up to 10,000 feet in altitude in the Maoke Mountain Range, an area where tree-kangaroos had never been seen. Within the territory of the Moni, this very tame tree-kangaroo is still common and can be easily approached by offering it some leaves; hunters take advantage of this trait by feeding it leaves and slipping a noose over its head (Flannery 1998). This beautiful animal is endangered, and should the protection of the Moni people end for some reason, it will likely become extinct, as it has already disappeared from the territory of the Dani tribe (Flannery 1998).

Focus on Indonesia: Page 4

Fig trees are among the most characteristic trees of Indonesia and other rainforests and are keystone species for wildlife. They are threatened by forest clearance and by loss of their seed dispersers. Some 800 species of fig trees

are found in tropical rainforests around the world. On Borneo alone, there are 140 species, 13 of which are endemic (Yates 1992). Among the tallest trees in these forests, they may attain a height of 150 feet. Strangler figs grow on the trunks of other trees, which they gradually kill by encircling them. All fig trees are dependent on wasps less than an inch long for pollination. (See "Borneo's Strangler Fig Trees," by Tim Laman in *National Geographic*, April 1997, which illustrates this pollination process in detail.)

A wide variety of birds and mammals feed on the abundant fig fruits, but few species actually disperse the seeds. Figs contain chemical compounds that have a laxative effect on the wildlife that eat them, a reproductive strategy designed to release seeds over a wide area. Animals as small as ants and as large as wild pigs, gibbons, and deer feed on the fruit (Laman 1997). Figs exist in such variety in unlogged, primary tropical forests that one species is always fruiting, supplying life-giving food to wildlife (Laman 1997). Hornbills may be more important than any other species in dispersing fig seeds because, rather than eating a portion of the fruit only, they eat the entire fruit, which is full of tiny fertile seeds, and then fly long distances, spreading the seeds in defecations. One ornithologist observed fruiting fig trees in Borneo with as many as 50 hornbills of eight species feeding together (Yates 1992).

Focus on Indonesia: Page 5

Hornbills also spread the seeds of other plants. In India, Great Pied Hornbills are vital to the dispersal of nutmeg seeds, since they are the only species with a beak large enough to open the seeds (Youth 1995). Ragupathy Kannan, a biologist studying this species in the Ghats region of southwestern India, discovered that the forestry department was intentionally cutting large fig trees in order to feed domestic Asian Elephants to haul lumber (Youth 1995). Kannan managed to convince them to ban fig tree cutting and, instead, to let Elephants browse freely in the forest (Youth 1995). If such conservation work took place throughout the ranges of hornbills, their future might be brighter.

The decline of hornbills throughout their Asian ranges highlights the loss of seed dispersers, as the forests themselves disappear or become logged over and fragmented. Hornbills are extraordinary birds, with their enormous beaks composed of horn-like material and, often, colorful facial markings. Some have a casque on top of the bill, giving the appearance of a double beak. The Rhinoceros Hornbill (*Buceros rhinoceros*), for example, has a typical downward-curving, white pointed beak, but atop it a bright orange-red casque curls upward at the tip like a rhinoceros horn. This species, native to Malaysia, Sumatra, Borneo and Java, has declined from trade and is listed on Appendix II of CITES. Averaging more than 4 feet long with 3-foot tails, hornbills make dramatic silhouettes as they fly over the forest canopy. Unfortunately, their size attracts hunters who kill them for sport or food, another factor in their rarity outside national parks. Their reproduction is highly unusual--unique, in fact--among birds. Courtship can involve spectacular head•on collisions between males, clashing their casques together. The hornbill pair, which mates for life, selects a nest hole high in a hollow tree, usually one that was created by a large limb falling off and the trunk area becoming rotted.

Since ideal nest sites are rare and found only in trees hundreds of years old, hornbills often use the same nest year after year. The female plasters the inside with droppings that harden, and the male plasters the outside, leaving a slit that effectively imprisons the female in the tree trunk hole for the next three months. She pokes her bill out to receive food from the male, who tips his beak into the female's open one and lets small round figs and other grape-sized fruits roll down. Other adults may help in feeding the chicks and female. Before the chicks are ready to fledge, the female breaks out and leaves the nest; the chick or chicks instinctively reseal themselves for another month, both parents continuing to feed them (Yates 1992). Finally, when ready, the chicks break out of the nest. It is thought that hornbills have evolved this method of reproduction to protect the female and young from tree•climbing predators, such as snakes and lizards. (The courtship behavior, nesting and feeding of the female and chick by the male Red-billed or Celebes Hornbill (*Penelopides exarhatus*) are beautifully photographed in the BBC film, fiCastaways of Sulawesi.fl See Video section.)

Hornbills, so important to fig trees and the host of species that feed on them, are themselves dependent on primary rainforest (Collins 1990). Their nest trees are often intentionally cut to obtain chicks for sale to zoos and in open wildlife markets. When these great trees crash down, they bring with them many adjoining trees, killing small mammals and birds in the process. The dual threats to hornbills of habitat loss and capture have resulted in dramatic declines in their populations. Should all the hornbill species that are threatened become extinct, the extinction of hundreds of other species may result, from the fig trees, whose seeds they spread, to many vertebrates and invertebrates. In 1980, only one species, the east Asian Helmeted Hornbill (*Buceros vigil*), was listed as Indeterminate by the International Council for Bird Preservation (ICBP) (now BirdLife International) as a result of killing to use their large casques for carving (King 1980). But by 1988, that organization listed seven Asian hornbills as threatened with extinction (Collar and Andrew 1988). In 2000, 18 of Asia's 30 species, or 60 percent, of hornbills were listed in *Threatened Birds of the World* (BI 2000). Seven of the 10 Philippine endemic hornbill species are threatened with extinction (BI 2000). The dramatic increase in threat to these keystone rainforest birds is a reflection of the destruction of Asia's rainforests.

Focus on Indonesia: Page 6

Other rare and declining inhabitants of Asia's rainforests play important roles in pollination. Many trees that produce important commercial products need to be pollinated by wild animals. An extremely valuable fruit is the Durian, which is almost unknown outside southeast Asia. In spite of a rank odor emanating from the outer fruit, the yellow core inside the rind is considered a great delicacy, worth more than $90 million a year in markets throughout Indonesia and Malaysia. What is less well known is the dependence of the Durian tree on a particular species of bat to pollinate it. The Cave Fruit Bat (*Eonycteris spelaea*) is the sole pollinator of these valuable trees, pollinating the flowers while feeding on the nectar of the flowering fruit. Yet this bat is unprotected from the persecution, hunting for food and destruction of its limestone caves that are causing its decline. The number of threatened bat species native to Asia has increased dramatically in recent years, according to the IUCN (Hilton-Taylor 2000). Throughout these rainforests, bats are disappearing, some before their ecological role was known.

Hundreds of tropical plants and trees have evolved for pollination by bats. Most flowers of such trees are found in the canopy, giving easy access to the nectar•feeding and fruit bats, either hanging on long stems, set clear of the surrounding foliage, or clustered on branch tips near twigs where bats can land (Mitchell 1986). These bat flowers open only at night, with odors quite unlike the day•blooming flowers that attract insects and birds; instead, they are musky and sour, which seem to attract the bats (Mitchell 1986). Evolved with shapes that conform to the muzzle of the bat in order to deposit pollen on the bat's face, some flowers have large, trumpet•like openings that almost engulf the bat's head. Others are brush•like with masses of stamens rich in pollen, while still others have numerous small flowers in a ball•like inflorescence producing both nectar and pollen (Mitchell 1986).

