Just after World War II, there were between 150,000 and 200,000 wolves in the Soviet Union, but beginning in 1947, an intensive government control program drastically reduced their numbers (Nowak 1999). The annual kill was 40,000 to 50,000 until 1962, when it dropped to 15,000; in the 1970s, some 50,000 wolves were estimated to survive in the entire country, including the Central Asian Republics (Nowak 1999). After an increase in wolf populations, a sizeable bounty was paid for killing them; and in 1980, 35,573 pelts were taken through aerial hunting, poisoning and other means (Nowak 1999). fiThe Russian Grey Wolffl (1993, Anderson Video, California) chronicled this bounty hunting and other persecution. In the past 70 years, more than 1.5 million animals have been killed; about 20,000 wolf pelts are marketed in Russia every year (Busch 1995). In the early 1990s, 17,000 men were employed by the Russian government to kill wolves. Since then, the national bounty has been rescinded, and only some state governments pay the equivalent of $25 for a female; the central government no longer encourages poisoning wolves (Binder 2000). In the Russian Far East, a bounty program to kill wolves has been in place for decades, but with the economic chaos following the fall of the Soviet Union, funds to pay the bounties dried up (Specter 1997). A 2001 Cable News Network (CNN) report profiled a government trapper who killed female wolves for the bounty, then raised the orphan cubs for release. The report suggested that persecution continued at high levels and that most Russians wanted the species exterminated.

The Wolf Almanac (Busch 1995) states that some 96 Russian wildlife reserves harbor wolves, and they are hunted actively in 41 of these. They are reported to be safest in certain large reserves, such as the Caucasian, Altai and Pechyora-Ilych reserves, unless they stray outside to prey on livestock (Busch 1995). Wrangel Island in the Arctic Ocean is to be made into a nature preserve with a wolf colony to cull the large herds of Musk Oxen and Caribou (Binder 2000).

Japan's wolves were killed off 100 years ago, and public opinion is negative about their reintroduction. Biologists want them reintroduced to control Japan's overpopulated Sika Deer, which are damaging forests (Binder 2000).

In Kazakhstan and Central Asia, wolves and Saiga antelope have coexisted for eons, but during this century, both have come under heavy hunting. A film, fiThe Saiga of Kazakhstanfl (see Video Section), describes the detrimental effect that wolf control programs have had on Saiga. Wolves are estimated to number between 90,000 and 100,000 in the country, but biologists claim that they kill large numbers of domestic camels, cows and sheep (Binder 2000). Killing wolves is considered a sport in Kyrgyzstan, south of Kazakhstan, where Golden Eagles are used as falconry birds to hunt foxes, badgers, Lynx and wolves (Kinzer 1999).

Mongolia has an estimated 10,000 wolves; China only about 400; and Afghanistan, 1,000 (McNamee 1997). In Tibet, wolves are heavily persecuted by livestock owners, and in the vast Chang Tang Reserve, it is the only species without legal protection. Wolf carcasses can be seen lying next to roads, the animals having been shot by hunters in vehicles, and biologist George Schaller (1998) saw three wolf bodies in a village dump with their jaws wired shut.

India has fewer than 1,000 wolves by some estimates (McNamee 1997), and between 800 and 2,000 in the opinion of Dr. Yadvendradev Jhala of the Wildlife Institute of India. The species is held in great fear by many Indian people, who regard wolves as man-eaters. A century ago, a bounty program resulted in the slaying of 2,600 wolves (Burns 1996). Indian Gray Wolves (*Canis lupus pallipes*) were finally accorded official protection in India in 1992. Rudyard Kipling's *The Jungle Book* tells the story of Mowgli, an Indian orphan raised by wolves. This story may have a basis in fact because many unwanted children are abandoned and placed in the woods, according to *The Wolf Almanac*, and Indian folklore recounts many cases of small children raised by wild wolves (Busch 1995). Such a child was discovered in 1972 at the age of four, apparently having been adopted by a pack of wolves. He was placed in Mother Theresa's refuge for orphans in Lucknow, where he died after seven years (Busch 1995). In spite of such true stories, the average Indian has little but fear and loathing for wolves.

Working to help India's wolves, Dr. Jhala and the Wildlife Institute of India are conducting surveys and appraising their status. For centuries, these wolves have lost habitat and prey species to the country's growing human population. When wolves turned to livestock, persecution followed. Dr. Jhala admits, "It is extremely difficult to conserve a

species when the majority of the human population is opposed to its survival" (*Earthwatch* 1996). Beginning in 1988, Dr. Jhala conducted the first-ever ecological study of Indian wolves for his doctorate at Virginia Polytechnic Institute, with funding from the National Geographic Society and the Smithsonian Institution (*Earthwatch*, 1996). Earthwatch contributed to this research in 1996 with its volunteer program of paying participants in Dr. Jhala's studies. These volunteers followed radio-tracked wolves in the 3,400-hectare (8,401-acre) Velavadar National Park of western India, one of the wolf's last strongholds, observed Blackbuck (*Antilope cervicapra*), Nilgai (*Boselaphus tragocamelus*) and other rare wildlife, and interviewed local farmers through interpreters about their opinions of this species.

Wolves, Wild Dogs and Foxes: Page 9

Official protection from hunting and trapping has been accorded very few wolf populations in the world, even where they are on the verge of extinction. In some areas, however, attitudes are changing, most dramatically in the United States, where documentary films and books on their behavior and importance in ecosystems, as well as recordings of their howls can now be seen in bookstores throughout the country. Superb photography illustrates some of these, most notably *White Wolf: Living with an Arctic Legend* (Brandenburg 1992), which provides glimpses into the lives of these fascinating canids in the Canadian north. Reintroductions of wolves into portions of their former range in the American West bode well for their future, unless the prejudices of many livestock ranchers hold sway. Canada may have the largest population of wolves in the world, estimated at between 30,000 and 60,000, with about 4,000 killed for fur each year (Nowak 1999). According to genetic studies, the wolves of southern Ontario and southern Quebec have apparently hybridized with Coyotes, as have wolves in neighboring Minnesota and Isle Royale, Michigan (Nowak 1999).

The ecotourism potential for wolf viewing in many parts of the world is considerable. In Ontario, Canada, visitors to Algonquin Provincial Park have come to hear packs howl since the 1960s. One of the first wolf conservationists, Canadian wolf biologist Dr. Douglas Pimlott, initiated these tours and educated thousands of people about the biology, importance to ecosystems and behavior of wolves. Their value in attracting tourists and contributing to healthy ecosystems far exceeds that of their pelts.

For some other species of wild dogs, attitude changes may not be enough to save them. The Dhole or Asiatic Wild Dog (*Cuon alpinus*), a small canid the size of a Coyote, is native to Asia, from southern Siberia and Central Asia east to India and Indonesia (Nowak 1999). This wild dog has rusty red fur on its upper parts, and white on its chest and belly. Hunting in large packs, Dholes pursue large prey, such as deer, wild pigs, antelope and wild sheep (Nowak 1999). Their social structure is not well known but appears similar to the Gray Wolf's, with a leader and lower-ranking members of the pack (Nowak 1999). Although Dholes seldom take livestock, they have been poisoned intensively and hunted throughout their range; they are also persecuted by hunters who regard them as competitors for game species (Nowak 1999). Dholes have disappeared from much of their habitat, and the *2000 IUCN Red List of Threatened Species* lists the species as Vulnerable, the category below Endangered, indicating a serious decline.

Similar in appearance, the Simien or Ethiopian Wolf (*Canis simensis*) is endemic to Ethiopia. Scientists were unsure in the past whether this animal was a dog, a wolf, a jackal or a fox. Most zoologists now describe it as a wolf. It may be related to the small race of Gray Wolf, *Canis lupus arabs*, that inhabits the Arabian Peninsula across the Red Sea (Nowak 1999). Simien Wolves have a head and body length of about 3 feet, are about 2 feet tall at the shoulder, and weigh from 11 to 19 kilograms (Nowak 1999).

The only wolf not preying on animals larger than itself, such as deer, but living in packs, Ethiopian Wolves feed mainly on small rodents (Gottelli and Sillero-Zubiri 1994). Once their range was far greater, encompassing most of Ethiopia's highlands, but with the development of agriculture and spread of livestock grazing, these wolves lost the majority of their habitat and came under totally unmerited persecution as a threat to domestic animals (Nowak 1999).

Today, they have become restricted to only about six locations in the Ethiopian highlands. Discovered in the Simien Mountains of the northwest, the subspecies, *Canis simensis simensis*, was estimated at only about 40 animals in the 1980s. These wolves are so shy that even in the Simien Mountains National Park they have become nocturnal and stay in burrows when humans are in the vicinity. A crew from Survival Anglia, a British nature film company, spent weeks in the early 1990s seeking to photograph the Simien Wolves in this park, finally having to settle for a long-distance view of a solitary wolf.

Wolves of the Bale Mountains, separated by hundreds of miles, are larger and redder than the Simien Mountains race, and this subspecies, *Canis simensis citernii*, is somewhat more numerous than the other race. Only about 440 Simien Wolves were thought to survive in the Bale Mountains in the early 1990s, with perhaps another 100 in the Simien Mountains (Gottelli and Sillero-Zubiri 1994). Today, estimates are even lower. The Bale Mountains population is estimated at 270 to 370 animals, and 70 to 150 survive in the Simien Mountains (Nowak 1999). This species is thus at the edge of extinction. It is listed as Critical in the *2000 IUCN Red List of Threatened Species*, protected by law in Ethiopia and listed as Endangered on the US Endangered Species Act.

The Wildlife Conservation Society (formerly the New York Zoological Society) has funded research projects on the Simien Wolf for many years, including the studies of two zoologists, Dada Gottelli and Claudio Sillero-Zubiri in Bale National Park. Simien Wolves use their long legs to dig into rodent tunnels, aided by their acute senses of hearing and smell. In Bale Mountains National Park, 14 rodent species are native and three dominant species are endemic to the region, providing a huge food base for the wolves. They specialize in preying on the endemic Ethiopian Mole Rat (*Tachyoryctes macrocephalus*). The mazes of tunnels that these rats excavate aerate the soil, creating rich topsoil which nourishes the lush grasses in this highland ecosystem. The wolves have been seen hunting cooperatively, chasing young antelope and hares (Nowak 1999).

Livestock grazing is allowed in Bale Mountains National Park, and Simien Wolves wander among the cattle, presenting no threat. The wolves in this park have not been persecuted, unlike those elsewhere in Ethiopia, and do not hide from people. Filmmakers shooting the 1990 BBC film, fiKing Solomon's Mountains,fl found the wolves in the open during the day, with adults hunting rodents, and pups playing wrestling games. Like other wolves, they are extremely affectionate with one another and yip in group choruses, sounding like Coyotes. Packs range in size from five to 13 animals, and they defend territories. As in Gray Wolf packs, only one female in the pack breeds, and because of limited habitat, nonbreeding females often stay with the pack, acting as "aunts" instead of leaving to begin their own packs (Gottelli and Sillero-Zubiri 1994).

Domestic dogs, brought into Bale Mountains National Park by the Oromo people to protect their flocks of sheep and cattle from hyenas, are a major threat to this species (Gottelli and Sillero-Zubiri 1994). Wolves have succumbed to diseases introduced by these dogs, which are not fed but set free to fend for themselves. Between 1992 and 1995, the Bale Mountains wolves were decimated by an outbreak of canine distemper acquired from these dogs, reducing the wolves from 240 to 140 (Anon. 1996). In the mid-1990s, more died of rabies. An even more ominous threat is their interbreeding with domestic dogs. The film fiKing Solomon's Mountainsfl showed a pack of wild Simien Wolves led by a large black dog that had become the lead female. Another film, fiLast Wolves of Ethiopia,fl shown on a National Geographic Explorer program in early 1998, recounted the story of a young female Simien Wolf who was ousted from her pack and, after a few years of wandering, paired with a hybrid wolf-dog. In general, male domestic dogs have bred with female wolves, diluting the genetic integrity of this highly endangered animal (Gottelli and Sillero-Zubiri 1994). Some populations of pure Simien Wolves are showing signs of inbreeding, due to their small genetic base. The combination of these threats has led scientists to predict imminent extinction for this beautiful wild dog.

To prevent their extinction, attempts are being made to convince the Oromo tribespeople to control their dogs, but scientists have concluded that captive-breeding may be the only way to save the species (Gottelli and Sillero-Zubiri 1994). There is no possibility of preventing these people from entering the park because of the tribe's centuries-old ties with this region and the potential of bad relations with them that could have serious repercussions on the conservation of park wildlife (Gottelli and Sillero-Zubiri 1994). As a means of controlling the domestic dogs, they could be

neutered, vaccinated against disease, and provided supplemental food to prevent their attacking native ungulates in the park. A vaccination program has recently been carried out in the Serengeti, where domestic dogs transmitted canine distemper that killed one-third of the Lions in the region.

The South American Maned Wolf (*Chrysocyon brachyurus*) has also declined, although not as drastically as the Ethiopian Wolf. This long-legged wolf, weighing only about 44 pounds, hunts in the tall grasses of pampas and llanos, and eats rodents and other small mammals, birds, reptiles, insects, fruit and other vegetation (Nowak 1999). With shaggy red fur and black legs, it has been called a Red Fox on stilts. It is the sole member of its genus and the only wolf in Latin America. The Falkland Island Wolf (*Dusicyon australis*), native to the Falkland Islands off Argentina, became extinct in 1876 after large numbers were killed by fur traders and poisoned by sheep ranchers (Allen 1942). The size of a large Coyote, it may have evolved from foxes. Maned Wolves have been falsely accused of killing livestock, and persecution has caused them to disappear from Uruguay and most of Argentina. They have become rare in Brazil and the rest of their range in south-central South America. The Maned Wolf is listed on the US Endangered Species Act as Endangered and on the *2000 IUCN Red List of Threatened Species* as Near-threatened.

Wolves, Wild Dogs and Foxes: Page 10

Small predators also underwent persecution in North America in the late 19th and early 20th centuries. Two tiny western foxes that were once considered to be the same species, the Swift Fox (*Vulpes velox*), native to shortgrass prairie, and the Kit Fox (*Vulpes macrotis*) of intermountain and desert grasslands further west, both declined as a result of predator-control programs. Both are shades of tawny, reddish-brown and tan, stand about 1 foot tall, measure 23 to 31 inches long, and weigh less than 5 pounds (Nowak 1999). Although not considered threats to cows or sheep, foxes traditionally have been killed because of their possible threat to poultry. In wilderness areas, they have been killed merely because of predator prejudice. These foxes subsist on small rodents and even insects, such as grasshoppers, and are, therefore, beneficial.

The Swift Fox was named for its speed when streaking across the prairie, clocked at about 25 miles per hour (Turbak 1993). The Canadian populations of the Northern Swift Fox (*Vulpes velox hebes*), native to southern Saskatchewan, Alberta and Manitoba, and the northern edge of the shortgrass prairie that once stretched to Texas, are listed as Endangered on the US Endangered Species Act but are extinct. They disappeared from the wild by the 1930s, after control programs were implemented, and Canadian wildlife authorities have reintroduced Swift Foxes of a related subspecies from Colorado, Wyoming and South Dakota (Nowak 1999). Some reproduction has taken place.

Swift and Kit Foxes began to decline in the 19th century, and Ernest Thompson Seton commented on the vulnerability of this species: "Harmless to man and mankind's interests; and yet he is going fast with all the other innocent and lovely wild things. Yes, faster than most, for he is the least cunning of our foxes--so guileless that he readily takes the poisoned baits used nowadays for killing coyotes" (Seton 1899). In fact, almost none of these foxes was seen in the wild from the early 1920s to the late 1950s, a period of heavy predator-control and poison campaigns (Chambers 1978). Both species have lost the majority of their habitats to agriculture. In North Dakota, the state lists the Swift Fox as an endangered species, with no breeding populations. The last known occurrence of the Swift Fox in this state was in the mid-1980s (Turbak 1993). Further south, this species is known to survive in southwestern Kansas, Nebraska, Montana, Wyoming and South Dakota (Chambers 1978). Some areas of unplowed prairie provide refuge. This fox has been able to colonize on roadsides next to fields and in the few remaining unpoisoned prairie dog towns. Some research has been carried out on the wild behavior and habitat needs of Swift Foxes in the Midwest, and there is room for cautious optimism that increased attention to this little fox will result in strong legislation to preserve it and prevent persecution and poisoning. Author Glenn Chambers was researching an article for *Audubon* magazine, "Little Fox on the Prairie" when he saw a fox family being killed by two farmers who poured gasoline in the den entrance and set fire to it. The male fox, provider of food for the vixen and pups, was found in a ditch a few yards away, his rib

cage ripped out by a high-velocity bullet (Chambers 1978). The vixen had escaped the burning den with two of the pups, but the farmers shot her as she watched over them (Chambers 1978).

Kit Foxes occupy deserts, dry grasslands, and montane areas with scattered trees from Utah north to Washington state and west to California. They prey mainly on kangaroo rats and other small rodents. A subspecies from southern California known as the San Joaquin Kit Fox (*Vulpes macrotis mutica*) is listed on the US Endangered Species Act as Endangered. Settlement and farming of the region reduced their habitat, and predator control has eliminated entire populations, causing them to dwindle to a few thousand animals. This delicate, little buffy-yellow fox is now restricted to a tiny remnant of its once immense habitat of mixed grasslands, deserts and shrub in California. Their original range stretched from San Joaquin and Stanislaus counties in the north to Kern County in the south. They probably numbered at least 12,000 prior to settlement (Turbak 1993). Tame and trusting, they became targets for hunters; even schoolboys with rifles have been seen shooting them as sport (Turbak 1993). One hunter was seen shooting a pair's tiny cubs one after another as they played at the den entrance, then killing the mother when she emerged to protect them (Turbak 1993).

Foxes have been considered threats to livestock and domestic poultry by European settlers. The Cape Fox (*Vulpes chama*) of dry country in southern Africa was the object of control programs by European settlers under the misapprehension that it preyed on domestic poultry. This resulted in declines in the numbers and range of this small, silvery-gray fox (Nowak 1999). The Hoary Fox (*Lycalopex vetulus*) of south-central Brazil, an endemic species of savannah grasslands, is persecuted by local people for presumed predation on domestic fowl (Nowak 1999). Although very shy, it courageously defends itself and its young when threatened (Nowak 1999). Little is known of its status, listed as Data Deficient by the IUCN. Argentine Gray Foxes (*Dusicyon griseus*), native to Patagonian grasslands, have been poisoned by livestock owners who distribute strychnine bait. Their populations have declined in many areas as a result, and thousands of non-target mammals and birds have died from these poisons. Such poisoning is illegal in Argentina, and efforts are being made by biologists and conservationists to stop this senseless killing.

Eight species of foxes are listed as Data Deficient by the *2000 IUCN Red List of Threatened Species*, and two species as Conservation Dependent. This is an indication of the lack of research on these ecologically important species, which perform the important role of consuming large numbers of rodents. Red Foxes (*Vulpes vulpes*), native to North America, Eurasia and northern Africa, have been persecuted as well, hunted as sport in England and parts of the United States, and killed by many farmers and livestock owners. One Midwestern town even rounded up these foxes once a year and beat them to death with sticks. After a *Life* magazine article describing this cruel persecution and the resulting public outcry, it ended. Fox hunting in England may end in the near future as the Parliament has voted to stop this cruel activity.

Bears

The immense Grizzly or Brown Bear, which once roamed the prairies and woodlands of western North America, inspired awe and fear in explorers and settlers alike. For thousands of years, Native Americans revered this bear. The Cree called it a four-legged human, and other tribes considered it a brother or cousin. They felt a kinship based on its intelligence and respected its great strength. They could not easily hunt it with bows and arrows, and when wounded, it showed great courage defending itself, able to cause severe injuries or death with its 5-inch claws.

The Grizzly reigned as the fearsome and unchallenged king of all wildlife on the continent, numbering at least 100,000 prior to the arrival of Europeans (Nowak 1999). These extremely adaptable bears lived in every western North American habitat except deserts. Arriving from Asia by way of the Bering Strait 12,000 years ago when sea levels were lower, Grizzlies gradually colonized western regions, the biggest of an array of large carnivores that inhabited the continent at that time, including dire wolves, hyenas and sabre-toothed cats. They survived the frigid and

harsh climate of the Pleistocene Ice Age. They thrived in prairies, especially those with scattered woodlands. In the 1500s, their range extended from the Arctic tundra south through the shortgrass prairie to the pine forests of northern Mexico, and west to the Pacific Ocean. In fact, the original range of the Grizzly Bear may have been larger than previously thought, reaching east to the Atlantic in Canada. A Grizzly skull has been found in a midden of the late 18th century, and pelts of these bears reportedly were taken in Labrador as late as 1927 (Nowak 1999).

Grizzly Bears of North America and Brown Bears of Eurasia were previously considered separate species, but today they are classified as a single one, *Ursus arctos*. The bears that live along the southern Alaskan coast and offshore islands, such as the Kodiak, are the world's largest carnivores (Nowak 1999). Weighing up to 780 kilograms (1,716 pounds), Kodiak Grizzlies have a shoulder height up to 1,500 millimeters (58.5 inches, or almost 5 feet), and a body length ranging up to 2,800 millimeters (109.2 inches, or 9 feet) (Nowak 1999). Standing height can be almost 12 feet. Adult males are larger than adult females. North American Grizzlies are far larger than bears of the same species native to southern Europe, which average only 70 kilograms (154 pounds) (Nowak 1999). Grizzlies of the northern portion of the lower 48 states are only somewhat smaller than the Alaskan bears, while those native to Arizona, New Mexico and Mexico, all now extinct, were smaller still, weighing less than 1,000 pounds.

Reproducing at a very slow rate, Brown Bear females have an average of two cubs only once every two to four years, and the cubs stay with their mother for this entire period (Nowak 1999). On occasion, only one cub is born, and sometimes up to four. If the mother is killed at any time before the cubs leave to be on their own, the cubs will also die because they are unable to fend for themselves, destroying two generations. The training period of these bears is extremely long, an indication of their slow maturation and the complexity of learning about food sources and other keys to survival. Another reason for this long apprenticeship is the potential of attacks by male Grizzly Bears. Until a young bear is 3 years old or older, it is not large enough to withstand an attack by an adult male, requiring the protection of its mother. Males continue to grow until they are 10 to 11 years old, and may provoke fights with younger bears to chase them from the territory, which prevents inbreeding. Females remain fertile until well into their 20s. Females in the Yellowstone region are known to live to be 25 years old, and Grizzly Bears may have the potential to live 50 years in captivity (Nowak 1999). They do not reach sexual maturity until they are at least 4 to 6 years old. These bears have a low natural death rate, and when combined with their slow reproduction, they are very vulnerable to extinction should they suffer high mortality.

A large habitat requirement is another aspect of their vulnerability. In the Arctic, a single Grizzly requires more than 100 square miles of tundra, and in the Yellowstone area, each bear occupies about 88 square kilometers (Nowak 1999). In regions where they are distributed sparsely, they can be eliminated easily, and even where they are more numerous, persecution and trophy hunting have caused local extinctions.

The strength, intelligence and size of the Grizzly, which have served it so well for thousands of years, were no match for European guns. Explorers, trappers and, later, settlers, slaughtered thousands of Grizzlies, killing them on sight. The first to disappear were the bears of the Great Plains, where the landscape was open and provided little cover. In some cases, these bears showed almost mythic strength upon being shot. Meriwether Lewis of the Lewis and Clark expedition of 1804 reported that one wounded bear ran at a fast clip for nearly a quarter of a mile before it fell dead after being shot through the heart (Peck 1990). Persecution of bears often includes the killing of their cubs. Early in the 20th century, President Theodore Roosevelt refused to kill bear cubs pointed out by his hunting guide, and when this was publicized in newspapers, he became a folk hero as a result. Toy manufacturers took advantage of the story by producing stuffed animal "Teddy Bears," which remain popular today. President Theodore Roosevelt left a legacy of destructive trophy hunting, however, including the killing of many adult bears.

Settlers moving into the West hunted these bears, and during the late 19th and early 20th centuries, government predator-control agents began campaigns to eliminate these bears. Much of the zeal with which the bears were slaughtered was based on a misconception: they were thought to be vicious man-eaters. In fact, they are mainly vegetarian and only occasionally kill animals for meat. The most common animals killed by Grizzly Bears are various types of rodents, such as ground squirrels and, in some areas, fish. Elk calves are killed as part of their diet in some

areas. The staple foods of the Grizzly diet are green shoots, sedges, clover and lilies early in the spring and, later in the summer, berries, roots, fruit, acorns and nuts, with occasional rodents (Peacock 1996). These bears do not consider humans to be natural prey, and attacks are rare. Prejudices dominated, however, and hunters who killed them were considered heroes and rewarded with bounty money. To protect their livestock, ranchers insisted that government hunters kill off every Grizzly Bear, and after several centuries of uncontrolled hunting, trapping and poisoning, the bears became extinct in their vast original realm south of Canada except for a few hundred animals protected in Yellowstone and Glacier National Parks.

All 26 subspecies of Grizzly Bears south of Canada and Alaska, except *Ursus arctos horribilis*, became extinct by the 1950s, and some disappeared during the 19th century. The latter subspecies, named from specimens obtained in northeastern Montana, barely survived. In fact, *Ursus horribilis* was the species' scientific name until recently, an indication of the prejudice against it. Now considered a subspecies, *Ursus arctos horribilis* is listed on the US Endangered Species Act as Threatened, and this subspecies is used to indicate all Brown Bears in the lower 48 states.

Grizzly populations still occupy only 1 percent of their original range in the lower 48 states and number fewer than 1,000 (Nowak 1999). This includes Yellowstone and Glacier National Parks, whose protection prevented their total extinction south of Canada, a few wilderness areas in Idaho, western Montana, and Washington. Human activities such as road building disturb them and cause them to desert otherwise prime habitat. They are no longer the fearless animals that Lewis and Clark encountered, but have become very shy outside of national parks after centuries of persecution. Although they may pose a potential threat to humans who enter their last retreats, people are a far greater threat to them.

Their rugged wilderness habitat in Montana is being developed rapidly, and Grizzly populations, which had risen somewhat after their listing on the US Endangered Species Act, are now in danger of disappearing again. Added to this, some ranchers in the region still persecute them. A prime habitat for Grizzly Bears, the 329,000-acre Swan Valley of northwestern Montana borders the Bob Marshall Wilderness area, a country of open grassland and forest with breathtaking mountain views. Until recently, this landscape remained almost unchanged from its original state. Ranching, road building and other activities, and an increasing human population in this region, however, are now ruining its wilderness character and threatening the Grizzlies (Pelletier and Servheen 1995). Through cooperation with local residents, the Fish and Wildlife Service is identifying important habitat areas and linkage corridors for the Grizzly Bears in this part of Montana to prevent conflict with humans. These zones would be a link between the small population of bears in the Mission Mountains to the west and those in the Bob Marshall Wilderness area (Pelletier and Servheen 1995). The land is a checkerboard of ownership by private individuals, state, federal and corporate entities; in an unusual project, all private and public lands will be included in a management plan, with input by local citizens (Pelletier and Servheen 1995). These bears remain under the continual threat of being shot by ranchers fearful for their livestock and apprehensive about possible land restrictions in areas where Grizzly Bears are resident. Sport hunting of this small population is also allowed.

Grizzly Bears are still depicted in the media as dangerous man-eaters, resulting in a prejudiced view by the American public. A number of television programs produced by the National Geographic Society, CBS, the Discovery Channel, Fox and others have perpetuated this image. With titles such as "Dangerous to Man!," "Bear Attacks" and "Man-eaters," these programs often demonize the bears and interview people who have been attacked while camping in the bears™ habitat. Very few such attacks have occurred, and almost none has been fatal. After centuries of being shot at and harassed by humans, Grizzly Bears tend to avoid people. When camping inside national parks where Grizzlies are resident, special precautions must be taken, and it should be kept in mind that the parks are *their* home, and humans are the intruders. The national parks, where hunting is banned, are their only refuge. Some documented cases of attacks have occurred when a mother bear felt her cubs were threatened by humans, especially if they approached the cubs. Mother Grizzlies may be the fiercest protectors of their young in the animal world, a trait that should be admired from a distance. Television programs that sensationalize the potential threat of animals do not note the hundreds of Grizzly Bears killed by humans every year in North America. They also fail to show the many bears that are merely wounded by hunters and suffer a long death, or the cubs that are orphaned and die of starvation.

The irrational fear and hatred aroused by misinformation often result in mortalities to these bears by armed tourists and residents in their range who misinterpret the bears' behavior. Many bears have had to be destroyed because tourists fed them, and they became fearless, capable of swiping food or destroying tents and property. Information on avoiding Grizzly Bear encounters is available from National Park Service rangers, other federally employed biologists, and many conservation and humane organizations. Only with tolerance, respect and an informed public concerned about preserving these bears can they survive.

Ecotourism in the threatened and unprotected portions of the Grizzlies™ range is in the early stages of development. Portions of the revenues from tours could be spent to acquire habitat and conduct local education programs. In Alaska, this has been highly successful, with tourists coming from around the world to see these bears fishing for salmon. Montana has some of the most spectacular scenery on the continent, sweeping vistas and vast open spaces that rival those of East Africa. They could be a magnet for tourists anxious to see Grizzly Bears and other native wildlife against a background of snow-capped peaks. Unfortunately, much of their prime valley habitats have been taken over by ranchers and private homes. The tourism in the area has been of a highly commercial and exploitative nature. For example, in some Montana towns, tourists see many stuffed Grizzlies in local businesses, and one can have one's photograph taken posed in a cutout painting of a Grizzly Bear appearing to attack.

If sizeable portions of Montana valley habitats were acquired for the Grizzly Bears, tourists could be taken on van tours, similar to those that now operate in East Africa. For the more athletic, groups of tourists could be taken on guided walks into the high country. Portions of the funds from the tours could be used to purchase privately owned land, to fund public education about these bears and their survival, and to compensate ranchers for livestock losses. The Nez Perce tribe is working with the Fish and Wildlife Service on a project to reintroduce the Grizzly Bear into the Selway Bitterroot wilderness of Idaho and Montana, another magnificent area for ecotourism (Robbins 1997).

Plans to reintroduce Grizzlies into the 1.9 million-acre San Juan National Forest in southwestern Colorado have sparked controversy and prejudice (Papich 2000). Decades after Grizzlies disappeared from the state, the Fish and Wildlife Service reintroduction project has been applauded by local conservation organizations, such as the Colorado Grizzly Project, and opposed by ranchers and even hiking groups who fear attacks (Papich 2000). Returning the Grizzly Bear to portions of its former range in the lower 48 states, even into immense wilderness areas, will be a slow process, possible only after extensive education and a change in the accepted practice of releasing livestock in national forests without sheepdogs, herders or other protections.

The Mexican Grizzly (*Ursus arctos nelsoni*) persisted in the remote mountains of northern Mexico until it was poisoned, shot and trapped to extinction in the late 1960s (Day 1981). This race was smaller than northern Grizzlies, weighing about 700 pounds. Quite numerous and widespread, the Mexican Grizzly had an enormous range in the pine forests of the northeast until efforts began to exterminate it. Only about 30 animals remained by 1960. Although some individuals tried to protect these last bears, others set out to destroy them, and a campaign of poisoning, trapping and hunting, sponsored by ranchers, resulted in the killing of the last animal in the early 1960s (Day 1981). In 1968, biologist Carl Koford conducted a three-month survey in the isolated mountain canyons of Chihuahua where they had last been seen, and he saw no sign of Grizzly Bears (Day 1981). Subsequently, they were declared extinct.

Hunters in many parts of the Grizzly Bear's range in Canada kill the species in such numbers that many biologists consider it to be threatened there. The Canadian Broadcasting Company's "Nature of Things" program produced a film, fiGrizzlies: Losing Ground,fl which painted a dim picture of this bear's future in Canada. They are killed by ranchers and hunted for trophies and for their gallbladders, which are used in Traditional Medicine. Many are killed by park rangers merely because they come too close to tourists. They are being driven from their wilderness homes by unrestricted logging and mining as well.

Brown Bears are already extinct in North Africa, Austria, Belgium, Denmark, Germany, Israel, Jordan, Lebanon, Liechtenstein, Luxembourg, the Netherlands, Portugal, Switzerland, Syria and the United Kingdom. They are

endangered in the few countries where they remain in Western Europe. In Scandinavia, there may be as many as 700 Brown Bears, with populations of less than 1,000 in Slovia, Romania and Bulgaria, and possibly 2,000 in the former Yugoslavia (Nowak 1999). Fewer than a dozen Brown Bears survive in France's Pyrenees Mountains where, despite protests from around the world, a major highway was built through the center of their habitat. Brown Bears are heavily persecuted throughout Eurasia for body parts, especially gallbladders. They are considered endangered in Central Asia's mountains where *Ursus arctos isabellinus* occurs, a CITES Appendix I race, and the Tibetan Brown Bear (*U.a. pruinosus*) is listed as Endangered on the US Endangered Species Act. Outside Russia, only about 4,500 to 7,600 of these bears remain in China, and isolated populations survive in Mongolia, northern Japan and Turkey (Nowak 1999).

The South American Spectacled Bear (*Tremarctos ornatus*) is classified as Vulnerable by the IUCN, with persecution by ranchers a major cause (Nowak 1999). These 300-pound black bears have large circles of white fur around the eyes and white circular markings on the neck and chest. They feed on fruit, bamboo hearts, corn, and other vegetation with about 4 percent of their diet composed of rodents and insects (Nowak 1999). Spectacled Bears are native to the Andes of western Venezuela, Colombia, Ecuador, Peru and western Bolivia. This high-altitude, shy bear is active mainly at dusk and at night and poses no threat to livestock, yet ranchers and landowners have persecuted and hunted it in Peru and other countries because of the mistaken belief that it kills livestock (Nowak 1999).

With the destruction of their high-altitude, humid forest and grasslands replaced in many areas by agriculture, some bears have raided corn fields to survive; many of these bears have been shot by farmers (Nowak 1999). This bear is declining throughout its range, and few areas remain where it can forage without being hunted, either by livestock ranchers, farmers, or for its body parts to sell to Asian markets for traditional medicine. Only a few national parks exist within its range, and populations have become fragmented and isolated from one another. A biological study of these bears in Bolivia by British zoologist Susanna Paisley is uncovering new information about their natural history and the threats posed by radio-tracking. A film about her study and the local people helping her, fiBears of the High Andes,fl was shown on a National Geographic Explorer television program in 1998, providing a unique glimpse into the lives of these rare bears.

Otters

The Eurasian or Common Otter (*Lutra lutra*) has been persecuted since the
13th century in Britain, and a dog, the Otter Hound, was bred to hunt it (Chanin 1985). This otter was officially designated as a pest by a 1566 English law, which authorized local constables to offer bounties for their destruction because of their supposed predation on fish (Chanin 1985). At that time, fish ponds on the estates of the wealthy were stocked to supply the tables of the affluent (Chanin 1985). They were also thought to be competitors with fishermen for game fish such as trout. For hundreds of years, high bounties were paid, contributing to their disappearance from many areas (Chanin 1985). Hunting otters with dogs was the only effective manner of pursuit, and in the 16th century, the Assembly of Norwich decreed that fishermen should conduct two or three otter hunts per year to avoid being fined (Chanin 1985). Estate game keepers continued over the centuries to persecute these playful animals in the British Isles, pushing them close to extinction.

In Europe, prejudices are gradually fading, but the Common Otter, despite its name, is no longer common. It has declined drastically in Britain and most of western Europe, and is rare throughout much of its range elsewhere in eastern Europe and Asia as a result of continued persecution, fur trapping, habitat loss and chemical contamination of its environment (Chanin 1985). This species is listed on Appendix I of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), the category designating species in danger of extinction, and in which commercial trade is not allowed between the Party nations. The *2000 IUCN Red List of Threatened Species* classifies the species as Vulnerable. An increasing number of people are becoming acquainted with this delightful

animal. Not until 1978 did the otter receive official protection from hunting and trapping in England and Wales, and in the intervening years, a strong "Save the Otter" campaign, begun by Friends of the Earth, has had positive results (Chanin 1985). Surveys completed during the 1970s found that otters had become extremely rare in England, and were in steep decline. In parts of southwestern England, otters are now increasing with legal protection, and they are being reintroduced into areas where they had been hunted or trapped out. In 1982, protection was added in Scotland, in spite of continued opposition from otter hunters and those who harbored old prejudices (Chanin 1985). In the Netherlands, reintroductions of otters are returning them to long vacant habitat.

Izaak Walton's views of the otter were not scientifically refuted until the 20th century. Best known as the author of the 17th century book, *The Compleat Angler*, a compendium of information about fishing in England, he quoted a fishermen of the times: ". . . my purpose is to bestow a day or two in helping to destroy some of those villainous vermon; for I hate them perfectly, because they love fish so well, or rather, because they destroy so much, indeed, so much, that in my judgment, all men that keep otter-dogs ought to have pensions from the King to encourage them to destroy the very breed of these base otters, they do so much mischief." Scientific studies of otter diets established that these animals did not pose threats to game fish populations. A 1942 study found that North American River Otters (*Lutra canadensis*) prefer slow-moving forage fish, such as suckers, mudminnows and sticklebacks, to fast-moving trout. Some game fish are taken, but subsequent studies established that such fish make up a small percentage of the otter's diet. A 1955 study by biologist Richard Ryder examined stomachs of River Otters (*Lutra canadensis*) trapped in Michigan and found forage fishes (primarily mudminnows) in 56 percent, crayfishes in 22 percent, amphibians in 17 percent, insects in 13 percent, and trout in 13 percent of all otters examined. Ryder concluded that otters are opportunistic feeders, catching prey items in proportion to their abundance and in inverse proportion to their swimming ability. Thus they benefit game fish by removing overpopulated fish species that compete with trout for food from streams and waterways. In a dramatic demonstration to illustrate its food preferences, a River Otter was placed in a large tank with both trout and crayfish. Ignoring the fast-moving trout, the otter went directly for the crayfish.

Other species of otters also have been found to prefer slow fish, especially bottom-dwellers not desired by either sport or commercial fishermen. Yet they are still being persecuted in many parts of the world. The Marine Otter (*Lutra felina*), a small otter native to the Pacific coast of western South America, has been so persecuted by fishermen for alleged damage to fisheries (Nowak 1999) that it is now listed as Endangered on the *2000 IUCN Red List of Threatened Species*. The Sea Otter (*Enhydris lutris*), protected from previous hunting for the fur trade, began to recover its numbers in the North Pacific, but has recently declined to Endangered status as well as a result of persecution by fishermen, oil spills and predation by Killer Whales.

One young California Sea Otter filmed by Jacques Cousteau became very tame, cavorting with the cameramen and allowing itself to be petted. A few days after the Cousteau crew left the area, this young otter washed up dead on the beach, having been shot. It was conjectured that this friendly otter had approached a boat with fishermen who shot it. Fishermen have overharvested abalone beds for these extremely valuable mollusks and blamed Sea Otters for depleting them, yet abalone form only a small part of their diet. Some Sea Otters eat no abalone at all, specializing in other foods. Moreover, they eat sea creatures that prey on the kelp, without which abalone and other wildlife would not flourish. This species is considered a positive element in the ecosystem.

River Otters in North America were persecuted by European colonists, many of whom shot them on sight. These animals, described by early explorers as highly visible, bold and playful, became shy, secretive and nocturnal after centuries of persecution and fur trapping in the United States and Canada. By the 1950s, they had disappeared altogether from vast areas in the country, from Pennsylvania south to northern Georgia and throughout the Midwest south of Michigan and Minnesota, west to Utah (Nilsson 1985). Beginning in the 1970s, reintroductions of otters live-trapped in Canada, Michigan and other areas where they are still relatively common, have taken place in West Virginia, Arizona, Tennessee, upstate New York, Missouri and several other Midwestern states. In some cases, the reintroductions have failed, but for the most part, the North American River Otter is on the way to reoccupying its original range.

Otters are not regarded benignly by fish hatchery managers and commercial catfish farmers in the South. State Fish Departments and the Fish and Wildlife Service operate hundreds of hatcheries throughout the country, raising trout and other fish. Many of these are non-native species, such as Brown Trout, a European species, or native species, such as Rainbow Trout, that are released far from their natural ranges for the benefit of sport fishermen. These hatchery programs are regarded negatively by many ecologists who have documented that the released fish often cause great damage to ecosystems, outcompeting native fish and introducing diseases. Yet state and federal agencies conduct control programs on otters who raid their ponds. Rather than screen the ponds from otters, who can hardly be blamed for finding hatchery fish easy to catch, these authorities have had laws changed in many states to allow shooting and trapping of otters that come onto hatchery property. Placing screening over fish ponds and hatcheries--and fencing them--will prevent otters, as well as fish-eating birds such as egrets, herons, Ospreys and Bald Eagles, from preying on the fish being raised. This should be carried out instead of lethal methods, which also sometimes kill protected waterbirds. Such control programs do not achieve success in any case because even if depredating River Otters are killed, other otters will be attracted to the ponds, replacing those killed.

Eleven species of otters are listed by the *2000 IUCN Red List of Threatened Species*, four as Endangered, three as Vulnerable, one as Near-threatened, and three as Data Deficient. This represents a high rate of threat, 85 percent, as the otter, or Lutrinae family, has only 13 species. Otters tend to be thinly distributed in their ranges, wide-ranging, slow-reproducing and long-lived--all qualities that make them vulnerable to population declines.

Seals and Sea Lions

The Caribbean or West Indian Monk Seal (*Monachus tropicalis*) was the first animal seen by Christopher Columbus in the New World in the late 15th century, and his crew slaughtered these seals on an islet off the coast of Hispaniola (Day 1981). The only seals native to the Caribbean, they were quite large--6.5 feet long (Nowak 1999). They were heavily exploited beginning in the 17th century for their oil, which was used as a fuel for lamps and, later, for their fur. Scattered populations of the Caribbean Monk Seal survived on islets and beaches far from human habitation until the 20th century (Nowak 1999). Even these last seals were persecuted by fishermen who regarded them as competitors. The last known population of these seals lived on the Triangle Keys, small sandy islets off the Yucatan Peninsula of Mexico, and in 1911, fishermen slaughtered every one of the remaining 200 Monk Seals (Day 1981). Although a few seals were seen after that time, including the sighting of a small colony on a bank midway between Jamaica and Honduras in 1952, an aerial survey of all possible habitats carried out in 1972, and a 1980 expedition, failed to find any sign that the Caribbean Monk Seal remained alive (Nowak 1999). The species was officially declared extinct a few years later, although a few recent reports have given hope that the species may have reappeared (Nowak 1999).

The Japanese Sea Lion (*Zalophus californianus japonicus*), a subspecies of the California Sea Lion, was native to Japan, North Korea, and South Korea, and shooting by fishermen played a major role in its extinction (IUCN 1978).

Commercial fishermen have been responsible for the near-extinction of the Mediterranean Monk Seal (*Monachus monachus*). Once common along the coasts of the Mediterranean Sea, and along the Atlantic coasts of northwestern Africa, this seal is on the verge of extinction, its status listed in the *2000 IUCN Red List of Threatened Species* as Critical. Although resort and industrial development contributed to its decline, shooting by fishermen has been the major cause (Nowak 1999). Many seals drown when they become entangled in fishing nets as well. In past centuries, these seals could be seen on beaches along the Mediterranean, where they would have their pups. After severe persecution, however, they began to hide in the remote caves along the coasts and on uninhabited islets (Attenborough 1987).

In 1981, Greek fishermen threatened to kill off all the remaining Monk Seals on Greek shores if they were not paid compensation for the fish the seals would eat. The Fauna and Flora Preservation Society (now Fauna and Flora International), a London-based organization, raised the money after public appeals in newspapers, which amounted to several thousand dollars.
Fishermen throughout the region became even more intent on eliminating these seals after commercial factory fishing ships began to deplete fish stocks in the Mediterranean.

In spite of legislation protecting the seals, fishermen continue to shoot these seals, which are suffering from lost food supply in most areas. The once pristine waters are now overloaded with sewage and contaminated by chemical and oil spills (Attenborough 1987). The total population of this seal was fewer than 350 in the late 1980s (Attenborough 1987). A 1996 survey found 288 animals, mainly along the African coast in the Atlantic (*BBC Wildlife* 1996). Unfortunately, the largest population in the African islands was decimated in 1998 by a die-off, apparently caused by toxic chemicals.

Mediterranean Monk Seals are extinct in Cyprus, Lebanon, the Canary Islands and Syria, and probably extinct in most other Mediterranean countries. Researchers are conducting radio tracking studies of young seals to discover breeding calves with the goal of reintroducing the seals in the Canary Islands where they have been extinct for over 400 years (*BBC Wildlife* 1996).

The attitude that seals and other fish-eating animals are depriving humans of food is prevalent in many parts of the world and has resulted in the killing of countless fish-eating mammals and birds. The Marine Mammal Protection Act (MMPA) of 1972, which prohibits killing marine mammals in US waters, allows killing of "depredating" seals and sea lions under permit. Such permits are given to kill seals destroying nets to steal fish and/or having a deleterious effect on commercial fish species through their predation. Some Alaskan fishermen, who net the largest fish catches in the world, still resent that the fish are taken by seals and other marine mammals in their waters, and illegal shooting of these protected mammals frequently occurs. Sea lions along the coasts of California, Oregon and Washington have been shot illegally by the hundreds since the MMPA went into effect, and many permits have been given for legal killing. These killings have had a negative effect on many populations of these sea mammals.

Wild Cats
While it may be difficult for most Americans to think of the regal Cheetah as vermin, in the southern African country of Namibia, cattle ranchers treat these endangered and beautiful cats as enemies, trapping and shooting, and even poisoning them. White South Africans have acquired huge landholdings to raise cattle at the expense of the environment in this arid land, fencing off large sections from native wildlife. The majority of Namibian ranchers lack compassion or respect for this graceful cat and, without any compunction, kill females, young kittens and any adult Cheetah on their properties, whether or not the animals pose a threat to their livestock. One rancher told American conservationist Laurie Marker, who is seeking to reverse this trend, that he personally had killed 160 Cheetahs on his property. Marker has taken on the daunting task of trying to convince ranchers of the importance of protecting these endangered cats.

Cheetahs are the world's fastest land animal, reaching 70 miles per hour in pursuit of gazelles, foals of large ungulates, such as zebra and, occasionally, smaller mammals, such as hares. For hundreds of thousands of years, they have adapted to changes in the environment of their once vast range, and are superbly designed as predators. In the North American Pleistocene, more than 10,000 years ago, a cheetah-like cat ranged over the continent, preying on the Pronghorn, the world's fastest hoofed animal. This cat became extinct, perhaps as a result of hunting by Pleistocene hunters.

Prior to the 20th century, Cheetahs remained common in savannah habitats south of the Sahara, and in 1900, their population may have totaled 100,000 animals. Since then, a steady decline in their populations and a shrinking of their range have placed them in endangered status. Cheetahs underwent a dramatic decline in the 1960s when spotted cat fur became fashionable. US imports were stopped when the species was listed on the US Endangered Species Act in the late 1960s, and commercial international trade became illegal when Cheetahs were included on Appendix I of CITES in the early 1970s. Killing them for the fur trade devastated their populations because they are distributed so sparsely over their range--even a kill of a few thousand in each country endangered them. Added to this, they have endured persecution by livestock herders and ranch owners, combined with loss of savannah habitat and their prey species. In areas where there are large populations of Lion and hyena, adult Cheetahs and their cubs are preyed upon by the latter predators, who also steal their kills (Hunter 1998). Trophy hunting also has taken a toll on these cats.

By the early 1970s, they numbered only 15,000, according to Peter Jackson, head of the Cat Specialist Group of the World Conservation Union (Newman 1997). Cheetah biologist Luke Hunter (1998) estimates their total population today at a maximum of 12,000 animals, with safe populations in only five or six of the 26 countries where they may be present. In parts of southern Africa, Cheetahs were numerous until a few decades ago when white ranchers fenced off thousands of square miles of grassland. Within these ranches, which cover much of the land area in Namibia and Botswana, landowners killed off predators as well as native ungulates. The once abundant wildebeests, zebras, oryx, gazelles and antelope that migrated in the hundreds of thousands in this region became reduced to scattered numbers.

Namibia, with its arid, open habitat, still has about 2,500 Cheetahs, perhaps the largest population in Africa, but at the present rate of killing by ranchers, they will be extinct there within a decade. In the 1980s, 1,000 Cheetahs were killed by ranchers, and the Namibian Cheetah population dropped about 50 percent between 1984 and 1994 (Schick 1994).

A 1997 PBS television special, fiIn the Wild,fl featured actress Holly Hunter traveling to southern Africa in search of Cheetahs. A visit to Namibia's Etosha National Park, where these cats were once fairly common, failed to find a single Cheetah, in spite of expert help from native Bushmen trackers. An outbreak of Anthrax, spread by domestic livestock, had recently occurred in the park. Some 20 Cheetahs had died, and the disease also killed elephants and other wildlife.

Marker co-founded the Cheetah Conservation Fund in 1990, and since it has been in operation, it has changed many ranchers from Cheetah-haters to Cheetah-protectors. Few knew of the Cheetah's worldwide plight, and many cooperated when informed. One successful strategy to protect livestock introduced by Marker has been the use of donkeys to guard cattle herds. These animals easily fend off Cheetahs with their powerful kicking hooves (Schick 1994). Baboons have also been trained to guard livestock because of their aggression toward Cheetahs (Schick 1994). Recommendations such as bringing cows closer to homesteads during calving season have also been made to ranchers (Schick 1994). Many ranchers did not realize that Cheetahs prey on livestock only when their own natural prey, primarily gazelles and Impalas, have become scarce because of killing or fencing by the ranchers (Schick 1994).

Within the past few years, many ranchers have been convinced to use box traps to capture Cheetahs unharmed instead of killing these cats. Marker ear-tags the animals and returns them to local protected areas (Schick 1994), or arranges to have them moved. In the early 1990s alone, 75 Cheetahs were removed from ranches where they were being persecuted and were introduced into other areas. One farmer caught a female with five cubs and wanted to keep the cubs as pets. Marker convinced him to give up the female and four of her cubs, but he insisted on keeping the largest one. Although keeping Cheetahs as pets is not good for their welfare or conservation, it is an improvement over their wholesale destruction. Leghold traps are used by some ranchers, and in 1996 Marker acquired two 3-week-old Cheetah cubs whose mother had been killed in one of these traps. They will have to remain in captivity because of their young age when orphaned.

An organization known as Africat has sponsored the capture and transport of 100 wild Namibian Cheetahs to South Africa. This organization reports that ranchers capturing Cheetahs in large box traps often sell them to breeders rather than reintroduction programs, a practice that it does not condone. Translocating adult Namibian Cheetahs to South African reserves where they had become extinct has been very successful. In one case in 1995, three males were

released in Madikwe Game Reserve where four other Namibian Cheetahs had been introduced in 1994, and all survived. A male, four females and five cubs were released in Pilanesburg National Park in 1995, and there were no fatalities (*Oryx* 1996). Most of South Africa's Cheetahs were eliminated by Boers in the 19th century, and the government is now returning them to their original range within national parks. Outside of national parks, they may be in as great danger as the Cheetahs further north.

Lions have continued to decrease in Africa south of the Sahara from a variety of factors, of which persecution by livestock raisers is a major one. Outside of national parks, these big cats have become rare or absent, and in 1996, the species was first listed by the IUCN as Vulnerable. The *2000 IUCN Red List of Threatened Species* also classified the African Lion as Vulnerable. They disappeared long ago from areas with scarce ungulate populations and large numbers of herdspeople who persecuted them, such as the arid regions of southern Africa and the sub-Saharan. In recent years, they have declined throughout the continent. Outside of parks, the Maasai and other tribes with livestock herds routinely kill Lions and other predators to protect their cattle (Hunter 1998). Lions are particularly vulnerable to persecution and hunting because, like wolves, they hunt in groups. When persecuted, they may not be able to survive hunting alone or in pairs.

Some parks are not large enough to maintain healthy Lion populations, and when they leave parks to wander in search of prey, they are often killed by ranchers or hunters. In the southern African country of Namibia, for example, the 300-mile-long, 25-mile-wide Skeleton Coast National Park skirts the Atlantic coast. Two filmmakers, Jen and Des Bartlett, chronicled the disappearance of Lions from the park. A small population of Lions inhabited the park in the early 1990s, and one pair was radio-collared by park rangers. Shortly thereafter, both Lions were shot dead by livestock herders when the Lions left the park. The Bartletts had known the female for five years, and she was pregnant with four cubs when shot. The killing of Lions to protect livestock is legal in Namibia, and with the death of the last specimen in the park, an elderly and emaciated animal shown in their National Geographic Society film, fiSurvivors of the Skeleton Coast,fl these great cats are now extinct in the area.

Wild cats have been hunted heavily and killed off throughout the Middle East. Leopards (*Panthera pardus*) still persist in small pockets, escaping detection with nocturnal hunting, and hiding in rock crevasses and trees during the day. As a general rule, wherever Leopards are seen in the Middle East, they are shot or poisoned as potential threats to the ubiquitous sheep and goats. In a few areas, such as remote portions of the Saudi Arabian Peninsula, Leopards are protected in national parks. These Leopards are very adaptable in their prey and can subsist on small animals, such as hares--unlike the Lion, which requires larger prey.

Eight subspecies of Leopards are listed on the *2000 IUCN Red List of Threatened Species*, all in Endangered or Critical categories. They range from North Africa across Asia to Java, Indonesia. Races such as the South Arabian Leopard (*Panthera pardus nimr*) of Saudi Arabia, United Arab Emirates and Yemen; North Persian (*P.p.saxicolor*) of Afghanistan, Iran and Turkmenistan; and the Anatolian Leopard (*P.p.tulliana*) of Turkey, have populations so small that they may become inbred and disappear within a few decades. The South Arabian Leopard is the focus of a conservation program organized by officials and conservationists from Saudi Arabia, Yemen, Oman and the United Arab Emirates. Only 100 to 200 of these cats survive, and they continue to be persecuted by livestock owners and hunters (*Oryx* 1996). The "Leopard Group of Arabia" was formed in 1995, and each country will prepare a plan for conservation of the Leopard, review its own wildlife legislation, conduct surveys, and make proposals for protected areas (*Oryx* 1996). This group is also working to increase populations of native prey, reduce livestock numbers in the Leopards™ habitat, and conduct public education programs (*Oryx* 1996).

Snow Leopards (*Panthera uncia*), native to the mountains of Asia, from Pakistan east to China, are endangered from hunting for pelts and as trophies, and by persecution from herdsmen who kill them as a threat to their livestock. Their total population may be as low as 4,500 or as high as 7,500 (Sunquist 1997). In their stark, rocky and high desert habitats, these cats prey upon wild sheep, goats, deer and marmots (Sunquist 1997). Their original range stretched for 4,000 miles and encompassed 1.2 million square miles in a wide arc, curving from east to west in the Himalayas through former Soviet Republics, Nepal, Pakistan, Afghanistan, Bhutan, Sikkim, and Mongolia to China, including a

total of twelve countries (Baillie and Groombridge 1996). They have disappeared from vast areas within this region, however, and continue to decline.

Until the 20th century, few herdspeople roamed these remote and forbidding regions, and Snow Leopards and their prey were left unmolested in most areas. In the past 50 years, however, human populations have risen dramatically. In western China, the government has used subsidies to encourage settlement of the western steppe, and large numbers of people have entered previously uninhabited areas with their livestock. In western Nepal, villages now dot the Himalayan slopes at 9,800 feet, and people scratch out a living from meager potato, barley and wheat crops (Sunquist 1997). Each household has only a few sheep and goats and cannot afford to lose even one to predators (Sunquist 1997).

Some 1 million Mongolian herders subsist in a barren landscape, dependent on their yaks, goats and sheep. These people, whose livestock compete with wildlife for the scarce grasses, also hunt native animals which the Snow Leopard needs to survive--Blue Sheep, ibex, deer and others. Even marmots are killed in very large numbers for their meat and skins (Sunquist 1997). When their natural prey disappears, and Snow Leopards begin to prey on livestock, herders poison, trap or shoot these cats in retaliation. In many areas, herders kill Snow Leopards as a potential threat, even when they have not lost livestock, in order to sell their valuable pelts.

Dr. George Schaller of the Wildlife Conservation Society has conducted studies on the diet of Snow Leopards and, in most areas, found less than 5 percent of livestock in their diet, based on feces analyses (Schaller 1998). As numbers of livestock in the Snow Leopard's range rise and herders penetrate further into the mountains and high pastures, livestock losses occur that sometimes result in extermination campaigns (Schaller 1998). Herding practices in these areas often encourage predation by Snow Leopards, with sheep and goats, and mares with their foals left unguarded (Schaller 1998). Depletion of their prey has increased in recent years, with government policies that encourage marmot hunting, pika poisoning and, until the late 1980s, Blue Sheep market hunting (Schaller 1998).

In Tibet, Dr. Schaller has arranged with local herdspeople to pay them for any losses they incur to Snow Leopard predation, and he has hired local Tibetans to assist in field studies of these cats, giving them a financial incentive to protect the cats. Likewise, in Pakistan, a new program organized by an American conservationist, Helen Freeman, founder of the Seattle-based International Snow Leopard Trust, has sponsored some 90 projects for the species, including many field studies. Its web page (www.snowleopard.org/islt) follows the movements of radio-tracked Snow Leopards. Gary Larson, the popular *Far Side* cartoonist, created a Snow Leopard design for the organization to use on its shirts (Sunquist 1997). Grade-schoolers all over the country have raised money by selling T-shirts for the International Snow Leopard Trust. In 1988, through the education programs and compensation for livestock losses conducted by this organization, a Pakistani livestock owner trapped a young Snow Leopard found preying on livestock, contacted the government and, before news crews, set it free. In the past, it would have been killed routinely.

The International Snow Leopard Trust and the Mongolian Association for Conservation of Nature and Environment are providing tea, noodles and clothing to livestock grazers in Snow Leopard territory in the Altay Mountains of Mongolia, with the understanding that they will protect wildlife (Schaller 1998). One village requested children's clothing, flour, candles, soap and tea, and these requests were filled (Sunquist 1997). The concept of involving local people in the conservation of wildlife is extremely important and, wherever practiced, has had beneficial long-term results for all concerned.

Bats

Bats live on every continent except Antarctica and serve extremely important ecological roles as pollinators, seed

dispersers and consumers of vast quantities of insects. Although some societies value these useful animals, many persecute all bats, based on irrational prejudice and fears of rabies. The Romanian legend of Dracula, in which a man turns into a blood-thirsty vampire bat at night and flies about seeking victims, has created a ridiculous and false impression. Real vampire bats are small, only about 3 inches in length and weighing about an ounce (Wilson 1997). The three species inhabit neotropical forests and are rare in natural habitat. Only when large numbers of livestock are grazed in an area do these mammals, who suck blood from large animals such as livestock, become common (Wilson 1997). They rarely cause the livestock harm. They are capable of transmitting disease to their host animal, but very rarely do so (Wilson 1997). Bat Conservation International has worked effectively to allay fears about vampire bats and helped many people to see them in the positive light of their value to ecosystems, economies (through pollination), seed dispersal and insect control and their interest as diverse, successful species. But Dr. Merlin Tuttle, founder and Executive Director of the organization, believes that persuading the public that bats are not to be feared is still an uphill battle, in spite of progress made in education programs (Raver 2001). Exaggerated headlines about bats and rabies tend to undo rational education programs. In fact, Dr. Tuttle says that over the past 20 years, the United States has had 1.5 human cases of bat rabies per year, hardly deserving the hysteria that so many people feel at the mere mention of bats (Raver 2001).

One positive change in recent years is the increase in people who rise to the defense of bats when newspaper stories appear about the threats of vampire bats and bat control in buildings (Garvin 1999, Gross 2000). Letters to the editor often make the point that bats are basically beneficial, and articles depicting them as fearsome enemies are misleading and cause persecution of wild bats. One article in *The New York Times* (Gross 2000) profiled a bat control professional who paid house calls when people complained of bats having entered their homes. He set glue traps, which bats blundered into and then broke their necks, and sent their bodies to a laboratory in the state capital for rabies testing (Gross 2000). Experts have found that only 1 to 4 percent of bats are rabid, and conservationists suggest that bats be set free rather than killed (Gross 2000). A more humane approach to the problem of bats in the attic was developed by Cal Kosky, a wildlife biologist with the Pennsylvania Game Commission. He tapes a piece of plastic or netting over the top of the entrance hole on the outside of the house (Raver 2001). Bats are able to fly out, but are blocked on return. A bat house is placed strategically close to the old hole to provide them with a new home (Raver 2001). Bat Conservation International has an educational video, "Building Homes for Bats," which explains how to construct bat houses to attract bats to backyards where they eat mosquitoes and other insect pests (Raver 2001).* Sensible advice can also be obtained from Dr. Tuttle's 1988 book, *America's Neighborhood Bats. Understanding and Learning to Live in Harmony with Them*.

Prejudice against bats has had serious consequences for many populations that roost in accessible places, such as open caves. The largest bat colony in the United States, located in Eagle Creek Cave in Arizona, had 30 to 50 million individuals until the 1960s, when vandals and human disturbance reduced them to only 30,000 (Wilson 1997). Several species of North American bats have become endangered as a result of deliberate killing by people, disturbance by spelunkers, and tourists entering the caves (Nowak 1999). The Gray Bat (*Myotis grisescens*) and the Indiana Bat (*Myotis sodalis*) of the eastern and Midwestern United States, for example, are both endangered as a result of these activities. Dr. Tuttle has found that the total number of Gray Bats in 22 major summer colonies declined from 1.2 million prior to 1968 to 293,600 in 1976, a loss of 75 percent (Nowak 1999). The Indiana Bat fell from 640,361 in 1960 to 459,876 in 1975; by 1993, 347,890 remained (Nowak 1999). Both species are listed as Endangered by both the *2000 IUCN Red List of Threatened Species* and the US Endangered Species Act. In Europe, the Pond Bat (*Myotis dasycneme*), a related species, has been reduced to only 3,000 in western Europe and fewer than 7,000 in its entire range (Nowak 1999). It is listed as Vulnerable by the IUCN. Many other European myotis bats also have declined to Endangered or Threatened status from habitat loss, disturbance of hibernating colonies in caves and mines, and blocking up of nursery sites in large buildings, such as cathedrals and castles (Nowak 1999). Rather than killing bats that roost in buildings, or blocking up entries, Bat Conservation International encourages the placement of bat houses nearby, which the bats tend to occupy instead. Similar efforts are needed in Europe. Even when allowed to roost in buildings, many bats are poisoned by chemicals used to treat wood in western Europe (Nowak 1999).

Bat caves are often vandalized when bats hibernate in the winter. Vandals enter caves and knock semi-conscious bats

to the ground, killing them by the thousands, or even millions. Even entering a hibernation cave can result in mortality because disturbances can arouse them and they use up so much stored energy that they do not survive the winter (Wilson 1997). Many bat caves now have gates that allow bats to fly through the open grating, but keep people out; they have helped protect important bat hibernation areas where bats from large areas congregate (Wilson 1997).

The importance of bats as pollinators is discussed at length in *The Natural History of Pollination*, by Michael Proctor, Peter Yeo and Andrew Lack (1996). Many types of flowers have evolved to be pollinated by bats, opening only at night. Their internal pollen-carrying structures are designed to drop pollen on the bat's face when it feeds on nectar (Proctor *et al*. 1996). A great variety of bats and plants coexist, perfectly adapted to one another. Dr. Tuttle's dramatic photos of many such flowers have been published in *National Geographic* magazine and in the useful book, *Bats in Question. The Smithsonian Answer Book* (Wilson 1997). He also has made films of bats for nature documentaries. Many bats are extremely attractive, and their sonar is so complex and sensitive that it is only partially understood by scientists. *Walker's Mammals of the World*, by Ronald Nowak (1999), is another important source of information on bat biology, taxonomy, behavior, conservation and related subjects.

After rodents, bats have the greatest number of species of any mammals, with the most diversity in tropical areas. The number of threatened species has increased dramatically over the past decade as a result of persecution, killing for food, pesticides and other toxic chemicals, and loss of their habitat (see Appendix for list of threatened species). The majority of species at risk suffers from a combination of these factors.

Birds of Prey

Birds of prey have been persecuted for hundreds of years in Europe and other parts of the world, usually as suspected predators of chickens or small livestock, such as goat kids or lambs. In most parts of the world, they still are given no official protection.

Hawks, eagles, owls, falcons and other birds of prey that breed in North America were excluded from the 1918 Migratory Bird Treaty Act (MBTA), signed with Great Britain on behalf of Canada. The Treaty covered almost all other species of native birds, banning hunting and killing as well as harassment and destruction of nests. This exposed birds of prey to continued indiscriminate shooting for sport, hunting from aircraft, poisoning and even capture in pole traps, which catch birds by the feet and hang them upside down in nooses.

Populations of birds of prey that breed in Canada and the northern United States migrate south during the fall, some to Latin America and others to southern states. Flying along thermal wind currents, they funnel into flyways as they pass through mountain chains. In the eastern United States, thousands of hawks, and a smaller number of eagles and falcons, pass over the Allegheny Mountains of Pennsylvania during October, November and December every year. Kittatinny Ridge, near the town of Kempton, came to be known as Hawk Mountain because of the huge numbers of birds of prey passing near it. For generations in the 19th and early 20th centuries, hunters gathered every fall on the rocky ridge to shoot these birds by the hundreds as they soared by. Dead hawks, falcons and eagles accumulated in huge piles, while wounded birds staggered around or lay helplessly immobile on the ground (Brett 1973).

This carnage was considered a form of sport, justified by old prejudices. Rosalie Edge, an ardent conservationist, spearheaded the movement to stop this hunt in the 1930s (Brett 1973). This courageous woman publicized the slaughter of birds of prey, and after a campaign in which she enlisted the help of influential conservationists, she succeeded in purchasing the mountain as a sanctuary (Brett 1973). Edge persuaded an ornithologist, Maurice Broun,

and his wife, to oversee the sanctuary and prevent hunting. They remained on Hawk Mountain for 32 years and served as guides for the more than 40,000 visitors who come every year to see the spectacle of hawks flying over and alongside the mountain ridge (Brett 1973). Rosalie Edge died in 1962, but the sanctuary continues as a non-profit organization staffed with ornithologists, educators, and volunteers, who chronicle by species and number the birds that fly past the ridge.

Hawk Mountain Sanctuary is one of the country's first examples of private ecotourism, and it has accomplished a great deal in teaching the public about birds of prey as useful animals in ecosystems, as well as providing exciting views of these birds as they soar past the ridge. In the morning, before the thermal winds warm up, hawks fly at low elevations, giving visitors a view of their tails and backs from above, an especially colorful sight in the case of the Red-tailed Hawk (*Buteo jamaicensis*), while in the afternoon, they fly higher, transported along by the thermals. Sometimes a visitor to Hawk Mountain can see a hawk or other bird of prey at close range, only 15 or 20 feet away, as they fly close to the ridge, the intricate patterns of their feathers in full view.

In spite of the preservation of Hawk Mountain and several other key hawk habitats, legal protection from hunting did not come in the United States until 10 years after the death of Rosalie Edge. During these years, thousands of hawks and other birds of prey were shot because of ignorance or as sport. Little was understood about their value in controlling rodents and rabbits. In 1960 alone, 12,000 Golden Eagles (*Aquila chrysaetos*) were killed in Texas in a massive campaign to eliminate them. A major victory for birds of prey was their addition to the Migratory Bird Treaty Act in 1972. The bans on hunting that have protected other native land birds were finally accorded these raptors. This was carried out through a memorandum enacted with Mexico, which had signed the Migratory Bird Treaty Act in 1936. It prohibits, except as allowed under specific conditions, the taking, possession, purchase, sale, or bartering of any migratory bird, including the feathers or other parts, nests, eggs or migratory bird products. "Taking" is defined as pursuing, hunting, shooting, shooting at, poisoning, wounding, killing, capturing, trapping, or collecting migratory birds. Individuals and organizations may be fined up to $5,000 and $10,000 respectively, and those convicted may face up to six months imprisonment for misdemeanor violations of the Act. Felony violations may result in fines of up to $25,000 for individuals and $500,000 for organizations and up to two years imprisonment for those convicted. This strong legislation has not stopped the killing of birds of prey altogether, but it has deterred the type of slaughters that were once common.

Although Bald Eagles were revered by native tribes, especially those in the Pacific Northwest, they became victims of prejudice by European colonists, who accused them of damaging fish stocks. A bounty in Alaska resulted in the killing of some 150,000 of these eagles between 1917 and 1953. This species is the national bird, the official symbol of the United States of America, yet historically it has been given little respect. Some even called them "gangster birds" because they were thought to be scavengers of fish caught by other birds. In truth, they are superb fishers with extraordinarily keen vision and are acrobatic in flight. Bounty programs and random shooting of Bald Eagles from colonial times onward caused these birds to disappear from much of their original range, which encompassed the entire continent of North America, including arid regions in the Southwest.

The Bald Eagle Protection Act was enacted in 1940 to protect it from extinction, and amended in 1962 to extend protection to Golden Eagles, primarily to protect immature Bald Eagles, which resemble them. A 1972 incident involving the slaughter of hundreds of Golden Eagles by western ranchers shooting from aircraft resulted in increasing fines under the law from $500 to $5,000 and/or one year imprisonment for subsequent offenses. The amendments also specifically included poisoning in the definition of taking, since both Bald and Golden Eagles had been poisoned by ranchers. These amendments also included the same high penalties for possession of eagle feathers, nests or eggs, and made federal grazing permits subject to cancellation for violations of the Act. In addition, they added a new facet to the enforcement of the Act: one-half of any fine can be paid to a person who provides information leading to a conviction. To augment this protection, the Airborne Hunting Act was enacted in 1972 to prevent the killing of wildlife from aircraft.

After 1973, the killing of a Bald Eagle constituted a violation of the US Endangered Species Act, the Bald and Golden

Eagle Protection Act, and the Migratory Bird Treaty Act, the combined penalties of which could amount to long jail sentences and very high fines. In spite of all these legal steps taken to protect eagles, killings continue. Many are deliberate and carried out in remote areas where there is little fear of prosecution, and others are done by hunters ignorant of the law or the identity of their targets. The protection of native birds, their identification, and laws applying to them should be taught in schools in North America, but such information is usually acquired by chance if at all. Each year, 300 to 400 eagles--Bald and Golden--are found dead. In some cases, hunters still believe folklore about birds of prey being destructive, and shoot them intentionally. A Bald Eagle shot in Maine in 1994 was killed by an 85-year-old man who deliberately killed the bird because he believed these birds were killing geese. He told game wardens that they should "do something about the eagles;" because of his age, he was only given a $2,500 fine, which was suspended. Bald Eagles feed mainly on fish and are not major predators of waterfowl.

Although the majority of eagles are killed when shot, many are found wounded, some in emaciated condition, unable to fly to obtain food and near death. One such Bald Eagle was found crippled in 1983 in Georgia, having been shot in the wing. He had been on the ground for a week, his wing bone exposed. In spite of attempts to save his wing, veterinarians had to amputate it because of infection, and the eagle was taken into a rehabilitation program. Named Osceola, he has played an important role in Wings of America, an education program at Dollywood in Tennessee. John Stokes, Osceola's caretaker, teaches children and adults about the effects of such shooting, stressing the impoverished life that Osceola leads, unable to fly and be free. Stokes decided to bring Osceola along on his hang-gliding trips to treat the bird to some of the sights the eagle had not seen in the many years since being shot. Harnessed into a specially made sling, the pair hang-glided, with Osceola positioned above Stokes, looking intently at the ground far below, turning his head frequently in apparent fascination. The film of Osceola hang-gliding was shown on nationwide television in 1996, and some 500,000 people attend lectures featuring this maimed eagle every year. The National Audubon Society series for young people, "Audubon's Animal Adventures," featured Osceola in the program entitled "Eagle Adventures," shown on the Disney channel.

In the past, it was impossible to prosecute offenders unless there were witnesses or other direct evidence to the killing. Today, a state-of-the-art forensic laboratory run by the US Fish and Wildlife Service in Washington state is able to necropsy dead eagles for cause of death. If shot, ammunition extracted from the birds is analyzed forensically, and cases are made with as much precision and scientific evidence as criminal investigations in which people are the victims.

Prejudices against birds of prey still persist among many who wrongly believe that they harm wildlife or present major threats to domestic animals. Biological studies have documented their ecological importance as major controls on rodent populations. Some birds of prey feed on snakes, insects or other potential pests. No species of raptor poses a significant threat to domestic animals.

The continent's densest population of birds of prey breeds in the craggy canyons and sagebrush shrubland of Idaho. This area has been set aside as the Birds of Prey National Conservation Area, lining 81 miles of the Snake River and covering 485,000 acres. Prior to its protection, this land was in the process of being converted to agriculture. The birds of prey had begun a steep decline from shooting and loss of habitat. Conservationists faced strong opposition to the plan, but overcame it, establishing this area in 1971, a year prior to the inclusion of birds of prey on the Migratory Bird Treat Act. It has since become a leading ecotourism destination for rafters and hikers, who are led on tours by naturalists from the Bureau of Land Management (BLM), which oversees the refuge. Fourteen species of raptors breed in the area or migrate through it, and the breeding population of hawks, eagles, owls and falcons has been estimated at 800 pairs. They provide exciting views of high-speed hunting of ground squirrels and birds, and their eerie shrieks resound through the canyons.

Waterfowl hunting is regulated by the Migratory Bird Treaty Act under regulations by the Fish and Wildlife Service. Unfortunately, the regulations have serious shortcomings that have resulted in many shootings of birds of prey. First, hunting can begin before dawn, when hunters are unable to identify birds by species. Each year, hundreds of birds of prey, including such endangered species as Peregrine Falcons, are shot accidentally. Second, the regulations do not

require that hunters be able to identify birds by species, including protected and endangered species. Since many ducks and geese are extremely difficult to identify, the failure of the Fish and Wildlife Service to require hunters to pass identification tests and begin hunting well after daybreak means that protected and endangered birds will continue to be shot.

In October, 1995, a Peregrine Falcon (*Falco peregrinus*) shot in Massachusetts was migrating south from Canada or Greenland during hunting season. It suffered neurological damage after being shot in the left wing while it was flying in a wildlife refuge area. The Assistant Director of the State Division of Fisheries and Wildlife, Tom French, stated that it appeared that the bird was not shot accidentally. This was the second shooting of a Peregrine Falcon in as many years. The reintroduction of captive-bred specimens of these birds into the eastern United States has been a success, with over 130 nesting pairs. Their long-term survival, however, will depend on adherence to laws prohibiting shooting or harming them.

For the future, the Migratory Bird Treaty Act would be far more effective if signed with Latin American and Caribbean nations to protect North American birds wintering in those countries. This would be especially important in view of the decline in many of the continent's birds of prey, which are persecuted and killed by pesticides and poisons in their wintering grounds.

The California Condor (*Gymnogyps californianus*), North America's largest bird of prey, once soared over most of the continent. Its bones have been found among Florida's Pleistocene fossils, and 20,000 years ago, it was very common and widespread, feeding on the carrion of mastodons, bison and other large mammals. This giant bird's superb aerodynamic flight makes the most sophisticated man-made aircraft look clumsy by comparison. Condors have a positive role to play in ecosystems, feeding on carcasses and thereby ridding the environment of these potentially infectious contaminants. Although they declined in range over the centuries, condors were still widespread from Baja California, Mexico, north to Washington state, where Lewis and Clark saw them along the Columbia River in the early 19th century. They were often observed scavenging seal and whale carcasses along the California coast, and they nested as far east as the Sierra Nevada Mountains.

Settlers looked on condors as large targets, with their 10-foot wing span, and perhaps thought they were predatory birds. Hundreds were shot. These birds feed exclusively on carrion and do not hunt live animals. When word spread in the last years of the 19th century that the condors were approaching extinction, egg and specimen collectors preyed on the remaining birds. Between 1881 and 1910, 288 birds were killed as museum specimens (ICBP 1981). By the turn of the century, only a few hundred birds remained, yet killing was still legal. The ornithological journal *The Condor* began publication at this time and recorded many instances of these killings. In one case, an individual named Frank S. Daggett reported shooting a California Condor in 1901, wounding it in the wing and then, when it fell to the ground, shooting it three more times, still not killing it. Finally he clubbed it and shot it yet again before the bird died (Daggett 1901).

The California Condor continued its decline until only 60 birds remained in 1939 (Greenway 1967). The last population survived in a wilderness area of southern California. In spite of legal protection and the establishment of the Sespe Condor Refuge, the birds suffered high mortality from shooting, ingestion of lead shot from deer killed by hunters, feeding on animals killed by predator poisons, collisions with power lines, and accidental capture in leghold traps. Biologists from the Fish and Wildlife Service and the National Audubon Society were assigned to study and protect this small population in the 1960s and 1970s, but they did not publicize its precipitous decline or insist on further protection from the threats that continued to kill these birds. As these birds headed toward imminent extinction, nothing was done to stop deer hunting in their refuge, nor to prevent the use of steel jaw leghold traps or predator poisons in their diminishing range.

One of the last nests was in a regal setting befitting this massive bird: a huge natural hole in a giant, old Sequoia tree. The eggs from this nest and others were taken by the Fish and Wildlife Service for captive hatching. In 1980, one of the last wild chicks hatched in a cave and was being weighed and tested by biologists when it suddenly died. It had

been handled for more than an hour, during which time it repeatedly hissed and jabbed at the researcher. Later it was revealed that shock caused its death. The incident was filmed and shown on national television, resulting in the cancellation of the recovery program by the state of California, followed by a long period of re-evaluation and controversy. By 1981, the state reached an agreement with the Fish and Wildlife Service to allow capture of the last nine California Condors, but the program was delayed by lawsuits and wrangling over details. By the time it was finally decided to capture all remaining condors in 1987, only six survived (BI 2000).

The sad decision to remove all wild California Condors turned out to be the correct path to preserve the species, since its wide-ranging behavior exposed it to countless perils that were beyond the control of its protectors. To the amazement of many, the captive-breeding program succeeded beyond all expectations. The eggs laid by the captive condors were artificially incubated, and chicks were fed by workers, with puppets resembling adult condors covering their hands. So many birds were captive-bred at special facilities run by the Los Angeles Zoo and other breeding centers that by 1992, a reintroduction program began with release of captive-bred birds into the wild in southern California. Some of the released birds died after striking electric power wires or were injured and had to be returned to captivity. Several landed in suburban locations, perching on the decks and roofs of private homes and even, in one case, entering someone's home. Most residents did not recognize the birds™ great rarity and protected status, and put out food, such as hot dogs, for them. Finally, wildlife authorities and television news stations learned about the situation, and many Californians became aware of these giant and extremely rare birds. To many ornithologists, the behavior of these young condors indicated that the birds were tame and considered humans a source of food. The puppets apparently had not fooled them into thinking they were being fed by parent birds.

By July 1994, California Condors numbered 89 birds, 85 of which were in captive-breeding facilities, and four released birds (Collar *et al*. 1994). Six young condors were released in the Grand Canyon area in late 1996, with Fish and Wildlife Service personnel staying close to provide food and to radio-track the birds. Within a short time, one of the condors was killed by an eagle, an unexpected setback. The total California Condor population grew to 120 birds by early 1997, and only a year later it had increased to 147 birds, of which there were 97 in captivity, 28 returned to the wild in California's Los Padres National Forest, and 22 released in Arizona (BI 2000). The released birds are provided with livestock carcasses until they are able to find food on their own. The success of this program has not yet been proven by breeding in the wild, as all released birds are too young. Only time will tell whether these birds survive and reach the goal of 150 birds in separate populations. They are being trained to avoid some of the sources of mortality that killed them in the past, such as power lines, but as long as lead shot is used in deer hunting in their range, this will remain a potential threat to them.

Elsewhere in the world, birds of prey receive little or no protection from persecution. In Italy, shooting of migrating birds of prey has long been a "sport" in which gunners position themselves in concrete bunkers on hillsides and kill hawks, falcons and eagles as they fly by. One woman decided to fight the hunters and worked successfully for an official ban on shooting these birds. In spite of this, illegal shooting takes place in Italy, and every year during the migration season, conservationists from many parts of Europe come to help her enforce the ban. The campaign to stop hunting of these birds was described in a film, fiAnna and the Honey-Buzzardsfl (see Video section). In Australia, persecution of eagles and hawks is rampant. After shooting these birds, especially Wedge-tailed Eagles, they are often nailed to fence posts with their wings spread. Few of the ranchers who kill thousands of these birds seem aware of the important role they play in controlling rabbits.