The trees that have evolved to be pollinated by bats, some even by a particular species of bat, while providing food for the bats, represent a classic example of mutual dependency. Current logging practices and the killing of many of these bats for food, or destruction of their caves, endanger both trees and bats. Many of Indonesia's threatened bats are fruit bats, and a large number are found only in Indonesia. The Pygmy Fruit Bat (*Aethalops alecto*), for example, is found only on Borneo; the Small•toothed Fruit Bat (*Neopteryx frosti*) is native to Sulawesi; the Javan Tail•less Fruit Bat (*Megaerops kusnotoi*) is restricted to Java; four others are confined to the island of New Guinea. Half of Borneo's 140 mammal species are bats, and more than 50 of these feed primarily on insects (Yates 1992), another major benefit of these poorly understood mammals.

Focus on Indonesia: Page 7

The threats to Indonesia's environment are strongly linked to the growth of its human populations. With the largest number of people on Sumatra, Java and Bali, lowland forests on these islands were cut for cities and farmland during the first half of the 20th century (Collins *et al.* 1991). Beginning in the 1960s, industrial, government-sponsored logging began on many islands for valuable timber. Uncontrolled logging and wildfires have consumed millions of acres for decades, destroying 44 percent of original habitats and nearly all the lowland rainforests in Indonesia (Mittermeier *et al.* 1999a). Java has become nearly denuded, due mainly to the massive growth in human population that totals more than 110 million, almost half the entire population of the United States (Mydans 1996a). The tiny satellite island of Bali has similar crowding problems, and very little forest remains. Between 65 and 80 percent of Sumatra's lowland forests have been cleared to make way for the ever-expanding human population (Collins *et al.* 1991). By June 2000, an estimated 224.8 million people inhabited Indonesia, the equivalent of 82 percent of the US population, living on 741,000 square miles, or 20 percent of the US land area (New York Times 2000).

Among the first casualties of this deforestation and population growth were Tigers, who numbered in the thousands on Sumatra, Java and Bali up until 1900. The populations of each island had been separated for at least 8,000 years (Matthiessen 2000), as each evolved into a separate race. The Javan (*Panthera tigris sondaica*) and Bali Tigers (*Panthera tigris balica*) were far smaller than other Tiger races, with males weighing only about 200 pounds, one•fourth the size of a male Siberian Tiger. Several Javan Tigers were kept in the Berlin Zoo in the early 1900s without any effort to breed them in captivity (see photo in Tilson and Christie 1999). After massive deforestation of these islands and heavy hunting pressure, their populations crashed (Simon and Geroudet 1970). Udjung Kulon, a large national park, was set aside for the Javan Tiger in 1921, but only 20 to 25 of the species survived by 1955, of which 10 were in this park (Simon and Geroudet 1970). By the 1970s, they had disappeared from Udjong Kulon, and only a few were left in Meru Betiri National Park in the far south. In 1980 a careful survey found tracks of at least three Javan Tigers, but there have been no signs since (Jackson 1990). Bali Tigers were once common in the western portion of the island, but not since 1952 has there been a confirmed report (Simon and Geroudet 1970). Both these races are now considered extinct in the wild, and none survives in zoos (Jackson 1990). These Tigers represented unique genetic strains that are now lost forever. They were the chief predators at the top of their food chain, and their loss impoverished these ecosystems.

The Sumatran Tiger (*Panthera tigris sumatrae*), the largest of the three, is the only surviving Indonesian Tiger. Highly endangered (Jackson 1990), its wild population may total only 500 or fewer animals (Nyhus *et al.* 1999). An intensive conservation program, begun in 1995, involves an international team of biologists who are attempting to determine just how many Tigers are left, whether they have sufficient prey species, how many are being killed by local people and the status of their habitat (Franklin *et al.* 1999). In Way Kambas National Park in the southeast, researchers, using cameras placed on trails, have photographed them. An estimated 36 Tigers inhabit the second-growth forest and degraded grassland habitat in this park of about 1,500 square kilometers. It is completely surrounded by villages, and nearly all its lowland primary rainforest has been cut (Franklin *et al.* 1999). Villagers resent the park's ban on using forest and grassland products, and when Tigers prey on livestock, often because of a lack of natural prey, the villagers put out poison. Sumatra's forest fires and rampant poaching of all large animals in Indonesia may extinguish the last of these Tigers, but the conservation research program intends to involve local villagers in saving the Sumatran Tiger and help address many of their needs in the process (Franklin *et al.* 1999). This race of Tiger is kept in many zoos around the world, unlike the Bali and Java Tigers, and has reproduced. The fragmentation of the forest range of Tigers throughout Asia to India has isolated populations, caused inbreeding, and exposed them to poaching, even in national parks.

The parks created for the Javan and Bali Tigers protect a great diversity of other wildlife and plants. Meru Betiri

National Park preserves the last remnants of lowland rainforest in Java (Whitten and Whitten 1992). A population of about 75 to 100 endangered wild cattle, or Banteng (*Bos javanicus*), and Leopards (*Panthera pardus*) are also resident (Whitten and Whitten 1992). Unfortunately, illegal cutting of trees and rattan within the Meru Betiri National Park has been extremely destructive (Whitten and Whitten 1992). Udjung Kulon National Park on the western tip of Java is home to a small population of Javan Rhinoceros (*Rhinoceros sondaicus*), the rarest of all rhinoceros, along with Sambar Deer (*Cervus unicolor*) and Barking Deer (*Muntiacus muntjak*) and Banteng (Whitten and Whitten 1992). Sumatra has several important national parks as well. Mount Leuser National Park's swamp forests protect the last Sumatran Rhinoceros (*Dicerorhinus sumatrensis*), second rarest of the rhinos. This extremely primitive and hairy rhinoceros has been captured for zoos, where most have died and none has been born in captivity. Researchers in the park have tried to prevent further captures of these highly aquatic rhinos in order to preserve the last wild members of the species. This park also has resident Orangutans (*Pongo pygmaeus*), Siamangs (*Hylobates syndactylus*) and endangered Sun Bears (*Helarctos malayanus*). Unfortunately, some of Sumatra's national parks have been overrun with people cutting trees, causing erosion, and replacing forest with agriculture. The Kerinci-Seblat National Park, located along a mountain range in southern Sumatra, encompasses 14,847 square kilometers of forest, but within the park is a virtual city of 273,000 people, growing at a rate of 3.6 percent a year, who denude the hillsides and convert forest to cinnamon, cloves and coffee. They are gradually destroying this entire forest and the watersheds of the island's two most important rivers (Collins *et al.* 1991).

Focus on Indonesia: Page 8

Until about 30 years ago, Borneo had extensive, unspoiled and magnificent forests. The third largest island in the world after Greenland and New Guinea, it covers 215,000 square miles (Smythies 1960). Prior to recent logging and forest fires, it was described as "one enormous forest" by Bertram E. Smythies, author of *The Birds of Borneo* (1960); 75 percent of the island was primary forest, and 10 to 15 percent, secondary forest (Smythies 1960). Mangrove forests grew abundantly along the southern and southeastern coasts, extending far inland, lining major rivers and blending into vast swamp•forests (Yates 1992).

By the late 1970s, an estimated 66 million acres of the country's forests had been classified as denuded (Allen 1980). Forest clearance on Borneo and in Sumatra took a dramatic turn in the early 1980s when landowners and settlers set fire to forests felled for commercial timber, palm oil and tree plantations and homesteads to destroy stumps and brush. This was done in spite of a law banning the setting of fires. The largest forest fire ever recorded on Earth took place in the old-growth forests of Borneo during 1982-83 and lasted for 18 months (Collins *et al.* 1991). More than 9 million acres, or 33,000 square kilometers, were destroyed in east Kalimantan, including 8,000 square kilometers of unlogged dryland primary rainforest and 5,500 square kilometers of peat swamp forest; the rest was selectively logged forest and settlement areas (Collins *et al.* 1991). This was the first time that living rainforest had been seen to burn. Half the new Kutai National Park was destroyed, and another 2.5 million acres burned in Sabah in the northwest of Borneo (Yates 1992). Wildlife was seriously affected, and some burned land was later converted to tree plantations (Collins *et al.* 1991).

During the 1990s, more fires erupted, spreading to adjoining forests. Logging practices involved the removal of the largest trees, leaving leaf litter, small trees and broken branches that dry out (Paul 1998). The logging opened up the canopy, allowing further drying-out of the forest floor, and humidity dropped (Paul 1998). Fires set in clearcuts entered logged rainforest through these logging openings, setting the entire forest afire (Paul 1998). In 1991, another 190 square miles of East Kalimantan burned, and in 1995, massive fires broke out in Kalimantan and Sumtra (Paul 1998). Two years later, an estimated 750,000 to 1.5 million acres of forest burned in Sumatra and Kalimantan (Howe 1997), including a devastating fire in Tanjung Puting National Park, a prime refuge for Orangutans (Paul 1998). So immense were these wildfires that the smoke spread to neighboring countries, causing severe air pollution in cities and towns, and the fires were seen clearly from satellites orbiting the Earth. A Canadian observer from a vessel in the

China Sea during these fires wrote to *National Geographic* (December 1998): "Even at 250 kilometers [155 miles] distance from the coast of Kalimantan, the air was thick with smoke. For nearly three weeks we could not see the sun's disk, only smoke-diffused light. The most astonishing and sad event we witnessed happened one night when we were surveying . . . Our ship was engulfed by an ever increasing flock of exhausted birds and bats, all fleeing the fires of Sumatra. Dozens of birds landed all over the deck, where, too fatigued to move, they could easily be approached and handled. In the morning we found several tired bats dangling from overhead steel gratings. I sincerely hope that a new and more benign Indonesian government will prevent such awful, and needless, environmental calamities from happening again" (Christopher Woodworth).

In Borneo and Sumatra alone, 14.8 million acres are estimated to have been destroyed prior to 1998, still charred and black years afterward (Paul 1998). A zoology student and his girlfriend traveled across Kalimantan in the late 1990s, seeing no green except along roads--small farms and banana trees (Paul 1998). In parts of the region, underground fires burn for years, igniting deep beds of peat and coal seams. The Indonesian government's reforestation funds were rerouted, first by President Suharto, then by his successor, President Habibie, to develop industrial oil palm and timber estates (Paul 1998).

After worldwide publicity and protests from other countries about the fires, and condemnation of Indonesia's failure to act against those responsible, in early October 1997, the government revoked the operating permits of 29 companies that had set illegal fires. This had little effect on fire-setting, as more fires broke out in the following year. In 1998, another million acres burned, and in 1999, an area the size of Vermont and New Hampshire burned on Borneo. In the summer of 2000, smoke from Indonesia's illegal forest fires again blanketed nearby Malaysia's capital, Kuala Lumpur, and Singapore (Mydans 2000). After the fires, floods made the forest loss in Kalimantan permanent by washing away soil, leaf litter and nutrients from the fires ashes (Kaplan and Rogers 2000). Exotic Imperata grasses took hold in many areas, poisoning the ground with substances that inhibit the growth of trees, signaling the end of the rainforest (Kaplan and Rogers 2000). Some 80 percent of the forests in the southeast of Borneo are now gone.

During these fires, wildlife, including such critically endangered species as Sumatran Tigers, Orangutans (*Pongo pygmaeus*) and Asian Elephants (*Elaphus maximus*), fled the fires into villages, where many were killed or captured for sale as meat or pets. Stephanie Fried, a scientist with the Environmental Defense Fund in Washington, DC, who has studied the timber trade in Indonesia, described these fires as the result of "appalling forestry practices and rapacious greed" (Howe 1997).

The fires destroyed most of Borneo's lowland rainforests, where 267 of the world's 600 dipterocarp trees, or trees with "two•winged fruits," dominate; 150 of these exist nowhere else (Whitten and Whitten 1992). This family of trees, Dipterocarpaceae, has species from the Seychelles to New Guinea, but Borneo has by far the most species (Whitten and Whitten 1992). Many reach heights of 250 feet or more and are pollinated by tiny thrip insects. They are extremely important to wildlife, producing fruits, flowers and digestible leaves that are fed on by birds, gibbons and a variety of other animals (Whitten and Whitten 1992). Each year, 2,500 square kilometers of dipterocarp forest are logged in Sarawak, and these old-growth forests are often replaced with tree plantations (Collins *et al.* 1991). Elsewhere in Indonesia, these are the preferred trees to be logged, with their unbranched, wide trunks used in furniture, plywood, resins and camphor (Whitten and Whitten 1992). It was almost inevitable that many of these trees became extinct. The *1997 IUCN Red List Plants* lists a dipterocarp trees native to west Sumatra as Extinct. Another species is extinct on Sumatra but still survives in Peninsular Malaysia, along with 95 other members of the family listed as Threatened or Extinct on the island of Borneo and the rest of Indonesia. Four species of the giant kauri *Agathis* that grow in Borneo's higher altitude forests are also threatened with extinction (Walter and Gillett 1998).

Focus on Indonesia: Page 9

Orangutans once ranged in mainland southeast Asia as well as Indonesia, but hunting and forest cutting eliminated them from 98 percent of their original territory, leaving populations only on Sumatra and Borneo. These islands were home to tens of thousands of Orangutans at the turn of the century, but since then, these intelligent apes have been pushed into pockets of shrinking rainforest. Orangutans are unable to adjust to second-growth forest and depend on very large ranges within primary rainforest, where they feed on ripe fruit and flowers. Their populations have become scattered from loss of old-growth forest, and even national parks are no longer safe havens for them, as poaching and illegal logging increased in the late 1990s. Orangutan populations decline between 60 percent and 95 percent in selectively logged forests (Newman *et al.* 2000). The logging scares them out of their territories, and they often die of starvation or accidents (Newman *et al*. 2000).

One of their former strongholds was the Tanjung Puting National Park, 741,000 acres on a peninsula on the south coast of Borneo. It was upgraded to national park status in 1982, primarily to protect the Orangutan. This is the largest swamp forest in southeast Asia, with a mosaic of habitats, including primary rainforests. The Environmental Investigation Agency (EIA) of London conducted an in-depth study of illegal logging in this park, publishing a report, *The Final Cut*, in 1999 (Newman *et al.* 1999). Illegal loggers were so blatant that they built a wooden railway to slide out the giant logs. When government officials were notified, they did nothing, as they had apparently been corrupted by bribes from the loggers (Newman *et al*. 1999). In December 1999, biologists in the park found themselves ordered by armed loggers to leave. Similar illegal logging took place in other parks and reserves crucial to the survival of the Orangutan, leaving few areas not seriously degraded (Newman *et al*. 1999). EIA turned over to Indonesian government authorities, including the Governor of the Province, copies of its detailed report on illegal logging, which had uncovered the fact that 70 percent of the timber being processed in Indonesia came from illegal logging (Newman *et al*. 2000).