Snakes

The prejudice against snakes may be traced in some cultures to the Biblical story of Adam and Eve, in which the snake represents the evil temptor. For many, snakes inspire great fear and loathing, and they are often killed upon sight. In the American West, rattlesnake hunts are carried out in many towns as an annual event, with thousands of

snakes captured. After being prodded and manhandled, they are killed, often by being skinned alive. The New Mexican Ridge-nosed Rattlesnake (*Crotalus willardi obscurus*) is a threatened species on the US Endangered Species Act, persecuted and overcollected in its limited range. In Eastern states, especially in the South, snakes are also hunted for sport, burned alive with gasoline poured down their dens, and killed in bizarre religious ceremonies. One town in Georgia has an annual war on rattlesnakes, killing as many as possible. For some species, this has resulted in serious declines. The Eastern Timber Rattlesnake (*Crotalus horridus*), the largest snake native to the United States, inhabits forested areas with rock faces, crevices and caves in the Northeast. It has become threatened in many parts of its range. These snakes, which range in size from 35 to 74 inches in length, are vulnerable to persecution because they congregate in large numbers in rocky dens and overwinter with other types of snakes for warmth. They hide under rocks where hunters and collectors find them. Timber Rattlesnakes are long-lived, known to survive 30 years or more. Females give birth only every other year, do not mature until age 4 or 5, and have only 5 to 17 young (Behler and King 1979). With such slow reproduction, they are vulnerable to declines when hunted.

This species has legal protection from hunting in Pennsylvania and New York and is listed on their state endangered laws, yet hunting still kills hundreds each year. One rattlesnake hunter, profiled by CNN, bragged that he had captured 9,000 Timber Rattlesnakes in his lifetime and planned to continue openly flouting laws protecting the species. He claimed that he enjoyed catching and killing these snakes so much that he would never stop, and some herpetologists accuse this man of single-handedly causing declines. He has been arrested many times and jailed for trading in endangered species, but refuses to stop. These snakes do not pose a threat to people unless they are sought out in their retreats.

Biologists point out that snakes are extremely useful ecologically, feeding on squirrels, mice, rats and other rodents, but since laws in the United States and around the world either fail to protect snakes or are not enforced, snakes often are persecuted and killed senselessly.

Rodent Control

Prior to settlement of North America, prairie dogs of many species inhabited towns of burrows that covered some 98 million acres of shortgrass prairies, from southern Canada to Mexico. One prairie dog town in the Texas Panhandle stretched over 25,000 square miles and held an estimated 400 million animals (Dold 1998). Prior to the 19th century, they are thought to have numbered 5 billion animals (DeBlieu 1993). These towns have since been destroyed, the prairie dogs killed, and the habitat used for agriculture, pastureland and development. A keystone species, prairie dogs create habitat for hundreds of other animals who live in their complex burrow systems. These rodents have been driven to endangered status after centuries of persecution and poison campaigns that were based on the belief by cattle ranchers that prairie dogs ate too much grass, depriving cattle of fodder. The US government sponsored the destruction of prairie dog towns beginning in 1900. The poisoning program was bolstered by inaccurate information from the US Biological Survey, which stated in 1902 that prairie dogs decreased productivity of grasslands by 50 to 75 percent (Dold 1998). Poison bait was distributed in the towns, gasoline was poured into their burrows and set afire, and they were shot by the thousands. A highly toxic poison, 1080, was used from the 1960s on, devastating prairie dog towns and killing vast numbers of animals, from foxes to Golden Eagles, who fed on the poisoned prairie dogs. This reduced prairie dog habitat to about 1.5 million acres, a fraction of their original range.

Modern biological research has unveiled the truth about the effect of these rodents on grasslands. Rich Reading, Director of Conservation Biology at the Denver Zoological Foundation, stated flatly that the Biological Survey's figures claiming that prairie dogs reduced grass by up to 75 percent, were "vastly in error" (Dold 1998). Studies by Dan Uresk, a Forest Service biologist, have concluded that prairie dogs eat only a small percentage of grass--from 4 to 7 percent (Dold 1998). James Detling of Colorado State University in Fort Collins has found that prairie dogs are natural fertilizers, whose incessant grass clipping increases the protein content and digestibility of grass (Long 1998).

Other studies have examined the claims of cattle ranchers against prairie dogs and have demonstrated again and again that these rodents actually improve forage quality for livestock and, by cropping the shortgrass prairie, stimulate it to grow, increasing the amount of grasses around the towns (Wuerthner 1996). The American Bison prospered in herds of 50 million, much of the species range lying within prairie dog towns of the short-grass prairies. Their major predator, the highly endangered Black-footed Ferret (*Mustela nigripes*), has been eliminated in the wild as a result of poisoning and shooting campaigns. At least 130 grassland species are associated with prairie dog towns (Godbey and Biggins 1994), and up to 170 vertebrate species have been seen in these towns.

Another complaint of cattlemen, that cattle fall into prairie dog burrows and break their legs, has also been refuted. Don Sharps, a wildlife consultant, asked an audience of 200 ranchers if any of them knew of a case of a horse or cow that had broken its leg in a prairie dog town, and no one said yes (Dold 1998). Such prejudices are passed down from generation to generation and fuel the persecution programs against these ecologically important rodents.

Slow-acting poisons, such as zinc phosphide, are used by many animal damage control programs. This chemical takes up to 12 hours to kill prairie dogs, who suffer extremely painful deaths (Wuerthner 1996). Another technique is the placement of gas cartridges in prairie dog burrows. These are ignited and burn the prairie dogs alive (Wuerthner 1996). On federal lands, these programs are conducted by the Wildlife Services unit of the Department of Agriculture at public expense. In the 1980s, more than $6 million was spent to eradicate 460,000 acres of dog towns on the Pine Ridge Indian Reservation in South Dakota (Line 1997). This was the largest remaining prairie dog town in the United States (Dold 1998) and the site of the only population of Black-footed Ferrets known to exist in the 1970s. In 1993, Animal Damage Control (now called fiWildlife Servicesfl) used, sold or distributed 220,000 fumitoxin tablets, 60,000 gas cartridges, and 21,000 pounds of zinc phosphate baits in the northern plains states to eradicate prairie dogs (Wuerthner 1996).

Studies about prairie dogs have revealed them to be surprisingly intelligent. They communicate in yips and chirps, some of which are warnings to other members of the town. A study by Professor Con Slobodchikoff of Northern Arizona University has revealed that prairie dogs™ calls convey specific information, such as what size a predator is, what type of animal, its speed of travel and level of threat (Dold 1998). Slobodchikoff created experiments in which two people walked through a prairie dog town that had experienced hunting; one carried a simulated rifle, while the other did not. The prairie dogs gave different calls for each person, and when the "hunter" returned in a few weeks without his rifle, they still gave the call for a man carrying a rifle (Dold 1998). Such communication goes far beyond what most people consider rodents to be capable of and shows their ability to react to a variety of threats, including the most serious one, human beings. Unfortunately, their warnings could not protect them from poison, shooting, and even bulldozing of their burrows.

Knowledge about the true role that prairie dogs play in grassland ecosystems has yet to reach most ranchers and others who have a hatred for these rodents that seems to reach no bounds. Many compare notes on how many prairie dogs they have killed, usually by high-powered bullets that cause them to disintegrate on contact (Long 1998). One group in eastern Colorado with 30 members calls themselves the Varmint Militia and kills prairie dogs as a sport. They recently spent two full days shooting prairie dogs until activity in the prairie dog town slowed (Long 1998). One militiaman bragged of having shot 20,000 prairie dogs and wants to retire from his exterminating business to shoot them full time (Long 1998). These shooters recount with glee the story of a recent protest. Some animal rights protesters tried to stop one of these hunts and chained themselves together, refusing to move; the Varmint Militia called the Kit Carson County sheriff, who placed them in jail for the weekend (Long 1998).

Although private shooting may be difficult to stop, many biologists and conservationists have recommended that all government poisoning and shooting on public land be halted and that subsidies be offered to ranchers who do not kill prairie dogs on their property (DeBlieu 1993). Unfortunately, no action has been taken in this direction.

Sport hunting of these rodents is encouraged by state game departments, and many towns organize hunts as a form of recreation. These hunts, which often involve the killing of hundreds of prairie dogs in a single afternoon, are taking a

high toll of these declining animals in many areas (Wuerthner 1996). A South Dakota organization, Varmint Hunters Association, brags that its 45,000 members do society a favor by killing prairie dogs. The vice president, Marc Minkin, told a reporter, "I'd like to be able to step out my back door in the morning and take a couple of shots before my morning coffee" (Dold 1998). The organized prairie dog shoots draw "hunters" from around the country; one hunt held in Nucla, Colorado, obliterated an entire town (Dold 1998). This hunt, which involves taking pot shots at prairie dogs emerging from their burrows, which they must do to feed, is totally unsportsmanlike--a virtual slaughter.

Even in national parks, poisoning takes place as a result of pressure from neighboring ranchers. In spite of abundant habitat in Theodore Roosevelt National Park, Badlands National Park, Wind Cave National Park and various national monuments in the Great Plains, only 6,000 acres of prairie dog towns have been protected (Wuerthner 1996). In most cases, park authorities have been threatened with lawsuits unless they poison prairie dogs. In South Dakota, home of Badlands National Park, a prime potential area for reintroduction of the endangered Black-footed Ferret, the state has declared prairie dogs to be noxious pests and mandates their control (Long 1998). At Devils Tower National Monument in Wyoming, the park rangers use rifles and poison to thin the ranks of its prairie dog colony (Long 1998).

Increasingly, development in the form of housing complexes, malls, highways and industrial centers, has gobbled up millions of acres of land in the West, much of it inhabited by prairie dogs. Some developers merely bulldoze the towns, while others pay to have a company use a giant vacuum cleaner that sucks prairie dogs out of the ground amid deafening noise similar to that of a jet airplane taking off. The proud inventor of this machine bragged that it was non-lethal, and the rodents could then be killed humanely or otherwise disposed of to allow development programs to proceed. In fact, most of the prairie dogs taken in this manner are killed or injured in the process (Dold 1998). The trauma involved for the prairie dogs must be extreme. Many of the prairie dogs removed from their burrows have been offered for sale as pets, advertised in eastern newspapers. Although loveable and cute, these animals are not suitable house pets because they are wild rodents who require extensive dirt to burrow in. They cannot adjust to the unnatural environment of a home. Unfortunately, this new invention has been given favorable publicity in the media. The majority of prairie dogs that survive this operation end up as pet food, according to CNN (December 15, 1996).

A more humane program involves the moving of prairie dogs to safer environments. A Colorado organization, Prairie Ecosystem Conservation Alliance, hoses prairie dog burrows with water and a biodegradable dish soap that creates frothy suds below ground. The suds irritate the eyes of the prairie dogs, who come to the surface where members of the Alliance are waiting to scoop them up and place them in carriers. They then truck them to a safe area, preferably one with empty burrows, and release them (Dold 1998). An even better solution is to save the towns, since the latter method will not save all the other animals inhabiting the burrows. The city of Boulder, Colorado, became the first town in the state to officially designate land to protect prairie dogs. In 1987 it set aside a preserve for prairie dogs, which now covers almost 5,000 acres (Dold 1998). Fort Collins, further north, began with a reserve of 268 acres and now has 1,700 acres (Dold 1998).

A Native American Gros Ventre tribesman, Mike Fox, has come full circle, from sponsoring prairie dog shoots on the Fort Belknap Indian Reservation in Montana to understanding their positive effect on grasslands by watching Bison graze near the towns on the "best grass around" (Long 1998). There are 400 American Bison on the reservation, and Fox, who manages the reservation's wildlife program, has sharply curtailed prairie dog shooting and accepted 23 Black-footed Ferrets to be reintroduced into the 500,000 acres of prairie on the reservation (Long 1998). He tells Indian ranchers, who still kill prairie dogs, that these animals were here before, and the ferret is not a new animal, but an old one returning (Long 1998).

All but 2 percent of original prairie dog populations are now gone, having been poisoned out to make way for livestock or agriculture. The majority of remaining towns are still unprotected, and the poisoning continues. Grasslands with prairie dogs support far higher densities of mammals, birds and other wildlife than those without them.

Several prairie dog species have been driven to near extinction. The Utah Prairie Dog (*Cynomys parvidens*), native to

south-central Utah, became endangered from these programs and the loss of habitat to livestock and agriculture. Listed on the US Endangered Species Act, this species has a restricted range in southwest Utah, and after poisoning programs, its population fell from an estimated 95,000 animals in 1920 to only 3,300 in 1972 (Nowak 1999). Through protection accorded by the US Endangered Species Act, Utah Prairie Dogs began to rebound, and by 1984, the species was downgraded from Endangered to Threatened on the US Endangered Species Act. Populations of prairie dogs fluctuate widely, and counts of Utah Prairie Dogs in the early 1990s ranged from 6,400 in the fall to 24,000 after they had pups in the spring (Nowak 1999). The species has recovered somewhat overall, mainly as a result of the Fish and Wildlife Service program of transplanting prairie dogs from private to public lands (Turbak 1993). Initially, many of the released prairie dogs failed to survive, and not until they began releasing males in the spring, who industriously spent the summer excavating burrows to accommodate other prairie dogs released in the fall, did transplants succeed (Turbak 1993). Utah Prairie Dogs hibernate each winter in compartments in the complex maze of their underground tunnels.

Although some Utah Prairie Dogs have been placed on public land, 60 percent of them still live on private land, where special US Endangered Species Act regulations allow farmers and ranchers to shoot or trap an annual quota of prairie dogs; a high of 6,000 were killed one year, and in 1992, 1,543 were killed (Turbak 1993). Education campaigns and tax incentives to protect prairie dog towns would be far preferable to quota systems.

Mexican Prairie Dogs (*Cynomys mexicanus*) of southern Coahuila and northern San Luis Potos, Mexico, have declined as their habitat has been converted to agriculture and grazing land for livestock, and many colonies were exterminated by poisoning. The largest remaining town covers only 4,400 hectares (Nowak 1999). The species is listed as Endangered by the US Endangered Species Act as well as by the *2000 IUCN Red List of Threatened Species*.

A third species, the Black-tailed Prairie Dog (*Cynomys ludovicianus*) has declined by 98 to 99 percent (Wuerthner 1996) in a range which once extended from Montana and southern Saskatchewan to northern Mexico (Nowak 1999). The Biodiversity Legal Foundation in Colorado filed a petition in October 1994 to list it as a Category 2 species under the US Endangered Species Act, a category just below Threatened. Although the Fish and Wildlife Service's own biologists supported this listing, the petition was denied after political pressure from ranchers (Wuerthner 1996).

Thus, at least three of North America's five species of prairie dogs are in grave danger of extinction, and the remaining two have declined precipitously. Their ecosystems are threatened as well, as are many of the species that depend on them. Although they are extremely photogenic and likeable, prairie dogs are not ecotourist attractions at present. With protection and more publicity, such as nature films and education programs, they could become so, and this would enhance their conservation.

Conservationists have proposed some huge reserves for prairie dogs that would link remnant populations in parts of the West, where much of the land is now under the control of the Bureau of Land Management of the Department of the Interior. The latter department favors cattle ranchers more than prairie dogs, but with outside pressure and publicity, such a plan might become reality. The Fish and Wildlife Service has had difficulty locating prairie dog towns that are protected from poison programs in which to reintroduce captive-bred Black-footed Ferrets.

For their long-term survival, prairie dogs need extremely large territories. At present, fragmented populations, which are often reduced to a few hundred animals widely separated from the nearest prairie dog town, have lost viability from lack of genetic interchange, and some scientists fear that their natural behavior may be altered by this isolation. These loveable animals need more friends to speak out on their behalf and demand that they be protected from poisoning, "sport" hunting and other persecutions, and that sanctuaries be established.

Economically, they may be worth far more alive than dead. The potential for using prairie dogs as a focal point for ecotourism is great. Tourists would be delighted by their behavior and fascinated to see the rich wildlife that inhabits their towns.

Trophy and Sport Hunting
During the late 19th and early 20th centuries, wealthy European and American big game hunters traveled to Asia, Africa and South America to "bag" large animals that they proudly displayed as stuffed animals and heads mounted on the walls of their homes. Maharajahs of India and British hunters took what Vincenz Ziswiler (1967), in his interesting book, *Extinct and Vanishing Animals*, describes as "a morbid pleasure in killing." Lord Ripon, an Englishman who died in 1923, was credited with killing 500,000 game birds and mammals--about 67 creatures for every shooting day of his life (McClung 1976).

One maharajah turned away from hunting and became a famous conservationist. Brajendra Singh, the last Maharajah of Bharatpur, hosted hundreds of hunts on his estate at the Keolada Ghana marsh 100 miles south of Delhi. A shoot organized by an English lord resulted in the killing of 4,323 ducks by 39 hunters in one day. In 1970, Brajendra Singh converted the duck shoot marsh into India's best known bird sanctuary. Singh died in 1995, having presided over the preservation of this vast marsh and its rare resident birds.

Trophy and Sport Hunting: Page 1
The most prestigious trophy for maharajahs and colonial hunters was the Tiger (*Panthera tigris*), largest of all cats. One maharajah shot at least 1,000 Tigers in his lifetime, while another complained that his total bag of Tigers was only 1,150 (McClung 1976). The number of Tigers killed by these two maharajahs equaled the entire population of these cats in India by the late 1960s. Tiger hunts were a royal pastime and employed hundreds of native "beaters," who drove the frightened cat toward a hunter who was perched safely atop an elephant.

Tigers require large territories. Even in the best habitats, their natural density is low. They probably once numbered 50,000 in India alone, however, when forests covered much of the country. Tigers were hunted to extinction on the Indonesian islands of Java and Bali, where each was a separate subspecies, and they have been hunted to endangered status on Sumatra. In the western portion of their range, the Anatolian or Caspian Tiger (*Panthera tigris virgata*) once ranged from Turkey eastward through the Caspian Sea region of Central Asia. Hunting eliminated these Tigers in Central Asia centuries ago, and only a few isolated populations remained in Turkey by 1900. The last individuals in Turkey were shot in 1972. This subspecies was driven to extinction by trophy hunting and persecution by livestock owners. By the 1960s, Indian Tigers were endangered, yet trophy hunting and killing by livestock herders for the fur trade continued. Indian President Indira Ghandi established a conservation program called Project Tiger in the 1970s, which set aside many reserves and accorded strong legal protection. When the species was beginning to increase in numbers, a trade in their body parts for Traditional Chinese Medicine reversed this recovery.

Today, fewer than 5,000 Tigers remain in the wild. At the present rate of killing--one Tiger per day--the species will become extinct in the wild within 30 years or less. Hunting of these magnificent cats intensified in the 1980s and has accelerated everywhere. They are killed by poison, traps and guns wherever they survive. Villagers and professional

hunters sell Tiger pelts, bones and other body parts in a network of smugglers that reaches from rural India, Bangladesh and Indochina to China, Japan and Taiwan. Tiger pelts are openly sold as trophies in many Asian countries, including Pakistan, Cambodia and Vietnam. They are displayed on shop walls, often with head attached. Some Tiger cubs are even part of this trade, killed and stuffed to be sold as tiny curios.

This magnificent cat will not survive long without legions of rangers guarding the remaining animals. Anti-poaching funding is inadequate in almost all its range. Indian parks and sanctuaries, many of them set aside for the Tiger, are understaffed, and dedicated wildlife wardens are underpaid and poorly equipped to combat poachers (Currey 1996). Some Indian park wardens have been bribed by poachers and watch as they skin dead Tigers (Breeden and Wright 1996). Elsewhere in the Tiger's range in Thailand, Cambodia and Burma, for example, few parks and protected areas have been set aside, and wildlife conservation has low priority.

The market for the pelts and stuffed trophies of these last Tigers among wealthy status-seekers in Asia and elsewhere has increased in recent years. One Taiwanese businessman profiled in a *National Geographic* article (Zich 1993) proudly displayed three stuffed Tigers which he had placed in his bedroom; one of the Tigers was standing on a Lion pelt with the head attached. He protested, "I worked so hard to make money. Now I spend it" (Zich 1993).

In spite of what appear to be overwhelming odds, new projects are attempting to turn the tide. Anti-poaching work in Siberia has helped arrest the steep decline of this critically endangered race of the Tiger in a joint United States-Russian program (Galster 1996). An international fund begun by Exxon Corporation, whose logo is a Tiger, has sponsored anti-poaching work and research throughout its range as well as education programs to persuade Asians not to purchase Tiger products. The US Congress appropriated several million dollars for anti-poaching campaigns, and organizations, such as the Wildlife Conservation Society based in New York City, have worked in Cambodia, Indonesia and other countries to survey and aid in conservation of the species. Scientists have cooperated in studies of the Tiger and aided governments in conservation programs, as described in the recent book, *Riding the Tiger. Tiger Conservation in Human-dominated Landscapes* (Seidensticker *et al*. 1999).

The Asiatic Cheetah (*Acinonyx jubatus venaticus*) once occurred throughout the Middle East as far as India. In the 16th century, the Indian emperor Akbar the Great kept more than 1,000 Cheetahs for hunting. Only one litter was produced by his Cheetahs, and the species died out in India and all of its Asian range except Iran, where fewer then 200 animals remain (Hunter 1998). It is classified as Critical, the most endangered category by the *2000 IUCN Red List of Threatened Species*. The Northwest African Cheetah (*Acinonys jubatus hecki*) is listed as Endangered by the IUCN. In reality, it is nearly extinct, with possible survival only in Algeria, Morocco and Niger, having disappeared from Egypt, Libya and Western Sahara. In the Saharan region, nomadic tribes, such as the Tuareg and Toubou, hunt Cheetah in desert areas of Mali, Niger and Chad, using saluki dogs (Hunter 1998). On occasion, Cheetah prey on young camels in the area, their natural prey having been eliminated. The tribes have such a hatred for Cheetah that they pursue them if they see their tracks, with or without proof of predation (Hunter 1998). Being followed for days in the extreme heat, the Cheetahs sometimes die from heat and stress even before the men and dogs reach them (Hunter 1998).

Trophy and Sport Hunting: Page 2

In the stark deserts of the Saudi Arabian Peninsula and the Mideast, wildlife is not abundant. Animals struggle just to survive in the harsh environment. A wild desert equine became a casualty of unrestricted hunting after World War I. The Syrian Wild Ass (*Equus hemionus hemippus*) was hunted to extinction for sport and meat. These wild asses had been hunted out of most of their original range by the 19th century, but in 1850, they were still seen commonly in large herds in the region once known as Mesopotamia, between the Tigris and Euphrates Rivers. Perfectly adapted to the searing desert heat and sparse vegetation, they ran from natural predators at great speed, and their sand-brown

coloration camouflaged them. After thousands of years of adaptation and survival, these delicately hued wild asses found themselves shot at by 20th century soldiers and other hunters. World War I troops and later, civilians in all-terrain vehicles, chased them at high speeds, killing entire herds of these equines for "sport." With no natural cover and unable to outrun jeeps, entire herds were slaughtered. The last known Syrian Wild Ass was shot in 1927 as it came down for water at the Al Ghams oasis in northern Arabia (Day 1981). The surviving populations of this species, the Asian Wild Ass (*Equus hemionus*), are listed as Endangered by the US Endangered Species Act.

After World War II, Arab sheikhs began hunting Arabian Oryx (*Oryx leucoryx*), Arabian Gazelles (*Gazella arabica*) and Arabian Ostrich (*Struthio camelus syriacus*) in all-terrain vehicles and trucks, mowing them down with repeating rifles, shotguns and even machine guns. These macabre and senseless hunts even involved the use of planes and helicopters for spotting. Sometimes animals were pursued until they dropped dead from exhaustion. In 1955, some 482 cars took part in a hunt during the course of a "royal goodwill tour" in northern Saudi Arabia, and every living animal seen was gunned down (McClung 1976). The Arabian Ostrich formerly ranged from Syria to the Arabian Peninsula, and it became a casualty of these forays. The last wild Ostrich was killed and eaten by Arabs near the Trans-Arab oil pipeline north of Bahrain between 1940 and 1945 (Greenway 1967).

The Arabian Oryx nearly followed the Ostrich into extinction when the last three individuals left in the wild were killed off in 1972 in southern Oman (IUCN 1978). This statuesque white antelope, with long, curved horns that arch over its back, once inhabited a wide range in the Middle East, from Syria and Israel to the Arabian Peninsula (Nowak 1999). It was saved from extinction by actions of the Fauna Preservation Society, headquartered in England, and the IUCN, which had undertaken an expedition in 1962 to capture some of the last wild Arabian Oryx for captive breeding. In eastern Aden, four oryx had been taken into captivity, and this herd was augmented from private game farms and zoos by another eight animals, which were transported to the Phoenix Zoo in Arizona. They adjusted easily to the desert climate of the American Southwest and soon bred in captivity. This herd has grown, and several zoos now breed them. Some of these stately animals have been reintroduced successfully into preserves in Oman and other parts of their original range. They have been studied by field biologists who have found that they reverted to wild behavior, with females in separate herds, and males solitary or in bachelor herds defending territories (Nowak 1999). Eighteen breeding herds occupied 14,121 square kilometers in Oman in two 1988 studies (Nowak 1999). In 1990, more Arabian Oryx were reintroduced into Saudi Arabia. There are now about 500 of these oryx in the wild and an additional 300 in captivity on the Arabian peninsula; 2,000 are held in zoos (Nowak 1999). For many Arab conservationists, the return of the Arabian Oryx has been an important event because this species has been very important to the cultures of the Arabian Peninsula for thousands of years. The reintroduced oryx have been guarded zealously to prevent another tragic disappearance.

Gazelles of dryland and open country were at one time abundant throughout North Africa and the Middle East, able to survive in the hottest and dryest of deserts. People have long hunted them for food, and there is little cover where they can hide. In ancient times, stone corrals were constructed into which gazelles were driven for slaughter, and until the early 20th century, these were still in use (Nowak 1999). Some Arab hunters still use captive and trained falcons to harass gazelles in order to frighten and confuse them so they can then be chased down by dogs (Nowak 1999). Two of these small and dainty ungulates have been hunted to extinction, and others have become very rare throughout the region. The Antelope Specialist Group of the IUCN lists the Saudi Gazelle (*Gazella saudiya*) as extinct in the wild and the Queen of Sheba's Gazelle (*Gazella bilkis*) of Saudi Arabia as extinct, with no captive populations. Until the 1990s, the latter species had been classified as Endangered. But the *2000 IUCN Red List of Threatened Species* reports that this delicate animal, which was considered very common in 1951, has not been seen in decades. A survey in 1992 in its range in mountains near Ta'izz failed to find any of these gazelles.

The *2000 IUCN Red List of Threatened Species* categorizes many other gazelles of the region as Threatened and Endangered. The Arabian Gazelle (*Gazella gazella*), native to the Arabian Peninsula, Israel and Palestine, is classified as Conservation Dependent, a category indicating that without strict protection it would decline to Threatened status. Five subspecies of this gazelle are listed in various categories, the most endangered being the Palestine Mountain Gazelle (*Gazella gazella gazella*) (Conservation Dependent) and the Acacia Gazelle (*Gazella gazella acaciae*)

(Critical) of Israel, and the Muscat Gazelle (*Gazella gazella muscatensis*) (Critical) of Oman. Another threatened gazelle is the Arabian Sand Gazelle (*Gazella subgutturosa marica*) (Vulnerable). These little Mideastern gazelles have been heavily persecuted and hunted. Added to the hunting, which is not well controlled, the Arabian Peninsula and much of Israel and Palestine have been heavily overgrazed by livestock, and the scarce oases are used for agriculture and livestock, leaving little natural vegetation for wildlife.

Reintroduced gazelles in Israel's Golan Heights increased to about 4,000 in the late 1980s, and government officials decided to allow the hunting of 2,000 of them by Arabs, who shot to wound rather than kill so that the animals could be killed ritually through throat slitting. This hunt, filmed by Afikim Productions and Survival Anglia in 1990, was a gruesome sight of crippled and dazed gazelles, stumbling about after the shooting.

The most avidly pursued animal by Arab sheikhs is undoubtedly the Houbara Bustard (*Chlamydotis undulata*). The meat of this large, long-legged bird of scrubby desert and sandy grasslands is considered an aphrodisiac by Arabs, although in fact it is a mild diuretic (Weaver 1992). It has been hunted relentlessly on the Arabian Peninsula, causing many populations to disappear. Arab sheikhs have hunted these birds for centuries using a trained falcon that catches the bird as it flies to escape. The great oil wealth accumulated by sheikhs of Saudi Arabia, Qatar, Bahrain, Kuwait and the United Arab Emirates has allowed them to indulge in this "sport" in a manner befitting the bejeweled and pampered rulers of ancient kingdoms. With these bustards so rare on the Arabian Peninsula, they now hunt them in Pakistan. Traditionally, the sheikhs used camels as transport, but today they drive in fleets of 60 or 70 customized all-terrain vehicles, careening through the desert at speeds up to 80 miles per hour, flattening the landscape, vegetation and small animals under their wheels (Weaver 1992). Armed with high-powered guns to shoot any animal that comes into view, the sheikh occupies an elevated seat that swivels 180 degrees to enable him to spot the Houbara Bustards and their tracks in the sand (Weaver 1992). The ecological damage done by the armies of vehicles that flatten vegetation, scar the landscape, and slaughter every animal they see is so severe that it may result in the local extinctions of many rare and delicate species of the Pakistani desert (Hoyo *et al*. 1996).

Many Houbara Bustards winter in Pakistan, converging from breeding areas in Kazakhstan and other countries in the region. Their breeding range extends to North Africa east across Asia to China. In Pakistan and 23 other countries, including India, Iran and Russia, the Houbara Bustard is totally protected from hunting (Weaver 1992). Yet by means of lavish gifts and payments to high government officials and landowners, wealthy Arabs have received special dispensation to pursue and kill thousands of these birds, which are considered endangered and declining in many parts of their range, especially in North Africa, Bahrain, Jordan, Iran, Iraq and India (Hoyo *et al*. 1996, BI 2000).

These extraordinary birds present a spectacular show with their elaborate courtship, strutting and displaying beautiful white puffs of head and body feathers.* Some hunting, mainly illegal, also occurs in their breeding grounds, which greatly disrupts their courtship, nesting and care of chicks.

*"Red Desert," a film in the series fiRealms of the Russian Bearfl described in the Video section, shows these birds displaying and hunting lizards.

The hunts have been carried on for decades in Pakistan, and Houbara Bustards have declined steadily as a result. As early as 1983, scientists and conservationists at a symposium on bustards convened by the International Council for Bird Preservation (now BirdLife International) unanimously called for a five-year ban on hunting (Weaver 1992). Although Pakistan's President at that time supported the symposium, he ignored the appeal and, the following year, allowed 25 parties from the Saudi Arabian Peninsula to hunt; they killed more than 5,000 Houbara Bustards (AWI 1985). Since that time, hunts have continued in spite of changes in administration in Pakistan, and although Arab hunters realize that these birds are heading toward extinction, they have not decreased their kills or practiced conservation. Moreover, they are now hunting in new areas, close to breeding grounds (BI 2000).

One sheikh, the cousin of the ruler of Dubai, found no Houbaras in the tract where he had arranged to hunt. He then moved his camp into Kirthar National Park, where he illegally killed more than 200 Houbaras in 10 days, along with

protected gazelles and ibex (Weaver 1992). As recently as the 1960s, Houbara Bustards were so numerous in Pakistan that they could be counted "like butterflies in a field," but by the 1990s, they became scarce in many areas, and their populations have experienced sharp downward trends (Weaver 1992). No restrictions are placed on the take of Houbaras by the visiting sheikhs.

Some Pakistani conservationists have fought the illegal arrangements made between the Arabs and government officials, and the Society for Conservation and Protection of the Environment (SCOPE), took the issue to the Sind High Court, which ruled in their favor (Weaver 1992). However, because Pakistani government officials rarely follow such provincial court decisions, the hunt did not end. When asked why the government has done so little to protect its wildlife, a well-known Pakistani environmentalist, Wahajuddin Ahmed Kermani, the retired Inspector General of Forests, replied, "Because we lack the moral fibre and the moral courage" (Weaver 1992).

Protests from conservationists in Europe and elsewhere have had no real effect either. Paul Goriup, the bustard expert at BirdLife International in Cambridge, United Kingdom, believes that populations of Houbara Bustards in Sind and Punjab provinces of Pakistan have become "terribly diminished," and hunting of breeding populations has a disastrous effect (Weaver 1992). Goriup contends that the species must be protected by the United Nations' Bonn Convention on Migratory Species to bring the issue to an international level (Weaver 1992). The Houbara Bustard is listed on Appendix I of CITES, which bans all commercial trade between member nations. Yet each year, 500 or more eggs, chicks and adult Houbaras are smuggled from Pakistan, a CITES member, by sheikhs who use them to train their falcons and for captive-breeding programs of dubious effectiveness. Abrar Mirza, the wildlife conservator for the Province of Sind, confiscates many such shipments, but most provincial wildlife officials merely look the other way, especially after receiving diamond-studded, gold Rolex watches and other such gifts from the Arabs (Weaver 1992). The confiscation of so many Appendix I birds in the United States would result in severe penalties, including possible jail sentences, but the effectiveness of CITES depends on the legislation each member country enacts to enforce it and the zeal with which these laws are enforced.

Sheikhs from the United Arab Emirates (UAE) were not so well-received in Turkmenistan in 1995 when they applied to the Ministry of Foreign Affairs to hunt Houbara Bustards. This Ministry forwarded the request to the Ministry of Nature Use which, quite unexpectedly, turned it down because the birds would be breeding (Zatoka 1995). Certain that they would be able to overcome this opposition, the sheikhs arrived in Turkmenistan ready to hunt without official approval, bringing their falcons (Zakota 1995). To their amazement, they were issued an official complaint by the Director of the Department for Animal Conservation and fined $40,000 (Zakota 1995). The sheikhs then turned to Turkmenistan's President Niyaziv, confident that they would be able to overturn the decisions of the wildlife department; instead, he backed up the decision of the Ministry of Nature Use, stating that it had jurisdiction in this issue (Zakota 1995). This was an extremely important precedent and a fine example of a country according its wildlife the respect and protection it deserves. Turkmenistan has a record of combating poaching and conducting environmental research and conservation programs (Zakota 1995).

One sheikh has renounced hunting and fostered environmental programs. Sheikh Zayed of the United Arab Emirates, while hunting gazelles with a rifle, realized that this amounted to "an outright attack on animals" and a cause for their possible extinction (Morgan 1998). He then began a program of setting tracts of land aside for wildlife and setting up breeding herds of endangered oryx, gazelles and other desert ungulates on an island off the coast (Morgan 1998). Other UAE sheikhs have obtained special favors when hunting on the African continent. The government of Tanzania granted exclusive hunting rights in one of the country's most important wildlife areas to a high-ranking official from UAE (Alexander 1993). The agreement was reached in secret with the Deputy Minister of Defense of that country, and he apparently has been allowed to hunt endangered species, such as Cheetah, with automatic weapons (Alexander 1993). The influence of wealthy Arabs in bending wildlife laws has reached to many corners of the world. One of their prime targets is North America for its beautiful Gyrfalcons (*Falco rusticolus*), listed on CITES Appendix I, one of the most coveted of all birds of prey for falconry. Their attempts at bribery, often successful, to obtain these protected birds from Canada resulted in the listing of this species on CITES to prevent any further commercialization of these birds, which was causing declines in their wild populations.

Trophy and Sport Hunting: Page 3
The vast Sahara has been the scene of similar hunts. Scimitar-horned Oryx (*Oryx dammah*) originally had a wide range in arid grasslands from Morocco and Senegal east to Egypt and the Sudan. In historic times, herds of 100 animals were commonly seen, and during wet season migrations, they traveled in groups of 1,000 animals or more. Their white and brown coloration allowed them to blend into the desert, and they were admired for their extremely long, back-curving horns. Their populations and range gradually shrank with hunting, overgrazing and agricultural encroachment on natural grasslands; the species disappeared from Egypt and Senegal in the 1850s. In the 1970s there were still an estimated 6,000 of these spectacular animals in the southern Sahara (Nowak 1999). The Haddad tribe of northern Chad centered their way of life around hunting these oryx, driving them into nets and killing them for their meat (Simon 1995).

Although traditional hunting made inroads into Scimitar-horned Oryx populations, the use of four-wheel-drive vehicles and modern firearms by prospectors and military personnel within the past 30 years drove the species to near extinction (Simon 1995). Groups of wealthy Middle Eastern hunters arrived with all-terrain vehicles and automatic rifles, eliminating these animals from most of their range. Chad's Ouadi Rime-Ouadi Achim Faunal Reserve became one of their only refuges by the 1970s, but the outbreak of war between that government's forces and Libyan-backed rebels in 1978 brought about an unregulated slaughter of the last population of Scimitar-horned Oryx within the reserve, reducing them to only a few hundred animals (Simon 1995). In an attempt to reintroduce these majestic antelope to their original range, 41 were captured in western Chad in 1966 and placed in captivity (Simon 1995). Some 500 of these oryx are part of the American Zoo Association's Species Survival Plan, and another 700 are in other zoos; an unknown number are in ranched herds, especially in Texas (Nowak 1999). A small number of Scimitar-horned Oryx were released into a national park in Tunisia in 1991 (Simon 1995), and others may be released in Niger (Nowak 1999). The IUCN listed this species as Critical in 1996, Extinct in Algeria, Egypt, Libya, Mauritania, Senegal, and Western Sahara, and Probably Extinct in Burkina Faso, Chad, Mali, Niger, and Sudan. The *2000 IUCN Red List of Threatened Species* listed the Scimitar-horned Oryx as Extinct in the wild.

The Addax (*Addax nasomaculatus*), a desert antelope which once ranged from Western Sahara and Mauritania to Egypt and Sudan, is now nearly extinct in the wild as a result of heavy hunting combined with loss of its grassland and shrubland habitat to agriculture and competition with livestock. Perfectly adapted to life in the desert, Addax are able to spend their lives without drinking water, deriving moisture from plants on which they feed (Nowak 1999). Instead of the long, arched horns of the Scimitar-horned Oryx, the Addax has horns that grow outward, then bend inward and upward. A stocky antelope that is not able to run quickly enough to flee men on horses, it has been easy prey for hunters and feral dogs. In recent years, remnant populations literally have been run to death by tourists in four-wheel-drive vehicles who pursue them until the animals fall dead in the sand (Nowak 1999). A herd in northeastern Niger was reduced to 50 to 200 animals when, according to some reports, they were wiped out by hunting. Fewer than 200 remained in north-central Chad, and another 50 along the border of Mali and eastern Mauritania in 1994 (Nowak 1999). The *1996 IUCN Red List of Threatened Animals* listed the Addax as Endangered, Extinct in Algeria, Egypt, Libya, and probably Sudan. The *2000 IUCN Red List of Threatened Species* upgraded its status to Critical. A small reintroduced population survives in Tunisia, but the wild population is at risk of disappearing altogether. More than 400 animals are in captivity, including a herd in a large dryland safari park in Texas called Fossil Rim.

Other Saharan animals have been ruthlessly pursued. Pelzeln's Gazelle (*Gazella dorcas pelzelni*) have been pushed to Vulnerable status by hunting. They are listed on the US Endangered Species Act. The Slender-horned Gazelle (*Gazella leptoceros*), native to North Africa, is now endangered throughout its range, according to the *2000 IUCN Red List of Threatened Species*. The hunting of these desert animals by men in all-terrain vehicles, some armed with

machine guns, reached such heights in the 1970s that they nearly became extinct, and their status has not improved in the intervening years. The endangered Dama Gazelle (*Gazella dama*), also a heavily hunted species, is extinct in Algeria, Libya, Mauritania, Morocco and Western Sahara; it has been reintroduced into Senegal, and populations are now confined to Chad, Mali, Niger and Sudan (Baillie and Groombridge 1996). Cuvier's Gazelle (*Gazella cuvieri*), another North African species, is also extinct in the Western Sahara and survives in endangered populations in Algeria, Morocco and Tunisia, according to the IUCN. In some cases, antelope and gazelles have been pursued by hunters in helicopters who shoot at them with rockets, a method also used to kill African Elephants in Chad, where the last Greater Kudus (*Tragelaphus strepsiceros*) were destroyed in 1976 (Anon. 1977).

Trophy and Sport Hunting: Page 4

Poachers have caused the extinction in Somalia of the endangered Hunter's Hartebeest or Hirola (*Damaliscus hunteri*), which now survives only in a restricted portion of scrubby desert of south-eastern Kenya. Looking somewhat like an Impala, this delicate, dryland antelope can live for weeks on very little water. This species is considered an evolutionary relic, having lived on earth for 15 million years, and is a progenitor of other hartebeests and the Topi; fossil evidence indicates that the Hirola's range once extended to South Africa (McKinley 1996). Kenyan populations totaled 14,000 in 1976, living along the Tana River and in the arid Garissa region to the east (McKinley 1996). In the 1980s, poachers killed off the region's African Elephants, who had kept the land clear of thorn bushes for grazers, such as the Hirola (McKinley 1996). A rinderpest epidemic brought in by cattle herders wiped out half the region's antelope between 1983 and 1985.

In the early 1990s, Somali refugees and troops fleeing from civil war in Somalia crossed into Kenya and began slaughtering the Hirola (McKinley 1996). By 1993, only 2,000 Hirola survived, and with unregulated hunting, a 1995 census found a total of 306 animals scattered in small groups over 45,000 square miles (McKinley 1996). Rangers from the Kenya Wildlife Service decided to capture and move as many as possible of the remaining animals to Tsavo National Park, where they could be guarded against illegal hunting. One hundred animals were moved to the park in 1995, and a year later, about 57 survived. In 1996, more were chased by helicopter into nets, sedated, blindfolded, and then taken by truck to a small plane which airlifted them to Tsavo. The habitat in Tsavo is lusher and greener than their native desert shrub, and the Hirola may not thrive there. Only time will tell. The *2000 IUCN Red List of Threatened Species* lists the species as Critical.

Trophy and Sport Hunting: Page 5

In South Africa, the Quagga (*Equus quagga*), a zebra-like equine, became extinct from hunting. Some zoologists consider these animals to have been a race of Burchell's Zebra (*Equus burchelli*), but others classify them as a full species. They had black, vertical stripes on the head and neck, while their back and haunches were uniform grayish or faintly striped. Native to the Cape Colony grassy plains, their limited and open habitat made them vulnerable to the Boer settlers, who killed them by the thousands (Day 1981). Many were tamed and used to guard domestic livestock at night because they gave loud alarm calls upon seeing predators (Day 1981). Some were even shipped to London and used as harness animals. The Boers used their skins for sacks and other practical purposes. By the 1850s, it had nearly disappeared from the Orange River area from relentless hunting (Nowak 1999). The last wild Quagga was killed in 1878, and in 1883, the last captive Quagga died in the Amsterdam Zoo (Day 1981). Photographs (Nowak 1999) and specimen skins exist with DNA that has been compared with living zebras. There has been talk of restoring a Quagga-like animal through selective breeding with Plains Zebras.

Many other South African species were reduced to endangered status or eliminated from the country altogether by

Boer hunting and their policy of clearing the land for livestock and agriculture. Although many parks have been set aside, wildlife as a whole has been crowded out of its natural environments in South Africa. Elephants became restricted to an area in the northeast that later became Kruger National Park, and only recently have they been reintroduced into a few parks elsewhere. Zebras have become extremely rare, with several races critically endangered (see Grasslands, Shrublands and Deserts chapter).

The high-altitude Simien Mountains National Park (6,234 to 14,535 feet) has many endangered endemics. A Survival Anglia film, fiEdge of the Abyss,fl records many of these species, including the Walia Ibex (*Capra walie*), a mountain goat found only in Ethiopia. It has a population of about 300 in the park and stays above 10,000 feet, browsing in the giant heath. These goats were common until the 1930s when hunting decimated their numbers. They also have lost habitat to agriculture and livestock. By the 1960s, there were only 200 Walia Ibex in the park, and although they have recovered somewhat, they still are poached for their magnificent, massive curved horns, hides and meat. Poachers enter the park and place nooses on the narrow mountain trails they must use to travel from one part of the park to another.

Trophy and Sport Hunting: Page 6

Local villagers in Kankani, India, have turned the tables on hunters of the threatened Blackbuck. This town, located in the Rajasthan desert of western India, has a history of preserving nature, refusing to allow an 18th century maharajah to cut their trees by encircling them and vowing to be killed rather than let the maharajah's men cut the trees (Bearak 1998). When hunters in all-terrain vehicles awoke the villagers with gunshots in October 1998, the villagers chased them off and got the license plate number of the driver (Bearak 1998). Some bucks of these striking black-and-white antelope had already been killed. "These animals are considered sacred to us, and we consider their lives more important than even our own," said a village elder of the Bishnoi people (Bearak 1998). The license turned out to belong to a famous movie actor, Salman Khan, star of many high-action, violent films (Bearak 1998). The story was told in many newspapers, and public opinion turned against Khan, who came to symbolize the callous rich who take pleasure in poaching endangered species like the Bengal Tiger and Sarus Crane (Bearak 1998). The week before, he had hunted Chinkara (*Gazella bennetti*), a Conservation Dependent species, according to the IUCN. On October 12, 1998, the actor was arrested, but he was unlikely to go to jail, as a result of his fame and wealth. The village elder said: "Between us and the animals there is complete trust. Our teachings tell us that we must serve as protectors and nurturers of all living things" (Bearak 1998).

Trophy Hunting Clubs

The US-based Boone and Crockett Club keeps records of trophy animals for North American mammals, and Safari Club International (SCI) maintains international records and promotes trophy hunting of animals worldwide. US state wildlife departments tend to favor sport hunting, and many earn large license fees from the trophy hunting of Bighorn Sheep, Elk, Grizzly Bear, Gray Wolf and other mammals. Trophy hunters in North America vie with one another to receive the "Outstanding Hunting Achievement" trophies awarded each year, primarily for having killed one each of 29 big game animals, some of which are on the US Endangered Species Act list (Williams 1991). Trophy hunting organizations have "master measurers" who check the size of horn, antlers and other measurements of animals killed for record books. SCI gives awards to those who kill at least 13 of the world's 22 species of "available" wild sheep (Williams 1991).

Rifles that fire at distant targets with telescopic lenses, elaborate blinds, heat sensors, and other technological gadgetry have weighted the contest so much in favor of the hunter that animals have become mere targets, with virtually no

hope of escape. Hunters using these high-powered rifles revel in recounting their experiences in hunting publications, whose writing fees help pay for their trips. One hunter's 1997 account recorded his delight in seeing the look of total shock of an Alaskan Dall Sheep (*Ovis dalli*) as it died from a shot he fired without it even having been aware of his presence. The hunter had selected the largest male with the most massive horns, which curved into a complete circle. Such hunting can so terrify animals that they run off cliff edges or flee into places from which they cannot escape.

Bernard Grzimek's *Animal Life Encyclopedia* recounts a hunt in the Canadian Rockies of Mountain Goats (*Oreamnos americanus*), in which five animals were pursued by hunters. They fled in terror, becoming entrapped on the ledge of an overhanging cliff, unable to move in any direction (Grzimek 1968). The hunters returned to their camp where they could see the goats as they stood on the ledge. The next day, the goats were still standing on the spot, but during the following days, they gradually became weakened and fell, one after another, usually at night, to their deaths. The last of the animals fell after 10 days (Grzimek 1968).

One US trophy hunter, Donald G. Cox, has hunted in 68 countries, taken 208 different species, including 125 from Africa, and has killed 23 of the world's spiral-horned antelope (Williams 1991). Trophy hunters try to kill as large a number of species as possible and as many trophy-sized animals as they can shoot. Many trophy hunting organizations claim to have made major contributions to conservation, but documentation is often lacking. SCI has published brochures in which it claims that it purchased habitat for endangered species. As it turned out, on investigation these claims were unsubstantiated (Williams 1991). Endangered animals are often the prime targets of trophy hunters. Safari Club International makes regular applications to the Fish and Wildlife Service to import trophies of endangered species. A 1978 application was particularly stunning because it requested permits to import 1,120 animals of a wide range of species, including Orangutans, various species of monkeys and crocodiles, and 39 species of endangered deer, gazelles, wild sheep, antelope, rhinoceroses, and 12 species of endangered wild cats. After a public outcry, the Safari Club withdrew its application, but in 1982, it was successful in its long battle to allow importation of Leopard trophies.

Trophy hunting clubs have made financial contributions to officials in foreign countries to receive permission to hunt endangered species and have convinced wildlife officials in countries such as Pakistan, Zimbabwe and Botswana that trophy hunting fees pay for conservation and should form the basis of wildlife management programs. The profits from trophy hunting pale beside those of ecotourism, however (see Trophy Hunting vs. Ecotourism Revenues section below).

Illegalities

Trophy hunting organizations have lobbied the US Department of the Interior for decades to weaken law enforcement "overzealousness" and have, on occasion, been successful. The Law Enforcement Division of the US Fish and Wildlife Service has tended to be strict in prosecuting trophy hunters for violations. In one case that inflamed Safari Club International members, it subpoenaed pages of the SCI™s *Record Book*, which listed many endangered species, to determine the details of the killing of various protected animals. To shield its members from prosecution, SCI returned information to their members on trophy animals killed at a time when they could not have been imported legally, and deleted this information in the SCI database to avoid further investigations (Williams 1991).

In another case, however, SCI influence won favors from the Department of the Interior. A highly placed official with the Fish and Wildlife Service, Richard Mitchell of the Office of Scientific Authority, allegedly accepted money from SCI in exchange for facilitating permits to get endangered species trophies into the United States (Williams 1991). Correspondence between Mitchell and SCI members included advice on registering as an institution with CITES on behalf of the trophy museum that the organization maintains in Arizona. Mitchell suggested that he would arrange to register several institutions in China and Pakistan in order to trade endangered species "specimens" with them

(Williams 1991). Another official, Assistant Secretary of the Interior G. Ray Arnett, who later co-founded a lobbying organization for trophy hunters, helped a fellow hunter caught importing an endangered species in the early 1980s by ordering agents to return the trophies to the smuggler, Thornton Snider (Williams 1991). Rick Parsons, who founded the Permit Office within the Fish and Wildlife Service, which gave permits to trophy hunters and others wishing to import endangered species, later became the Washington Counsel to Safari Club International, using his government experience to facilitate the permit process for trophy hunters and also lobbying at CITES Conferences on behalf of trophy hunters.

Ted Williams, in a 1991 article in *Audubon* magazine, tells of an appraiser for the Safari Club, R. Bruce Duncan, who arranged for many members of the club to mislabel the trophy animals they killed in foreign countries in order to import them into the United States without prosecution under the US Endangered Species Act (Williams 1991). One Club member imported a Jaguar (*Panthera onca*) pelt from Venezuela, labeled as a "goat hide" under Duncan's advice, and valued at $60; Duncan had appraised it at $11,000 (Williams 1991). Another SCI trophy hunter, Andrew Samuels, was the winner of the 1990 "Weatherby Award" given by a firearms company to the hunter who kills the greatest number of average, as well as record-sized, game animals throughout the entire world and whose character and sportsmanship are "beyond reproach" (Williams 1991). An undercover Fish and Wildlife Service Law Enforcement investigation revealed that Samuels had confided having illegally killed a Bighorn Sheep and numerous endangered foreign animals and smuggled them into the United States by falsifying shipping documents (Williams 1991). These included Jaguars, endangered wild Markhor goats (*Capra falconeri*), rare African antelope, Jentinck Duikers (*Cephalophus jentinki*), Ocelot (*Leopardus pardalis*), and a wild Asian sheep, the Punjab Urial (*Ovis orientalis punjabiensis*) (Williams 1991). Samuels paid $100,000 in fines, spent 30 days in jail, and performed 800 hours of community service; he also forfeited his world hunting rights for three years (Williams 1991).

In another case, John Funderburg, the curator of the North Carolina Museum of Natural Sciences in Raleigh, acquired more than 1,800 animals as "specimens," many of them endangered, that had been killed by trophy-hunting acquaintances (Williams 1991). They were donated to the museum as tax-exempt, but had little scientific value because they lacked information about the location or date where they were killed, and many were merely heads mounted for hanging on walls. Scientific specimens consist of the skins of entire animals, or their skeletons. A number of the donated trophy animals mysteriously disappeared from the collection, apparently returned to the donors (Williams 1991). In exchange for financial "donations" to the museum, the trophy hunters received the title of "associate curator," with certificates that allowed them to misrepresent themselves to foreign wildlife officials in order to obtain permits to kill protected animals (Williams 1991). Funderburg urged the hunters to send him the trophy animals via private taxidermists to avoid the attention of authorities, but a five-year undercover investigation by Fish and Wildlife Service Law Enforcement revealed all the details of this scam (Williams 1991).

The highly respected Smithsonian Institution has not been invulnerable to such unprincipled arrangements. A wealthy real estate developer, Kenneth Behring, pledged $20 million to the Institution's National Museum of Natural History in 1999, the largest donation in the 151-year history of the museum (Golden 1999). Behring, a trophy hunter and past president of Safari Club International, donated the remains of four endangered Central Asian wild sheep, including the Kara-Tau Argali (*Ovis ammon nigrimontana*) of Kazakhstan, listed as Critical by the *2000 IUCN Red List of Threatened Species*, to the museum. This animal cannot be imported legally because it is listed on the US Endangered Species Act, but on behalf of Behring, the Smithsonian petitioned the Department of the Interior to waive the ban in order to have the trophy shipped into their collection (Golden 1999). This action set an unfortunate precedent for this august institution. Behring is also under investigation for illegally killing three bull elephants in Mozambique, in spite of a $20,000 "donation" he made to a local hospital in the province (Golden 1999). The head of Mozambique's wildlife department, Arlito Cuco, said that the hunt was illegal, "Because according to the law in Mozambique, you cannot hunt for sport" (Golden 1999).

Hunting magazines often glorify the pursuit of endangered species. An article in *Sports Afield* encouraged the hunting in Mexico of Jaguar, Ocelot, and "crested Guan," or Horned Guan (*Oreophasis derbianus*), a highly endangered pheasant-like bird (Anon. 1981). It noted parenthetically, "However, United States laws prohibit bringing in skins"

(Anon. 1981).

Effects of Trophy Hunting on Animals

Among the most coveted of the "Grand Slam," or the most prestigious trophy animals, is the Brown Bear. The Kodiak Bear (*Ursus arctos middendorffi*) of Alaska represents a major trophy for hunters who come from all around the world to kill large males. This bear exceeds other subspecies in size, weight and skull size. These bears have been isolated since the end of the last Ice Age, and the abundant food supply of salmon runs, berry bushes and other edible plants in their habitat has produced this giant bear (Chadwick 1990). Trophy hunters pay $20,000 or more to private hunting guides for the privilege of shooting these bears. A recent study has revealed a potentially disastrous effect on the species of this trophy hunting. According to *The Kingdom. Wildlife in North America*, by the respected author and National Geographic Society correspondent Douglas Chadwick, "Continued harvesting of the biggest animals by trophy hunters has caused a decline in the average size of Kodiak Bears over the years" (Chadwick 1990). Thus, this record-size animal is gradually becoming smaller and smaller as a result of trophy hunting.

The pressure of hunters on some populations of Alaskan bears is so intense that it has altered the behavior of males, preventing their normal feeding on salmon runs. On Admiralty Island in southeastern Alaska, part of the Tongass National Forest, tourists watch female Brown Bears fishing with their cubs, but rarely see males because they have become so wary of people after years of being hunted; even females without cubs can be hunted on Admiralty Island (Crittenden 1997). The rich salmon rivers on this island are among the world's most productive, and since clearcutting of timber has been banned, salmon thrive in the clear water. Salmon is an important portion of the diet of male bears, yielding a great deal of protein and helping to fatten them for the winter. By frightening the male bears from the salmon rivers, which they have fished for thousands of years, humans may be affecting the health, survivability and size of these bears. Each year more than 40 Brown Bears are killed on Admiralty, and hunters are lobbying to reopen hunting in areas such as Pack Creek that are now closed to protect the fishing spots (Hanson 1998). This island deserves to be declared a National Park, which would protect these bears from hunting.

Another effect of hunting male bears has recently been documented by Swedish and Norwegian biologists, who found that in areas where resident adult male Brown Bears had been killed to thin the population, bear cubs suffered very high mortality for several years until dominant males reoccupied the territory (O'Neil 1997). Male bears, who have traditionally been considered threats to cubs, may be a danger only to cubs they have not fathered. Thus, the killing of bears by sport and trophy hunters may also result in the deaths of hundreds of bear cubs.

Russian Brown Bears have been hunted heavily in recent years. When a prominent government official, Prime Minister Viktor S. Chernomyrdin, announced early in 1997 that he wanted to trophy hunt a Brown Bear, local guides bulldozed a path to the den of a sleeping female bear (Filipov 1997). Tractors plowed a campsite for a large tent with mobile kitchen and cafeteria, and the Prime Minister flew in by helicopter (Filipov 1997). Chernomyrdin, accompanied by 12 hunters, rode a skimobile to the site, roused the bear and killed her two cubs and the mother. This incident received much adverse publicity in Russia. When the Prime Minister was criticized for his lack of sportsmanship, he replied: "What's wrong with that? Hunting of bears is not banned; it's a normal thing . . . I'd like to watch those who are writing about this meet those bears eye to eye to see their reaction" (Filipov 1997).

In Greece and Turkey, where Brown Bears are avidly hunted in spite of their dwindling numbers, cubs orphaned when their mothers are killed are often sold to zoos or to gypsies who treat them abusively. This trade is illegal in both countries, and the World Society for the Protection of Animals (WSPA) has saved many of these gypsy bears, who are dragged through the streets with nose rings and made to perform tricks. WSPA has placed several hundred of these abused bears in large wooded compounds, unfettered for the first time in their lives. Some had to be euthanized because of severe infections that had caused them extreme pain and serious physical disabilities that they had endured

for many years without veterinary treatment. The majority suffered the effects of malnutrition.

The animals trophy hunters seek--the finest specimens--are the very ones that should be left in the wild to maintain the species. Killing the largest specimens of a species, subspecies or population is likely to diminish it in size and survivability. This would seem elementary, but trophy hunters, state game departments, many in the Fish and Wildlife Service, the World Wildlife Fund and other organizations in favor of trophy hunting do not discuss or acknowledge this fact. Claims are made on behalf of trophy hunters that only old and non-breeding adults are killed, but this contention has been proven wrong in case after case. Brown and Grizzly Bears continue to breed until an advanced age. Other trophy animals have also been shown to be at their prime when shot.

Lions are a prime target of trophy hunters, who select the largest male specimens, especially those with enormous manes. Two filmmakers, Derek and Beverly Joubert, in producing their dramatic series, fiLions of Darknessfl for the National Geographic Society, followed three exceptionally large males for a long period. These magnificent Lions spent most of their lives in a national park in Botswana, but made the fatal mistake of leaving the park and entering a wildlife management area where trophy hunting was allowed. All were shot within a short time at the prime of their lives by trophy hunters.

Trophy hunting took a tragic and highly controversial turn when the government of Tanzania sold trophy hunting rights for African Elephants at more than $4,000 per animal in the early 1990s. The *2000 IUCN Red List of Threatened Species* classifies this species as Endangered. The government claimed that the largest animals, which for trophy hunters were the most desirable, were not active breeding males, but past the breeding age and, therefore, "excess." Tanzania issued 50 permits a year for trophy-hunted elephants (Brody 1994). At least four very tame bull elephants that had been studied for decades in Amboseli National Park in southern Kenya by biologist Cynthia Moss, author of two classic books, *Echo of the Elephants* and *Elephant Memories*, wandered into Tanzania in 1994, where they were shot at point-blank range by trophy hunters (Moss 1995). The hunters had received CITES permits from the Tanzanian government to export the tusks as hunting trophies (Moss 1995). Northern Hunting Enterprises, which organized the Tanzanian elephant hunt, is run by Rick Trappe, a German Tanzanian; the hunters were two Germans and an American (Brody 1994). One of the bulls killed, called "R.B.G.," was 47 years old at the time of his death, based on aging of the jaw--not old in elephant years--and so habituated to vehicles that he could be easily approached to within a few feet (Moss 1995). Cynthia Moss said she was "devastated" by the loss of the animals, who had come to trust researchers, tourists and rangers. She stated: "The message they got from us was, 'It's OK, we're not going to hurt you, you can trust us.' Then one day they walk two kilometers into Tanzania, where they'd been going for most of their lives, and they're blown away . . . I feel as if was lying to them" (Brody 1994). A spokesperson for the African Wildlife Foundation said: "The ethics of shooting these virtually tame animals is appalling. You can't call this a hunt of any kind" (Brody 1994). Had R.B.G. not been shot, he would have lived another 18 years, according to Moss (Brody 1994).

These were among a relatively small number of large, old bull elephants left in East Africa, protected through the ivory slaughters of the 1980s by the presence of field researchers and tourists. The assertion that they were non-breeding males was refuted by Moss, who had documented that they were active breeders and, in fact, among the top breeding bulls in the Amboseli population (Brody 1994). This disputes the view that they were not contributing to the gene pool and were "excess," worthy only of being used as targets. After protests and adverse publicity on television programs that reached the United States and elsewhere, Tanzania announced a ban on trophy hunting of elephants near the Tanzania/Kenya border on December 13, 1994, and initiated an investigation into the granting of permits to shoot the Amboseli bull elephants.

In spite of the supposed ban, two other big bulls of the Amboseli, Sleepy and Beach Ball, both in their 50s, were killed in Tanzania by trophy hunters in 1996. Both had fathered calves that were born after their deaths. The largest bull in Cynthia Moss's study area is the gigantic Dionysus who, at 55 years old, weighs some 6,000 kilograms, with 100-pound tusks. He probably owes his life to Cynthia Moss and other researchers who have deterred poachers, but should he wander into Tanzania, he may be killed. The females in the family, headed by Echo, an old matriarch, prefer

Dionysus above all the males, and he has fathered many calves. In a BBC film about her work in Africa, fiEcho of the Elephants. The Next Generationfl (PBS--WNET 1996), Moss pledged that she would spend the rest of her life watching over these elephants.

Another effect of trophy hunting of elephants and many other animals is an imbalance that is created between the sexes. The largest elephant bulls of both the African and Asian species have been killed off, leaving far too few males for the number of adult females. In some parts of Africa where the ivory massacres were the most intense during the 1970s and 1980s, virtually no adult males remained prior to the 1989 CITES ban on ivory. In Asia, adult male Asian Elephants (*Elephas maximus*), also listed as an Endangered species by IUCN, have become extremely rare because they were killed by ivory poachers. Females do not have tusks, and most have been spared by ivory hunters. In parts of Asia, males without tusks, a recessive trait, have come to dominate some populations, since they are not valuable for their ivory. This is altering the traits of the species.

After the largest bull African Elephants were killed off, trophy and ivory hunters turned to the older females, who have large tusks. They are essential in maintaining and leading family groups, providing experience, protection and guidance (Moss 1995). These older females, or matriarchs, have accumulated survival lore over many decades, acquired from previous matriarchs and their long life experiences. They also know the location of scarce water holes in the dry season, where to find minerals in clay they need for their nutrition, what plants are poisonous and other bits of survival lore that can mean the difference between life and death of herd members. Yet these matriarchs also were killed in the 1980s, leaving young, traumatized teen-aged females, who wandered in disarray, without the knowledge or authority of the older females. Females as young as 10 years old found themselves matriarchs of bands of orphan calves, many just weaned. Without direction, they often blundered, placing the calves at risk.

Scientists studying elephants over the past 30 years have documented hundreds of cases of trauma and apparent mourning when family members were killed. The elephants that suffer the most are the young who see their mothers and relatives butchered in front of them. Researchers in the 1990s have noted that many of these young elephants fail to develop normally and are extremely shy, unable to find food and cope with predators as effectively as adults. Some young males, who were calves when they watched as their families were slaughtered by poachers or in culls in South Africa, were released in national parks where they later became unruly and destructive to property and to other animals. Only when older elephants were released to lead and discipline them did they calm down and assume the peaceful personality that characterizes the species.

Zimbabwe, Botswana and Namibia submitted proposals in 1997 to the CITES Conference that the African Elephant's population in their countries be down listed from CITES Appendix I to Appendix II to allow export of trophy-killed elephants. Zimbabwe requested commercial trade in trophies, and Namibia, non-commercial trade. This proposal was amended to read "for non-commercial purposes" and adopted by the CITES members at the 1997 Conference. This is a step in the wrong direction, as hunters will arrive in these countries from around the world to kill the largest, prime elephants as trophies. Shooting elephants in open country where they have no cover is hardly sport, yet the hunting companies tout their massacre as a feat of bravery. Killing them as they come to drink at the few water holes that remain in the dry season in southern Africa is also unsportsmanlike. Matupula Hunters of Texas calls such hunting "exciting and rewarding." Their brochure states, "With the country dry and surface water limited, the elephant bulls can be tracked going to and from water, or in amongst the woodlands and forest where they feed and lay up" (Scully 1997).

Trophy Hunting vs. Ecotourism Revenues

The irony of the slaughter of elephants and other large mammals for trophies is that the funds accrued from trophy hunting or ivory are miniscule in comparison to the value of these animals as ecotourist drawing cards. In Kenya, a

1989 analysis on the viewing value of elephants found that between $25 and $30 million per year was earned in tourist dollars from people attracted to the elephants alone (Brody 1994). A new project provides a local Maasai tribe with about $23,000 a year from tour operators who camp there primarily to show visitors the big bull elephants that are now so rare in East Africa (Brody 1994). During the long life of an African Elephant, it may produce tourist revenue worth $1 million, distributed to a wide range of recipients, from airlines to travel companies, and to local economies (Currey and Moore 1994). By contrast, a trophy-hunted elephant brings a one-time fee of $4,000 to $20,000. Estimates for African Lions are similar. A fully maned male Lion, according to Lee Durrell (1986) in *State of the Ark*, is worth $500,000 as a tourist attraction, whereas a Lion shot for sport or trophy is worth between $3,500 and $8,500, and its skin about $1,000.

Ecotourism has shown an astronomic rise within the past decade, with magazines, books and films aimed at the ecotourist and soaring revenues accruing to countries that protect their natural heritage. Most tourists prefer to come to a country where the animals are tame and where senseless killing is not carried out. Countries that allow hunting of the largest specimens of their wildlife, whether elephants or Leopards, are likely to suffer loss of tourist revenue because they have fewer larger animals and the hunted species often become either shy, hiding from tourists, or belligerent, charging them. A recent article in *Africa. Environment and Wildlife*, a magazine affiliated with World Wildlife Fund South Africa, gave advice to tourists coming to Okavango. Daryl and Sharna Balfour (1998) recommended that tourists avoid coming during hunting season, which runs from early April to mid-September, because game is "scarce in this areas, skittish and almost impossible to approach." They further noted that the sound of gunfire and the sight of carcass-laden vehicles can be disconcerting (Balfour and Balfour 1998). Wildlife can remain shy throughout the year, especially sensitive, gun-shy animals like elephants, and even beyond the suffering caused to the animals, this trophy hunting potentially deprives the country of far greater revenues that tourists could contribute. Several tourists have been killed recently by charging African Elephants in areas where the animals had been trophy hunted.

Tourists coming to South Africa have increased in number in recent years, producing revenues totaling $6 billion in 1995; a large percentage of this total derives from tourists coming to see scenery and wildlife. By contrast only $2 million in trophy hunting fees for rhinos, and a few million dollars more for other animals, were earned in that year, according to the Natal Parks Board (Hughes and Brooks 1996).

Botswana earns $100 million per year from tourism and only a tiny fraction from trophy hunting, yet the government actively promotes the latter activity and has failed to give national park status to its crowning jewel, the Okavango Delta. Portions of this superb wildlife area have been designated as game reserves which allow hunting, but most remains unprotected (Balfour and Balfour 1998). By contrast, Kenya has designated vast areas as national parks and has encouraged ecotourism for decades, with the result that the government earned $500 million in 1996, up from $452 million in 1995. A new organization, Okavango Peoples' Wildlife Trust, in Botswana, is pressing for a complete ban on trophy hunting in the immense Okavango Delta wetland (Jackman 1997). As a result of livestock fencing in the area, African Buffalo are declining 18 percent a year, and Lion, zebra, Sable Antelope and waterbucks are also becoming scarce (Jackman 1997). This organization has proposed that all hunting, except for subsistence or problem animals, be banned and that the Delta be promoted as an ecotourism center, with low-impact camps for luxury visitors (Jackman 1997). New fencing has blocked about one-fourth of the Okavango to wildlife, who migrate to this oasis from surrounding desert areas as a vital refuge for many months during the year. These fences also have blocked wildlife migrations between Namibia and Angola, a disastrous event for many thousands of animals (Jackman 1997). This region has enormous potential for ecotourism that would far outweigh the revenues from cattle ranching or trophy hunting.

In general, funds from trophy hunting end up in government coffers and in the pockets of a few tour operators; the people of a country receive little of the revenues. By contrast, ecotourism funds are spread throughout the local economies, with hotels, taxis, buses, restaurants, souvenir shops and others benefiting from the greater number of tourists than hunters. In fact, the number of trophy hunters is miniscule in comparison to the number of ecotourists. In most countries, hunters amount to a few hundred or thousand, versus hundreds of thousands--or even millions--of

tourists. In some countries, a portion of trophy fees and the meat from slaughtered animals are shared with local villagers, but if they were given the same share of tourist money, it could be very profitable. This trend of sharing tourist revenues or park fees with local people is making an enormous difference in the lives of people around the world.

Meat Hunting

Three Asian wild cattle are endangered from hunting, and one of these is on the verge of extinction. The Kouprey (*Bos sauveli*), discovered in 1937, is classified as Critical by the *2000 IUCN Red List of Threatened Species*. Native to open lowland forests of Southeast Asia in Cambodia, Laos, Thailand and Vietnam, it is the size of a steer. Adult males weigh up to 1,980 pounds and stand 6 feet tall at the shoulder (Nowak 1999). Originally, the Kouprey's habitat consisted of low, rolling hills interrupted by patches of forest; it grazed in herds of up to 20 animals, covering some 15 kilometers a day in the open areas and entering the forest for shelter from the sun and refuge from predators (Nowak 1999).

Page 1 (Asia)
Page 2 (Africa & Logging)
Page 3 (Markets)

Meat Hunting: Page 1

Today, much of the Kouprey's habitat has become a battleground for bands of guerrillas who have planted land mines throughout the region and hunt and snare wildlife for food. After the Vietnam War and the Khmer Rouge occupation of Cambodia, Kouprey were only seen rarely (Stewart-Cox 1995). A 1986 survey found fragmented, small populations remaining in most of its range (Nowak 1999). A few Kouprey were seen in the 1980s trying to migrate through the steep escarpment separating Cambodia and northeast Thailand, but they apparently died in booby-traps set for people (McNeely and Sochaczewski 1988). The skull and horns of a female Kouprey were offered for sale in a shop in Poipet, Cambodia, in 1994 for $400, according to biologists surveying illegal trade in the country (Martin and Phipps 1996). The Kouprey has little chance of surviving without protection from hunting unless a large sanctuary is set aside for it. No strong conservation measures have been taken to date. No Koupreys are in zoos. It is possible that this species is already extinct.

The Banteng (*Bos javanicus*) is similar in size to the Kouprey, with upturned horns and an extremely stocky build. Brown to bluish-black, Bantengs have white legs and a white rump patch. Their range is larger than that of the Kouprey, extending from India to Myanmar (Burma), Thailand and Indochina, south through the Malay Peninsula to Java and Borneo. These animals are being crowded out of their forest and shrubland habitat by settlements and logging, and they are extremely vulnerable to hunting. They have become wary and shy, and large herds are now rare. Banteng have been domesticated in Indonesia and bred with domestic cattle, producing fertile offspring (Nowak 1999). Wild, genetically pure Bantengs are extinct in Bangladesh, Brunei, and probably India as well, according to the *1996 IUCN Red List of Threatened Animals*. The 2000 version of this list also classifies the species as Endangered.

The Gaur (*Bos gaurus*), largest of the three Asian wild cattle, is the most numerous, yet it is listed as Vulnerable by the *2000 IUCN Red List of Threatened Species*. Ranging from Nepal and India to the Malay Peninsula, these massive animals weigh up to 1,000 kilograms (2,200 pounds) (Nowak 1999). They have become extremely rare to absent in all

but protected national parks, and their populations have been estimated as extremely low, only about 1,000 animals (Nowak 1999). These animals are killed whenever possible for their meat throughout their range.

The Annamite Mountains extend along the border between Laos and Vietnam, rising to more than 6,000 feet in some areas, where stands of wet evergreen broadleaf forest harbor some of the strangest and rarest mammals on earth. Not until the 1990s were these remote forests explored by scientists, who examined skins and horns of rare animals killed by Hmong tribespeople. First to come to light in 1992 was the extraordinary Sao la or Vu Quang Ox (*Pseudoryx nghetinhensis*), a beautiful, gray, goat-like antelope. Its genus, *Pseudoryx*, meaning false oryx, indicates its superficial resemblance to oryx because of its long, straight, backward pointing horns. Weighing up to 200 pounds and 35 inches tall, this relatively large animal somehow had escaped the attention of scientists. (See photo in Nowak 1999.) Soon after discovery of several pairs of its horns, rewards were offered for live specimens. Two young calves were captured in Vietnam and placed in the Hanoi Zoo; within weeks, both were dead (Rabinowitz and Schaller 1994). Others were captured by villagers hoping to receive rewards, and some of the animals died (Nowak 1999).

The Hmong people know the Sao la well and hunt them whenever they can. They believe these antelope number at most a few hundred animals (Rabinowitz 1997). Many have been killed since their discovery, and hunters indicate that it has disappeared from some areas (Nowak 1999). Only a few hundred Sao las are thought to exist in Vietnam and Laos, where heavy hunting presents a major threat to them in spite of official protection by the Vietnamese and Laotian governments (Nowak 1999). Wildlife Conservation Society biologist Alan Rabinowitz (1997) estimates that they are restricted to an 800-square-mile portion of the rugged mountain forests along the border. In 1994, soon after this animal was given its scientific name, it was listed on Appendix I of CITES to prevent international commercial trade. The *2000 IUCN Red List of Threatened Species* lists it as Endangered. Vietnam set aside the Vu Quang Nature Reserve for these very rare animals and prohibited snaring in the reserve (Rabinowitz and Schaller 1994).

Other rare and newly discovered or rediscovered animals of the Annamite Mountains include two species of muntjac, or barking deer, one of which is the largest of all muntjac species; a long-snouted, yellowish wild hog rediscovered from a skull fragment; a striped rabbit, based on fur pelts found in a local village, which may be the same species or related to the endangered Sumatra Short-eared Rabbit (*Nesolagus netscheri*); and a very endangered palm civet (Rabinowitz 1997). The muntjacs and palm civet were discovered as captive animals, but nothing is known of the others, and searches for the wild hog have been unsuccessful (Rabinowitz 1997). Had these intriguing and unusual animals been discovered in a wilderness area in North America, they would be the subjects of field surveys and strict protection, as well as extensive media coverage. In Asia, where diversity is far greater and conservation a luxury few can afford, even such fascinating species may fade into extinction for lack of funding for conservation programs.

Throughout the region, much of the larger wildlife, from deer to large predators, has been hunted out, and guerrilla warfare has left the land marked with bomb craters and land mines. Alan Rabinowitz (1997), who has lived in Southeast Asia and witnessed overhunting in many countries, says, "The killing of wildlife in Laos was unlike anything I had seen elsewhere." Even within the Nakai Nam Theun Reserve, "walls of death" were constructed of thatch, bamboo and small trees, with openings rigged with snares; animals walking along the wall would be caught when trying to pass through an opening, snared by a leg or the neck, to "die a slow death" (Rabinowitz 1997).

Meat Hunting: Page 2

A wildlife slaughter of enormous proportions is taking place in Central and West African countries. Rural people who once killed animals only for personal consumption now hunt professionally, and markets in villages and cities now sell thousands of monkeys, antelope, wild cats, pangolins and even endangered apes (Pearce 1995, McRae 1997). Hunters use wire snares and leghold traps, high-powered rifles and dogs to track down animals. The tropical rainforests of west-central Africa, which once teemed with wildlife and echoed with their calls, are now falling silent.

For miles surrounding villages, wildlife has largely disappeared as local peoples throughout this vast region are killing every animal to sell its meat and body parts. Professional hunters have taken so much wildlife that little is left for local tribes. Logging corporations based in Europe have launched this commercialization of bushmeat by opening up previously impenetrable wilderness areas with logging roads and offering to buy animals that local people kill. Both the forests and the wildlife are being devastated.

Logging companies have taken advantage of these impoverished countries' national debts, buying rights to clearcut the majority of the remaining primary tropical rainforest in West and central-west Africa at bargain prices. The last primary forests in Cameroon, the Congo, the Democratic Republic of Congo and the Central African Republic are being cut and bulldozed, and their wildlife exterminated. Five-hundred-year-old trees with massive trunks 20 feet around, standing more than 100 feet tall, fall daily. The old-growth forests that provide homes for a myriad of wildlife will soon be gone at the present rate of cutting. In some areas, the logging is selective for certain species of trees, but this reduces forest diversity, and hundreds of trees are destroyed in the process of obtaining a few. When great trees fall, they bring down others, and logging roads and entry roads into forest tracts take thousands more trees.

In a shocking and moving report, *Slaughter of the Apes. How the Tropical Timber Industry is Devouring Africa's Great Apes* (Pearce 1995), the World Society for the Protection of Animals documents the tragic and gruesome slaughter of hundreds of Gorillas, Chimpanzees and other wild animals in Central African countries in this trade. The commercialization of wildlife and environmental devastation that have resulted are activities totally antithetical to the legislation and conservation ethics of the European countries--France, Germany, Italy, the Netherlands, Belgium and Denmark--that are sponsoring the logging (Pearce 1995). Several documentary films shown on the National Geographic Explorer program and CNN have shown the markets with thousands of small antelope, Chimpanzees, Gorillas, monkeys and other mammals lying dead on tables, offered for sale. fiAfrica Extremefl and fiNdoki Adventurefl are National Geographic films shown in March 2001 that document the discovery of poachers' camps with dead forest antelope, Leopard skins and other wildlife. One incident of snaring was filmed. A hunter filmed in the remote Ndoki Forest of the former Zaire found a Forest Pig struggling in a wire snare. The hunter began hitting the pig in the head to cause death, while the animal screamed and kicked. Only after hitting the animal about six times did death finally occur. Local hunters interviewed by the photographers said they regularly killed Bongos (*Boocercus euryceros*), rare and extremely beautiful rainforest antelope that are closely related to giraffes. These films traced the 1,500-mile voyage by Wildlife Conservation Society biologist Michael Fay through the last rainforests of the Democratic Republic of Congo and Gabon to publicize the fact that these magnificent wildernesses are being logged and their wildlife killed, and urgent action is needed to stop these activities.

Hundreds of Lowland Gorillas are being killed for the meat trade and sold for $40 per animal. Loggers place orders for Gorilla meat, which encourages the snaring and shooting of virtually every Gorilla that local people are able to procure for this grisly trade. WSPA found that in one district of the Cameroon, 800 Gorillas a year were being killed (Pearce 1995). Swiss photographer Karl Ammann has spent years fighting this trade (McRae 1997), and in the late 1990s, conservationists from around the world began efforts to save these beleaguered apes from slaughter.

In the forests of southeastern Cameroon, Ammann and Michael McRae, a journalist, found an infant Gorilla being kept in a dark mud-hut; the tiny animal was cowering in the corner, grinding its teeth and straining against its tether. The owner explained that the Gorilla™s parents had been shot two weeks earlier by a village hunter, the male having been wounded as he charged to defend the family, but escaping. The mother Gorilla died clutching her baby; she was then gutted and carried out of the bush, cooked and eaten (McRae 1997). Malnourished baby Gorillas are kept to be sold to passing trucks, but usually die within days. Ammann, after years of witnessing these tragedies, concluded, "Chimpanzees have the will to live if they're separated from their family, but Gorillas fall into a depressive state, and just give up on life" (McRae 1997). One baby Gorilla photographed by WSPA had been stuffed into a suitcase, where the Gorilla died of starvation after days of suffering (Pearce 1995). Another baby Gorilla was filmed lying dead in a battered cardboard box. CNN reporter Gary Streiker filmed an orphan baby Gorilla, tied on a string leash, being kicked and taunted. Huge cargo boats chug along the Congo River and other waterways of the Central African rainforest that serve as highways, carrying hundreds of orphan Chimpanzees and Gorillas to markets, stuffed in boxes

and bound with rope. fiDown the Dark River,fl a 1996 film by CNN, captured the squalid and cruel conditions that baby Chimpanzees endured on these boats. When sold as pets, baby Chimpanzees are often placed in outdoor dirt yards, lonely, solitary little gnome-like figures with sad eyes, hugging themselves or clinging to dirty cotton cloths. When they grow older and become strong and difficult to manage, they are usually killed and eaten (McRae 1997).

The total Lowland Gorilla population is not known with any certainty, and "guesstimates" of 100,000 put forth in 1985 are probably greatly exaggerated. Their true numbers are probably half that, and in steep decline (McRae 1997). Several bushmeat hunters were interviewed in fiThe Bush Meat Trade,fl a film shown on the National Geographic Explorer television series in 1995. When asked why they shoot these magnificent and protected animals, the hunters defended themselves by saying: "What's wrong with killing a Gorilla? They're fierce." One of the hunters told McRae that he was sure Gorillas were plentiful: "In Cameroon there are a million Gorillas. Three weeks ago, I saw sixty in one day. I shot three and then stopped . . . Why should I feel bad for a Gorilla? He is just a stupid animal" (McRae 1997). The West African country of Gabon also has markets where huge amounts of bushmeat are offered for sale, including Chimpanzee heads and Gorilla parts (Walters 1996).

Monkeys are killed on sight by the hundreds by hunters for sale in meat markets. Traders on the boat trip filmed in fiDown the Dark Riverfl were transporting some 30 or more dead monkeys, strung together with cord wrapped around their necks. These colorful and delicate rainforest primates are rapidly disappearing throughout their range. Monkeys from the forests surrounding the Congo River are bought by traders from hunters along the boat routes, or by logging truck drivers, and sold for $1 each in cities such as Kinshasa to be smoked for human consumption. Some traders traveling on riverboats specialize in bushmeat and barter with local people for monkeys, apes, turtles and other animals, some kept alive for the journey to preserve freshness of the meat, and others dead, stacked in piles.

WSPA has launched a campaign called EscAPE to encourage African governments to enforce existing hunting laws and police the trade in ape meat and body parts. WSPA personnel have rescued baby Chimpanzees and Gorillas from being sold as pets or abandoned, placing them in zoos or sanctuaries. A conference organized by WSPA invited loggers, conservationists, government representatives and organization representatives to discuss the bushmeat market and possible ways of ending it. The loggers boycotted the meeting, but others attended and, after two days, drafted a long list of resolutions, including enforcing existing laws, instilling conservation ethics, and restricting the logging trade (McRae 1997). In December 1995, Ammann and WSPA presented information on the trade to a committee of the European Parliament, distributing their report (Pearce 1995), and at a subsequent meeting of Afro-Caribbean-Pacific nations and the European Union, 140 delegates passed a resolution urging action (McRae 1997).

The bushmeat trade has become the foremost threat to wildlife in Central and West Africa's forests, an even greater threat than logging (McRae 1997). Urgent action to substitute other sources of income is needed. Ecotourism has been suggested, as well as employing hunters to conduct wildlife counts and become rangers. To date, no coherent program has been set into place, and hunters claim that they will continue to kill large numbers of animals until they find an adequate substitute.

Bonobos (*Pan paniscus*), or Pygmy Chimpanzees, number only about 13,000 in a restricted area of the former Zaire's dwindling rainforests. As the most endangered of the apes, exploitation could cause their extinction. WSPA documented illegal trade in these primates (Pearce 1995).

A study of the bushmeat trade in western Cameroon found serious declines in several other species of primates, caused by the meat trade. The rare Preuss's Guenon (*Cercopithecus preussi*) and the highly endangered Drill (*Mandrillus leucophaeus*), a large monkey listed on the US Endangered Species Act and Appendix I of CITES, are also being hunted for market sale. In one hunt alone, 30 Drills were killed (King 1994). Troops in the area have declined in number. One monkey, the Russet-eared Guenon (*Cercopithecus erythrotis camerunensis*) has been hunted to extinction there, and all primates from the Mount Manenguba region have declined dramatically (King 1994). In Sierra Leone, 300 tons of monkey meat are exported to Liberia each month, decimating wild populations of Red

Colobus (*Procolobus badius*) and Diana Monkeys (*Cercopithecus diana*). All these primates are listed by the *2000 IUCN Red List of Threatened Species* as Endangered. Scientists predict extinction in the region for the Red Colobus in 10 years, and the Black and White Colobus (*Colobus guereza*) in 20 years. Gabonese markets also offer various species of monkeys for sale. In one market, three small monkey heads were lined up on a gutter curb. Two of the faces were expressionless, and the third was open-mouthed, its eyes staring under furrowed brows, "as if frozen in a final, terrified gaze" (Walters 1996).

The Gabonese bushmeat trade, while not linked to commercial logging, has nevertheless grown in size and, in 1993, accounted for almost 11 percent of the country's gross domestic product (Walters 1996). A 1993 study found that, in a single city, more than 5,000 animals of 43 species of mammals, reptiles and birds were sold per year. Guenons; the magnificent and colorful Mandrill (*Mandrillus sphinx*), a Vulnerable species; Black Colobus; Chimpanzees; Gorillas; four species of duiker antelope; pangolins; Brush-tailed Porcupines; mongooses; genets; civets; and African Golden Cats are among the mammals killed for sale in Gabonese markets (Walters 1996). Birds being sold in these markets include crowned eagles, vultures, hornbills, guineafowl and plaintain eaters (a type of turaco). Pythons, Gabon Vipers, Nile Monitors, hinge-back tortoises and even threatened West African Dwarf Crocodiles (*Osteolaemus tetraspis*) were being marketed. Even animals protected under Gabonese law as endangered species are offered openly for sale. In addition to Gorillas and Chimpanzees, the Giant Pangolin (*Manis gigantea*), a race of the Potto (*Perodicticus potto*), and Demidoff's Dwarf Galago (*Galagoides demidoff*), nocturnal primates, all threatened species, could be obtained clandestinely (Walters 1996). In some areas of Gabon, high-ranking government--as well as local--officials supply hunters in villages with rifles and ammunition. Hunters then decimate wildlife and exchange the dead animals with traders for beer or soap. The traders then sell them for large amounts in city markets (Walters 1996). Hunting takes place throughout the forests, which still cover much of the country, and even in protected reserves where hunting is not allowed (Walters 1996).

An environmental organization, ECOFAC, has set up an ecotourism project to attract visitors to one of Gabon's wildlife havens, the Lope Reserve. Paths have been made through the forests, and 24 elevated observation posts have been built by members of the Scottish Primate Research Group, who have spent years habituating mangabeys and Chimpanzees to human contact (Walters 1996). The goal is to provide local communities with an alternate form of income from tourism and, perhaps, to spread the concept throughout the country and elsewhere in tropical forests where viewing wildlife is not as easy as in open savannah habitats.

The wild animal trade of Central and West Africa is obliterating populations of small forest antelope, such as various species of duiker. Twelve species of central and west African duiker are listed in the *2000 IUCN Red List of Threatened Species*. The meat trade and unregulated hunting, accompanied by destruction of forests, are the major threats. These animals are killed by capture in snares, where they may struggle for days. Two small, delicate antelope, both on CITES Appendix II, the Blue Duiker (*Cephalophus monticola*) and Bay Duiker (*Cephalophus dorsalis*), are trapped in wire snares or taken in pit traps in the Cameroon (King 1994). Dismembered duikers were seen in a market in Libreville, the capital of Gabon, in 1995 (Walters 1996).

Illegal snaring for antelope meat in national parks has been a major threat to Mountain Gorillas (*Gorilla (gorilla) beringei*), who number only about 650 animals. Many have lost their hands to snares, but some have now learned to recognize these traps and spring them. In 1995, however, a baby Mountain Gorilla strayed from the group and became snared, crying and struggling in terror for almost 24 hours while family members watched helplessly until Virunga National Park guards cut him free. Others have died in these snares.

Congo's national park, Odzala National Park, an area of 1,000 square miles, until recently had the region's only unexploited populations of African Elephants, African Buffalo and other mammals. Because of a lack of guards, poachers are now invading the park. The European Economic Community has agreed to fund the hiring and training of guards, with help from the Congolese army. This country is nearly bankrupt, like neighboring countries, making wildlife protection extremely difficult. Private hunting safaris enter the Congo rainforest and, for a fee, a foreign hunter can kill rare species of antelope and other wildlife.

Those who eat African monkeys and apes may be risking death. Several people who ate a dead Chimpanzee they found in the forest in Gabon died of the dreaded ebola virus, and the disease threat is not well-known to those who eat the meat of primates. Sooty Mangabeys harbor a virus related to HIV-2, an AIDS-like virus, and McRae (1997) saw a hunter carrying dead mangabeys, dripping blood into scratches on his leg.

In the Amazon, primates are avidly hunted for meat. Russell Mittermeier, head of the IUCN Primate Specialist Group, states that thousands of primates are killed by hunters, causing local extinctions of woolly monkeys (*Lagothrix* spp.) and spider monkeys (*Ateles* spp.) in Peru and Brazil. Forest tribes in Suriname kill very large numbers of primates for food, selling the meat in many local markets. The Wildlife Conservation Society (WCS) has been working with several native tribes in South America, evaluating the effect of their hunting on wildlife. They have found that in many cases, natives were overhunting many animals, causing local extinctions, even when only killing for subsistence. Peccaries of various species have been extremely vulnerable.

Meat Hunting: Page 3

Fruit bats of Asia and Pacific islands are killed in large numbers for food, sold by the tens of thousands to markets in Southeast Asia. Two species of the western Pacific, the Little Mariana Fruit Bat (*Pteropus tokudae*) of Guam and the Mariana Fruit Bat (*Pteropus mariannus mariannus*) of Guam, Rota, Tinian, Saipan and Agiguan have both been exploited so heavily that they are nearly extinct. Both bats are listed on the US Endangered Species Act as Endangered, yet the trade continues. On Sulawesi Island in Indonesia, thousands of bats are caught by young boys using kites to entangle them as they fly overhead. These bats are vital as pollinators of many species of commercially important fruit.

Bushmeat hunters in Indonesia and Malaysia are wiping out the populations of many animals. On the island of Borneo, a study conducted by the Wildlife Conservation Society found that hunting, legal and illegal, was the single greatest threat to wildlife (Bennett 1994). In Sarawak and Sabah, two northern states on Borneo, Elizabeth Bennett and her assistants conducted a three-year study of native hunting. These rural people, who previously had hunted only for subsistence, now hunt to sell the meat to town markets (Bennett 1994). Areas that had been inaccessible were opened up by logging roads, and hunters now swarm in the forests, killing any animal they see (Bennett 1994). Except in the most remote areas, all local people now possess shotguns. Squirrels, which have a great diversity of species on Borneo, nearly disappeared in some areas, along with leaf monkeys (Bennett 1994). Bearded Pigs, macaques, deer and porcupines are hunted, speared and trapped by some tribes (Bennett 1994). The only taboo involves the killing of Orangutans, who are protected by legend. Hunting pressures were so great that Bennett predicted extinctions for many animals, and the effects on the forest ecology were equally dire, as seed dispersers are killed off (Bennett 1994). WCS is working with local peoples to educate them about the effects of their hunting, with the cooperation of the Forest Department of Sarawak and the Wildlife Department of Sabah (Bennett 1994).

On the neighboring island of Sulawesi, formerly known as Celebes, WCS conducted a similar study in the Tangkoko-DuaSudara Nature Reserve. The study found that in the past 15 years, populations of the endemic Bear Cuscuses (*Ailurops ursinus*), bear-like marsupials who hang by their prehensile tails from branches, had declined by 95 percent from hunting (Kinnaird and O'Brien 1996). Crested Black Macaques or Celebes Apes (*Macaca nigra*), tailless, all-black monkeys found only on Sulawesi and listed as Endangered by the *2000 IUCN Red List of Threatened Species*, have declined by 90 percent, due in large part to meat hunting (Kinnaird and O'Brien 1996). An extraordinary turkey-like bird that incubates its eggs in large, leaf mounds, the endemic Maleo (*Macrocephalon maleo*), a Vulnerable species (BI 2000), has declined 75 percent from hunting (Kinnaird and O'Brien 1996). Other endemic species affected by this hunting are the Mountain Anoa (*Bubalus quarlesi*), a CITES Appendix I threatened dwarf buffalo found only on Sulawesi that is on the verge of local extinction, and the threatened, gargoyle-headed

Babirusa (*Babyrousa babyrousa*), a tusked wild pig, whose total wild population is about 5,000 (Kinnaird and O'Brien 1996). Highly organized networks hunt and trade the meat from these threatened species. Some dealers acquire animals on order for traders in North Sulawesi by driving up to 375 miles to buy Babirusa and other meat from forest hunters (Kinnaird and O'Brien 1996).

When native peoples cease hunting for subsistence only and begin hunting for markets, wildlife can be decimated quickly. Even subsistence hunting has been shown to be detrimental in some areas, but when wild animal meat becomes an economic commodity, overhunting usually results. Market hunting in the United States caused the extinction of the Passenger Pigeon (*Ectopistes migratorius*) and Labrador Duck (*Camptorhynchus labradorium*). The Eskimo Curlew (*Numenis borealis*), heavily hunted for meat in the 19th century, is probably extinct as well. The American Bison, Elk, White-tailed Deer and many waterfowl species also nearly disappeared. Following the 19th century slaughters that decimated these animals, laws banning the sale of wild meat from mammals and birds were enacted and remain in force today. In other parts of the world, only extinctions may bring about strong legislation banning market hunting of wildlife.

Endangered Species Handbook

Trade:

Trade

Introduction

Trade in live animals, plants and the product made from them threatens many species with extinction. Approximately 15 percent of highly threatened mammals and birds have declined as a result of trade (Hilton-Taylor 2000). Internationally, billions of dollars are earned legally and illegally, and each year, more species become exploited. In a classic pattern, wildlife and plants are captured or extracted from their natural environments until they become rare. This rarity adds to their value, and in many cases, such as exotic cage birds, live reptiles and amphibians, and rare plants, for example, the rarer they become, the more they are sought after, increasing their value. Much of this trade is for luxury products or to supply collectors who have a desire to own rare birds, frogs, lizards, turtles or snakes, with no regard as to the effect on wild populations. For others, such as snakes and lizards killed for their skins to be made into exotic leather products, or whales slaughtered for their meat, one species is exploited until it becomes commercially extinct, and then non-endangered species are exploited until these, too, become endangered. Some animal products, such as ivory, are as valuable as gold, threatening elephants, among the most intelligent of all animals. Fisheries for expensive gourmet items, such as caviar, have endangered all Eurasian sturgeon. A majority of fish and shellfish species have been overfished to depleted status.

The fur trade has endangered many species and continues to use the skins of rare cats and canids. A major market for plants and animals to supply the Traditional Medicine (TM) trade has devastated Tigers, rhinoceros and hundreds of species, in spite of laws protecting these species. For the majority of species exploited for this trade, substitutes exist or they are not effective remedies. National and international laws and treaties, such as the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES)*, have had major effects on trade in endangered and threatened species, but the illegal trade continues to flourish, worth an estimated $3 billion a year in protected live animals and animal products. Ecological systems worldwide are being disrupted by the removal of predators and other keystone species, causing a loss of biodiversity.

---

*CITES is discussed in detail in the Legislation section and reproduced in the Appendix.

The methods used to capture and kill animals for the wildlife trade are often cruel in the extreme. Steel jaw leghold traps and wire neck snares, which cause great pain and injury, produce pelts for "fun furs." Whales die from exploding harpoons thrust into their heads and bodies. Frightened live animals are crowded into cramped, dirty cages and transported to pet shops and laboratories, suffering high mortality along the way. Man's inhumanity to animals reaches an extreme in the wild animal trade.

Whaling

While whales are revealing their intelligence and amazing communication abilities to scientists in one part of the world, they are being ruthlessly slaughtered in another. Once whales swam in enormous numbers in all oceans, communicating in complex sounds that resonate through the water. The beautiful and eerie songs of the Humpback Whale (*Megaptera novaeangliae*) resound for a thousand miles.* Each complex song lasts as long as half an hour, and different populations of these whales improvise their own dialects, evidence of an extremely evolved communication system. We are unable to decipher this language, and our knowledge of whales is extremely primitive. Hydrophones lowered into the icy waters near Bowhead Whales have picked up strange calls ranging from

groans to trumpet-like blasts to loud squeaks.* Through limited contacts, whales have shown intelligence and sensitivity. They soon become tame and friendly when approached by whale watchers. In recent years, Pacific Humpback Whales have approached boats of whale watchers in the manner of the friendly Gray Whales (*Eschrictius robustus*), which swim up to tourists in Baja California, Mexico. The Humpbacks swim close to these boats and turn on their sides, flapping their huge white flippers on the water surface.

---

*These sounds can be heard in fiGentle Giants of the Pacific: Humpback Whalesfl (Sierra Club Films) and fiThe Bowhead Whalefl (Wildlife in Production Films and Discovery Productions, 1998), which give an intimate glimpse into the lives of these whales and their feeding, habitat and the animals that share their world.

The devotion of whales to one another has been observed for centuries by whalers whose boats were attacked by distraught and angry whales after a member of the pod was harpooned. Carl Sagan, in *Cosmos* (1980), considered whaling to be monstrous when, instead, we should be seeking to communicate with these "intelligent masters of the deep." Whaling destroyed millions of these marine giants, pushing them close to extinction. A half century of protection has not resulted in their recovery. Many are still killed illegally. Whaling nations, many of them among the wealthiest in the world, continue to kill smaller whales openly, often in defiance of international agreements.

Early Whaling and its Effects

The decimation of the great whales has been going on for centuries, one species after another hunted to commercial extinction or to levels so low that it is no longer profitable to hunt them. Atlantic Gray Whales were hunted to actual extinction as described earlier in this book, and populations of these whales that once inhabited the waters off Korea and the western Pacific were hunted until 1966, when they disappeared (Reeves *et al*. 1992). In the early 1990s a Gray Whale was seen off the coast of Japan for the first time in decades, giving hope that the species might repopulate this area.

In the 8th century, the Basques of northern Spain hunted the Northern Right Whale (*Eubalaena glacialis*) for meat and whalebone in the Bay of Biscay, where they came to winter and have their calves. These whales once swam along the Atlantic coasts of Europe and North America in annual migrations, spending the summers in northern waters and winters in the warm waters off Florida and Spain. They were so named by English whalers because they were "right" for their purposes: they were easy to kill; they yielded large quantities of oil and whalebone, which was used for women's corsets; and they floated when dead (Allen 1942). The slow-moving Right Whales feed on plankton and krill, which they strain through baleen plates in their huge mouths.

By 1800, almost no eastern Atlantic Right Whales survived, and whalers sailed to American waters, where New England colonists slaughtered the western population. Where once thousands of these whales swam along coasts of eastern North America each fall, few remained after centuries of whaling (Allen 1942). Killing of this beleaguered species continued from whaling stations off Ireland and the Hebrides in spite of catches of only 10 to 18 whales a year. These whalers could find no more Right Whales by about 1910. Fortunately, a few remained elsewhere, but the species is the most endangered of all whales. Still extinct in the eastern Atlantic, they number only about 350 animals in the western Atlantic. In the eastern North Pacific, Right Whales once ranged from central Baja California, Mexico, to the Gulf of Alaska and into the Bering Sea; along the Asian coast, they were seen from the Bonin Islands north to the Kamchatka Peninsula of Russia (Leatherwood and Reeves 1983). Today, the North Pacific population is estimated by some experts at fewer than 300, having failed to recover from early whaling (Harrison and Bryden 1988). This species is on the edge of extinction.

The remnant eastern Atlantic population no longer swims close to shorelines, which are now cluttered with vacation homes, marinas and cities. Their ancestral feeding grounds are polluted, and constant boat traffic presents the threat of collisions. Swimming far offshore, they take months to reach their wintering grounds. A dead Right Whale calf was discovered in salt marshes in Georgia about a decade ago, probably the victim of a boat collision. This launched a research program to locate wintering whales by air and to tag and identify them as individuals. Dredging boats along the Georgia coast are notified when Right Whales are spotted nearby, and they must stop until the whales swim away. Further north, another team monitors the whales off New England in the summer with spotter aircraft, notifying ship pilots of their presence (McFarling 1994). Most collisions have taken place off Boston, where a stream of liners and giant cargo ships arrive from Europe. Off Florida there have been fewer incidents, as the Coast Guard keeps a very careful watch by air and immediately radios any ship in the area of the whales™ location.

Genetic analysis of the DNA of Northern Right Whales has indicated that they may be inbred and becoming sterile, having been so reduced by whaling that only a very small number of whales remain alive. Scientists have obtained small tissue samples from these whales by firing arrows attached to lines that can be retrieved after firing. Preliminary results indicate that all North Atlantic Right Whales may have descended from only three families on the female side and, perhaps, from as few as three individual females (Allen 1995). Since the majority of individual whales have been identified, it is known that at least 13 of 65 sexually mature females have had no calves since 1989 (Allen 1995). In a species that reproduces so slowly and is suffering such casualties from ship collisions, this may spell extinction. The rate of increase for these whales is only about 2 percent. By contrast, Southern Right Whales (*Eubalaena australis*) in the South Atlantic and Antarctic waters, which numbered 100,000 until they were decimated by whaling (Leatherwood and Reeves 1983), are increasing at a rate of 7 to 8 percent a year, far faster than the North Atlantic population. However, with a population of only about 3,000, they are still highly endangered (Allen 1995).

The Bowhead Whales (*Balaena mysticetus*) of the North Atlantic and Arctic Oceans were killed in great numbers from early times by whalers from England and the Netherlands, nearly causing the whales™ extinction (Lean and Hinrichsen 1992). Beginning in the 17th century, on the other side of the Atlantic, whalers from Nantucket Island, Massachusetts, pursued Sperm Whales (*Physeter catodon*) for their valuable oil, which was used in lamps and as lubrication. With a fleet totaling 150 ships, they eliminated the majority of these whales. Then in the 18th century, whalers discovered the enormous numbers of Sperm Whales in the Pacific. By 1846, New England whalers had 736 ships at sea, and only the discovery of petroleum in Pennsylvania saved the Sperm Whales. Right Whales, Gray Whales and Bowhead Whales of the Pacific were all mercilessly hunted until they, too, neared extinction (Allen 1942).

When an explosive harpoon was developed in Norway in 1865 that could be fired into a whale's body from a cannon mounted in the bow of a ship, a new wave of slaughter began (Allen 1942). Its deadly power was soon turned on the rorquals (Humpback; Blue (*Balaenoptera musculus*); Fin (*Balaenoptera physalus*); and Sei Whales (*Balaenoptera borealis*) far away from shore. These whales had been difficult for whalers to take prior to the development of the explosive harpoon because they were swift and strong swimmers of the open ocean (Allen 1942). The new explosive harpoons, although deadly, did not kill instantly, and these whales suffered slow deaths. The huge numbers taken by these harpoons over the next decades caused their populations to decline to commercial extinction.

Factory Ship Whaling

Whalers then turned to the Antarctic where vast numbers of Blue, Humpback, Sei and Fin Whales migrated each summer to feed on the abundant krill. In 1903, the first "floating factory" whaling ship sailed from Spitzbergen, Norway. These ships, when moored near a land base, could process whales brought alongside by small killer boats.

The initial victims of these new ships were the Antarctic Humpback Whales which congregated each summer near the Antarctic Peninsula. The factory ships were joined by some older vessels, and exploitation was unrelenting. About 70,000 Humpback Whales were killed between 1909 and 1913, and by World War I, these whales were almost extinct in the Southern Ocean (Garrett 1981). The toll of Antarctic whales taken in the early 20th century was staggering: more than 122,000 were killed between 1909 and 1927 (Reeves 1979). Humpback Whales finally received protection in 1966 from the International Whaling Commission (IWC), but pirate whalers as well as certain Caribbean nations continue to hunt them.

Factory ships were developed in 1925 with rear slipways through which whales could be winched onto the ships. Whales could be killed either in the open ocean or near ice floes and pulled onto the deck for flensing and rendering (Garrett 1981). With this development, the fate of the vast populations of Blue and Fin Whales of the Antarctic was sealed. First the Blue Whales were slaughtered. They stayed close to the pack ice, convenient for both factory ships and moored vessels. More than 15,000 a year were taken in the 1920s, with a high of almost 30,000 in 1930 (Allen 1942). Soon these mammoth whales, the largest animals on Earth, declined. By 1934, the average length of Blue Whales killed had dropped to 79 feet; 41 percent of the females caught were immature (Allen 1942). These great whales do not reach sexual maturity until females attain a length of 78 feet. The 1937 International Agreement for the Regulation of Whaling reduced the limit to 70 feet for Blue Whales, thus failing to conserve breeding females (Allen 1942). Between 1910 and 1966, a staggering 330,000 Blue Whales were killed in the Antarctic (Lean and Hinrichsen 1992).

After World War II, the IWC was established under the International Convention for the Regulation of Whaling to "provide for the conservation, development, and optimum utilization of the whale resources" (Ehrlich 1981). Member nations now include both whaling and non-whaling countries. The Scientific Committee of the IWC recommends restricting the number of whales killed when it determines that the species will decline as a result. In the early years of the IWC, these recommendations were rarely followed by whaling nations, and so little knowledge of great whale population, biology and status had been uncovered that quotas were far too high to sustain these slow-reproducing species. The destruction of the great whales is a true biological tragedy. Even after almost 40 years of protection, their populations have increased only slightly. Their life histories are certainly part of the explanation. Blue Whale females, for example, are thought to become sexually mature only when they reach 10 years of age. Gestation lasts 12 months, and the single 23 to 27-foot long calf stays with its mother for about two or three years. Sperm Whales do not mature until they are past 20 years of age, and mature bulls, who are the major breeders, are at least 50 years old. Killing of these whales, which did not end until 1983, wiped out the vast majority of big bull Sperm Whales.

Until recently, it was not known how long whales live. New findings are astounding. A Bowhead Whale recently killed by Eskimos was found to have two stone harpoon blades embedded in its blubber; as reported by *National Geographic* ("Geographica," March 1996). This discovery fixed the whale's age at more than 100 years because the use of stone harpoons ended a century ago when metal tools were brought to Alaska. The whale was only a few years old when it was wounded by the handmade pointed tool, and Stephen Loring, an Arctic specialist at the Smithsonian Institution, estimated that when killed, it was between 100 and 130 years old. Further research by the Scripps Institution of Oceanography on three Bowhead Whales killed by Inupiat Eskimos in northern Alaska estimated their ages at death at between 135 and 172 years old. The age of a fourth Bowhead was estimated at 211 years old, which would make the Bowhead Whale the longest-living of all animals, surpassing the oldest known land tortoises. The ages were determined by studying changes in amino acids in the lenses of the whales' eyes. Harpoon points made of ivory and stone, not used since the 19th century, have been found in other Bowhead Whales killed in recent years. Moreover, several generations of hunters have spoken of seeing the same Bowhead Whales, which they recognized as individuals based on their markings.

Whales knew few enemies in the sea before man, and they evolved no defenses that could have protected them from harpoons tearing through their flesh, nor could they increase their rate of reproduction to compensate for the extremely high kill. Another factor hampering their recovery has been illegal whaling. Blue Whales and other endangered species were illegally harpooned long after they received official protection, and this is still taking place.

During its first 30 years, the IWC permitted the deaths of 1.5 million great whales (Bright 1991). It pushed the very species that it had taken responsibility to conserve closer to extinction. Blue Whales, the largest whales, measuring up to 100 feet, were totally eliminated, and smaller and smaller whales were caught. The average length of the Blue Whales caught had declined to 73 feet by 1965 (Scheffer 1974). At this point, when the species had been reduced to only 6 percent of its original numbers, the IWC finally accorded protection (Scheffer 1974). Blue Whales number only about 12,000 worldwide. All populations of this whale in the Southern, Atlantic and Pacific Oceans are listed as Endangered by the *2000 IUCN Red List of Threatened Species*.

Decimation of 81-foot Fin Whales in the Antarctic followed until their populations collapsed early in the 1960s. Fin Whales in the North Atlantic became overexploited in the 1970s. Whalers then turned to the Sei Whales, fastest of the whales, a sleek species reaching a length of up to 58 feet (Heintzelman 1981). When these whales became depleted, the Minke Whale (*Balaenoptera acutorostrata*), the smallest of the great whales at less than 33 feet long, became the major prey of whalers.

The Cruelty of Whaling

Added to the decimation of entire species, whaling involves great cruelty. An eyewitness on an Australian whaler in 1977 described the long death of a great whale:

> *The harpoon seemed to pass right through it, which can happen and the second explosion took longer. The whole event this time seemed in slow motion. The whale dived, and a great green cloud burst up to the surface. Blood turns green underwater at 50 feet...or was this some of its intestines? It came up on the starboard side, its huge head, a third of its total body size, shaking itself, and then it gave out a most terrible cry, half in protest, half in pain, and then it dived again. They loaded the next harpoon, the killer, but could not get a shot at it as it twisted and turned, hurting itself all the more. Finally, the lookout in the crow's nest shouted down that it was coming up dying. Its mouth was opening.*

Australian Government Printing Office. *Whales and Whaling*. 1979.

No method exists to kill whales instantly. The cold harpoons used by some native peoples and by other whalers to kill thousands of Minke Whales are cruel, sometimes taking an hour to kill. Native whaling methods are not regulated. The trauma and rage experienced by stricken whales was documented by Greenpeace activists who sailed to the North Pacific in 1975 in order to place themselves between Russian whalers and their prey, the Sperm Whale. One of the first observations was a small whale, well under the 30-foot limit, floating dead on the water. The Greenpeace crew positioned their rubber raft between the killer boat and the whales, believing that the harpooner would not shoot the 250-pound harpoon with the possibility of killing their crew, but they were mistaken (Ellis 1991). The harpooner fired over their heads, scoring a direct hit on a large Sperm whale; the whale died in a sea of its own blood and guts. Then another whale in the pod charged at the Greenpeacers (Ellis 1991). As soon as the huge Sperm Whale perceived they were not the harpooners, it headed instead for the Soviet whaler, with its powerful jaw clapping; "this whale charged the harpoon boat and seemed to leap out of the water in an attempt to get to the gunner" (Ellis 1991). When the whale was close to the whaling boat, the gunner pointed his cannon almost straight down and shot the whale, killing it (Ellis 1991).

The whale filmed by Greenpeace had made a valiant attempt to destroy the gunner who had killed its fellow whale, perhaps its mate, and had also realized that the Greenpeacers were not at fault. Killing such an intelligent and courageous animal for commercial profit is absolutely unjustifiable. Sperm Whales have, in fact, the largest brains of any animal, weighing 20 pounds (Ellis 1991). Yet we know little of their intelligence, habits and biology. Some scientists have theorized that Sperm Whales stun their prey with sonic blasts; they descend to depths up to 2 miles and are known to feed on Giant Squid, perhaps after stunning and holding the squids™ slippery bodies in their sharp teeth (Ellis 1991). There is oil in the whales™ heads, which may play a role in such acoustical feats.

In 1981, a major humane victory was won. The cold harpoon was banned for all commercial whaling effective at the end of 1982. The decision was a precedent-setting event. Humaneness became an issue to be considered, and the IWC undertook the responsibility to insure that methods are not unnecessarily cruel. This is a relative term, however, since all existing methods are intrinsically painful and inhumane. At the 1995 IWC meeting, a Workshop on Whale Killing Methods heard a research paper on the killing of Minke Whales. These whales are first mutilated by an explosive grenade then, several minutes later, shot with rifles or prodded with an electric lance. Although some have considered these methods to result in a quick death for the whales, researchers have maintained through examination of physiological evidence that breathing and heartbeat continue even when the body is immobilized. The limp and dying Minke Whale may be sensitive and capable of experiencing both fear and physical distress for significant amounts of time. In fact, the IWC tacitly acknowledged at its 1995 meeting that the electric lance was inhumane by passing a Resolution calling for a suspension of its use. At the 1996 IWC meeting, a United Kingdom/New Zealand proposal to ban the use of the electric lance failed.

During a recent investigation of the killing of Minke Whales by Norway for *National Geographic*, a whale already struck by a lance carrying a thermal grenade revived as it was being reeled on board (Chadwick 2001). It rammed the ship, causing the mast to break and sending two crew members into the sea; it then escaped (Chadwick 2001). Its fate is unknown, but its survival is unlikely.

Another cruel aspect of whaling is the killing of female whales, leaving their calves to starve. Some whalers in the past killed calves first, knowing their mothers would not desert them. In 1935, the killing of mothers and calves was finally prohibited by the IWC, but some whalers did not abide by the prohibition. Moreover, the rule may be impossible to enforce. The harpooner who fires into a pod of whales can hardly be sure that the whale he hits is not a female with calf.

Pirate Whaling

A young female Blue Whale was harpooned off the Peruvian coast in 1978, more than a decade after their killing was made illegal. As described by Craig Van Note in his expose, *Outlaw Whalers*:

A 150-lb. harpoon had been fired into the side of the whale . . . after penetrating three feet, a massive grenade at the tip of the harpoon exploded, tearing the whale's internal organs to a bloody pulp with jagged, fist-sized metal fragments. In her agony, the . . . whale tore at the heavy barbs that had expanded from the sides of the harpoon. Wrenching her 75-ton body, she pulled free from the harpoon and heavy rope that ran back to the catcher boat. With a gaping wound in her side, the whale dove deep to successfully escape her pursuers. But the terrible wound caused massive hemorrhaging and each succeeding day the whale grew weaker. Finally she could not hold herself up to the surface to breathe. So she swam ashore through the surf, sliding to a halt on the coarse sand at Conchan. There Peruvian conservationists gathered to witness the final hours of life of the blue whale. She lay on her side, with the harpoon-wound facing shore, gasping for breath" (Van Note 1979). The late Felipe Benavides, a Peruvian conservationist who fought to drive the foreign whalers from Peru's shores for 30 years said, 'This young whale was one of the most beautiful creatures I have ever seen. Watching her die was one of the saddest experiences of my life' (Van Note 1979).

In *The Blue Whale*, which won the National Book Award, George Small (1971) described case after case of illegal whaling. The Greek shipping magnate Aristotle Onassis, one of the world's wealthiest individuals, wantonly killed thousands of critically endangered whales. In the 1950s, a whaling fleet owned by Onassis illegally slaughtered numerous female Blue Whales as well as their nursing young. Its factory ship, the *Olympic Challenger*, registered in Panama, became a notorious pirate whaler; seven German citizens who served on this ship signed affidavits at the Norwegian Consulate in Hamburg in 1956, testifying that they had witnessed innumerable illegal whaling practices and had photographic evidence of whale carcasses and ship's logs (Small 1971). Among the infractions of the *Olympic Challenger* in 1954 was the slaughter of 285 Blue Whales, 169 Fin Whales, 105 Humpbacks, 4,648 Sperm Whales, and 21 Sei Whales. The ship declared a catch of only 2,348 Sperm Whales. Of the Blue Whales killed, many were young: 35 were 59 feet or less in length and two were less than 49 feet (Small 1971). IWC rules at that time prohibited all factory ship whaling of baleen whales between the Antarctic and the Equator (Small 1971). Onassis' ships shot baby Sperm Whales before they even had teeth; some were only 5 meters long and must have been newborn calves (Small 1971). On occasion, four young whales at a time were hauled on board by winch; often a whale was so small that it was only necessary to remove the harpoon and entrails before the carcass was dropped whole into the cookers (Small 1971). The entrails of baby whales jettisoned by the *Olympic Challenger* floated for some time, providing evidence of its illegal whaling (Small 1971). After many protests were lodged, Onassis made a payment of $3 million to a special fund, which was taken as an admission of guilt (Small 1971).

In 1994, records from Soviet whalers were uncovered, documenting the illegal killing of hundreds of Blue Whales for decades, beginning in the 1950s and continuing long after they had been officially protected. These whales, under the direction of the KGB, developed sophisticated methods of preventing detection. The decks were surrounded in steam, hiding the carcasses of protected species, including highly endangered Right Whales. Several hundred of these whales were killed in the Okhotsk Sea in the 1960s, and more in the South Atlantic (AWI 1994). The Soviets™ radio communications were coded, and messages such as "Sink the prohibited whales" were sent when aircraft appeared overhead. Professor Alexey V. Yablokov, a member of the Animal Welfare Institute's Scientific Committee, examined these records, which revealed this shocking flouting of whaling bans. Yablokov studied cetacean morphology during the 1950s and 1960s and received many specimens from Humpback and Right Whales that had been killed illegally (AWI 1994).

EFFECTS OF WHALING ON THE GREAT WHALES (chart)
The figures below represent estimates based on the sources cited.

Species	Northern Hemisphere		Southern Hemisphere		Totals		
	Original	Present	Original	Present	Original	Present	% Change
Blue ***Balaenoptera musculus***	20,100	4,300	200,000	10,000	220,100	14,300	- 94%

The Long Battle for the Whales

The first major step toward ending whaling came in 1971 when the U.S. Secretary of the Interior banned commercial whaling by the United States. Also in 1971, Congress passed a Resolution calling on the Secretary of State to negotiate a 10-year moratorium on commercial whaling with other nations. The 1972 Marine Mammal Protection Act (MMPA) banned all harming and killing of marine mammals without a permit, further protecting whales. The same year, Canada stopped commercial whaling after failing to fill quotas allocated by the IWC (Ellis 1991). Years later, however, Canada became one of the countries voting against whaling moratoriums at IWC meetings. Listing of the great whales on the U.S. Endangered Species Act of 1973 banned import and export of eight species, thereby cutting off commercial imports of whale meat. At its 1972 meeting, the IWC rejected the U.S.

proposal for a moratorium, instead voting a quota of 45,000 whales.

The Long Battle for the Whales: Page 1

For more than a decade, conservation and humane organizations fought to reduce quotas set by the IWC of whales that could be killed. Gradually over the years, representatives from non-whaling countries joined the IWC and voted for lower quotas. Public opinion in most countries is solidly on the side of the whales. The fight to stop commercial whaling through decisions of the IWC was finally won when a moratorium was passed in 1982. At present, virtually all the large whales and several smaller whales have been listed on the U.S. Endangered Species Act and banned from international trade through their listing on Appendix I of CITES. Japan refused to accept the CITES listings and took reservations on most species of great whales, meaning that it gave notice it will not enforce these listings. Any country may choose to do this without losing its membership--a major CITES loophole. Today, Japan retains reservations on Baird's Beaked Whale (*Berardius bairdii*), Sei, Bryde's (*Balaenoptera edeni*), Fin, Minke and Sperm Whales, although officially it stopped importing whale meat in 1992 (Chan *et al*. 1995a). When the ban on commercial whaling voted by the IWC took effect in 1986, many believed that the long fight had been won. Unfortunately, whaling continued in various forms--some allowed by the IWC, and some in defiance of it. On May 19, 1992, the U.S. House of Representatives set an excellent example when it voted unanimously to pass a Resolution supporting an indefinite moratorium on whaling, stating, in part, "Whereas there is significant widespread support in the international community for the view that, for scientific, ecological, aesthetic, and educational reasons, whales should no longer be commercially hunted . . ." This Resolution did not, unfortunately, change the minds of the few nations who continue to kill whales.

Aboriginal whaling by the Inuit tribe and other native peoples has long been permitted under quota by the IWC, even for endangered species such as Bowhead and Humpback Whales. The IWC, at its 1993 meeting, called upon its Scientific Committee to investigate management regimes to govern subsistence whaling in order to minimize depletions of whale populations. Inuits in Alaska have continued whaling as a tradition--more than a need--since they have received substantial settlements from the U.S. government, and some lease their lands to oil and gas companies for high royalties. A Bowhead Whale killed in a hunt in 1996 had been stabbed by 14 harpoons and shot with countless bullets before it died (Vlessides 1998). After two days, it rose to the surface and was towed to shore, one of the few of these endangered whales to have been taken in the eastern Canadian Arctic since hunting the species without a license became illegal (Vlessides 1998). Bowhead Whale populations in the eastern Arctic had fallen from more than 10,000 to about 700 in 1996, but this hunt was to be a rebirth of an old Nunavut tradition (Vlessides 1998). The Inuit used sonar devices to search for the whale after it had been struck and shot, and they carried satellite phones. When the whale was towed to a rocky beach, 100 villagers sliced a ceremonial piece of blubber from the whale, then the hunters left and the meat was never cut. The dead Bowhead rotted on the beach, and the following spring, the community members paid to get rid of the carcass, some of which was set adrift on ice floes and the rest burned (Vlessides 1998). This whale, which might have been more than 100 years old, died a slow and painful death for no good reason.

Another Bowhead Whale was killed off the Northwest Territories in 1998, with an exploding harpoon gun. It was

smaller than normal adults, only 43 feet instead of 60 feet long, and was fed on by natives of various Inuit settlements (Nickerson 1998). The International Whaling Commission condemned the hunt in a formal Resolution and implored Canada to ban it, as did many activists and conservation organizations (Nickerson 1998). In the waters where this whale was killed near Baffin Island, these whales have not rebounded in numbers from past whaling. Canada left the IWC in 1982, insisting that it is no longer a whaling nation, and defended the hunt as "sustainable" because designated communities may kill a single Bowhead every other year (Nickerson 1998). With a population of only about 7,200 worldwide, and a low population in the Canadian Arctic, any take might be more than the species can sustain. Moreover, the meat and blubber are laden with highly toxic chemicals (see below). Should the Inuit choose to let the Bowhead Whales increase without killing any of these extremely rare animals, they might come to realize that certain ancient traditions can be left behind without harming their culture.

Our knowledge of whales is only fragmentary, a science in its early stages. Research investigations are only gradually accumulating crucial data. Yet in 1974, effective in 1975, the IWC adopted the so-called "New Management Procedure" (NMP), under which whale populations were allowed to be reduced to 54 percent of their estimated original numbers. Changed somewhat, it became the "Revised Management Procedure" in the 1980s. This highly simplistic procedure is based on a lack of scientific data, including inaccurate estimates of populations and inadequate information about whale reproductive biology. Whale numbers are estimated by research vessels counting whales seen to surface, in itself a highly unscientific method resulting in "ball park" or vague estimates. First, whales spend only about 5 percent of their time on the surface. Second, estimates of original numbers, a crucial aspect to this approach, are based on records of whales killed, with guesses as to what percentage of the population these represented. Third, in order to understand the population biology of a species--its longevity, rate of reproduction, natural mortality rate, differences in survival between populations, diet, and behavior--other aspects of its life history must be known. This crucial information is lacking for every species of large whale.

A dramatic illustration of the inaccuracy of whale population estimates is that of Norway's whaling of North Atlantic Minke Whales. Norway killed an average of 3,500 Minkes a year in the North Atlantic in the mid-1950s, before cutting back to 1,800 a year until 1983 (Chadwick 2001). In Antarctic waters, Russian and Japanese whalers killed 65,000 between 1971 and 1981 (Chadwick 2001). In 1986, the year the moratorium on commercial whaling became effective, Norway, along with Japan, Peru, the U.S.S.R. and Iceland, filed objections (Bright 1991). IWC members may defy regulations merely by filing such objections. Norwegian whalers killed 383 Minke Whales in 1986 and 375 in 1987; in 1988 Norway announced it would kill whales for scientific research, which is allowed by IWC (Bright 1991).

For several years, Norway killed small numbers of whales for "scientific research" but, in 1992, resumed killing large numbers of these whales. The population estimate upon which they based their self-imposed quotas was 86,700 Minke Whales in the North Atlantic. On this basis, it killed 301 whales. Scientific estimates later revised the population number to 69,600--an enormous difference of 17,100 whales. Norway then lowered its own quota to 232, which the IWC's Scientific Committee believed to be still too high. To its credit, the IWC denounced the whaling and, at its annual meeting in 1995, passed a strongly worded Resolution against Norway. Not only did Norway begin commercial whaling in defiance of IWC resolutions, but attempts were made to smuggle the meat--mislabeled--to Japan. This scheme was uncovered, and even this blot on Norway's international reputation did not result in a change of heart regarding this slaughter. In January 2001, Norway announced that it would openly sell whale meat and blubber to Japan, breaking a long-time agreement with the United States against international sale of whale products. Japan and Norway, recently supported by Iceland, have unsuccessfully petitioned the IWC to lift the moratorium on commercial whaling and allow Minke Whales to be hunted and have attempted to ease CITES restrictions that list the species on Appendix I, banning commercial trade, also without success.

How the IWC can arrive at <u>any</u> quota on Minke Whales is beyond reason, since almost nothing is known about Minke Whales--not even where they mate or calve (Chadwick 2001). These elaborate population estimates are obviously totally unscientific. Minke Whales have no distinguishing characteristics that might allow them to be identified as individuals as is the case with Humpback and Right Whales. Humpback Whales have a great variety of

black and white patterns on their tails, and no two are exactly alike. Northern Right Whales have callosities of various parasites, such as crustaceans, different with each whale. More than a decade has been spent by researchers working to document these individuals in the northwest Atlantic and enter the information into a database. No such research is possible as a means of counting Minke Whales.

The Long Battle for the Whales: Page 2

Off the coast of Scotland, where Minke Whales are protected, they approach boats and lift their heads above water, eyeing the boat and its occupants (Chadwick 2001). They have been seen leaping out of the water in apparent games that went on for more than an hour. Recently one was rescued after stranding on rocks. The Scottish rescuer said: "Off it went until it was almost out of sight. Then it returned. We were worried it would go onto the shore. But it swam away, and we decided the animal just came back to say thanks and cheerio. That's when we started to worry the poor thing might be going to Norway next" (Chadwick 2001). These whales have been swimming around boats and scuba divers along the Great Barrier Reef since the early 1980s, and some ecotours offer Minke-watching (Chadwick 2001). Some of these whales stay close to boats and divers for up to 11 hours, and while they seem silent in northern waters where they are killed, here they communicate in grunts, growls and "boi-oi-oings" (Chadwick 2001).

Whales have shown friendliness toward one another as well as toward humans who dive with them. An encounter between Blue Whales in the 1970s was witnessed by researchers on a vessel off the eastern Canadian coast. They spotted four Blue Whales: "Two pairs of whales coming from opposite directions met, churning the water as they rolled and dove about one another in what seemed, to human eyes, a tumultuous greeting. During the commotion one of the whales breached a third of its length . . ." (Vontobel 1975). This must have been a truly unforgettable sight and an indication that these whales communicate and form bonds with one another. Within the past decade, Blue Whales have increased somewhat. In the Pacific, they have recently begun congregating in or near a marine sanctuary off California's Santa Barbara Islands, where scientists from the National Oceanic and Atmospheric Administration (NOAA) are studying them. Almost 2,000 whales are regularly seen here, creating excitement for whale watchers and scientists alike.

The Long Battle for the Whales: Page 3

As one of the wealthiest countries in the world, Norway has profited from rich offshore oil reserves, and has a highly educated, liberal society. As the world's second largest oil exporter, it earns so much revenue that the government has been setting aside about $8.2 billion a year (AP 1997). It does not have an economic need for whaling income. The Prime Minister who first endorsed Norwegian whaling, Gro Brundtland, was known as a "Green" world leader, preaching environmental concern and backing strong national legislation to preserve Norway's environment. As a conserver of marine life, however, Norway has recently proven to be wasteful and destructive. Its centuries-old fishery has collapsed, putting thousands of employees out of work, and causing resentment among a population dependent on Atlantic Cod as a dietary and economic mainstay.

As a totally flawed and specious argument, Norway explained its return to whaling by stating it was needed to allow cod to recover. A 1990 report by the Norwegian Fisheries Ministry concluded that the Atlantic Cod catch would jump 5.6 percent the year following a kill of 1,700 Minke Whales, and higher employment would result (Bright 1991). Other Norwegian researchers have suggested that causing actual *extinctions* of marine mammals would increase fisheries value by 150 percent! (Bright 1991). Olaf Flaaten, a Norwegian professor who advised Brundtland, described marine mammals in 1988 as "vermin," causing great losses of fishes, citing Minke Whales and Harp Seals as the worst offenders. Apparently, Norway has been conducting control operations of marine mammals for some

time. At least 60,000 Harp Seals died in Norwegian fish nets in 1987, taken intentionally (Bright 1991). A Norwegian seal hunt killed 14,000 seals in 1989, and Harp Seal populations in the Barents Sea have been halved since the early 1980s (Bright 1991). Scientists from the IWC and the National Marine Fisheries Service (NMFS) have called the theory that fish populations will be increased by killing marine mammals totally baseless (Bright 1991). The underlying cause of the fisheries collapse is overfishing of Atlantic Cod and other fish and their prey, Capelin and Atlantic Herring. In 1996, 10 tons of whale meat were allegedly smuggled from Norway to Japan, and the same year, Norway announced that it would increase the kill of North Atlantic Minke Whales to 425, almost double 1995's catch. Minke Whale meat is sold in Norwegian markets, and the country plans to begin exporting it--in defiance of CITES--to other countries that have taken reservations on whale listings (Chadwick 2001).

The views of Norwegians who endorse slaughter of marine mammals may not reflect the consensus of the Norwegian public. In 1995 a Norwegian newspaper, *Oslo Arbeiderbladet*, representing the Prime Minister's own Labor Party, editorialized: "The Norwegian battle to gain international acceptance for whaling is already lost. The sooner we realize this, the better. The only argument that could be used to defend the whaling, namely that the science is on our side, is no longer valid. The so-called 'secure' figures of Norway were shown to be based on wrong figures and mistakes in the data programs." The editorial concluded that Norway must stop whaling if it wishes to be taken seriously as an environmentally concerned nation. Some Norwegian whalers, however, claim that whaling does not differ from cod or herring fishing, and that whales are just "big mountains of meat" (Gibbs 1997).

The United States chose not to punish Norway for its illegal whaling. In Section 8 of the U.S. Fisherman's Protective Act, the "Pelly Amendment" permits the President to embargo any and all fisheries products from countries whose nationals have engaged in taking a marine resource in such a manner as to "diminish the effectiveness of an international fishery conservation program." In 1979, an additional sanction was voted into law, the Packwood-Magnuson Amendment. This amends the Fishery Conservation and Management Act to cut fish allocations by half on certification by the Secretary of Commerce that a nation has violated the provisions of the Pelly Amendment. If a nation persists, all fishing rights are canceled. For Norway, its exports of fisheries products to the United States are considerable, amounting to more than $140 million each year. The Secretary of Commerce took the initial action of certifying Norway under the Pelly Amendment, but President Bill Clinton chose not to place an embargo on its fishery exports to the United States. In a letter to Congress in October 1993, President Clinton said the United States™ objectives could best to achieved by "delaying the implementation of sanctions until we have exhausted all good-faith efforts to persuade Norway to follow agreed conservation measures." Prime Minister Brundtland came to the United States and successfully lobbied to prevent economic sanctions against Norway. Before leaving office in 2001, President Clinton decided not to impose import restrictions on Japan under the Pelly Amendment for expanding its "scientific" whaling to include Bryde™s and Sperm Whales.

The Long Battle for the Whales: Page 4

Traditionally, the United States has maintained a strong anti-whaling stance and has been a major force in bringing about reductions in whaling quotas and the 1982 moratorium. Japan and Norway, however, are now whaling without any basis on sound science, and in violation of the spirit of the moratorium. Iceland is planning to reenter commercial whaling as well. Japan's high take of Minkes in Antarctic waters violates the 1994 sanctuary designation of the seas surrounding Antarctica (Chadwick 2001). To open markets worldwide to many types of whales, Japan has presented numerous proposals to downlist whales on CITES: two would have placed North Pacific and Southern Hemisphere stocks of the Minke Whale on Appendix II, one would have transferred eastern Pacific stock of the Gray Whale to Appendix II, and one would have downlisted the northwestern Pacific stock of Bryde's Whales from Appendix I to II. Bryde™s whales occur in all the world's oceans.

Japan has also continued its "scientific" whaling and announced in November 1994 that it would begin selling 65

tons of meat from Minke whales caught in the northwest Pacific. In an eight-year period from 1980 onward, Japan killed 28,818 Minke whales, and it has also imported enormous amounts of whale meat--123,955 tons between 1980 and 1991 (Chan *et al*. 1995a). This country provides the world's largest retail market for whale meat, buying illegally caught meat from pirate whalers around the world. A recent AWI-supported investigation by Steven Galster and Rebecca Chen (1994) uncovered enormous caches of illegal whale meat stockpiles held in Russia for eventual sale to Japan; 232 metric tons were found in Vladivostok alone, including thousands of pounds of meat from Bryde's Whales. This 50-foot species has been on Appendix I since the 1970s, and the illegal meat was being smuggled from Taiwan to South Korea and then to Japan. The latter smuggling operation began in 1988 and continued until at least 1994 (Galster and Chen 1994). Investigators found Bryde's Whales™ skin and fat being openly sold in a Japanese shop in 1995 (Chan *et al*. 1995a). Yet Japan claims it has legal stocks of frozen Sei, Fin, Bryde's and Sperm Whale meat (Chan *et al*. 1995a). Similar studies in the intervening years have determined that, based on DNA studies of whale meat sold in Japan, protected and endangered whales, including the Blue Whale, are still sold in Tokyo (ABC News, July 14, 2001).

Japanese and American toxicologists have also analyzed whale and dolphin meat and found extremely high levels of heavy metals (such as mercury) and toxic chemicals (such as dioxin and PCBs)--high enough to pose a serious health threat merely by eating a few ounces of blubber (Chadwick 2001). A study in the Faroe Islands north of Scotland found brain and heart damage in children whose mothers had eaten whale meat (Chadwick 2001).

Japanese national legislation does not cover the regulation of all whale meat sales, and it retails at an average of $64 per pound. In 1993 Japan enacted legislation that prohibited the capture, possession or sale of Blue and Bowhead Whales without a permit issued by the Minister of Agriculture, Forestry and Fisheries. However, this is not meaningful legislation since the Blue Whale has been legally protected from killing and international trade for decades, and Bowhead Whale meat can only be consumed by the native peoples who kill them. In another recent investigation by two scientists working for Earthtrust, DNA analyses were conducted on whale meat being sold in Japan. This sophisticated forensic study determined that the meat came from Humpback, Fin, and North Atlantic Minke Whale (AWI 1994). Humpback and Fin Whales are endangered species, and the revelation of this trade should have resulted in international sanctions, but it did not.

In 1996, the U.S. Secretary of Commerce formally certified Japan under the Pelly Amendment for outlaw whaling. Japan™s continued defiance of the IWC by granting itself "Scientific Permits" for research represents a lack of compliance with international treaties. An IWC Resolution recommended that scientific whaling be non-lethal. Yet in 1996, Japan announced that it increased the quota its ships can kill in the Antarctic from 330 to 440 Minke Whales, and continued to kill 100 whales in the north Pacific (Kristof 1996). At the 1996 IWC meeting, a Resolution was passed requesting Japan to halt its scientific whaling, in particular in the Southern Ocean Sanctuary, and Japan's request for 50 Minke Whales from the North Pacific was turned down for the ninth year in succession. Although the Pelly Amendment allows trade sanctions on the enormous quantities of fisheries products that are imported into the United States, President Clinton announced on February 9, 1996, that he would not impose any penalty on Japan. The Animal Welfare Institute, through full-page newspaper advertisements and mailings, opposed the illegal whaling of both Japan and Norway, urging boycotts of products and services from these countries.

South Korea and Taiwan, while not permitting whaling, have shipped illegal whale meat to Japan. In 1993, South Korea received 3.5 tons of Minke Whale meat being smuggled from Norway, and one of its freighters was caught smuggling whale meat into Japan in 1994 (Chan *et al*. 1995a). Investigators found baleen whale meat and dolphin for sale in a vast fish market in Pusan, South Korea, in April 1995 (Chan *et al*. 1995a). Taiwan exported 14,590 boxes of whale meat to Singapore in 1993, and it is suspected of laundering illegal whale meat (Chan *et al*. 1995a).

The United States and other countries are under pressure to agree to a return to commercial whaling should whale populations increase. The IWC's "Revised Management Procedure" would authorize the slaughter. Estimates of a very large population of between 510,000 and 1.4 million Minke Whales in the Southern Hemisphere have proven to be too high, yet the IWC's Scientific Committee has approved a management plan that would permit the killing of

5,000 to 10,000 of these whales a year (Chadwick 2001). Japan's request for a Scientific Permit to kill Bryde's and Sperm Whales was turned down by the IWC in 2000, but it proceeded to take five Sperm Whales, 43 Bryde's Whales and 40 Minke Whales in a hunt in the North Pacific during that same summer. The same year, its proposals to downlist this species from Appendix I at the CITES Conference also failed. In the fall of 2000, Japanese whalers sailed to Antarctica for a five-month "research" trip, with plans to harvest up to 440 Minke Whales (Chadwick 2000). Both the IWC and CITES lack any enforcement powers, and the effectiveness of these Treaties depends on national legislation. For this reason, whalers have flouted regulations by killing protected whales for decades, with little fear of retribution. The Environmental Investigation Agency (EIA) compiled a list of known violations by whalers since 1942, involving thousands of rare and endangered whales to illustrate this (AWI 1995). Those countries and organizations that believe in a return to commercial whaling support a cold-blooded approach to whales that does not recognize their intelligence, friendliness, and the lack of information on the extreme stresses they endure from other threats, including: pollution by toxic chemicals; ozone depletion that is destroying phytoplankton, which is the basis of marine food chains; collisions with ships; entanglements in fishing nets; and coastal development, to name just a few.

The Long Battle for the Whales: Page 5

To end whaling and trade, economic alternatives such as whale watching should be seriously considered by those countries that continue to whale. Even Japan has recently begun whale watching tours in the Ogasawara Islands, bringing in sizeable revenues. One Japanese fishermen said: "Whales have always been regarded as a kind of divine omen in this area. I feel it is an atrocious thing to kill whales. We Japanese do not have to eat whales anymore" (Anon. 1992). In 1992, an estimated 19,267 people participated in whale watching in Japan, a $10 million business according to *New Scientist* (May 8, 1993), which also reports that Japanese people are increasingly critical of their government's whaling. In 1996, anti-whaling pressures increased within Japan, and many young Japanese now consider the whale a mammal rather than a meal, but this has not influenced the government's policies (Kristof 1996). A Japanese harpooner quoted in *The New York Times* angrily disputed critics of whaling, saying: "I don't think of whales as especially smart. They're just like ordinary fish. We feel that they're just a big present from the sea" (Kristof 1996). Most Japanese are unaware that Japan is still involved in whaling (Kristof 1996).

In the United States, almost $200 million was earned by whale watching boats and associated businesses in 1991 (WDCS 1991). In 1992, revenues from the whale watching industry increased to $260 million, and a survey found that whale watching was carried out in 37 countries (*New Scientist*, 8 May 1993). By 1998, the worldwide total revenues from whale watching topped $1 billion, according to a study by the International Fund for Animal Welfare (IFAW). This far exceeds revenues from whaling (BG 2000). Nine million people whale watched in 1998 in 87 countries, according to the IFAW study. The sale of whale meat represents a one-time profit, as opposed to the renewable benefits from watching whales that may live to be 50 or more years old. An adult Minke Whale brings about $100,000 on the market (Talmadge 2000)--a significant amount, but a fraction of its potential income from whale watching. Products obtained from whales are not essential, and economically, far more people profit from whale watching than from the whale products industry. They include whale watching boat companies, local motels and restaurants and tourist shops. By contrast, whaling profits the whaler, the wholesale buyer and the retail seller. These arguments should not be necessary, however, in view of the extraordinary qualities of these fascinating animals. Whales possess tremendous appeal, and the research that will reveal the most about them will be based on observations of live whales, not necropsies of dead ones.

A growing number of people condemn the killing of all cetaceans. Iceland's illegal whaling in the late 1980s was halted when conservation and humane organizations persuaded many commercial importers of Icelandic fish to cancel orders, costing that country some $50 million. The actions of governments, individuals, organizations and consumer boycotts, combined with public opinion, have brought about whaling moratoriums and country bans. Only stronger

enforcement of laws and better public awareness in the whaling countries themselves about the cruelty to these gentle and intelligent creatures may bring whaling to an end. The presence of these sentient beings in the ocean is an inspiration to all, but their survival may depend on active opposition to their killing.

Dolphin and Small Cetacean Fisheries

The killing of dolphins and Pilot Whales is not covered by the IWC regulations, and as restrictions on killing the great whales increase, some countries are turning to small cetaceans. The true extent of dolphin killing around the world is not known but is presumed to be well over 100,000 animals per year, with more than 60 species subject to commercial harvest. Sri Lanka, Turkey and other countries have unregulated--but considerable--dolphin fisheries. No international treaties cover this slaughter other than CITES, which lists some dolphins and porpoises on Appendix I, banning trade, and the rest on Appendix II, which regulates it. The fisheries may be endangering numerous species and eliminating local populations. Japanese fishermen are killing Dall's Porpoises (*Phocoenoides dalli*) in large numbers. These porpoises are known to "bow-ride" in the wake of their small dories. Taking advantage of this apparent dolphin game, fishermen are harpooning the frolicking dolphins in their backs with steel-barbed weapons, causing a painful and slow death. The meat is then marketed as "whale." At least 560 boats are killing these small black-and-white porpoises off the Japanese coast (Currey 1990). Approximately 111,500 of these porpoises were killed by Japan from 1986 to 1989 (Nowak 1999). In 1990, the IWC passed a Resolution calling for a reduction in the number of Dall's Porpoises killed to at least 10,000, but Japan killed 17,634 the following year (Chan *et al*. 1995a). The Japanese continue this killing, using 80 fishing boats that pursue migrating herds throughout the year. An estimated 67 percent of Dall's Porpoises have been killed by the Japanese, who killed 65,159 of these porpoises between 1990 and 1993 (Chan *et al*. 1995a). Annual kill is now about 20,000 and seems to involve mainly immature animals (Nowak 1999). The *2000 IUCN Red List of Threatened Species* lists this species as Conservation Dependent, in spite of the fact that there seems to be little conservation preserving this species.

Striped Dolphins (*Stenella coeruleoalba*) have been nearly eliminated along the Japanese coast (Currey 1990). Recent statistics from the IWC show that Japan whales 18 species of small cetaceans, and kills many thousands more as incidental catch in its fisheries (Chan *et al*. 1995a). The 76,295 of these dolphins killed directly make up only a portion of their human-caused mortality; added to this, 35,002 Striped Dolphins drowned in fishing nets, for a total of 111,297 killed between 1990 and 1993 (Chan *et al*. 1995a). The combined killing from these two causes is resulting in declines. It, too, is listed as Conservation Dependent by the *2000 IUCN Red List of Threatened Species*.

When Atlantic Pilot Whales (*Globicephala melaena*) gather in the bays of the Faroe Islands of the North Atlantic, as they probably have for thousands of years, they encounter local fishermen, who herd them toward the shore in small boats. Others wade into the water and kill the friendly animals with hooked fishing gaffs--perhaps the cruelest of all the whaling methods. Some use large meat cleavers to literally saw off the Pilot Whales' heads, while the animal writhes in the shallow water. The Faroese people consider this annual slaughter a "sport" and even encourage very young children to participate. Years of campaigning by groups such as the Environmental Investigation Agency, which has filmed the hunt in all its gore and shown wounded animals dying slow deaths, have failed to stop it. In spite of their name, Pilot Whales are actually closely related to dolphins and are social, forming very close-knit clans in which only a few young are born each year. The entire herd cares for the young. DNA analyses of animals killed in the Faroe Islands showed that all members of individual groups are related to one another. These herds are led by older females, who are the repositories of learned information about food sources and other survival lore (Harrison and Bryden 1988). This partly explains why they follow one another when one becomes stranded and keep returning to the beach if turned back to sea.

Chilean fishermen kill thousands of Commerson's Dolphins (*Cephalorhynchus commersonii*) to use their meat as crab bait. These small dolphins resemble miniature Killer Whales (*Orcinus orca*) with their black-and-white

coloration, although their body form is similar to that of Harbor Porpoises. Only about 4.8 feet long, these dolphins are found only in the Southern Hemisphere from Argentina south to the Kerguelen Islands (Harrison and Bryden 1988). So many have been killed that their population has declined precipitously. A closely related species, Hector's Dolphin (*Cephalorhynchus hectori*), native to New Zealand waters, has declined from pollution and trawling, which drowns thousands. The New Zealand government banned trawling within a 1,170-square- kilometer area where the species congregates. Its status has become more endangered in the past four years, and the IUCN raised its status from Vulnerable in 1996 to Endangered in 2000.

Russia announced early in 1997 that it is considering a return to commercial whaling, targeting Belugas, or White Whales (*Delphinapterus leucas*). They claim that these whales are depleting cod stocks in the White Sea, echoing the unscientific claims of Norway's scientists. These small whales have declined in many parts of their ranges. In the Arctic, Belugas swim in small groups, using their sophisticated echolocation system to navigate and locate fish in this frozen environment (Harrison and Bryden 1988). They have extremely flexible bodies, enabling them to rotate their flippers and heads, to twist their bodies around, and even to swim backwards using their flukes (Harrison and Bryden 1988). Recent research on captive Belugas at the Shedd Aquarium in Chicago has revealed them to be talented mimics, able to imitate a great variety of sounds (Yovich 1996). In one case, Belugas in a tank next to another tank used to train a dolphin with a low-frequency tone, began making the identical sound, which was a signal for the dolphin to swim away. Researchers were at first confounded when the dolphin would swim away before they gave her the tone sound, only to find out that the Belugas were mimicking it, either out of mischief or as a normal behavior (Yovich 1996). Their talents at mimicry extend to imitating whistles, human-produced sounds, bird calls, fire alarms, and scuba regulator sounds, among others (Yovich 1996). Research on the use of this talent by wild Belugas is now beginning.

There are separate populations of Belugas in the Arctic region, and several of these are in steep decline: the Cumberland Sound population has declined to only about 600 animals; and the St. Lawrence Belugas have declined from 10,000 to only 350 animals, decimated by the effects of pollution from factories (Nowak 1999). They are now so contaminated that their bodies constitute hazardous waste. These beautiful whales are hunted in Canada and Greenland by natives in a totally unmonitored fashion, with only fragmentary knowledge of their life history. Some populations have been reduced 20 percent by hunting (Darling *et al*. 1995), and for the first time, the IUCN listed this species in the Vulnerable category in its *1996 Red List of Threatened Animals* (Baillie and Groombridge 1996). The *2000 IUCN Red List of Threatened Species* also listed the species as Vulnerable. Worldwide populations have declined from 250,000 in 1965 to between 100,000 and 150,000 in 1996 (Yovich 1996), with the lower figure considered more likely (Nowak 1999).

Small cetaceans have incurred major declines from direct and indirect killing. Dolphins and porpoises have only one calf per year, and for some species, many adults are non-breeding members of the herd. Unrestricted hunting has the potential to endanger many species, and international controls are needed. Many species and populations of dolphins continue to drown in large numbers in tuna purse seine nets, and pollution has killed a large percentage of the Atlantic, North Sea and Mediterranean dolphins in the past decade. The number of threatened and possibly threatened small, saltwater cetaceans has grown from 35 species listed in the *1996 IUCN Red List* to 47 species, almost all in the category Data Deficient, indicating that more information is needed about their status, which might show the species to be threatened. It is an indication of the lack of conservation attention these species have received that so many are listed in this category. Obviously, much more research is needed. Dolphins and porpoises have captured our imaginations after many true stories of their having saved people from drowning and their role in the mythology of the Greeks and others. It is incumbent on us to maintain the diversity of these small cetaceans and prevent them from declining to endangered status or disappearing altogether.

Fur: A History of Endangering Species

The history of the fur trade, past and present, is evidence that no animal, no matter how abundant, is immune to possible extinction should its pelt become valuable to the fur trade. A pattern develops as fur pelt prices rise, and the species becomes rare from overtrapping. These pelts become more avidly sought out. Commercial extinction can result fairly quickly if animals with valuable pelts are killed at a rate greater than they can reproduce. Animals whose populations numbered in the millions and whose ranges extended over entire continents have been reduced to near extinction within the space of a few decades, as demonstrated by the trade in spotted cats. For those animals that are naturally rare in the wild, or rare due to ecological or geographical reasons--the Falkland Island Wolf (*Dusicyon australis*), the North American Sea Mink (*Mustela macrodon*) and the Rufous Gazelle (*Gazella rufina*), for example--extinction came quickly when their pelts were in demand by the fur trade.

Extinctions

The Falkland Island Wolf was an extremely tame and fox-like wolf about 3 feet in length, with a short bushy tail 11 inches long (Nowak 1999). This brown canid had a large skull with a short nose, broad muzzle and small ears. It was the only land mammal native to these subantarctic islands, and it lived on birds, especially geese and penguins (Nowak 1999). How these wolves arrived on the islands, which are 400 kilometers from the mainland, is not known, but in prehistoric times, natives may have brought them as domestic animals. Another theory is that sea levels during the Pleistocene might have been low enough to permit their migration from South America (Nowak 1999).

Charles Darwin, on his voyage in the Beagle, collected three skin specimens of the Falkland Island Wolf, two of which were presented to the London Zoological Society (Day 1981). Darwin found these animals very common and tame during his visit in 1833. They approached visitors to the islands out of apparent curiosity (Day 1981). According to some accounts, they even came to campsites and carried away supplies (Nowak 1999). The Falkland Island Wolf was exploited by fur trappers shortly after British settlement of the islands in 1800 (Allen 1942). The American fur magnate, John Jacob Astor, sent men in 1839 to collect pelts, and great numbers were taken; others were poisoned by sheep farmers. Darwin noted that they were so easily killed that men could hold out a piece of meat in one hand and stab the animal with a knife held in the other when it came within reach (Day 1981). By 1870, they had become very rare, and the last individual of this species was killed in 1876 (Allen 1942).

The Sea Mink of the coasts of northeastern North America was another casualty of the fur trade. Its brutal extinction was described in Chapter One. Both this species and the Falkland Island Wolf had very limited distributions, making their populations vulnerable to overexploitation. Also, both were the objects of intensive hunts for their furs. Only the very large distributions of some species whose populations were reduced to near-extinction, such as the large spotted cats and many species of otters, saved them from the same fate as the Falkland Island Wolf and Sea Mink.

A beautiful and delicate animal of North African forests, the Rufous Gazelle, was also killed for its pelt. One of the largest gazelle species, it was 5 feet long, with foot-long spiraled horns (Day 1981). Little is known of this species other than sightings of small groups of gazelles in the mountainous forests above the Chelif valley of Algeria. The only people who were familiar with the Rufous Gazelle were furriers of Oran who saw it as a rare and costly pelt that they acquired every three or four years in the 1920s (Day 1981). These delicate, reddish gazelles disappeared during this period and, by the 1940s, were considered extinct. Three specimens were taken by museums (Day 1981).

Prior to the 20th century, a long list of furbearers were nearly eliminated by the fur and hide trade. In North America, the Bison, Beaver, River and Sea Otters, Marten, Fisher and Kit Fox, disappeared from most of the continent by the end of the 19th century. Today, the Beaver has made a comeback, largely as a result of reintroduction, but the other species have greatly reduced distributions and numbers.

The international fur trade's beginnings in the 18th century endangered one species after another and continued unabated through the 19th century. This period marked the most extensive wildlife slaughter in recorded history. Vast numbers of wild animals which roamed continents and swam ocean waters were reduced to scattered remnants. Heavy fur trading continued into the 20th century. During the 1920s, U.S. sales peaked at more than 50 million wild animal pelts (Osborn and Anthony 1922). The fur trade soon discovered new species to replace those overharvested.

Trapping of fur animals involves extreme cruelty. One of the most widely used traps to take fur animals throughout the world is the wire snare. Loops of strong wire are designed to tighten until they cut through skin and organs. Leg snares are placed on the ground, and the animal walks into the loop, which then springs and tightens on the leg. Sometimes the animal is caught by other parts of the body and dies slowly. Neck snares, set higher up on tree trunks, are intended to grab the animal by the neck and strangle it. In tropical countries, these snares have been responsible for the agonizing deaths of hundreds of thousands of wild cats, antelope, primates, and perhaps an equal number of non-target animals. Elephants have blundered into neck snares and become entrapped by a leg--or even the trunk--and died slowly of infection after weeks of pain. These snares are totally non-selective, and present a major threat to virtually all mammals and many other types of animals, even in national parks. In Africa, Leopards, civets, and Cheetah are among intended victims snared and often found severely wounded. Wire snares are legal in many U.S. states, although they have been banned in some.

Trapping methods in North America, which produces the largest number of wild furs in the world, have changed little since the 18th century. The steel jaw leghold trap, used to obtain the majority of these wild fur pelts, is extremely inhumane. Holding the animal's paw or leg tightly, it usually cuts off circulation, and it often breaks bones. Many animals are so frantic to escape that they chew off their own trapped paws. These traps were decried by Darwin in an article in the *Gardeners' Chronicle and Agricultural Gazette* of August 1863. Darwin described the suffering of animals caught in these traps, "We must fancy what it would be to have a limb crushed during a whole long night, between the iron teeth of a trap, and with the agony increased by constant attempts to escape." He spoke of rabbits, still alive when the trap was approached, who started up, struggling violently to escape, "shrieking pitiably from terror and the pangs occasioned by their struggles." Darwin pleaded for a ban on these traps, but it was not enacted in England until the 1950s.

Trappers in many U.S. states and Canadian provinces do not have to check their traps for days on end; and in Alaska, Michigan, North Dakota and Montana, there is no time limit for trap-checking. The trapped animal suffers pain, trauma, hunger and thirst. There are even cases of trappers failing to return to check traps until the snow cover melted, revealing animals that had taken weeks to die. Gangrene and fatal infections result from injuries received in these traps to animals, such as pets, that had been trapped for long periods. Thousands of non-target animals, many of these endangered species, are caught in leghold traps every year. The AWI publication, *Facts About Furs*, discusses this and other traps and provides photographic documentation of the suffering animals endure to become fur coats. In 1994, the World Veterinary Association declared the leghold trap to be inhumane, and many other veterinary organizations, including the American Animal Hospital Association (AAHA) and the American Veterinary Medical Association (AVMA), have condemned it. The steel jaw leghold trap has been banned in 88 countries, including all European Union countries; but these traps are officially endorsed by U.S. and Canadian wildlife agencies, both federal and regional. Some U.S. states have restricted or banned use of the steel jaw leghold trap, and in several states, all lethal traps have been banned by voters through Referendums that bypassed state legislatures, which tend to support these traps and refuse to allow votes on their prohibition. New Jersey bans sale, possession and use of steel jaw leghold traps. California, Colorado, Florida, Massachusetts, Rhode Island and Washington prohibit their use (with exceptions under special circumstances). In Arizona, these traps are banned on public land (80 percent of land in Arizona is public), with exceptions permitted to protect public health and safety.

Fur Seals

The 18th and 19th centuries saw a massive slaughter of fur seals wherever they were found, from the Aleutian Islands to the Antarctic and shores and islands of all the major continents. These animals are especially vulnerable when on land, breeding and having their young, as they are slow and ponderous and can easily be blocked from entering the sea and being bludgeoned. Hundreds of thousands of fur seals lined coasts and off islands in cold water areas throughout the world. The Northern Fur Seal (*Callorhinus ursinus*) inhabits the North Pacific from the Channel Islands off California in a large arc to the Sea of Japan (Nowak 1999). Estimated to number 4.5 million in 1870, sealing reduced them to 200,000 by 1914 (Sparks 1992). Pelagic sealing had a catastrophic effect on these seals; more than 1 million Northern Fur Seals, of which 60 to 80 percent were females, were taken at sea from 1868 to 1911 (Nowak 1999). Many of the females were lactating and had left their pups on land while they foraged at sea. Major conflicts erupted between the countries where the rookeries were located, Russia and the United States, and the two major pelagic sealing nations, Canada and Japan (Nowak 1999). The situation was resolved when the fur seal rookeries on the Kuril, Commander and Robben Islands in the western Pacific were almost completely eliminated (Nowak 1999).

Pelagic sealing was banned by treaty in 1911, but commercial harvests on the Northern Fur Seal's breeding islands did not stop until the 1980s, when the species became depleted. This seal also suffers from a mortality of some 50,000 a year drowning in driftnets (Nowak 1999). When the regulated kill in Alaska was stopped, it was expected that the species would rebound, but numbers of pups born dropped on the Pribilof Islands from 450,000 in the mid-1950s to 253,000 in 1992, and the species population there is half what it was in the 1950s (Nowak 1999). The National Marine Fisheries Service, which has jurisdiction over marine mammals, designated it a depleted species but refused a petition to list it on the U.S. Endangered Species Act. It is a species "undergoing its most serious crisis since the era of pelagic sealing a century ago" (Nowak 1999). The *2000 IUCN Red List of Threatened Species* lists it as Vulnerable, the category below Endangered, indicating a dangerous decline. The species spends much of the year in open sea, and there has been speculation that, in addition to losses from entanglements in fishing nets and gear, illegal killing for fur may be taking place by fishing and other vessels.

Three of the eight other species of fur seals are also listed as Vulnerable by the IUCN. They inhabit waters further south, from Guadalupe Island off Baja California, Mexico, to the Galapagos and Juan Fernandez Islands off South America. All originally had limited populations in restricted distributions and were heavily hunted for their fur. After a century of protection, they have not recovered their numbers, and were even thought extinct for a period. The Juan Fernandez Fur Seal (*Arctocephalus philippi*) is native to the islands made famous by Alejandro Selkirk, upon whom the novel *Robinson Crusoe* was based. Prior to any sealing, the species may have numbered 4 million; after 18th century sealers began exploiting them, they were quickly reduced to 2 to 3 million (Nowak 1999). Up to 3.5 million were taken from 1793 to 1807, with as many as 15 ships all killing seals at the same time (Nowak 1999). By 1824, the species was considered commercially extinct (Nowak 1999); it disappeared in 1891, considered extinct (Allen 1942). Small numbers were discovered in 1968 near Isla Robinson Crusoe, and a census in 1983-1984 counted 6,300 fur seals throughout the islands. Another count in 1990 estimated 12,000 Juan Fernandez Fur Seals, but there is some poaching and harassment by fishermen (Nowak 1999).

The Southern Fur Seal (*Arctocephalus australis*), native to the coast of South America, was also heavily exploited beginning in 1515 (Nowak 1999). Not until the 1940s was the killing controlled, but even with an authorized kill of about 12,000 seals a year, the population in Uruguay fell from 252,000 to 5,000 from 1987-1991, a precipitous drop (Nowak 1999). The species has not recovered from sealing and now numbers about 83,000 (Nowak 1999). Although its population is below that of the Northern Fur Seal, it is not listed as Vulnerable by the IUCN. Darwin saw these seals on Chiloe Island, off southern Chile. He described them in his notes on the epic voyage on the *Beagle:* "I

accompanied the Captain in a boat to the head of a deep creek. On the way the number of seals which we saw was quite astonishing: every bit of flat rock, and parts of the beach were covered with them. They appeared to be of a loving disposition, and lay huddled together, fast asleep . . .fl

The smallest fur seal is the Galapagos (*Arctocephalus galapagoensis*), with males weighing only 64 kilograms and females weighing 27 kilograms, (Nowak 1999). So heavily hunted by commercial sealers in the 19th century that it was thought extinct by the early 20th century, small populations were seen in 1932 (Nowak 1999). It has recovered to a population of 30,000 to 40,000. Although protected by Ecuadorian law in these islands, it is attacked by feral dogs (Nowak 1999) and, in view of the oil spill that took place in early 2001, is vulnerable to that threat as well.

The Guadalupe Fur Seal (*Arctocephalus townsendi*) was once found from Guadalupe Island off Mexico and along the coast of Baja California, Mexico, north to the Channel Islands, California. Originally numbering up to 200,000 seals on Guadalupe alone, thousands more lived along the coasts (Nowak 1999). Early in the 19th century, sealers killed the majority of the population, returning regularly to kill more seals until 1894 when no more could be found. It was twice considered extinct (1895 to 1926, 1928 to 1949) (Nowak 1999). Rediscovered on Guadalupe Island in 1926 by two fishermen, several seals were sent to the San Diego Zoo in 1928. After a quarrel between one of the fishermen who discovered the seals and the Director of the zoo, the former stormed off to Guadalupe Island in 1928 to kill the entire herd; he killed every seal he found and sold the skins in Panama, where he was killed in a barroom fight (Curry-Lindahl 1972). Not until 1949 was a lone male seen on Nicolas Island in the Channel Islands off southern California; in 1954, a small colony of 14 seals was found on Guadalupe Island, hiding in caves along the shore (Curry-Lindahl 1972). They were accorded protection by Mexico and, later, by the 1972 U.S. Marine Mammal Protection Act, but their populations have remained low. Several bulls of this species have been seen in the Channel Islands off California, but no breeding has been recorded there. The population on Guadalupe Island increased to about 1,600 by 1984 (Reeves *et al*. 1992) and to 7,000 in 2001 (Nowak 1999), a fraction of the original numbers.

Other fur seal species in South Africa, islands in the Antarctic region, New Zealand and Australia were also heavily hunted, nearly causing their extinctions. Exploitation of South African Fur Seals (*Arctocephalus pusillus*) began in 1610 and is still continuing. Their major population is along the southwestern coast of Africa, but they range as far as Australia, Tasmania and New Zealand (Nowak 1999). By the end of the 19th century, their populations along the coasts of Angola, Namibia and South Africa reached dangerously low levels, when sealing was curtailed (Nowak 1999). After increases in the 20th century, a large commercial harvest of 75,000 was authorized on a population estimated at 1.1 million (Nowak 1999). This species is the only fur seal still killed in a large, legal kill. In 2000, 60,000 were killed. Fishermen pressure the government to maintain this kill, claiming that the fur seals harm fish stocks, and fur dealers also exploit the seals for their pelts. The hunt in Namibia was filmed in 2000 and aired on CNN (Cable News Network), showing young male seals on shore being killed by men hitting them with heavy wooden bats. Activists are working to end this hunt, which is not humane. Ecological studies of their population status, food supply, persecution by fishermen, effects of the frequent oil spills that occur in this region, and other important factors affecting their populations have not been carried out. Populations in the Australia area numbered about 200,000 after several decades of sealing, and by the end of the 19th century, regulations limited the kill. The species gradually recovered to about 25,000 in the 1940s, and because of mortality from persecution by fishermen and drowning in nets, the population still only numbers about 30,000 to 50,000 (Nowak 1999). The New Zealand Fur Seal (*Arctocephalus forsteri*), which also inhabits coasts of Australia and Tasmania, was devastated by early sealing and has been slowly recovering. Originally numbering 1.5 to 2 million, they may number only about 27,000 at present (Nowak 1999). Along the Australian coast, they are strictly protected and now cluster in large numbers on the shore of Kangaroo Island, where boardwalks have been built above the rocks for tourists to see them.