The World Bank in Jakarta estimated that between 1985 and 1997, Indonesia lost an average of 1.5 million hectares of forest cover every year, with dry tropical forest, an endangered ecosystem, suffering the greatest losses. Sulawesi has been logged out, and this forest type could disappear from Sumatra and Kalimantan in the near future (Newman *et al.* 2000). Logging supplies 2 million cubic meters of timber to its many pulp mills (Mittermeier *et al.* 1999a). The lack of strong government control has allowed corrupt timber barons to emerge and control the rampant illegal logging that is leaving little of the country untouched (Newman *et al.* 2000). In spite of international publicity about this disastrous state of affairs, and pressure from international donor agencies, the Indonesian Government stated that it would stop the illegal logging, but did not take action. The bribery scandal apparently reaches into high levels within the government (Newman *et al.* 2000). In May 2000, student activists, frustrated by the government complicity in the looting of their national heritage, held four government officials at a port in West Kalimantan after Customs and other officials failed to halt the shipment of an illegal consignment of timber to Singapore. This shipment, with 70 containers of logs, was forced to return to port and its cargo seized (Newman *et al.* 2000). China and the European Union import more than half the timber exported from Indonesia, and to date, no action has taken place by importing countries to confiscate illegal shipments of timber (Newman *et al.* 2000).

The status of Orangutans has gone from endangered to critical. Decades of logging, clearing and forest fires have destroyed the majority of their primary, old-growth forests on Borneo and Sumatra. Thousands were killed during these fires and hundreds that fled burning forests and entered open areas near villages were killed by villagers wielding machetes. Mothers were hacked to death to obtain their babies, who were often wounded in the process. Hundreds of orphaned Orangutans, pitiful, sickly and malnourished, were confiscated during this period and placed in rehabilitation centers. Many died, and the traumatized survivors clung to one another in crowded pens and crates, mass fed by volunteers and workers of these centers. The Leakey Research and Rehabilitation Center for Orangutans in southern Borneo, and two other centers on the island, have cared for hundreds of these orphans. In 1997, the Wanariset Orangutan Reintroduction Project in East Kalimantan received 118 baby Orangutans, and in 1998, 60 more arrived (Paul 1998). In August, 1998, the station held 171 refugee and injured Orangutans, most very young (Kaplan and Rogers 2000). Many mother Orangutans died of starvation, trying to sustain themselves on acacia bark, and their young were so weak they could hold on no longer and fell to the ground. Some mothers were eaten by the starving

local people, and others succumbed to disease (Kaplan and Rogers 2000). Even those saved and rehabilitated have a low rate of survival. Fewer than half survive in the wild, according to Martinus de Kam, site manager of the Wanariset Forestry Research Project (Paul 1998).

Birute Galdikas, a renowned primatologist and the world's foremost expert on the species, runs the Leakey center and was almost overwhelmed by the numbers of orphans to care for. Moreover, quite a few Orangutans that had been rehabilitated over the past decade and returned to the rainforest came back to the Leakey center for food as their forests were burned or fruit trees cut. In the early 1990s, Orangutan populations were estimated at more than 22,000, with 9,200 on Sumatra and up to 15,546 on Borneo (Nowak 1999). Few believe that more than 15,000 survived the forest destruction and fires of the late 20th century. Galdikas has stated that the species may be doomed to extinction, left with too little habitat to survive. Two primatologists, Gisela Kaplan and Lesley J. Rogers (2000), who have studied Orangutans for many years, conclude that these fires may have been enough to set the final scene for their extinction in Borneo before too many years. Wild populations are unable to sustain the removal of so many female Orangutans. Their reproduction is among the slowest of any mammal. Males are solitary, and females live with their single young for eight to nine years before having another baby (Kuznik 1997). A loss rate of only five Orangutan females out of 1,000 per year can cause a stable population to decline, according to Mark Leighton, a Harvard ecologist conducting research in Borneo's rainforests (Kaplan and Rogers 2000). This rate was surpassed many times during the 1990s. This picture has been further complicated by the recent genetic analysis of Orangutan DNA, which has revealed that there are two, not one species: the Sumatran has been renamed (*Pongo abelii*) and the Bornean retains the original scientific name, *Pongo pygmaeus*. These two primates have been long separated from one another and developed changes in their genes that warrant separating them as species (Kaplan and Rogers 2000; Hilton-Taylor 2000). There are physical differences as well. The Bornean Orangutan is far larger than the Sumatran, perhaps because it has not had to be agile to flee from Tigers, since the species is absent on Borneo. Both species are listed in the *2000 IUCN Red List Species*, the Sumatran as Critical and the Bornean as Endangered.

Focus on Indonesia: Page 10

Many islands, including Borneo (Kalimantan), Sulawesi and western New Guinea have had to absorb millions of people relocated from overpopulated Java under a government program. Beginning in 1978 with partial funding from the World Bank, more than 100,000 people per year were relocated to these and other out-islands costing $2 billion by 1992 (Durrell 1992). By 1996, 6 million people had been relocated from Java; Sumatra received the greatest number of people, followed by Kalimantan, Sulawesi and Irian Jaya (Mydans 1996a).

Irian Jaya™s 350,000 square kilometers of forests are still largely intact, but they are rapidly being destroyed by settlers. More than 250,000 people have been sent here, pushing aside the native New Guinea tribes who have witnessed their pristine rainforests cleared, even on steep slopes, for subsistence farming (O'Neill 1996). One tribesman said, "While we believe we are descended from the forest, most Indonesians believe that devils live in the forest and that the forest must be destroyed" (O'Neill 1996). The Indonesian government clearcuts 5 acres of forest for each family and supplies tin shacks, seeds and tools (O'Neill 1996); these shacks are lined up in rows on the remnants of the rainforest that once rang with the calls of birds-of-paradise. Villagers are encouraged to cut trees and are paid $1.30 for each tree by the government (O'Neill 1996). Roads, schools, clinics and other modernizations are planned, and towns of up to 250,000 people are being carved out of the virgin rainforest (Flannery 1998). New Guinea tribespeople are resentful about the forest cutting and have documented many instances of killing and cruel treatment they have received from the Indonesian military (Flannery 1998). They believe that Indonesia has invaded their lands, and they have organized a resistance movement, demanding that the land be returned to them (Flannery 1998).

The relocation program has been a dismal failure, not only for the people who were unable to farm the thin,

infertile soil of cleared rainforests, but for the devastated environment and wildlife (Durrell 1992, Flannery 1998). The rainforest is not the only ecosystem that has been destroyed by these settlers. On heath and sandstone ridges on Borneo, stands of Ironwood (*Eusideroxylon zwangeri*) grow. These are very unusual trees for tropical areas (Mittermeier *et al.* 1999a). Many of the Javan immigrants are unhappy with the conditions of their new lives and return home (Mydans 1996a). Irian Jaya is expected to remain a center for relocation, however, since only 4 million people live here, and the giant Freeport mine that has removed entire forests employs large numbers of people who come from abroad to work in the mines, living in air-conditioned, newly built homes. Family planning over the past decade reduced the rate of growth on Java from 2.1 percent to 1.5 percent, or half a million fewer births every year (Durrell 1992), but an influx of as many as 1 million people a year still flood into Java from elsewhere in Indonesia and Southeast Asia (Mydans 1996a). Had Indonesia devoted more of its financial resources to family planning a generation ago, as did Singapore, which now has a stable population with a low birth rate, the highly expensive relocation program would not even have been considered.

Focus on Indonesia: Page 11

The future of Indonesia's forests and their wildlife may be as bleak as that of other tropical forests in the Philippines, Thailand, West Africa and many parts of Latin America and the Caribbean. The disappearance and endangerment of large, wide-ranging mammals, followed by fragmentation and loss of the fauna and flora of entire regions, is a pattern that is being repeated here. The government has set aside many national parks, but as in other parts of the world, they are rarely given a high priority for protection, and local people are allowed to log and even establish agriculture plantings and villages within them. The native tribes of Papua and Kalimantan may force a change in the attitude of the government toward the forests and even end in a return of the land to the people who have lived there for thousands of years and have a strong bond with the native trees and animals. Violence has broken out between natives and immigrants on both islands, leading to the forced departure of hundreds of people in Kalimantan after many were killed by Dyak tribesmen in 2001. In Papua New Guinea, international rainforest organizations have become allied with native tribes in fighting corporate loggers from Australia, and they have been successful in taking legal actions that negated corrupt agreements made between their own leaders and the loggers.