Chinchillas

Chinchillas, native to the high Andes, have silky, gray fur, which became very popular in the fur trade in the late 19th century. These rodents were once abundant, and early explorers reported seeing hundreds in a single day (Nowak 1991). Somewhat larger than guinea pigs, chinchilla females are heavier than males, weighing up to 800 grams (28 ounces), while males weigh about 500 grams (17.5 ounces) (Nowak 1999). They are long-lived, with records of individuals surviving to be 20 years old and reproducing until the age of 15 (Nowak 1999). Pelt hunting intensified, with exports rising to an estimated 2 million pelts between 1895 and 1900 (IUCN 1994). In 1905 alone, 217,836 pelts were imported into the United States from South America (Poland 1892). These shy animals were relentlessly pursued when they became rare, and their skins rose to $200 per pelt; fur buyers gave instructions to agents to obtain pelts "at any price" (Allen 1942). Early in the 20th century, populations of both species--the Long-tailed (*Chinchilla laniger*) and the Short-tailed (*Chinchilla brevicaudata*) Chinchilla, collapsed. In 1910, an agreement was signed by Andean countries where the two chinchilla species occur, to prohibit capture, trade and export (IUCN 1994). Once found throughout the Andes in Peru, Chile, Bolivia and Argentina, chinchillas remain highly endangered. A wild chinchilla coat sold for $49,000 in Japan in 1981, and others have sold for as much as $100,000 (Nowak 1999).

Wild populations of both species are now listed on CITES Appendix I, banning commercial trade. The Long-tailed Chinchilla is restricted to the Cordillera de la Costa and the Andean slopes of Chile; it has an estimated population of 5,500 in Las Chinchillas National Reserve and may occur outside the reserve (IUCN 1994). The Short-tailed Chinchilla once had the wider distribution of the two, extending from the mountains of Bolivia and Peru through Chile to northwestern Argentina, but information indicates that it is extinct in Peru and Argentina and is close to extinction in Chile and Bolivia (Thornback and Jenkins 1982; IUCN 1994). In fact, there are no recent records of the species in Lauca National Park in northern Chile, where it had previously been thought to occur, and Short-tailed Chinchillas have never been recorded in the adjoining Sajama National Park in Bolivia (Thornback and Jenkins 1982). Attempts have been made to introduce chinchillas into the wild, but without success to date (Nowak 1999).

As early as 1900, chinchillas were taken into captivity to breed for the fur trade. The International Fur Trade Federation estimates that 200,000 chinchilla pelts are produced annually, with the United States breeding the largest number; pelts sell for up to $98 (IUCN 1994). Japan is the major market for this fur, followed by South Korea and China (IUCN 1994). The domesticated animals have been bred into different sizes and colors; they are larger than the wild species, with pelt colors ranging from gray and brown to various pastel shades (IUCN 1994). In 1994, films of genital electrocution taken on chinchilla farms resulted in a Sonoma Valley, California, farm being charged with cruelty to animals. Prosecutors documented that, according to veterinarians, the animals suffer during this process, in which the chinchilla is held upside down by the tail and electrodes are placed in the ear and in the anal canal or penis; a switch is then pulled to electrocute. According to guidelines established by the American Veterinary Medical Association, such euthanasia should be carried out only on unconscious animals.

Since ranched pelts are considered superior to wild ones, fur dealers have stated that no demand exists for wild chinchilla fur, and the government of Chile successfully proposed in 1994 that domesticated chinchillas and their fur not be covered by CITES Appendices. The *IUCN Mammal Red Data Book* stated, however, that "hunting of chinchillas still continues," and the highly endangered Short-tailed Chinchilla, whose fur is more valuable than that of the other species, was avidly pursued (Thornback and Jenkins 1982). This species has not been bred in captivity, and domestic animals represent hybrids between the two species. The *2000 IUCN Red List of Threatened Species* lists the Long-tailed Chinchilla as Vulnerable, and the Short-tailed Chinchilla as Critically Endangered.

Koalas

The loveable Koala (*Phascolarctos cinereus*) of Australia, which never recovered from killing by the fur trade in

the 19th and early 20th centuries that nearly caused its extinction, is now in decline again. Symbol of Australia's national airline, Qantas, and one of the most famous and popular animals in the world, it is threatened by a variety of factors, including logging, urban development, and disease. Prior to European colonization of Australia, Koalas numbered in the millions in eucalyptus forests from Queensland in the north to Victoria in the south (Phillips 1994). Koalas date back at least 14 million years, having evolved in rainforests that once covered large portions of Australia. Although climatic change turned much of Australia into desert, their range in 1800 still covered millions of square miles in a continuous forest zone (Phillips 1994). These slow-moving marsupials became quite specialized in their diets, feeding mainly on about 32 of the 500 species of eucalyptus trees native to Australia; but within this habitat, they thrived (Dayton 1991).

Beginning in the 19th century, Koalas were hunted mercilessly by European settlers for their soft fur pelts and were entirely helpless in the face of guns and dogs. The major means used by professional hunters were poisoning and snaring, and by the late 19th century, 300,000 Koala pelts a year were being shipped to the London fur market (Phillips 1994). By the early 20th century, they were almost eliminated in the southern half of the country and became extinct in South Australia in the early 1930s. In 1898, legislation was passed in Victoria to attempt to stem the killing, but it was not enforced (Phillips 1994). In 1908, 57,933 Koala pelts were exported, and hunting spread to Queensland; beginning in 1915, year-round hunting was allowed (Phillips 1994). The U.S. fur trade sold millions of Koala pelts during the 1920s; from 1919 to 1921, 208,677 Koala pelts were sold in the U.S. fur trade, along with more than 7 million Australian opossum and wallaby pelts, according to a study by two American Museum of Natural History biologists, Henry Fairfield Osborn and Harold Anthony (1922). After signs of depletion and public outcry, the Queensland government closed the hunting season in 1921, but commercial pressure resulted in a re-opening of hunting five years later. In a one-month season in 1927, 584,738 Koalas were killed and their pelts sent to the United States (Phillips 1994). This was the last year of hunting. The U.S. market was finally shut down at this time when President Herbert Hoover, who had worked in the gold fields of Western Australia, signed an order permanently prohibiting the importation of both Koala and Wombat skins, an order that remains in effect today (Phillips 1994).

Populations of these animals had been devastated, however. Extinct in South Australia, they numbered only about 200 in New South Wales by 1940 and a few thousand in Victoria. In Queensland, perhaps 10,000 or more Koalas survived, but they declined when millions of acres were cleared for construction and road-building (Phillips 1994). Fragmentation of their habitat throughout their range has played a role in preventing them from returning to former abundance (Phillips 1994).

Even in the 1990s, a time when public sympathy for Koalas had grown considerably along with an awareness of their habitat needs, the government of New South Wales granted a massive woodchip contract to a multinational company, Boral, which may level every native forest left in the northeast of this state. This is the only area in New South Wales where Koalas are reasonably common (Arnold 1992). Citizen lawsuits to halt logging and other development have no legal standing in Victoria and Queensland, and in New South Wales, the government uses taxpayer money to destroy habitat and fight lawsuits (Arnold 1992). An activist organization fighting to save the Koalas, Australians for Animals, states that a mid-1990s drought on the heels of devastating forest fires in 1993 eliminated the species from much of its remaining habitat (Arnold 1992). The Koala requires a large, undisturbed eucalyptus forest. Like many animals devastated by slaughter by the fur trade and failing to recover, it reproduces very slowly. Koalas do not mature until age 5, have only one young per year (although twins have been reported) and can live to be 18 years old in the wild (Nowak 1999).

Beginning in 1985, Koalas faced yet another devastating threat. The first diseased animals suffering from an epidemic of chlamydia were found, many of them blind, sterile or dead (Dayton 1991). Dr. John Woolcock, a veterinary microbiologist at the University of Queensland, has studied the organism attacking Koalas, a pathogen known primarily as an avian disease; the disease affects the eyes and the urinary and reproductive tracts of its victims (Dayton 1991). "It brings tears to the eyes to see blind animals or those with weeping inflamed eyes," said Woolcock (Dayton 1991). The Koala Preservation Society of New South Wales, first organized in 1972 by Jean and Max Starr, began caring for injured and diseased Koalas and constructed a Koala Hospital in the Macquarie Nature Reserve to

rescue the growing number of diseased animals that were brought to them (Phillips 1994). Enclosures were built with eucalyptus trees for their first patients; by 1990, more than 2,000 Koalas had been treated (Phillips 1994). A second hospital had to be built in 1986 near a regional headquarters for the National Parks and Wildlife Service; blind Koalas are kept in large enclosures and hand fed by volunteers (Phillips 1994). *Koalas. Australia's Ancient Ones*, a book by Ken Phillips (1994), describes the extraordinary care given by the organization to these sick and injured animals, who are remarkably stoic and patient throughout their recuperations.

According to some Koala experts, chlamydia is endemic to Koalas, yet few healthy animals succumb to the infection (Phillips 1994). Many biologists and veterinarians believe that the increase in the spread and the number of animals succumbing to the disease is a result of the species' vulnerability from combined stresses. The loss of 80 percent of their habitat in the last 200 years has resulted in their overcrowding in fragmented bits of forest. They are stressed by the threat of dogs that hunt and kill them when they walk on the ground between trees, and many are injured or killed by cars when they try to cross roads. Stranded Koalas have been found clinging to huge electric poles with high-tension wires on all sides; they had climbed up the poles in desperation, as the only tree-like structures in a denuded landscape (Dayton 1991). Removal of just one or two species of eucalyptus from a forest may force Koalas to travel far afield to find edible species, and if they eat leaves not compatible with their digestion, they will die of starvation (Phillips 1994). Very few preserves have been set aside for them, and they are a symbol of the many endangered Australian marsupials threatened by habitat loss.

After the 1993 forest fires, many of which were intentionally set by arsonists, hundreds--and perhaps thousands--of Koalas died or were seriously burned. One critically injured Koala was dubbed Terry Glen, for the two men from the electric company who rescued him with a cherry picker, so blackened by fire that they thought at first he was a bubble of burned sap in the top of the charred tree (Phillips 1994). Terry Glen had lost most of his fur, his ears and eyelids were singed, his nails burned off and he was in deep shock. In the Koala Hospital's intensive care unit, veterinarians treated him as if he were a human burn victim, with special bandages and rehydration. For months he had to be carried around because he could not walk on his bandaged feet; remarkably, he survived. After more than a year in treatment at the hospital, with volunteers providing eucalyptus leaves and special attention to encourage eating and exercise, Terry Glenn, looking like a normal, healthy Koala, was released back to the wild (Phillips 1994). Many burned Koalas were rescued by private citizens during the 1993 fires and treated in their homes, with guidance from the Koala Hospital and other veterinarians. Some were lucky enough to recover to be released to the wild. Although Terry Glen apparently survived after release, several Koalas, after lengthy care, were released only to be killed by dogs. The majority of Koalas, however, do not survive forest fires, another factor contributing to their decline.

The combined effects of land clearing, fire, hunting, disease, automobile collisions, predation, and continued failure by Australian states to protect Koala habitats may end in their extinction. The Koala's gene pool has been depleted, and its extreme vulnerability to disease in the late 20th century may be a symptom of a weakened species declining to extinction. The U.S. Endangered Species Act lists the species as Threatened, but it is not protected by CITES.

Spotted Cats

In the early 1960s, a disastrous fashion trend in spotted cat furs was launched when First Lady Jacqueline Kennedy appeared in a Leopard (*Panthera pardis*) coat sold to her by Ben Kahn Furriers in New York (*The New Yorker* 1967). An instant craze for spotted fur coats developed, and in 1968, 9,556 Leopard skins, 1,283 Cheetah (*Acinonyx jubatus*) skins, 13,516 Jaguar (*Panthera onca*) skins, and 133,064 skins of the small Ocelot (*Leopardus pardalis*) were imported into the United States (Stewart 1977). Profits were at first considerable, as skins were plentiful and reasonably priced to the importers. Soon, however, the spotted cats became rare in the wild, and prices for pelts rose. One employee of a fur manufacturer, who specialized in cutting the pelts of spotted cats into coats, told a reporter

from *The New Yorker* (1967) that as many as eight Somali Leopards were needed to make a coat, and at least 25 of the smaller cats. In 1966, he paid $250,000 for spotted cat skins which he made into 900 coats. "They must be killing these animals off very fast," he said. "I handle the skins of animals that were in the jungle three days before. They are flown here with the blood still on the fur" (*The New Yorker* 1967). Tiger skins were also used, though only for extremely expensive coats. In the early 1960s, the actress Gina Lollabrigida appeared in a Tiger coat that had cost the lives of at least six of these endangered cats. When questioned about the morality of wearing such a coat, she exclaimed that they were already dead when she bought the coat.

By 1969, the fur industry had pushed many species of these beautiful and regal animals to the verge of extinction. The animals declined because they were rare in the wild, had large territories, were trophy hunted, were persecuted by livestock farmers, or pushed from their territories as a result of habitat destruction. Protests and publicity began to mount to ban sale of their fur. In 1969, the U.S. Congress enacted the Endangered Species Conservation Act, which included prohibitions on the importation for commercial purposes of many foreign species. Several subspecies of critically endangered Leopard and Tiger populations were added to the list, but entire species did not receive protection. Exploitation was scarcely affected because once they are made into coats, subspecies cannot be distinguished from each other. Even when skins are imported, Customs officials and even Fish and Wildlife Service Inspectors are usually not able to distinguish one subspecies from another. The trade in spotted cats continued until passage of state laws, beginning with the Mason Act in New York in 1970, which banned the sale of fur from the Leopard, Cheetah, Snow Leopard (*Panthera uncia*), Clouded Leopard (*Neofelis nebulosa*), Tiger, Jaguar, and two small spotted cats, Margay (*Felis wiedii*) and Ocelot. Six other states followed suit. The U.S. Endangered Species Act of 1973 finally cut off imports by adding the full species of most large and many small spotted cats.

World trade in spotted cat pelts remained a major threat to them, as Paris, London, Rome, Tokyo and other cities provided markets for garments made from endangered wild cats. In 1975 when CITES came into force, several species of large spotted cats received protection on Appendix I, banning legal commercial trade. CITES listings, and the worldwide publicity concerning the plight of spotted cats, stopped most legal trade, although the majority of countries had not yet ratified the treaty. Many countries in Europe and elsewhere enacted domestic legislation to cut off their markets. Education and public opinion condemning the wearing of these coats discouraged this trade in North America and most of Europe.

In 1977, the remaining wild cat species of the Felidae family were listed on CITES Appendix II, covering all species not already listed on Appendix I. Had this designation been properly enforced, requiring all export countries to allow trade only if it does not result in a decline in wild populations, many other wild cat species would not have become endangered. Unfortunately, the fur trade merely switched from Appendix I species to Appendix II species, the majority of which were small cats. Exports from Latin America of four species of small cats--Ocelot, Geoffroy's Cat (*Felis geoffroy*), Tiger Cat or Oncilla (*Felis tigrina*), and Margay--increased in spite of national bans. Brazil banned wildlife exports in 1967 and Paraguay in 1975, but the latter country did not enforce its ban. It continued to export skins of cats killed in Brazil as well as its own country, with the majority going to Europe and Japan in the early 1980s. More than 123,000 Ocelot skins were exported from Paraguay from 1980 to 1985 (Fitzgerald 1989). In 1980, Europe imported at least 430,000 small cat skins from Latin America and Asia. This decreased to 250,000 in 1984 (Fitzgerald 1989). West Germany was the world's largest importer for more than a decade, importing between 220,000 and 370,000 skins a year until 1984, when imports dropped to 90,000 skins (Fitzgerald 1989).

The Margay is a smaller version of the Ocelot, and the Tiger Cat is a tiny spotted cat weighing only 3 to 6 pounds, native to tropical forests from Costa Rica south to Argentina (Sleeper 1995). At least 50 pelts from the Tiger Cat are needed for a fur coat. After these two species experienced steep declines in their wild populations, they were listed on CITES Appendix I along with the Geoffroy's Cat, a spotted cat the size of a domestic house cat, after it, too, became threatened from the fur trade. The U.S. Endangered Species Act lists all three species as Endangered.

The exploitation of these small cats was carried out, for the most part, in countries totally protecting these species,

and is a shocking example of greed, lack of enforcement of laws in their countries of origin, and total disregard for conservation on the part of importing countries. Many of these cats remain endangered from illegal hunting and habitat destruction. The Ocelot, for example, has a low reproductive rate and requires dense forest cover and abundant small prey, making it vulnerable to declines resulting from the rampant deforestation occurring in much of its range. Moreover, in many parts of South America, spotted fur coats are still openly sold or exported to countries that lack strict legislation relating to the sale of endangered species. Population surveys have not been carried out for the majority of these wild cats, and their numbers are estimated based on available habitat, a less than precise method. The Ocelot and many other small spotted cats remain in the Endangered category on the U.S. Endangered Species Act and on CITES Appendix I.

The Asian Leopard Cat (*Prionailurus bengalensis*) became exploited when Latin American small cats declined until it, too, became endangered in India, Bangladesh and Thailand. These populations are now on Appendix I, but cannot be distinguished from other populations when in coat form, making the listing meaningless. In 1993, CITES committees made a recommendation to all member countries that they suspend imports of Leopard Cat pelts from China until that country implemented recommendations for the conservation of this species. One after another of the small cats have become threatened and listed on CITES Appendix I or the U.S. Endangered Species Act.

Exports of North American Bobcats (*Felis rufus*) and Lynx (*Lynx canadensis* or *Felis lynx*) rose during the 1980s for this voracious market. This has caused declines in many populations of both species, especially the Lynx, a northern wild cat with low population density. It is dependent on the cycles of the Arctic Hare, its main prey. At the height of the wild fur boom of the 1980s, trappers pursued Lynx into Alaskan national parks. In one case, a trapped Canadian Lynx was brought food for six weeks by other Lynx. South of Canada, Lynx are extremely rare and are listed by the U.S. Endangered Species Act as Threatened as of March 24, 2000. Eurasian Lynx (*Felix lynx*) are also being killed for the fur trade. In western Europe, this species verges on extinction from centuries of persecution and habitat destruction, but in eastern Europe and Central Asia exploitation continues. CITES committees recommended in 1993 that member countries suspend imports of Lynx from Azerbaijan, Latvia, Lithuania, Moldova and Ukraine until these countries implement the recommendations of the Animals Committee relating to the need for population surveys because of the listing of this species of Appendix II. These recommendations are not, however, legally binding.

Open sale of even the most endangered spotted cats continues in some countries. At various times in the 1990s, highly endangered spotted cat garments have been openly sold in Japan, Taiwan, Hong Kong, Greece and West Germany, as well as in some of the countries of origin, such as Argentina, Kenya, Nepal, Vietnam, Laos, India, South Africa and Indonesia. Tiger skins are still being sold illegally for as much as $20,000 each. At a time when each Tiger's life is of utmost importance in conserving the species, illegal hunting is killing off the remaining Tigers at a far greater rate than they can sustain. In the first months of 1994, two Tiger skins were confiscated in India; one of the skins was from a Tiger that had been recently killed with poison near Kanha National Park (TRAFFIC 1994). In Ho Chi Minh City, Vietnam, Tiger skins and heads are sold in souvenir shops, with no apparent control of this trade by authorities. Leopard skins are also being smuggled by an international criminal network from India to the Persian Gulf (TRAFFIC 1994). Logging companies in Myanmar, formerly known as Burma, capture and kill wildlife on a large scale, offering Leopard and Marbled Cat (*Felis marmorata*) skins for sale (Hill 1994). The world's fastest land animals, Cheetah, number only between 9,000 and 12,000 in Subsaharan Africa, yet many are still killed and their pelts smuggled to parts of Europe and Asia. Farmers and ranchers in Namibia and other countries of southern Africa kill Cheetah as predator control, and then sell their pelts.

In Katmandu, Nepal, surveys in the late 1980s and 1990s by conservation organizations uncovered a major illegal trade in protected animals. In a 1988 survey, researcher L.J. Barnes posed as an American tourist and found 50 shops selling furs. In these stores, he counted 60 Leopard Cat coats, 19 Leopard coats, four Clouded and four Snow Leopard coats on open display (Heinen and Leisure 1993). In 1988 to 1989, a full-length Snow Leopard coat was openly offered for sale in a store along with two Clouded Leopard coats; in February 1992 and early 1993, Clouded Leopard coats were still being offered (Menon 1994). Coats made of the pelts from small cats, such as the Fishing Cat, Jungle

Cat and Desert Cat, were commonly offered for sale in 1991. The number of stores selling furs in Katmandu increased by 44 percent between 1988 and 1991, and the sale of endangered spotted cat coats had not declined. A few years later, a third survey of fur stores found that sales of these items actually increased: 29 Leopard coats made from an estimated 203 Leopards, and two Appendix I Snow Leopard coats made from at least 14 of these endangered animals were seen (Menon 1994). The 1993 survey found 76 shops selling 1,225 fur items from a variety of endangered species. An official from the CITES Secretariat traveled to Nepal in 1993 to meet with senior officials from the wildlife department to inform them of the surveys and their findings; the Nepalese officials agreed to take action to investigate irregularities (Menon 1994). A follow-up visit to Katmandu later in 1993 found no change; 35 shops were visited, and all continued to sell protected species openly (Menon 1994). A 1993 Nepalese law prohibits the killing, sale or trade in Snow or Clouded Leopards, with fines of $1,200 to $2,250 for offenses and a prison term of one to 10 years for killing or wounding; for illegal trade, fines of $1,500 to $3,000 and a prison term of five to 10 years, according to TRAFFIC International. Both the Clouded and Snow Leopards are listed on Appendix I of CITES, to which Nepal is a Party.

In neighboring India, the sale of certain furs was banned in 1979, but fur traders in Delhi received permission to continue to display their fur items for sale until stocks were depleted. This led to an indefinite reprieve in 1987 by the Delhi government, according to TRAFFIC India. The latter organization petitioned the government in 1993 to stop this trade, and the ban was reinstated, but delays in implementation resulted in the continued sale of many banned furs. A second petition to the Delhi High Court by TRAFFIC India and WWF India resulted in a court order calling for traders to stop sale by January 1994, pending a final decision. This applies only to Delhi, however, and endangered cat furs continue to be sold elsewhere in India. In 1996 alone, the skins of 14 Tigers and 64 Leopards were seized in various parts of the country, some as they were being exported, according to the Wildlife Protection Society of India.

The break-up of the Soviet Union has resulted in a wildlife slaughter by fur hunters in Central Asia. The poverty of rural people in Kazakhstan and other republics resulted in an appreciated value of furs; the skin of a Snow Leopard is worth 60 times the minimum yearly wage, or $500 to $2,000 (Koshkarev 1994). The scale of poaching is enormous; 12 Snow Leopard skins and 34 Turkestan Lynx (*Lynx lynx isabellinus*) were offered for sale in 1994 in a single village, and another 10 were trapped in the winter of 1993 to 1994 by a shepherd in the Bzhety-Oguzskiy region (Koshkarev 1994). In much of Central Asia and the Tibetan Plateau, Lynx and Snow Leopards are killed because they are considered a threat to sheep and also for their pelts (Schaller 1998). Hundreds of Snow Leopard skins from Tibet have entered the international fur trade, and so many of this species have been killed in Bhutan and India that the species is nearly extinct there (Schaller 1998). Even in the immense Chang Tang Reserve of Tibet, an area with extensive habitat for Snow Leopards, they are rare even though their major prey, Blue Sheep, were present (Schaller 1998).

Many people in Central Asia have turned to hunting furbearers at an unprecedented level, killing an estimated half of the Snow Leopard population in one region in a single winter (Koshkarev 1994). The major prey of the Snow Leopards in the area, Grey Marmots (*Marmot baibacina*), are also being eliminated by fur hunters, with 600 to 800 caught in a season (Koshkarev 1994). The Snow Leopard pelts are being sold through the black market to foreign tourists and Russian cities (Koshkarev 1994). These elusive and shy cats are among the most beautiful in the world, and their skins are one of the most coveted of all furs. They have been hunted, trapped and pursued throughout their high-altitude range in India, Pakistan, Afghanistan, China, Nepal, Mongolia, Bhutan and the former U.S.S.R. from the Altai Mountains to the Hindu Kush to the Himalayas (Sleeper 1995). Snow Leopards are rare throughout their distribution, ranging up to 18,400 feet, dependent on prey such as Blue Sheep, Ibex, Musk Deer, Tahr, Wild Boar and Marmot, which are themselves rare in this mountainous terrain, and are subject to heavy trophy and meat hunting. Fewer than 10,000 Snow Leopards may remain in the wild (Schaller 1998).

Vietnam and Laos also sell coats and skins of large spotted cats, and China has provided a new market for many of these products. In 1997, a survey in Yunnan Province on the border with Vietnam found skins of Asiatic Golden Cat (*Catopuma temminckii*), Marbled Cat (*Pardofelis marmorata*), Leopard Cat and Fishing Cat (*Felix viverrina*) being

sold in cities in the region (Li and Wang 1999). Officials in the region consider this trade, which includes many endangered species, to be of minor importance in spite of regulations and laws prohibiting it (Li and Wang 1999). Also in Yunnan Province, Customs officials uncovered a scheme to smuggle large numbers of animals by mail. Tracing information relating to packages of animal skins, officials arrived at a house where 11 Tiger skins and many Leopard skins were kept (*TRAFFIC Bulletin* 1999). Another raid in Fuzhou, Fujian Province, China, netted a large number of animal skins and parts in a truck; among the items were Tiger and Leopard skins. In a seven-month period between 1998 and 1999, 11 Tiger skins were seized, many near Kanha Tiger Reserve, along with Tiger skeletons and bones for the Traditional Medicine trade (*TRAFFIC Bulletin* 1999).

A survey of markets in Cambodia in 1994 revealed the pelts of Tigers and Leopards openly displayed in villages on the border with Thailand; Thai buyers cross the border to purchase these pelts (Martin and Phipps 1996). The investigators were told that live Tigers, usually young animals, are sold for $200 to $250 to traders in Phnom Penh, who then ship them alive to Vietnam, especially Ho Chi Minh City, where they can be sold for as much as $5,000 (Martin and Phipps 1996). Leopard skins were seen in both 1994 and 1995 in Phnom Penh and Ban Long, offered for $50 each (Martin and Phipps 1996). Cambodia is a member of CITES, and prohibits hunting and export of wildlife, but does not have strong legislation regulating sale of animals (Martin and Phipps 1996).

Leopards are still being killed for their fur in African rainforests as well. In 1999 and 2000, Michael Fay, a wildlife biologist with the Wildlife Conservation Society, walked 1,500 miles across Congo and Gabon to draw attention to the urgent need to protect this wilderness from loggers and bushmeat hunters. The National Geographic Society filmed the walk (fiExtreme Africafl and fiNdoki Adventure,fl shown in March 2001 on National Geographic Explorer), documenting the discovery of a large poaching camp with hundreds of dead animals, including the skin of an extremely large Leopard. Fay and the others set fire to the skin and burned the campsite down. The last rainforests of Central and West Africa are being stripped of their wildlife by bushmeat and animal skin hunters at a completely unsustainable level.

Clouded Leopards were not heavily exploited until the 1980s, but Appendix I listing has not prevented continued exploitation of these endangered Asian cats. Coats from these beautiful cats can sell for as much as $80,000. The tale of one Clouded Leopard's death was recounted in the newsletter of the World Endangered Species Protection Association of Taiwan:

> *. . . in the jungles of South Pahang in Malaysia ..some aborigines came to my camp and told me they had caught a tiger. A few hours later I saw her. She lay in a bamboo cage with a shattered front paw; a mess of rotting tissue and splintered bone. I was filled with misgivings and should have put her out of her misery at once, but I loved her on sight and couldn't bring myself to do it. She was not a tiger, but that most handsome of felines, a clouded leopard. Her captors . . . gathered around, indifferent to her suffering. She was caught in a 'Jerat' or steel trap which tightens when the animal struggles. No trace of suffering showed as she faced me with eyes blazing with menace . . . Despite her terrible wounds and the cramped conditions of her cage, she looked magnificent . . . I got it back to my camp and amputated its wounded paw . . . [later]. I found her tearing at the bandages on the stump of her paw with her teeth . . . Two days later it was eating out of my hand, although growling menacingly as it did so. It seemed to be well on the road to complete recovery then, suddenly its wound became infected and it died. Few events have saddened me more.*
>
> Charles Shuttleworth, from *Adventures of a Sapient Primate* reprinted in *WESPA NEWS* November 1994, Taipei, Taiwan

It is rare that one hears of the suffering wild animals endure in order to be turned into frivolous clothing. The pelt of the Clouded Leopard is a mosaic of large black, yellow and white rosettes, somewhat like the markings of a Giraffe, yet its beauty may spell its extinction.

Wild cats, especially large species like Tigers and Leopards, like many other endangered species, require a great deal of territory and are thinly distributed over their range. They live at least 10 years in the wild and have very few young each year, far fewer than domestic cats. Kittens stay with their mothers for up to two years, learning how to hunt and survive. Hunters killing a wild mother cat with kittens, even when they are 6 to 8 months old, kill two generations. All cat mothers are fiercely devoted to their kittens, willing to confront all types of dangers, including hunters and trappers, to protect them. These characteristics are shared with other families of animals that can quickly become endangered by killing and are slow to recover their numbers.

The trade in large and small spotted cats continues to decimate their wild populations because buyers for their pelts can be found throughout the world, whether sold openly, as in some countries, or as hidden merchandise. Official indifference, either from failure to enforce strict laws against hunting or sale, non-membership in CITES, or the failure to enact strict domestic legislation, can contribute to this trade. The present lack of enforcement powers or even sanctions by CITES has dire consequences for endangered species in view of the enormous market for their products. The *2000 IUCN Red List of Threatened Species* lists some, but not all, subspecies of the Tiger as Critically Endangered, and the species as a whole as Endangered. The actual status of this magnificent animal throughout its range appears to be Critically Endangered as a result of the fur trade; the Traditional Medicine trade, which uses its body parts for various purposes; along with persecution and habitat loss. At the present rate of loss of one Tiger per day out of a population totaling only about 5,000 animals, many conservationists and scientists have predicted its extinction in the wild within a decade or less. The IUCN also fails to list the full species of Leopard or Ocelot in any category, while including some of their subspecies. In the view of many, legislation and International Treaties have solved the problem of killing of these animals, but surveys of markets and seizures of poached animals indicate otherwise.

Otters

Among the most playful and intelligent of all animals, otters have been unfortunate in having durable, waterproof fur that is highly desired for coats, jackets and other fur items. Otters of 13 species are found on all continents except Antarctica and Australia, but throughout their ranges, they are thinly distributed and vulnerable to overtrapping.

Many species have incurred great losses from the fur trade. All species of otters (family Lutrinae) are now listed on CITES, with five species and one subspecies on Appendix I, and the remaining on Appendix II. Four species and two subspecies are listed on the U.S. Endangered Species Act. Seven species were listed in the *1996 IUCN Red List of Threatened Animals* (one as Endangered, four as Vulnerable and two as Near-threatened) (Baillie and Groombridge 1996). The downward trend of otters was reflected in the fact that the *2000 IUCN Red List of Threatened Species* listed 11 species (four as Endangered, three as Vulnerable, one as Near-Threatened, and three as Data Deficient). This represents 85 percent of all otters. The large number of species that are threatened is an indication of the massive declines that otters have suffered over the past century, in large part due to the fur industry.

The Sea Otter (*Enhydra lutris*) is a large marine species, heaviest of all otters, weighing up to 45 kilograms (Reeves *et al*. 1992). Living in groups called rafts that float just offshore, they were nearly exterminated throughout their range by the fur trade. Killed for their extremely valuable pelt, pursuit of these otters during the 18th and 19th centuries was among the most destructive and thorough of any in the history of the fur trade. Originally numbering from 250,000 to 300,000, Sea Otters once occurred throughout the North Pacific rim, from Baja California, Mexico,

north along the coasts of North America to Alaska, the Aleutian Islands, Russia and the northern Japanese archipelago (Reeves *et al*. 1992). The German-born Arctic explorer George Steller encountered thousands of Sea Otters during his stay on Bering Island in 1741; his party killed and ate 700 animals, describing adults as fifairly good to eat,fl and the young as fidainty as suckling lambfl (Peck 1990). Steller's navigator, Vitus Bering, considered the soft, thick pelts a resource which could provide great potential wealth, bringing 900 pelts to Russia (Allen 1942). When Catherine the Great, Empress of Russia, saw one of the skins, she ordered a cloak of Sea Otter to cover her from throat to ankles, launching an onslaught of hunting. Many pelts were traded to the Chinese, who valued them highly (Allen 1942). By the late 19th century, its pelt sold for up to $165, and as it became rarer, the price rose to $1,125 by 1903 (Nowak 1999).

At first, Sea Otters were easy to kill, having no fear of humans (Peck 1990). One Russian traveler wrote, "They covered the shore in droves; they would come up to our fires and would not be driven away." Sea Otters approached the Russians on Bering Island and rubbed their noses against the legs of sailors, who immediately bludgeoned them to death (Nickerson 1984). "When it receives a vigorous blow upon the head," one hunter observed, "the otter falls upon the ground, covers its eyes with its paws, and keeps them so, no matter how many times it is struck." The native Aleuts considered them to embody spirits of their own dead, and at first refused to hunt them at all (Peck 1990). Russian seamen forced the Aleuts to produce otter pelts by threatening to rob and pillage their villages and take their women hostage for the furs (Peck 1990). If Aleut hunters failed to produce the furs, the hostages were raped and murdered (Peck 1990).

The Sea Otters were shot as they lay in kelp beds, clubbed when they surfaced from dives to breathe, and netted in wide coarse nets (Allen 1942). On land, they were pursued as they sought shelter among rocky shores, and then clubbed to death. Perhaps the cruelest method was the capture of a pup when the mother dove for food. A cord was tied to the foot of the pup, with fish hooks placed close to its body and attached by the cord. Retiring to the shore, the hunter would pull the cord, hurting the pup so it would cry, bringing the mother, who would become caught in the line or hooks or, so occupied in freeing her offspring, easy prey (Nickerson 1984). The killing of 15,000 Sea Otters by the Russian and English near Bering Island caused the otters™ extinction on the island, and they remain absent there today. After less than a century of intense hunting, only 15 otters were found and killed in the entire Aleutian chain in 1826. During the next decade, however, new herds were discovered in Alaskan waters, and in the mid-19th century, about 5,000 Sea Otters were taken per year. Over the 30 years that they were hunted in southern California, an estimated 50,000 were taken, with at least 5,000 a year killed in San Francisco Bay (Nickerson 1984). By 1833, only 54 Sea Otters were found in the Farallon Islands off California; they were soon killed off. This hunting was carried out by enslaved Aleuts brought from Alaska (Nickerson 1984).

By 1900, the Alaska Commercial Company, operating five trading posts and 16 schooners, was able to find only 31 Sea Otters, whose pelts were sold at $1,000 each (Allen 1942). In 1910, Sea Otters finally received protection under the North Pacific Fur Seal Act, but they had reached the verge of extinction, numbering, in the opinion of biologist Karl Kenyon, only between 1,000 and 2,000 animals (Nickerson 1984). They had been hunted out of much of their territory, including the long coastline from southeastern Alaska to northern California, where a tiny remnant population survived. An estimated 500,000 Sea Otters had been killed between 1740 and 1911 (Reeves *et al*. 1992). The scattered remnants of this species continued to be killed wherever they were found. When small numbers of Sea Otters were spotted between the 1890s and 1917 in the waters off San Luis Obispo and Monterey, California and near islands off Baja California, Mexico, they were immediately shot (Nickerson 1984). Although the Russians predominated in the hunts, Americans, alerted by Captain James Cook in the 18th century, were almost as responsible for the near-extinction of these beautiful animals.

In the 1950s, after an apparent recovery of the species in Alaska, the state Department of Game began a program of experimental harvesting; from 1962 to 1971, 2,933 pelts were taken for zoological data and for possible sale in the fur market (Reeves *et al*. 1992). Their world population numbered about 32,000 by 1965 (Nickerson 1984), and hunts were ended in U.S. waters by passage of the Marine Mammal Protection Act of 1972. Take by native Alaskans is permitted under certain conditions, and some native hunters have killed large numbers of Sea Otters (Reeves *et al*.

1992). Populations totaled an estimated 100,000 to 150,000 in the early 1990s, with the largest numbers off Alaskan coasts (Nowak 1999). The Sea Otter has not reoccupied many parts of its original range, including former strongholds such as the Pribilof Islands, Bering Island, the Queen Charlotte Islands off British Columbia, Oregon, Mexico and most of California (Reeves *et al*. 1992); and reintroduced populations have not fared well (Nowak 1999). The species numbers about 17,000 off Russian coasts (Nowak 1999).

The *Exxon Valdez* oil spill in 1989 killed up to 10,000 otters in this center of their population in Prince William Sound, Alaska (See Aquatic Ecosystems chapter for more about this spill). Yet another unexpected threat is killing large numbers of Sea Otters off Alaska. In an ecological catastrophe caused indirectly by human activity, Sea Otters are now being preyed upon by Killer Whales (*Orcinus orca*). The latter animal has been deprived of its traditional prey in Alaska, Steller Sea Lions (*Eumetopias jubatus*), which have become endangered as a result of overfishing of their prime food supply--herring, pollock and ocean perch--by commercial fishing boats (Stevens 1999). Scientists began noticing the decline of Sea Otters in the early 1990s in the Aleutian Islands and western Alaska, a coastline stretching for 2,000 miles. Populations in some areas had declined by 50 percent, and by 1997, a survey found losses up to 90 percent (Stevens 1999). In one 500-mile stretch, Sea Otters had dropped from 53,000 in the 1970s to only 6,000 (Stevens 1999). The entire ecosystem has also been affected by the decline of Sea Otters. They are a keystone species, keeping kelp forests healthy by eating large numbers of sea urchins, which feed on kelp. Now large stretches of coast have lost their kelp beds, causing the entire ecosystem, from mussels to Bald Eagles, to decline (Stevens 1999). Other threats to Sea Otters include persecution by fishermen, shooting, oil and toxic chemical pollution, loss of food supply from overfishing, and ship traffic. The small population in Southern California has also been declining. In 1996, the Sea Otter was not listed in the *IUCN Red List*, but its sudden loss in numbers in Alaska and elsewhere in its range has again placed the species in danger of becoming extinct. The *2000 IUCN Red List of Threatened Species* lists the Sea Otter as Endangered.

During the 1960s, otter fur became popular in the fur industry, causing an enormous decline in wild otters as trappers combed tropical rivers and wetlands for these vulnerable animals. The United States imported 45,000 otter skins per year from South America between 1965 and 1969, primarily from Brazil and Colombia, according to U.S. Department of Commerce statistics. All four of the Neotropical otters occurring from Mexico south to the southern tip of South America are now on Appendix I and have declined to threatened or endangered status from trapping.

The Giant Otter (*Pteronura brasiliensis*) is the largest of all otters, reaching almost 8 feet in length from its nose to the tip of its tail (Nowak 1999). Once common in river systems in Colombia, Venezuela, Guyana, French Guiana, eastern Ecuador, Peru, Brazil, Paraguay, Uruguay and northeastern Argentina, it has disappeared from most of its range and become extremely rare where it survives as a result of killing for the fur trade (Nowak 1999). These otters have been relatively easy to hunt because they live in large, friendly groups in feeder creeks and quiet, slow-moving rivers, denning in river banks. They vocalize to one another as they swim and gather on land, often in very loud chirps and barks. Thousands were killed, even after the species was protected by CITES Appendix I and hunting was banned throughout its range. When one otter is trapped or shot, others quickly come to its aid, becoming vulnerable to shooting; this seals the fate of entire groups of these beautiful animals. This trait of altruism is shared by other species of otters and has contributed to their elimination from entire areas. Trappers often set traps next to one another to take advantage of the extremely close ties between otters; one trapped otter might then bring others, which would become trapped as well. Pelts of Giant Otters were smuggled to European furriers in the 1980s, and this illegal trade has not been completely controlled by either exporting or importing countries. The Giant Otter is classified as Endangered on the *2000 IUCN Red List of Threatened Species*.

The Southern Marine Otter (*Lutra felina*), a very rare species, is considered one of the most endangered of all otters. These very small otters, less than 4 feet long, are native to the cold coastal waters along the coasts of Peru and Chile; they have been hunted for centuries for their valuable pelts (Reeves *et al*. 1992). Darwin found them abundant in the Cape Horn and Tierra del Fuego region in 1830, but 130 years later they had been hunted to extinction in that region (Thornback and Jenkins 1982). Although now protected and listed on Appendix I of CITES, they continue to be hunted for their fur and persecuted by fishermen. In Chile, where the Marine Otter is highly valued for its pelt, *The*

IUCN Mammal Red Data Book reported that the fur of this species is the most valuable of all otter fur, with hunting carried out from boats that cruise the coast for months at a time, killing any otters seen (Thornback and Jenkins 1982). On land, hunters with dogs chased them down and they were shot on sight, with pelts selling for up to $75 in the 1970s (Thornback and Jenkins 1982). Legal protection in Peru was accorded in 1977, before which a trapping season had been designated. The extent of illegal trade in South American otters is not known. Fishermen persecute Peru them for supposed damage caused to freshwater prawns, killing many (Mason and Macdonald 1986). There may be as few as 1,000 Marine Otters left in the wild (Nowak 1999), and they are listed as Endangered by the *2000 IUCN Red List of Threatened Species*.

Trade in the late 1960s also affected the other two species native to the continent. The Southern River Otter (*Lutra provocax*) is listed as Endangered by the *2000 IUCN Red List of Threatened Species*, an upgrade from Vulnerable in the 1996 version of the list. It has a limited range in Patagonia in Argentina and southern Chile. Having been eliminated from the majority of its range by trapping for fur, the Southern River Otter is now confined to remote and inaccessible areas in Argentina, such as national parks. The species has been reduced to small, isolated populations in south-central and southern Chile, where illegal hunting continues (Mason and Macdonald 1986). The Neotropical or Long-tailed Otter (*Lutra longicauda*) occurs from northwestern Mexico south to Uruguay. Both are CITES Appendix I species and listed as Endangered on the US Endangered Species Act; the *1996 IUCN Red Data Book* omitted the Long-tailed Otter (Baillie and Groombridge 1996), while the 2000 version of the list classified it as Data Deficient. The Long-tailed Otter, in spite of its extensive distribution, is considered by some experts to be "severely depleted" in many parts of its range in South America. The majority of the 113,718 otter skins exported from Peru from 1959 to 1972 were of this species (Mason and Macdonald 1986). In the early 1970s, between 6,000 and 8,000 Long-tailed Otters were legally killed per year, with probably an equal number taken illegally (Mason and Macdonald 1986).

In 1973, Colombia banned the killing of otters, but poaching continued because otter pelts have a very high value; in Chile, for example, an otter skin is worth two or three months' wages to an unskilled worker. In spite of legal protection since 1924 in Chile, otters continue to be hunted with very little enforcement of the law (Mason and Macdonald 1986). During the 1960s and early 1970s, trade records did not differentiate between the four South American otter species. Since that period, all trade has been illegal, but in spite of CITES Appendix I listings, a large number of pelts of these species are exported to the fur markets of Germany and Italy, and others are sold locally in fur stores in Buenos Aires and other South American cities.

Otters of all species produce relatively few young, and have evolved with a low natural mortality rate. They are known to live to an average age of 15, and perhaps as long as 30 years (Nickerson 1984). Species with these traits, along with their large habitat requirements and protective behavior toward one another, are extremely vulnerable to extinction. Otters play an important role in aquatic ecosystems by taking slow and injured fish, thus preventing fish overpopulation, which results in undersized fish.

Tibetan Antelope

Few people have ever heard of an antelope known as the Chiru, or the Tibetan Antelope (*Pantholops hodgsonii*), yet it produces shahtoosh, a wool far more valuable than gold. This statuesque animal is native to treeless steppe above 5,000 meters in Chinese Tibet and adjacent northwest India. Its extremely lightweight, delicate wool has traditionally been woven into shawls and sold in a limited trade in Tibet and Kashmir, India. Within the past few decades, however, a growing market has developed in major cities in India, Nepal, several western countries and Japan (Schaller 1998).

The Chiru has been listed on Appendix I of CITES since 1979, a listing which bans commercial international trade, and CITES Parties passed a resolution (Resolution Conf. 11.8) on the fiConservation of and control of trade in

Tibetan antelopefl in 2000. It is totally protected by Indian (Kumar 1993) and Chinese law (Schaller 1996). Until recently, however, the major trading state of Kashmir in India allowed trade in shahtoosh, in defiance of a ban included in the national Indian Wildlife Protection Act (Currey 1996). In Tibet, illegal hunting, even by government officials, supplies the trade, with many thousands of Chiru killed each year--with the wool smuggled to India (Schaller 1998).

Populations in India probably do not exceed 200 animals, while in Tibet these antelope were estimated to number fewer than 75,000 animals in the mid-1990s, reduced from an estimated million animals a century ago. Great herds were seen on the steppe in the 19th century (Schaller 1998). The *1996 IUCN Red List of Threatened Animals* listed the species as Vulnerable. In the 2000 version of the list, the species was upgraded to Endangered. Illegal trade and continued killing have pushed the species closer to extinction, with an estimated 20,000 killed per year.

In spite of this antelope's remote habitat, the enormous prices paid for shahtoosh (up to $1,250 per kilogram), and low fines for infractions, have fueled this illegal trade (Kumar 1993). Dr. George Schaller, who has conducted many years of research on Himalayan wildlife, found this wool being illegally traded in a Nepalese town on the Indian border in the early 1990s (Kumar 1993). Forty shawls of shahtoosh were seen in several shops in New Delhi in 1993; half of these were in one shop, which is state-owned (Kumar 1993). Indian tradesmen have misrepresented the wool as obtained from bushes that the antelope rubbed up against; in fact, Chiru are killed to obtain the wool (Schaller 1996). In the early 1990s, shawls retailed at $2,000 to $8,500 in western markets. A single Chiru provides about 150 grams of wool, and each scarf represents at least two dead Chirus, according to Schaller (1996, 1998). In 1992, the wool of at least 13,000 Chirus was confiscated in India (Schaller 1996), and in 1993 and 1994, the wool of at least 17,000 Chirus reached Indian markets (Schaller 1998). In June 1993, Indian Customs officers at Delhi airport seized a shipment of 105 kilograms of shahtoosh arriving from Katmandu, Nepal (Kumar 1993).

Large numbers of Chiru are poached near the Chang Tang Reserve, established in 1993 to preserve Tibet's wildlife, and smugglers trade shahtoosh for Tiger skins and bones, providing conduits through which the contraband travels (Currey 1996). Schaller saw Tibetans in the early 1990s with truckloads of Chiru hides, and at least one driver was arrested with 300 hides. Families moved into the Aru Basin, a great stronghold for the species within the Chang Tang Reserve, specifically to hunt Chiru in 1991 (Schaller 1998). These previously impoverished nomads were able to purchase a truck from the profits of their sale of Chiru hides, which they offered to Schaller (1998) and his group in 1992 for the equivalent of $28 each (Schaller 1998). In 1999, government officials came upon seven herds of just-slaughtered Chiru, including many females and newborns. Several wildlife organizations are organizing anti-poaching teams, but in such an enormous territory, patrolling every herd will not be possible. The herds are in constant motion, migrating from summer to winter areas. The Tibet Forest Bureau began an effort in the early 1990s to stop the shahtoosh trade, raising the fine for killing Chiru to $118. Ten poachers were arrested in a two-month period in 1993, and checkpoints were set up in several areas (Schaller 1998). In 1995-1996, patrols in remote portions of Qinghai in western China encountered Chinese hunters armed with high-powered rifles and confiscated more than 1,600 Chiru hides (Schaller 1998). China's State Council issued a directive in 1996 that Chirus must receive better protection (Schaller 1998).

A record shipment of 400 kilograms of shahtoosh that had originated in Tibet was seized in northern India in January, 1994. Samples were sent to the U.S. Fish and Wildlife Service Forensic Laboratory, which verified them as wool from the Chiru, according to TRAFFIC International (1994). Indian courts released the 400 kilograms of seized shahtoosh in May 1996 after requests from tradesmen who claimed that the wool was perishable, according to TRAFFIC India. This decision was challenged by TRAFFIC India to India's Supreme Court which overturned the lower court's decision, keeping the wool in the possession of Customs authorities until the case was decided.

Research by the Environmental Investigation Agency (EIA) in Delhi uncovered large quantities of shahtoosh being sold in the mid-1990s, having been manufactured in factories in Kashmir (Currey 1996). A Delhi salesman offered to supply 200 to 300 shahtoosh shawls every three months, claiming that his best customers were Germans, French, Italians and Japanese, who provided a demand that exceeded supply (Currey 1996). In Bombay and Calcutta,

likewise, this wool is readily available and openly sold, marketed at $1,085 a shawl, with bulk orders of 15 shawls sold for $805 each (Currey 1996). One Calcutta dealer alone offered to supply 10 shahtoosh shawls every three months, and even instructed on methods of smuggling them abroad labeled as "handicrafts" with double invoices. Shahtoosh shawls offered at a government emporium in Bombay had official Kashmir Government labels and stamps and came with a certificate of authenticity (Currey 1996). The Bombay store offered 50 shawls per month (Currey 1996). Illegal trade has not stopped in spite of new education campaigns and a tightening of national legislation. The Indian Government appears to have little interest in enforcing its own regulations prohibiting sale of shahtoosh, although Kashmir finally banned sales in 2000 after much publicity on their role in endangering this animal. Elsewhere in the world, shahtoosh is still available. On January 22, 1997, for example, 21 shahtoosh shawls were confiscated in Hong Kong from a hotel room after a raid; the guilty party was fined $2,580 two years later, in 1999 (*TRAFFIC Bulletin* 1999).

The New York luxury department store, Bergdorf Goodman, advertised shahtoosh in 1995 as a "royal and rare" fabric, making incorrect statements about the wool having been obtained from the Mountain Ibex goat of Tibet which "sheds its down undercoat by scratching itself against low trees and bushes" from where it is gathered by local shepherds (Schaller 1998). This misinformation created the false impression that the wool was legally obtained --without hurting the animals--by hardworking, indigenous people, in order to market it as a "politically correct luxury item" (Schaller 1998). Subsequently, scarves and shawls were removed from the shelves of luxury stores in the United States, and the CITES Authorities in Italy and France took action against several major fashion houses. In February 1997, police in London seized 200 shahtoosh shawls worth an estimated $500,000 (Schaller 1998). Many famous and wealthy New York City socialites have worn these shawls, and in the late 1990s, many were interviewed during an investigation to find the stores illegally selling the shawls. By 1999, the price of a shahtoosh shawl had risen to $10,000.

This situation is very dire for the Tibetan Antelope. A major campaign is needed to stop this trade. Efforts to guard wild herds and police markets for shawls and other goods made from this wool have been underfunded. The idea of ranching Chirus for their wool has been proposed, but Schaller considers such an idea disastrous for this species (Kumar 1993). Schaller has been interviewed by CNN several times about this situation, and he has expressed his extreme concern about the trade, stating that tens of thousands of Chiru are being killed, threatening the very survival of the species.

Reptile Trade

Reptile Trade: Sea Turtles

Huge sea turtles have been laboring up the beaches of tropical shores for 50 million years, digging deep holes with their flippers and depositing their slippery eggs before making their way back to the sea. Remains of extinct species of sea turtles 12 feet long have been found. The largest living sea turtle is about two-thirds that length. Other than humans, adult sea turtles have few enemies except sharks. Even today, the great turtles are enigmas. How they find their way over thousands of miles of open sea to return to the same beach on which they hatched--often a tiny islet--is not known with certainty. In 1986, scientists discovered that the temperature at which eggs incubate determines the

sex of the hatchlings. Cool nests produced males and warm ones, females. This discovery has influenced some conservation programs which hatch eggs in captivity for release to the wild. Research is very slowly unraveling some of their secrets through tagging and radio-tracking by satellite. Within the next few decades, much more will be learned about their movements and life history. Available data indicate that females may not nest until they are at least 10 years of age or older.

All seven species of sea turtles are now endangered. They face myriad threats. Killing for leather, meat, tortoiseshell, and to be stuffed for sale as curios is one of the foremost threats. For centuries, sea turtles were exploited by native peoples, most of whom did not kill large numbers or sell them as a commodity. Only when the products entered international trade and high-volume markets were created did turtle hunting have serious consequences. "They have a unique, and for them disastrous combination of characteristics; they are . . . excellent to eat, ridiculously easy to catch, and with virtually no way of defending themselves," in the words of turtle expert, Dr. Peter Pritchard (Lehrer 1990).

Commercial exploitation of the Green Turtle (*Chelonia mydas*) began in the 1600s in British colonies in Jamaica and Bermuda. Thousands of adult turtles were killed for their meat. As early as 1620, the Bermuda Assembly passed an act to outlaw the killing of young turtles because, even by that early date, they had been decimated (Carr 1973). The British colony in Jamaica sent ships in the mid-1600s to the Cayman Islands, once considered the species' largest breeding grounds in the world, to bring back turtle meat for the colony (Lehrer 1990). By 1688, ships were transporting 13,000 Green Turtles a year to Jamaica, and this meat became a staple food for colonists. By the early 1700s, Jamaican laws protecting the dwindling turtle colonies were enacted, but were not enforced, and by the late 1700s, Green Turtles had been almost eliminated from the Cayman Islands (Lehrer 1990).

In the 20th century, nearly every part of the Green Turtle's body and shell became valuable in international markets. These turtles are found throughout the world in all tropical oceans, and exploitation was relentless. Eggs and meat were sold locally and in gourmet restaurants, and the oil was used in cosmetics; the shell was carved into jewelry, and the neck and flipper skin was tanned for leather. Even baby turtles were stuffed and sold as souvenirs. Turtle hunters discovered their most remote nesting beaches and killed the females as they laid their eggs. Whenever they were spotted on the open ocean, they were caught and slaughtered. At the beginning of the 20th century, it was not unusual to catch Green Turtles that weighed almost 1,000 pounds, but after heavy exploitation, their average size began to decrease. Today, 300-pound animals are considered large (Lehrer 1990). By the early 1970s, Green Turtles were listed as Endangered in the *IUCN Red List of Threatened Animals,* but exploitation continued to decimate them. Both families of sea turtles (Cheloniidae and Dermochelyidae) were added to Appendix I of CITES in 1977, banning commercial trade between member nations. Unfortunately, several countries, including Japan, took reservations, a formal refusal to enforce the listing, and in the 14 years before 1994 when Japan finally withdrew its reservation, it imported 130,000 Green Turtles (Thornton 1994).

The U.S. Endangered Species Act finally listed Green Turtles in 1979, seven years after they had been proposed. Breeding populations in Florida and on the Pacific coast of Mexico are listed as Endangered, while the rest of its populations around the world are in the lesser category of Threatened. Green Turtles are still being killed in large numbers in Indonesia, where an estimated 20,000 are slaughtered each year for meat, shell and eggs, according to Reuters (August 1994). The Governor of Bali set a quota of 5,000 per year for use in Hindu festivals on the island; even the latter quota will result in the extinction of these turtles in these islands within a few years. Stuffed sea turtles with polished shells are sold openly in tourist shops throughout Indonesia.

Hawksbill Turtles (*Eretmochelys imbricata*) have been slaughtered to near-extinction worldwide, mainly for their beautiful shells, which are made
into tortoiseshell jewelry and other items. Like the Green Turtle, the Hawksbill is found in all tropical oceans but is most commonly seen in coral reefs and along coastlines in mangroves and marshes. This 3-foot-long turtle received the protection of the U.S. Endangered Species Act as early as 1969, an indication of the depletions that it had undergone throughout the century. About 10 to 12 pounds of tortoiseshell are obtained from each turtle (Ernst and

Barbour 1989). Cutting off the U.S. market did not stop slaughter of these turtles, however. Tortoiseshell from Hawksbill Turtles is made into eyeglass frames that sell for up to $4,000 in Tokyo luxury stores. The shell is also fashioned into bracelets, earrings and other trinkets. The meat and eggs are consumed, and hatchlings--as well as adults--are killed and sold as stuffed curios. Listing on Appendix I of CITES in 1977 hardly slowed the trade because Japan and several other countries took reservations on the species and continued trading. International trade in Hawksbills totaled more than 250,000 animals in 1976 and 1977, and shells from 500,000 of these turtles were traded in 1978, primarily exported from Asian and Central American countries to Germany, the United Kingdom and Japan (Fitzgerald 1989). Between 1970 and 1986, Japan imported 570,000 stuffed Hawksbills, which were used to adorn the walls of houses (Fitzgerald 1989). In an average year during the 1980s, Japan imported the shells of 28,000 adult Hawksbills that had been killed in the Comoros Islands, Jamaica, Haiti, the Maldives and Cuba; the latter country was the largest supplier (Fitzgerald 1989). By 1994, when Japan withdrew its CITES reservation on Hawksbill Turtles, it had imported 400,000 of these endangered animals in the previous 14 years (Thornton 1994).

Although the Hawksbill originally nested in 60 countries in the tropics and sub-tropics (WCMC 1993), decades of heavy exploitation caused major declines and the extinction of many nesting populations. Vietnam now kills and markets thousands of these highly endangered sea turtles. They are processed at seven nesting sites along the Vietnamese coast, and tortoiseshell and stuffed turtles are sold openly in Ho Chi Minh City (formerly Saigon) and in other cities (Duc and Broad 1995). The number of Hawksbills killed in Vietnam has increased greatly in recent years. Also, eggs are collected, and local operations hatch them--another loss to wild populations. Japan announced in 1994 that it is developing a simulated tortoiseshell made of laminated silk, but it continues to provide an illegal market for Hawksbill tortoiseshell. Urgent action is needed to protect nesting turtles and stop Vietnamese exploitation to prevent extinction of Hawksbills in this region (Duc and Broad 1995). Scientists and conservationists are pessimistic about the long-term survival of the Hawksbill Turtle because of continued killing for its valuable shell. The *2000 IUCN Red List of Threatened Species* lists it as Critically Endangered.

The Olive or Pacific Ridley Turtle (*Lepidochelys olivacea*) is found only in the Pacific region, with the majority of nests located along the coasts of Mexico and Central America. They have been slaughtered mercilessly on their nesting beaches, where they gather by the thousands. The market was controlled by one man in Mexico, Antonio Suarez, a Spanish national. In 1978, one of Suarez' plants processed 50,000 Olive Ridleys, 90 percent of which were females; this was 16,000 more than the quota permitted. Mexican government quotas were far higher than the turtle populations could sustain, and catches fell precipitously in 1979 and 1980. This exploitation endangered Pacific Ridley turtles on Mexico's coasts, which brought about listing on the U.S. Endangered Species Act in 1979 of breeding populations on the Pacific coast of Mexico as Endangered and other populations as Threatened. Prior to this, skins, shells and meat from hundreds of thousands of Mexican Olive Ridleys had been imported into the United States, the major consumer of these animals.

In 1980, some 106,000 pounds of Olive Ridley meat were seized as they were being smuggled in from Mexico to various dealers in the United States; the meat came from an estimated 8,800 turtles. Turtle slaughterhouses were still operating in Mexico in 1990, and Suarez owned three processing plants. Not only was Suarez indicted for smuggling thousands of pounds of turtle meat into the United States, but his purchases of turtles from fishermen in Mexico exceeded government quotas. The species is still exploited for other markets, and the *2000 IUCN Red List of Threatened Species* lists the species as Endangered.

Rarest of all the sea turtles, the Kemp's or Atlantic Ridley (*Lepidochelys kempii*) was once widely distributed throughout the Caribbean region. By the 1940s, it had become restricted to one nesting beach in northeastern Mexico on the Gulf of Mexico. In the 1960s, a mass nesting aggregation, or "arribada," of Kemp's Ridleys, totaling an estimated 40,000 animals, was filmed. A few days of slaughter over several consecutive years reduced the enormous arribadas to only 500 nesting female turtles by 1978. This species was listed on the U.S. Endangered Species Act in 1969 as Endangered, but this did not stop the slaughter. In 1995, nests totaled 1,430, showing a gradual recovery of the species as a result of intensive protection of nesting females and their eggs by the combined work of Mexican and U.S. patrols (Hastings 1996).

Between 1978 and 1988, more than 22,000 eggs were taken from the Mexican nesting beach to Padre Island off the south Texas coast, where they were allowed to hatch and were then kept in captivity for one year prior to releasing them into the wild. For many years, this project was thought a failure, but to the surprise of all, two female Kemp's Ridley Sea Turtles that had been released from Padre Island, one in 1983 and the other in 1986, returned to nest in 1996 (Hastings 1996). The only effective way of tagging young sea turtles is a skin graft of a special light-colored spot placed on the shell, and these turtles' grafts indicated the year each was released (Hastings 1996). One female was 11 years old, and the other 14. This highly unusual project is the first known success story for sea turtle egg transplants. These turtles are also dying in large numbers in the nets of shrimp fishermen, and hundreds more die when they become disoriented while migrating in the fall, ending up in cold New England waters. The *2000 IUCN Red List of Threatened Species* classifies the Kemp's Ridley as Critically Endangered.

Loggerhead Sea Turtles (*Caretta caretta*) also drown in shrimp nets and suffer from a loss of nesting habitat. The Loggerhead is a large turtle, up to 7 feet long (213 centimeters), second in size only to the massive Leatherbacks (*Dermochelys coriacea*). Museum specimens of Loggerheads taken in past centuries weighed an estimated 1,188 pounds; today, they average only about 330 pounds (Ernst and Barbour 1989). Loggerheads have been so persecuted on their nesting grounds around the world that the original nesting range is unknown. Development of their nesting beaches and losses from drowning in shrimp nets and will probably result in the extinction of North American Atlantic populations, which nest from Florida to the Carolinas (Ernst and Barbour 1989). Within the past five years, Loggerheads of the Florida region have been found suffering from a mysterious disease which causes tumors on the head and neck, and a lethargy. Most do not survive. A sea turtle hospital in the Florida Keys has treated some of these and, in March 2001, found themselves treating more than 35 Loggerheads, only one of which responded to treatment. It is assumed that for every sick turtle found, hundreds more die at sea. The malady may be a virus caused by pollution, a toxin affecting their food supply of crustaceans and other invertebrates, or another cause as yet unknown. Although the *2000 IUCN Red List of Threatened Species* lists this species as Endangered, the U.S. Endangered Species Act classifies it as Threatened.

The Flatback Turtles (*Natator depressus*) of the Australian region may be more secure than other species but still face losses from accidental drowning and some illegal hunting. This small sea turtle, only about 39 inches in length, is found mainly in shallow, coastal waters (Ernst and Barbour 1989). They are not hunted for their meat, which is considered unpalatable, but their eggs are exploited, which could eliminate the species from many nesting beaches (Ernst and Barbour 1989). The species is listed as Vulnerable by the *2000 IUCN Red List of Threatened Species*, indicating a decline that might place it in Endangered status.

Largest of all living turtles, Leatherbacks can reach 8 feet in length and weigh up to 1,900 pounds (Ernst and Barbour 1989). They are highly endangered, as a result of overharvesting of their eggs, illegal slaughter and drowning in fishing nets. Of all sea turtles, the Leatherback is the most likely to be seen in temperate areas, even cold waters off Iceland, Labrador and Norway in the north, and Chile and the Cape of Good Hope in the south (Ernst and Barbour 1989). It also ranges through tropical oceans, occasionally entering shallow bays and estuaries. It nests on tropical beaches (Ernst and Barbour 1989). The body temperature of these turtles has been measured at 18^{o} C. above the sea water temperature, an indication that their large body size retains heat from muscular activity, and their circulatory system in fore and hind limbs allows homeothermy (Ernst and Barbour 1989). Thus, these turtles can hardly be called "cold-blooded."

Until recently, western Mexico had enormous breeding colonies of Leatherbacks, but because of killing and egg-taking, nests at Mexiquillo, a major nesting beach, they declined from 6,500 in 1984 to fewer than 500 in 1995 to 1996, according to the *Turtle Newsletter*. So many of these huge turtles have drowned in driftnets that the IUCN reclassified the species from Endangered in the 1996 list to Critically Endangered in the *2000 Red List*. In spite of having an enormous range worldwide, this species also seems destined to become extinct in the near future.

All of these sea turtles continue to be exploited, either illegally, by local peoples, or by countries not Party to

CITES. In spite of CITES and U.S. Endangered Species Act listing, the high rate of mortality from many causes is proving disastrous for these ancient reptiles. An enormous market for meat, leather and shell exists, fueled by countries that provide markets for turtle products. Hawksbills and Leatherbacks, in search of jellyfish, consume balloons and plastic bags, which prove fatal, blocking the turtles' intestines or suffocating them. Globs of floating tar and oil slicks can kill them. Many of their nesting beaches have been developed for tourism or business, discouraging nesting females, and lights at night along nesting beaches cause newly hatched baby turtles to turn away from the sea and proceed inland, instinctively crawling toward the greatest source of light. In natural conditions, this light would come from the direction of the sea and the horizon, but the misdirected hatchlings end up crushed by cars and piled up against buildings. Some seaside towns in the United States and elsewhere are prohibiting any type of beach lighting during the months when sea turtles hatch. Thousands more young sea turtles die when they swim off course during the fall and winter, ending up in frigid waters. In the winter of 1995 to 1996, hundreds of Kemp's Ridley and other species of sea turtles washed ashore on the beaches of the northeastern United States, from Long Island, New York, to Cape Cod, Massachusetts. The majority were about a year old, but some adults also died. Rescue centers were set up and saved the lives of some of these turtles.

To kill these fascinating and ancient animals to supply the tables of thoughtless diners in gourmet restaurants, or for knickknacks and eyeglass frames, is unjustifiable. At present, there is no evidence that these turtles, who breed at glacial speed and are dying from many causes that probably already exceed their rate of increase, can ever be taken in a sustained manner. Total protection from killing is needed to prevent the extinction of these venerable reptiles.

Reptile Trade: Crocodiles and Alligators

All 23 species of large crocodiles and alligators have been overexploited by hide hunting; they are now in varying degrees of threat and listed on Appendix I or II of CITES. South American caimans were so abundant in the early 1950s that millions were killed for export to Europe and the United States. Their hides are fashioned into shoes, handbags and suitcases for the luxury trade. Elsewhere, crocodiles in Africa, Asia and Australia came under similar pressure, as did the American Alligator (*Alligator missippiensis*). In fact, the depletion of wild crocodiles which began in the 1950s caused reptile hide traders to turn to turtle skin, lizards and snakes, continuing their record of massive overexploitation.

One Colombian conservationist said that prior to this massive slaughter, it was easy to see 200 adult caimans on the banks of the River Ariari and elsewhere in Colombia, but within a few years, they had disappeared (Anon. 1981). In the 1950s and early 1960s, 6 to 8 million skins were traded per year, resulting in the near-extinction of the American Alligator and many other crocodilians (King 1994). One Brazilian state exported 5 million hides in 1950 (King 1994), and in that year 12 million Black Caiman (*Melanosuchus niger*) skins were taken from the Amazon basin (Fitzgerald 1989). By the late 1960s, Brazil and many South American countries had prohibited export of wildlife. The Black Caiman, a member of the Alligatoridae family, was listed on CITES Appendix I in 1975, along with most other large crocodiles, members of the family Crocodylidae. This designation officially bans international commercial trade among member countries.

Combined with CITES protection, these trade restrictions allowed some species to recover, but much of the trade went underground, involving the smuggling of hundreds of thousands of caimans poached in Colombia, Venezuela and Brazil. The skins were hidden in shipping crates, or transshipped from other countries. Paraguay, in spite of its export ban, was a major conduit for illegally taken wildlife, and remains so today. Another species that was highly sought after for its soft skin was the Broad-snouted Caiman (*Caiman latirostris*). This crocodile also became endangered from the trade and is on Appendix I, but during the 1980s, a black market for its skins was uncovered in West Germany, supplied by 20,000 skins poached annually in Brazil (Fitzgerald 1989). In 1980 alone, a Frankfurt, Germany, company imported--under false documentation--some 200,000 caiman skins of various species from

Paraguay (Fitzgerald 1989). Many caiman skins came from the Pantanal, a vast wetland in western Brazil that once teemed with these reptiles.

Approximately 85 percent of the world's crocodilians became endangered by the reptile product trade of the 1950s and 1960s. New World species were especially targeted. Besides the South American Black and Broad-nosed Caimans, two subspecies of the Spectacled Caiman (*Caiman crocodilus*)--the Yacare Caiman (*Caiman crocodilus yacare*) and the Apaporis River Caiman (*Caiman crocodilus apaporiensis*)--declined so precipitously that they were listed on both the U.S. Endangered Species Act and CITES Appendix I. Exploitation of the remaining subspecies of Spectacled Caiman continues, however. Identification of reptile products by subspecies is nearly impossible, thereby preventing proper protection of this species. In 1986 alone, the United States imported more than 65,000 Spectacled Caiman skins and more than 530,000 caiman handbags, shoes and other leather products (Fitzgerald 1989). A large portion of the trade in Spectacled Caiman is illegal, with violations including the poaching of endangered Yacare from Paraguay and caimans from national parks and other protected areas.

Other endangered New World species include the American Crocodile (*Crocodylus acutus*), whose range includes the Florida Keys; the Cuban Crocodile (*Crocodylus rhombifer*); Morelet's Crocodile (*Crocodylus moreletii*) of Mexico, Belize and Guatemala; and the Orinoco Crocodile (*Crocodylus intermedius*) of Colombia and Venezuela. All the latter species are listed as endangered on the U.S. Endangered Species Act. An additional 10 species and subspecies from Africa, Asia and the Philippines are also listed on the Act. Fifteen species of crocodilians are listed on Appendix I of CITES. All other alligators and crocodiles are listed on Appendix II.

Many of the CITES listings include exceptions that allow trade in some populations or subspecies. Also, some crocodile species are ranched, or raised in captivity expressly for commercial slaughter, in South America, Africa, Madagascar, Australia and Asia. Eggs laid by wild crocodiles are taken to supply these farms, and a percentage of the young crocodiles are released back to the wild. In Brazil, for example, the Yacare, an endangered subspecies of crocodile listed on the U.S. Endangered Species Act, is being exploited for the reptile products trade through ranching. Licenses are granted by the government to remove eggs based on the number of nests on each property. The eggs are hatched and raised in captivity, and 10 percent of the 1-year-old Yacares are returned to the wild (Bampi and Dal'Ava 1994). Through this ranching, 80,000 crocodile hides were produced between the 1992 and 1994 seasons (Bampi and Dal'Ava 1994). Brazilian Government officials maintain that in nature, fewer than 10 percent of the young would survive and, therefore, this is an environmentally benign activity (Bampi and Dal'Ava 1994). These animals, however, produce hides that are different from wild Yacare (Bampi and Dal'Ava 1994) and may differ in many other respects from their wild counterparts. They have been raised in unnatural conditions, and captive-raised crocodiles may not be able survive in the wild. The natural selection of crocodile egg and hatchling survival is also interfered with, negating the "survival of the fittest" principle with the possible effect of weakening the species. Another effect of ranching programs is the role that newly hatched crocodiles and alligators play in food chains; they provide a major food source for many waterbirds and are fed on by a variety of animals. By removing a large percentage of wild crocodilian eggs of a species, adverse ecological consequences may result.

A major trade in American Alligator hides began in the 1950s, and in the 1960s, state laws were passed banning killing and trade because of steep declines in its populations. In 1973, it was listed on Appendix I of CITES. In 1979, the species was removed from CITES Appendix I and placed on Appendix II, allowing trade. The federal U.S. Endangered Species Act originally listed it as Endangered, but reclassified it as Threatened throughout its range in the Southeastern United States under the Similarity of Appearance clause. Under this designation, some states may harvest Alligators. Louisiana supplies the largest number of skins, and also farms this species. The meat is also marketed in restaurants. Many Alligators that wander out of national parks and reserves are immediately killed as pests and threats to humans, and their skins are sold. In Florida, private companies respond to citizen calls about Alligators being present in waterways, and they send personnel in vans to capture and kill all Alligators over a minimum size limit, whether or not they present a threat. Although alligator hides entering trade must be marked by the U.S. Fish and Wildlife Service as legally taken according to management regulations, shipments are rarely inspected, and once out of the country and turned into handbags and shoes, their legality cannot be verified.

After 25 years of legal protection, about one-third of all alligators and crocodiles, or eight species, have increased their populations (King 1994). Many of the latter species are reentering trade, and advocates for the trade are stating that they are now "harvestable" (King 1994). This is being called a great conservation success, in spite of the fact that two-thirds of the species remain critically endangered, or "safe" but unharvestable (King 1994).

The incentive is high to poach crocodiles for this luxury trade. Crocodile handbags sell for as much as $3,000. Briefcases can cost $10,000 or more. Major markets for these products have been Tokyo, Singapore, New York, Los Angeles, Frankfurt, Berlin and Rome. By purchasing crocodilian products, one may be contributing to the overexploitation of a species, or unknowingly buying an endangered species product. Moreover, crocodilians have an important ecological role to play in nature. Adult crocodiles and alligators are at the top of their food chains. They weed out overpopulated fishes, including the voracious piranha, and dig water holes in times of drought that save the lives of numerous animals. In fact, when populations of South American caimans were decimated in the 1960s, piranhas increased to epidemic proportions. They also present a wildlife spectacle when large groups of caimans sun themselves on river banks, and are one of the prime attractions for ecotourists who travel to the tropics. If calculations were made of their value in ecotourism and in ecological systems, they would be considered worth more alive than dead.

Reptile Trade: Lizards and Snakes

The use of lizards in the reptile products trade began growing when crocodiles declined and became protected. Millions of Red Tegu (*Tupinambis rufescens*) lizard skins, exported from Argentina, have been used in the exotic leather trade. Heavy exploitation of this species and the Common or Banded Tegu (*Tupinambis teguixin*) of South America caused an overall decline in populations throughout their range (Fitzgerald 1989). All tegu lizards, *Tupinambis* spp., are listed on CITES Appendix II. Several Asian monitor lizards, extremely large reptiles including the world's largest lizard, the ten-foot-long Komodo Dragon (*Varanus komodoensis*), are listed on CITES Appendix I. The Bengal Monitor (*Varanus bengalensis*), Yellow Monitor (*Varanus flavescens*) and the Desert Monitor (*Varanus griseus*) are all endangered species. When they were added to Appendix I in 1975, Japan refused to abide by the listing and filed a reservation on these lizards, not lifted until 1994. All other monitor lizards (*Varanus*), which occur in Asia, Australia and Africa, are listed on Appendix II of CITES. In spite of the latter listing, African monitor lizards are killed in very large numbers for the reptile products trade.

The Caiman Lizard (*Dracaena guianensis*) is listed on Appendix II of CITES because it is threatened by exploitation, along with related lizards of its genus. In 1995, skins and boots of this species worth $1 million wholesale were confiscated from the Tony Lama Boot Company of El Paso, Texas, by the U.S. Fish and Wildlife Service. Among the seizures were 907 pairs of Caiman Lizard cowboy boots and 2,554 pairs of boot vamps. A 15-count felony indictment for smuggling and violations of the Lacey Act was issued by a Grand Jury against two people who sold the skins to Tony Lama, using fraudulent export permits obtained in Mexico. The Lacey Act prohibits importation-- without permits--of species protected in their country of origin. This lizard is native to the Amazon Basin, and its lustrous skins are highly prized for boots, which can retail from $700 to $1,000 per pair. Four lizards are used to make one pair of boots. More than 13,800 Caiman Lizards were killed and sold to the Tony Lama Boot Company for the manufacture of the boots and skins seized. The indictment was the result of an undercover investigation by the Fish and Wildlife Service, begun in 1993.

Millions of snakes are killed for the reptile product trade, mainly in Asia. Indian Whip Snakes (*Ptyas mucosus*) and Oriental Water Snakes of the family Acrochordidae are heavily exploited. In the late 1970s, India supplied more than 3 million snake skins. India listed the Indian Whip Snake on Appendix III of CITES in 1984, indicating that it was protected by national law. After this export ban, a single government company held 5.7 million snake skins

which it exported in what was supposed to be controlled trade; smugglers removed thousands of snakes from India illegally, however (Fitzgerald 1989). The Indian Government made a seizure of one such smuggling operation with 150,000 snake skins destined for West Germany (Fitzgerald 1989). This system of controlled trade did not succeed in ending India's exports, since the stockpile actually grew to 6 million skins by 1979, after exports of hundreds of thousands of skins from this supposed stockpile (Fitzgerald 1989). Wild Whip Snakes continued to be killed and added to this stockpile, causing population declines and increases in grain-eating rodents.

Pythons are among the most popular snakes for shoes and handbags, and one subspecies of Indian Python (*Python molurus molurus*) is listed on CITES Appendix I, while other subspecies enter trade. This listing is totally ineffectual because of confusion with other subspecies of this snake. All pythons (*Python* spp.) are listed on Appendix II, but this has done little to slow the trade in their skins. The massive take of wild pythons in Asia for shoes, handbags, and even clothing has resulted in infestations of rats, which spread disease to humans and damage crops. Peter Brazaitis, a herpetologist and former curator of animals at the Central Park Wildlife Center in New York City, commented: fiI think we have to ask ourselves, what is the value of a python? Is it as a pair of expensive pants? Or is it as a means to check exploding rat populations in nations where communicable diseases are rampant? (Chivera 2000).

Likewise, Argentine Boa Constrictors (*Boa constrictor occidentalis*) are listed on CITES Appendix I, and other subspecies on Appendix II. Once made into reptile products, races of Boa Constrictor resemble one another, making the CITES listing meaningless. The largest Boa Constrictors, which are the oldest, have been a prime target for skin hunters in South America, and the enormous snakes of this species, once commonly seen in tropical forests, have disappeared as a result of this trade. Many are also taken for the pet trade. Retail prices indicate the popularity of snakeskin for luxury leather goods. A python handbags sell for $300 or more, and a python belt costs $120.

Lizards consume large quantities of insects and are extremely vital to ecosystems. Reptiles play an important role in nature, and the killing of millions of these useful animals is disrupting the balance of nature in many parts of the world.

The luxury reptile leather trade has pushed many species toward extinction, and it shows no signs of declining. Lizard and snakeskin products are now being sold in the volume that turtle and crocodilian leather once were. Handbags, wallets and shoes from these reptiles can be seen in department and shoe stores throughout the world. The endangered reptile species of tomorrow can be seen in the advertisements and luxury shops of today.

Traditional Medicine Trade

The Traditional Medicine (TM) trade has been disastrous to many species of wildlife. Even highly endangered species listed on CITES Appendix I continue to be killed to supply this huge market in southeast Asia and in Chinese communities around the world. In many cases, enforcement is impossible because endangered animals are sold in forms difficult to detect by Customs officials, such as powder made from ground bones. The majority of potions sold in this trade have substitutes from non-animal sources, and many do not cure the diseases they claim to, nor do they restore male potency. Yet the return to a capitalist economy in China and the relative wealth of many Asians has placed such high prices on the heads of rare animals that many species may not survive. This would mean the end of some of Earth's most magnificent animals. Among these is the Tiger, whose bones and body parts are highly prized and extremely valuable in the TM trade. All five species of rhinoceros are teetering on the edge of extinction, with this trade a major cause. While hundreds of rangers in Asia and Africa have lost their lives protecting Tigers and rhinos, and many government officials and conservationists have struggled fervently to stop the slaughter, bureaucratic indifference and weak enforcement have combined to negate conservation work in many markets. Internal trade bans on these animals have recently been enacted by China and Taiwan, but enforcement is not strong. Many of the animal products are intended to increase male potency, and a recent drug marketed in the West, Viagra,

may reduce demand for wildlife products such as Tiger and seal penises that have been sold at high prices for this purpose in the past. In fact, the market for seal sexual organs has already collapsed, resulting in a huge decline in the number of Harp and Hooded Seals killed in Canada, from 280,000 in the late 1990s, primarily for this market, to 91,000 in 2000 (Nickerson 2001). The price paid for seal has dropped from $25 per animal to a few dollars, if a buyer can be found (Nickerson 2001). This is good news for some animals, but many others are killed to make products for other purposes, such as to lower fevers, treat rheumatism and heart disease and promote general vigor. Several organizations and national governments are combating the killing of rare animals for this trade through education programs which provide information on effective alternative medicines.

A 19th century victim of the Traditional Medicine trade was Schomburgk's Deer (*Cervus schomburgki*). Discovered in eastern Thailand in 1862, no European ever saw the species in the wild (Day 1981). They were heavily hunted for their large and many-tined antlers that supposedly possessed medicinal and magical properties (Day 1981). In the mid-19th century, herds of Schomburgk's Deer were seen in swamps, and during floods, they were pursued by boat, marooned on small islands, and speared (Day 1981). When swamp drainage and irrigation added to their threats, they retreated to bamboo jungles, to which they were not well adapted, until these, too, were cleared for rice fields (Day 1981). The last known Schomburgk's Deer was shot by a policeman in September 1932 (Day 1981). The species was considered extinct and officially listed as such by the IUCN (WCMC 1993). In 1991, a pair of antlers from an unknown type of deer was seen by Laurent Chazee, an agronomist with the United Nations, in a Traditional Medicine shop in a remote part of Laos (Schroering 1995). Chazee photographed the antlers, which were later identified as coming from a Schomburgk's Deer; the shop owner told him that the animal had been killed the previous year (Schroering 1995). Forests nearby may shelter more of these deer, and the site is considered by local people to have sacred animal spirits; hunting is prohibited there (Schroering 1995). A shop in Phnom Penh, Cambodia, in February 1994 offered antlers of what were represented as Schomburgk's Deer for $10 a pair (Martin and Phipps 1996). The seller was obviously unaware of the extraordinary rarity of this deer. There is still no proof that the species survives, and it has been listed as extinct in *2000 IUCN Red List of Threatened Species*.

Rhinoceros horn, Tiger bone, ground deer antlers, gallbladders from many species of bears, musk glands from deer, and softshell river turtles are among the thousands of raw materials for Traditional Medicine. This trade has pushed a host of magnificent species precipitously toward extinction within the past few decades. Many were already rare from persecution, hunting and habitat loss. While these products have played an important role in Traditional Medicine for centuries, only within the past decade has the trade spiraled out of control, with a potential market of more than 1 billion people. A recent survey of Cambodia's markets found the products and body parts of numerous endangered species, including Asiatic Black Bear, Sun Bear, Tiger, Leopard and many rare and endangered deer and wild cattle, being openly sold (Martin and Phipps 1996). Civets, cat-like mammals, are roasted and their meat sold in the winter to warm blood (Schaller 1993).

Obviously, all the remaining wild rhinos, Tigers, Musk Deer, bears and other animals used by this trade cannot fill the demands of this enormous market. This trade has proven the most difficult in the world to control. Even the threats of international sanctions, strict national laws and CITES Appendix I listing of most of the species involved have not stopped it.

Snakes by the thousands are kept alive in Asian markets, offered as fever cures and tonics. When a customer selects one, it is hung up still squirming, and the gallbladder is cut out. Some are skinned alive, and customers drink the blood. In Cambodia, great numbers of snakes are sold, and at one market alone 4.4 tons of pythons were sold in 1993; cobras are shipped live by the thousands to Vietnam (Martin and Phipps 1996). A mongoose is often kept next to the snake cages to keep them angry and lively. In Taiwan's capital city, Taipei, a vast marketplace called "Snake Alley" sells thousands of live snakes in this fashion.

Traditional Medicine Trade: Primates, Pangolins and Fruit Bats

Slow Lorises (*Nycticebus coucang*), nocturnal primates with huge eyes and thick fur, are gentle and shy tropical forest dwellers. Thousands are captured in Southeast Asia for Traditional Medicine. They are killed and cooked in lemon leaves in China to provide tonics. In Cambodia, hunted with crossbows, they are among the commonest wild animals sold in markets, with racks of hundreds of dried lorises exhibited for the buyer (Martin and Phipps 1996). Live lorises are often sold in Chinese markets to be killed later, or kept as pets. These nocturnal animals suffer in the bright daylight, blinking and cowering in their tiny cages. Educators from the Wildlife Conservation Society (WCS), headquartered in New York City, visited a Chinese market in Yunnan province with local schoolteachers to show them the many endangered species being offered for sale, and saw two threatened Pygmy Lorises (*Nycticebus pygmaeus*). A mother and her young cringed in a tiny wire cage with barely enough room to turn around; the mother loris wrapped her body around her tiny infant, shielding it from the noise and dazzling sunlight (Naiman 1997). In all likelihood, they would die from malnourishment, disease or dehydration, and one teacher suggested that the educator buy them to save their lives, but the WCS representative believed that this would only have resulted in more lorises being captured. This species is considered Vulnerable, a category for species only slightly less threatened with extinction than endangered species, by the *2000 IUCN Red List of Threatened Species*.

The very rare and beautiful Golden Monkey (*Rhinopithecus roxellana*) is killed so that its brain may be used for Traditional Medicine. Macaques from Southeast Asia are being captured in Vietnam and shipped across the border to China, where they are kept alive in tiny wire cages and killed on order for the Traditional Medicine trade.

Pangolins, scaly armored mammals of Africa and Southeast Asia are so heavily hunted for their scales, which are used in various remedies, that all three species (*Manis* genus) are now listed on Appendix II of CITES.

Fruit bats are collected in Southeast Asia for sale in Traditional Medicine markets. The BBC filmed their capture for a PBS Nature special, fiCastaways of Sulawesifl (1995). In Sulawesi, Indonesia, the island formerly known as Celebes, young boys fly kites with hooks that entangle the fruit bats as they fly off to feed in the evening. The fruit bats scream and squeal as they are hauled in and placed in boxes with rods for perches. Trappers ship them for four days, often without food or water in extreme heat, to tradesmen who kill them for use in Traditional Medicine. This trade is having a disastrous effect on the island's fruit bats. The loss will be significant if these bats are eliminated, because of their enormous value as pollinators of numerous species of trees, many of which provide economically important fruit. Fruit bats and flying foxes throughout Asia and the Pacific are killed for food and TM. Nine species of fruit bats have been placed on Appendix I, and the entire genus *Pteropus* of flying foxes on Appendix II of CITES, but this has had little effect on the trade.

Traditional Medicine Trade: Dolphins and Seals

Ganges River Dolphins (*Platanista gangetica*) of the Ganges and Brahmaputra River systems in India, Bangladesh, Bhutan and Nepal, are extremely rare throughout their range, with a total population that may number only about

2,000. In Nepal, where there are fewer than 100 animals, fishermen net them to sell their flippers for the TM trade which uses the bone for gastric problems. Appendix I listing has not stopped trade because Chinese authorities have failed to enforce it strictly. It is listed as Endangered on the *2000 IUCN Red List of Threatened Species*.

Once common in the Amazon and Orinoco River systems from eastern Brazil to the Andes of Peru and Bolivia, Pink or Amazon River Dolphins (*Inia geoffrensis*) have disappeared from most of this region. A 1995 film, fiLegend of the Pink Dolphin,fl on National Geographic Explorer, depicted the species as threatened or endangered in all but the most inaccessible areas and described the bizarre trade in its body parts. A book on the subject, *Journey of the Pink Dolphins. An Amazon Quest* (Montgomery 2000), is an in-depth study of the people and their relationship with these dolphins. Shantytowns established on riverbanks built when forest clearance forced many people out of their traditional regions, have been the center of the illegal hunting of these dolphins. Many of the residents of these towns kill the gentle Pink Dolphins for their body parts, which are considered magical. Some fishermen drown them on purpose, and others accidentally. Many people in the Amazon believe that these dolphins can impregnate women, and others buy body parts, such as the left eye, penis, teeth and head, as good luck charms. Entire baby dolphins are sold in these towns as charms. Roxanne Kramer, an American biologist who has studied these animals since 1984, has become an active conservationist on their behalf. She found jars of Pink Dolphin eyes being sold in local villages for $1.50 per eye in 1995, and estimates that in Brazil alone, more than 100 Pink Dolphins are killed a month just for their left eyes, considered to have magical properties. Dolphin corpses that have been mutilated now wash up on riverbanks their heads removed. Roxanne and another biologist, Fernando Trujillo, have conducted separate campaigns to persuade local people not to kill these dolphins, but at the present rate of loss, they may soon disappear altogether.

The decline in the seal hunt in Canada will mean a decrease in extreme cruelty that has been documented by various witnesses. The Earth Island Institute's *Journal* reports that in a 1994 hunt, seal pups' skulls were crushed, they were strangled with nooses, and in one case, a mother Harp Seal was beaten with the body of her screaming pup. When Paul Watson of the Sea Shepherd Conservation Society protested the hunt in early 1995 in the Gulf of St. Lawrence's Magdalen Islands, 150 angry sealers broke down the door to his hotel room. He was saved by police, who rushed him into a police cruiser, according to wire service accounts. Other seals, such as South African Fur Seals (*Arctocephalus pusillus*), are killed both for their pelts, which are sold to European furriers, and their penises for the TM trade. As described above, many thousands of young male seals are killed each year. Hopefully, this hunt will decline as well.

Traditional Medicine Trade: Saiga and Deer

The horns of Saiga antelope (*Saiga tatarica*), a species being slaughtered by the hundreds of thousands in Russia and Central Asia, are thought to cure many illnesses; in 1990, China imported 80 tons (Schaller 1993). This curious species has become so threatened by this trade that it was listed on CITES Appendix II at the 1994 Conference. The Saiga once numbered in the millions in the Central Asian steppes, an ecological equivalent of the American Bison or African Wildebeest, but were slaughtered to near extinction during the 19th century.

A trade study found that in 1994, 44 metric tons of Saiga Horn were exported illegally to China, South Korea, Japan and some European nations. One metric ton is equivalent to 5,000 horns; horn sold for as much as $30 per kilogram in East Asia (Chan *et al*. 1995b). In a random survey in August and September 1994, TRAFFIC International investigators found Saiga horn in 131 shops in Hong Kong, from an estimated 15,000 animals. Taiwan banned the sale of Saiga horn in 1994 (Chan *et al*. 1995b). Populations of this species have declined in Kazakhstan and Kalmykia and have become endangered in Mongolia. Today, the trade in Saiga horn is so uncontrolled and massive that it threatens the species' future survival (Chan *et al*. 1995b). The status of the Saiga declined rapidly between 1994 and 1996. The 1994 edition of the *IUCN Red List* included only the Mongolian subspecies (*Saiga*

tatarica mongolica), but in the 1996 list, the entire species was listed as Vulnerable; two subspecies, the Mongolian was listed as Endangered, and the Russian (*Saiga tatarica tatarica*) was listed as Vulnerable. The *2000 IUCN Red List of Threatened Species* classified the Saiga as Conservation Dependent, with the Mongolian race Endangered, and the Russian also Conservation Dependent. (For more on the Saiga, see Grasslands, Shrublands and Deserts chapter; and in the Video section, Mammals, fiThe Saiga of Kazakhstan.fl)

Asian Red Deer (*Cervus elaphus*), known in North America as Elk, have been heavily exploited for their antlers to use in the TM trade, and many races are endangered. The *2000 IUCN Red List of Threatened Species* lists five subspecies or races of the Red Deer native to China. The Yarkand Deer (*Cervus elaphus yarkandensis*) is listed as Endangered, and the other races are in lesser categories. The U.S. Endangered Species Act lists McNeill's Deer (*Cervus elaphus macneillii*) of Sinkiang and Tibet, and the Shou (*Cervus elaphus affinis*) of Tibet and Bhutan as Endangered. The Chinese Shou is on the brink of extinction, a tiny population having been rediscovered in a park in Lhasa, Tibet in 1988. The Yarkand Deer is considered probably extinct by *Mammals of the World* (Nowak 1999). Another Chinese race, the Kansu (*Cervus elaphus kansuensis*), is endangered by hunting. The Tibetan Red Deer (*Cervus elaphus wallichi*), which possibly exists in Bhutan and Tibet, and the Alashan Wapiti (*Cervus elaphus alashanicus*), endemic to China, are both possibly threatened. Shops in cities in Yunnan Province, China, visited in 1997, were selling numerous body parts from Red Deer including the velvet from antlers, a fetus, blood, tails, ligaments, genitalia, hooves and antlers (Li and Wang 1999). They also found similar items from other Asian deer.

A threatened species of deer, Eld's Deer or Thiamin (*Cervus eldii*), which ranges from India to Southeast Asia, is a CITES Appendix I species. A survey in Cambodia found 14 sets of Eld's antlers being offered for sale in 1994 at $150 to $200 a pair (Martin and Phipps 1996). The survey in Yunnan Province in 1997 also uncovered body parts from these threatened deer (Li and Wang 1999). Wild Asian deer are being slaughtered without restriction for commercial sale. One shop in Lomphat, Cambodia, reported receiving 100 to 300 whole Sambar deer (*Cervus unicolor*) and other deer per month, their antlers selling for $200 to $300 per set (Martin and Phipps 1996). Cambodian officials reported that Eld's Deer and Sambar are usually hunted with dogs in the wake of forest fires, which are sometimes started deliberately, or with torches at night (Martin and Phipps 1996).

Endangered wild cattle horns were also seen in Cambodian shops. Banteng (*Bos javanicus*), a statuesque species of wild cow verging on extinction throughout its Southeast Asian range, is still being killed for its horns and meat. A pair of horns on the skull were offered in Poipet market, Cambodia, in February 1994 (Martin and Phipps 1996). A skull with horns of Gaur (*Bos gaurus*), largest of the wild cattle and nearly as endangered, was seen for sale in the same market for $40. Rarest of all wild cattle, the Kouprey (*Bos sauveli*), has been considered nearly extinct in the forests of Cambodia and possibly Laos and Vietnam (Baillie and Groombridge 1996). Yet a shop in the Poipet market, Cambodia, offered a Kouprey skull, a female with horns, for $400 in February 1994 (Martin and Phipps 1996).

Five species of Musk Deer inhabit high-altitude forests from 2,600 to 3,600 meters. Ranging from Afghanistan to Siberia, and south to Vietnam and Myanmar, all species have declined as a result of hunting for their musk glands. The musk is used in Traditional Medicine, and buyers for Asian markets offer huge sums of money for the glands and for the pouch containing this valuable liquid. Their musk is also valuable in the perfume trade, worth $65,000 per kilo (Fitzgerald 1989). Male Musk Deer mark their territories with the musk. Females do not have this gland, but snares set for these deer kill females and fawns along with the males. These once common and widespread deer have became rare or endangered throughout their ranges, especially in China, the Himalayas and Siberia (Nowak 1999); they suffer the additional pressure of habitat loss as their forests are stripped for firewood. Although there are musk deer farms in China, very little musk is produced, encouraging the wholesale slaughter of wild deer (Schaller 1993). They are known to be difficult to breed in captivity (Fitzgerald 1989). One species, the Siberian Musk Deer (*Moschus moschiferus*), native to mountains of China, Korea, Mongolia and Far Eastern Russia, has declined to endangered status as a result of this trade and is listed on Appendix I of CITES.

In 1987, 800 pounds of musk worth $14 million were smuggled out of China, the product of 53,000 male deer.

More than 100,000 deer had been killed in the quest for these glands, since many of the dead deer were females and young which were discarded. The glands were exported to Japan (Schaller 1993). An average of 700 pounds of musk are sold in world markets each year, much of it going to Hong Kong, the international center for musk; Japan is a major consumer, using musk to treat a variety of illnesses (Fitzgerald 1989). Between 1974 and 1983, Japan imported between 250 and 700 pounds of musk per year, worth an average of $4.2 million; imports increased in 1987 to 1,800 pounds, an all time high, and sold for $32,468 a pound! (Fitzgerald 1989). French perfumes known to use musk include Chanel No. 5 and Madame Rochas (Fitzgerald 1989). From 1990 to 1994, half of Russia's musk deer were killed by poachers, and their glands were smuggled into northeastern China and South Korea (Galster 1996). A 1997 survey found that stores in southern Yunnan sold musk and medicine from these deer (Li and Wang 1999). Musk and medicine from it from three other species of musk deer were also seen in this survey. Musk deer native to Afghanistan, Bhutan, India, Myanmar, Nepal and Pakistan are listed on CITES Appendix I, while other species and populations are on Appendix II. Such listing is completely illogical in terms of enforcement, since only the glands are traded and cannot be identified as to species or population.

Musk deer (genus *Moschus*) are so different from other deer that some scientists place them in a separate family, the Moschidae (Nowak 1999). These small deer resemble hares because of their large hindquarters, the shape of their heads, and their long, thin legs. These are the only deer that climb low trees to feed on leaves, mosses and nuts (Grzimek 1968).

Traditional Medicine Trade: Tigers

The magnificent Tiger, largest of all cat species, may be driven to extinction because its body parts are in such demand in the Traditional Medicine trade that it is pursued and killed even in sanctuaries and national parks. The illegal trade in Tigers grew astronomically in the 1980s concurrent with the burgeoning of economies in many countries in Southeast Asia, and it continues at uncontrolled levels. These endangered animals are no longer safe, even in the remotest parts of their range. Fewer than 5,000-- and many believe that as few as 3,000--remain (Matthiessen 1997). Most experts say they will not survive in the wild more than a few decades at the present rate of killing, which is calculated at one Tiger a day for this market (Jackson *et al*. 1996).

This species has lived on Earth for at least a million years, and until the 20th century, its range covered most of Asia. During the Pleistocene Age, when sea levels were low, Tigers colonized Indonesian islands and Japan, spreading into almost every habitat except deserts (Matthiessen 1997). Thousands of years ago, warriors in Central Asia and China killed Tigers in shows of manhood, which are depicted in works of art. Even in 1900, an estimated 100,000 Tigers roamed from eastern Turkey to Russia's Far East, and south to Bali in Indonesia. Since the turn of the century, an estimated 95,000 Tigers have been killed. These great cats have played an important role in the mythology, art, culture and even religion of cultures throughout Asia. Their courage, even when cornered and trapped, has contributed to the almost mythic role in which Tigers have been cast. This is a major reason many practitioners of TM believe that Tiger body parts will impart virility and restore health to those consuming them.

Traditional Medicine practitioners use nearly every part of Tigers, from their whiskers to their eyes, claws, pelts, flesh and bones. Their bones are ground into a powder that is used to manufacture "Tiger Bone Wine," of supposed medicinal value, and elixirs from ground Tiger bones are used to treat rheumatism, convulsions, scabies, boils, dysentery, ulcers, typhoid and malaria (Ward and Ward 1993). There are medicinal substitutes to treat all these maladies. The male's penis is made into soup, said to give potency, for rich Asian businessmen who pay as much as $18,000 for a dinner featuring it (Highley and Highley 1994). The trade continues because of the ingrained and widespread beliefs by the Chinese and many other Asians in traditional potions. The Chinese government encouraged the trade by sponsoring Tiger-bone medicine production until mid-1993 (Schaller 1993), and evidence indicates that the trade continues today without interference from Chinese authorities.

Tiger medicine products are marketed in China, Southeast Asia, and in Chinese pharmacies throughout the world. All of this trade is illegal under most national laws and CITES, but enforcement in Southeast Asia is weak. Because the Tiger bone is sold in powder form, it can be traded surreptitiously, even in countries with strict wildlife laws.

Not only are Tigers being killed in great numbers, but they are dying cruelly. Poisoned meat is spread in national parks in India that kills slowly and painfully. Pesticides, such as the toxic Aldrin, are placed in buffalo or cow carcasses already killed by a Tiger, to poison the Tiger when it returns to feed; sometimes water pools are laced with poison (Currey 1996). Steel jaw leghold traps and wire snares, which maim and slice through the flesh, are set in forests throughout its range. In Russia, they are trapped or pursued by howling packs of dogs. Tigers have been filmed as they were being killed by a knife inserted into the throat while strung up spread-eagled, all four legs stretched apart by tight ropes. Females have been shot and their cubs left to starve to death. Dealers in poached Tigers now employ villagers to kill Tigers for a fee, supplying the villagers with poison and traps. In the 1970s, bold Tigers lolled in national parks for tourist cameras, but today they have either disappeared or become frightened, nocturnal hunters.

Should the Tiger disappear, a remarkable animal will have been lost. The male Siberian, largest subspecies of Tiger, can reach 6 feet in length, with a tail another 3 feet long, and weigh more than 670 pounds, while females weigh about 360 pounds and are smaller in stature (Nowak 1999). The Lion, second largest cat, weighs--at most--550 pounds, well under the weight of the Siberian male (Nowak 1991). Its immense strength enables it to carry large deer for long distances and up into high trees. Tigers are able to leap vertically 10 or more feet while carrying a deer. Tiger mothers are extremely devoted to their cubs, which number up to four per litter. Cubs remain with the mother for almost two years, requiring a long apprenticeship to learn to hunt and survive in the wild. In some cases, cubs do not become independent until they are 3 years old (Nowak 1999). About half the cubs die in their first two years, but adult Tigers have a low natural mortality, with a potential longevity of 26 years (Nowak 1999).

The 20th century was witness to a drastic reduction in the numbers and ranges of the Tiger. It was eliminated in vast areas with the growth of human populations and the spread of cities, and when guns came into common use, its long tenure as the supreme predator was over. Wilderness areas that provided refuge in Central Asia and Russia became the domain of livestock, and prey species were hunted out by local people. In the absence of natural prey, Tigers killed domestic livestock, becoming the object of unregulated slaughter. Added to this, they were a great prize for trophy hunters, and killing for Traditional Medicine in Southeast Asia caused them to disappear from vast areas. Gone from Java, Bali, East Asia and most of its remaining range in Asia, it is probably extinct in south China and close to extinction in Sumatra (Matthiessen 1997). The Indonesian government admitted at an October 1995 Asia Regional Meeting of CITES that poaching of the Sumatran Tiger was "uncontrolled" and "overwhelming" (Jackson *et al*. 1996).

Education programs have been launched to discourage the use of Tiger products within China, attempting to kindle conservation zeal among the Chinese people. Jackie Chan, the star of many action films, volunteered to do Public Service Announcements discouraging the use of Tiger products. But the resistance is strong. A Traditional Medicine practitioner commented angrily to CNN news in July 1996 that laws against the use of Tiger products were thwarting his practice. American conservationists in the southern province of Yunnan found Tiger bone pills being sold in markets in 1996, in spite of legal prohibitions (Naiman 1997), and they were still being sold when another survey was taken in 1997 (Li and Wang 1999). The Kumming Zoo in the province has a "Tiger Shoot," an arcade game in which a player aims a model rifle at a target bearing the image of a Tiger. Speakers attached to the rifle amplify the sound of its firing, and a counter keeps score (Naiman 1997). This describes, in a nutshell, the attitudes that have pushed the Tiger to near-extinction in China and are providing the market that is killing hundreds of Tigers.

An investigation of Cambodian markets in 1994 and 1995 found Tiger products being sold in many cities. In one market alone, the bones and other body parts of an estimated 33 to 43 Tigers were found (Martin and Phipps 1996). Very large Tigers have been reported from Cambodia, with bones weighing almost double those of the average Tiger

(Martin and Phipps 1996). Prices in Phnom Penh have risen in the 1990s from $80 per kilogram of bone to $250, and live Tigers are sold for $200 to $250 each; these Tigers are sent to Vietnam, where they can be sold for as much as $5,000 each prior to their slaughter (Martin and Phipps 1996). A 1995 workshop estimated populations in Vietnam at only 150 to 300, with another 300 in Cambodia (TRAFFIC 1995). The same year, Cambodia announced that two to three of its Tigers were being killed per month (Jackson *et al*. 1996). Tiger skins and body parts were offered for sale in November 1995 in Poi Pet, a town on the Cambodian-Thai border, with two large skins stretched out next to leopard pelts. This was only eight months after Cambodia had pledged at a World Wildlife Fund workshop to clamp down on the trade (Jackson *et al*. 1996). In January 1996, Tiger skins and products were still being openly sold in Phnom Penh, Cambodia, an indication that enforcement is not taken seriously in this country. The government of Cambodia granted logging concessions on 6.5 million hectares of forest land. This country still has sizeable forests, unlike Thailand, whose ancient teak forests were clearcut during the 1970s and 1980s. Burma is also opening its forests to logging, and once these forests are gone, the Tiger will have little habitat left in Indochina. In the process of constructing logging roads and opening the forests, hunters will enter and pursue the last Tigers in the region.

Throughout Indochina, wildlife is being decimated. According to biologists Alan Rabinowitz and George Schaller of the Wildlife Conservation Society, "People are literally wiping out everything--sambar, barking deer, even young elephants. The forests look good, but there are no Tigers because there is nothing for them to eat" (Matthiessen 1997). Alan Rabinowitz (1999) has spent years in the region and has documented the open sale of Tiger parts in towns and cities throughout the region. He found that Tigers remain mainly in isolated blocks of forest, and poaching is the most insidious threat to these populations; no effective Tiger management policies have yet been designed or implemented in Indochina (Rabinowitz 1999). Trade has increased since 1990 and occurs at local, regional and international levels, made more difficult to control by the political chaos in several countries and the fact that Laos is not yet a Party to CITES. Rabinowitz (1999) placed such importance on the effects of the trade that he concluded, "If the trade in tiger and other wildlife parts cannot be effectively controlled, the protection and management of tiger populations will become an almost insurmountable task in most range countries."

India's 23 Tiger Reserves lost 35 percent of their Tigers between 1989 and 1993, and at least 600 were killed between 1990 and 1994, according to the BBC film *Tiger Crisis* and *Time* reporter Eugene Linden (1994). Low fines and corruption among some wildlife enforcers and judges mean that such crimes, even when they result in arrests and indictments, are usually dismissed (Currey 1996). Despite the fact that hundreds of poachers and traders have been caught red-handed, they escaped conviction of Tiger-related offenses until very recently (Kumar and Wright 1999). Many cases of Tiger killing do not even result in arrests when corrupt park rangers accept bribes from poachers. Assam, a reserve with 90 Tigers lost almost half of them in just four months in 1994 (Linden 1994). The Indian government announced in October 1995 that it had seized 1,000 pounds of Tiger bone so far that year (Jackson *et al*. 1996). A scathing 1996 report by Dave Currey of the EIA, *The Political Wilderness. India's Tiger Crisis* (Currey 1996), revealed the depth of official indifference to the plight of the Tiger. It documented case after case of failures by the Indian government to preserve the Tiger and its habitat. The most notorious smuggler of Tiger skins and products, as well as other protected wildlife, Sansar Chand, has been arrested many times with smuggled animal skins that total almost 30,000, including Tiger skins, and 30 kilograms of Tiger bones. Each time he has avoided jail by various legal maneuverings and the refusal of the government of Uttar Pradesh in northern India to prosecute him (Currey 1996). The EIA undercover investigation in the State of Madhya Pradesh, where more than a quarter of India's Tigers are found, exposed the illegal offering for sale of the skins and bones of 39 freshly killed Tigers; they were informed that an additional 45 Tiger skins had been poached (Currey 1996). Leopard and Tiger skins were found in stores in all major towns and cities in Madhya Pradesh (Currey 1996).

India's 80 national parks and 441 sanctuaries have the highest designation of protection of all government lands, and they preserve 19 percent of the country's forests (Currey 1996). Yet EIA investigations have revealed an extraordinary deterioration in the quality of protection, with mining, tree-cutting, fishing and other illegal activities permitted in the parks, and underpaid and demoralized staffs. Kaziranga National Park, considered the jewel of the park system, has a highly dedicated staff, according to *The Political Wilderness* report by EIA (Currey 1996), but there are far too few rangers, and they receive very low pay ($68 per month), out of which they must pay for

waterproof clothing and shoes, as well as food for their families. Often they have to go barefoot, and suffer from malaria (Currey 1996). The equipment and facilities are so inferior that the rangers are unable to properly protect the park's 70 Tigers, 1,100 Asian Elephants (*Elephas maximus*), Indian Rhinoceros (*Rhinoceros unicornis*) and Swamp Deer.

To combat this situation, Valmik Thapar and Bittu Sahgal, editor of the wildlife magazine *Sanctuary ASIA*; Belinda Wright, a prominent conservationist; and Tiger biologist Ullas Karanth founded the Wildlife Protection Society of India (WPSI) in 1994. Its major purpose was to protect Tigers from poachers and bring smugglers to justice (Matthiessen 1997). Ashok Kumar of TRAFFIC India joined the group in 1996, and this small organization has brought 82 people to court for wildlife violations; unfortunately, all have been set free because of the total failure of the Indian government to enforce its own laws (Matthiessen 1997). The organization has not given up, however, and they have recently seen signs of progress. They and other Tiger defenders believe that "The Tiger is the very soul of India" (Matthiessen 1997).

In Nepal, a $650,000 U.S. government grant coordinated by U.S.-based conservation organizations will promote eco-development near Royal Chitwan National Park (Jackson *et al*. 1996). This park was once an important Tiger sanctuary, but it lost 25 Tigers to poachers between 1988 and 1990 alone (Ward and Ward 1993). In the 1990s, poaching has continued, and in spite of intensified anti-poaching patrols, nine seizures of Tiger parts--most of them complete skeletons--took place in 1995 alone in villages adjoining two protected areas, and 23 poachers were arrested (Jackson *et al*. 1996). Those Tigers that survive in Nepal remain in Royal Chitwan and Royal Bardia National Parks, and Royal Sukhla Phanta and Parsa Wildlife Reserves, which border on northern India. Tiger populations in 1993 were estimated at about 250, but no recent surveys have been carried out for the country. A program of paying rewards for information leading to Tiger smugglers has led to many arrests in the vicinity of Royal Chitwan National Park (Jackson *et al*. 1996).

Siberian Tigers have been pursued by hunters in snowmobiles, all-terrain vehicles, on horseback and with dogs, but most are caught in steel jaw leghold traps or wire snares. Some hunters are equipped with automatic weapons and night-vision devices (Specter 1995). U.S. researchers were offered Tiger body parts for sale at airports in 1995. Those who are caught poaching or selling illegally taken animals receive minimal penalties--119 people were arrested in the first nine months of 1995 in Primorsky, and none received jail sentences; fines were minimal (Specter 1995). Rangers in the reserves have few vehicles and are not permitted to carry weapons to protect themselves; in 1994, the leader of the Tiger task force was hospitalized when a poacher ran him down with a truck (Specter 1995). In one area near Lake Khanka near China, all 10 resident Tigers were killed between 1992 and 1995 (Specter 1995). Chinese poachers have entered Russia to kill Tigers, and the Russian Mafia is marketing Tiger skins and bones in China in an underground organized crime network (Specter 1995).

Linden participated in a 1995 undercover operation organized by Steve Galster. Posing as American businessmen, Linden, Galster, *Time* photographer Anthony Suau, and Russian environmentalist Sergei Shaitarov were approached by a poacher offering the bones and skin of a year-old Tiger for $11,000 (Linden and Yar 1995). They met the poacher in Krasny Yar, homeland of the Udege people who have fought lumbering and Tiger poaching, and were told by the poacher that killing the Tiger was a bad thing for the Udege, but that it was okay for him to sell the skin because he had not killed the animal. "They all say that," Galster said later (Linden and Yar 1995). After photographing the poacher posing proudly with the Tiger skin, they told him that his price was too high, and informed a local biologist of the poacher's activities. They learned that this was not the poacher's first crime (Linden and Yar 1995). The Bikin Valley, where the Udege live, is besieged for Tiger goods by foreign buyers from Korea and China and some fly helicopters or small aircraft across the border to shoot Tigers and Brown Bears (Galster 1996).

Between 1992 and 1993, more than 100 Siberian Tigers were slaughtered (Galster *et al.* 1994), and in 1994, 20 to 30 (Linden 1995). Some suggest that far more--as many as 65 Tigers--were killed in 1994 (Specter 1995). In view of the enormous land area to be patrolled and the relatively small force of rangers, the actual number of Tigers killed may never be known. Numerous poachers were arrested in 1995, but local authorities failed to prosecute, as a result

of government corruption.

To counter this devastating slaughter, anti-poaching brigades were organized by various conservation groups. The U.S.-based Global Survival Network has funded patrols that have been in the field since January 1994 (Galster and Eliot 1999). The Russian Ministry of Environment launched fiOperation Ambafl with the ceremonial burning of confiscated Tiger bones and skins in Turrisk. It is a specialized, well-equipped brigade that patrols rivers and reserves in Primorski Territory, where 85 percent of Tigers remain (Galster 1996). Some 25 to 30 employees, showing courage and competence, slowed the rate of poaching from 60 or more Tigers a year to 10 to 15 (Galster 1996). The Russian government issued a decree in August 1995 calling for a national strategy to protect Tigers and their habitat and to order all government agencies to cooperate on saving the Tiger. By 1997, $750,000 had been spent on anti-poaching patrols, and this special force has new uniforms, modern weapons and vehicles. Intensive work on the part of the joint U.S.-Russian team in early 1997 uncovered a major Tiger skin trading route and a sea route from Vladivostok to South Korea (Galster and Eliot 1999). Inspections of vehicles, hunters and potential poachers have turned the tide for the Siberian Tiger, aided by outside funding and public relations films, television shows and the help of non-governmental organizations (Galster and Eliot 1999).

In both China and Taiwan, facilities house captive Tigers for the express purpose of killing them for the Traditional Medicine trade. Caged Tigers on truck beds were paraded through the streets of Taipei, Taiwan, in 1986, with loud speakers blaring the date, time and location of the big cats' impending slaughter; their bodies were publicly auctioned (Highley and Highley 1994). Taiwan reportedly had more than 100 Tigers on farms in 1994, 60 more were kept in similar facilities in mainland China (Song and Lu 1994), and another 35 in Thailand. Humane organizations have inspected and filmed these facilities and found animals being kept in filthy conditions, and even starved to death.

China has attempted--unsuccessfully--to obtain permission from CITES members to sell body parts from these Tigers in international commerce.
Two representatives of the Chinese government, Wang Song and Houji Lu (1994), made such an appeal in an official magazine of the CITES Secretariat, *CITES/C&M*. They claimed that the Felids Breeding Centre in Heilongjiang Province had bred 73 Tigers, and now has financial difficulties which would be relieved if they could sell Tiger products from animals that "die from natural causes" (Song and Lu 1994). They both admit that the two subspecies kept there, the Siberian and South Chinese, have been interbred and suffer from various effects of inbreeding (Song and Lu 1994).

In Thailand, Tiger farms have received government approval but are provoking a bitter controversy. In late 1994 one Thai farm had 35 Tigers, and the owner bragged that a dead Tiger fetches up to $10,000 on the black market (AP 1994). He showed a display case with a male Tiger™s dried sex organs that sell for $4,500. Dr. Parntep Ratanakorn, an advisor to the Thai Royal Forestry Department which licenses Tiger farms, believes that Tigers could be farmed as easily as pigs. "The West is too sentimental about animals," he said. "Western people must open their minds and accept the ideas of Asian people because this is mainly an Asian issue" (AP 1994). Maitre Temsiripong, a former pig farmer, runs a farm with two pairs of Tigers that have produced 20 cubs in three years. The Royal Forestry Department's Khao Pardap Chang Captive Breeding Center has bred cubs from a female Tigress mated with her brother. The cubs show signs of inbreeding; they have skeletal abnormalities and cerebral defects, as documented by the U.K. Tiger Trust. A cub photographed by Tiger Trust at the Kaho Pardap Chang facility has a haunted and crazed expression known as "star-gazing," a classic symptom of inbreeding (Tiger Trust 1994).

Cubs in these farms are removed from the mother at birth so that she will immediately mate again, and cages have been constructed at the Thai government's Khao Pardap Chang facility to house many more of these pathetic animals (Tiger Trust 1994). In a change of position, the Thai government stopped granting permission to the farm to kill any of its Tigers beginning in January 1996. Valmik Thapar, at a 1996 Tiger conference, expressed vehement opposition to Tiger farms, urging that they be banned. He stated that such legitimization of the sale of Tiger parts, far from relieving pressure on wild Tigers as its proponents claim, will actually put a bounty onto the heads of the last remaining wild Tigers by legalizing trade. These farms present a major threat to remaining wild Tigers as well as

extreme cruelty to these magnificent animals. International sanctions should force their closure. In the words of Tiger Trust (1994), if present plans are carried out in Thailand, cages will "soon be full of the mournful cries of wailing Tiger cubs awaiting their final and undignified journey to the slaughterhouse."

Maimed Tigers are used as tourist attractions in Thailand. Samutprakan Crocodile Farm outside Bangkok, Thailand, was visited by John Nichol (1987), author of *The Animal Smugglers*. Nichol described a captive Tiger at the farm: "He looked magnificent, lying in a sort of summerhousefl; a chain led from his collar to the wall. Nichol expressed concern that this restraint was inadequate, but he was told, "Tiger very tame," and they encouraged him to take a photo of the animal as it lay on a bed of straw (Nichol 1987). When he approached the Tiger, he saw why they called him "tamefl; his feet were simply floppy stumps half hidden by the straw. He could not even stand. "I should have taken a photograph, but I felt too sick and felt I had to at least make a show of not encouraging the practice. Poor tiger . . ." (Nichol 1987). What had happened to this Tiger will never be known. Perhaps he was captured by both feet with wire snares or leghold traps, and wounds became septic, necessitating amputation. He may have had bones surgically removed for use in Traditional Medicine. Either way, his fate could not have been crueler.

China, a CITES member, legally banned exports of Tiger products in December 1992 (TRAFFIC 1995) but has turned a blind eye to this trade. South Korea obtained two-thirds of its imported Tiger bones from Indonesia (Jackson *et al*. 1996). The Republic of Korea finally prohibited the sale of Tiger products in 1994, and Singapore also banned sale. Japan has not prohibited internal trade in Tiger parts and derivatives (Jackson *et al*. 1996). Chinese Customs statistics show that more than 71,000 kilograms of Tiger bone medicines were exported between 1990 and 1992 to Japan, making it the largest importer in the world (TRAFFIC 1995). Investigators in 1994 and 1995 found wine and pills labeled as containing Tiger bone in Japanese stores (TRAFFIC 1995).

Chinatowns in North America and Europe have provided additional illegal markets for Tiger products. Some products labeled as Tiger bone in these stores were sent to the U.S. Fish and Wildlife Service Forensics Laboratory for analysis and found to be other material. Some real Tiger bone is being imported, however. A Chinese businessman was caught smuggling a Tiger skeleton worth up to $50,000 into the United States in the early 1990s. In the United Kingdom, 28 Oriental pharmacies were visited in August 1994 by TRAFFIC investigators and, in cooperation with police and the Department of the Environment, they confiscated quantities of Tiger bone, rhino horn and bear bile from 14 stores. An investigation in Antwerp, Belgium, uncovered even more such items (TRAFFIC 1995). In 1992, China exported 250,000 pills and five containers of Traditional Medicine containing Tiger to Belgium; its world exports totaled 27 million items in the form of pills and other products from 1990 to 1992 (TRAFFIC 1995).

An upwelling of public concern in the United States and other countries about the impending extinction of the Tiger has inspired many efforts to preserve remaining wild populations. In the U.S. Congress, legislation enacted in September 1994, the Rhinoceros and Tiger Conservation Act, created a fund of appropriations of up to $10 million per year until the year 2000 to be used for conservation programs and projects to enhance enforcement of existing legislation throughout the Tiger's range. The bill also required the Department of the Interior to identify which countries engage in activities that abuse international accords protecting Tigers and rhinoceros. In 1998, the Conservation Act was amended by adding a prohibition on fithe sale, importation, and exportation of products intended for human consumption or application containing, or labeled or advertised as containing, any substances derived from any species of rhinoceros or tiger.fl

In October 1995, a meeting between conservationists, Traditional Medicine practitioners, and traders in Tiger products was organized by TRAFFIC East Asia. The participants came from China, Hong Kong, Japan, Singapore and South Korea. Cooperation between these users and conservationists was the objective (Jackson *et al*. 1996). Its major goal was to convince practitioners to educate consumers to use substitutes for Tiger products.

There are about 1,000 Tigers in zoos, of which at least 360 are Siberian. Captive-bred animals have little chance of surviving if released to the wild, however, lacking survival knowledge which is passed on from generation to generation. Still, one day, they may be the only Tigers left in the world and will have to be used in reintroductions.

Peter Matthiessen, in his 1997 article in *Audubon* magazine entitled fiThe Last Wild Tigers,fl imagined a ". . . future in which the mysteries of wild tigers will be gone and the only tigers left on earth will be these listless specimens cooped up in zoos." The spine-tingling roars that once echoed for miles in tropical forests are fading, and epitaphs are already being written. A 1993 book by Geoffrey C. and Diane Raines Ward, *Tiger-Wallahs*, was subtitled, *Encounters with the Men who Tried to Save the Greatest of the Great Cats*.

The traditional lore upon which the trade in Tiger products is based can be traced to ancient veneration of this animal and the belief that it was capable of warding off evil; children in China wear caps with Tiger designs for luck and protection. Every 12 years, the Chinese celebrate the Year of Tiger, symbol of strength and good fortune, the source of which they are in the process of destroying.

The potential market of Asian consumers of Tiger products is approximately 2 billion people, and ancient traditions resist the reasonable approach of modern medicine and conservation concerns. In order to prevent the extinction of the last wild Tigers, much needs to be done in a very short time. Education must change traditional views to convince consumers to buy substitutes, anti-poaching patrols must be set up throughout their range, and enforcement of trade bans must be strong. Conservationists are working to achieve these goals with the hope that at least some wild Tigers will survive, but a lack of strong commitment on the part of the key governments involved, and the enormous market of uncaring or uneducated consumers, may doom their efforts.

Traditional Medicine Trade: Rhinoceros

All five species of rhinoceros are highly endangered, and within the past decade, illegal trade has pushed them to the brink of extinction. These ponderous, primitive mammals have survived on earth for millions of years. During the Pleistocene period, more than 10,000 years ago, species of rhinoceros now extinct lived in what is now Europe and North America. Today, three species occur in Asia, from India east to Sumatra, and two in Africa south of the Sahara. The White Rhinoceros (*Ceratotherium simum*) of Africa is the largest of the rhinos, with males weighing up to 8,000 pounds (Nowak 1999).

Within the past 25 years, at least 60,000 of the world's rhinoceros have been illegally slaughtered for the Asian trade (Ricciuti 1993). Their numbers have been reduced by more than 90 percent since 1970, and today the combined total of the five species does not exceed 12,000 animals (Kelso 1995). Their horns, which grow vertically atop their heads, have been their undoing. In great demand in the Traditional Medicine trade, and as carved ornaments on dagger handles in the Mideast, these animals have been pursued by poachers into national parks and even zoos. Some rhinos in Africa are guarded 24 hours a day against poachers. In Asia, they are disappearing even more quickly than in Africa because there are too few rangers to protect them, and the price of their horn is higher than for African rhino horn.

Rhinoceros horn is not actual bony tissue, but compressed, fibrous keratin, the material of hair and nails (Nowak 1999). It is ground into powder that has been a traditional medicine for hundreds of years in China and southeast Asia, used for various purposes, such as treating fevers. Asian rhinos vary in terms of horn size, two species having only one horn and the other two-horned species have horns that are often mere knobby bumps. African rhinos have two horns, in general longer than the Asian species, the front far longer than the rear horn, with a record length of 4.8 feet (Stuart and Stuart 1996).

With the invention of powerful guns in the 19th century that could penetrate rhinoceros™ thick hides, they began a long decline. At first, the hunting was primarily for trophies, but also for their horns. Heavy hunting in India by maharajahs and Europeans in the 19th century, and elsewhere in Asia for sport, devastated rhino populations. By the beginning of the 20th century, all three Asian rhinoceros species were near extinction (Nowak 1999). India, followed

by many Asian countries, extended protection to the remaining populations and established national parks and reserves in the first decades of the 20th century.

The Great Indian Rhinoceros (*Rhinoceros unicornis*) was once found throughout the Indian subcontinent, including Nepal and Pakistan east to Bangladesh and Assam (Nowak 1991). As early as 1600, hunting caused these rhinos to begin disappearing from northwestern India and Pakistan, and they continued to decline over the next three centuries (Nowak 1991). By the first decade of the 20th century, they were nearly extinct. In Kaziranga, only 12 Great Indian Rhinos remained; and in Nepal, perhaps another 50. The Indian government banned hunting and bounties and established reserves (Nowak 1999). Rhino numbers rose until the 1980s and 1990s when poaching decimated them again. Nepal now has an estimated 460 of these rhinos, protected by nearly 1,000 armed troops and rangers, while Kaziranga National Park in eastern India has about 1,200. With scattered numbers elsewhere, the species totals about 2,000, with 134 in captivity (Nowak 1999).

Even in parks, poaching occurred in the 1980s and 1990s. Gangs in Kaziranga National Park, the stronghold of this species, cut high tension lines, letting them drop to a height of 2 to 3 feet above rhino paths, electrocuting the hapless animals when they encountered the wires (Speart 1994). Between 1979 and 1989, 500 Indian Rhinos were poached, and this continued in the 1990s, with 48 killed in 1992, and 46 in 1993 (Speart 1994). Since 1992, 123 Indian Rhinos have been poached in Kaziranga, and the species has been completely exterminated in Laokhawa Wildlife Sanctuary where, 13 years ago, 5 percent of its population survived (Currey 1996). In 1993, a Bhutanese princess attempted to smuggle 22 Indian rhino horns into Taiwan to raise cash for a bottling company she owns. Her factory is located near Manas National Park, northern India, where it is thought the rhinos were poached (Speart 1994). The horn was intercepted and confiscated, and legal actions were taken against the princess. An investigation into the smuggling of rhino horn and other wildlife products in the Himalayas found that poachers are exploiting civil conflicts in nations in the region, and they trade rhino horn and other endangered species items in exchange for drugs or Chinese arms which are used to supply the Burmese military (Currey 1996).

The Sumatran Rhinoceros (*Dicerorhinus sumatrensis*) is the most primitive and smallest of all the rhinoceros. This rhino is only 4 feet tall at the shoulder and weighs 2,200 pounds, compared with the 6-foot-tall, 8,000-pound African White Rhino (Line 1997). Although they have two horns, the upper one is usually a mere bump, and the lower one closest to the muzzle is less than a foot long, far smaller than horns of other rhinos. Sumatran Rhino calves are born with a long, dense coat of hair that becomes sparse and bristly as the animals age. The hairs scrape off from abrasion as these bulky animals move through forest undergrowth; captive animals are often very hairy (Line 1997). Different genetically and physically from other Asian rhinos (Rabinowitz 1994), Sumatran Rhinos have three populations, one of which, the Bornean, has been isolated from the others for many thousands of years, and is considered a separate subspecies. Only about 70 Bornean rhinos survive in Sabah province at the northern tip of the island (Line 1997). The majority are in Peninsular Malaysia, where there are between 85 and 126, and on Sumatra, with an estimated 233 to 241. Thailand has only an estimated 10 rhinos (Nowak 1999). Thus, the total population is only about 400 to 541 animals. Some zoologists believe that a few may survive in Myanmar as well (Rabinowitz 1994). The habitat of the Sumatran Rhino is a prehistoric setting of swampy tropical forests with dense vegetation and hilly country near water.

Originally, Sumatran Rhinos ranged from eastern India's Assam province and southeastern Bangladesh to the Malay Peninsula, and possibly Vietnam, south to Sumatra and Borneo (Nowak 1999). Centuries of hunting for their horns for the Traditional Medicine trade eliminated these rhinos in one country and region after another. Surviving Sumatran Rhinos inhabit only remote forests, primarily in national parks, and their populations are scattered. Because of the difficulty of studying them in the wild, their behavior and ecology remain a mystery. A few are now being radio-tracked by biologists, and in the future, more will be uncovered about these unique animals. The International Rhino Foundation (IRF) and the Asian Rhino Specialist Group of the World Conservation Union have proposed projects to save the species from extinction. Poaching is a major threat throughout its range, with local peoples entering reserves and national parks because the horn is so valuable that it represents many years' income.

The Javan Rhinoceros (*Rhinoceros sondaicus*) is the most endangered of the rhinos, with a population which may

total only about 58 to 72 animals (Line 1997). The majority of their population, about 50 to 60 animals, live in Udjung Kulon National Park on the western tip of Java, and an additional eight to 12 live in Vietnam (Nowak 1999). Almost as tall as the Greater Indian Rhinoceros, but less massive at 3,300 to 4,400 pounds, the Javan Rhino has a single short horn, and females often lack a horn or have only a small bump (Nowak 1999). This animal once occurred from eastern India to Vietnam and south to the Malay Peninsula, Sumatra and western Java in three distinct subspecies (Nowak 1999). Habitat loss and persistent killing drove them out of almost all their original range, and one subspecies of eastern India, Bangladesh, Assam and Burma is extinct (Nowak 1999). Poaching continues, and in November 1988, a Javan Rhino was killed 130 kilometers northeast of Saigon, Vietnam (Nowak 1991). There are no Javan Rhinoceros in captivity, and this species has been called the most endangered mammal in the world (Nowak 1999).

Asian rhino horn sells for $27,000 per pound, and most pharmacies in Taiwan and other parts of Asia sell this horn (Rabinowitz 1994; Line 1997). So far, captive-breeding programs have failed, and 21 Sumatran Rhinos have died during capture or in captivity, leaving only 18 in zoos in the United States, United Kingdom, Peninsular Malaysia, Sabah and India (Line 1997). A major controversy has arisen about further captures. A Sumatran Rhino Trust was set up in 1985 to coordinate conservation of wild rhinos and those in zoos, but after eight years, during which time $3 million was spent, it was disbanded in 1993. The program had been undermined by politics, greed and corruption, according to the Wildlife Conservation Society (Rabinowitz 1994).

During the 19th century, African rhinos were heavily hunted for sport, as well as for their hides and horns, which were shipped to Asian markets. In recent times, the Black Rhonoceros (*Diceros bicornis*) ranged from Subsaharan Chad and Sudan south to the tip of the continent (Nowak 1999). By 1900, it had been eliminated from West Africa, but its populations below the Sahara may have totaled 100,000 (Cunningham and Berger 1997). Both the White and Black Rhinoceros occupy different habitats in Africa, based on their diet. The White Rhinoceros is a grazer, cropping grasses at ground level with its square lips, while the Black Rhinoceros is a browser, feeding on brush and low tree branches with its almost prehensile lips. Both are steel gray, despite their common names. During the first decades of the century, East African colonial governments persecuted rhinos on the grounds that their presence was incompatible with human settlement (Nowak 1999). When Asian rhinos became scarce, sport and market hunters turned to the African species and named them as one of the fibig fivefl game animals of Africa, attracting hunters from around the world. Market hunting for Traditional Medicine became an increasingly important factor in reducing African rhinos in the 1970s and 1980s. China and other countries in East Asia grew wealthy, and customers were able to pay high prices for rhino horn. Of all rhinoceros, the Black Rhinoceros declined the most dramatically in the 20th century. From 100,000 in 1900, its population fell to 15,000 in 1980, to only about 2,400 at present (Nowak 1999). Even in national parks where they were heavily protected, these rhinos were gunned down by gangs using machine guns, or strafed and allowed to die slowly of their wounds. Many orphan Black Rhinos were cared for by centers in Zimbabwe and Kenya, but most were killed by predators or died from other causes. At Daphne Sheldrick™s animal orphanage in Kenya, tiny rhinos are tended around the clock, and play chase games with one another or with baby elephants. Contrary to the image that big game hunters disseminated about rhinos being fierce, dangerous animals likely to charge people to gore them to death, they are gentle and near-sighted and lack binocular vision. They are often unable to make out animals or vehicles approaching them and will charge only when they feel threatened or, in the case of females, if their calf is being stalked by predators.

The White Rhinoceros is only somewhat more numerous than the Black, totaling 7,533 in 1996, with the majority in South Africa. It, too, has been eliminated in most of its original range, and killed on sight in and out of national parks.

While some species of rhinoceros have bred in captivity, others, like the Sumatran, have not, and many animals have died while being captured or after short periods in captivity. A few herds of Black Rhinos have been established in semi-wild conditions in Texas and Australia, although for several of these, the purpose may be less to preserve them than to raise animals for trophy hunters to pay high sums to kill. Several captive herds of Black Rhinoceros in Zimbabwe are at extreme risk of being slaughtered as a result of political chaos in which government land seizures for

distribution to black farmers and uncontrolled snaring and hunting of wildlife has already killed many rhinos (Roberts 2001).

In Asia, rhino horn sells for an average of $15,000 per kilogram, with higher prices paid for horn of Asian species. By 1996, black market values ranged from $46,000 to $150,000 per horn. The penis sells for $600 or more and is used as an aphrodisiac. The skin is also valuable, worth at least $7,000 per animal, for use in Traditional Medicine (IUCN 1994). Another threat that has caused the deaths of thousands of rhinos is their use in dagger handles in North Yemen. The rhino horn is carved into intricate designs for these daggers, which sell for $300 to $13,000 each (Fitzgerald 1989). From 1982 to 1984, about 3,700 pounds of horn entered North Yemen every year (Fitzgerald 1989). Taiwan's 22 million people use about 700 pounds of horn a year, or 80 rhinos.

Prior to the major killing spree that began in the early 1980s, CITES members voted to list one rhino species after another on Appendix I, banning commercial trade in their horns and bodies, whether for Traditional Medicine or trophies. By February 1977, the entire family Rhinocerotidae had been listed. Conservationists believed that this would stop the slaughter. Thousands of rhinos remained in national parks in Asia and Africa, and national legislation in many countries of origin banned hunting. Tragically, illegal trade nullified all legal prohibitions except in South Africa, where White Rhinos were effectively protected, and increased during the 1980s. For the rest of the world's rhinos, an all-out slaughter occurred. Organized gangs of poachers, some armed with machine guns, eluded the less well-armed rangers. They entered African national parks and strafed the helpless rhinos, cutting off their horns and leaving their maimed bodies to rot in the sun. In Asia, these enormous animals made easy targets for poachers, and many were poisoned, snared or fell into spiked pit traps.

One smuggling ring was broken up in 1993 by undercover work by Steve Galster, Executive Director of the Global Survival Network, and Rebecca Chen, a Taiwanese colleague. The two tracked shipments of rhino horn from Mozambique to Taiwan to Hong Kong, and finally to China, where they found a warehouse in Wuchuan housing the horns of more than 500 dead rhinos, a supply worth $13 million (Linden and Yar 1995). They fabricated a reason to see the horn and produced a videotape that jailed guilty parties and called international attention to the smuggling (Linden and Yar 1995).

The United States banned all wildlife products from Taiwan in 1993 when it was revealed that open sale of Tiger parts and rhino horn was occurring. This embargo was lifted in less than a year when Taiwan showed evidence of controlling its illegal wildlife trade. Taiwan's new Wildlife Conservation Law brought about a registration of all privately held rhino products in late 1994; a total of more than 457 kilograms of whole rhino horns, taken from 153 animals, horn pieces and powder was registered (TRAFFIC 1995). These items are identified and photographed along with Tiger products but, unfortunately, allowed to remain in private hands.

In the past, confiscated rhino horns in Africa have been destroyed to keep them from entering commerce. A CITES resolution in 1994 changed this recommended procedure. Significantly, it urges Party countries with rhino horn to identify, mark, register and secure these stocks (Kelso 1995). This overturns the recommendation made in 1987 for these stocks to be destroyed, which was repealed. The current Resolution (Conf. 9.14) notes that Parties view destruction as being "no longer appropriate" because it may cause prices to escalate and lead to new poaching for rhino horn to replace the destroyed stock (Kelso 1995). Since stocks of seized rhino horn kept by various countries are, by definition, not available in any way to traders unless they are stolen or somehow given out, this appears to be the first step toward releasing these stocks for trade, and to allow trade in horns sawed off living rhinoceros.

Many conservationists believe that traders have built up private stockpiles of rhino horn for possible future sales (Ricciuti 1993), and some government stocks, such as China's, are considerable. An estimated 1.1 million pounds of horn from slaughtered rhinos are thought to be stockpiled in Taiwan and China. Other parts of the 1994 CITES Resolution were more laudable: it urged stricter domestic legislation to reduce illegal trade, and the education of Traditional Medicine sellers and users to eliminate consumption (Kelso 1995). South Africa had attempted at the 1994 CITES meeting to remove the South African population of the Southern White Rhinoceros from Appendix I, which bans commercial trade, and downlist it to Appendix II to open up trade. This proposal was not accepted, but

CITES Parties voted to allow sale of live animals and trophy hunts until the following meeting. The government of South Africa reproposed downlisting to Appendix II at the 1997 CITES Conference, again unsuccessfully, offering to submit annual quotas to CITES for approval and to use stockpiled horn and horn from natural mortalities, calculated at 230 per year. This would be augmented by horn obtained from dehorning of animals in the private sector (Hughes and Brooks 1996). Zimbabwe hopes to legalize trade in rhino horns, with state farms where herds of rhinos would have their horns cut off to supply the Chinese medicinal trade (Keller 1994). Both Zimbabwe and South Africa have enormous stockpiles of rhino horn obtained from poachers and dehorning programs that would be worth millions if the ban on international trade was lifted (Keller 1994).

Legalizing trade in rhino horn would prove disastrous for the species, just as the trade in ivory nearly caused the extinction of both species of elephants. The horns of Southern White Rhinos are not distinguishable from other rhino horn, except perhaps through forensic methods not available to import and export personnel. Even the live animals are difficult to distinguish by race (Hughes and Brooks 1997). The market for this horn far exceeds the supply and would not be appeased by the few hundred horns that enter trade each year from South Africa. Poaching would accelerate, and horns from illegally killed animals would not be distinguishable from those that had been stockpiled. This would further endanger the remaining wild populations of rhinos around the world, since their horns might be represented as legally obtained. In view of the enormous revenues that South Africa accrues from tourism--$6 billion in 1995 by its own accounting (Hughes and Brooks 1997)--the funds from sale of rhino horn can only be considered of minor importance. Efforts should be made to funnel ecotourism funds to rhino conservation, since that is one of the arguments being used to justify reopening the trade.

Dehorning of rhinos with the declared objective of making the animals unattractive to poachers has been carried out in Zimbabwe and Namibia. They are darted with tranquilizer guns, and the horn is sawed off the unconscious animal. The horn grows back in about one year, and the process must be repeated. Preliminary evidence in countries conducting dehorning indicates that rhinos continue to be poached, apparently just for the stump or, perhaps, because the poachers were unable to see whether the animal had its horn (Keller 1994). Even more importantly, females that have been dehorned have, without exception, lost their calves to predators (Speart 1994). Rhinos use their horns in territorial displays, mating, and defense and, it has now been established, to defend their calves from hyenas, Lions and other predators. Moreover, this procedure is expensive and involves trauma and possible death to rhinos.

Zimbabwe, a country that prides itself on its "sustained yield" approach to wildlife, has an entirely different approach to protecting rhinos than East Africa and most other African nations. The government launched fiOperation Strongholdfl in 1984 to prevent poaching, with highly armed rangers trained to kill poachers, and a goal of preserving its once large rhino populations. Once a stronghold for the Black Rhinoceros, with a population of at least 1,400, the country's rhinos declined to 400 by 1992, and to 300 by 1994 (Speart 1994). Only 200 White Rhinos remain in Zimbabwe, and their numbers are also in decline (Stuart and Stuart 1996). Anti-poaching efforts failed to stop the killing of 954 rhinos between 1984 and 1991; during that period 145 poachers and four conservation officers were shot (Stuart and Stuart 1996).

The market in rhino horn has been extremely difficult to control, since the horn can be reduced to a powder that is easily smuggled, sold surreptitiously, or in some countries openly, in a vast network of apothecary shops in Asia and Chinatowns throughout the world. With fewer than 12,000 rhinos remaining alive and a potential market of millions of Asians, the future of these ancient animals is bleak. Throughout the millions of years that rhinoceros have existed, their armored hide and horns have helped them defend themselves against a wide variety of predators, but against a legion of new weapons and cold-blooded greed, they may not survive much longer.

Traditional Medicine Trade: Bears

Bears of all species have come under siege from a variety of causes, including habitat loss, hunting, killing for meat and as "nuisances." Their greatest threat today, however, is their slaughter for the market in bear products, mainly their gallbladders and paws. All of the world's eight species of bears, except the Giant Panda, have suffered population declines as a result of this Traditional Medicine trade (Knights 1996). Their gallbladders are ground into powder, and bile is extracted for various medicinal purposes, including digestive problems, inflammation and blood purification. Sold at extremely high prices, a record $45,000 was paid for a single gallbladder (Barron 1991). To illustrate the avid market in this product, an Asian dealer in New York City was murdered in 1991 to obtain his profits from the sale of bear gallbladders. Japan imported 1,500 pounds of bear bile in 1989 alone (Schaller 1993).

The largest consumer of bear bile is now South Korea, and Koreans have even hunted Black Bears (*Ursus americanus*) in California and placed ads in newspapers to purchase bear gallbladders from hunters (Knights 1996). A Grizzly or Brown Bear (*Ursus arctos*) gallbladder can sell for up to $10,000 on the black market, and the larger the gallbladder, the higher the price. A Black Bear gallbladder can be purchased from a poacher in Idaho for $15, but in Hawaii, it brings $1,500, and in Korea, as much as $15,000 (Barron 1991). Some AIDS patients in the United States take extracts of bear gallbladder as a supposed cure for this disease, according to CBS News (July 7, 1993).

The Asiatic Black Bear (*Ursus thibetanus*), already endangered and listed on Appendix I of CITES before the 1980s, may now be verging on extinction, according to the Chairman of the IUCN Bear Specialist Group (Servheen 1989). Native to most of Asia from Iran and India east to Mongolia, Russia and Vietnam, this species has been the major target of the gallbladder trade. From 1979 to 1988, up to 59,000 gallbladders were illegally exported from China to Japan (Servheen 1989). A wild Korean Black Bear shot in 1982 was sold at auction for $18,500 (Servheen 1989). Fewer than 10 of these bears remain in Korea, according to the Korean Federation for Environmental Movement after they were finally given protection. In 1996, five Koreans and two Thais were arrested in South Korea after they were caught with the carcasses of six wild bears with the paws chopped off and internal organs extracted (WuDunn 1997). Hunters of these bears will often frighten or wound the bear first in order to let it die slowly, in pain, in the belief that the gallbladder becomes larger when the animal suffers (WuDunn 1997). South Korea recently banned sale of bear parts except for U.S. bears, which are still allowed to be sold. The bear bile is touted as a magical cure-all, used in health tonics and aphrodisiacs throughout Korea (WuDunn 1997). An average of more than 2,000 Asiatic Black Bears per year are killed in Japan, and many are exported as live animals or parts, primarily to Korea.

The World Society for the Protection of Animals (WSPA) reported in 1995 in *The Protector* that an illegal shipment of 21 live small bear cubs, of which 20 were Asiatic and one was a Sun Bear, was seized in Thailand. All had been captured in Burma, and the smuggler had made an arrangement with airport authorities in Thailand to let these Appendix I species pass on their journey to Korea to be killed and their paws removed for restaurant diners. The Thai forestry department was informed and confiscated the bear cubs. After the seizure, three died of disease, brought on by their crowded and unhealthy captive conditions. These cubs, which would still have been with their mothers, were placed by the World Society for the Protection of Animals in a humane rescue center. This species has declined so dramatically throughout its range that the Traditional Medicine trade has turned to other bear species. The Asiatic Black Bear ranges into Siberia, where it is being slaughtered for its gallbladder in spite of being legally protected (Galster 1996). The IUCN Bear Specialist Group's Chairman, Christopher Servheen, in his report *The Status and Conservation of the Bears of the World* (1989), predicted that without strict controls on trade and hunting, the Asiatic Black Bear could become extinct throughout most of its range in the very near future.

An estimated 8,000 to 9,000 Brown Bear gallbladders are exported from Russia annually, of which half are legally hunted bears and half are poached animals, but no official records are being kept (Knights 1996). The Brown Bear is the national symbol of Russia, and yet the combined effects of disintegrating law enforcement, financial gain from selling bear body parts, and official corruption pose serious threats. Russian poachers receive about $200 per gallbladder, and they are sold in Korea for up to $5,000 apiece (Galster 1996). In 1995, in the Bikin Valley of Russia's Far East, bear poaching was reported on the rise, and the Amba patrol protecting Siberian Tigers reported seeing an increasing number of orphaned bear cubs (Galster 1996). Some cubs are killed along with their mothers; a

report by the Investigative Network included a photograph of a dead mother Brown Bear and her slaughtered infant cub, killed for their gallbladders in Russia (Galster 1996).

After floods in northeastern China in mid-1995, many Brown Bears crossed over the Amur River into Russia to reach higher ground, and hunters converged on them (Galster 1996). They were pursued into forests by four-wheel drive vehicles, and at least 60 were shot. Because the trade in bear parts is legal in Russia, little can be done to stop the poaching (Galster 1996).

The grisly consumption of bear paws, which are cooked as a gourmet delicacy that to some is also health promoting, is widespread in Asia. Served at Japanese business banquets, they can cost $1,000 per person; a Seoul restaurant advertised bear paw soup in 1994 at $1,000 per bowl (Knights 1996). More than 900 kilograms of paws were imported annually into Japan from China in the mid-1970s, and about 600 kilograms per year entered in the 1980s (Servheen 1989). In 1987, one Chinese city, Harbin, consumed 4,000 pounds of Brown and Asiatic Black Bear paws, and nine live bears were smuggled into Guangzhou City to lease to restaurants in order to lure customers (Schaller 1993). In 1990 a single load of 4,000 kilograms of bear paws from 1,000 bears was intercepted at the Chinese border headed for Japanese and Korean buyers (Knights 1996). Live bears, imported with the pretext of going to zoos, are killed in front of Korean restaurant customers (Servheen 1989). A Korean newspaper reported that live bears are lowered onto beds of hot coals, where they are held until their feet are cooked (Knights 1996). In China, servings of bear paws sell for between $346 and $576 each. At the Beijing Lou restaurant, braised bear paws are advertised on a three-sided, revolving, illuminated sign, with enlarged photos of the paws (Highley and Highley 1994).

Sun Bears (*Helarctos malayaunus*), smallest of all bears, are native to southeast Asia. Populations of this species have been severely reduced by the capture of many animals shipped to South Korea for their paws (Highley and Highley 1994). The Sun Bear is an endangered species on Appendix I of CITES, and total populations are thought to be less than 20,000; it ranges from India though Thailand to Sumatra and Borneo (Knights 1996). Another rare Asian species, the Sloth Bear (*Melursus ursinus*) of India, Sri Lanka, Bangladesh, Nepal and Bhutan, is thought to number less than 10,000 (Knights 1996). It is listed on Appendix I of CITES and listed as Vulnerable by the *2000 IUCN Red List of Threatened Species*. An estimated 728 to 1,548 Sloth Bears in India alone are also being killed for the restaurant and gallbladder trades (Nowak 1999; Servheen 1989).

Asians are not the only ones who consume bear paws. An American entertainer, Tommy Tune, joked on a U.S. talk show about a banquet he attended in Japan where he ate a bear's left paw. It had been ordered one week in advance, probably so that a live bear would be killed or maimed for the purpose. Jay Leno, the host of the fiTonightfl show, on which Tune was a guest, said "Imagine a bear getting its paw cut off! How could you eat that?" Tune replied, "Oh, you just don't think about it."

Bear fifarmsfl have been established in several Asian countries, keeping these animals in captivity to extract bile from their gallbladders. China had an astounding 10,000 Asiatic Black Bears in bear farms throughout the country (Knights 1996); but that number has been reduced to fewer than 8,000 at the beginning of the new millenium. They represent at least a third of the species' entire population. An investigation by two researchers (Highley and Highley 1994), who visited a number of these farms and published a report, *Bear Farming & Trade in China and Taiwan*, found bears being kept in extremely cruel conditions in cages only 3 feet by 4 feet by 8 feet, so small they could barely move (Highley and Highley 1994). Some cages are raised off the ground like rabbit cages, and others are placed on the ground, with bears often lying in their own excrement. Films and documentation of the conditions in which these bears are kept have provoked international outcries (Highley and Highley 1994).

The extraction of the bile from caged bears is another cruelty. Christopher Servheen, a bear biologist, witnessed such an operation, in which the owner used a metal pole to harass the small bear, which already had a badly scabbed nose, into a narrow portion of its cage. As his wife distracted the bear with a pan of sweets, a door was lowered and metal rods inserted to confine the bear and keep its legs from interfering with its abdomen. The owner reached in,

unlocked the metal panel, and a plastic bag attached to a catheter dropped down, which was half full of a green-brown liquid. The bear scraped and clawed wildly at the cage when the owner proceeded to extract the liquid from the bag with an oversized hypodermic needle, withdrawing two full syringes (Highley and Highley 1994). Several caged bears with one or more paws cut off for sale to the restaurant trade have been seen on these farms (Highley and Highley 1994).

An organization based in Hong Kong, Animals Asia Foundation, run by Jill Robinson, has begun a rescue operation to save at least 500 Asiatic Black Bears from bear farms. They will live in a sanctuary where they are able to roam free. The organization signed an agreement with the China Wildlife Conservation Association in Beijing and the Sichuan Forestry Department to close the worst bear farms in Sichuan with the goal of expanding the initiative to other provinces and promoting the manufacture and use of synthetic or herbal substitutes for bear bile. Many of the bears rescued had severe wounds from the catheters implanted to drain bile, or from banging their heads against the bars. Their teeth were broken and worn down from biting cage bars in a vain attempt to escape. They are being given veterinary care at the Animals Asia Foundation.*

*Animals Asia Foundation, Hong Kong Headquarters Office, P.O. Box 82, Sai Kung Post Office, Sai Kung, Kowloon, Hong Kong; Web site: www.animalsasia.org. Donations are needed for this important rescue work.

The World Society for the Protection of Animals (WSPA) has been extremely active in rescuing bears from inhumane conditions in Europe and Asia, and its recent research on 44 bear farms was published in two reports in 2000: *The veterinary, behavioural and welfare implications of bear farming in Asia* details the conditions on these farms, in which cages are tiny metal boxes with holes punched for ventilation; the extremely abnormal behavior exhibited, such as self-mutilation; and the untreated wounds, deformities and health problems. *From Cage to Consumer* is a market survey showing that bear gallbladders and bile are being sold in most major U.S. and Canadian cities, with prices of up to $650 for a whole gallbladder. The United States and Canada thus help to keep these cruel farms in business. Legislation to ban U.S. sales failed in recent Congressional sessions, but was reintroduced in 2001.

According to the Association of Chinese Medicine and Philosophy in Hong Kong, there are at least 54 alternatives to bear gall, including common rhubarb and a type of gardenia (Knights 1996). A chemical used in Western medicine to dissolve gallbladder stones, Ursodeoxycholic acid (UDCA), has been synthesized from cattle bile acid for the past 50 years (Knights 1996). Twelve tons of this chemical are produced by a single pharmaceutical company in Korea every year. This product has been approved by the U.S. Food and Drug Administration. Many practitioners of Traditional Medicine are unaware of synthesized UDCA, and most prefer to stock products from rare wild animals (Knights 1996). Korean practitioners claim that only the real bear bile is effective, a totally false assumption but one that keeps the demand strong (WuDunn 1997).

The Traditional Medicine trade in bear products is also practiced in South America, where the endangered Spectacled Bear (*Tremarctos ornatus*) is struggling for survival in its Andean habitat. Bear fat is used for bone bruises and claws for strength and fertility; machismo is associated with killing these bears (Servheen 1989). Total numbers of this rare species are estimated at only 10,000 animals (Knights 1996). Although protected throughout its range, enforcement is poor (Servheen 1989). It is listed on Appendix I of CITES.

The Fish and Wildlife Service's Forensics Laboratory, after intensive research, is now able to identify bear gallbladders by species if a bit of tissue is attached for DNA analysis (Knights 1996). However, law enforcement officers are unable to distinguish by sight alone whether the gallbladders come from an endangered species of bear. Detection of smuggled bear gallbladder in packages and luggage by trained dogs is one step in the right direction. British Columbia has begun training dogs for this purpose, and should this become widespread, confiscations might have a major effect on smuggling.

Traditional Medicine Trade: Sturgeon

Caviar, the eggs of sturgeon of many species and several other species of fish, is considered a great delicacy by gourmet diners around the world. The killing of sturgeon for the most valuable types of caviar has pushed many species of these ancient fish close to extinction. Caviar is the most valuable of all fisheries products. Prime Beluga caviar from Russia sells for as much as $80 per ounce ($1,280 per pound), and Iranian Beluga for $125 an ounce ($2,000 per pound) (Fabricant 2000). Beluga sturgeon (*Huso huso*) breed in the Volga River and spend their lives in the Caspian Sea, which is bordered by Russia, Kazakhstan, Turkmenistan, Azerbaijan and Iran. Two other species native to the Caspian, Russian Sturgeon (*Acipenser gueldenstaedti*) and the Sevruga or Stellate Sturgeon (*Acipenser stellatus*), have also declined to endangered status. Prior to the overfishing, damming of their spawning river and pollution of the Caspian by industry, pesticides and offshore oil rigs, these sturgeon were abundant and reached great lengths and weights (Tyler 2000). A Beluga caught in 1926 was estimated to be 75 years old, weighed 2,000 pounds and yielded 396 pounds of caviar (Sparks 1992). Even larger individuals weighing 2,500 pounds and measuring up to 28 feet in length have been reported (Sparks 1992). As recently as the 1970s, Beluga at least 60 years old were regularly caught (Platt 1995). Today, few giant sturgeon remain anywhere in the world. Ninety percent of Caspian Sea sturgeon are killed before they are mature enough to reproduce; the typical adult is now less than 18 years old and weighs only about 77 pounds (Platt 1995).

Sturgeon of the Caspian Sea produce 95 percent of black caviar, the most sought-after of all caviar. Their decline began with the construction of large dams on the Volga River which disrupted their migration to spawn. Fewer and fewer sturgeon are able to negotiate this river and its tributaries (Stewart 1992). The older females, aged 50 or more, produce great amounts of caviar, at least 3 million eggs, then go back to the Caspian for several years before returning to spawn again (Sparks 1992). Large sturgeon, because of their armor-like skin, become immobile and passive when caught (Stewart 1992). The fish are stunned and transferred to a fish barge in legal fisheries, where they are kept alive until processing. Then the sturgeon is cut open while still alive, and the roe is scooped out and placed in buckets (Stewart 1992).

After the breakup of the Soviet Union in 1991, well-armed poaching groups replaced the strict legal fishery and began netting female Beluga (Stewart 1992). Russian citizens offered small jars of illegal caviar to foreigners at hotels and airports at exorbitant prices (Stewart 1992). As proof of the continued illegal trade, 450 tons of caviar from Russia and Iran were sold by the European caviar trading company Dieckmann & Hansen in 1995, but legal production of caviar was only 225 tons (DeSalle and Birstein 1996). The U.S. Department of Commerce statistics on caviar imports show a recent increase of 100 percent since 1991, according to investigations by two molecular biologists with the American Museum of Natural History in New York, Rob DeSalle and Vadim J. Birstein (1996). In order to determine the species from which various caviars derive, these two scientists did DNA analyses on 25 samples, 23 from gourmet stores in New York City, and two brought from Russia. Many were mislabeled, and several had come from threatened species. One sample of Siberian Sturgeon (*Acipenser baerii*) was labeled as Beluga (DeSalle and Birstein 1996). The quota for the latter species was 200 to 300 tons for all Siberian rivers, but in 1994, in the Ob River alone, the illegal catch was 250 to 300 tons (DeSalle and Birstein 1996).

By 1995, populations of sturgeon in the Caspian Sea reached new lows. In 1996, the *IUCN Red List of Threatened Animals* listed Beluga, Sevruga and Russian sturgeon as Endangered. The vast majority of sturgeon species of Eurasia were also listed, as a result of overfishing. In June 1997, the entire Order of sturgeon, Acipenseriformes, including all species of sturgeon and paddlefish, was listed on CITES Appendix II. Appendix II does not necessarily ban trade, but only requires export permits that certify catch did not deplete wild populations, and it is generally not strictly enforced. Illegal fishing by organized poaching gangs in countries lining the Caspian Sea continued, pushing depleted populations closer to extinction in the following years. It was estimated in 2000 that actual catch totaled 25 tons, 5 to

10 times the official catch (Tyler 2000). Even this was 0.1 percent of the 22,000 tons regularly caught each year in the 1970s (Higgins 2001). In 1999, official U.S. Commerce statistics showed 14 tons of Beluga as imported into the United States, representing the eggs of 1,600 female fish (Revkin 2000). Twice that many Beluga are killed by poachers because of the difficulty in distinguishing between male and female (Tagliabue 2000). In an effort to stop international commerce in Beluga, the most endangered of the Caspian Sea sturgeon, the Natural Resources Defense Council, the Wildlife Conservation Society, and SeaWeb petitioned the U.S. Fish and Wildlife Service in December 2000 to list the species as Endangered under the Endangered Species Act. These organizations established a website, www.caviaremptor.org, urging consumers to stop buying caviar (Revkin 2000).

A scientific report compiled for CITES by TRAFFIC, an organization of the World Conservation Union, was issued in December 2000. It concluded that Beluga and other sturgeon from the Caspian were not being sufficiently protected under the terms of their Appendix II listing (Tyler 2000). Proposals to list Beluga and other critically endangered sturgeon were discussed at a meeting of a CITES Scientific Committee in December 2000. The committee agreed that Beluga and Kaluga (*Huso dauricus*), a sturgeon of the Amur River of eastern Siberia and northeastern China that can weigh up to a ton, merited listing on Appendix I, banning all commercial trade, because of their status (Revkin 2000). However, the committee decided against placing them on Appendix I because the members concluded that the trade ban would cause economic disruption in the impoverished Caspian region and would bankrupt legal traders, importers and hatcheries (Revkin 2000). Instead, it recommended a reduction of 80 percent in fishing quotas. In June 2001, the CITES committee formally rejected Appendix I listings for these sturgeon, giving countries bordering the Caspian until the end of the year to formulate a management plan that would conserve the species (Higgins 2001). The black market in caviar, unaffected by quotas and management systems, was estimated by Russia's Prosecutor General's Office in 1999 at between $2 billion and $4 billion a year (Filipov 2001a). It has not been controlled by any country along the Caspian Sea, with the possible exception of Iran. A Russian program to stop all vehicles on roads bordering the Caspian Sea to check them for illegal caviar has been a failure, as a *Boston Globe* correspondent found when traveling in a sedan with a hidden 70-pound Beluga. The car was waved along by a policeman after he asked if the driver had any fish or a secret compartment but did not search the car (Filipov 2000b).

In June 2001, four former Soviet republics on the Caspian Sea agreed to cooperate to try to stem the precipitous decline in sturgeon by conducting a scientific survey of populations and then setting quotas, along with coordination of anti-poaching campaigns (Higgins 2001). Russia, Azerbaijan and Kazakhstan agreed to stop all fishing for sturgeon for 2001, and Turkmenistan is expected to approve management plans (Tagliabue 2001). This does not stop the international trade, however, either legal or illegal. Most chefs and restaurants in the United States and Europe have failed to boycott Beluga and other endangered caviar. An exception is the famous French chef, Jacques Pepin, who wrote an Op-ed essay for *The New York Times* on July 3, 2001, urging a boycott and stating that the temporary fishing ban in the Caspian was inadequate to protect these sturgeon. He commented: "There are many luxuries in life in which we can still indulge. The beluga sturgeon can't afford for us to indulge in this one" (Pepin 2001).

The snob value of caviar has been promoted for generations, and this, too, encourages overfishing. A lack of conservation among those who buy caviar may push Russian sturgeon past the point of recovery. Sturgeon are not alone in their dramatic declines from overfishing. Orange Roughy, Atlantic Bluefin Tuna, Atlantic Cod and Haddock, Chilean Bass and many species of shark are among other fish pushed toward extinction in the past decade.

Traditional Medicine Trade: Seahorses

Among the most unusual and delicate of marine creatures, seahorses have been admired for centuries by naturalists. They have been harvested since the 14th century Ming Dynasty in China, and their bodies dried and ground to a powder used to cure a variety of ills, including asthma; broken bones; impotence; kidney disorders; heart,

skin and thyroid ailments; and as an aphrodisiac (Vincent 1995). About 35 species of seahorses are found in both tropical and temperate oceans, all of the genus *Hippocampus*. They vary greatly in size and form. The smallest is about 10 millimeters (0.39 inches) long, and the largest, 300 millimeters (11.7 inches); they weigh from about 3 grams up to 25 grams (Vincent 1995). Some seahorses have evolved elaborate lacey fins resembling seaweed, but most have a distinctive armored body with an extended abdomen and long, tapered snout evoking the profile of a horse; their tails wind forward into a spiral. They swim in an erect posture, moving tiny, spineless fins at great speed. Their method of reproduction is highly unusual. The female deposits fertilized eggs in the male's abdominal pouch, and after gestation, he thrusts the young seahorses out of his belly. Seahorses mate for life, and if one of the pair is killed, the remaining one does not readily remate (Vincent 1995). Wherever they occur, seahorses tend to be sparsely distributed in their seagrass, coral and mangrove habitats (Vincent 1995).

A two-year study (1993 to 1995) by biologist Amanda Vincent in Southeast Asia, found an extensive trade in seahorses for Traditional Medicine, aquariums and the curio trade (Vincent 1995). Collectors in the Philippines receive as little as 25 cents, while dried seahorses sell for up to $1,200 per kilogram at retail (Vincent 1995). They are also ground up and sold in pill form, mixed with other ingredients. By 1997, Vincent calculated that the worldwide trade consumes at least 20 million seahorses per year (quoted in fiKingdom of the Seahorsefl film; see Video).

Hong Kong is the center of the trade, and Vincent™s research revealed that traders offered to buy 500 kilograms to a ton a month, far more than the supply of wild seahorses can support. In Hong Kong, seven seahorses sell for $75. They are shipped to China, which provides the largest market, followed by Taiwan, and Singapore. The Chinese market in the United States is also substantial. Some 200,000 dried seahorses were imported from the Philippines in 1987 (Vincent 1995). U.S. fishermen are now a source of seahorses. In the mid-1990s, Florida supplied 100,000 seahorses a year to the market, mainly gleaned from nets set for shrimp. Many of the seahorses caught in shrimp nets are injured, and the shrimp fishermen discard them, sweeping them overboard. A large percentage consist of pregnant males, whose young do not survive, according to Vincent. A single Japanese order for 100 kilograms involved the killing of 28,000 seahorses; Australia imported 140,000 dried animals in May 1995, and another million live ones for the aquarium trade (Vincent 1995).