The potential for ecotourism in Indonesia is great. The islands are already a major draw for tourists, spending more than $1 billion per year. A powerful movement for democracy is making strides in the country, and with more help from the United States and other democracies of the world, this would become a reality. With a radical change in Indonesia's government, priorities might change to benefit the Indonesian people and their environment instead of making the rich richer at the expense of biodiversity. If that happened, more and more people would learn the value of preserving forests and the country's extraordinary biodiversity for their own benefit as well as that of the entire world. The thin, tropical soils of the country have proven to be best for growing trees, and when this is better appreciated, the tide may turn.

Strong and immediate action is required, however, to prevent biological diversity losses that will dwarf those of any other area on Earth. Stabilizing the human population would be a major step in the right direction. By 2025, it is projected that Indonesia's population will exceed 275 million (Mittermeier *et al.* 1999a). If the government does not stop the disastrous and unsuccessful resettlement program, there will be no wilderness forests left, and the remotest national parks will be invaded for tree and rattan cutting and other destructive uses that will inevitably cause massive animal and plant extinctions.

The participation of international conservation organizations in programs to educate Indonesians to live in harmony with nature and to protect biodiversity is in its early stages. Several of these groups have helped produce field guides, books, posters, pamphlets and textbooks, and the series *Ecology of Indonesia*, in Indonesian (Mittermeier *et al.* 1999a). Protected areas total about 110,000 square kilometers, and the important work of protecting them from

encroachment and destruction is being aided by projects such as The Nature Conservancy (TNC) work in a huge, 231,000-hectare national park in southern Sulawesi, Lore Lindu National Park (Mittermeier *et al.* 1999a). In cooperation with the government conservation agency and local groups, TNC is conducting a comprehensive education program that also encourages butterfly farming and ecotourism to stem forest clearing and rattan collection (Mittermeier *et al.* 1999a). Other programs to encourage ecotourism and create sustainable models for local economies have been launched. In some cases, international programs have failed. In the 1980s, the World Bank funded a program to protect a 300,000-hectare national park in northern Sulawesi and help local farmers irrigate rice fields while protecting the watershed. These worked at first, but enforcement lagged and gold miners have entered the park and poisoned rivers with mercury. Forest clearing, hunting and rattan collection have also occurred within the park (Mittermeier *et al.* 1999a). Emergency programs to stop incursions into national parks are needed.

A new and potentially major source of income to benefit wildlife and the environment involves the placement of videocameras connected to the Internet in wilderness areas. These cameras can be solar-powered and placed in tree tops, animal dens, waterfalls or other attractions. Such videocameras, using satellites to beam live pictures or web pages to Internet users around the world for a small fee, are helping to finance the conservation work of national parks in South Africa and Central America. Internet users have increased exponentially in the past decade and are expected to continue to grow in number. Many "surf" the Internet for amusement, while others seek wilderness views or natural history information. If the funds were managed so as to be devoted entirely to protection of the environment and related programs, many millions of dollars could accrue. A conservation organization could publicize the fate of a particular species, group of species or region to raise funds for its protection. Certainly Indonesia has hundreds of appealing animals. Orangutans, Sumatran Tigers, Proboscis Monkeys, gibbons, Babirusa, tiny deer, cockatoos and parrots (some as small as sparrows), birds-of-paradise, bower birds and Komodo Dragons are among animals that could appeal to millions of people around the world. Spectacular and magnificent coral reefs, ancient forests, giant flowers, carnivorous plants, mangroves and wild rivers could also be filmed for the Internet. An Internet site could have biodiversity data for students and the general public and lists of projects that need financial aid. Ecotourism opportunities could also be part of this site.

On behalf of American consumers and those in Japan and countries importing plywood and concrete forms from Indonesia, conservationists could approach importers, building companies, stores and builders to propose substitutes. In many cases, users of these products have little idea where they came from or the effect their purchase has on forests half a world away. The key to saving Indonesia's wild heritage lies in making it more profitable to conserve it than destroy it, and educating these already highly literate people to preserve their own future in the process.

Endangered Species Handbook

Grasslands, Shrublands and Deserts:

Grasslands, Shrublands, Deserts

Introduction

Providing splendid scenic vistas, grassland, shrubland and desert environments cover two-thirds of the world's land surface. The greatest diversity of grazing animals on the planet calls these open habitats their home, and they are preyed on by a variety of wild cats, dogs, wolves and hyenas. Grassland habitats appeared on Earth some 70 or 80 million years ago, following the extinctions of the dinosaurs. As flowering plants, grasses grow in great concentrations in semi-arid climates Œ where, as a general rule, annual rainfall ranges between 10 and 39 inches (Brown 1985). The root systems of perennial grasses and forbs form complex mats that hold the soil in place. Mites, insect larvae, nematodes and earthworms inhabit deep soil, which can reach 20 feet underground. These invertebrates, along with symbiotic fungi, extend the root systems, break apart hard soil, enrich it with urea and other natural fertilizers, trap minerals and water and promote growth (Chadwick 1995). Some types of fungi make the plants more resistant to insect and microbial attacks.

Among the various grasses grow many kinds of wildflowers, succulent plants and other non-woody species. On savannahs, trees and small woodlands are scattered in the grasslands. Flowers brighten grasslands in annual splashes of dazzling colors. An array of gentians, poppies, wild tulips, irises, orchids, bluebells, daisies, asters and myriad other flowers bursts into bloom each year, creating a brilliant montage against the green of new grasses.

A great diversity of insects, including colorful butterflies and tiny bees, pollinate these plants. Their seeds are dispersed by the wind, as well as by birds and mammals. Natural grasslands are the ideal habitat for herds of hoofed animals who fertilize the soil with their dung, which is later broken into nutrients by a host of invertebrates, fungi and microbes. Rodents and other burrowing animals excavate holes and chambers that feature complex side passages and multiple entrances, providing escape routes, birth chambers and sleeping areas. Other animals, including snakes, tortoises and ferrets, use the burrows as their habitat. Natural grasslands are intricate webs of animal, plant and fungal communities, and much remains to be learned about their functions.

Ecologists divide grasslands into two major types: tropical and temperate. Temperate grasslands tend to grow in the rain shadow of mountain ranges (Simon 1995). The Central Asia steppe Œ a treeless plain Œ has a low rainfall because the Himalayas and other mountain ranges block humid winds. The Rocky Mountains impede Pacific winds that bring rainfall from the North American prairies. Winters in temperate grasslands are usually severe, with freezing temperatures and howling winds. While temperate perennial grasses regenerate from dormancy each spring by sprouting from their roots, grasses in the tropics do not enter a dormancy period and instead grow year-round. Tropical grasslands tend to be located between forests and deserts (Simon 1995). Climate in the latter type of grassland is generally mild, and most have seasonal dry and wet seasons, each lasting about half the year. In some environments, especially those bordering on shrub or desert, temperatures can rise to searing heights in the dry season, drying up natural ponds and streams.