The major capture method, scooping the seahorses in nets in shallow water, is used throughout Southeast Asia. Vietnam and the Philippines are the largest suppliers (Vincent 1995). Vincent interviewed many fishermen in widely divergent areas from India, where the fishery was state-sponsored, to Java, Bali and the Philippines. In the Philippines, catches are half or one-third what they were in 1993, indicating how fast the decline has taken place (Vincent 1995). With the high price offered, more fishermen are pursuing seahorses, causing declines. Another sign of depletion is the decline in size of seahorses caught, most of which represent immature animals that never bred before capture.

The *IUCN Red List* included more than 30 species in 1996, all as Vulnerable, a sign of the widespread decline of these fish. The majority were native to the Indian and Pacific Oceans, although the Atlantic, Mediterranean and Black Seas also harbored threatened seahorses. Without strong conservation programs, seahorses and their close relatives are likely to disappear from the wild.

Vincent has helped set up programs, in close cooperation with Philippine fishermen, in which sanctuaries are set aside where no fishing is allowed. They are patrolled by boat, and pregnant males are placed in these sanctuaries to have the young. The villagers, at first suspicious of Vincent's motives, have realized that this is the only way to prevent the extinction of the seahorses, and the management program is now being copied in other coastal fishing villages. The villagers, especially the children, are taken to the sanctuary to see these fascinating creatures in the wild, and have a new appreciation for them.

Wild Pets and Laboratory Animals

Wild Pets and Laboratory Animals: Birds
Enormous numbers of wild birds are captured for the cage bird trade. The Environmental Investigation Agency conducted a field research project in Senegal in which they documented the capture of as many as 20 million wild birds, mainly finches. EIA™s films and research of the trapping of wild birds in Senegal and Argentina revealed that 50 percent or more die of shock or injury prior to export. The birds are traumatized by the capture and often injure themselves trying to escape; few receive humane care and proper nutrition. In fact, EIA found birds held prior to shipping to export centers in unsanitary, crowded conditions, and cared for by people with little or inadequate knowledge about their feeding and care, causing considerable mortality in the first days after capture. In Senegal, EIA filmed the transport of thousands of these birds to export centers hundreds of miles away, in the tropical heat, crammed into cages strapped to the tops of the buses. At stops, the dead and dying birds were thrown out along the side of the road.

Wild Pets and Laboratory Animals: Birds: Page 1
Customers in pet stores, seeing docile parrots and chattering finches, rarely realize that these birds are the survivors of a trade that kills as many as 15 million birds per year. In the homes of pet owners, many wild-caught birds, especially large parrots, fail to adjust to captivity and die from a variety of illnesses, from salmonella contracted in quarantine stations to the lethal wasting disease which is untreatable. Since large parrots, such as macaws, cockatoos and Amazon parrots, may live to an advanced age, birds captured for the pet trade may have spent 20 years or more in the wild, in the company of other parrots, flocking, foraging and roosting together 24 hours a day. In recommending against the purchase of macaws, ornithologist Charles Munn (1988) said:. "A long life in a small cage is dismal and cruel compared with life in the wild . . . For such intensely social birds, life alone in a cage must be the ultimate psychological torture." Parrots are long-lived birds, surviving 80 or more years, but in captivity, their lives usually last less than a decade.

Research has revealed that many parrots are highly intelligent. Their brain size is far larger in proportion to their bodies than other birds. One Gray Parrot (*Psittacus erithacus*), Alex, studied for many years by Dr. Irene Pepperberg, has an IQ equivalent to a 3-year-old child, and a vocabulary of more than 100 words that he understands the meaning of; he does not just repeat them. He recognizes more than 30 objects which he can identify by name, and when asked conceptual questions (fiWhich key is green?fl), he is able to select the correct one more than 80 percent of the time. He understands what "round" and other shapes and sizes mean, and can tell what different objects might have in common, such as color (Kaufman 1991). Parrots compare in intelligence with primates, yet most pet parrots are treated like animated tape recorders, taught to repeat phrases. There are different standards for captive birds than for mammals. For example, if we saw a case of a pet deer or antelope hobbling about with its legs tied together to prevent it from running away, we would alert the local humane society and police. Yet bird owners routinely clip the wing feathers of their pets to prevent flight. This results in an equal hindrance of movement and causes the bird anxiety because it cannot fly from a potential threat, yet it is neither illegal nor frowned upon.

Until recently, the United States was the world's largest importer of wild birds, providing an enormous market for exotic finches, parrots, cockatoos, mynahs and other birds. Almost 1 million birds a year were imported during the 1980s. A large percentage of these birds, approximately 80 percent, were wild-caught in the tropical forests and grasslands of Latin America and Asia and the sub-Saharan region of Africa. All parrots (Order Psittaciformes)--except the Budgerigar, Cockatiel and Rose-ringed Parakeet-- were added to Appendix II of CITES in 1981. However, because of failure to enforce the provisions of the treaty, which require that export be allowed only if it does not adversely affect the species, this had little effect on limiting the massive trade. At the height of the 1980s wild bird trade, the Royal Society for the Preservation of Birds estimated that 500,000 wild parrots were being captured per year worldwide.

The U.S. Congress enacted the Wild Bird Conservation Act (WBCA) in 1992, a law that effectively stopped commercial imports of wild parrots and all other birds listed on the Appendices of CITES. It allows zoological imports, non-CITES birds, and some captive-bred birds. The law sharply reduced the importation of wild birds. For example, from January 1996 to July 1998, according to a study by the Animal Welfare Institute, 273,288 birds were imported, based on U.S. Fish and Wildlife Service import data and U.S. Department of Agriculture bird quarantine forms. Of those, an estimated 70 percent, or 191,324 birds, were captive-bred canaries, finches, budgerigars and cockatiels. Some illegalities were noted, such as the import of some 1,379 wild parrots from Latin America, of which only 457 were seized. Most of the other wild birds were finches from Tanzania, China and Vietnam. Since this study was done, China has ceased exporting wild birds. The study uncovered the need for a better system of recording bird imports by the Fish and Wildlife Service to assure accuracy and allow proper enforcement of the WBCA as well as CITES, the Endangered Species Act and other legislation. The data entry system of the Fish and Wildlife Service is based on a letter code assigned to individual species, but a large number of entries at the ports of entry were found to be inaccurate, and there was insufficient oversight at headquarters.

Wild Pets and Laboratory Animals: Birds: Page 2

More than 40 species of birds have become endangered by the pet and aviculture trade, and many more have declined to threatened status. The spectacular, large pink Salmon-crested or Moluccan Cockatoo (*Cacatua moluccensis*) of Indonesia is endemic to the island of Seram and its satellite islands in the Moluccan Islands. In the 1980s, international exploitation began with thousands exported yearly, the majority to the United States. Although once considered abundant in its restricted range, the overall population could not withstand such high rates of capture. The Indonesian government placed an export quota of 5,000 in 1988, and 3,000 in 1989. These high quotas were not based on scientific surveys of the birds™ populations. In 1989, U.S. imports alone totaled 5,252 Salmon-crested Cockatoos, exceeding the export quota by 2,252 birds, a clear indication that the Indonesian government had not

controlled this trade. Between 1980 and 1990, when U.S. imports finally ended, 43,083 of these beautiful parrots had been imported, threatening this species with extinction; thousands had died in capture, transport and quarantine. World trade in the 1980s may have totaled as many as 100,000 birds. In 1989, the Salmon-crested Cockatoo was finally listed on CITES Appendix I, banning international commercial trade. *Threatened Birds of the World*, compiled by BirdLife International, classifies this species as Vulnerable and in a decline that is expected to continue (BI 2000).

During the 1990s, Salmon-crested Cockatoo populations did not recover as a result of the new protection accorded, but surveys found that this species had disappeared from several islands within its range and had become confined to Seram, where it declined 20 to 40 percent during the 1990s (BI 2000). In spite of the CITES Appendix I listing and an Indonesian export ban, Salmon-crested Cockatoos continued to be illegally captured on Seram. The Royal Society for the Protection of Birds (RSPB) filmed the capture of these cockatoos on their roosting trees at night in the early 1990s. When caught by the feet, these birds shrieked in terror. This film, entitled fiBird Trafficfl (see Video Section), chronicles this poaching and subsequent smuggling out of Indonesia. The RSPB researchers found that local villagers within the range of this cockatoo had not been informed by the government of the species' rarity and legal protection, with the result that villagers willingly captured them when logging company employees placed orders. Outside Manusela National Park, these cockatoos are extremely rare, and their rainforest habitats are being destroyed by logging (BI 2000). Captive birds now far outnumber wild populations. Salmon-crested Cockatoos are no longer imported into the United States or Europe but are still sold in Asian markets. Should this beautiful cockatoo become extinct in the wild, the U.S. market will have to bear much of the blame, having been responsible for depleting a once common species. Wild-caught specimens of these magnificent birds are still seen in U.S. pet stores, exhibiting extremely neurotic behavior reflecting their inability to adapt to living in a tiny cage. They bob in circles while shrieking loudly, or shift rapidly from one foot to another, continuing this behavior for long periods.

Equally high quotas for other species of Indonesia's beautiful parrots and lories ended in endangering many species. By the end of the 1980s, five species of large Asian cockatoos, Salmon-crested, White (*Cacatua alba*), Goffin's (*Cacatua goffini*), Yellow-crested (*Cacatua sulphurea*), and Philippine (or Red-vented) Cockatoos (*Cacatua haematuropygia*), had become threatened with extinction as a direct result of massive, uncontrolled capture for the pet trade (Collar *et al.* 1994). Only the Goffin's, Salmon-crested and Red-vented Cockatoos are listed on Appendix I of CITES. The Yellow-crested Cockatoo, endemic to a small range in East Timor, Sulawesi and nearby islands, is now Critically Endangered, in imminent danger of extinction (BI 2000). As noted in *Threatened Birds of the World* (BI 2000), "Its precipitous decline is almost entirely attributable to unsustainable exploitation for internal and international trade." Logging, pesticide use and persecution have also played roles. This white cockatoo with yellow crest was imported into the United States in very large numbers for the cage bird trade during the 1980s. Although a program to recover its populations and preserve them in the national parks and reserves where they occur has been adopted, CITES Appendix I listing would provide additional protection. In parts of Indonesia, ecotourism based on bird watching is being developed. This country has an enormous variety of beautiful, dramatic and colorful parrots and other endemic birds.

Wild Pets and Laboratory Animals: Birds: Page 3

In the early 1980s, Bolivia was the largest exporter of parrots from South America, illegally transshipping the protected birds of neighboring countries, and depleting its own parrot populations. The Red-fronted Macaw (*Ara rubrogenys*) and the Blue-throated Macaw (*Ara glaucogularis*), for example, are endemic to Bolivia, and trade nearly extinguished their already small populations. These birds are now on Appendix I but are at risk of extinction. In 1984, the Government of Bolivia publicly admitted that its wildlife export trade was out of control, its bird exporters funneling protected birds from neighboring countries, and its own CITES personnel had forged export permits. A temporary export ban was enacted, and this later became permanent--to the great credit of this country, which harbors a wealth of bird life and extensive tropical forest. The Red-fronted Macaw, imported into the United States in the

hundreds during the 1980s, is now Endangered in the *2000 IUCN Red List of Threatened Species*. Its population has declined to as few as 1,000 birds, with continued illegal capture for wealthy bird collectors (BI 2000). The Blue-throated Macaw, native to northern Bolivian rainforests, is in Critically Endangered status, according to IUCN and BirdLife International with fewer than 249 birds left in the wild; it, too, continues to be illegally captured for trade (BI 2000). A 1984 study by two South American biologists, Manuel Nores and Dario Yzurieta (1984), found that eight of the 11 macaw species in Bolivia were endangered, rare or declining as a direct result of the wild bird trade. Bolivia's forests are largely intact, and the enormous trade in wild parrots during the 1980s is the sole explanation for the depletion of all the large parrots and many of the small ones in that country.

Numerous other Latin American parrots, once common, were so heavily traded in the 1980s that they, too, became threatened with extinction and were listed on CITES Appendix I. Among these is the beautiful Scarlet Macaw, symbol of tropical forests, which was listed in 1985, along with the Military Macaw (*Ara militaris*) and the similar Great Green or Illiger's Macaw (*Ara ambigua*), all being overexploited for the pet trade (BI 2000). The Scarlet Macaw has disappeared from areas close to villages and towns throughout its large range, which extends from southern Mexico to Amazonian South America. In Mexico and Central America, it has been protected from trade since the early 1980s, but illegal capture and smuggling continue to decimate wild populations. With passage of the Wild Bird Conservation Act, this species is now more secure, making illegal sales in U.S. pet stores much more conspicuous. By the end of the 1980s, 10 of the 17 macaw species had been listed on Appendix I of CITES, and others were experiencing steep declines.

Further west in Peru's massive Manu National Park, biologist Charles Munn has been studying macaws and parrots since 1984, climbing 100-foot trees to observe them closely, locating wild nests and researching their productivity. He found that in spite of the undisturbed extensive rainforest habitat in the park, large macaws raise very few young; 100 pairs of large macaws might fledge as few as 15 to 25 young per year (Munn 1988). He concluded, "Such a low reproductive rate indicates that macaws *cannot* be harvested from the wild without depleting their populations." This explains how species of macaws and parrots that had flown in huge flocks of hundreds of birds became reduced to scattered numbers within a few years after the onslaught of the parrot traders. Another factor in the vulnerability of parrots is their refusal to leave trapped flock-mates. Trappers would continue capturing birds that flew to the aid of their fellows until entire flocks were caught. North America's only native parrot, the Carolina Parakeet, had this trait as well and was trapped to extinction.

Trapping breaks bonds between lifelong mates and leaves females with chicks that often starve when the male is caught. This cruel trade causes the premature deaths of thousands of parrots from disease, improper care and stress. Methods of capture are particularly inhumane. Some trappers set nooses on tree limbs that flip the bird upside down when its foot becomes trapped. Birds can remain caught in this manner for hours or days, screaming and flapping their wings, while fellow parrots gather around squawking helplessly, unable to free them. Other parrots and many types of small finches are caught by bird lime, an adhesive that is smeared on tree branches. Birds' wings or feet become stuck to the branches, and they struggle in vain to free themselves, often resulting in injury or death. Decoy birds are also used to attract flocks to baited nets which are sprung by a trapper hidden in the bushes. So efficient are these methods that trappers nearly caused the extinction of South American Military Macaws that congregated annually when the fruit of a certain type of tree in northwestern Argentina ripened. The flock members returned annually to this ancestral feeding area, and trappers set nooses on and near these trees, using decoy birds to attract them. Only CITES Appendix I listing saved the remnant population of these magnificent birds from extinction. The taking of nestling parrots from tree holes, often cutting down entire nest trees in the process, is another method of capture that had extremely serious consequences for the once abundant Blue-fronted Amazon (*Amazona aestiva*) of Argentina (Bucher and Martella 1986), so depleted that only the threat of a CITES Appendix I listing forced the Argentinean government to enact an export ban, which remains in force.

The world's largest parrot, the beautiful Hyacinth Macaw (*Anodorhynchus hyacinthinus*), is another casualty of the cage bird trade. These magnificent cobalt blue parrots, more than 3 feet long, are native to open, palm-studded grassland and gallery forests of west-central Brazil, with small populations in neighboring Bolivia and possibly

Paraguay. They are endangered by a totally illegal bird trade. From an original population estimated in the hundreds of thousands, the species has been reduced to between 3,000 and 5,000 birds. The United States imported a minimum of 2,130 Hyacinth Macaws between 1977 and 1988, and thousands more were imported by European countries. These birds were imported under "legal" papers from Bolivia and Argentina during the early 1980s, having been illegally captured in Brazil, which bans export of all its native birds. Bolivia has a very small population of fewer than 100 Hyacinth Macaws, yet thousands were exported from that country, listed as native on CITES documents. Transshipment of this type has nearly decimated many species of wild birds. They were sold in U.S. pet stores for $10,000 or more per bird, and shown on television shows, which whetted the public's appetite to possess these beautiful birds. Bolivia's 1984 export ban and the listing of the Hyacinth Macaw on Appendix I of CITES in 1987 stopped the disastrous "legal" trade, but unfortunately, many continue to be smuggled. Their status is now Endangered, and declining, with fewer than 10,000 birds remaining in the wild (BI 2000).

Of three other blue macaws native to South America, one is extinct, and the other two verge on extinction. The Glaucous Macaw (*Anodorhynchus glaucus*) has not been seen this century. It was the smallest of South America's three blue macaws and, in the 18th and 19th centuries, was considered numerous along major rivers in southeastern Brazil, adjacent Paraguay, northern Argentina and perhaps Uruguay (Forshaw 1989). Captured for the cage bird trade and zoos in the 19th century, trade may have caused its extinction, since its habitat remains intact (Forshaw 1989). There are continued rumors of sightings, and BirdLife International includes it in *Threatened Birds of the World* (BI 2000) as Critically Endangered.

Lear's Macaw (*Anodorhynchus leari*), which inhabits an arid, rugged terrain in northeastern Bahia, Brazil, numbers fewer than 150 birds (BI 2000). Although a few specimens had been captured in the mid-19th century, the bird was not seen in the wild by ornithologists until 1978 when Dr. Helmut Sick, a Brazilian ornithologist, finally located a small population of about 60 birds; two more tiny populations of 14 and three birds were discovered in the early 1990s a few hundred kilometers away (Collar *et al*. 1994). The main population numbered about 117 birds in 1995, but illegal trapping took as many as 25 birds in the late 1990s. In May 1999, three of these macaws were seized in a raid in North Yorkshire after being smuggled into England (*TRAFFIC Bulletin* 1999). This species faces extinction in the near future from destruction of its licuri palm trees, which provide its major palm fruit diet, hunting by local people and illegal capture for aviculture collections (BI 2000, Collar *et al*. 1994). Only a portion of the Lear's Macaw's habitat is protected by a reserve (BI 2000).

The fourth blue macaw, Spix's Macaw (*Anodorhynchus spixii*), is the most endangered bird in the world. Endemic to a very small area of northern Bahia, an arid region of northeast Brazil, hundreds of these macaws were smuggled out of Brazil in spite of being officially protected from capture, trade and export since 1967; it was listed both on the U.S. Endangered Species Act and CITES Appendix I by 1975, but this did not discourage unscrupulous aviculturists and zoos who offered prices as high as $40,000 per bird. By 1986, only three birds were known to remain in the wild (da Re 1995), and these were illegally captured by 1988. In 1990 a single male bird was discovered, the very last wild bird of his species. With no females of his species left in the wild, he began courting another species of macaw, a female Blue-winged Macaw (*Ara maracana*). A captive female Spix's Macaw was released to the wild in 1995 in the hope that they would breed, but although the two birds stayed together for a short period, they then separated and the male returned to the Blue-winged Macaw (da Re 1995). The female Spix's Macaw disappeared altogether, and is thought to have collided with a power-line (BI 2000). While kept in a zoo, this female macaw had been paired with a male, who remains in captivity (da Re 1995). Eggs laid by captive Spix's Macaws were to be placed in their nest in 2001 to be raised by this pair (BI 2000). However, this last wild Spix's Macaw, a repository for the knowledge and skills of survival for his species and crucial to the success of future releases, was illegally captured in the Fall of 2000, rendering the species extinct in the wild. Some people hope that others of his species remain undetected, since the original habitat is extensive.

About 60 wild-caught Spix's Macaws are in captivity (BI 2000), and they could provide additional vital genes and experience for reestablishment of the species. Most of these are captive-bred, and may be inbred because they descend from only ten wild macaws (da Re 1995). Undoubtedly, many more Spix's Macaws are held in unknown locations by private collectors who purchased these smuggled birds. This species' habitat of gallery forests near the Sao Francisco River has become degraded by tree cutting and livestock overgrazing, preventing the growth of young trees (da Re 1995). Only 30 square kilometers of this gallery forest remains in three fragments (BI 2000). Although the remaining wild birds are being guarded by rangers, no reserve has been established. The smuggling of these birds continues. In April 1995, three Spix's Macaws that had been illegally captured in prior years were confiscated in Chile as they were being smuggled to Russia, according to the World Society for the Protection of Animals (WSPA). The Costa Rican representative of WSPA flew with the birds to Sao Paulo, Brazil, where they were placed in the zoo with others of this species. The Spix's Macaw is an extreme example of the avid pursuit of rare birds by aviculturists--and even zoos--in defiance of all national and international protective legislation. Some of the individuals who obtained these birds illegally have refused to donate their birds to breeding projects, even though the species' status could not be more precarious. Other Spix's Macaws are possessed in secret, and owners have not stepped forward to allow their birds to be part of a cooperative breeding program.

These cases represent the tip of the iceberg of birds that have been threatened by the cage bird trade. Many island species have been endangered by this trade. Amazon parrots from Caribbean islands are among the most coveted of birds. The magnificent Imperial Amazon (*Amazona imperialis*), a highly endangered endemic from Dominica, has iridescent purple and green feathers, making it one of the most beautiful of parrots. Smugglers have paid as much as $50,000 for a single Imperial Amazon, which now number only about 300 birds in the wild. Fortunately, it is finally increasing, and a new national park protects a portion of this endangered bird's population (BI 2000). The St. Vincent Amazon (*Amazona guildingii*), of the island of St. Vincent, is the most numerous of the endangered Caribbean amazons, numbering about 800 birds as of 1994 (BI 2000). The rarest is the Puerto Rican Amazon (*Amazona vittata*), which declined from a population of 2,000 in the 1930s to about 41 birds in 1993, in large part due to illegal capture for the pet trade (Collar *et al*. 1994). It numbered 44 birds in the wild and 87 in captivity in 1996 (BI 2000). Once reduced to small numbers, many parrot species, like the Puerto Rican Amazon, do not recover. This parrot's population has not increased substantially in spite of legal protection for almost a century and an intensive conservation program. There is still a demand for Caribbean parrots, with collectors offering $20,000 or more per bird for smuggled specimens. In the book, *The Parrots of Luqillo: Natural History and Conservation of the Puerto Rican Parrot* (Snyder *et al*. 1987), the authors state: "Clearly, the high price that some aviculturists are willing to pay for rare parrots is one of the most serious threats to survival faced by the West Indian *Amazona*. It is ironic that the rationalization often used by such individuals for obtaining rare species is that they hope to 'save' them from extinction by captive propagation" (Snyder *et al*. 1987).

For one Caribbean parrot, the future is brighter. A very successful conservation program is bringing the St. Lucia Amazon (*Amazona versicolor*), endemic to the island of St. Lucia, back from near-extinction. This parrot was in steep decline until a biologist, Paul Butler, working for RARE Center for Tropical Bird Conservation in Philadelphia, Pennsylvania, began a long term project to prevent its extinction. From 150 birds in 1976, the population has risen to 200 to 250 birds in 1990 (Butler 1992), to 300 to 350 in 1996 (BI 2000). The program educated children in grade schools using songs, parrot costumes and puppets, and enlisted the help of many local businesses to use the bird as their logo or in their ads. In 1979, the St. Lucia Amazon was named the country™s official bird (Butler 1992). Posters and billboards illustrating St. Lucia Amazons were put up in public places throughout the island, and the program has sought to identify the species with national pride. Its protection is now a concern of most members of the public, and this enthusiasm to protect "their" parrot has made illegal capture and shooting almost unknown (Butler 1992). Paul

Butler's work has been so successful that he carried his program to St. Vincent to protect its native parrot, and to other islands for programs conserving their native birds (Butler 1992). The National Audubon Society's film, fiCaribbean Cool,fl about Butler's work on St. Lucia, shows the beautiful St. Lucia Amazon and programs in schools in the Caribbean region (see Video, Activism and Attitudes).

Wild Pets and Laboratory Animals: Birds: Page 5

A bird that has proven almost impossible to protect from bird trappers is the lovely, white Bali Starling or Rothschild's Myna (*Leucopsar rothschildi*), endemic to the island of Bali, Indonesia. It is now confined to a tiny area on the island's extreme northwest tip inside the Bali Barat National Park. By 1990, the wild population had been reduced to 13 birds, although the captive population was about 700 (Collar *et al*. 1994). The Bali Starling Project sought to reintroduce captive birds and reinforce guarding of the park. By 1994, the population had risen to between 35 and 55, but poaching continued, off-setting gains of successful breeding (Collar *et al*. 1994). In 1999, the wild population totaled 12 birds; the same year, 39 captive individuals in the park awaiting release to the wild were stolen by an armed gang (BI 2000). The park and conservation program have suffered from mismanagement and corruption, and the price for these birds on the black market has risen to $2,000 a bird (BI 2000). The protection offered these reintroduced birds has been inadequate, and possibly involves complicity with poachers by park guards.

The keeping of sparrows and finches is extremely popular in Latin America and parts of Asia. Two songbirds, the Brown-backed (*Myadestes occidentalis*) and Slate-colored Solitaires (*Myadestes unicolor*) in Central America, are heavily trapped, disappearing from many areas. Two ornithologists commented, "It is a sad morning indeed that one experiences forests deprived of these fine songsters" (Howell and Webb 1995). A finch that has long been subjected to bird trapping because it is bred with domestic canaries for "Red Factor Canaries," the Red Siskin (*Carduelis cucullata*), of northern Venezuela and a small area in Colombia, has become endangered from this illegal trade (Collar *et al.* 1994). This bright red bird requires moist evergreen forest, dry deciduous woodland and shrubby grassland habitat, moving from one to another seasonally. It has disappeared from Trinidad and from almost all its original range in Venezuela and Colombia (Collar *et al*. 1994) and is listed as Endangered by the *2000 IUCN Red List of Threatened Species* and the U.S. Endangered Species Act. It is also listed on Appendix I of CITES.

Steve Howell and Sophie Webb (1995), authors of a guidebook on birds of Mexico and northern Central America, commented on the bird trade in Latin America: "Paradoxically, keeping parrots and songbirds in cages about the house is considered an appreciation of nature. Sadly, the desire to have birds, particularly parrots, as pets has spread far beyond Middle America . . . Within 20 years or less, we predict that wild Scarlet Macaws and Yellow-headed Parrots may be things of the past in Mexico."

The Java Sparrow (*Padda oryzivora*), endemic to the Indonesian islands of Java, Bali and Kangean, once flocked in large numbers to towns, villages, gardens and agriculture fields. Within the past few years, however, it has undergone a precipitous decline as a direct result of heavy trapping for the cage bird trade and has become scarce, listed as Vulnerable in BirdLife International's (2000) *Threatened Birds of the World* and by the IUCN. It is not listed on CITES. In 1995, an embargo on exports from Java and Bali was put in place by the Indonesian government, and the species occurs in several national parks (BI 2000).

Sold for a Song. The Trade in Southeast Asian Non-CITES Birds, by Stephen V. Nash (1993), found that a number of birds not protected by CITES were threatened by the trade. For the most part, the species and numbers involved in the Asian bird trade are undocumented (Nash 1993b). The dual threats of bird trapping and habitat loss are causing declines in many Southeast Asian birds. Endemic species can become endangered by relatively low levels of trade because of their limited habitat. For Asian finches and other species not listed on CITES, most trade is legal, with little concern for their status in the wild. In Southeast Asia, the majority of countries allow capture and sale of wild

birds. The few countries that ban trade in wild birds, such as Thailand, have not shut down illegal bird markets in Bangkok and other cities. In Bangkok's Jatujak Market, on a given day, 616 species of native birds are offered for sale (Nash 1993b). Most Western bird owners would be startled at the types of birds sold in these markets. Although doves and finches are sold in great numbers, partridges, pheasants, geese, and barbets are offered, as well as species totally unsuited to captivity, including kingfishers, bee-eaters, storks, woodpeckers and flycatchers. Native birds that are not listed on CITES lack any protection in Indonesia, Vietnam, Laos, and Cambodia (Nash 1993b). Nowhere else in the world are there so many endemic bird species with so many countries in the region that fail to protect them, or that serve as exporters of non-native birds, such as Hong Kong and Singapore.

Wild Pets and Laboratory Animals: Birds: Page 6

Although the United States has strict laws prohibiting importation of endangered birds without permits, some aviculturists have managed to smuggle birds by using complex and clandestine routes. One truly stunning case was the indictment in 1994 of Tony Silva, an aviculturist who had represented himself as a parrot conservationist, and served as Curator of Birds at Loro Parque, a parrot zoo in the Canary Islands. This zoo has many endangered birds, including several Spix's Macaws, which have never been legally exported from Brazil, either for zoos or any other purpose. Silva was caught in a Fish and Wildlife Service Law Enforcement sting called fiOperation Renegade,fl after search warrants were issued on business records in his home and that of his mother. Searches of their premises uncovered documentation of a major smuggling operation specializing in endangered birds. Silva and his mother, who was also indicted, conspired to smuggle numerous rare birds from 1985 onward with the cooperation of a Paraguayan citizen who was also indicted, as was Hector Ugalde, a Miami citizen who aided in the conspiracy (USDJ 1994). Silva earned an estimated $1.3 million from this smuggling. Among the CITES Appendix I birds smuggled were 186 Hyacinth Macaws, seven Blue-throated Conures (*Pyrrhura cruenta*), several highly endangered Vinaceous Amazons (*Amazona vinacea*), and two endangered Golden Conures (*Aratinga guarouba*), the latter being one of the most coveted of all birds by collectors. The latter three species are also listed on the U.S. Endangered Species Act. Silva also smuggled Red-fronted and Great Green Macaws, listed on CITES Appendix I and extremely rare in the wild. Other rare species smuggled by Silva included three protected Brazilian Crimson-bellied Conures (*Pyrrhura rhodogaster*) and another Brazilian bird, and threatened Yellow-faced Amazons (*Amazona xanthops*), along with several endangered primates. Silva also illegally exported Gray Parrots from the United States to New Zealand and smuggled two endangered Red-vented Cockatoos from the Philippines, according to the indictment. In 1987, Silva received an illegal shipment of nine protected Chilean Flamingos (*Phoenicopterus chilensis*), a CITES Appendix II species (USDJ 1994). He smuggled three endangered Yellow-shouldered Amazons (*Amazona barbadensis*) as well.

According to Fish and Wildlife Service Law Enforcement agents, Silva and his co-conspirators were the foremost illegal dealers in rare birds during the entire decade of the 1990s. Lois J. Schiffer, Assistant Attorney General in charge of the Justice Department's Environment and Natural Resources Division, said: "The defendants were involved in nothing less than plundering the national treasures of other countries. These crimes threaten not only our ability but that of the international community to protect endangered species and global biodiversity" (USDJ 1996). An affidavit by an undercover Fish and Wildlife Service Special Agent (Marks 1992) attested that Silva had invited an unnamed source to his home and showed him resin-like glue that was extracted from a certain species of tree and was used in South America for the express purpose of trapping Hyacinth Macaws. Silva showed the source photographs of rare parrots dyed to look like other species of birds to avoid detection in transport. Enrique Basan, an unindicted co-conspirator who resided in Brazil, trapped many of these endangered birds and shipped them to Gisela Caseres in Paraguay, who then smuggled them to the United States (USDJ 1994).

The Hyacinth Macaws were then transported by charter aircraft and across the Mexican border, placed in PVC plastic tubing and hidden in car door panels. Many died of suffocation and overheating on the way. Some smuggled parrots were placed in false-bottomed suitcases under mounds of clothing. In 1989, wasting disease ravaged Silva's

aviary, killing many of the surviving rare birds, which he kept in a basement aviary (Marks 1992). Silva shipped 35 of the smuggled Hyacinth Macaws to Mario Tabraue, who spent time in prison on a 100-year sentence for murder and drug-related crimes. Prior to his conviction, he ran a quarantine station and wildlife importation business known as Zoological Imports. Tabraue paid Silva and his mother $100,000 for this shipment and had previously bought other smuggled animals; he would then offer the wildlife for sale in interstate and foreign commerce (USDJ 1994). All the macaws were dead on arrival (Marks 1992). Silva used closed legbands to identify fraudulently smuggled Hyacinth Macaw chicks as bred in captivity, and conspired with a bird importer, Larry Lafeber of Rosemont, Illinois, to use the latter's quarantine facilities to launder smuggled wildlife. He and Silva illegally removed U.S. Department of Agriculture quarantine seals from Lafeber's station to take smuggled wildlife out of the station. Lafeber also forged health certificates for two smuggled Hyacinth Macaws (USDJ 1994).

Silva wrote a book on endangered parrots, in which he described the Hyacinth Macaw as being "worth its weight in gold," and regularly gave lectures on parrots, presenting himself as a conservationist. In a 1991 article on the Hyacinth Macaw, he stated, "Unless all of the pressures are brought under control, this species may be unable to survive in the world to greet the 21st century" (USDJ 1996). In fact, he contributed to its endangered status. With its very slow reproduction rate, lack of protected reserves or parks in its range, and continued threats by hunters and destruction of its nesting trees, this beautiful macaw may indeed fade into extinction as a result of smuggling. Since these birds are easily recognized, and the CITES listing ended legal trade, only an extremely well-financed operation such as that conducted by Silva, involving the use of small aircraft that carried the birds from remote parts of South America to Mexico where they were smuggled over the border, could have succeeded in obtaining these birds. Australian government studies have documented that up to 10 birds die for every bird that survives smuggling, and most operations incur a mortality rate of 80 percent (PCA 1976). The Fish and Wildlife Service investigation uncovered high mortalities among the macaws Silva smuggled and, thus, he is probably responsible for the deaths of 1,860 (10 times the 186 for which he was indicted) of these rare birds.

Silva had warned of the serious consequences of rampant poaching of wild birds in a 1991 speech at the Parrot Symposium International (*The New York Times* 1996), and in a November 1995 interview, he stated, "I love birds. I could never be involved in anything that killed them" (*The New York Times* 1996). Through his smuggling, Silva was responsible for the deaths of hundreds--and perhaps thousands--of birds, of which the majority were rare and endangered species. Prior to the indictment, but after it was revealed that he was being investigated, he was interviewed by the public television station WGBH in Boston for a NOVA program, *The Great Wildlife Heist* (1994); he made statements admitting an uncontrollable desire to own rare birds (See Video - Trade).

Smuggling is the cruelest activity associated with the bird trade. Smugglers have used hundreds of concealment techniques to avoid detection when crossing borders. These include placing small birds in the center of hair curlers stacked in enclosed boxes or suitcases; stuffing parrots inside
tire wells and even hubcaps in cars; and placing them inside clothing being worn and in stifling secret compartments in shipping crates and suitcases. Birds are smuggled on rafts across the Rio Grande River, and in many cases, the rafts have overturned and the birds drowned. Sometimes when smugglers believe that they have been spotted by law enforcement officers, they kill the birds they are smuggling by intentionally drowning them or throwing them out of moving cars. Often the birds are wrapped tightly, with their wings unable to spread and their beaks taped. They die of overheating.

Silva faced a combined maximum prison term of 45 years and a maximum total fine of $2.5 million, but he reached a plea bargain with the Justice Department the day his trial was to begin in January 1996. In early June, he was jailed as a flight risk prior to sentencing. Because he was fluent in Spanish and had many contacts in other countries, the Justice Department was convinced that, in spite of the fact that a lien had been placed on his house and his passport had been seized, he might leave the country to avoid going to jail. His plea of guilty to conspiracy to violate wildlife and Customs laws, and filing a false income tax return, resulted in the longest prison term ever given to a bird smuggler, handed down in late 1996: 6 years and 10 months. His mother received a sentence of 27 months in jail. This case, like other smuggling cases in fiOperation Renegade,fl was based on a long investigation which uncovered

indisputable proof of the Silvas' guilt, as have many such indictments. Most, however, end in penalties far below what would be allowed by law. Judge Elaine Bucklo of the U.S. District Court, Northern District of Illinois, deserves considerable praise for rendering this stiff jail sentence, and also for ruling that Silva be jailed for six months prior to the sentencing. In another fiOperation Renegadefl case involving the indictment of a Florida bird importer, Louie Mantas, the defendant left the country prior to the commencement of his trial and is now a fugitive with outstanding warrants for his arrest.

Much progress has been made in giving longer sentences to wildlife smugglers. A decade ago, jail sentences for wildlife crimes were virtually unknown. New sentencing guidelines enacted by Congress recommending higher penalties have had a major role in the imposition of longer jail sentences, and judges have begun taking these crimes far more seriously than in the past.

Wild Pets and Laboratory Animals: Primates

All gibbons, tailless apes of the Hylobatidae family, are endangered, listed on Appendix I of CITES and as Endangered on the U.S. Endangered Species Act. Ten species are listed in the *2000 IUCN Red List of Threatened Species*. Gibbons inhabit the rainforests of Southeast Asia, where they have declined as a result of logging and capture for the zoo and pet trades. They communicate in whoops and haunting songs that carry for miles in the forest, and they mate for life. Their long, spidery legs and arms give them great agility as they leap large distances between trees. Until the 1970s, thousands of gibbons were imported by U.S. zoos and laboratories. CITES Appendix I listing stopped this trade, but in Asia, they are still captured for the pet trade, and babies are used to pose for photos with tourists. This trade involves the killing of many mother gibbons in order to obtain a few baby gibbons, which are so poorly treated that most die within months. In Thailand, there were an estimated 1 million gibbons as recently as 1975, but only a fraction of that number survives today. Thai forests have become fragmented, and old growth, which most species require for habitat, is nearly gone. Thailand is a country that now has laws prohibiting logging and capture and sale of most native wildlife, but enforcement is very weak. Gibbons are sometimes used as mascots in bars and stores. This is often done in the evenings on busy streets, and the gibbons are given drugs to keep them awake. In Bangkok, Leonie Vejajiva has worked for 20 years to rescue these orphaned and mistreated gibbons. Some are abandoned by their owners when they grow too large, and others are confiscated by wildlife authorities. Vejajiva estimates that 20 mothers and 19 babies are killed to get one baby for sale. The gibbons in her care have been very traumatized and abused. One is missing a finger and had all his teeth filed down to the gums to prevent him from biting. Pileated Gibbons (*Hylobates pileatus*), native to Cambodia, Laos and Thailand, are so endangered that 15,000 at most remain in the wild. Vejajiva has taken in many Pileated Gibbons, and one female had been owned by someone who put cigarettes out on her back and beat her for years. It has taken a long time for her to trust Leonie, but she remains angry and hates men. Leonie has seen her gibbons show great emotions and pine away when sad, and considers them extremely emotional and sensitive. The Thai government recently set aside a tract of 80 acres where confiscated gibbons can be kept in large, treed enclosures.

Other primates are captured for the pet trade throughout the tropics. Most countries have laws banning this practice, but it continues, nevertheless. In Vietnam, it is illegal to capture native primates, but baby macaques are commonly seen by the roadside, offered for sale by hunters who have shot the mothers. In cities, these pathetic, underfed and traumatized monkeys are kept in tiny, dirty cages and sold as pets to locals and tourists. Vietnam is exploiting its wildlife commercially on an unprecedented scale. Markets in Ho Chi Minh City and other cities offer many primates for sale, even including gibbons, and thousands are exported for the pet and laboratory trades.

In many countries, regulations ban importation of primates for the pet trade because the Public Health Services have deemed them to be a health hazard to humans. They can spread rabies and many respiratory diseases. Importation of primates for the pet trade was banned in Denmark in 1965; in the United States in 1975; and in

Finland, West Germany, Italy and Switzerland during the 1960s and 1970s (Fitzgerald 1989). Pet monkeys are still occasionally seen advertised, however, and many are brought into the United States and other countries illegally by travelers to tropical countries.

In the 1950s, 15 million monkeys were exported annually from tropical countries for medical research, primarily to develop a polio vaccine, endangering a number of species. During the 1960s, many South American countries banned commercial exports of their wildlife, but exports of primates continued. Conservationists began protesting the enormous drain on wild primate populations, and humane organizations protested the cruel treatment they received. The U.S. Endangered Species Act of 1973 listed a number of species, banning their importation, but some countries continued to export primates for this trade. Laboratory dealers would switch from one species to another to continue high imports. The U.S. Congress enacted the Laboratory Animal Welfare Act in 1966 (later renamed the Animal Welfare Act) with standards for the care of monkeys and other animals used in research. When CITES came into force in 1975, the trade was restricted greatly. All primates are now listed on either Appendix I or II. By 1979, the world primate trade dropped to 65,000 per year (Fitzgerald 1989). In the 1980s, African monkeys and Asian macaques became the major laboratory primates. These animals were often subjected to extremely cruel and unnecessary experiments. American taxpayers financed hundreds of these through grants from the National Institutes of Health. Many laboratory monkeys are now bred in captivity, yet thousands continue to be captured for the laboratory animal trade.

Almost 50,000 primates were listed by the Department of Agriculture as used in research in U.S. laboratories in 1993, according to a study by the International Primate Protection League; 19,461 of these primates were used in research causing pain and distress alleviated by drugs; and 1,353 were used in experiments causing pain and distress *not* alleviated by drugs (*IPPL News* 1995). Many of these animals are endangered species such as Chimpanzees, kept in isolated, sterile cages and used in AIDS research.

There are approximately 1,500 Chimpanzees in U.S. laboratories. The Coulston Foundation is a facility that maintains hundreds of these intelligent primates, with a record of high mortality, poor care and more than 40 violations under the Animal Welfare Act of 1966. In May 2000, the National Institutes of Health (NIH) took title to 288 Chimpanzees. Coulston tried to get them back, and NIH decided to leave them in the facility prior to a final decision about their fate. During this period, one 10-year-old Chimpanzee died after "allegedly being left sick for days without receiving veterinary care" (AWI 2001). In spite of its record, NIH continues to award funds to The Coulston Foundation, preventing its bankruptcy (AWI 2001). The 600 Chimpanzees at this foundation need to be transferred to a sanctuary where they would receive needed veterinary treatment and compassionate care (AWI 2001).

Many laboratories have made public statements indicating that when they have completed research studies on these Chimpanzees, the animals will be euthanized. Humane organizations have loudly protested this, and campaigns are being waged to place these animals in spacious enclosures so that at least the last years of their lives will be spent without trauma. When the New York University Medical Center disbanded its animal research laboratory, it planned to donate its Chimpanzees to The Coulston Foundation. Dr. Jim Mahoney, veterinarian for these primates, took it upon himself to place them in humane surroundings where they would never be experimented on again. At his own expense, even driving them to the centers in a special van, he found homes for 90 Chimpanzees in various rescue centers, including Primarily Primates in Texas and a center in Quebec where they could socialize in large areas with sleeping shelves, toys, soft blankets and jungle bars. One Chimpanzee who had never slept anywhere except the cold cement floor of his cage or felt a soft object, hugged a blanket, rolling in it in joy when he first entered the sanctuary. Jane Goodall encouraged this project and spoke of the need to treat these very sensitive animals with respect and kindness on a National Geographic Explorer program, *Chimp Rescue*, shown in November, 1998, which traced Dr. Mahoney's steps in rescuing the chimps as well as 100 monkeys.

The Chimpanzee Health Improvement, Maintenance, and Protection Act, signed into law in 2000, will facilitate projects such as Dr. Mahoney's. It will provide $30 million from the budget of the National Institutes of Health to

establish a national system of sanctuaries to provide for the long-term care of Chimpanzees no longer needed in biomedical research.

Wild Pets and Laboratory Animals: Land Turtle and Tortoise Pets

In Europe there is a sizeable market for pet tortoises and land turtles. The Mediterranean area--Greece, the Mideast and North Africa--provided millions of tortoises for decades. The Royal Society for the Prevention of Cruelty to Animals (RSPCA) investigated this trade in the 1970s and found a mortality rate of more than 80 percent in the first year of captivity (RSPCA 1980). A 1982 study found that 92 percent of 2,000 tortoises imported did not survive more than three years in captivity (Fitzgerald 1989). The number of tortoises involved was astounding--almost 2 million Spur-thighed Tortoises (*Testudo graeca*) were imported for the British pet trade between 1965 and 1977 (RSPCA 1980). More than 350,000 Hermann's Tortoises (*Testudo hermanni*), native to the northern Mediterranean, were imported during the same period (RSPCA 1980), and this species was categorized by the IUCN in 2000 as Near-Threatened (Baillie and Groombridge 1996). A species from Afghanistan, Iran, Russia and other countries of Central Asia, Horsfield's Tortoise (*Testudo horsfieldii*), has been collected in enormous numbers; 150,000 per year are taken from the wild, with nearly 100,000 exported to western Europe (Fitzgerald 1989). It is now listed as Vulnerable by the IUCN. All these species have declined precipitously in the wild (Fitzgerald 1989), and these slow-reproducing species rarely rebound quickly, even after receiving protection.

Because of the heavy exploitation of these land tortoises for the pet trade, the entire genus *Testudo* was placed on Appendix II of CITES in 1975, but this scarcely slowed the trade. Some import restrictions were enacted in 1979 by the United Kingdom, and internal trade and possession of Spur-thighed, Hermann's and Marginated Tortoises became prohibited under the 1982 Convention on the Conservation of European Wildlife and Natural Habitats (Fitzgerald 1989). However, these measures served only to slow the trade. A major development occurred when the European Economic Commission (EEC) banned imports of all three species in 1984. Hermann's Tortoises are not fully protected, however. They have been sold in California for $525 each (Fitzgerald 1989). Hundreds of protected Sri Lankan Ceylon Star Tortoises (*Testudo elegans*) were smuggled to an Australian animal dealer in the early 1980s (Fitzgerald 1989). In 1984, the only record for Horsfield's Tortoise trade was 18,000 shipped to Italy from Turkey (Fitzgerald 1989). Trade has switched to Egyptian Tortoises (*Testudo kleinmanni*), native to Egypt, Libya and Israel. This species is now one of the most threatened of Old World tortoises, listed as Endangered by the *2000 IUCN Red List of Threatened Species*. This is the smallest of the *Testudo* tortoises, only 6 inches in length, and is now being exploited only because the other species have reached near extinction.

Bolson's Tortoise (*Gopherus flavomarginatus*), native to a small remnant habitat in northern Mexico, has been decimated by the pet trade and is now listed as Endangered by the U.S. Endangered Species Act to stop imports of these tortoises across the border into the United States. The South American Chaco Tortoise (*Geochelone chilensis*) was imported from Argentina and Paraguay by European traders in the 1980s, prompting Argentina to prohibit exports in 1986 (Fitzgerald 1989).

Following the depletions of the Mediterranean tortoises, the European pet trade began exploitation of North American box turtles, genus *Terrapene*. Terrapin turtles occur in eastern North America and northern Mexico. Box turtles are about 4 to 5 inches long, with yellow geometric patterns on a black background on their shells and bodies. They spend the majority of their lives on land, and the most familiar of these, the Eastern Box Turtle (*Terrapene carolina*), lives in moist deciduous forests and grasslands. The Ornate Box Turtle (*Terrapene ornata*) inhabits grasslands and dryer areas, and the endangered Coahuilan Box Turtle (*Terrapene coahuila*) is strictly aquatic and lives only in the Cuatro Cienegas basin in northern Mexico. Until the early 1990s, the Eastern and Ornate Box Turtles were quite common, although declining from fragmentation and development of their habitat and losses from road traffic and lawn mowers. More than 3,000 Eastern Box turtles were exported from the United States in 1990 to pet dealers in

Europe and Japan, and exports increased exponentially thereafter. Records show that at least 13,585 Eastern Box Turtles were exported in 1991; 26,361 in 1992; and 23,420 in 1993, for a minimum total of 66,366 for the four years. Ornate Box Turtle exports also increased, from 7,018 in 1992 to 7,768 in 1993 (IUCN 1994). Thus, at least 78,152 of these two species of box turtle were exported in these four years alone; they are sold in European pet stores for $100 or more (Lieberman 1994). Herpetologists have been shocked at the numbers of box turtles involved in this trade, and Dr. Michael W. Klemens of the Wildlife Conservation Society said that the pressure from the collection of these turtles is "just disastrous" and "if it continues at the present rate, it is not sustainable" (Stevens 1994).

England has been a major market, as it was for the Mediterranean tortoises. "The British have always been turtle crazy," said Dr. Klemens. The irony is that the English are animal lovers, and yet many apparently fail to realize that the deaths in captivity of these long-lived turtles are a direct result of their captive conditions, improper food and treatment, and that purchasing them contributes to the turtles' endangerment. The Fish and Wildlife Service requested information from scientists and government agencies on North American box turtle status prior to the 1994 CITES meeting and documented that both the Eastern and Ornate Box Turtles are rapidly disappearing as a result of this trade.

Declines have already been recorded for these box turtles in 16 U.S. states, from Massachusetts, Connecticut and New Jersey south to Florida and west to Missouri, Oklahoma and Wisconsin (Liebermen 1994). Many states protect them from capture, and illegal trade has resulted in more than 20 arrests (Lieberman 1994). State regulations differ greatly, making conservation of the species difficult. In Florida, for example, one may possess two box turtles, Virginia allows capture of five turtles, and Mississippi as many as 20. At least 17 of the 28 states where box turtles are found prohibit or regulate commercial trade. In states without regulations, turtles can be possessed, sold or shipped out of state. Suzanne Dohm, President of the New York Turtle and Tortoise Society, which has begun a program of conservation for these turtles, expressed frustration at the legal loopholes allowing these species to decline toward extinction: "That foreign market is absolutely draining us. You can't buy a box turtle legally in New York State, but you can ship thousands of them out of Kennedy Airport. We cry about saving animals, and yet we let situations like this go on. Something's not quite right" (Stevens 1994). Based on information gathered, the United States proposed that the entire genus *Terrapene* be listed on Appendix II, which the CITES Parties did in November 1994. This listing is meant to prevent further overexploitation, since Appendix II requires that exports not be detrimental to the wild populations of a species.

The State of Louisiana applied in 1996 to export two subspecies of the Eastern Box Turtle--Gulf Coast Box Turtles (*Terrapenne carolina major*) and Three-toed Box Turtles (*Terrapenne carolina major*). Fortunately, the U.S. CITES Office of Scientific Authority recommended a zero quota for U.S. exports. Herpetologists have determined from studies of the closely related Ornate Box Turtle that long-term population declines result if total annual adult mortality exceeds 5 percent, according to the Office of Scientific Authority. Moreover, the Authority determined that domestic trade in Louisiana totaled 9,500 Gulf Coast Box Turtles, and 3,800 Three-toed Box Turtles, a significant local market. The high proportion of adults that were collected, and the very slow reproductive potential of the species, led the Scientific Authority to conclude that insufficient information on the Louisiana population exists to allow export that would not result in depletions. They, therefore, recommended a zero quota on exports of North American box turtles, an important step in preserving these animals. The lack of long-term studies showing that these turtles can be collected without harming their wild populations is another argument against the trade.

Added to the declines in wild populations is the cruel treatment these turtles receive. Many die or are greatly weakened when jammed together without food or water for shipping. A Fish and Wildlife Service inspector at Kennedy Airport in New York described their condition, "What we've been seeing is very large numbers in shipments, 1,000 or more, sometimes 2,000 box turtles going to Europe in horrible condition, kept in wet burlap sacks and cardboard boxes in their own excrement, with no food or water" (Stevens 1994). Article IV of CITES requires that the Management Authority of the export country must be satisfied that "any living specimen will be so prepared and shipped as to minimise the risk of injury, damage to health or cruel treatment." This cannot be assured under U.S. law, since no legislation exists that requires humane treatment of reptiles or amphibians in shipment. The Humane

and Healthful Transport of Mammals and Birds regulations of the Lacey Act should be expanded to include reptiles and amphibians.

Box turtles, like many land turtles and tortoises, can live very long lives, and a female box turtle typically takes a half century or more to produce just two offspring (Stevens 1994). According to Dr. Klemens, box turtles reproduce for 50 years or more, and one is said to have died at the age of 138 (Stevens 1994). This slow reproduction explains why their populations suffer immediate declines when exploited.

Trade in Radiated and Plowshare Tortoises, two of the most endangered species in the world, native to Madagascar, is discussed in the Islands chapter.

Wild Pets and Laboratory Animals: Snakes

The keeping of snakes as pets is a growing trend in the United States and elsewhere. It involves the removal of thousands of these animals from the wild, endangering many species. Some species of American snakes have become threatened by trade. The Florida Indigo Snake (*Drymarchon corais couperi*), listed as Threatened on the U.S. Endangered Species Act and a protected species throughout its range in the Southeast, can sell for $300 or more, and illegal trade has been very difficult to control. Snakes and other reptiles may be illegally captured in states protecting them, then transported to other states that allow sale of reptiles. These poached rare reptiles are also misrepresented as having been bred in captivity to avoid Lacey Act prosecutions. Many of these illegal reptiles are advertised on the Internet, where a new and huge market for reptile pets has developed, and many are sold illegally through the mail. Some pet shops sell illegally obtained reptiles, either knowingly or unknowingly. The market for rare snakes has grown to such an extent that an increasing number of species are threatened by capture.

Snakes have become prestigious status symbols for some people. Pythons and boa constrictors of various species are popular pets in spite of--or perhaps because of--their enormous size. They can reach lengths of 20 feet or more, and these large constrictors prefer live prey the size of rabbits. They present a danger to their owners and to the public, especially children, should they escape from captivity. In the summer of 1996, a 9-foot-long Burmese Python, kept as a pet by a man and his pregnant wife, was allowed to roam the house freely. The snake wrapped itself around the wife and began biting her in the back, refusing to let go even when the husband tried prying it off with a crowbar. He then called emergency 911 paramedics, who cut off its head with a hacksaw to kill it. Several cases of large constrictors, such as boas and pythons, biting adults and children have been publicized in recent years.

Wild Pets and Laboratory Animals: Frogs

A thriving trade in terrarium frogs has resulted in a worldwide market for many species of these amphibians. The world's largest frog, the Goliath Frog (*Conraura goliath*) of Central Africa, weighs 7.2 pounds and reaches a length of at least 32 inches. It is found along major rivers in dense tropical rainforests in Equatorial Guinea and southwest Cameroon (FWS 1991). Throughout its range, it is very rare and has unusual habitat requirements. It needs rapids and cascades with sandy bottoms and very clean, oxygen-rich water; deforestation has reduced this habitat (FWS 1991). Collectors have offered huge sums up to $2,500 for capture and export of Goliath Frogs--for personal pets or public exhibition. This species is listed on the U.S. Endangered Species Act as Threatened and protected from export in most of its range. Yet unscrupulous dealers capture them and ship them to collectors under false documentation. The Fish and Wildlife Service Law Enforcement Division conducted an undercover investigation in which an English animal dealer in Cameroon shipped 10 Goliath Frogs to California with false documents. Nine arrived dead, and a California judge sent the dealer to jail for 70 days. The trade in live frogs, which have extremely high death rates in

transport, extends to rare poison dart frogs of South America and threatened frogs of Madagascar (see Islands chapter). Wealthy collectors are willing to pay high prices for these amphibians. This destructive and unnecessary trade is now growing, threatening more species each year.

Legislation

The Endangered Species Act

Legislation mandating a list of rare and endangered species was first enacted by Congress in 1966. The Endangered Species Act (ESA) was amended in 1969 when foreign species were added to the list. In 1973, a comprehensive model Act replaced the latter act, providing the most extensive safeguards of any legislation in the world to protect declining species.

The ESA prohibits harassing, harming, pursuing, hunting, shooting, wounding, killing, trapping, capturing and collecting listed species, unless specifically permitted, or attempting to engage in such activities within the United States or its territorial seas. Taking on the high seas is also prohibited, as are possessing, selling, delivering, carrying, transporting or shipping any species unlawfully taken within the United States, its territorial seas or on the high seas. It is also unlawful to deliver, receive, carry, transport or ship in interstate or foreign commerce in the course of commercial activity listed species, or to sell or offer listed species for sale in interstate or foreign commerce. The prohibitions apply to listed species, live and dead, their parts, and products made from their parts.

Species are listed in two categories: Endangered and Threatened. Endangered is defined as any species which is in danger of extinction throughout all--or a significant portion--of its range. Prohibitions on activities that affect species may be less strict for animals listed in the Threatened category, but these are regulated by the U.S. Fish and Wildlife Service (USFWS) on a species-by-species basis. The ESA also allows listing species similar in appearance to those that are Endangered or Threatened, when doing so would provide additional protection for the listed species.

Stiff penalties may be imposed for violations of the Endangered Species Act. Felonies may be punished with fines up to $50,000 and/or one year imprisonment for crimes involving endangered species, and $25,000 and/or six months imprisonment for crimes involving threatened species. Misdemeanors or civil penalties are punishable by fines up to $25,000 for crimes involving endangered species and $12,000 for crimes involving threatened species. A maximum of $1,000 can be assessed for unintentional violations. Rewards of up to $2,500 are paid for information leading to convictions.

The ESA has been extremely effective in saving wildlife and plant species in danger of extinction. Contrary to some who have claimed that the Endangered Species Act has interfered with government and private projects, there have been very few conflicts, and on the whole, these have been resolved to the satisfaction of both parties. The Northern Spotted Owl controversy was resolved by government retraining of loggers and an increase in high technology jobs that more than compensated for jobs lost. Other arrangements have been made with paper companies to protect the endangered Red-cockaded
Woodpecker and, in southern California, with developers to protect the Coachella Fringe-toed Lizard. As of August 2001, the USFWS had issued 500 permits for 360 "Habitat Conservation Plans.fl Many involve financial benefit to landowners. If landowners donate land where endangered species are found to a nonprofit organization or the federal government, the transaction is tax-deductible. In spite of economic interests who wish to weaken the ESA, the majority of Americans support the law and protection of endangered species (see Vanishing Species chapter).

As of July 31, 2001, the Act listed 1,802 species of animals and plants as Endangered or Threatened. Of these, a total of 507 animal and plant species were native to the United States. The Act has been instrumental in saving native species, including endangered species such as the California condor, the Black-footed Ferret and the Bald Eagle, and Threatened species such as the Northern Spotted Owl. Programs of habitat protection, captive breeding, and other means of aiding in the recovery of listed species have prevented the extinction of hundreds of plant and animal species, many little known to the American public. The Hawaiian Islands have the largest number of listed species as a result of the destruction of native ecosystems and species by introduced animals and diseases, and clearing of forests

for agriculture and ranching.

The Endangered Species Act has also been important in regulating the importation and exportation of exotic species listed. Foreign species listed totaled 555 animal and three plant species on July 31, 2001. These species include Leopards; Tigers; all species of rhinoceros; the great whales; the Andean Condor; Harpy Eagle; Imperial Parrot, among many other parrot species; Resplendent Quetzal; all sea turtles; numerous endangered tortoises; endangered caiman and crocodiles; iguanas; and fish, as well as seven endangered foreign invertebrates. Mammals comprise the majority of foreign species--251 Endangered and 17 Threatened (compared with only 63 Endangered and 9 Threatened U.S. species). These listings have prevented importation of many endangered species and their products. Prior to importation of any listed species, or part thereof, a permit must be obtained from the USFWS. Permits are not granted for commercial exploitation of non-captive-bred endangered species. Commercial importation of Leopard, Tiger or Ocelot skins, for example, is not allowed under the ESA. In spite of the severe penalties that can be exacted under the law, including jail sentences, illegal imports continue, and thousands are confiscated by USFWS agents each year. Many are tourist purchases, such as stuffed sea turtles, fur coats, and taxidermy specimens. Others are commercial items, such as reptile skins and, recently, products for the Asian medicine trade--Tiger bones and powdered rhinoceros horn.

For zoos, importation of live wild-caught specimens of endangered species requires ESA permits. If the species is listed on the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), which lists many of the same species on Appendix I (the category for species threatened with extinction), both import permits from the U.S. CITES authorities and export permits from foreign CITES authorities are required. The USFWS has required rigid proof that importation of listed species would not result in declines in wild populations of that species, except for emergency situations where wild populations are under extreme threats such as uncontrolled poaching or habitat destruction. The combined burden of proof needed for ESA and CITES has been essential in preventing needless removal from the wild of endangered species. With the proliferation of wild animal parks, small zoos, and animals used in entertainment, the pressure to weaken the ESA to allow importation of endangered species has increased. One wildlife dealer wrote an editorial in a trade journal, *Pet Business* (March 1995), that encouraged weakening the ESA: "There is no logical reason for our government to pay hundreds of thousands of dollars, if not millions, a year to control non-indigenous endangered species." Without strict regulations under the ESA, however, the Act will lose its value in preventing commercialism of endangered species around the world.

Convention on International Trade in Endangered Species of Wild Fauna and Flora

The Endangered Species Act of 1973 also implements the provisions of the Convention on International Trade in Endangered Species of Wild Fauna and Flora, known as CITES. The purpose of CITES is to prevent international trade from contributing to the endangerment of any species. To achieve this, CITES establishes a system of trade controls that vary in their restrictiveness, depending upon the degree of jeopardy each species faces. The trade controls imposed by CITES apply only to the species listed on three Appendices to the Treaty. The species listed on Appendix I of the Treaty receive the most protection; they cannot be imported or exported for primarily commercial purposes. To be traded for other purposes, such as zoological or scientific imports, a specimen of any species listed in Appendix I must be accompanied by an export permit from the exporting country and an import permit from the importing country.

Species on Appendix II of CITES, which are the vast majority of all species protected by the Treaty, can be traded for both commercial and noncommercial purposes. However, they must be accompanied by an export permit, which may be issued only upon the finding that the export of the specimens concerned will not be detrimental to the survival of the species. This requirement allows countries to control trade in those species listed on Appendix II.

Member countries may unilaterally list species on Appendix III that are protected within the countries' borders. The purpose of Appendix III is to obtain international cooperation in the enforcement of national conservation laws. Countries importing specimens of a species listed on Appendix III--from the country responsible for including the species on the Appendix--must insist upon presentation of a permit showing that the specimens were lawfully acquired and exported from that country.

Marine Mammal Protection Act

Prior to passage of the Marine Mammal Protection Act (MMPA), millions of dolphins were drowned in purse seine nets set for tuna. The MMPA, enacted in 1972, established a moratorium on the taking and importation of marine mammals except under permit. The authority for protecting these animals is divided between two departments. The U.S. Department of the Interior™s Fish and Wildlife Service (USFWS) is responsible for management authority for the Sea Otter, Walrus, Polar Bear and Dugong, among others; while the U.S. Department of Commerce™s National Marine Fisheries Service (NMFS) has authority over cetaceans and seals. Under the MMPA, it is unlawful to harass, hunt, capture or kill any marine mammal on the high seas, in water or on lands under the jurisdiction of the United States except under permit.

The MMPA requires a permit prior to capturing marine mammals in all waters worldwide for public display or scientific research. These permits are issued by the USFWS or the NMFS under strict regulations. Once in captivity, the animals are under the jurisdiction of the Animal Welfare Act, which is enforced by the U.S. Department of Agriculture (USDA). Fishing vessels must apply for permits if their operations result in incidental kills; permits can be issued only if the killing, such as drowning in fishing nets, would not cause declines in wild populations below fipotential biological removal levels,fl defined as the largest number that can be killed in optimum sustainable populations. This means that populations of a particular area, such as the California Sea Lions, are used as a basis for permits, not the species™ overall population. The funding for Observers on fishing boats to verify the reports of numbers of seals, sea lions and cetaceans drowned in nets is not great enough to require Observers on all fishing boats. In general, NMFS has stated that reports of mortalities on boats without Observers total in the hundreds, but when Observers are present, thousands of marine mammals are documented as drowned. The influence of the fishing industry on issuance of these permits and formulation of regulations by the U.S. Congress has been significant. Between 1988 and 1994, all regulations on incidental kills were suspended prior to the development of present regulations under Sections 117 and 118, allowing the deaths of untold numbers of marine mammals. The present rules are far less stringent and allow higher mortality of whales, such as Humpback Whales, in ground fisheries. Regional Advisory Commissions assess each fishery to determine methods of reducing mortality. Fishing lines, nets and other apparatus have been responsible for the deaths of many endangered Northern Right Whales along Atlantic coasts in recent years, and far more regulations are needed under both the MMPA and the ESA to prevent these deaths.

Importation and exportation of marine mammals is regulated by permit as well, and very few wild marine mammals have been allowed to be imported or exported under the MMPA. In addition, the MMPA prohibits the use of any port or harbor under U.S. jurisdiction for any purpose connected with the unlawful taking or importation of any marine mammal. It is prohibited to possess any unlawfully taken marine mammal, including parts or products, and it is prohibited to transport, purchase, sell, or offer to purchase or sell any marine mammal, including parts and products. Unfortunately, the importation of Polar Bear trophies from Canada has become easier through weakening of the MMPA. The Safari Club International, a powerful trophy hunting lobby, was successful in obtaining the latter weakening of the MMPA.

Lacey Act - Feather Trade

The fashion of wearing bird feathers in women™s hats began in the court of Louis XVI of France when Marie Antoinette appeared in a headdress with feather plumes (Doughty 1975). The fashion gradually spread in Europe and later in the colonies of the United States. By 1850, the business of killing birds for the millinery trade was practiced on a large scale, involving the deaths of hundreds of thousands of birds in many parts of the world. Egrets were a prime target, especially birds in breeding plumage when their most elegant plumage was displayed. Hunters killed adult birds, leaving the chicks to die in the scorching sun. Sometimes feathers were pulled from wounded birds, which were left to die of exposure or starvation. Herons and other wading birds along the east coast and in the Everglades were slaughtered in huge numbers. Songbirds were also popular, and entire birds were stuffed and exhibited on the hats of Victorian women. The plumage of terns and gulls was commonly used, and entire breeding colonies numbering more than 10,000 birds were killed. One New York woman negotiated in 1884 with a Parisian millinery to deliver 40,000 or more bird skins; she hired gunners to kill as many terns as possible at ten cents a skin (Doughty 1975).

In order to stop this disastrous trade, as well as the trafficking in wild deer and other animals for the meat trade, the Lacey Act was passed in 1900. The Lacey Act enhanced existing laws by prohibiting interstate commerce in wildlife protected by state statute. Fines of $500 for "knowingly" transporting wildlife or products protected in another state, and $200 for "knowingly" receiving such articles, were at first assessed. Many states had protected their native birds from the feather slaughters and banned the sale of feathers, but bird hunters would transport the feathers to states where the birds were not native to sell them. The Lacey Act prohibited this interstate commerce in protected species. If, for example, egrets protected from killing by Alabama law were shot and their feathers shipped across state lines to New York, a Lacey Act violation would have been committed. The Act ended most of the commercial plume trade in Native American birds. The failure of some states to enact laws to protect their wildlife kept the Act from being 100 percent effective. The Migratory Bird Treaty Act of 1918 closed these loopholes by protecting all native migratory birds.

The Lacey Act prohibits the import, export, transportation, sale, receipt, acquisition or purchase of fish, wildlife or plants that are taken, possessed, transported or sold in violation of any federal, state, tribal or foreign law. By the turn of the century, the feather trade had nearly eliminated egrets in the United States, and populations of numerous other bird species were approaching extinction. The National Audubon Society employed guards to protect the few remaining colonies in remote parts of Florida. Three of the wardens lost their lives protecting the birds, and if the Lacey Act of 1900 and accompanying state laws had not been enacted, many species of birds would almost certainly have become extinct.

One of the first violations of the Act involved feather merchants. On Laysan Island in the Pacific, a shocking slaughter occurred. Hundreds of thousands of Laysan and Black-footed Albatross nested on this 2-mile-long island west of Hawaii. In 1909, a feather merchant hired 23 Japanese laborers to kill the nesting birds, which are tame and unwilling to leave their nests, even when attacked. Clumsy on land, the albatross need to run with wings spread, allowing the wind to buoy them before they can take flight. This makes them helpless in the face of men striking them with sticks and bats. During several months, 300,000 sea birds were killed, mainly to obtain their wings. The wings were cut off the living birds, leaving them to bleed to death; others were herded into a dry cistern and kept by the hundreds to starve to death in order to use up the fatty tissue next to the skin so that little or no cleaning was required to prepare the feathered skin (Hornaday 1913). A zoology professor from the College of Honolulu heard of this slaughter and wired federal authorities in Washington, since the island was part of U.S. territory, and the birds were protected. The merchants planned to take the bird feathers and wings to the Orient to sell. The Secretary of the Navy dispatched a cutter to Laysan, finding the carcasses, bones and three carloads of wings, feathers and skins. The

poachers were arrested and taken to Honolulu for trial (Hornaday 1913). The same year, President Theodore Roosevelt issued an Executive Order creating the Hawaiian Islands Reservation for Birds, including Laysan Island, which is now a national wildlife refuge. Unfortunately, the same feather merchant who committed the albatross slaughter, introduced rabbits to the island, which stripped the vegetation. The Laysan Rail later became extinct as a result of the rabbits and predation by rats introduced in the 1940s. The albatross have slowly recovered but, being long-lived and slow-reproducing, they are extremely vulnerable to any losses in their populations.

The feather merchants fought state laws banning killing of migratory birds after passage of the Lacey Act, especially in East Coast cities, where the millinery trade was headquartered. The Millinery Association lobbied for the repeal of a New York law banning sale of native bird feathers and brought many witnesses to Albany to prove that enforcement of the law would cause thousands of people to lose their jobs (Hornaday 1913). In 1911, the New York State Legislature refused to repeal this law. The millinery workers did not, in fact, lose their jobs; hat decorations were merely changed from feathers to silk, ribbons and lace (Hornaday 1913).

The problem remained, however, as exotic birds continued to be slaughtered for the millinery trade. Plume hunters combed the marshes of Central America, killed entire rookeries of egrets and herons, netted thousands of tiny hummingbirds in Brazil, and killed rare birds of paradise in New Guinea, and even Andean Condors in South America. In 1911, the feathers of 129,000 egrets; 13,598 herons; 20,698 birds of paradise; 41,090 hummingbirds; 9,464 eagles, condors and other birds of prey; and 9,472 other birds were sold at auction in London for the millinery trade (Hornaday 1913). The scope of the Lacey Act was later enlarged to cover foreign species.

The Lacey Act applies to all wildlife, and the once rampant trade in deer, elk and other game species killed for the restaurant trade was also severely curtailed. More recently, the Lacey Act stopped much of the illegal killing of American Alligators for the reptile products trade prior to the passage of the Endangered Species Act. Sale of alligator skins in the Northeast from alligators killed illegally in the Everglades, for example, was a Lacey Act violation if the source of the skins could be proven.

Amendments to the Act in 1981, which provided, among other things, the authority for warrantless search and seizure when violations are suspected, were designed to: 1) strengthen federal enforcement of laws to protect wildlife; and 2) improve relevant federal assistance to states and foreign governments. The Act is used to control the smuggling of and trade in illegally taken wildlife. Amendments raised maximum penalties under the Lacey Act to sentences of up to one year in jail and/or fines of up to $100,000 for misdemeanors, and five years imprisonment and/or fines up to $250,000 for felonies. Maximum fines for organizations in violation of the Lacey Act are $200,000 for misdemeanor violations and $500,000 for felonies. In addition, vehicles, aircraft, and equipment used in a violation, as well as illegally obtained fish, wildlife, and plants, may be subject to forfeiture. Persons who provide information on violations of the Lacey Act may be eligible for cash rewards.

Humane and Healthful Transport Regulations

The Humane and Healthful Transport of Wild Mammals and Birds into the United States are regulations authorized by Congress in 1981 under the Lacey Act. These regulations are extremely important in curtailing the high mortality and inhumane treatment animals receive on importation into the United States. Between 1980 and 1991, 348,318 cage birds arrived dead at U.S. ports of entry, according to USDA records. In some cases, entire shipments of birds had been so poorly crated, fed, and watered, that most of the birds were dead on arrival. CITES, to which the United States is a Party, requires that "any living specimen will be so prepared and shipped as to minimize the risk of injury, damage to health or cruel treatment."

Until the United States finalized its humane transport regulations, little could be done to stop these high-mortality

shipments, either under the Live Animal Regulations of the International Air Transport Association, which are approved by CITES, or existing regulations of the Lacey Act, which were vaguely written. The first version of the humane transport regulations was finalized in 1987, but the USFWS decided to delay the effective date for six months. The Animal Welfare Institute and 10 other animal protective organizations filed suit in U.S. District Court in March 1988 and succeeded in obtaining an injunction requiring the USFWS to enforce the regulations immediately. Later in 1988, the Service began work to modify the regulations, which were not finalized until June 1992. Thus, a delay of 11 years took place between Congress' mandate to formulate these regulations and the finalization. The final regulations require spacious cages, adequate food and water, frequent inspection during airline flights for both birds and mammals, and other safeguards to prevent mortality. In 1993, numerous violations of these regulations resulted in court cases and high fines. Most of the violations involved crowding too many birds in each crate. Present regulations allow 25 psittacine birds per crate and 50 non-psittacine perching birds, and many importers attempt to flout the regulations.

African Elephant Conservation Act

The purpose of this Act, passed in 1988, is to provide additional protection for the African Elephant. The Act established an assistance program to the countries of Africa where Elephants are indigenous and provided for the establishment of an African Elephant Conservation Fund. In addition, the Act placed a moratorium on the importation of raw or worked ivory from African countries. The ban on U.S. imports was crucial in cutting off a major market in ivory and led the way to the listing of this species on Appendix I of CITES, which ended the legal trade worldwide in 1989.

Migratory Bird Treaty Act

Signed in 1918, the Migratory Bird Treaty Act (MBTA) between Great Britain on behalf of Canada and the United States prohibited the killing of non-game migratory birds. This Treaty represented decades of effort by conservationists attempting to stop the slaughter of native birds for sale in meat markets and the millinery trade. A patchwork of state laws, bolstered by the Lacey Act of 1900, had not been entirely successful in stopping the sale of protected wildlife, especially birds, in the United States. In addition, it was recognized that many of the birds killed in the United States were Canadian in origin. The continent's birds do not recognize national boundaries. Moreover, many species migrate between North America, Russia and Japan. Others winter in, or migrate through, Mexico. In 1936, Mexico became a signatory; in 1976, the Soviet Union; and in 1972, Japan. Sea birds and birds of prey were added to the MBTA in 1972 in a signed agreement with Mexico. All these Treaties are implemented under the Act. Except for those birds hunted during seasons established by the U.S. Secretary of the Interior, all migratory birds are protected by law from killing, capture, possession and sale. The USFWS, through its Law Enforcement Division, has interpreted the MBTA strictly.

Some 65 species of birds can be legally hunted in the United States under regulations promulgated annually by the Department of the Interior. These birds include most species of ducks, geese, swans, wild pigeons, doves, Sandhill Cranes, American Woodcock, grouse, crows, Wild Turkey and quail.

For the majority of the estimated 800 species of birds breeding in North America, the MBTA has allowed recovery from the disastrous free-for-all market hunting of the 19th and early 20th centuries that caused the extinctions of the Labrador Duck, Great Auk, Passenger Pigeon, Eskimo Curlew and Heath Hen, and the near extinction of many others. The Act also prohibits the capture of live birds for the cage bird trade. It is not legal to trap Cardinals, American Robins, Blue Jays or other songbirds, either for use as personal pets or for sale in pet stores. While most

Americans are aware of the protection of their native birds, an increasing number of problems have arisen involving immigrants from countries where birds are not protected. While knowledge of the U.S. Constitution and many aspects of U.S. history are required for citizenship exams, little or no knowledge of laws relating to wildlife and natural resources is required, nor is such information given to newly arrived immigrants.

The regulations prohibit, except as allowed under specific conditions,
the taking, possession, purchase, sale, or bartering of any migratory bird, including the feathers or other parts, nests, eggs or migratory bird products. "Taking" is defined as pursuing, hunting, shooting, shooting at, poisoning, wounding, killing, capturing, trapping, or collecting migratory birds. Migratory bird hunting regulations established by the USFWS allow, during designated seasons, the taking of ducks, geese, doves, rai, woodcock and some other species. In addition, permits may be granted for various noncommercial activities involving birds bred in captivity. Individuals and organizations may be fined up to $5,000 and $10,000 respectively, and those convicted may face up to six months imprisonment for misdemeanor violations of the Act. Felony violations may result in fines of up to $25,000 for individuals and $500,000 for organizations and up to two years imprisonment for those convicted.

For the future, binding treaties with Latin American and Caribbean nations would protect North American birds wintering in those countries. This would be especially important in view of the decline in many of the continent's songbirds and shorebirds, partly attributable to deforestation on the birds' wintering grounds. In some Latin American countries, North American shorebirds are hunted for food.

Eagle Protection Act

Passed in 1940, this Act makes it illegal to import, export, or take Bald or Golden Eagles or to sell, purchase, or barter parts, nests, eggs or products made from the animals. "Taking" encompasses pursuing, shooting, shooting at, poisoning, wounding, killing, capturing, trapping, collecting, molesting, or disturbing. Permits may be granted for scientific, exhibitory, or Indian religious purposes. However, no permits may be issued for the import, export, or commercialization of eagles. Misdemeanor violations may result in fines of up to $100,000 for individuals and $200,000 for organizations, and one year imprisonment. For felony violations, fines of up to $250,000 and $500,000 for individuals and organizations, respectively, and two years imprisonment may result. Persons providing information leading to the conviction of violators of the Eagle Protection Act may be eligible for cash rewards.

This legislation provides additional protection for the nation's two native eagle species, beyond the protection offered by the Migratory Bird Treaty Act and, in the case of the Bald Eagle, the Endangered Species Act. Numerous prosecutions have taken place of persons poisoning, shooting and otherwise harming these birds. Many sheep ranchers in the West, wrongly convinced that Golden Eagles are predators of lambs, have poisoned and shot hundreds of these birds. Bald Eagles have been shot for an active trade in Indian artifacts, such as feather headdresses. The Bald Eagle has been proposed for removal from the Endangered Species Act even though its populations remain at a fraction of original numbers and mortality in some areas is high. Should the Bald Eagle be removed from the Endangered Species Act, the Eagle Protection Act will remain a strong protection.

Wild Bird Conservation Act

The Wild Bird Conservation Act (WBCA) of 1992 is an extremely important law restricting the massive importation of wild birds into the United States for the cage bird trade. This law bans the importation into the United States of the majority of wild-caught birds. All species listed on the various appendices of CITES were banned from commercial importation one year after passage of the law. This effectively banned importation of wild parrots,

hummingbirds, birds of prey and many other birds on CITES. Regulations allow importation of birds for captive breeding under permit, and exempt species that are available only as captive-bred birds, such as canaries, cockatiels and budgerigars. Importation of birds bred in foreign countries is regulated. Zoos are exempt from the law's provisions, except that they must obtain permits for imports and provide documentation on species to be imported. The USFWS issues permits for all imported birds not specifically exempted or unlisted by CITES. The net result of the passage of this bill has been a drastic reduction in bird imports. (For more information on this law, see the Trade chapter.)

NAFTA and WTO

Two major trade treaties have been enacted that affect wildlife and the environment: the North American Free Trade Agreement (NAFTA) and the World Trade Organization, formed from the General Agreement on Tariffs and Trade (GATT). These international treaties establish panels to adjudicate conflicts over trade involving domestic legislation. NAFTA is a trade agreement negotiated with Canada and Mexico that, in principle, is intended to create a free market similar to the European Economic Union. GATT is a worldwide treaty that also encourages free trade, but through its World Trade Organization (WTO), a legal panel, it can require countries whose domestic legislation interferes with free trade to pay high fines, change the law or face retaliatory trade sanctions by other GATT nations. In 1991, for example, the Director-General of GATT appointed a panel to mediate a trade dispute between Mexico and the United States concerning the U.S. embargo on tuna products caught by setting lethal purse seine nets, which catch dolphins and drown untold thousands of these intelligent mammals. The Panel found that the Marine Mammal Protection Act was inconsistent with the treaty because domestic legislation could not interfere with free trade, a major component of this treaty. Since this was prior to the participation of the United States in WTO, U.S. government officials, after heavy lobbying from animal protection and environmental organizations, chose to block adoption of the Panel ruling. Now that the United States is a member of WTO, the Panel's decisions will have to be adhered to.

It is conceivable that the Marine Mammal Protection Act, along with the Endangered Species Act, the Lacey Act, and other laws affecting the environment, might be seriously weakened if rulings by the WTO determine aspects of these laws to be anti-free trade. For example, the WTO ruled against the United States in a case involving the importation of shrimp from countries that did not use nets designed to exclude sea turtles to prevent their drowning. U.S. laws allow such an embargo, but WTO decided this regulation was against the principles of free trade and ordered the United States to change its laws to allow shrimp to enter no matter how it was caught. WTO and NAFTA threaten U.S. sovereignty and may negate important legislation protecting wildlife and the environment, opening up trade in endangered, threatened and mistreated animals.

Legislation

http://www.endangeredspecieshandbook.org/legislation_lacey.php

The Endangered Species Act

Legislation mandating a list of rare and endangered species was first enacted by Congress in 1966. The Endangered Species Act (ESA) was amended in 1969 when foreign species were added to the list. In 1973, a comprehensive model Act replaced the latter act, providing the most extensive safeguards of any legislation in the world to protect declining species.

The ESA prohibits harassing, harming, pursuing, hunting, shooting, wounding, killing, trapping, capturing and collecting listed species, unless specifically permitted, or attempting to engage in such activities within the United States or its territorial seas. Taking on the high seas is also prohibited, as are possessing, selling, delivering, carrying, transporting or shipping any species unlawfully taken within the United States, its territorial seas or on the high seas. It is also unlawful to deliver, receive, carry, transport or ship in interstate or foreign commerce in the course of commercial activity listed species, or to sell or offer listed species for sale in interstate or foreign commerce. The prohibitions apply to listed species, live and dead, their parts, and products made from their parts.

Species are listed in two categories: Endangered and Threatened. Endangered is defined as any species which is in danger of extinction throughout all--or a significant portion--of its range. Prohibitions on activities that affect species may be less strict for animals listed in the Threatened category, but these are regulated by the U.S. Fish and Wildlife Service (USFWS) on a species-by-species basis. The ESA also allows listing species similar in appearance to those that are Endangered or Threatened, when doing so would provide additional protection for the listed species.

Stiff penalties may be imposed for violations of the Endangered Species Act. Felonies may be punished with fines up to $50,000 and/or one year imprisonment for crimes involving endangered species, and $25,000 and/or six months imprisonment for crimes involving threatened species. Misdemeanors or civil penalties are punishable by fines up to $25,000 for crimes involving endangered species and $12,000 for crimes involving threatened species. A maximum of $1,000 can be assessed for unintentional violations. Rewards of up to $2,500 are paid for information leading to convictions.

The ESA has been extremely effective in saving wildlife and plant species in danger of extinction. Contrary to some who have claimed that the Endangered Species Act has interfered with government and private projects, there have been very few conflicts, and on the whole, these have been resolved to the satisfaction of both parties. The Northern Spotted Owl controversy was resolved by government retraining of loggers and an increase in high technology jobs that more than compensated for jobs lost. Other arrangements have been made with paper companies to protect the endangered Red-cockaded
Woodpecker and, in southern California, with developers to protect the Coachella Fringe-toed Lizard. As of August 2001, the USFWS had issued 500 permits for 360 "Habitat Conservation Plans.fl Many involve financial benefit to landowners. If landowners donate land where endangered species are found to a nonprofit organization or the federal government, the transaction is tax-deductible. In spite of economic interests who wish to weaken the ESA, the majority of Americans support the law and protection of endangered species (see Vanishing Species chapter).

As of July 31, 2001, the Act listed 1,802 species of animals and plants as Endangered or Threatened. Of these, a total of 507 animal and plant species were native to the United States. The Act has been instrumental in saving native species, including endangered species such as the California condor, the Black-footed Ferret and the Bald Eagle, and Threatened species such as the Northern Spotted Owl. Programs of habitat protection, captive breeding, and other means of aiding in the recovery of listed species have prevented the extinction of hundreds of plant and animal species, many little known to the American public. The Hawaiian Islands have the largest number of listed species as a result of the destruction of native ecosystems and species by introduced animals and diseases, and clearing of forests

for agriculture and ranching.

The Endangered Species Act has also been important in regulating the importation and exportation of exotic species listed. Foreign species listed totaled 555 animal and three plant species on July 31, 2001. These species include Leopards; Tigers; all species of rhinoceros; the great whales; the Andean Condor; Harpy Eagle; Imperial Parrot, among many other parrot species; Resplendent Quetzal; all sea turtles; numerous endangered tortoises; endangered caiman and crocodiles; iguanas; and fish, as well as seven endangered foreign invertebrates. Mammals comprise the majority of foreign species--251 Endangered and 17 Threatened (compared with only 63 Endangered and 9 Threatened U.S. species). These listings have prevented importation of many endangered species and their products. Prior to importation of any listed species, or part thereof, a permit must be obtained from the USFWS. Permits are not granted for commercial exploitation of non-captive-bred endangered species. Commercial importation of Leopard, Tiger or Ocelot skins, for example, is not allowed under the ESA. In spite of the severe penalties that can be exacted under the law, including jail sentences, illegal imports continue, and thousands are confiscated by USFWS agents each year. Many are tourist purchases, such as stuffed sea turtles, fur coats, and taxidermy specimens. Others are commercial items, such as reptile skins and, recently, products for the Asian medicine trade--Tiger bones and powdered rhinoceros horn.

For zoos, importation of live wild-caught specimens of endangered species requires ESA permits. If the species is listed on the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), which lists many of the same species on Appendix I (the category for species threatened with extinction), both import permits from the U.S. CITES authorities and export permits from foreign CITES authorities are required. The USFWS has required rigid proof that importation of listed species would not result in declines in wild populations of that species, except for emergency situations where wild populations are under extreme threats such as uncontrolled poaching or habitat destruction. The combined burden of proof needed for ESA and CITES has been essential in preventing needless removal from the wild of endangered species. With the proliferation of wild animal parks, small zoos, and animals used in entertainment, the pressure to weaken the ESA to allow importation of endangered species has increased. One wildlife dealer wrote an editorial in a trade journal, *Pet Business* (March 1995), that encouraged weakening the ESA: "There is no logical reason for our government to pay hundreds of thousands of dollars, if not millions, a year to control non-indigenous endangered species." Without strict regulations under the ESA, however, the Act will lose its value in preventing commercialism of endangered species around the world.

Convention on International Trade in Endangered Species of Wild Fauna and Flora

The Endangered Species Act of 1973 also implements the provisions of the Convention on International Trade in Endangered Species of Wild Fauna and Flora, known as CITES. The purpose of CITES is to prevent international trade from contributing to the endangerment of any species. To achieve this, CITES establishes a system of trade controls that vary in their restrictiveness, depending upon the degree of jeopardy each species faces. The trade controls imposed by CITES apply only to the species listed on three Appendices to the Treaty. The species listed on Appendix I of the Treaty receive the most protection; they cannot be imported or exported for primarily commercial purposes. To be traded for other purposes, such as zoological or scientific imports, a specimen of any species listed in Appendix I must be accompanied by an export permit from the exporting country and an import permit from the importing country.

Species on Appendix II of CITES, which are the vast majority of all species protected by the Treaty, can be traded for both commercial and noncommercial purposes. However, they must be accompanied by an export permit, which may be issued only upon the finding that the export of the specimens concerned will not be detrimental to the survival of the species. This requirement allows countries to control trade in those species listed on Appendix II.

Member countries may unilaterally list species on Appendix III that are protected within the countries' borders. The purpose of Appendix III is to obtain international cooperation in the enforcement of national conservation laws. Countries importing specimens of a species listed on Appendix III--from the country responsible for including the species on the Appendix--must insist upon presentation of a permit showing that the specimens were lawfully acquired and exported from that country.

Marine Mammal Protection Act

Prior to passage of the Marine Mammal Protection Act (MMPA), millions of dolphins were drowned in purse seine nets set for tuna. The MMPA, enacted in 1972, established a moratorium on the taking and importation of marine mammals except under permit. The authority for protecting these animals is divided between two departments. The U.S. Department of the Interior™s Fish and Wildlife Service (USFWS) is responsible for management authority for the Sea Otter, Walrus, Polar Bear and Dugong, among others; while the U.S. Department of Commerce™s National Marine Fisheries Service (NMFS) has authority over cetaceans and seals. Under the MMPA, it is unlawful to harass, hunt, capture or kill any marine mammal on the high seas, in water or on lands under the jurisdiction of the United States except under permit.

The MMPA requires a permit prior to capturing marine mammals in all waters worldwide for public display or scientific research. These permits are issued by the USFWS or the NMFS under strict regulations. Once in captivity, the animals are under the jurisdiction of the Animal Welfare Act, which is enforced by the U.S. Department of Agriculture (USDA). Fishing vessels must apply for permits if their operations result in incidental kills; permits can be issued only if the killing, such as drowning in fishing nets, would not cause declines in wild populations below fipotential biological removal levels,fl defined as the largest number that can be killed in optimum sustainable populations. This means that populations of a particular area, such as the California Sea Lions, are used as a basis for permits, not the species™ overall population. The funding for Observers on fishing boats to verify the reports of numbers of seals, sea lions and cetaceans drowned in nets is not great enough to require Observers on all fishing boats. In general, NMFS has stated that reports of mortalities on boats without Observers total in the hundreds, but when Observers are present, thousands of marine mammals are documented as drowned. The influence of the fishing industry on issuance of these permits and formulation of regulations by the U.S. Congress has been significant. Between 1988 and 1994, all regulations on incidental kills were suspended prior to the development of present regulations under Sections 117 and 118, allowing the deaths of untold numbers of marine mammals. The present rules are far less stringent and allow higher mortality of whales, such as Humpback Whales, in ground fisheries. Regional Advisory Commissions assess each fishery to determine methods of reducing mortality. Fishing lines, nets and other apparatus have been responsible for the deaths of many endangered Northern Right Whales along Atlantic coasts in recent years, and far more regulations are needed under both the MMPA and the ESA to prevent these deaths.

Importation and exportation of marine mammals is regulated by permit as well, and very few wild marine mammals have been allowed to be imported or exported under the MMPA. In addition, the MMPA prohibits the use of any port or harbor under U.S. jurisdiction for any purpose connected with the unlawful taking or importation of any marine mammal. It is prohibited to possess any unlawfully taken marine mammal, including parts or products, and it is prohibited to transport, purchase, sell, or offer to purchase or sell any marine mammal, including parts and products. Unfortunately, the importation of Polar Bear trophies from Canada has become easier through weakening of the MMPA. The Safari Club International, a powerful trophy hunting lobby, was successful in obtaining the latter weakening of the MMPA.

Lacey Act - Feather Trade

The fashion of wearing bird feathers in women™s hats began in the court of Louis XVI of France when Marie Antoinette appeared in a headdress with feather plumes (Doughty 1975). The fashion gradually spread in Europe and later in the colonies of the United States. By 1850, the business of killing birds for the millinery trade was practiced on a large scale, involving the deaths of hundreds of thousands of birds in many parts of the world. Egrets were a prime target, especially birds in breeding plumage when their most elegant plumage was displayed. Hunters killed adult birds, leaving the chicks to die in the scorching sun. Sometimes feathers were pulled from wounded birds, which were left to die of exposure or starvation. Herons and other wading birds along the east coast and in the Everglades were slaughtered in huge numbers. Songbirds were also popular, and entire birds were stuffed and exhibited on the hats of Victorian women. The plumage of terns and gulls was commonly used, and entire breeding colonies numbering more than 10,000 birds were killed. One New York woman negotiated in 1884 with a Parisian millinery to deliver 40,000 or more bird skins; she hired gunners to kill as many terns as possible at ten cents a skin (Doughty 1975).

In order to stop this disastrous trade, as well as the trafficking in wild deer and other animals for the meat trade, the Lacey Act was passed in 1900. The Lacey Act enhanced existing laws by prohibiting interstate commerce in wildlife protected by state statute. Fines of $500 for "knowingly" transporting wildlife or products protected in another state, and $200 for "knowingly" receiving such articles, were at first assessed. Many states had protected their native birds from the feather slaughters and banned the sale of feathers, but bird hunters would transport the feathers to states where the birds were not native to sell them. The Lacey Act prohibited this interstate commerce in protected species. If, for example, egrets protected from killing by Alabama law were shot and their feathers shipped across state lines to New York, a Lacey Act violation would have been committed. The Act ended most of the commercial plume trade in Native American birds. The failure of some states to enact laws to protect their wildlife kept the Act from being 100 percent effective. The Migratory Bird Treaty Act of 1918 closed these loopholes by protecting all native migratory birds.

The Lacey Act prohibits the import, export, transportation, sale, receipt, acquisition or purchase of fish, wildlife or plants that are taken, possessed, transported or sold in violation of any federal, state, tribal or foreign law. By the turn of the century, the feather trade had nearly eliminated egrets in the United States, and populations of numerous other bird species were approaching extinction. The National Audubon Society employed guards to protect the few remaining colonies in remote parts of Florida. Three of the wardens lost their lives protecting the birds, and if the Lacey Act of 1900 and accompanying state laws had not been enacted, many species of birds would almost certainly have become extinct.

One of the first violations of the Act involved feather merchants. On Laysan Island in the Pacific, a shocking slaughter occurred. Hundreds of thousands of Laysan and Black-footed Albatross nested on this 2-mile-long island west of Hawaii. In 1909, a feather merchant hired 23 Japanese laborers to kill the nesting birds, which are tame and unwilling to leave their nests, even when attacked. Clumsy on land, the albatross need to run with wings spread, allowing the wind to buoy them before they can take flight. This makes them helpless in the face of men striking them with sticks and bats. During several months, 300,000 sea birds were killed, mainly to obtain their wings. The wings were cut off the living birds, leaving them to bleed to death; others were herded into a dry cistern and kept by the hundreds to starve to death in order to use up the fatty tissue next to the skin so that little or no cleaning was required to prepare the feathered skin (Hornaday 1913). A zoology professor from the College of Honolulu heard of this slaughter and wired federal authorities in Washington, since the island was part of U.S. territory, and the birds were protected. The merchants planned to take the bird feathers and wings to the Orient to sell. The Secretary of the Navy dispatched a cutter to Laysan, finding the carcasses, bones and three carloads of wings, feathers and skins. The

poachers were arrested and taken to Honolulu for trial (Hornaday 1913). The same year, President Theodore Roosevelt issued an Executive Order creating the Hawaiian Islands Reservation for Birds, including Laysan Island, which is now a national wildlife refuge. Unfortunately, the same feather merchant who committed the albatross slaughter, introduced rabbits to the island, which stripped the vegetation. The Laysan Rail later became extinct as a result of the rabbits and predation by rats introduced in the 1940s. The albatross have slowly recovered but, being long-lived and slow-reproducing, they are extremely vulnerable to any losses in their populations.

The feather merchants fought state laws banning killing of migratory birds after passage of the Lacey Act, especially in East Coast cities, where the millinery trade was headquartered. The Millinery Association lobbied for the repeal of a New York law banning sale of native bird feathers and brought many witnesses to Albany to prove that enforcement of the law would cause thousands of people to lose their jobs (Hornaday 1913). In 1911, the New York State Legislature refused to repeal this law. The millinery workers did not, in fact, lose their jobs; hat decorations were merely changed from feathers to silk, ribbons and lace (Hornaday 1913).

The problem remained, however, as exotic birds continued to be slaughtered for the millinery trade. Plume hunters combed the marshes of Central America, killed entire rookeries of egrets and herons, netted thousands of tiny hummingbirds in Brazil, and killed rare birds of paradise in New Guinea, and even Andean Condors in South America. In 1911, the feathers of 129,000 egrets; 13,598 herons; 20,698 birds of paradise; 41,090 hummingbirds; 9,464 eagles, condors and other birds of prey; and 9,472 other birds were sold at auction in London for the millinery trade (Hornaday 1913). The scope of the Lacey Act was later enlarged to cover foreign species.

The Lacey Act applies to all wildlife, and the once rampant trade in deer, elk and other game species killed for the restaurant trade was also severely curtailed. More recently, the Lacey Act stopped much of the illegal killing of American Alligators for the reptile products trade prior to the passage of the Endangered Species Act. Sale of alligator skins in the Northeast from alligators killed illegally in the Everglades, for example, was a Lacey Act violation if the source of the skins could be proven.

Amendments to the Act in 1981, which provided, among other things, the authority for warrantless search and seizure when violations are suspected, were designed to: 1) strengthen federal enforcement of laws to protect wildlife; and 2) improve relevant federal assistance to states and foreign governments. The Act is used to control the smuggling of and trade in illegally taken wildlife. Amendments raised maximum penalties under the Lacey Act to sentences of up to one year in jail and/or fines of up to $100,000 for misdemeanors, and five years imprisonment and/or fines up to $250,000 for felonies. Maximum fines for organizations in violation of the Lacey Act are $200,000 for misdemeanor violations and $500,000 for felonies. In addition, vehicles, aircraft, and equipment used in a violation, as well as illegally obtained fish, wildlife, and plants, may be subject to forfeiture. Persons who provide information on violations of the Lacey Act may be eligible for cash rewards.

Humane and Healthful Transport Regulations

The Humane and Healthful Transport of Wild Mammals and Birds into the United States are regulations authorized by Congress in 1981 under the Lacey Act. These regulations are extremely important in curtailing the high mortality and inhumane treatment animals receive on importation into the United States. Between 1980 and 1991, 348,318 cage birds arrived dead at U.S. ports of entry, according to USDA records. In some cases, entire shipments of birds had been so poorly crated, fed, and watered, that most of the birds were dead on arrival. CITES, to which the United States is a Party, requires that "any living specimen will be so prepared and shipped as to minimize the risk of injury, damage to health or cruel treatment."

Until the United States finalized its humane transport regulations, little could be done to stop these high-mortality

shipments, either under the Live Animal Regulations of the International Air Transport Association, which are approved by CITES, or existing regulations of the Lacey Act, which were vaguely written. The first version of the humane transport regulations was finalized in 1987, but the USFWS decided to delay the effective date for six months. The Animal Welfare Institute and 10 other animal protective organizations filed suit in U.S. District Court in March 1988 and succeeded in obtaining an injunction requiring the USFWS to enforce the regulations immediately. Later in 1988, the Service began work to modify the regulations, which were not finalized until June 1992. Thus, a delay of 11 years took place between Congress' mandate to formulate these regulations and the finalization. The final regulations require spacious cages, adequate food and water, frequent inspection during airline flights for both birds and mammals, and other safeguards to prevent mortality. In 1993, numerous violations of these regulations resulted in court cases and high fines. Most of the violations involved crowding too many birds in each crate. Present regulations allow 25 psittacine birds per crate and 50 non-psittacine perching birds, and many importers attempt to flout the regulations.

African Elephant Conservation Act

The purpose of this Act, passed in 1988, is to provide additional protection for the African Elephant. The Act established an assistance program to the countries of Africa where Elephants are indigenous and provided for the establishment of an African Elephant Conservation Fund. In addition, the Act placed a moratorium on the importation of raw or worked ivory from African countries. The ban on U.S. imports was crucial in cutting off a major market in ivory and led the way to the listing of this species on Appendix I of CITES, which ended the legal trade worldwide in 1989.

Migratory Bird Treaty Act

Signed in 1918, the Migratory Bird Treaty Act (MBTA) between Great Britain on behalf of Canada and the United States prohibited the killing of non-game migratory birds. This Treaty represented decades of effort by conservationists attempting to stop the slaughter of native birds for sale in meat markets and the millinery trade. A patchwork of state laws, bolstered by the Lacey Act of 1900, had not been entirely successful in stopping the sale of protected wildlife, especially birds, in the United States. In addition, it was recognized that many of the birds killed in the United States were Canadian in origin. The continent's birds do not recognize national boundaries. Moreover, many species migrate between North America, Russia and Japan. Others winter in, or migrate through, Mexico. In 1936, Mexico became a signatory; in 1976, the Soviet Union; and in 1972, Japan. Sea birds and birds of prey were added to the MBTA in 1972 in a signed agreement with Mexico. All these Treaties are implemented under the Act. Except for those birds hunted during seasons established by the U.S. Secretary of the Interior, all migratory birds are protected by law from killing, capture, possession and sale. The USFWS, through its Law Enforcement Division, has interpreted the MBTA strictly.

Some 65 species of birds can be legally hunted in the United States under regulations promulgated annually by the Department of the Interior. These birds include most species of ducks, geese, swans, wild pigeons, doves, Sandhill Cranes, American Woodcock, grouse, crows, Wild Turkey and quail.

For the majority of the estimated 800 species of birds breeding in North America, the MBTA has allowed recovery from the disastrous free-for-all market hunting of the 19th and early 20th centuries that caused the extinctions of the Labrador Duck, Great Auk, Passenger Pigeon, Eskimo Curlew and Heath Hen, and the near extinction of many others. The Act also prohibits the capture of live birds for the cage bird trade. It is not legal to trap Cardinals, American Robins, Blue Jays or other songbirds, either for use as personal pets or for sale in pet stores. While most

Americans are aware of the protection of their native birds, an increasing number of problems have arisen involving immigrants from countries where birds are not protected. While knowledge of the U.S. Constitution and many aspects of U.S. history are required for citizenship exams, little or no knowledge of laws relating to wildlife and natural resources is required, nor is such information given to newly arrived immigrants.

The regulations prohibit, except as allowed under specific conditions,
the taking, possession, purchase, sale, or bartering of any migratory bird, including the feathers or other parts, nests, eggs or migratory bird products. "Taking" is defined as pursuing, hunting, shooting, shooting at, poisoning, wounding, killing, capturing, trapping, or collecting migratory birds. Migratory bird hunting regulations established by the USFWS allow, during designated seasons, the taking of ducks, geese, doves, rai, woodcock and some other species. In addition, permits may be granted for various noncommercial activities involving birds bred in captivity. Individuals and organizations may be fined up to $5,000 and $10,000 respectively, and those convicted may face up to six months imprisonment for misdemeanor violations of the Act. Felony violations may result in fines of up to $25,000 for individuals and $500,000 for organizations and up to two years imprisonment for those convicted.

For the future, binding treaties with Latin American and Caribbean nations would protect North American birds wintering in those countries. This would be especially important in view of the decline in many of the continent's songbirds and shorebirds, partly attributable to deforestation on the birds' wintering grounds. In some Latin American countries, North American shorebirds are hunted for food.

Eagle Protection Act

Passed in 1940, this Act makes it illegal to import, export, or take Bald or Golden Eagles or to sell, purchase, or barter parts, nests, eggs or products made from the animals. "Taking" encompasses pursuing, shooting, shooting at, poisoning, wounding, killing, capturing, trapping, collecting, molesting, or disturbing. Permits may be granted for scientific, exhibitory, or Indian religious purposes. However, no permits may be issued for the import, export, or commercialization of eagles. Misdemeanor violations may result in fines of up to $100,000 for individuals and $200,000 for organizations, and one year imprisonment. For felony violations, fines of up to $250,000 and $500,000 for individuals and organizations, respectively, and two years imprisonment may result. Persons providing information leading to the conviction of violators of the Eagle Protection Act may be eligible for cash rewards.

This legislation provides additional protection for the nation's two native eagle species, beyond the protection offered by the Migratory Bird Treaty Act and, in the case of the Bald Eagle, the Endangered Species Act. Numerous prosecutions have taken place of persons poisoning, shooting and otherwise harming these birds. Many sheep ranchers in the West, wrongly convinced that Golden Eagles are predators of lambs, have poisoned and shot hundreds of these birds. Bald Eagles have been shot for an active trade in Indian artifacts, such as feather headdresses. The Bald Eagle has been proposed for removal from the Endangered Species Act even though its populations remain at a fraction of original numbers and mortality in some areas is high. Should the Bald Eagle be removed from the Endangered Species Act, the Eagle Protection Act will remain a strong protection.

Wild Bird Conservation Act

The Wild Bird Conservation Act (WBCA) of 1992 is an extremely important law restricting the massive importation of wild birds into the United States for the cage bird trade. This law bans the importation into the United States of the majority of wild-caught birds. All species listed on the various appendices of CITES were banned from commercial importation one year after passage of the law. This effectively banned importation of wild parrots,

hummingbirds, birds of prey and many other birds on CITES. Regulations allow importation of birds for captive breeding under permit, and exempt species that are available only as captive-bred birds, such as canaries, cockatiels and budgerigars. Importation of birds bred in foreign countries is regulated. Zoos are exempt from the law's provisions, except that they must obtain permits for imports and provide documentation on species to be imported. The USFWS issues permits for all imported birds not specifically exempted or unlisted by CITES. The net result of the passage of this bill has been a drastic reduction in bird imports. (For more information on this law, see the Trade chapter.)

NAFTA and WTO

Two major trade treaties have been enacted that affect wildlife and the environment: the North American Free Trade Agreement (NAFTA) and the World Trade Organization, formed from the General Agreement on Tariffs and Trade (GATT). These international treaties establish panels to adjudicate conflicts over trade involving domestic legislation. NAFTA is a trade agreement negotiated with Canada and Mexico that, in principle, is intended to create a free market similar to the European Economic Union. GATT is a worldwide treaty that also encourages free trade, but through its World Trade Organization (WTO), a legal panel, it can require countries whose domestic legislation interferes with free trade to pay high fines, change the law or face retaliatory trade sanctions by other GATT nations. In 1991, for example, the Director-General of GATT appointed a panel to mediate a trade dispute between Mexico and the United States concerning the U.S. embargo on tuna products caught by setting lethal purse seine nets, which catch dolphins and drown untold thousands of these intelligent mammals. The Panel found that the Marine Mammal Protection Act was inconsistent with the treaty because domestic legislation could not interfere with free trade, a major component of this treaty. Since this was prior to the participation of the United States in WTO, U.S. government officials, after heavy lobbying from animal protection and environmental organizations, chose to block adoption of the Panel ruling. Now that the United States is a member of WTO, the Panel's decisions will have to be adhered to.

It is conceivable that the Marine Mammal Protection Act, along with the Endangered Species Act, the Lacey Act, and other laws affecting the environment, might be seriously weakened if rulings by the WTO determine aspects of these laws to be anti-free trade. For example, the WTO ruled against the United States in a case involving the importation of shrimp from countries that did not use nets designed to exclude sea turtles to prevent their drowning. U.S. laws allow such an embargo, but WTO decided this regulation was against the principles of free trade and ordered the United States to change its laws to allow shrimp to enter no matter how it was caught. WTO and NAFTA threaten U.S. sovereignty and may negate important legislation protecting wildlife and the environment, opening up trade in endangered, threatened and mistreated animals.

Projects

Profile of an Endangered Species

Project Summary

Select a species threatened with extinction from the lists of endangered species in the Appendix of *The Endangered Species Handbook*, the *2000 IUCN List of Threatened Species* or another list mentioned below. Using the list of numbered information below as a guide, list its common name, scientific name and other information in that order. Not all of the questions listed below can be answered from available sources, but give an overview with as much information as possible.

Background

Species threatened with extinction may be classified in categories such as Critical, Endangered, Threatened, Vulnerable or Imperiled on various lists such as the US Endangered Species Act, the International Union for the Conservation of Nature and Natural Resources' (IUCN) *2000 Red List of Threatened Species*, publications of The Nature Conservancy or other organizations listed in the Organizations list in the Appendix. (For definitions of the US Endangered Species Act and the IUCN categories, see the list of Endangered and Threatened Species of Mammals, Birds, Reptiles and Amphibians in the Appendix.) This project seeks to describe species in decline or those on the verge of extinction. The number of plants and animals in these categories has increased in the past few decades. Of the many causes threatening species, the disappearance of wild habitats is the most important overall. But for many species, rampant trade and introductions of non-native species are the primary causes. Pollution, pesticides and other toxic chemicals, thinning of the ozone layer and other environmental problems play roles as well. For some species, several of these factors contribute to their decline.

The attitudes of people toward the environment and wildlife in areas where these species are found are often of extreme importance in deciding whether habitats are conserved, laws passed to prevent killing and trade and other conservation measures taken. In some countries, such as Bhutan in the Himalayas, wildlife is held in high regard, and heavy penalties are exacted for destroying the natural landscape or killing animals. In others, high population pressures, faltering economies and political chaos result in destruction of forests and wildlife for commercial purposes, in spite of protective laws and many concerned citizens. In the United States, the US Endangered Species Act is supported by the majority of people, but opposed by a large segment, who see it as politically and economically intrusive. Thus, the conservation status of species threatened with extinction is a complicated picture.

Legal protection, if not enforced, can leave the species open to poaching, even in protected reserves. In spite of strict laws, the Tiger, for example, has been killed in national parks and reserves throughout its range, as a result of high prices paid for its body parts in Traditional Medicine. Thus, a species must receive many types of protection, from habitat to hunting and sale restrictions, combined with a strong protective attitude by people living within its range and elsewhere. Also, funding for research and habitat protection is a major factor that is often lacking for the less charismatic species, such as invertebrates and many plants. The reports generated in this project may consist of only a page or a long report, depending on the wishes of the teacher, student or individual participating in this project.

Methods

Answering as many of the questions listed below as possible concerning an individual species selected is the purpose of the project. It might be easiest to select a native species of animal or plant on the US Endangered Species Act or listed by state Natural Heritage Programs for information that is readily available, or a species about which books or reports have been written, such as the Gray Wolf, the Tiger or the Whooping Crane. One can contact the state Natural Heritage offices in care of each state capital, the US Endangered Species Office in Washington, DC, for federally listed species or the regional offices of the US Fish and Wildfire Service. The US Fish and Wildlife Service has a website as well (see the Organizations list in the Appendix). For information on birds threatened with extinction

worldwide, *Threatened Birds of the World*, by BirdLife International, published in 2000 by Lynx Edicions, Barcelona, provides status and other background information, illustrations and references on more than 1,000 species of birds. *Mammals of the World*, by Ronald M. Nowak (1999, Sixth Edition, Johns Hopkins University Press), is another reference providing much of the information listed below. The *2000 IUCN Red List of Threatened Species*, available in CD-ROM disk and on the Internet (www.redlist.org), lists animals and plants of the world in various categories of threat along with basic background information. It is published by The Red List Programme Officer, 219c Huntingdon Road, Cambridge CB3 0DL, UK; e-mail redlist@ssc-uk.org. Additional books and articles can be found in the Books and Publications Section of the Appendix of this book and in reference lists following each chapter. Within the text of *The Endangered Species Handbook* are many case histories that might provide background information as well. Read Traits of Vulnerable Species in Chapter 2, Vanishing Species**,** to better understand the importance of many of the following questions.

Activities

Answer the following questions with the best available information.

Part I. Description and Characteristics of the Species

1. Species common name, scientific name
2. Class and Family
3. Past range: in recent years and historically
4. Present range: country or countries, region or location
   Does the species have a small breeding range, but a large wintering range?
5. Is the species endemic to a restricted area or region**,** such as an island?
6. What type of habitat does the species inhabit? (For example, oceans, undammed rivers, lakes, old-growth forests, grasslands, mixed habitat.)
7. What is the approximate size of its territory? For example, Siberian Tigers may require 500 square miles per animal, while a small gazelle might survive in an area of only a few square miles. The territorial needs of a species are crucial to its conservation.
8. Does the species require a specialized habitat or diet? Is it adaptable to a variety of habitats or diets?
9. Does the species show altruism, or the unselfish care for members of its own kind?
10. What is the species longevity, if known?
11. What is the species rate of reproduction? (How many young or seeds does it produce, at what intervals and what is their survival?)
12. What is the species rate of natural mortality? (Does the species have few natural enemies or causes of mortality or do large numbers of the species die each year?)
13. Is the species a flightless bird or slow•moving animal? How does this affect its ability to defend itself against predators--human and animal?
14. Is this a large or small animal? The term is relative and denotes size that humans consider large, such as elephants, and other large ungulates, such as antelope, giraffes or rhinoceros, as opposed to small gazelles; for predators, Tigers are large as compared to Ocelots or Margays.
15. Does the species breed in colonies or require large numbers of its own kind for protection, to locate food sources or for other means of survival?

Part B. Status and Conservation

1. Status: What are the threats to this species' survival? (For example, habitat loss, effects of exotic species, trade or other causes.) Describe them in detail.
2. Population numbers, where known, past (historic) and present. (In most cases this would be general information, such as common and widespread in the past, and small population numbers at present.)
3. Current situation: Is the species in steep decline, making its status Critical, or in gradual decline, making its status Vulnerable. Is its population stable, but threatened because of very small numbers?
4. If in decline, does the present rate of decline exceed annual recruitment by reproduction? If so, by how much?
5. Legal status: Is the species legally protected from killing, capture, sale and harm in all or a portion of its range? If a species is found in many countries, provide as much information as possible. If protected, is the protection enforced?
6. Status of habitat: Are there reserves or national parks protecting the habitat? Is the habitat being destroyed, or is land use compatible with the needs of the species?
7. What are the attitudes of most people who live in the range of the species toward it? Are they aware of its presence and status? If so, do they support its protection or are they neutral or even negative, persecuting it?
8. Adequacy of existing conservation: What is being done, either by governmental or private conservation organizations or individuals, to help the species survive? Is the present program effective? Is adequate funding available for its protection? What would be needed to better ensure its survival?
9. What are the potential threats to the species, such as future habitat destruction from expanding human settlements and government policies of land development? For example, the wildlife of India will be under increasing pressure as the population increases and wild habitat is destroyed. Government policies, such as resettlement of people or development of grassland or rivers for human use, can present major threats to wildlife. China, for example, is gradually resettling millions of people into the steppe grasslands of its far west who are having a negative effect on native wildlife and the environment. Through data in almanacs on the rate of human population growth**,** calculate the threat of habitat loss in the future.
10. Can you think of something that needs to be done for the species, such as research; publicity in the form of articles or a film about its status; increased commitment from government or organizations to its conservation; or a website on the Internet asking for more information and suggestions? Can you think of a way you or your class could help the species?

Biodiversity

Project Summary

Biodiversity is a term used to describe the numbers of species, families and other biological divisions of life forms on Earth. Studies of this subject in various parts of the world will be discussed. Certain regions and countries in the world harbor very large numbers of plant and animal species, yet these same areas are threatened by habitat destruction. What is being done to preserve such areas will be explored. The importance of preserving biodiversity to human society and environmental balance is a major purpose of the project. A related topic integral to the study of biodiversity is the variety of ecosystems and environments that provide habitats for the great diversity of life on Earth and their protection.

Background

As studies of the natural world have blossomed over the past century, scientists have documented Earth's amazing array of plants and animals, each species interrelated with others in its environment. Although life exists even in inhospitable environments, such as frigid mountain tops and hot springs, certain ecosystems, primarily tropical forests and coral reefs, harbor the greatest diversity of species. Research on the species of plants and animals in these areas is just beginning, but remarkable findings have emerged. In a single tree in Peru, for example, Dr. Edward O. Wilson, a famed biodiversity expert and entomologist, found 43 species of ants, a number equal to all the species of ants found in the British Isles.

Studies of biodiversity have increased in recent years, and one country, Costa Rica, is now carrying out a biological inventory of all its species, a massive and important task that may take a century. A study that has gone on since the building of the Panama Canal measures the decline in the number of species living on Barro Colorado Island as the waters of the Panama Canal rose around it. It has documented the loss of many wide-ranging species as the range grew smaller. Such studies add to the understanding of habitat requirements for various species and how the loss of some affects ecosystems as a whole. A study in the Brazilian Amazon measured the biodiversity of an extensive rainforest prior to cutting it into parcels of varying size to determine the effects on species (see Lovejoy *et al.* 1984). As a result of extensive deforestation, especially in tropical countries, many studies of forest fragmentation and its effects on biological diversity are taking place, finding that losses of even a few species can result in major ecological damage (see Laurance and Bierregaard 1997 and description in the Forests chapter). Biodiversity studies known as RAPs, or Rapid Assessment Programs, last only a few days and seek to identify areas of high diversity that are in danger of being destroyed. "Environmental S.W.A.T Team" is a film about biologists who conduct one of these RAPS, inventorying a tropical forest for Conservation International, an organization which was able to convince the country's government to protect a threatened region based on the results of the study (see Video section).

Brazil's Atlantic Forest, one of the world's most diverse environments, which once covered millions of square miles along the southern coast and well inland, has been reduced by 92 percent. Remnants of this forest have been found to harbor the greatest diversity of trees in the world: 476 species in a plot of only 2.5 acres. By contrast, a plot of similar size in a North American temperate forest has fewer than 80 species of trees. This is known as a "hotspot," or an area of great biological diversity. Others include forests in the Andes, Madagascar and Indonesia (see Mittermeier *et al.* 1999). A vast array of plants and animals can be found in the hot spots, including many extremely unusual and unique examples of evolution that are in imminent danger of extinction. New Caledonia, for example, an island in the southwestern Pacific Ocean, is home to a variety of plants and animals of ancient origin. It is a small portion of Gondwana, the southern supercontinent that broke up into pieces some 140 million years ago at the dawn of the age of birds. The ancestors of the most primitive avian families originated in Gondwana, and the Kagu, a bird still resident on New Caledonia, is a direct descendant (see Cracraft 2001). Related to cranes, rails and bustards, the elegant, gray Kagu is flightless, with a stunning pattern of wing and head crest feathers. It possesses characteristics so unusual that it has been placed in its own avian family. The Kagu is threatened with extinction along with scores of other ancient species on New Caledonia, many of which had survived for millions of years (see *Threatened Birds of the World*). This hotspot is in grave danger of losing diversity to nickel mining, feral dogs that kill the Kagus and other wildlife, and deforestation.

The huge growth in human population over the past century, now totaling some 6.5 billion, is responsible for colonization of previously remote wilderness areas and for providing a market for the decimation of ancient forests and rare wildlife for commercial purposes. Land is being cleared for grazing livestock and farming, while mining, industry, corporate logging and other development are obliterating species throughout the world. Forests have the largest number of threatened species of any habitat, although the oceans have scarcely been explored for biodiversity. Tropical forests throughout the world harbor about half the world's plants and animals on only 7 percent of the planet's land area. Hot spots also exist in temperate regions, such as the Appalachian mountains of the eastern United States, which have more types of salamanders than exist anywhere in the world, now threatened by pollution and logging. Rivers and waterways of the southeastern United States have the greatest number of mussel species in the world, but government dam and water projects have caused hundreds of extinctions. Grasslands, where only a century ago wild antelope, bison and other ungulates roamed in untold millions, have been converted into farms or pastureland for livestock, the wildlife killed off or driven away. In Earth's history, mass extinctions have occurred on at least five occasions, nearly obliterating the majority of life forms. These were natural events, but the present catastrophic situation is considered the sixth mass extinction, one that may end in destroying or seriously damaging the remaining rainforests, coral reefs and other precious centers of biodiversity within the next century (see Wilson 1988, Leakey and Lewin 1995). By some estimates, half of the estimated 5 million animals and plants that now exist, only a fraction of which have been scientifically identified, could be gone within a century.

Just as the diversity and ecological roles of species are beginning to be seen as components of an immense and beautiful living tapestry, the strands of this tapestry are unraveling. The disappearance of even a single species can result in extinctions of others dependent on it. For example, elephants and hornbills are the primary dispersers of many forest plant seeds, upon which a host of animals rely. Both are now in danger of extinction, threatening entire ecosystems. Thus, biodiversity is not an abstract concept, but a blueprint of the Earth's life forms. It is vital that its many parts be preserved. Once destroyed, many ecosystems, such as old-growth forests and other key environments, may never regenerate. In most such cases, our knowledge of diverse systems is inadequate to gauge just how many species--or which species--could disappear from an ecosystem before it collapses. Nor do we know how much genetic diversity a species can lose through loss of individuals before it can no longer adapt to changes in its environment. Drastic changes caused by human activities are outpacing research on such situations. The healthy functioning of ecosystems is key to human survival. Although the majority of biologists consider the loss of biodiversity to be the greatest problem facing humanity, few members of the public are even aware of this critical situation. Ignoring these experts' opinions of the precarious status of our planet's health, upon which our lives depend, is the equivalent of ignoring the opinion of a team of eminent doctors recommending urgent action to remedy an emergency medical condition.

Steps are being taken to preserve many critically important regions. Through acquisition of habitats and reintroductions of species, entire ecosystems are being saved. In a growing trend, countries are setting aside large new national parks and reserves. Suriname, for example, has established a national park that encompasses the central core of the country, covered in virgin rainforest and teeming with wildlife. Bolivia has set aside massive parks in areas with high biodiversity and unusual types of forests. Brazil, with the help of conservationists from around the world, is now working to save the last 8 percent of its Atlantic Forest in the southeast. Several countries in southern Africa are establishing international parks that greatly enlarge protected areas and allow migratory species, such as African Elephants and other ungulates, to move freely across borders. Corridors for wildlife to move from one area to another are also being established in the Americas. These prevent isolation of small populations of animals that would likely dwindle to extinction. Education is key to the future of preserving biodiversity, which is vital in maintaining the planet's ecological stability. Studies on this and related subjects are now being taught in an increasing number of high schools and colleges so that future generations will not squander the planet's true wealth, its natural heritage. Appreciation of the sheer beauty of the natural world and its wealth of species is an important facet of this project.

Activities

o **Biodiversity study.** Organize a group of students or interested persons to conduct biodiversity studies in your

area. Ecosystems should range from low to high diversity. To study forest diversity, for example, you might select: (1) a small city park; (2) a suburban back yard or tree farm, and 3. a woodland, preferably old-growth. To study aquatic ecosystems, you might select: (1) a city creek or river; (2) a suburban pond, and (3) a sizeable natural wetland. The complexity of the project will depend on the experts available for identifying and recording species. The object will be to list as many species as possible from each area and provide a general description of the habitat. If there are rare, threatened or endangered species in any of the areas, these should be described and, if seen, carefully noted. Invite employees of the state's Natural Heritage Program to help in selection of sites and, if possible, accompany the group. A biodiversity day in the Boston area attracted many scientists, including botanists, ornithologists, herpetologists and mammalogists, who educated interested members of the public at various sites. Experts in birds do not have to be ornithologists but can be proficient bird-watchers, knowledgeable in bird song as well as sight identification. If the field trip is taken during bird migration, note which species breed in the area and which are migrating through. Mammals, reptiles, amphibians and fish (if in an aquatic environment) are less readily seen, and specialists in the latter animals might demonstrate methods of live-trapping or locating these animals by turning over rocks or netting. The identification of trees and plants, including ferns, mosses and lichens, will provide basic information about the habitat. If experts in some or all of these fields are available, or the team leaders are able to provide basic information, the group can be divided into subgroups, each of which will choose a type of life form, such as plants, invertebrates, birds or mammals. Once back in the classroom or environmental center, the various groups can meet and provide lists of the species they have seen in each area. Any rare, endemic or endangered species will be singled out and described in detail. This one-day project will not provide a complete picture of the biodiversity of an area but can give a general picture that is valuable. The effects that development has on nature and the need to protect wilderness and natural areas will become apparent through such a study. In general, biological diversity increases the farther one gets from large cities and suburban areas. Keep in mind, however, that some extremely rare species, especially plants and insects, have managed to survive in small pockets of wild habitat in unexpected places. Weedy growth next to railroads, for example, has been found to harbor many rare plants and insects. Such areas, never cleared for development, have remained natural. Open space, even with low biological diversity, is preferable to asphalt, and students may contribute ideas on making city parks and suburban backyards more diverse by planting trees and shrubs and allowing brushy areas to grow. More advanced students can participate in the CD-ROM biodiversity study listed below (see Wilson and Perlman 1999).

o **Bird feeding.** Another project involves appreciation of biodiversity with the potential for making a contribution to ornithology. Backyard bird feeders can provide an eye-opening education in biodiversity that is also extremely enjoyable. Bird feeders attract many common seed-eating birds. Adding suet and fruit can bring woodpeckers, orioles and other fruit-eating birds. The number of species that come to bird feeders is related to the habitat and surrounding area. Feeders in remote habitats or located on bird migratory flyways will attract more species than those placed in the city, which are likely to attract pigeons, sparrows and starlings, all European in origin. Sometimes, a rare species comes to the bird feeder to feed or is attracted as a predator on the birds. Bird feeders can provide important data on bird diversity and population trends. Cornell's Laboratory of Ornithology (159 Sapsucker Woods Road, Ithaca, NY 14850-1999 (Tel: 607-254-2473) conducts a program that enrolls volunteers to keep track of the birds that visit their feeders. By providing a wide variety of seed and other food, one can learn much about diets, how the birds feed, their behavior and plumage changes throughout the year. Books about bird feeding are sold in most book stores, and local chapters of the National Audubon Society provide information on feeders and feed. Television advice is given by Don and Lillian Stokes in their PBS series.

o **Bird-watching.** Bird-watching trips are important in learning about the majority of species that do not come to bird feeders or live in suburban backyards. Insect-eaters, such as warblers, flycatchers, vireos and other songbirds, can be seen only on migration or in their natural environments. During migration, especially in the spring, the beauty of these colorful birds, called "living jewels" by many naturalists, can be appreciated by using binoculars. Excursions to various habitats to see birds will also teach the diversity of environments, threats to them, and which types harbor the greatest diversity of birds. Local bird clubs, National Audubon Society chapters and naturalist clubs are sources of information on the best birding spots and times of year when one is likely to see the greatest number of birds. Many of these organizations conduct birding trips, both in the United States and in foreign countries. Declines in avian

diversity and in population numbers will become evident after participation in several of these trips. Sources of information on such trends include trip guides who have been conducting tours or breeding bird surveys of the US Fish and Wildlife Service or the National Audubon Society over a period of years in the same habitat. Ask them for information on species that have declined or disappeared altogether as a result of environmental changes, pollution or other causes. Note the species of birds seen on the trip and find out from the guide or other authority, such as the US Fish and Wildlife Service or National Audubon Society, whether these species have declined over recent years. For example, shorebirds seen on coastlines or in the Mississippi River region have suffered dramatic losses of up to 90 percent in some species over the past 30 years. The causes are diverse, from overfishing of food sources, disturbance of beach nesting areas, loss of habitat in wintering or nesting grounds to killing on their wintering grounds. On the list of species seen, note population trends and their causes in the area visited.

o **Worldwide perspective.** Learning about biodiversity from a worldwide perspective is key to understanding the subject. Dr. Edward O. Wilson of Harvard University coined the word "biodiversity" in the 1988 book of that title that he edited. His other book on the subject is also a primary resource. Both give overviews of the world's wealth of species and risks to them. Another important basic reference, *Conserving Biological Diversity*, by Jeff McNeely and other authors, is a 1990 overview of the problem, with key species and regions described. This leads to *Hotspots*, written a decade later in 2000 by Dr. R.A. Mittermeier and others. This book identifies hotspots as the world's most endangered high-biodiversity areas and discusses each in terms of geography; habitat; which species are native, especially those that are found only that in particular area (endemic species); statistical biodiversity for each area; threats to the area; and what is being done to conserve them. Clive Ponting's *A Green History of the World* helps explain why past civilizations have died out as a result of ignorance and overexploitation of their environment and the native wildlife upon which they depended. Michael J. Novacek of the American Museum of Natural History edited a 2001 book, *The Biodiversity Crisis. Losing What Counts*, a collection of essays by prominent scientists and conservationists who discuss the increasing rate of extinctions and give case history examples of areas at risk and what strategies are working to help protect them. The other references listed below provide additional information.

- Write an essay on the problem of the loss of biodiversity, emphasizing the reasons why it is important to the future of human society, as well as for the sake of conservation.
- List ways that consumers in the United States who buy tropical hardwoods and other goods, use large amounts of non-renewable energy and produce greenhouse gases, affect the loss of biodiversity.
- Choose a country or area that has high biodiversity, such as Colombia, Madagascar or Indonesia, and describe the geography, climate, type(s) of biological diversity, threats, unique species of plants and animals, conservation programs, and whether they are successful. Calculate the losses of species should the present rate of deforestation or other destruction continue, using references such as *Hotspots* and *Threatened Birds of the World.*

o **Species in danger.** Learning about threatened plants, birds, mammals and other species will provide in-depth knowledge of what is at stake. *Threatened Birds of the World* examines the 1,100 species whose future survival is in danger. This book illustrates each species with range maps, status and other background information. Many of these birds are illustrated in *The Life of Birds,* a book by David Attenborough, and in a 10-hour film series based on it seen on PBS. The Video section describes other films about threatened species. Other threatened animals and plants surveyed by the *2000 IUCN Red List of Threatened Species* are not described in depth by the International Union for the Conservation of Nature and Natural Resources (IUCN), which sponsors this list. The IUCN no longer publishes "Red Data Books," which gave background information on each species. The Internet site (www.redlist.org) provides some information, such as distribution and basic status category, but few listings give causes of the status and other related data. Such information gaps are filled in part by publications such as *Walker's Mammals of the World,* a two-volume, in-depth examination of mammals by Dr. Ronald Nowak, regularly updated and last issued in 1999. The IUCN Species Survival Commission sponsors many individual specialist groups that gather information on elephants, rhinos, whales, primates and many other categories. These groups issue newsletters and have websites. (Contact the SSC Red List Programme Officer, 219c Huntingdon Road, Cambridge CB3 0DL, UK; e-mail redlist@ssc-uk.org). Select a group of species, such as salamanders, frogs or orchids, and describe their general status. How many species are threatened? What are the general causes? What areas of the world do they inhabit? What will be the effect on

other animals or plants in their ecosystems should they disappear? What should be done to preserve them?

Biodiversity: Video
"Biodiversity: The Variety of Life" explains what biodiversity is and why we should protect it. This film uses maps, diagrams and examples to introduce new terms and concepts, including fragmentation, linkage, and viable population, to explain how ecosystems are dynamic and varied. It focuses on the North Cascades ecosystem, but presents general concepts.

"State of the Planet" is a 3-hour BBC Bristol film on the biodiversity crisis made for Discovery Communications in 2000. It examines the rise in extinctions and endangered species and causes such as "islandization" or isolation of habitat surrounded by development; it profiles Hawaii as leading the world in extinct and endangered species, its beautiful natural heritage being destroyed by exotic species and disappearance of native forests. The final hour of this film series, "The Future of Life," makes clear that if we do not act soon, great natural treasures will be lost.

"Natural Connections," produced by Howard Rosen for PBS in 2000, is a one-hour examination of the failure of the United States and other developed countries to protect nature. It links extravagant and unthinking lifestyles with the loss of biodiversity and proposes changes that will have direct effects in terms of preserving species.

Bats: Ecologically Important Mammals
Project Summary
Learning about bats and threats to them is the major purpose of this project, as well as understanding the importance of bats to the environment as pollinators, seed dispersers and insect-eaters. An endangered bat species will be selected as the subject of a report. Conservation of bats through the protection of their habitats and building of bat houses will be an important facet of this project.

Background
Bats comprise almost one-fourth of all mammals--nearly 1,000 species--yet they have not received the attention and credit they deserve as major insect-controllers and pollinators in ecosystems worldwide. Many species are becoming endangered, and others are declining from destruction of their nesting caves, direct persecution from ignorance, closure of mines which many bats had colonized, and indiscriminate use of pesticides.

Until recently, bats were routinely poisoned by commercial pest control companies in the mistaken idea that all bats pose the threat of rabies transmission. Only one-half of 1 percent of bats contract rabies. Over the past 45 years, only 20 people in the United States and Canada have contracted the disease from bats, according to Bat Conservation International, an organization dedicated to the conservation of bats and education about their ecological roles. Most problems involve people carelessly picking up obviously sick bats found out in the open or on the ground in the daytime. These should always be avoided, according to Dr. Merlin D. Tuttle, Founder and Executive Director of Bat Conservation International. Pest control companies in the United States are now adopting new and more informed policies regarding the removal of unwanted bats from buildings. The journal *Pest Management,* in its May 1992 edition, published several articles on how to "bat-proof" buildings without use of lethal means, and the usefulness of bats in controlling insects.

A single Brown Bat, one of North America's most common species, is capable of capturing 600 mosquitoes in an hour (see Tuttle and Smith referenced below). One colony of 20 million Mexican Free-tailed Bats in central Texas eats a quarter of a million pounds or more of insects each night, according to Bat Conservation International. Repercussions

have occurred when bats have been destroyed. In Israel, a campaign to eradicate fruit bats instead killed almost 90 percent of the country's insectivorous bats; moths that were formerly controlled by the bats proliferated and became major agricultural pests (Tuttle and Smith). To control these pests, huge amounts of pesticides were used, further eliminating natural predators of insects and beneficial insects.

Nectar-feeding and fruit bats pollinate more than 130 genera of plants. The co-evolution of many bats and plants, the latter evolving prominent, odoriferous large flowers blooming at night with copious nectar and pollen, and the former specialized tongues and muzzles for flower-feeding and acute senses of sight and smell, is a fascinating study in itself. The statuesque Century Plant of southwestern deserts has co-evolved with a pollinating bat, and this plant blooms at rare intervals, using nectar to attract its pollinator (see Howell referenced below). Among plants that bats pollinate are valuable fruits, nuts and spices: plantain, bananas, breadfruit, mangos, guavas, avocados, almonds, cashews, cloves, vanillin, carob and figs. In Southeast Asia, a bat that pollinates the Durian tree, which produces fruit marketed for $120 million per year, is being killed for food and its caves quarried for limestone. Few people in the region are aware of its economic importance and the need to conserve it. Fruit bats throughout the world are killed for food, and a growing number are becoming endangered.

Many US bats are listed on the US Endangered Species Act as Endangered or Threatened or on the *2000 IUCN Red List of Threatened Species*. The Indiana Bat's entire population winters in only a few caves in the United States. Approximately 95 percent of the entire known Gray Bat population hibernates in only nine caves with more than half in a single cave in northern Alabama. The threatened Rafinesques Big-eared Bat is found only in Indiana, but it receives no federal protection from the US Endangered Species Act. The Nature Conservancy and many state Natural Heritage Programs have been instrumental in purchasing numerous caves to protect these species.

The following bats are either listed on the US Endangered Species Act or on the *2000 IUCN Red List of Threatened Species*. Some experts estimate that approximately 40 percent of US bats are declining or already endangered. Many species recognized by mammalogists as threatened or endangered and listed by the IUCN as Vulnerable, a high category of risk, have not been listed on the US Endangered Species Act.

Threatened United States Bats
(Includes territories)

Key:
E = Endangered
NT = Near Threatened
T = Threatened
V = Vulnerable
X = Extinct

For definitions of these categories, see the list of Endangered and Threatened Mammals, Birds, Reptiles and Amphibians in the Appendix of this book.

Species	Distribution	US ESA	IUCN Red List
Big Long-nosed Bat *Leptonycteris nivalis*	US, Mexico, Guatemala	E	E
Brazilian Free-tailed Bat *Tadarida brasiliensis*	sw US to S. America		NT
California Leaf-nosed Bat *Macrotus californicus*	US, Mexico		V
	c. & se US	E	E

Gray Bat *Myotis grisecens*			
Hairy-legged Vampire Bat *Diphylla ecaudata*	US, Mexico to Peru		NT
Hawaiian Hoary Bat *Lasiurus cinereus semotus*	US (Hawaii)	E	
Hog-nosed Bat *Choeronycteris mexicana*	US, Mexico, C. America		NT
Indiana Bat *Myotis sodalis*	e. & Midwest US	E	E
Lesser Long-nosed Bat *Leptonycteris curasoae*	US to S. America		V
Sanborn's *L.c. yerbabuenae*		E	
Little Mariana Flying Fox *Pteropus tokudae*	Guam	E	X
Marianas Flying-fox *Pteropus mariannus*	SW Pacific		E
Guam *P.m.mariannus*		E	
Mexican Long-nosed Bat, see Big Long-nosed Bat			
Rafinesque's Big-eared Bat *Plecotus rafinesquii*	US (Indiana)		V
Townsend's Big-eared Bat *Plecotus townsendii*	US		V
Ozark *Plecotus townsnedii ingens*		E	
Virginia *Plecotus townsendii virginia*		E	
Underwood's Mastiff Bat *Eumops underwoodi*	US to Central America		NT

In addition, each state Natural Heritage Program has a list of threatened or rare mammals, many of which include bats. The major threats to bats in North America are similar to those in foreign countries. They include the cutting of old-growth forests that provide habitat, pesticide use, deliberate poisoning and destruction of caves where many bats winter.

Activities

o Find out which bats live in your area. For distribution information, consult guide books such as *North American Mammals*, published by the National Audubon Society. Use reference books such as *Bats*, by M. Brock Fenton (1992), *America's Neighborhood Bats*, by Merlin D. Tuttle (1988), and *Walker's Mammals of the World***,** by Ronald Nowak. Bat Conservation International has published a beautiful brochure, "Bats: Gentle Friends, Essential Allies," and a fact sheet, "Important Bat Facts." Different species of bats can occupy the same general area, yet have different

diets and habitats. How do the bats in your area differ in these ways? What do they eat? Contact the Natural Heritage Program of your state and ask them if there are important bat habitats, such as caves, that are endangered and how your class or local organization can help save these habitats.

o Select a threatened species of bat and write a report on its status, life history, threats and what is being done for its conservation. Consult the references below and your state's Natural Heritage Program.

o Discuss the ecological importance of bats. What fruits and other plants important to humans are pollinated by bats? What would be the effect on insect populations if bats disappeared? *Bats in Question*, by Don E. Wilson, listed below, is a very useful book for information on this subject.

o Help dispel the image of bats as dangerous, rabid creatures who should be eliminated. Humane means of keeping bats from entering buildings exist, and local animal control officials and public health officials should be provided with such information, available from Bat Conservation International. Also, letters to the editor of your local newspaper can be helpful, especially if an article about rabies or vampire bats has been printed. Point out that bats are extremely beneficial and vital to the survival of many plants.

o Build a bat house as a class project. The instructions for construction and placement are given in "The Bat House Builder's Handbook" from Bat Conservation International and a video that gives instructions and general information. This pattern prevents mortality to bats from improper design, materials and placement. Once constructed, calculate the number and species of bats that will occupy the house(s) and the number of insects they will consume.

o Bats have many highly unusual characteristics. Many have echo-location sonar far more sensitive than that designed by humans. Others are able to hunt unusual prey, such as fish or frogs. Their abilities are so finely developed that they are only beginning to be understood. They also are intelligent and devoted to one another. They are among the few species who aid one another during the birthing process, as "animal midwives." Consult the books and films listed below and write a paper on a particular trait that you find fascinating.

Books and Publications

Allen, Glover M. 1962. *Bats.* Dover Publications, New York.
Fenton, M. Brock. 1992. *Bats*. Facts on File, New York.
Fenton, M. Brock. 1998. *The Bat. Wings in the Night Sky*. Firefly Books, New York.
Howell, Donna J. 1976. Plant-loving Bats, Bat-loving Plants. *Natural History* (magazine of the American Museum of Natural History, New York), Feb.
Nowak, Ronald M. 1999. *Walker's Mammals of the World* (Volume I), Johns Hopkins University Press, Baltimore, MD. *(Walker's Bats of the World*, another reference by the same author, is derived from the latter volume.)
Tuttle, Merlin D. 1988. *America's Neighborhood Bats*. University of Texas Press, Austin, TX.
Tuttle, Merlin D. and Eileen C. Smith. 1992. Bats: Nature's Own PCO. *Pest Management,* May, Vol. 11, No. 5, pages 10-13.
Wilson, Don E. 1997. *Bats in Question. The Smithsonian Answer Book*. Smithsonian Institution Press, Washington, DC. (Source book with questions and answers about bats and superb photography by Merlin D. Tuttle; addresses of organizations concerned with bat conservation are listed at the end of the book along with a list of all bats with their conservation status.)

Films

"Korup. An African Rain Forest." A Cameroon forest where bats are seen pollinating flowers at night.

"The Secret World of Bats." Overall view with the role of bats as pollinators and insect-eaters is stressed, and unusual species, such as fish-eating and threatened fruit bats, are seen.
"Wet Side Story." Central American rainforest with bats as a focal point. The sensitivity of their sonar is beautifully filmed.
"Private Life of Plants." Includes pollination by bats of several species of plants and describes how plants and bats co-evolved.
"Castaways of Sulawesi." An Indonesian island is the scene of cruel capture of flying foxes for sale as food by young boys using hooks on kites that entangle them in flight.

The films above are described in detail in the Video section of this book.
In addition, other films that focus on bats include "Phantom of the Night" (bats of Central America); "Beneficial Bats" (Wild America series); "Land of the Giant Bats" (Comoros flying foxes); "Life Upside Down" (Quebec Government film emphasizing Canadian bats and their ecological role); "Night Stalkers" (bats of Belize--National Geographic Explorer TV program).

Conserving the Wood Thrush
Project Summary
Learn about the life history, distribution, ecology and conservation of the Wood Thrush, a songbird in steep decline. Using written materials and sources listed below, write a report on the threats it faces and what is needed to help it survive. For those who live in areas where the Wood Thrush is not native, select another declining songbird and follow the same suggestions.

Background
The Wood Thrush (*Catharus mustelinus*) is one of the most melodious songbirds in the world. Its beautiful, fluted song echoes through eastern North America's woodlands. In the words of Arthur Cleveland Bent, author of a series of authoritative life history studies of American birds: "The nature lover who has missed hearing the musical bell-like notes of the wood thrush, in the quiet woods of early morning or in the twilight, has missed a rare treat. The woods seem to have been transformed into a cathedral where peace and serenity abide. One's spirit seems truly to have been lifted by this experience."

The Wood Thrush is also useful to forest ecosystems, consuming vast amounts of insects. Unfortunately, its populations have declined in recent years from 40 to 80 percent, depending on the area. Major causes include the destruction of both its nesting and wintering forests, combined with parasitism on its nests by the Brown-headed

Cowbird, a bird that lays its eggs in the nests of other birds. These eggs tend to be larger than the eggs laid by the Wood Thrush, and the aggressive chicks crowd out the thrush chicks. Wood Thrushes are closely related to the familiar American Robin, a common denizen of suburban yards and forests. Unlike the Robin, however, the Wood Thrush is not common in suburbs and backyards. Although the species was occasionally seen near homes and villages in the first half of the 20th century, today it breeds only in undisturbed forest tracts. Its forest habitats have become fragmented into smaller and smaller blocks, causing the species to disappear from many areas.
Wood Thrushes migrate to Mexico and Central America each winter. They seek out old-growth rainforests from southern Mexico through Panama. Within the past 40 years, their forests have been logged and often converted into grazing land or agricultural fields. Researchers tracking these birds to their wintering grounds have discovered that they stay in the same area, even though it has been destroyed, and usually die within a short period from starvation or predation. The decline in this species' population was discovered through Breeding Bird Surveys conducted annually by the US Department of Interior. The Wood Thrush is close to endangered status, and conservation is critical to prevent its decline to extinction.

Other North American songbirds that migrate to tropical areas have declined as well. These birds, known as neotropical migrants, include tanagers, orioles, warblers, thrushes and vireos. These colorful birds brighten our forests and orchards, consume harmful insects and play important ecological roles. Almost all are in decline, some far more precipitously than others.

Activities

o Find out about the Wood Thrush, using the text in this book (see index), sources listed below and those available in your library and through computer on-line searches.

o Write a report answering as many of these questions as possible:
- What does the Wood Thrush look like?
- How large is it?
- Are males and females different in size or appearance?
- What is its diet?
- What type of woods does it prefer (for example, dry, old-growth forest or cool, damp forest near streams)?
- Does it build its nest on the ground, in bushes, or on tree branches?
- How large a territory does it establish?
- When does it sing? Describe its song (see reference on obtaining recording).
- How long does it live?
- What are its breeding and wintering ranges?
- How did early naturalists, such as John James Audubon, describe Wood Thrushes in the 19th century? (See Audubon and Coues book below.)
- How serious is the threat from Brown-headed Cowbirds who lay their eggs in Wood Thrush nests? (This was noted even in the 1930s by Bent (1964), and later by other authors such as Rappole *et al.* (1989), and Terborgh (1989.)
- How can people contribute to protecting both the breeding and wintering habitat of the Wood Thrush?

o Field study**:** If you live east of the Mississippi River in the range of this species, visit an area where Wood Thrushes live**.** First, listen to the recording of their songs (see below). Often they are more easily heard than seen. Do not approach a nest or disturb birds by playing recordings of their songs. Photograph the woodland setting where you hear the Wood Thrushes and try to observe them quietly from a distance. Describe what wildflowers, trees and other birds you see. If you live outside their range, see films listed below and listen to recordings or select another species of thrush or songbird found in your area that is in decline as a result of habitat loss, especially forests. Consult your

local Audubon Society, the US Fish and Wildlife Service, your state's Natural Heritage Program or the bird count programs listed below.

o Conservation project**:** Find out if there is a woodland near your home where Wood Thrushes breed. The local National Audubon Society or birding organization can provide this information. If so, is it protected from logging? Can your class or school help in protecting a woodland where they breed?

o Participate in a survey of native birds through programs sponsored by local Audubon or birding organizations. The American Birding Association publishes an annual guide, "Volunteer Opportunities for Birders," which lists day-long programs and more extensive studies. Available for $2 from Volunteer Directory, ABA Sales, P.O. Box 6599, Colorado Springs, CO 80934; 800-634-7736. For further ideas, see Nickens reference below.

o Why are some species rare and others common? Compare the Wood Thrush with the American Robin by answering the following questions: Does the Robin migrate? If so, where does it migrate? Are there dangers in its wintering ground, such as deforestation? Where does the Robin nest? Is there more habitat for American Robins or for Wood Thrushes? Explain why. Are there threats to the American Robin?

Books and Publications

Adams, George. 1994. *Birdscaping Your Garden. A Practical Guide to Backyard Birds and the Plants that Attract Them.* Rodale Press, Emmaus, PA. (On page 87, the Wood Thrush is profiled, providing information about migration, breeding range, nesting, feeding, garden bushes and fruiting plants that it will eat, as well as the woodland habitat it prefers.)

Audubon, Maria R. and Elliott Coues. 1986. *Audubon and His Journals*. Vols. I and II. Dover Publications, New York. (First published in 1897, Audubon's journals were collected by Maria Audubon with notes by the distinguished naturalist Elliott Coues. Wood Thrushes are mentioned many times.)

Bent, Arthur C. *Life Histories of North American Thrushes, Kinglets, and Their Allies.* First published in 1949 and reprinted by Dover Publications, New York, 1964, pages 101-122.

Bull, John and John Farrand, Jr. 1977. *The Audubon Society Field Guide to North American Birds. Eastern Region.* Alfred A. Knopf, New York. (A photo guide.)

Cherry, Lynne. 1997. *Flute's Journey. The Life of a Wood Thrush*. A Gulliver Green Book. Harcourt Brace and Company, San Diego, CA; New York.

DeGraaf, Richard M. and John H. Rappole. 1995. *Neotropical Migratory Birds. Natural History, Distribution, and Population Changes*. Comstock Press, Cornell University, Ithaca, NY. (This book has range maps of all North American breeding birds that migrate to Latin America and several pages of discussion of each species.)

Farrand, John Jr. (ed.). 1983. *The Audubon Society Master Guide to Birding.* (Has color photo of adult at nest with chicks and a color painting of the juvenile.)

Forbush, Edward Howe and John Bichard May. 1959. *A Natural History of a Bird of Eastern and Central North America*. Bramhall House, New York, pages 377-378.

Geffen, Alice M. 1978. *A Birdwatcher's Guide to the Eastern United States*. Barron's, Woodbury, NY. (This and the Pettingill book below list major parks, refuges and public lands by state; under each is a list of birds to be seen.)

Hagan, John M. III and David W. Johnston (eds.). 1992. *Ecology and Conservation of Neotropical Migrant Landbirds*. Smithsonian Institution

Press, Washington, DC. (This book is not indexed. It is a collection of papers from a 1989 symposium, containing much information on the problems of songbirds, including the Wood Thrush, especially an article on destruction of its habitat in Veracruz, Mexico, on pages 337-344.)
Harrison, Colin. 1978. *A Field Guide to the Nests, Eggs and Nestlings of North American Birds.* The Stephen Greene Press, Brattleboro, VT; Lexington, MA. (This book describes the nest and nestlings and gives the nesting dates; a color photo shows the egg.)
Keast, Allen and Eugene S. Morton (eds.). 1980. *Migrant Birds in the Neotropics: Ecology, Behavior, Distribution and Conservation*. Smithsonian Institution Press, Washington, DC. (Papers submitted at a symposium. Many discuss the threats that migrant songbirds, including Wood Thrushes, face on their wintering range. The introduction gives an overview of the songbird decline.)
Kricher, John C. 1988. *A Field Guide to the Ecology of Eastern Forests. North America*. The Peterson Field Guide Series. Houghton Mifflin Co., Boston, MA. (This book contains information on hundreds of species of plants and animals, many of which are illustrated with color photos.)
National Audubon Society Nature Guides. *North American's Eastern Forests and Wetlands*. Alfred A. Knopf, New York.
Nickens, Eddie. 1997. Beyond the Life List. *Wildlife Conservation* magazine, July/August. (Wildlife Conservation Society, Bronx Zoo, Bronx, NY 10460.)
(This article describes the work of volunteers who participate in surveys, banding, birdfeeder studies and other projects relating to North American songbirds; it provides addresses and phone numbers of various organizations.)
Peterson, Roger Tory. *A Field Guide to the Birds. A Complete Guide to All the Birds of Eastern and Central North America*. Houghton Mifflin Co., Boston, MA. (This classic guide has excellent illustrations, breeding range map and descriptions.)
Pettingill, Olin Sewall, Jr. 1977. *A Guide to Bird Finding East of the Mississippi*. Oxford University Press, New York. (Although many of the areas described in this indexed book have changed since it was first written, many are protected sanctuaries, parks and reserves.)
Rappole, John H., Eugene S. Morton, Thomas E. Lovejoy III and James L. Ruos. 1983. *Nearctic Avian Migrants in the Neotropics*. US Fish and Wildlife Service and World Wildlife Fund, Washington, DC. (This publication is not indexed, but is a well-organized report on North American songbirds, their ecology and threats. Range maps show breeding range as well as wintering range of all migratory species.)
Sibley, David A. 2000. *The Sibley Guide to Birds*. Alfred A. Knopf, New York. (Considered one of most inclusive guides because it includes information on subspecies, varieties and other aspects not covered in most guides.)
Stokes, Donald and Lillian. 1996. *Stokes Field Guide to Birds. Eastern Region.* Little, Brown & Co., Boston, MA. (Color photos.)
Terborgh, John. 1989. *Where Have All The Birds Gone?* Princeton University Press, Princeton, NJ. (Many mentions in the text, see index; this is a landmark book on the decline in North American songbirds, exploring their problems on both the breeding and wintering grounds)
Yoon, C.K. 1994. More Than Decoration, Songbirds Are Essential to Forests' Health. *The New York Times*, Nov. 8.

Organizations and Governments

National Audubon Society, 700 Broadway, New York, NY 10003. (212-979-3000); or local chapters.

Conservation International, 1015 18th St., NW, Suite 1000, Washington, DC 20036.

Cornell Laboratory of Ornithology (Breeding Bird Censuses), 159 Sapsucker Woods Rd., Ithaca, NY 14850-1999 (607-254-2473).

Breeding Bird Survey, Biological Resources Division, US Geological Survey, Patuxent Wildlife Research Center, 12100 Beech Forest Rd., Laurel, MD 20708.

Fish and Wildlife Reference Service, 5430 Grosvenor Lane, Suite 110, Bethesda, MD 20814 (800-582-3421).

Recordings

The Peterson Field Guide Series. A Field Guide to Bird Songs of Eastern and Central North America, recorded by the Cornell Laboratory of Ornithology. 2nd edition. Houghton Mifflin Co., Boston, MA. 1983. Two tape cassettes. (Wood Thrush on Side 3, Band 4). Other recordings, such as the Stokes audio guides, are also available.

Films

"On a Wing and a Song." This Canadian Broadcasting Company film gives an overview of the songbird decline in Eastern North America, illustrating the vast areas of boreal forest where many of these birds nest in Canada, which has been logged. It addresses the loss of habitat in their tropical wintering grounds; the millions killed by colliding with skyscrapers and antennas during migration; and the parasitism by cowbirds.

"On a Wing and a Prayer." A similar title to the above film, this film focuses on an Illinois woodland and the decline in songbirds, primarily Wood Thrushes. The parasitism by cowbirds is dramatically shown: Wood Thrush chicks starve to death next to huge, fat cowbird chicks. This film also has a teacher's guide.

(See Video section for more detail and distributor list.)

North America in the Year 1400

Project Summary and Background

North America has changed radically since 1400, prior to the arrival of Europeans. It was then a continent without roads, skyscrapers, massive farms and other signs of modern life. This project involves research to discover what the country looked like at this early date, how areas such as the eastern forests, prairies and western forests have changed, and what species of animals and plants disappeared or became threatened as a result of changes to their environment or losses in their populations from other causes.

Activities

o Read the section in this book entitled "Epitaphs for North America's Lost Species and Environments" in Chapter 1.

o Using this and other sources mentioned in the reference list and in local libraries, select an area somewhere in North America. Some possible choices are the following: Cape Cod, Massachusetts; the Chesapeake Bay; eastern old-growth forests; long-grass prairies of the Midwest; short-grass prairies of the West; Sequoia or Redwood forests of California; or the Mojave Desert in California. If there are parks in the area you choose, contact the park directors, conservation organizations and museums for natural history information.

- Describe the landscape as it was prior to the arrival of Europeans, without roads, modern buildings or other signs of the 20th century. What was the habitat like? Was it forest, mountain, grassland, desert, wetland, river or a combination of these? Were there beautiful vistas or dense woodlands with tangled vegetation? Describe a typical scene in the area you have chosen. For example, in a short-grass prairie, a herd of American Bison graze while, in the background, Pronghorn antelope run in close formation. On a distant hilltop, a pack of Gray Wolves watches the scene while a Grizzly Bear ambles through the low shrubs, looking for ripe berries. Overhead, flocks of Whooping Cranes soar, trumpeting to one another; and near a prairie dog town, grouse display in an open area, issuing booming calls.

- What species of mammals live here? If there are herds of deer, what species are they? Are there American Bison, Elk, Moose, Bighorn Sheep or Pronghorn? What kind of predators prey on these animals?

- Describe what bird species inhabit the area and whether they are abundant or rare. Are there Passenger Pigeons or Carolina Parakeets?

- What other kinds of animals are native? What reptiles, amphibians and fish, for example, inhabit the area? Apply the same questions about life history, habitats, reproduction and feeding.

- How do these animals interact ecologically? For example, if a western short-grass prairie were chosen, the prairie dog colony has abundant wildlife living underground in the burrows, including Black-footed Ferrets, Burrowing Owls, snakes and tortoises. Bison and other grazing animals feed on the grasses above, made greener by the cropping of the prairie dogs. Which species are the predators, and which the prey?

- Is there a tribe of Native Americans who live in this area? What is the name of the tribe? Are they nomadic, or have they established a permanent settlement? Are they hunters, fishers or farmers? What animals do they hunt or fish, or which crops are grown? What are their beliefs about the natural world and wildlife?

o Based on these descriptions of a past landscape, become acquainted with the present landscape and discuss the following:

- How has the natural environment changed? How does it appear today?

- What species no longer live here? Which ones are extinct altogether? (Check the list of extinct species in the Appendix and publications in the Books and Publications section on extinctions and extinct species accounts.)

- What do you think has been lost that should have been protected?

- Are there parts of this area that have not changed and remain as they were 600 years ago?

- Are there people or organizations working to preserve or restore parts of the original landscape and wildlife? How

can you participate in this?

Note: This project can be applied to foreign countries or used by teachers outside of North America. As a general rule, it is easier if the area selected is local because information is easier to obtain. As a class project, students might divide into groups, each selecting a species or group of species, such as mammals. This project may be shortened and parts deleted if time is limited, concentrating, for example, on a single species of the region or the general changes in the landscape. It may also be broadened to explore, in detail, the plants and animals of the region by contacting the Natural Heritage Program of your state in the Wildlife Department.

Sources

"Epitaphs for North America's Lost Species and Environments" in Chapter 1 of this book has extensive references listed. Also the fiGrasslands, Shrublands and Deserts,fl fiAquatic Ecosystemsfl and fiForestsfl chapters provide details on these ecosystems and changes in them since settlement. See the fiPersecution and Huntingfl chapter for the treatment of native predators and the effect of their disappearance on ecological systems.

Books and Publications

The following list contains many out-of-print books that may be difficult to obtain, as well as many in-print editions, covering a wide variety of habitats and species of plants and animals. Conduct searches for these and other books in your library and through the Internet.

Forests

Project Summary

This project involves learning about the types of forests that grow on Earth and selecting one type of forest to describe in detail in terms of the climate, what types of trees grow there and what species of native plants and animals are threatened. It also involves learning about the ways in which this type of forest is being conserved or destroyed.

Background

As described in the Forests and Madagascar and Other Islands chapters, forests harbor the largest number of endangered species of all habitats. Uncontrolled logging, especially of old-growth forests, has threatened the survival of thousands of native plants and animals. Forests are a crucial factor in maintaining the planet's oxygen supply and supplying moisture to the atmosphere. By absorbing vast amounts of carbon dioxide, forests reduce pollution and global warming. Their roots also anchor soils, preventing erosion, and store moisture that gradually seeps into rivers and streams so that they flow year-round, even in droughts.

The world land area covered by forests has been retreating for centuries. Although there are still extensive boreal forests in northern Canada and Siberia, and tropical forest still covers most of the Amazon, forests are being logged at a fast pace. The increase in human populations has resulted in growing numbers of people cutting forests for firewood or to clear land for agriculture. In many parts of the world, forests with extraordinary diversity of life have been nearly eliminated or are in the process of being destroyed. Central Africa's ancient rainforests are being logged for the largest trees, hundreds of years old, and their wildlife, including endangered chimpanzees and Gorillas, is being slaughtered to sell in bushmeat markets. Tropical rainforests, especially those growing in lowland areas, are the most threatened type of forest. These forests harbor the largest diversity of wildlife and plants and are, therefore, most in need of protection. In the United States, entire forest ecosystems have become endangered, and many species of native trees have become threatened, some from diseases of foreign origin, others from logging and development. Examples of threatened forest ecosystems in North America are the native pine forests of the Southeastern United States, the old-growth temperate rainforests of the Northwest and the old-growth forests of the East.

Many species of trees, including the stately American Elm and the American Chestnut, have been decimated by exotic species of fungi. These trees once numbered in the billions. The American Elm has declined and disappeared from many parts of the East, and the American Chestnut is almost extinct throughout its range in eastern North America. It once made up a large portion of the eastern hardwood forests. The wildlife of these forests has lost much of its diversity, as the Gray Wolf, Red Wolf, Mountain Lion, and their prey, the Elk, Eastern Bison and, in northern woods, the Caribou were all hunted to the last animal. Rainforests of the Pacific Northwest, with their towering American Redwoods and Sequoias, Western Hemlock, Red Cedar and other conifers, have been reduced to about 5 to 10 percent of their original range as a result of logging and development. Their wildlife, likewise, is under siege, and many species, including the Grizzly Bear, Fisher, Lynx, Gray Wolf, Northern Spotted Owl and Marbled Murrelet, are absent or extremely rare.

Endangered trees and wildlife of temperate forests in South America include the massive Chilean Larch or Alerce, which can grow for 4,000 years and reach sizes almost as great as the Sequoias of California, the world's most

massive trees. Alerces have been decimated, cut for their valuable wood, along with other trees in these forests--species which grew on Earth prior to the appearance of dinosaurs. Vast forests of beeches, for example, and primitive conifers covered millions of square miles in Chile and Argentina, but only a fraction remain, the rest logged to make way for agriculture and livestock. The wildlife of these forests, from the world's smallest deer, the Pudu, to the Andean Bear, is threatened. Likewise, the temperate rainforests of New Zealand and eastern Australia have been greatly reduced, threatening kiwis of several species and other unique wildlife.

Tropical forests of many types, from lowland rainforests to dry deciduous forests and, in higher elevations, montane cloud forests, grow in a belt around the Earth's tropical latitudes. They teem with millions of species of insects, birds, mammals, reptiles and amphibians. The last 5 percent of Brazil's Atlantic coastal forest harbors South America's greatest primate diversity, with species ranging in size from tiny lion marmosets, weighing only a few ounces, to the Muriqui, or Woolly Spider Monkey, the continent's largest primate. All are now threatened with extinction. Madagascar's tropical forests echo with the calls of 33 species of lemurs, charming and fascinating primates that exist nowhere else but in these forests that are being cut for farm plots and charcoal. In Amazonian and Indonesian rainforests, literally hundreds of kinds of colorful parrots fly in noisy flocks, each with its own ecological niche of food type and habitat. Almost one-third of all parrots are now threatened.

A large percentage of tropical forests have been destroyed over the past century, with some areas, such as the Philippines, Thailand, West Africa, Andean countries, the Caribbean and, most recently, parts of Indonesia, experiencing almost total deforestation. The losses here have been dramatic, as Orangutans, Tigers, rare birds and two species of primitive rhinos add to these countries' endangered lists. The countries with the largest numbers of endangered birds, Indonesia and Brazil, have lost, or are in the process of losing, large tracts of tropical rainforest. Entire ecosystems are collapsing in the process. The great variety of fig trees of Southeast Asia depend on hornbills to distribute their seeds, but these birds are fast disappearing. Pollinating species like bats, small primates and birds are also in sharp decline as the rainforests are destroyed. Many are found only in a limited area, surviving in the remnants of these forests.

On the positive side, many large preserves have been set aside in South America to protect this diversity, and conservationists are working in other parts of the world to protect parks and help establish new reserves to prevent massive extinctions in these forests. Paper recycling and using substitutes for wood-based products are also conserving trees.