Some grassland is in areas of high rainfall, but other conditions prevail that inhibit the establishment of trees and forest, such as shallow soil that prevents trees from taking root, or stony, nutrient-poor soil. The presence of large numbers of ungulates who crop the grasses also prevents trees from taking over the land. The Serengeti and other East African grasslands would soon become acacia woodland if not for the presence of millions of wildebeests and other ungulates. Fires, either ignited by natural lightning or set by people, and mowing also maintain grassland by removing young trees and shrubs. Grasslands and related habitats tend to grow in areas where forests have been cut and rich top soil has washed away; the moors of the British Isles, for example, are composed of heath, grasses and ground plants that replaced the forests cut centuries ago, following erosion of the topsoil (Simon 1995).

During the Pleistocene, 100,000 to 10,000 years ago, rich grasslands with thick topsoil covered millions of square

miles in Africa, Australia, Asia, South and North America. They supported an unparalleled diversity of large mammals. Sabre-toothed and huge lion-toothed cats, dire wolves, cheetahs, hyenas and bears preyed on herds of bison, deer, mastodon, mammoth, camel, rhinoceros, antelope, wild horses and gazelles on North America's rich grasslands. In Australia, giant marsupials were the predators of large kangaroos and wallabies. Outside Africa, almost all these wild species disappeared by the end of the Pleistocene, concurrent with heavy hunting by native peoples. Some large mammals survived, however, and in many areas great herds grazed the grasslands in untold millions until recent times. In these natural grasslands, each large mammal consumed a slightly different type of vegetation, whether new grass, forbs, mature grass or other plants, allowing many species to coexist without damaging or overgrazing the environment. Today, grasslands, shrub and mixtures of these habitats cover about one-fourth of the Earth's surface.

Shrubland ecosystems, characterized by bushes, shrubs and scattered trees, require very little water. This habitat is often degenerated woodland or grassland, as seen in many parts of coastal Greece and the Near East where topsoil has eroded. Desert and shrub habitats in Mediterranean countries are the product of thousands of years of abuse of the land, beginning with forest clearance for grazing and agriculture. Shrubland quickly turns to desert when desecrated by brush clearance or heavy livestock grazing. In some parts of the world, shrubland is a natural habitat; many species of birds, mammals, reptiles and invertebrates have evolved to adapt to live in such an environment.

Deserts, which cover almost 40 percent of the Earth's surface (Allan and Warren 1993), receive less than 10 inches of rain a year (MacMahan 1985). Within these ecosystems, the annual rainfall limits the types of vegetation able to survive. Arid zones receive less than 8 inches of rain per year, while in hyper-arid zones, less than an inch of rain falls per year (Allan and Warren 1993). Rainfall in deserts tends to be unpredictable. In some deserts, no rain falls for several years, followed by a series of torrential storms in one season. Desert life has evolved remarkable adaptations to these conditions. Many plants have leathery, water-retentive leaves or spongy trunks for storing water, and seeds that can remain dormant in the soil for many decades. A few species of desert animals never drink, only obtaining water from plants they eat. Desert toads can remain in a torpor underground for years until a rainstorm awakens them.

The Sonoran Desert of the southwestern United States and northern Mexico is the lushest and most botanically rich of all deserts, with 2,500 species of plants, 300 of which are cactuses. A fairly mild climate provides habitat for deer, peccaries, pronghorn antelopes (*Antilocapra antilocapra*), bighorn sheep (*Ovis canadensis*), various cat and canine predators, tortoises and many types of birds, snakes and lizards. In contrast, very little vegetation grows in the Sahara, where thousands of miles of sand stretch to the horizon. The Atacama Desert of Chile has the lowest rainfall of any desert in the world, and relatively few wildlife species are able to survive. Its temperature falls rapidly from searing hot during the day to freezing at
night. Desert animals have adapted to these extremes by living in burrows that insulate them from the heat and cold.

Benefits of Drylands

Grasslands have great biological diversity and stability; they are able to resist plant disease and drought. As such, they represent invaluable genetic banks. This diversity is being studied by scientists around the world and consequently uncovering chemical and biological secrets. Agriculture and other food production will profit from this emerging knowledge.

Wheat, corn, oats, barley and rye Œ the bases of most human diets Œ are domesticated types of grasses bred from wild plants. No longer perennial, they must be planted each year and have become extremely vulnerable to disease,

insect predation and drought. They are grown in monocultures, fields of a single species that often have insect pests or diseases sweeping through them. Moreover, soil that is artificially fertilized and sprayed with pesticides and herbicides lacks the millions of invertebrates, fungi and other creatures that make wild grassland soil rich and resistant to insect pests and disease. Wild plant genes have proven valuable in producing hardier varieties of domestic strains through cross-breeding (Chadwick 1995).

Many perennial wild plants have the potential to become food plants because of their natural resistance to insects and drought. These grains would not have to be replanted each year, which is a great benefit because plowing causes erosion and requires great amounts of energy. Maize, a type of corn closer to wild strains, is a major food source in Latin America and elsewhere. It is one of the most photosynthetically efficient grain crops in the world, able to transform the sun's energy into food very effectively (Viola and Margolis 1991). Grown in North America and Europe mainly as livestock fodder, it has great potential as a human food source. The Land Institute of Salina, Kansas, is working to discover new perennial grasses that might be sources of food (Chadwick 1995). Eastern gama grass, for example, native to the American prairie, needs far less water than conventional crops (Chadwick 1995).

Native peoples have traditionally utilized a wide variety of wild grassland and dryland plant seeds for food and other purposes, and many of these plants represent potential food sources. Another dryland plant native to the Americas and a staple food crop, the potato, has wild ancestor species that contain natural insecticides. Certain varieties of potatoes produce high levels of bitter, toxic glycoalkaloids, which make plants insect-resistant; native peoples of the Andes have long removed these toxins by cooking the potatoes with clay (Viola and Margolis 1991). Domestic strains of potatoes are prone to disease, most tragically illustrated by the 19th century famine in Ireland it caused.

Rainforest plants have been studied by scientists and pharmacological researchers for their medicinal value over the past few decades, but many grassland plants have been used for centuries by native peoples to treat various ailments. Extracts of the purple coneflower (*Echinacea purpurea*), for example, native to tallgrass prairies of America, have been found to be an effective treatment for symptoms of colds; they marketed as Echinacea in health food stores and pharmacies in the United States. This plant was used by Native Americans for many medicinal purposes (Madson 1993), and compounds within it have been found to kill insects (Chadwick 1995). So popular is this plant that many collectors have threatened the species by pillaging the last scraps of native grassland to dig up wild specimens that are reputed to have greater potency than cultivated plants**.**

Another plant being commercially marketed for its health effects is goldenseal (*Hydrastis canadensis*), a species of the buttercup family found in grasslands throughout eastern North America. Native Americans used it as a tonic, an astringent and an insect repellent, as well as a yellow dye. It is considered rare because its roots were overcollected (Niering and Olmstead 1979). Blue (great) lobelia (*Lobelia siphilitica*), a wildflower of eastern North America, was given its scientific name based on its supposed ability to cure syphilis. While not effective against syphilis**,** its root contains alkaloids that cause vomiting (Niering and Olmstead 1979). Other American grassland plants used for medicinal purposes include feverwort (boneset), prickly poppies, prairie larkspur, western ragweed and prairie goldenrod (Chadwick 1995). A type of prairie nematode is being tested as a possible cure for Alzheimer's and other neuro-degenerative diseases (Chadwick 1995).

American grasslands and shrub also home to Sassafras (*Sassafras albidum*) and Sarsaparilla (*Aralia nudicaulis*), from which medicinal teas, beverages and infusions are made. Wild plants of the Cactus family have been used traditionally by Native Americans and Mexicans for food, medicine and beverages. Some species, such as cactuses and baobabs, store water in their stems or trunks. Aloes of many species in North America and Africa have been found effective in treating burns.

Researchers seeking new treatments for human kidney problems are studying desert animals who recycle their own urine. Should the physiology of this phenomenon be discovered, it might be applied to kidney patients to prevent the need for dialysis. Deserts abound with poisonous snakes and lizards, whose venom has already proven to be

medically important as pain killers and for other purposes.

Many wild species that have endured the extremes of weather for eons and have traits that might be of great value to humans are in danger of disappearing altogether as humans take over their habitats for agriculture and development. Without conservation, they may disappear prior to discovery of their benefits.

Destruction of Drylands

Humans began adversely affecting natural grasslands some 50,000 years ago with the introduction of livestock. Herders set fires to grassland to maintain it for grazing, but frequent fires caused deterioration of these ecosystems and eliminated many native species of wildlife that could not adapt. To protect their livestock, herders killed off competing wild ungulates and persecuted predators and rodents, contributing to the decline of natural grassland ecosystems.

As livestock gradually replaced wild ungulates, grasslands around the world turned to shrub and desert. Millions of cattle, sheep, goats, domestic camels and yaks have come to dominate the ecology of grasslands wherever they exist, often eliminating native species of wild perennial grasses that anchored the soil with their extensive root systems. In their place, annual plants and exotic species of grasses now dominate many grassland environments. Domestic goats may be the worst offenders; they pull grass out by the roots, damage shrubs and trees by stripping them of all vegetation and climb low trees to graze. Once the vegetation has been stripped and the roots are removed, wind blows the topsoil away or rain carries it off.

When livestock is removed, grasslands may be able to recover if the damage is not too severe. But plowing, especially by modern deep plows, obliterates all vegetation, including dormant seeds, and wildlife. Natural grassland and shrubland are fast disappearing under the plow, endangering a growing number of plants and animals. Chemical fertilizers do not nourish the soil as well as natural invertebrates, decayed vegetation and animal dung. Unlike the soil in natural grasslands, chemically fertilized soil easily becomes hard and impermeable. The result is less productive soil that requires the use of more and more synthetic fertilizers each year to produce the same size crop. Because artificial fertilizers do not contain natural micronutrients, crops grown using them may be nutritionally deficient. Moreover, fertilizer nitrates that enter the water have produced algal growths in rivers and coastal regions that are so dense they choke out all forms of life, leaving "dead zones."

Many agricultural crops, especially those grown in arid regions**,** require artificial irrigation. Sources include underground reservoirs, fed by rainwater that fell thousands of years ago, that underlie many deserts and shrublands. Known as fossil aquifers, they have recently been exploited through deep wells and are rapidly becoming depleted in portions of the Sahara, Namibia, Saudi Arabia and the United States. The aquifer beneath the Great Sand Desert of Iran has been pumped out, leaving only a low flow of brackish water (Allan and Warren 1993). In Saudi Arabia, aquifers are being depleted by water used in wasteful forms of irrigation that cause salinization of the soil. Heavy applications of water bring natural salts in the soils to the surface, resulting in a surface soil covered with salt crystals that renders the soil sterile unless the crystals are removed (Allan and Warren 1993). Salinization is destroying land in many parts of the world, affecting more than 30 percent of all irrigated deserts (Allan and Warren 1993).

Grassland and dryland areas are among the most threatened of all habitats, according to an appraisal of ecosystems and centers of biodiversity that has designated 200 ecoregions in the world (Grove 1999). These include temperate grasslands and Mediterranean-type shrublands, which are also rich in diversity (Grove 1999, Mittermeier *et al*. 1999). Conservation plans for preserving many of these areas become ever more important as they disappear or are degraded.

The misuse and overuse of grasslands has already turned millions of square miles into shrub and desert. With the

rise in human populations around the world, the process is accelerating. Each year, an area the size of Texas turns to desert. The spread of deserts is threatening the livelihood of the 650 million people who live in these arid regions (Ponting 1991). The global warming climatic pattern may be accelerating this process. Studies in the early 1990s by the United Nations Environment Programme (UNEP) estimated an area equal to North and South America combined Œ about 8 billion acres of grassland and cropland Œ was in danger of desertification worldwide (Pitt 1993). Since then, the problem has worsened. An estimated 75 percent of Africa is already considered degraded (Simons 1994). Desertification has claimed 39 percent of the 76 million hectares (188 million acres) of once productive grassland in Mediterranean Europe and 82 percent of the 142 million hectares (351 million acres) of Western Asia's productive steppe land (Goriup 1988).

UNEP reported in 1986 that rangelands are turning to desert at an increasing rate: 85 percent of rangelands in North Africa, 30 percent in Mediterranean Europe and 85 percent in Western Asia (Goriup 1988). Some studies have projected that should present trends continue, within 30 to 40 years, over half of the African continent, much of Central Asia, the majority of southern and eastern South America, most of central and western North America and about 90 percent of Australia will become desert (Allan and Warren 1993).

Preserving Dryland Ecosystems

While there are treaties and international campaigns to save wetlands and forests, grassland and desert preservation has been accomplished on a national and regional basis. Some countries, including the United States, Russia, Mongolia and China, have set aside large areas of deserts, but grasslands are still considered prime grazing and farmland, an impediment to their protection. An international treaty such as the Ramsar Convention on wetlands protection (see Aquatic Ecosystems chapter) would help protect many remarkable and unique grasslands and deserts. Many have been designated as UNESCO World Heritage Sites under the World Cultural and Natural Heritage Convention for their "outstanding universal value" and/or Biosphere Reserves by the Man and Biosphere Programme**.** This has provided an incentive for protection**,** although unprotected land rarely receives such designations, which tend to be given to national parks or reserves.

The 1994 Convention on Desertification, a treaty drafted by the United Nations, attempts to slow the current trends turning grassland and shrub into desert. The treaty was negotiated at the urging of African nations attending the 1992 Earth Summit in Rio de Janeiro that requested funds for environmentally sustainable agricultural practices based on traditional methods in dryland areas (Pitt 1993). The United Nations estimates $10 billion to $22 billion will be needed annually over the next 20 years to finance the rehabilitation of land and arrest the desertification processes (Simons 1994). This treaty is one of the first to mandate cooperation with local communities and design methods incorporating input from local people. In late 1996, the Convention went into force, although the United States still had not ratified it. Estimates of the funding needed to slow the expansion of deserts rose to $43 billion by 1996.

One positive development is the designation of the Great Gobi National Park of southwestern Mongolia. The United Nations Development Programme, as part of a worldwide project financed by the Global Environment Facility organization, established a Mongolian biodiversity program with help from the Mongolian government (Possehl 1995). The United Nations agency has helped finance the park, one of the largest in the world, by funding the salaries of rangers who patrol on camels (Possehl 1995). The park is dotted with oases greened by poplar and tamarisk trees, waterholes and shrub vegetation. It has been divided into two sections that cover over 17,000 square miles. This

commitment to conservation on the part of such a poor country is extremely laudable.

The Convention on Biological Diversity, drafted at the Earth Summit in 1992, has provided funding for the purchase of drylands and grasslands through the Global Environment Facility, a financial institution created at the Summit (Mittermeier *et al*. 1999). Through this institution and other international funds, areas of biological importance have been protected, but much money has been wasted on expensive consultants and projects that did not preserve diversity (Mittermeier *et al*. 1999). The help of private organizations and more novel approaches to land preservation are needed. Conservation International**,** an organization that carries out biodiversity studies and helps protect areas rich in species, found that seven of 25 biodiversity "hotspots," covering all types of ecosystems, were mainly dryland areas; they include the Cape Floristic Province and Succulent Karoo of South Africa, Southwest Australia, California Floristic Province, the Brazilian Cerrado, Central Chile and the Mediterranean Basin (Mittermeier *et al*. 1999). They are especially rich in plants, with 61,373 native vascular species. They also harbor large numbers of endangered birds and mammals (Mittermeier *et al*. 1999).

These hotspots once covered 5,266,009 square kilometers, 30 percent of the entire land area. One region not included above, the Caucasus area between the Black and Caspian Seas of Central Asia, is part grassland and part temperate forest (Mittermeier *et al*. 1999). All of these ecosystems have been drastically reduced from their former size. The Mediterranean Basin's original dry ecosystems once covered 2,362,000 square kilometers, but they have been reduced to 110,000 square kilometers, 4.7 percent of the original area; only 1.2 percent remains of the Brazilian Cerrado (Mittermeier *et al*. 1999). None of these ecosystems is more than 27 percent of its old size. Only 154,408 square kilometers Œ 3 percent Œ of the original 5,266,009 square kilometers are protected; these areas represent 7 percent of intact portions of these ecosystems (Mittermeier *et al*. 1999).

While this seems to paint a dark picture of grassland and dryland preservation, much good is also being done. The identification and biological surveys of these areas of high diversity are major first steps. Many of these regions have been ignored both by conservationists and the nations where they are found. Once governments are informed of the biological importance and threats to these regions, many begin to set aside national parks and reserves.

The designation of reserves of temperate grassland and dryland by governments such as the United States, Canada, Argentina, Chile, Mongolia, Russia, Central Asia and China has protected portions of these ecosystems being destroyed by livestock grazing, agriculture and new human settlers. Some of the largest of these reserves have been set aside to preserve the Asian steppe. In addition to Tibet's Chang Tang Reserve, the Chinese government set aside a 6,000-square-mile area, the Taxkorgan National Reserve, an international sanctuary where Afghanistan, Pakistan, Russia and China meet (Goddard 1995).

Debt-for-nature swaps, in which a portion of a nation's debt is paid by a private conservation organization such as The Nature Conservancy, in exchange for the protection of land (generally in a national park), have been negotiated in several countries. Many of the countries harboring great biodiversity are also among the poorest, saddled with debt they are unable to pay, the result of loans made by the International Monetary Fund and the World Bank, among others, for projects such as large dams and timber extraction that often despoiled the land. A debt-for-nature swap preserved a large park in Brazil's Cerrado.

Ecosystem protection, a relatively new concept just now gaining acceptance, may become a major means of protecting the Earth's diversity. Reserves often fail to protect wide-ranging species that migrate out of them, and isolation may cause key ecological components of an ecosystem to die out, causing a biological collapse. In the United States, an organization of biologists and conservationists has urged protection of the Yellowstone Ecosystem, a mosaic of savannah, temperate forest and mountain environments surrounding Yellowstone National Park. The size of the park does not allow movements of its wildlife outside the park, such as the migrations of American bison (*Bison bison*), dispersal of grizzly bears (*Ursus arctos*) or the reintroduced gray wolf (*Canis lupus*), because cattle ranches and other private property now surround the park. Another even more ambitious proposal aims to link Yellowstone with other federal lands in the United States and Canada north to the Yukon, purchasing private lands where necessary, to create a wide corridor of undeveloped land. This would allow herd migrations and movements of carnivores to link them with other populations, while protecting the environment and species diversity. Such programs would help ensure permanent conservation of the region. A similar proposal in southern Africa would create a vast park system, stretching from southeastern South Africa north to Kenya, so that wide-ranging grazing animals and their predators could migrate freely.

The benefits to society of such preservation are significant. Ecotourism has a potential to make such projects pay for themselves. This industry is growing astronomically and yields far more income than consumptive uses of nature, such as trophy hunting, logging and mining. Likewise, use of video cameras in parks and reserves connected via satellite to the Internet for pay-per-view has emerged as a potentially enormous source of income for the funding of biological studies**,** national park expenses and land preservation.

Many organizations and scientific bodies have made great steps within the past decade to alert the public about the need to preserve these threatened grassland and dryland ecosystems. Books on the beauty and wild fauna and flora of the Serengeti, Tibet's steppe, and America's prairies, as well as films and television programs, are educating people about these beautiful areas.

Lady Bird Johnson, wife now-deceased former President Lyndon B. Johnson, initiated a program of planting wildflowers along the nation's highways. Traditionally, endless miles of clipped grass lined United States highways with cultivated flower beds in places. In much of the country this has not changed. Mrs. Johnson convinced the Department of Transportation to set aside less than 1 percent of the highway tax funds to be devoted to the planting of native wildflowers, and helped found the National Wildflower Research Center, which is dedicated to conservation and education (described in detail in *Wildflowers Across America* (Johnson and Lees 1993). The dazzling display of Texas wildflowers the Center has helped conserve draws tens of thousands of visitors from around the country. This work has directed attention to the conservation of native wildflowers, an important step to encourage protection of their ecosystems as well.

Within the past decade, the protection of remaining grassland, as well as its restoration, has taken hold in the United States, sponsored by states, private organizations and the federal government. Many student projects have involved propagation of native grassland plants for restoring these habitats. The establishment of the country's first tallgrass national park has been a recent highlight of these trends.

Worldwide, a similar effort is needed to restore these magnificent habitats. Grasslands have been "so massively transformed by the hand of man that one is hard put to find any landscapes in them that match the original," and if "ever a biome needed a champion, it is the grassland", Warwick Tarbotoni once said (*Africa--Environment & Wildlife*, November 2000). The rich variety of plants and animals native to grassland and shrubland ecosystems is being preserved in parts of the world as more people gradually see these environments not as grazing land for livestock or potential farmland, but as vital to the preservation of diversity of their region.

To preserve dryland from overgrazing by livestock, new approaches are being explored. Portions of Saudi Arabian desert have been fenced off from livestock on an experimental basis, and native plants reemerged from long dormancy, covering the sand in green. Much of this region (and the Sahara) is sandy desert; herds of camels, sheep and goats owned by nomadic people are allowed to graze year-round, eliminating the seedlings that attempt to regenerate. In an innovative approach to helping desert people survive without destroying deserts in the process, several villages in southern Africa have agreed to fence their livestock and stop gathering wood for firewood. They will use methane gas fuel generated from animal dung for their cooking and heating needs. These villages have also been supplied with electricity from solar roof panels and small wind turbines. Without furnishing a solution to the needs of desert inhabitants who depend upon their livestock, one cannot expect these people, many of whom live on the edge of poverty and hunger, to preserve desert vegetation. Solar collectors, solar-powered stoves, technology to produce methane from livestock dung and information on water conservation should be provided by international conservation organizations and governments through foreign aid.

Threatened Species

Over the millennia, vast herds of hoofed animals grazed grasslands throughout the world. In spite of their great numbers, they did not overgraze or destroy these habitats, migrating before the soils were robbed of nutrients and wild plants died out. Natural grassland can support at least 30 species of large ungulates without being damaged, but can be destroyed by a single kind of domestic livestock grazed in large numbers. Over the past few centuries, sheep, goats, cattle, yaks and other domestic livestock have greatly increased in number, either herded by nomads or grazing on private and public lands. The effects on native wildlife, especially ungulates, have been catastrophic. They have been crowded out of their habitats, and in many parts of the world, livestock has transmitted lethal diseases such as anthrax and rinderpest to wildlife, resulting in massive die-offs, endangering many species. Some African antelope and zebras, for example, have been reduced to a tiny fraction of their original populations and survive only in reserves. Even these reserves can become islands surrounded by development outside, which isolates the wildlife into zoo-like environments. Such wildlife often becomes inbred and extinction-prone.