Activities

o Examine as many of the books listed below, showing the great beauty and diversity of forests, as possible. These include *Jungles; The Rainforests*, *A Celebration; The Life and Mysteries of the Jungle*; *The Living Wild; Hotspots. Earth's Biologically Richest and Most Endangered Terrestrial Ecoregions*; *North America's Rainforest. The Endangered Paradise*; *Living Planet. Preserving Edens of the Earth*; *Ancient Forests. A Celebration of North America's Old-growth Wilderness*; and *The Enchanted Canopy. A Journey of Discovery to the Last Unexplored Frontier, the Roof of the World's Rainforests*. Also, read books on particular forest species, such as butterflies, birds, primates, bats or insects. Many are listed in the Books and Publications section. See films listed below and in the Video section of this book on forests, particularly threatened ones in Madagascar and other parts of the world, as well as films of endangered forest wildlife. This introduction is intended to create enthusiasm and curiosity as well as an appreciation of the wealth of plants and animals that are at stake as old-growth forests are destroyed.

o Select a forest from the list below to study its status and threatened trees and wildlife.
- United States southeastern Long-leaf Pine forests
- North American eastern hardwood forests
- North American temperate rainforests
- South American temperate rainforests
- Brazilian forests of Atlantic coast
- New Zealand or Australian temperate rainforests

- Madagascar tropical rainforest
- Hawaiian tropical rainforest
- Mascarene tropical forests
- West African tropical rainforests
- Andean tropical rainforests and cloud forests
- Central American cloud forests
- Colombian rainforests
- Caribbean tropical forests
- East African tropical forests
- Indonesian rainforests
- Philippine rainforests
- Indian montane forests of the Ghat region
- Himalayan forests
- Chinese tropical forests

o Read about this type of forest in *The Endangered Species Handbook* and in references listed in the Forests chapter and the Books and Publications section. Also consult the Internet.

o Describe the original extent of this forest several hundred years ago, and the present extent. (Collins 1990 and Mittermeier 1999a, cited below, are excellent references.) Explain how it has become threatened. For example, some forests have been gradually whittled away by cutting for firewood or land clearance, while others have been cut by corporate logging companies or government programs to establish large-scale agricultural farms. Still others have been officially conserved but, through failures in enforcement or misguided policies, their wildlife and trees have been lost.

o What species of wildlife and plants or trees have become endangered as a result of the destruction of these forests? Which species are unique to that forest region? Describe them.

o Select an animal or plant species that is threatened with extinction and write a short report about it, using the criteria in the project, "Profile of an Endangered Species." It can be a type of butterfly, orchid, ant, bird or mammal, for example. Write about the species in the context of its forest habitat, whether its habitat is being protected, and other threats to it that may include pollution, trade or competition with exotic species. As source material, consult this book, *Threatened Birds of the World, Walker's Mammals of the World*, and other references cited here or in the Books and Publications section of this book.

o By consulting books, such as *Hotspots* and other books listed below, list the threats to the forest you are describing and what is being done to protect the forest and its wildlife.

o Read the Forests chapter for information on the use of plants, such as kenaf, to make paper and building houses with little or no lumber. Discuss the role these measures could have in conserving forests. Write organizations, such as Earth Island Institute, for information.

Forests: Films

The films below are reviewed in the Video section, which gives information on their distributors and more detail on their content. Also, films on individual forest species, such as Tigers, are reviewed, along with additional films on many of the subjects and regions above.

General films on rainforests: "Rain Forest" and "Exploring the High Frontier," both by National Geographic Society.
Temperate rainforests in US: "Ancient Forests,fl fiLast Stands of the Giants"
Temperate pine forest of US southeast: "Remnants of a Forest"
US National Forests: "Our Vanishing Forests"
Regional: "Amazonia: A Burning Question;" "The Decade of Destruction" (Amazon rainforest); "Korup--An African Rain Forest" (Cameroon); "Spirits of the Forest" (Madagascar); "Forest Primeval" (Part 3 of "Heart of Africa") (Democratic Republic of the Congo & area); "Animalai, India's Elephant Mountain" about the Indian Ghats; "Monkeys on the Edge" (Brazil's Atlantic forest); "Song of Protest," "Land of the Kiwi," and "Mountains of Water" (New Zealand).

Grasslands

Project Summary

The purpose of this project is to learn about the wild grasslands of the world, their wildlife and threats to them. One particular region will be selected and its original extent, wildlife, and present status will be described. The ways in which this grassland is being conserved or destroyed will be a major focus.

Background

Just a century ago, grasslands covered much of central North America, from southern Canada through Texas to northern Mexico, and from west of the Rockies east to Midwestern and northeastern states. Tall-grass prairie, with grasses up to 12 feet in height, grew from Ohio west to the Mississippi River area. This savannah grassland had groves of oak and other trees. It had extremely rich soil and was plowed by American settlers into farmland. Today, less than 1 percent of the original extent remains, making it an extremely endangered natural ecosystem. West of the tall-grass prairies, a mixture of tallgrass and short-grass prairies existed, and further west, short-grass dominated. The short-grass and mixed prairies have also been plowed for crops, but some sizeable areas remain, primarily kept as pasture for cows. These grasslands have been greatly altered, leaving few examples of the original ecosystems. Vast herds of American Bison once grazed throughout these grasslands, with prairie dog towns covering millions of acres in the short-grass prairies.

The savannahs of East Africa, grazed by a great diversity of hoofed animals, represent a classic example of grasslands that are still in natural, intact condition. Although under stress from growing human populations, large reserves and national parks protect much of this region. By contrast, the dryer grasslands of southern Africa have been severely damaged by the introduction of large numbers of domestic cattle and the fencing off of wildlife from waterholes and

prime grasslands to prevent the spread of hoof-and-mouth disease to cattle. This has resulted in a large decline in overall numbers of both herbivores and carnivores. This is a repetition of the overuse of the Sahara and Sahel regions to the north, centuries before, by great herds of domestic camels and sheep, turning grasslands into sandy desert. Ethiopia, Somalia and countries to the north and east of the Serengeti in East Africa's horn were once covered in lush grasslands. Wildlife species found only in this region became threatened when Europeans introduced livestock, which infected wild ungulates with rinderpest and other diseases, causing massive mortalities.

In vast steppes that once stretched from the Black Sea to western China, livestock now far outnumber native ungulates, such as the Saiga antelope, a species that once thundered in herds of millions. Overgrazing and plowing of this dry land for crops has further degraded it, causing massive dust storms, similar to those that resulted from plowing the American prairie in the 20th century. South America has extensive grasslands in Venezuela and south-central Brazil, many of which become wetlands during rainy seasons. In Argentina and Chile's Patagonian grasslands, rheas, deer, Guanacos and other wildlife once abounded. After centuries of overgrazing by sheep and cattle, this wildlife has declined greatly, and the grasslands are turning to desert. Australia's grasslands have also been converted to use by livestock, displacing the varied marsupials and rodents that once thrived here.

Preservation of grasslands and their wildlife is now taking place in many parts of the world, including the United States, southern Africa and Australia. Reserves of remnant grasslands, with their great diversity of wildflowers, grasses and other plants, are being set aside and native wildlife reintroduced. This trend may spread to parts of Asia as well, but the pressures of human populations requiring farmland and grazing for livestock may prevent restoration in most areas.

Activities

o Read "Epitaph for America's Lost Species and Environments" in Chapter 1 to learn about the travels of Lewis and Clark through these prairies early in the 19th century, followed by the extermination of the great herds of bison, deer and Pronghorn. Read the Grasslands, Shrublands and Deserts chapter with references cited for more information on North American and other grasslands around the world and their endangered species. Write a short paper describing the changes in grasslands in North America since colonial times and the effects on wildlife.

o Select a grassland from the following list to study its wildlife and present status:

- North America's Tallgrass Prairie
- North America's Short-grass Prairie
- Central Asia's Steppes
- Australia's Grasslands and Drylands
- Saharan and Sahel Drylands
- East Africa's Serengeti
- Southern Africa's Grasslands
- Horn of Africa's Grasslands
- South America's Pampas
- South America's Patagonia

* What species of wildlife, plants or trees have become endangered as a result of the destruction of this region's grasslands or affected by related activities, such as grazing and meat hunting, by herdspeople? Which species are unique to that grassland region? Describe them.

* Select an animal or plant species native to this region that is threatened with extinction, and write a short report about it, using the criteria in the project, "Profile of an Endangered Species." It can be a type of wildflower, tortoise, butterfly, bird or mammal, for example. Write about the species in the context of its grassland habitat, whether its habitat is being protected, and other threats to it that may include pollution, trade or competition with exotic species. As source material, consult this book, *Threatened Birds of the World, Walker's Mammals of the World*, and other

references cited here or in the Books and Publications section of this book.

* By consulting books such as those listed below, describe the threats to the particular grassland or dryland you have selected, and discuss what is being done to protect the natural habitat and its wildlife?

o Use this project as a model to study the status of shrublands and deserts, as described in the Grasslands, Shrublands and Desert chapter of this book, with the emphasis on desertification of drylands into desert through grazing, firewood gathering and other activities. See the reference list of the latter chapter for further reading.

o If you live within the range of these habitats, participate in a project to restore native plants to a grassland. Grassland birds have undergone drastic declines in the past decade, mainly through loss of habitat. Identify the grassland birds in your area and help in a project to obtain habitat for them, improve existing habitat or grow seeds of native plants for planting. Several source books supply information on mail-order nurseries that sell native plants and seeds. *Noah's Garden* has chapters entitled, "In Respect of Grass" and "To Plant A Prairie," which give very specific information about these habitats. The National Wildflower Research Center (2600 FM 973 North, Austin, TX 78725) supplies native plant bibliographies for each region and lists native plant associations. A book written by Lady Bird Johnson, who founded this center, and Carlton B. Lees, *Wildflowers Across America*, is a dazzling showcase of native wildflowers as well as an excellent source of information on these ecosystems. If you live near a shrubland or desert, plant native flowers and plants in your garden instead of grass to restore the ecosystem and conserve water. See the list of books below for instructions on planting desert and dryland gardens.

o If you live in an area where grasslands are mowed for hay, begin a public relations campaign to convince farmers to wait until after bird nesting season is over to mow. This would be in late July or August for most species of grassland birds. Consult reference books to determine the nesting times of grassland birds in your area. Such measures would be of great help to certain birds that have lost most of their natural grassland habitat. Make up posters that illustrate one or more of the following birds, and text describing their decline and need for undisturbed nesting habitat. In the East, the Bobolink, Grasshopper and Henslow's Sparrows and Bluebird, among others, will benefit. In the West, various species of Lesser and Greater Prairie Chicken, Sage Grouse and other bird species mentioned in the Grasslands, Shrublands and Deserts chapter are among these. Ask farmers and landowners to help preserve these birds and other wildlife by mowing practices. Have signs made that landowners could post on their property saying, for example, "Grassland Birds Protected Here." Publicize the campaign through letters to the local newspapers and speeches at local organizational meetings.

o Construct nesting boxes for Bluebirds and Purple Martins to be donated to landowners in grassland with scattered trees or bordered by woods. Instructions on how to make and maintain Bluebird houses can be obtained from the North America Bluebird Society, P.O. Box 6295, Silver Spring, MD 20906. *The Complete Birdhouse Book*, by Don and Lillian Stokes, also gives instructions on building and upkeep for both the Bluebird and Purple Martin houses. Films made by Don and Lillian Stokes include advice on planting for birds by species, such as hummingbirds and grassland birds; advice on how to construct, place and maintain bird nesting boxes is also given (CPTV Offer, P.O. Box 82, Hopkinton, MA 01748). The placement and maintenance of bird nest boxes should be long-term so that they may provide permanent nesting homes. It is important to keep records on the occupancy and breeding success of each box.

o Help native butterflies by planting wildflowers of species that are needed for their life cycle. The Monarch Butterfly, for example, requires Milkweed plants for feeding and laying its eggs. Learn about the species of butterflies and other pollinating insects in grasslands in your area, especially those in decline. For species listed on the US Endangered Species Act, all conservation projects should be coordinated with the US Fish and Wildlife Service and your state Natural Heritage Program (affiliated with the Department of Game or Wildlife in each state). Roadsides next to highways or in median strips and along country roads or railroads provide important habitat for butterflies, especially in areas where grasslands are disappearing. Contact your state and local transportation departments to obtain permission to plant wildflowers in these areas. The North American Butterfly Association (909 Birch St.,

Baraboo, WI 53913) provides information about helping butterfly habitat and butterfly watching, a new and fascinating activity for which there are guide books. *A World for Butterflies. Their Lives, Behavior and Future*, by Phil Schappert, is a primary source of information about butterfly life histories, habitats, conservation and threats. It also contains beautiful photography of hundreds of butterfly species worldwide. More information can be obtained from Dr. Schappert via the Internet: www.aworldforbutterflies.com. *Butterfly Gardening: Creating Summer Magic in Your Garden*, published by the Sierra Club, was compiled by the Xerces Society, a conservation organization for native American butterflies, in cooperation with the Smithsonian Institution. Be careful not to use commercial wildflower seed mixes that include species not native to your area or even to the United States. Certain exotic wildflowers, such as Purple Loosestrife, a European plant, are spreading in the United States, drying up marshes and crowding out native wildflowers.

Grasslands: Films

All films mentioned below are reviewed in the Video section.

"Crane River" is a celebration of the huge flocks of Sandhill Cranes that migrate across North American prairies.
"Durrell in Russia" is a 12-part series which includes films on the Saiga, European Bison and grasslands of Russia.
"Emas. High Plain of Brazil" centers on this large grassland, surrounded almost entirely by agriculture that serves as an island for Brazil's unique grassland animals, including the Giant Anteater and Maned Wolf.
"Grasslands," a Canadian Broadcasting Company documentary, describes the biodiversity and ecology of North American grasslands and their destruction.

"Land of the Eagle," a series, concerns North America as it was prior to settlement by Europeans, with segments on the prairies and their wildlife.
"Mysterious Black-footed Ferret" focuses on this extraordinary and highly endangered prairie native, filming its graceful, sinuous movements and rapid leaps while hunting prairie dogs.
"Nature of Australia" explores the natural history of the continent in six parts, from its grasslands to drylands, how native wildlife has been affected and what ecological harm has been done by humans.
"The Saiga of Kazakhstan" chronicles the decline in the herds that numbered more than 1 million animals as a result of hunting, fencing off of grasslands and loss of habitat. They have disappeared from the center of their original range in Central Asia.
"Sea of Grass" (segment of "The Living Planet") is one of the parts to this BBC series that describes the evolution of various ecosystems of the Earth.
"The Tiny Carnivores" introduces one to Australia's small marsupials, many of which are nocturnal and endangered, driven from their habitats in grassland, savannah and desert by human activity.
"Vanishing Prairie," a Disney classic, shows the inside of a prairie dog burrow and the wildlife that teems in this habitat.
"Varmints" documents the decline of prairie dogs in the American West through systematic poisoning programs by federal, state and local authorities, placing them in endangered status, and explains their important role in prairie ecosystems.
"Wildebeest Race for Life" follows the trail of 1 million of these odd-looking ungulates as they migrate in a large circle around the Serengeti.

Aquatic Ecosystems

Project Summary

Aquatic ecosystems are the most varied of all ecosystems, ranging from freshwater ponds to rivers, lakes, saltmarshes, coasts, mangroves and coral reefs to open ocean. Although a single type of ecosystem will be chosen for the project, it is hoped that the reports will be presented to the class to acquaint students with the characteristics of as many of these habitats as possible. The project will consist of selecting a particular type of aquatic ecosystem that is threatened in a geographical area listed below. This ecosystem, the threats to it--whether through pollution, damming, diversion or other activity--will be described, including its wildlife. Also certain aquatic species that are in sharp decline will be among the subjects listed for special attention. The ways in which this aquatic ecosystem, species or group of species is being conserved or destroyed will be a major focus.

Background

The aquatic ecosystems of the world have never been more stressed and degraded. The rise in human population to more than 6 billion people by the end of the 20th century placed strains of overuse and pollution on the limited supplies of fresh water, leaving billions of people without adequate clean water supplies and creating rising tensions over water rights. In these conflicts, wildlife pays a high price, losing pristine habitat and becoming contaminated with toxic chemicals and oil spills that are killing wildlife around the world. Dams have endangered numerous fish by impeding their migrations, and developing countries have been damming their rivers at an increasing rate. Rivers that flowed swiftly become still ponds after damming, an alteration to which many fish cannot adjust. Many of these fish are also declining as a result of the introduction of non-native fish, which are out-competing them. The Nile Perch

was introduced as a food fish in Lake Victoria, and it has virtually eliminated hundreds of species of native cichlid fish, colorful and ancient species. The Colorado River of the US west has many dams on it, which have totally altered the river's flow patterns and temperature, endangering many fish that had evolved in the swift-flowing, silt-laden water. The most dramatic example of a dam endangering a wide variety of plants and animals, and dislocating 1 million people, is the Three Gorges Dam being built on the Yangtze River of China. It will almost certainly result in the extinction of the Yangtze River Dolphin, a very ancient freshwater species, the Yangtze Sturgeon and numerous plants that will be inundated by the waters. Although far upstream, it will also have the effect of drying up wetlands downriver and at the delta. With inadequate provision for sewage treatment for the millions of people and industry living alongside the new lake formed by the dam, the Yangtze is expected to become extremely polluted. Large dams inundate vast areas, displacing thousands of people from their homes and drowning rare trees, plants and wildlife.

Diversion of rivers for agriculture or water supply has left many riverbeds and deltas dry, causing entire ecosystems to collapse. An increasing problem with rising temperatures has been violent storms which cause severe flooding of rivers, made worse by the deforestation that robs hillsides and riverbanks of protective trees that absorb rainfall throughout the year and hold the soil in place. Lakes and spring ponds that dry up in the summer are also being filled in by developers and government projects, eliminating habitat for myriad aquatic creatures, from frogs and salamanders to turtles and water birds.

Overfishing, pollution and destruction of ocean environments have reached crisis proportions, with 70 percent of all fish caught commercially in depleted status or worse, including some of the most ecologically important species--sharks, tuna and others at the top of their food chain. Toxic chemical pollution has increased, especially in colder waters, where whales and other cetaceans are dying from massive build-ups of chemicals such as PCBs (Polychlorinated Biphenyls), pesticides, heavy metals and other toxins. Along the pristine coast of Washington state, Killer Whales are dying from these toxic chemicals, as are white Beluga Whales in the St. Lawrence River. A Sperm Whale that died recently of toxic chemicals had to be disposed of as highly toxic waste. Other waste in the oceans is killing wildlife. Abandoned driftnets drown thousands of birds, seals, sea lions and sharks, and fishing line entangles endangered Northern Right Whales and other wildlife, drowning them. Plastic sheeting, balloons, plastic from six-packs and other trash are killing seabirds, such as the long-lived and declining albatross, which unknowingly feed this trash to their chicks, killing them, or swallow the items themselves, later dying of blocked intestines. Collisions with ships and motor boats are causing large numbers of deaths in Florida Manatees and whales.

Coral reefs, the most beautiful and biologically diverse ocean ecosystems, are dying from many threats. Dynamite and cyanide used to kill and capture fish destroy the entire reef. Overfishing, pollution and silt that washes off nearby lands from agriculture and development can combine to kill a reef. Global warming causes coral bleaching that is affecting a growing number of reefs. More than one-third of all coral reefs are now dead or dying.

Wetlands have declined in the United States by 50 percent. This has resulted in more destructive floods and losses in fisheries production. Wetlands filter pollutants, and their reduction has lowered water quality. Elsewhere in the world, similar declines have taken place. Both fresh and saltwater marshes provide important benefits in cleaning water through a natural filtration system. In fact, the worldwide value of this benefit to the Earth and human society has been calculated at $1.7 trillion. Marshes also provide important flood controls by absorbing large amounts of water from nearby sources or rainfall, as well as a multi-billion dollar benefit of serving as nurseries for fish, shellfish and other wildlife. Traditionally, however, they are filled in for development, airports, seaports and other commercial uses which are considered to be far more beneficial to society. It is important to reexamine such an approach, especially in view of the tremendous costs of flooding in human lives and property and the decline in fish and shellfish harvests.

An atmospheric phenomenon caused, apparently, by CFCs, or chlorofluorocarbons, chemicals used in refrigeration and for other industrial purposes, is thinning the ozone layer, a protective shield that filters the sun's rays before they strike Earth. Large holes have developed over the Poles, especially the South Pole, allowing huge amounts of ultraviolet rays from the sun to enter the atmosphere, causing many cases of skin cancer in humans and

having unforeseen effects on animals with sensitive skin like frogs and salamanders. Frog species are disappearing at a catastrophic rate, especially those that lay their eggs in the open, exposed to the ultraviolet rays of the sun. Frogs are also suffering grotesque birth defects, which may be caused by pesticides or virus outbreaks. Frogs™ decline may be a warning sign that serious problems exist in the aquatic ecosystems of the world that will soon begin to affect human beings.

Activities

o Read the Aquatic Ecosystems chapter, which describes many of these problems in detail and parts of the world where large numbers of animals and plants are endangered. The references cited will provide more information.

o Select a species of wildlife or plant that has become endangered as a result of the destruction of aquatic ecosystems or related activities. Describe its status, threats to its habitat and what--if anything--is being done to prevent its extinction.

o Select an aquatic area from the following list to study its wildlife and present status:

- United States™ Colorado River
- Florida's Everglades swamp
- Rivers and wetlands of the US East and Southeast
- Russia's Lake Baikal
- Central Asia's Aral Sea
- East Africa's Lake Victoria
- Southern Africa's Okavango Delta
- Brazil's Pantanal wetlands
- Amazon River and its dams
- China's Yangtze River
- Australia's Great Barrier Reef
- Mississippi River Delta and adjacent waters

All are described in the Aquatic Ecosystems chapter. See also Video and Books and Publications sections.

o The following wildlife has become endangered as a result of the destruction of these aquatic ecosystems or related activities. Select one and discuss threats, species involved and conservation programs:

- albatross and other large seabirds
- frogs
- whales and dolphins
- sharks
- sea turtles
- penguins

o Select an aquatic animal or plant species that is threatened with extinction and write a short report about it, using the criteria in the project, "Profile of an Endangered Species." It can be a type of fish, frog, turtle, aquatic insect (such as a dragonfly), bird or mammal, for example. Write about the species in the context of its aquatic habitat, whether its habitat is being protected, and other threats to it, which may include pollution, trade or competition with exotic species. As source material, consult this book, *Threatened Birds of the World, Walker's Mammals of the World* and other references cited here or in the Books and Publications section of this book.

o Make comparisons between natural means of flood control, including marshes, beaver ponds and heavily forested stream and riversides, and artificial means, such as levees, dikes and canals. *Water, A Natural History*, listed below,

is helpful in pointing out the differences. Compare the cost and success of natural means of controlling pollution, such as sewage through marshes that filter waste, and artificial means through sewage plants. Individual homes in suburban and rural areas use septic tanks and cesspools to store sewage. In times of heavy rain, however, they often overflow into rivers, as do urban sewage plants. In many parts of the world, no sewage treatment exists, causing rivers and waterways near cities to become severely polluted. Some cities in California and elsewhere have constructed artificial marshes to filter sewage water, creating, in the process, wildlife havens. New types of toilets, known as compost toilets, are another less-polluting innovation. Read Chapter 9, "Aqueducts and Toilet Bowls" in *Water, A Natural History*, and write a short report on improvements needed in the present systems.

o Grassroots organizations throughout the world have been successful in restoring rivers and other aquatic ecosystems. Using a book, such as *How to Save a River. A Handbook for Citizen Action*, select a river, wetland, pond (including beaver ponds), lake or vernal pool (temporary wetland that dries up in the summer) to help preserve or clean up from pollution. Small projects can be of importance in conservation. For example, some high school classes in the Midwest sampled a nearby marsh for the types of frogs found there and discovered that the majority were deformed, having five or more legs, misplaced eyes or other grotesque malformations. The situation was given publicity, and research began on the causes. Pesticide contamination was considered the most likely cause, since water from the marsh used to grow frogs in captivity produced similar deformities. One organization, The Riverlands Conservancy, has helped purchase river habitat in Oregon, Missouri and Washington totaling 17,174 acres since 1993. Measuring pollution in local waterways is an excellent class project that can lead to environmental action on the part of state or federal authorities. Save Our Streams program, run by The River Network, headquartered in Portland, Oregon, and its sister organization, The River Clearinghouse, provide information to activists throughout the country on an 800 "hot line," using a database of volunteer experts who provide advice. The River Watch Network has been instrumental in helping communities monitor water quality in order to restore and protect rivers. (See *How to Save a River. A Handbook for Citizen Action* for more information and other organizations, which include American Rivers, the International Rivers Network and Riverkeepers, working to preserve aquatic ecosystems.) Using these examples, propose a class project to help conserve a local aquatic ecosystem**.**

Aquatic Ecosystems: Films
All films mentioned below are reviewed in the Video section.

General: "Acid Rain. Clouds with a Sulphur Lining" discusses the severe problem of acidification of rainwater caused by air pollution and its effect on forests and other environments. "Dead Ahead: The Exxon Valdez Disaster" is an examination of the 1989 oil spill in Alaska from many aspects. "Pollution: World at Risk" is a general look at various types of pollution and toxic chemicals and their environmental effects. "Vanishing Wetlands," produced by the Canadian Broadcasting Company, explains the ecological benefits of wetlands and threats to them. "The Wasting of a Wetland" focuses on the Everglades but describes the abuse of wetlands as it affects wildlife**.**

Ocean environments: "Cities of Coral"; "Coral Reefs. Rainforests of the Sea"; and "Jewels of the Caribbean Sea" all center on coral reefs. They show the great beauty and diversity as well as the threats to them. "Creatures of the Mangroves" and "Margins of the Land" (segment of "The Living Planet") treat the shoreline areas, and "Messages from the Birds" concerns the decline in shorebirds in North America. "The Open Ocean" (segment in "The Living Planet") explores the evolution of this habitat on Earth. "The Mirage of the Sea" discusses the overfishing and exploitation based on the assumption that there would always be plenty of fish. "Blue Whale: Largest Animal on Earth" is the first film to follow these giants in the ocean. "Desert Whales" are the Gray Whales that winter off Baja California, Mexico. "The Forgotten Mermaids" is a film about Florida Manatees. "Sperm Whales: The Real Moby Dick" gives glimpses into these deep-diving whales and discusses the fact that they have not recovered from whaling, with large males still very rare. "Colony Z" is about the very rare Yellow-eyed Penguin of the New Zealand region. "Whales Down Under" focuses on a population of newly discovered Southern Right Whales east of New Zealand, following them for a long period.

Freshwater environments: "Sweet Fresh Water" (segment in "The Living Planet") is an in-depth look at the planet's limited supply of water and the creatures who inhabit these environments. "Giant Otters" follows a boisterous group of these largest of otters in South America, discussing the causes for their decline. "Journey to Save a Crane" describes a project of the International Crane Foundation to preserve the endangered Siberian Crane through delicate negotiations with Chinese and Russian authorities. "White Water, Blue Duck" is a film about this threatened New Zealand duck and its remarkable adaptation to a very swift-flowing river. "Jewel of the Rift" (segment in "Heart of Africa" series) concerns Lake Victoria, its geology and the amazing, colorful fish native to it, which are now being eliminated by the Nile Perch. "Okavango: Jewel of the Kalahari" explores this huge wetland, second largest in Africa, set in the middle of a desert. "Amazon. Land of the Flooded Forest" illustrates how the flooding of the Amazon River each year nourishes a diverse ecosystem of fish, freshwater dolphins, fruits and trees. "Journey to the Sacred Sea" travels to Lake Baikal, where the unique fish and seals inhabit an extremely ancient and deep lake threatened by pollution. "Cadillac Desert" is an expose of the diversion of lakes and rivers to supply Los Angeles with its water supply at the expense of wildlife and the environment. "Prairie Waters" visits the potholes of Midwestern North America, temporary ponds and lakes that provide breeding habitat for millions of ducks and other birds each spring, yet are routinely filled in by farmers. "The Wild Colorado" is a thorough look at the geology and ecology of the Colorado River and the effect of dams on its wildlife and ecology.

Trade
Project Summary
To better understand the international wildlife trade in live animals and animal products, focus will be placed on one or more major categories of the trade. The major categories are: whaling, fur, reptile skins, Traditional Medicine products, fisheries, wild pets (including cage birds, lizards, turtles, snakes and frogs). Selection by a student of a species, group of species or general subject under one of these categories allows an overview that can be thorough and involve much research, or result in a short report. A classroom project could involve a subject such as Traditional

Medicine, in which groups of students would select individual species or groups of species, such as rhinos (killed for their horns), Tigers (killed for every part of their bodies), seahorses, snakes, turtles, monkeys and other primates and sharks. The reports would be presented together.

Background

Trade in live animals, plants and the products made from them has caused extinctions and has pushed many to the edge of extinction. At least 15 percent of highly threatened mammals and birds have declined as a result of trade, according to the International Union for the Conservation of Nature and Natural Resources (IUCN) (see Hilton-Taylor 2000). Internationally, billions of dollars are earned legally and illegally, and each year, more species become exploited. The trade is second only to the international drug trade in overall profits, worth an estimated $3 billion a year in protected live animals and animal products. As soon as one species becomes rare from exploitation and receives protection, the trade switches to a similar one, pushing it into threatened status. Much of this trade is for luxury products or to supply collectors and the wealthy who wish to own rare birds and other wildlife; wear the furs of endangered species, such as Snow Leopards or Cheetahs; purchase purses or clothes made from rare snakes or other reptiles; or consume luxury foods, such as endangered fish, whale and even Tiger meat. The wool of the Tibetan Antelope, the Chiru, ivory from elephants, the caviar of the endangered Beluga Sturgeon, rhinoceros horn and live Spix's Macaws, captured for collectors of rare animals, are worth far more than gold. The Traditional Medicine trade deals in a wide variety of animal products and plants and is a major factor pushing the Tiger, rhinoceros, seahorses and a host of other species toward extinction. For the majority of species exploited for this trade, substitutes exist or the products are not effective remedies. Ecological systems worldwide are being disrupted with the removal of predators and other keystone species, causing a loss of biodiversity.

This trade is taking place in spite of the landmark Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), enacted in the 1970s and now ratified by a majority of the countries in the world. It places animals at greatest risk of extinction on Appendix I, which prohibits commercial trade, and threatened species on Appendix II, which limits or controls trade on a species-by-species basis. CITES bans trade in species listed on either Appendix if the trade will be detrimental to the species' wild populations. In practice, many species that are threatened with extinction and listed on CITES Appendices are traded illegally or in countries which lack national legislation restricting wildlife trade. Although endangered spotted cat fur coats are no longer seen in New York City clothing stores, the fur trade continues to use the skins of rare cats and other wildlife, which are openly sold in many countries around the world. Enforcement funding is inadequate in the majority of countries, even the United States, where only 10 percent of shipments are inspected. Moreover, certain products, such as powdered rhino horn or Tiger bones, can be easily secreted in packaging while in transit. CITES has been an important deterrent to trade in endangered species, however, providing many threatened animals and plants with needed protection. Also, a growing number of countries have strict legislation prohibiting trade in protected species, including exports.

The methods used to capture and kill animals for the wildlife trade are often cruel in the extreme. Steel-jaw leghold traps and wire neck snares that cause great pain and injury produce pelts for the fur and bushmeat trades. Whales die from exploding harpoons thrust into their heads and bodies. Frightened live animals are crowded into cramped, dirty cages and transported to pet shops and laboratories, suffering high mortality along the way. Man's inhumanity to animals reaches an extreme in the wild animal trade.

Activities

o Read the Trade chapter in this book and other sources referenced.

o Select a subject among the following wildlife and plant trades for further study:
  - fur trade
  - whaling and sale of whale meat
  - sea turtles--trade in eggs, meat, shell and stuffed curios
  - fine wools--Shahtoosh from Tibetan Antelope and Vicuña

- bushmeat from endangered gorillas, chimpanzees, monkeys, turtles and other wildlife of Africa and Southeast Asia
- fisheries products--sharks for their fins and meat and caviar, for example
- reptile products for luggage, handbags and other luxury goods
- wild bird pets
- reptile pets, such as lizards, snakes and turtles
- fish for aquariums
- butterflies for collectors
- plants, such as orchids and cacti, for collectors

After reading about these trades in this book and other sources, write a report that discusses the following aspects:

- How many animals or plants are estimated taken per year for this trade?
- What species are they? What is their status in the wild?
- Where are the animals and animal products sold? Are they killed or collected in one country where they are protected and then sold in another?
- What controls exist to protect threatened and endangered species traded? Are they listed on CITES or the US Endangered Species List? Are they protected in their country of origin with high penalties for illegal take or killing, or are the penalties so low that there is an incentive to capture the species illegally? In India, for example, wildlife smugglers and killers of Tigers and other protected wildlife almost never receive jail sentences or large fines, while in China, the death penalty can result from killing a Giant Panda.
- What profits can be earned from sale of these animals or animal products? Find out the prices of expensive goods, such as Beluga or other Russian caviar, Shahtoosh and other items.
- What are the potential ecological effects of the disappearance of these animals? African and Asian Elephants are keystone species, distributing tree seeds, creating water holes and forest openings that benefit their ecosystems. Their disappearance from many areas has already had ecological effects. Find other examples, such as Tigers, which are at the top of their food chain; monkeys and other primates who pollinate flowers or distribute seeds; birds caught for zoos and collectors, such as hornbills, who distribute fig seeds; or animals that are important food items for wildlife.

o Traditional Medicine trade--a group project. Based on the information in the Trade chapter and the references below, divide the class into groups and have each group select from the various species used in this trade, such as Tigers and other wild cats, rhinoceros, monkeys, seahorses, musk and other types of deer, snakes, pangolins, bears of all species and rare plants. The information for each group to gather is the following:

- What is the extent of this trade? Are animals and plants being collected throughout the world to supply the trade?
- What percentage is sold in China, other parts of Asia or in

Asian pharmacies in other parts of the world?
- What prices are obtained for these animals at the level of the captor, the local markets, exporter, importer and retail sales? What effect is this having on the species? Will it become extinct if the trade continues at its present level?
- Is the trade legal in the animal's country of origin? Is the species listed on CITES or banned from importation or exportation? Is the species openly sold in some markets? Where and when?
- Are there education programs that are trying to stop the killing, marketing and purchase of these species or the over-harvesting of rare plants? What governments or organizations are trying to help these species through protection of habitat, bans on commerce or enactment of strong legislation to protect them?

o Enforcement of existing legislation is crucial to protecting threatened and endangered animals and plants. What state and federal laws ban the sale, killing and purchase of endangered species? How is evidence gathered for wildlife crime cases? How does CITES work?

o Visit stores that sell animal products and live animals.
- Fur and department stores with furs: List the kinds of animals used to make the garments being sold. It is required by US law that the species of animal and country of origin be listed on the label. List the ranched animals, such as mink and chinchilla, and wild-trapped ones, such as lynx, beaver and raccoon. Write down the number of coats and other garments of each type of animal, the date, the store and its address. Neither ranched nor wild animals are humanely treated prior to their deaths. Learn about the methods of killing of wild animals (types of traps, number of animals killed per country and US state) and the numbers and species of animals farmed. Contact the Animal Welfare Institute, the Humane Society of the United States and PETA for films that show the cruelty of trapping. Farmed animals are kept in tiny cages, where they become neurotic, and killing methods are unregulated.

- Visit department and shoe stores to determine whether reptile products are being sold. This trade kills millions of animals and threatens many species, as well as causing rats and other rodents they prey on to increase to pest proportions when too many snakes and other reptile predators are killed. List the species from which the item is made, if possible. Laws regarding labeling of reptile products are less strict than those regarding furs, and some do not list the species. If possible, determine if any endangered species are sold and how many items are being sold in your area.

- Visit pet stores to inventory reptile pets, such as iguanas, lizards, snakes and turtles. Find out how many are wild-caught, what species and whether threatened. Also visit pet stores to inventory their cage birds. Ask if the birds were taken from the wild or are captive-bred. In the United States, wild-caught parrot imports are allowed only for a few breeders, and parrots in pet stores should be captive-bred. Ask if the birds were bred in captivity. Many finches and other birds are also banned from importation. Obtain a copy of the Wild Bird Conservation Act and see

if any of the species listed as fibannedfl are being sold. If so, tell the store owner and report this to the US Fish and Wildlife Service Law Enforcement Division. Contact the Environmental Investigation Agency (EIA) for films that show the capture of wild birds in Senegal and Argentina and the cruelty involved in the cage bird trade. If any pet store is selling primates, find out the species. It may be endangered, as in the case of a Diana Monkey sold in a Long Island pet store a few years ago. Primates do not make good pets and should not be purchased. Many organizations receive unwanted primate pets to care for, after they have bitten their owners. Ask your local pet store to avoid sale of live animals. This is a trend in many pet stores that now sell only pet food, leashes, books and other non-living items. Patronize such stores. Contact your local humane society to learn of rejected wild pets and the difficulty in finding homes for them and recount these examples in a letter to your local newspaper, asking people not to buy wild-caught animals of any type.

o Attitudes are crucial to the protection of native wildlife by the people living within their habitat. Killing of animals for food and sale as pets has increased in recent years as international trade provides worldwide markets. It has become all the more important for wildlife to be valued and protected by people living in their range. Effective education is a key. A program in Saint Lucia, an island in the West Indies, is run by Paul Butler, working for the organization RARE. He has taught pride and appreciation of native wildlife and convinced the people living on the island to protect their native parrot, a species in high demand among collectors and numbering only a few hundred in the wild, as well as their forests and other wildlife (see reference below). The smuggling of the St. Lucia Parrot has virtually stopped as a result, and its forest is now protected as the habitat for this national bird. In the rainforests of the Congo, a Gorilla family being studied by a primatologist was filmed. In order to acquaint local people with these animals, the film was shown to them. They had considered these apes to be fierce, dangerous animals, worthy of being killed for the bushmeat market. When they saw the tender affection among family members and the playfulness of the young Gorillas, they were pleased and surprised, saying "They are like us!" They had the forest declared a protected reserve and now teach their children to protect these Gorillas. (This was filmed by Moses Films and shown on National Geographic Explorer, entitled "Living with Gorillas" in 2000.) Write a report about the need for similar programs and find out about others being conducted to educate people about their wildlife. Think of species that would benefit from such programs, and write a short summary of an education program you think would be effective for an individual species or group of species. For example, turtles are being heavily exploited for meat and the pet trade throughout the world, endangering many species. If they were better appreciated in their native lands, especially Southeast Asia, where tradition and folklore hold them in high esteem, their future might be brighter. Design a poster and educational brochure about Asian turtles that could be distributed in Viet Nam, Laos, China and other countries where turtles are being captured in enormous numbers.

o While great profits can be derived from the sale of wildlife, even greater ones can come from tourism. Elephants killed for their ivory bring the hunter a one-time profit of several thousand dollars, but tourism centered around elephants can benefit local people throughout the long life of the elephant, a life of some 60 years, totaling $100,000 or more. The capture of rare parrots, likewise, is far less profitable than ecotourism, which is worth 100 times or more the value of their sale in the pet trade. Whale meat is far less valuable than live whales that are whale watched. Whale watching now earns $1 billion per year worldwide from the 9 million people who take part in excursions in almost 90 countries, according to the International Fund for Animal Welfare. Think of other examples of non-lethal or non-invasive programs that benefit wildlife and ones that might be started to provide local people with income without harming wildlife. Another form of non-lethal business concerning wildlife involves the placement of videocameras in wild habitats, connected with the Internet. Internet users pay a small fee to see live views of the animal or scene, or to access the website for more films and information. South Africa's national parks are profiting from such a system, and the potential is great for other such videocamera placements. Videocameras can be solar-powered, as engineered by Daniel Zatz in Alaska, who has placed these cameras near bear feeding areas, with the images sent to a museum in Washington state (seemorebears.com). They also have the advantage of not injuring or invading the habitat of shy species which might be disturbed by large numbers of tourists. Think of species that might benefit from videocameras in their habitats. Examples might be wild parrots at their nests or Tigers filmed in national parks along trails.

Trade: Films
All films are described in detail in the Video section.

General: "The Business of Extinction," produced in 1977, is a classic film on wildlife trade and is extremely hard-hitting, showing smuggling and animal cruelty in the wildlife trade. "The Rangers of Nepal" profiles the bravery and dedication of Nepalese rangers who protect Indian Rhinoceros, Tigers, Asian Elephants and other animals from poachers. "Wildlife for Sale. Dead or Alive" is a Canadian Broadcasting Company film documenting the multi-billion dollar trades--legal and illegal--in wildlife that endanger thousands of species worldwide.

Ivory trade: "Echo of the Elephants," "Elephant," "The Elephants of Tsavo" and "Daphne Sheldrick and the Orphans of Tsavo" all deal with the slaughter that elephants endured during the 1980s and the effects on their populations and behavior. These sensitive and intelligent animals are traumatized when a family member is killed. The last film concerns the orphan elephants, tiny victims of the killing for ivory, affectionately cared for by Daphne Sheldrick in Kenya.

Fur and Traditional Medicine Trade: "Empire of the Red Bear" is a series about Russian wildlife that includes the discovery of two dead Siberian Tiger cubs who starved to death when their mother was killed. "Tiger. Lord of the Wild" profiles many of the activists trying to stop the trade in Tiger pelts and body parts in India and elsewhere.

"Giant Otters" was filmed in Guyana, one of the few places left where these animals can be seen because of their killing for fur throughout their South American range, which is discussed.

Whaling**,** Sealing and Sea Turtle Killing: "The Great Whales," "Return of the Great Whales," "Blue Whale: Largest Animal on Earth," "Sperm Whales: The Real Moby Dick" and "Whales Down Under" all discuss the effects of whaling on the great whales. The latter film focuses on the Southern Right Whale, a species heavily hunted and only beginning to recover 50 years after receiving protection. "Sea of Slaughter" is based on Farley Mowat's history of the decimation of wildlife along the North Atlantic coasts. Walrus, whales, seals, sea mink, seabirds and other species that teemed in these waters in colonial times were killed for market sales--several species to extinction. "Long Live the Turtle" is part of a series on Japanese wildlife. "In the Shadow of Fujisan" discusses Japanese killing of sea turtles and their trade in these animals, as well as whaling and dolphin-killing. "Ancient Sea Turtles Stranded in a Modern World," by the Sea Turtle Restoration Project of Earth Island Institute, chronicles the many threats to sea turtles, especially drowning in shrimp nets, urging remedial effort to protect them.

Cage Birds: "Bird Traffic" is an excellent expose of the illegal capture of Salmon-crested Cockatoos at the roosts in Indonesia, showing the trauma and cruelty of their caging and shipment to Singapore and other Asian markets, endangering the species. "Caribbean Cool" is a film about the work of Paul Butler in St. Lucia and other Caribbean islands to protect the native parrot and its habitat. Children are taught about the parrots and dress in parrot costumes, singing songs about these birds and other wildlife of the island. The parrot is the national bird and is given much publicity and positive attention on the island.

Predator Prejudice

Project Summary

The purpose of this project is to research the general subject of predator prejudice and its effect on predators in various parts of the world. Read the material below and the Persecution and Hunting chapter in this book. The subject in general or a particular predator which has become endangered as a result of prejudice and persecution will be selected for a short report, including information on past and present distribution, control measures taken and the present status of the species.

Background

In the United States, Grizzly Bears, Gray and Red Wolves were eliminated from 98 percent of the country south of Canada by European settlers in control programs using poisons**,** guns and traps. Today, through natural recolonization and reintroduction, these predators are reoccupying small portions of their original ranges. Unfortunately, outside national parks, these animals are encountering prejudice. Local livestock owners, whose ranches surround the protected national parks and forests, oppose their presence. Livestock owners near one Gray Wolf reintroduction site in Yellowstone National Park in Montana attempted unsuccessfully through a lawsuit to have wolves removed from the park. Wildlife research over the past century has found that wolves rarely kill domestic livestock, and their predation on deer, elk and other ungulates keep these species strong and healthy. Grizzly Bears are mainly vegetarian, with occasional predation on small rodents or the calves or fawns of elk or deer, yet they have been hunted out of all but about 1 percent of their original range in the western United States south of Alaska.

Predator prejudice is common throughout the world wherever livestock is grazed in large numbers. In Ethiopia in East Africa, the Simien Wolf, a small canid that preys mainly on rodents, has been killed off by livestock owners who mistakenly believe them to present threats to their sheep and cattle. The species is near extinction. Likewise in South America, Europe and Asia, predators have been heavily persecuted, with wolves, bears, big cats and others eliminated from areas near human habitation and many wilderness areas.

Seals, sea lions and otters are also the object of prejudice from fishermen who believe that they take too many fish. In

fact, they often prey on fish that are not taken for human consumption, many of which are predators of food fish. The Caribbean Monk Seal was persecuted to extinction, and its close relative, the Mediterranean Monk Seal, is now critically endangered as a result of killing by fishermen. Its remaining populations, numbering fewer than 1,000 animals, hide in caves along the coasts. Sea otters eat invertebrates that eat kelp and sea grass, thereby playing a key role in maintaining these ecosystems in which fish and shellfish flourish, but abalone fishermen consider them unwanted predators.

Birds of prey have also been persecuted as threats to livestock or because they competed for the same food as humans. The Bald Eagle was killed for a bounty in many parts of the United States because it fed on fish, causing fishermen to believe that it was an unwelcome competitor. Hawks and eagles around the world are shot and poisoned by ranchers and others, reducing many species to endangered status. In some areas, birds of prey are shot on sight. Legal protection for these birds has only recently been enacted in the United States, but many other countries fail to accord protection. They have an important ecological role to play by preventing rodents, snakes and other species from multiplying to pest proportions. The majority of species specialize in killing rodents, which helps farmers raising and storing grains.

Likewise, bats prey on insects and are important pollinators of plants, but they are persecuted in most parts of the world.

Snakes are also important predators of rodents, yet they, too, are routinely killed around the world. They are either considered pests or inspire great fear that they might present a threat to human beings. Snakes tend to be afraid of people, who are not their natural prey, and if left alone, will not attack.

Crocodiles perform a useful role in preying of overpopulated fish, yet they are killed as potential threats or for the leather trade. A majority of crocodile species are now endangered.

Activities

o Research: Using the sources listed in the Persecution and Hunting chapter, and others listed below, as well as those available in your library and through computer on-line searches, learn about the subject in general. Consider the following aspects of the issue:

1. Laws have been enacted since the Middle Ages in Europe encouraging the killing of predators and even punishing those who did not kill and deliver their hides to authorities. Many of these laws have been altered over the years and now remain in the form of bounties paid for pelts, and regulations permit and encourage persecution of predators. Are there state laws that allow persecution of predators, including endangered species? (Read the US Endangered Species Act and the Marine Mammal Protection Act to find examples of legalized killing of species considered predators of livestock or fish.)

2. What attitudes prevail in various parts of the world toward predators? While negative fears and hatred dominate in many areas, trends are changing in many countries. North American native tribes traditionally revere predators and incorporate them into their folklore. Europeans settling America had an opposing view, instituting predator control programs. What is unusual about the legal status and attitude toward the Gray Wolf in Italy? (See Persecution and Hunting chapter.) What happens to endangered Cheetahs when white ranchers who hate predators take over land in Namibia and South Africa? What education programs are taking place to change prejudices? The reintroduction in the United States of both Gray and Red Wolves was a result of this new view and the application of the US Endangered Species Act, but education programs have had mixed success. In some areas, such as Yellowstone National Park, however, tourists are coming in large numbers, spending money in local towns, and watching the Gray Wolves in an open environment considered the best "wolf watching" area in the world. Could tourism help save predators? The survival of predators depends entirely on attitudes of people living in their habitats.

3. Biological Studies: Studies on Gray Wolves in Alaska in the 1940s by Adolph Murie began a major change in

knowledge of these animals and their relations with their natural prey that overturned previous misconceptions, many of which assumed that they were destructive to their prey. These studies have been augmented by other biologists on various predators throughout the world, confirming the important and positive role that predators play in ecosystems. What studies can you find that examine the biological role of predators of various types, including birds, fish (such as sharks) and reptiles (such as snakes and crocodiles)?

4. Economic Damage: Control programs against predators are based on real or assumed damage to livestock or other property or assets, but they have rarely been based on fact. Exaggeration and fear have distorted estimates of actual losses to predators. Moreover, the ranchers or herders tend to release their livestock into the wild without guard dogs or other protection. When their animals are found dead, predators are blamed, when proof is often lacking. When livestock is guarded by dogs or fences, or housed in buildings or pens at night and when giving birth, mortality is usually very low. Unfortunately, US government programs, such as the Animal Damage Control (ADC) Division of the Department of Agriculture, routinely trap and poison hundreds of thousands of animals each year without proof of their predation on livestock. Contact the ADC and ask how many traps, how much poison and how many animals of all types have been killed in recent years. Also ask for the numbers and species of no-target animals, such as endangered Grizzly bears, Bald and Golden Eagles and other wildlife, taken in these programs. Ask the ADC how it avoids killing endangered animals? How much is spent on these programs per year, and what alternative programs could protect livestock in non-lethal ways, including guard dogs or other guard animals, such as llamas and donkeys, and by providing information on protecting livestock for far less money?

o Reports and Discussion: Select the subject of predator control in general for a report based on the information you have gathered in accordance with the categories above. Discuss this issue in class.

o Select a particular species that has been persecuted to endangered or threatened status by predator control programs. What was the original range of the species? What is its present range? What are the natural prey species of the animal and its habitat? When did control programs begin to eliminate the species and what were the reasons on which they were based? Was the species gradually, or rapidly, reduced in both numbers and range? Were control methods directed at adult animals only or on the young, such as killing pups in the den? What is the natural behavior of the animal in terms of its social nature with others of its kind, number of young, number of breeding adults in a group, whether it is solitary, and whether it can easily recover its population once control is stopped or tends to decline to extinction? What are the attitudes of the people who live within its habitat? What is being done to help the species? What do you think should be done to prevent its extinction?

o Conservation: Describe various means of protecting predators that are persecuted. For example, bats have been conserved through education programs in local communities and schools about their ecological role and how to bat-proof buildings. Ecotourism is another means of protecting bats, since their flights at dusk can be spectacular. The economic value of predators in controlling insects or rodents, for example, is an important argument in their favor. Many approaches are needed, depending on the attitudes held by the local people, the type of damage alleged and the economic factor. In some cases, the same species can be reviled in one part of the world and admired in another. The Gray Wolf is now a valued and protected predator in a growing number of countries, but in Russia and other countries, it is still tainted by folklore that bears no relation to fact. Make recommendations for the conservation of the Gray Wolf or another species in a country where it is persecuted. Write a brochure and design a poster for a species of your choice that would educate the public about why this species should not be persecuted.

Predator Prejudice: Films
All films are described in detail in the Video section.

Wolves: "Crying Wolf," "Wolf" (Spain), "Wild Wolves" (general), "Return of the Wolves" (Yellowstone National Park). All discuss the persecution, disappearance from large portions of its original range, and facts about the Gray Wolf's true ecological role and behavior. "Wild Dogs of Africa" is a sensitive portrayal of these endangered canids, including discussion of their persecution by ranchers, especially in southern Africa.

Bears: "Grizzly and Man--Uneasy Truce" (US persecution); "Grizzly Bears: Losing Ground" (British Columbia, Canada). These two films show the extreme ignorance and fear with which these bears are seen in North America, resulting in their killing for presumed threats and a lack of commitment on the part of the public and some officials to preserve the species.

Seals: "Orphans of Time" concerns the two surviving species of monk seals, the Mediterranean and the Hawaiian, both of which are highly endangered. "Seals--the Salmon Eaters," a film about seals in the Pacific Northwest (primarily Washington state) describes the intense hatred felt by fishermen toward seals and their desire to kill large numbers of them to increase the take of salmon.

Birds of Prey: "Anna and the Honey-Buzzards" is an inspiring film about a woman who has protected migrating birds of prey in southern Italy from being killed illegally by hunters who shot them from bunkers on hillsides. She has been joined by others who help her patrol the area since the film was made. "Eagles: The Majestic Hunters" is a beautiful film about these superb hunters and their life histories. It includes shocking footage of persecution of eagles in various parts of the world where they are killed and nailed to fences or poisoned.

Snakes**:** "Snake" is an excellent film to dispel irrational fears about snakes, 85 percent of which are harmless to humans, and to show their value in controlling rodents and other snakes.

Bats: See film list at end of "Bats: Ecologically Important Mammals" project.

Saving the American Elm and Chestnut Trees
Project Summary

This is an action-oriented project in which students or individuals obtain seedlings of these endangered trees and plant them to help restore the species, which were once widespread. For those living in areas outside the range of these species in Eastern North America, other threatened trees may be planted.

Background

Both the American Chestnut and the American Elm have been decimated by diseases brought to the United States on wood or trees. Millions of these magnificent trees have died, but within the past decade, plant geneticists have produced disease-resistant types. The Elm Research Institute distributes seedlings grown from trees that have natural resistance to Dutch Elm Disease and have survived exposure to it. The tree that is cultivated by this institute is called the American Liberty Elm, and since 1983, more than 250,000 seedlings have been distributed to organizations, such as the Boy Scouts of America and others, who grow them from seedlings, then sell them to local towns, public parks and organizations for planting. The organization hopes to bring back the American Elm to Main Street America. The Elm Research Institute also provides advice on saving diseased elms. One teacher in Michigan organized local neighborhood groups who located diseased trees and succeeded in treating them to prevent their deaths.

The American Chestnut, a massive tree of eastern forests, made up about one-fourth of the original eastern forests in colonial times. It provided nuts that were fed on by populations of the now extinct Passenger Pigeon, American Turkeys, Black Bears, squirrels and other wildlife. These trees grew to heights of 100 feet or more and had deeply furrowed trunks, earning them the name "Eastern Redwood." Their near-extinction has been catastrophic to forest ecosystems. The Chestnut Blight that attacked them was first seen in 1904 on American Chestnut trees lining avenues near the Bronx Zoo, and apparently entered the country on another species of chestnut tree imported for botanical purposes. Like Dutch Elm Disease, this disease cuts off nutrients and water, gradually killing the trees. It has killed almost all American Chestnut trees in the east, and only a hundred or so remain in southern Canada. Some trees that were planted outside the natural range, such as in Oregon, survive. The stumps of American Chestnuts still produce sprouts that can grow up to 20 feet tall until they die from the disease.

Old-growth Longleaf Pine forests once covered millions of acres in the Southeast, with one of the world's richest diversity of forest floor plants and native wildlife, including the Ivory-billed Woodpecker. These forests have declined to 2 percent of their original size, and many of their former denizens are endangered or gone. The Southern Live Oak, a magnificent semi-evergreen tree that has a massive, spreading crown and twisted branches, has declined in many areas within its natural range. These native trees should be brought back through massive planting programs. In more Western areas, Redwood, native oaks and many types of pines and conifers have declined from former abundance and should be replanted.

Activities

o Help conserve endangered trees, such as the American Elm. Plant American Liberty Elms if you live in eastern North America. The Elm Research Institute will send an application to those who wish to receive 500 to 1,000 free elm seedlings. Teachers who wish to participate in the program must pledge several years commitment in order to care for the trees prior to their sale. The trees are guaranteed if properly maintained, and the Elm Research Institute will replace any trees that die. This is potentially a fund-raising program because the trees can be sold after a few years of care. The Elm Research Institute can be contacted at 1-800-FOR ELMS; Fax 603-358-6305; website: http://www.forelms.org.

o Plant American Chestnut trees if you live in the range of the east where this tree once grew. The American Chestnut Foundation was formed in 1983 to save this species through selective breeding of resistant strains. At present, they have succeeded in growing resistant trees and are developing seeds from these trees. They distribute kits of resistant seeds, which can be grown in one™s back yard, for $50. When they are old enough, they can be pollinated with pollen from blight-resistant trees being cultivated in Virginia. This is somewhat more complex than the growing of American Elms, but for a high school class, it would be an excellent way of learning about plant reproduction while helping to save an endangered native tree. A 17-year-old resident of Somerville, New Jersey, Timothy Van Vliet, is an enthusiastic supporter of the program and has grown a number of Chestnut trees in his back yard, one of which is

10 feet tall. With more people like Timothy Van Vliet, the American Chestnut may return to its former abundance. The American Chestnut Foundation can be contacted at P.O. Box 4044, Bennington, VT 05201, or telephoned at 1-802-447-0110. Membership in the organization is $40.

o Plant other threatened native trees. Those who live in western North America can help a rare or declining species of tree. Contact the Redwoods National Park (1111 Second St., Crescent City, CA 95531; and the Save-the-Redwoods League (114 Sansome St., San Francisco, CA 94104) for information on obtaining seeds and seedlings. If one lives in the Pacific Northwest, native trees, such as Western Hemlock, Sitka Spruce and Western Red Cedar, have been reduced by 95 percent because of logging. Replanting these magnificent trees will help to bring back these forests and provide habitat for the threatened Northern Spotted Owl, Marbled Murrelet and other native species. Help protect the stands of these forests that remain by contacting organizations such as the Native Forest Council (P.O. Box 2190, Eugene, OR 97402); Save America's Forests, Washington DC (202-544-9219); and The Nature Conservancy (1815 N. Lynn St., Arlington, VA 22209; (703-841-5300).

Read "Smiles of Vanished Woods," Chapter 11 of *Noah's Garden. Restoring the Ecology of Our Own Backyards*, by Sara Stein, which discusses the importance of planting only native trees and the threat of exotic species, such as the Norway Maple, which can crowd out indigenous species. This book also stresses the importance of preserving old trees with hollow trunks and snags that wildlife can use and of planting understories of native bushes that hundreds of species of wild animals use for shelter and feeding.

Bees and Other Pollinators

Project Summary

Study the behavior of bees, using written materials, films and observations of actual beehives. Learn about plants that would become extinct without pollination by bees and what species of bees are indigenous to your area, especially those that are rare or declining. Learn what plants and habitats these species require and, if possible, plant their preferred flowers and erect a bee house.

Background

Many native bees in North America are important pollinators. A growing number are becoming rare as a result of

pesticides, competition with non-native bee species and destruction of natural habitats. Very few types of bees sting humans. There are 500 species of native bees in New England, for example, but the most commonly seen bees are the European honeybees used to pollinate orchards and other crops. Some native bees are green, blue or red, and many are as small as flies. Others are twice the size of bumblebees. A few are nocturnal.

The communication system bees use to identify sources of nectar and pollen to one another was first discovered in European Honeybees (*Apis mellifera*). When one bee locates a source of food, such as a flowering tree, it returns to the hive and through a complex series of movements with its feet, called dances, communicates to the other bees the location of the food source. The type of dance performed by the bee indicates the distance from the hive to the pollen and nectar. This system of communication involves a highly sophisticated integration of perceived and memorized information and was first discovered by an Austrian scientist, Karl von Frisch, a world-renowned animal behaviorist. He wrote two books on his discoveries: *Bees, Their Vision, Chemical Senses and Language*; and *The Dance Language and Orientation of Bees*. (See Reference list below.)

Methods

Learn about pollinators and their ecological importance and behavior. *The Natural History of Pollination*, by Michael Proctor, Peter Yeo and Andrew Lack, describes bee communication in terms of the extreme importance of bees as the pollinators of many native plants. Consult various reference books that describe bee behavior in detail. "Dancing the Good News" in the book, *Alien Empire. An Exploration of the Lives of Insects*, by Christopher O'Toole, clearly illustrates this remarkable phenomenon. This book is a companion to the excellent television series of the same name shown on Nature, the PBS program produced by WNET and filmed by BBC, which shows the dance of the honeybees as well as the behavior and ecology of many insect pollinators.

Activities

o Take a field trip to see a beehive. Teachers may contact local nature education centers, Audubon societies, state Natural Heritage Programs and US Department of Agriculture extension services to learn about local bee hives that could be visited.

o Contact the Natural Heritage Program connected with your state wildlife department, and find out which species of wild bees live in your area and which species are rare or declining. Discuss these species and what can be done to help them. What plants would become extinct if pollinating bees were to disappear? (*The Natural History of Pollination* is a good source of information for this subject.)

o Plant flowers and flowering trees that attract native bees. Find out which plants are preferred by bees in your area. Do not use pesticides or herbicides of any kind.

o Erect a beehouse in your back yard to attract native, stingless bees. A few holes drilled in scrap lumber and mounted under the eaves of a house, or some paper straws glued into a milk carton and placed on a tree branch, will entice native bees. To attract the large and colorful Bumblebees, build a house such as the one described in *Attracting Backyard Wildlife*, by Bill Merilees.

o Using *The Forgotten Pollinators*, by Stephen L. Buchmann and Gary Paul Nabhan, *The Natural History of Pollination* mentioned above, and other references on insects listed in the Books and Publications section of the Appendix of this book, select one or more pollinators, whether butterflies, ants or other insects, birds, bats or primates. Learn about these pollinators and which plants they pollinate, especially those that are threatened with extinction.

o By consulting the books mentioned above, the main text of *The Endangered Species Handbook*, and books listed in the Books and Publications section of this book, learn about the importance of pollinators in maintaining the world's ecosystems and how crucial it is to protect pollinating animals. Describe a pollinator or group of pollinators that are crucial to an ecosystem. For example, read the section in the Forests chapter in *The Endangered Species Handbook*

concerning tiny wasps that pollinate a wide variety of figs which, in turn, nourish hundreds of species of wildlife. Learn about mammals, such as bats that pollinate many types of plants, through descriptions in this book and others listed in the project, "Bats, Useful Insectivores and Pollinators." Find an example of a species of plant that has lost its natural pollinator through extinction and now exists only through human intervention.

o The economic importance of pollinators has been calculated in several books and studies. In *Nature's Services: Societal Dependence on Natural Ecosystems*, edited by Gretchen Daily, for example, the role of wild pollinators, such as insects and other animals, is valued at $117 billion worldwide. This means that the wild bees, ants and other species that pollinate commercial crops, such as fruit trees and wild plants, perform tasks that are worth $117 billion per year to the world's economy. The authors of *Forgotten Pollinators* estimate that pollinators save farmers in the United States an estimated $1.6 billion annually. Select a farm crop and find out from local US Department of Agriculture offices whether wild species of insects or other animals pollinate it. Through data from the US Department of Agriculture and almanacs, calculate the value of this crop and the losses to farmers should the wild pollinators disappear.

o Wild pollinators are in decline in many areas as a result of heavy pesticide use, which kills insects and other wildlife, and habitat loss, as in the cutting of forests, which causes declines in bats, tropical birds and insects. The Forests chapter discusses this in detail. Write a report on this problem, giving as many examples as possible of the loss in these essential species and the types of threats that pollinators face.

o Select a pollinator**,** such as a type of butterfly**,** and learn about what plants it pollinates. Does it pollinate a single species of plant or many species? Where does it live? What is its status? If threatened, how can it be helped?

Learning Animal Anatomy Without Dissection

Project Summary

Learn about animal anatomy in non-lethal ways. New communication technology may provide better knowledge about anatomy, through videos and virtual learning, than does dissection. Learn about these new resources and discuss their use in the classroom.

Background

In a growing trend, biology classes are being taught about the anatomy of frogs, cats and other animals from CD-ROM software, such as "Digital Frog and Cat Lab**,**" rather than killing live animals for dissection or dissecting dead animals. An estimated 6 million vertebrates, half of which are frogs, are dissected each year by high school students, who are often so upset by the experience that they turn away from future science courses. Such school projects are inhumane, often requiring that frogs be killed by the student, for example. Moreover, frogs are in decline in the wild from a variety of causes, including the capture for such dissections. Their populations need protection. Many of the cats killed for use in high school dissection had been house pets that were illegally caught and sold to animal dealers in the United States and Mexico. Humane organizations have been promoting non-lethal substitutes for many years.

Activities

o Find out if your state's education department allows use of alternatives to animal dissection in classrooms.

o Review a copy of "Digital Frog and Cat Lab" or another software from the organizations below. The National Geographic Society sells various films, film-strips and other materials on animal anatomy. The lessons include function, taxonomy and structure. The Society's "Educational Services" catalog lists these products (P.O. Box 98019, Washington, DC 20090; 800-368-2728; www.nationalgeographic.org).

o Contact the American Anti-Vivisection Society (Suite 204 Noble Plaza, 801 Old York Rd., Jenkintown, PA 19046, 215-887-0816), which publishes the brochure "Animals in Education: An Outline for Student Activists" and distributes audio-visual materials. Also contact the American Fund for Alternatives to Animal Research (175 West 12th St., Suite 16G, New York, NY 10011, 212-989-8073) and the American Society for the Prevention of Cruelty to Animals (ASPCA) (441 East 92nd St., New York, NY 10128, 212-876-7700), which publishes the pamphlet, "ASPCA Guidelines for Student Experiments Involving Animals." The Animal Legal Defense Fund (1363 Lincoln Ave., San Rafael, CA 94901) has a "Dissection Hotline": 800-922-FROG, and publishes the brochure "Objecting to Dissection: A College Students' Handbook." The Humane Society of the United States (2100 L St., NW, Washington, DC 20037, 202-452-1100) publishes the brochure, "Does the Idea of Dissecting or Experimenting on Animals in Biology Class Disturb You?" Also, the National Anti-Vivisection Society (53 West Jackson Blvd., Suite 1550, Chicago, IL 60604, 312-427-6065) publishes "Reverence for Life: An Ethic for High School Biology Curricula" and "School Project Packet." The Student Action Corps for Animals (P.O. Box 15588, Washington, DC 20003, 202-543-8983) is dedicated to empowering young people in high school to work effectively for animal rights and acts as a communication network; it began the national "Say No to Dissection" campaign in 1984 and publishes *SACA News* and brochures such as "Say No to Dissection," "Suggestions for High School Student Animal Rights Groups" and "1-0-1 Non-Animal Biology Lab Methods."

Attitudes and Ethics

Project Summary

Examine the list of principles related to the treatment of animals entitled "An Animal Bill of Rights" (see below) and consider how these principles relate to declining and endangered species. Suggestions are given on how to use this document for classroom discussion or reports on endangered species.

Background

Our attitudes about animals have undergone radical changes in the past few decades. For most of human history, people have believed, like the philosopher René Descartes, that animals were merely machines, blindly obeying instincts. The opinions of many people have been greatly changed by the results of work with animals, for example, the intelligent Chimpanzees who make tools and exhibit many of the same emotions that humans have, such as fear, love, anger, joy and even despair. Elephants have also shown extraordinary qualities of altruism, and many examples of their intelligence have been documented by zoologists. Whales and dolphins, too, have been shown to be intelligent and extremely devoted to one another.

Attitudes towards animals are also changing rapidly as a result of films and books and closer contacts with domestic cats and dogs. The popularity of house pets, with whom we form strong bonds, has encouraged a growing number of people to regard animals as having many of the same emotions as humans, and their friendship and loyalty toward us have been an inspiration to many. The popularity of nature films and books has educated the public to have a greater affection and respect for wild animals and a desire to protect and appreciate them. Still, many people treat animals as having neither sensitivities nor even the ability to feel pain. Fur trapping, research involving cruel experiments on animals, and baiting or attacking animals as an amusement are examples of a lack of compassion. A comment by a Canadian forester represents such a point of view that is, fortunately, disappearing: "Our instinctive attitude toward other species seems to range from indifference to antipathy . . . Concern for other species, particularly for those that have no immediate economic value to us, is a learned response, one we still struggle with" (Don Gayton, British Columbia Forest Service, "Terms of Endangerment" article in *Canadian Geographic*, May/June 1997).

Having a set of values and principles is a logical step in reevaluating how we treat animals--domestic and wild. The famed British zoologist Desmond Morris, in his book *The Animal Contract* (Warner Brothers, 1990), recommends 10 principles that human beings should adopt in their treatment of animals. This book discusses in detail the basis for the principles and gives many examples of our treatment and mistreatment of animals. He states that brutality to animals affects all our conduct and dealings with humans as well, and that a culture that is sympathetic to animals is a culture that is sensitive and caring in all respects. Moreover, he believes that a culture that feels a kinship with animals will be a culture that keeps faith with its roots in recognizing that humans are also animals, relatives of other species. These principles, as related to threatened species, are discussed below. They could also be used as interesting subjects for classroom discussions or for reports.

An Animal Bill of Rights

1. No animal should be endowed with imaginary qualities of good or evil to satisfy our superstitious beliefs or religious prejudices.

2. No animal should be dominated or degraded to entertain us.

3. No animal should be kept in captivity unless it can be provided with an adequate physical and social environment.

4. No animal should be kept as a companion unless it can adapt easily to the lifestyle of its human owner.

5. No animal species should be driven to extinction by direct persecution or further increases in the human population.

6. No animal should be made to suffer pain or distress to provide us with sport.

7. No animal should be subjected to physical or mental suffering for unnecessary experimental purposes.

8. No farm animal should be kept in a deprived environment to provide us with food or produce.

9. No animal should be exploited for its fur, its skin, its ivory or for any other luxury product.

10. No working animal should be forced to carry out heavy duties that cause it stress or pain.

Source: *The Animal Contract* by Desmond Morris. Warner Books. 1990.

Although many of these principles relate to domestic animals and can be discussed in another setting, others relate to our treatment of wildlife, including endangered species. Discuss the way in which these principles apply to threatened species.

Activities

o Principle number 1 could apply to wolves and bats, which are considered by many societies and individuals to be evil. Read the Persecution and Hunting chapter in this book for other such cases and consider the implications of such prejudices on the survival of many animals.

o Principle number 2 can also be applied to endangered species in that Lions (now considered Vulnerable species), Tigers, chimpanzees and elephants (all Endangered species) are trained to perform tricks in circuses that degrade them. Brown Bears used by gypsies in Europe and Asia are another example. They are dragged about by leashes attached to nose rings and trained to perform extremely unnatural acts, such as "dancing" on their hind legs. Discuss this principle and learn how circus animals are trained and how they are treated. Contact organizations such as PAWS (Performing Animal Welfare Society, P.O. Box 849, Galt, CA 95632) or the Animal Welfare Institute to learn more about this.

o Principle number 3 can apply to zoos that house endangered species. If the captive conditions do not allow the animals adequate physical and social environments, they would be considered to be violations of these principles. Examples might be the keeping of an elephant, a highly social species, by itself, in a small enclosure without water to bathe in or space to exercise. These animals are also chained at night in many zoos. Are there animals at your local zoo kept in such conditions?

o Principle number 4 can be applied to wild pets of many species that are kept in unnatural conditions. Tigers and other big cats, wild-caught parrots and many reptiles and amphibians are kept in peoples' back yards in cages or in indoor conditions that are highly unhealthy or psychologically traumatic for the animal. Many states ban various wild pets for this reason. Read the Trade chapter in this book for more information on wild pets and zoos. Find out the laws of your state or country regarding the keeping of exotic pets, especially endangered species.

o Principle number 5 is an extremely critical one in relation to endangered species. Although the US Endangered Species Act specifically addresses the issue of driving species to extinction as unacceptable, the law has been weakened by its opponents and faces further weakening. Moreover, only listed species receive such protection. Many threatened and endangered species that are not listed on the US Endangered Species Act receive no legal protection. In other countries of the world, such as Canada, no law prohibits driving a species to extinction or protects endangered species. Human overpopulation is a major cause driving species to extinction. This is an extremely important moral dilemma, one that is being faced by countries such as Indonesia, which has relocated people from overpopulated islands, such as Java, to areas still forested, such as Borneo and western New Guinea. These new immigrants are burning forests, with the encouragement of the Indonesian government, to create farms and grazing land for livestock. In the process, they are driving endangered species, such as the Orangutan, toward extinction. What should societies do in these circumstances, which will become more and more common in the future?

o Principle number 6 states that causing pain or distress in animals for our amusement is reprehensible and must not take place. Most examples of such cruelty involve domestic animals, such as steers in bull fights, roosters in

cockfights and pit bulls in dog fights. Consider situations in which threatened or wild animals are used in such ways. For example, Asian bears are abused in street shows, and Tigers and elephants suffer in circuses. Hunting rare animals for sport might be considered to fall into this category, especially when it is carried out by means that do not usually kill quickly, such as by bow and arrow, and when it is not done for food, but for amusement.

o Principle number 7 concerns causing unnecessary pain for experimental purposes. Such experiments often involve the use of threatened animals. Chimpanzees and monkeys are involved in painful experiments to test drugs, in simulated car crashes or other research. The use of these animals is justified by many research laboratories and others as being important because it can help human beings in various ways, such as finding cures to diseases. However, many experiments are unnecessary and repetitive of already published research. Does the treatment of these animals, especially long-lived chimpanzees who must spend a lifetime that can reach 60 or more years in sterile confinement, justify the research, or are there alternatives to using these animals? (Contact the Animal Welfare Institute for its published reports and articles on this subject.)

o Principle number 9 regards exploitation of animals for furs, skins and other luxury items. Many threatened species are legally traded for such purposes. All the wild cats that are listed on Appendix II of the Convention on International Trade in Endangered Species of Wild of Fauna and Flora (CITES) may be traded with export permits, for example. The trade in elephant ivory during the 1980s nearly caused the extinction of both the African and Asian species. In 1989 all ivory trade was banned by CITES. Today, many countries want to reopen trade in African ivory, claiming they have stockpiles and overpopulation of elephants in some areas. Discuss the ethics of killing animals for luxury goods and select a species that is threatened with extinction as a result of such killing. This principle could also apply to the trade in live wild pets that threatens many species. Read the Trade chapter in this book for more information.

Film

"The Animal Contract," based on the book by Desmond Morris. Garner MacLennan London and Lifetime Pictures in association with Island Visual Arts and G.C. Films, UK.

Wildlife Music

Project Summary.

People once thought that animals were "dumb" because they could not speak in human language or that the seas were silent because we were unable to hear their sounds. Many still think that birds sing for people. We now know that wild animals communicate with one another and other species in thousands of different sounds. This project will acquaint students and others with many of these sounds. They have definite purposes and can communicate a wide variety of messages, whether territorial, warnings to members of their own species, mating calls or other meanings we have yet to understand. Human activities are having negative effects on the communications of some animals, even causing mortality. This project will encourage appreciation of the great variety of animal sounds, especially those of disappearing species. Means of preventing interference with animal communication and working to reduce human-created noise will be explored.

Background

A chorus of bugles as flocks of Sandhill Cranes take flight, the eerie violin-like songs of Humpback Whales or the croaking of frogs can evoke emotion and deep appreciation. Human response to wildlife songs reflects the universality of music. Virtually all human societies have their own music (see Milius 2001). Just as we are drawn to the sounds of nature, animals have been attracted to human music. The now-extinct Laughing Owl of New Zealand would fly close to a person playing an accordion after dusk, remaining in the vicinity until the music stopped (see Fuller 2001). Researchers in the Pacific Northwest have dangled microphones playing music from their boats and found that dolphins and Killer Whales approached and listened for long periods. The mournful, musical howls of wolves caused fear in the superstitious medieval times, but today they are appreciated as true animal songs, each wolf contributing a slightly different melody. In fact, when a recording of wolf howls was released during the 1970s, the music critic of *The New York Times* judged the musical talent of each wolf singer. (Wolf Education and Research Center: www.wolfcenter.org provides information on howling.) Songs play an integral role in wildlife communication and survival. Endangered denizens of American grasslands, prairie dogs, also have complex languages, giving different calls to one another to warn of birds of prey, land predators, humans with guns and other threats. Some bird songs, like those of many birds of paradise, stunningly beautiful birds of New Guinea, are so loud and bizarre that they seem to have been electronically produced. They are designed to penetrate dense foliage for long distances. Bellbirds and howler monkeys of Latin America and gibbons of Asia also sing so loudly that the songs carry for miles in the rainforests. Gibbons mate for life and sing duets in whoops that echo through the forest. Many wildlife songs are used to defend territories or to find a mate. Beluga whales and Mountain Lions communicate with one another in bird-like chirps. Elephants are now known to emit deep sounds, inaudible to humans, which carry for great distances to elephant herds miles away (see Payne 1998). Likewise, bats and dolphins emit ultrasonic sounds to find their prey and to navigate. Some of these are audible to the human ear. Many of these species are now listed as Threatened, however (see Endangered and Threatened Species list in the Appendix).

As the world becomes filled with human-made noise, from the giant engines of ships, planes, trucks and earth-moving machines to jet skis, snowmobiles, snow blowers and chainsaws, wildlife songs and calls are being drowned out. Each Humpback Whale has its own individual song. The males vary the songs each year, and females seem to be attracted to the males who emit the most complex songs. Marine mammals emit a great variety of squeaks, hums, squeals and chirps to communicate with one another and echo-locate, but they can be drowned out by ships, motorboats, jet skis and other human-made sounds. It is critical for the survival of these marine mammals that they be able to communicate.

Some ship noises are even lethal to marine mammals. The US Navy has been testing an anti-submarine sonar called Low Frequency Active Sonar (LFAS). Powerful sonar waves are broadcast underwater to test a means of detecting quiet enemy submarines (see White 2000a). These sonar waves can travel hundreds of miles and be extremely loud. Humpback Whale males have stopped singing or moved away when these waves were broadcast. More ominously, testing in 1995 off the coast of Greece coincided with an unusual stranding of Cuvier's Beaked Whales, resulting in the deaths of these seldom-seen whales. In March 2000, Ken Balcomb, a biologist familiar with sonar, was present in the Bahamas when a stranding occurred at the same time Navy LFAS tests were taking place nearby. Fifteen whales stranded, including Dense Beaked Whales, a Minke Whale and a Spotted Dolphin. All washed up on the shores, and when pushed back into deep water, they were unable to remain upright, clearly unbalanced, disoriented and apparently in pain. Without their hearing, they cannot find their way in the ocean. Nine died. Along with Harvard biologist Darlene Ketton, Ken Balcomb performed necropsies on several whales, finding their ears full of blood. In one case, hemorrhages striped the lungs. Further testing revealed that a whale had suffered a concussion, apparently the result of acute trauma from pressure (White 2000a). A press conference organized by the Animal Welfare Institute following these findings featured Ken Balcomb of the Center for Whale Research and other whale experts, who attested to the fact that LFAS is reckless, unnecessary and lethal to whales. Soon after, the Navy canceled testing of active sonar off New Jersey and also its scheduled tests on Sperm Whales in the Azores (White 2000a). The Navy has not cancelled these tests altogether, however, claiming that more research by Woods Hole Oceanographic Institute is needed to reach a final conclusion.

Bird reproduction has also been affected by the sounds of highway or airplane traffic. Researchers have found that male birds living near such loud noises cannot hear their own songs or those of their rivals and, in a few generations, begin singing songs so different from their instinctive ones that other males do not respond, nor do females, preventing reproduction. Frogs living near highways have also been found to lose their natural calls in the din of traffic noise. It is not known whether these animals have suffered hearing damage or are simply unable to hear fellow creatures over the din. Much of the noise created by human machines could be reduced or eliminated with muffling devices. Design of machines that will not interfere with animal communication should become a priority.

Activities

o Listen to recordings, such as fiMusic of the Birds,**fl** listed below. Visit websites that play animal sounds and songs. One, intended for visually-impaired people, plays bird songs: www.nhest.org; and www.naturesongs.com has many types of natural music. The largest collection of natural sounds in the world is at the Macaulay Library of Natural Sounds at the Cornell Laboratory of Ornithology (www.birds.cornell.edu). It has 150,000 recordings. The British Library's national sound archive has more than 130,000 recordings: www.bl.uk/collections/sound-archive/wild.html). The Nature Sounds Society website (www.naturesounds.org) gives information on other sites. For an academic approach, consult the site of the World Forum for Acoustic Ecology: interact.uoregon.edu/MediaLit/wfae/home/. Watch wildlife films that include songs and calls, especially those of threatened and endangered species, such as birds of paradise, whales, wolves and elephants (see list below and Video section). Write an essay on the songs of one group of species, such as whales, or a particular species, describing the variety of the songs or calls.

o Compare the wildlife sounds heard in environments far from highways and airports with those near them. Take walks in several types of habitats with experts who can identify wildlife sounds, such as frog chirps and croaks, bird songs and insect noises. Tape record the sounds heard and count the number of species in a quiet habitat versus those heard near a busy highway or airplane flight path. Note that each species' song can be heard in normal conditions

because of its own frequency and rhythm. Discuss the effect of noise on these species, and describe the various calls heard without interference.

o Learn about means of lessening human-created noise. Write the Environmental Protection Agency (EPA) in Washington, DC (see Organizations list, Teachers™ Aids section) for information on noise pollution and how existing engines can be muffled for quieter substitutes. For example, electric-powered lawn mowers and leaf blowers make far less noise than gas-powered ones. Airplane engines that are quieter than those currently in use have been designed, but no strong government mandate has encouraged their manufacture. Automobile and truck engines can be made quieter, and certain road surfaces can decrease traffic sounds. Snowmobiles that emit far less noise have been manufactured, but without legislation mandating their use, there is little demand. Consult the Internet for organizations working actively to require that quieter machines be in use. Write a report on the need for noise pollution equipment.

o Research the effects of snowmobiles, jet skis and all-terrain vehicles on wildlife. Contacting various organizations, including the National Parks and Conservation Association (see Organizations list in Teachers™ Aids section) for information on their work to keep these vehicles out of the national parks because of the negative effects the noise has on wildlife. Find out the decibel levels of various vehicles that are allowed in wildlife areas and off-road wilderness parks and their effects on various species of wildlife.

o The US Navy testing of anti-submarine sonar, Low Frequency Active Sonar (LFAS), described above, has been shown to be extremely dangerous to some marine mammals and drives others away from their traditional migration and feeding areas. Write the Animal Welfare Institute for more information on this program and how to help stop it.

Films

The following represent only a few of the many films concerning animal calls and music. See the Video section of this book for further listings. Also, many audiocassettes are available with wildlife sounds of various types.

"Attenborough in Paradise." 1 hour. Nature (PBS). BBC. 1996.
David Attenborough visits New Guinea and describes the birds of paradise and their extraordinary calls.

"Crane River." 1 hour. National Audubon Society. PBS Video. 1988.
Hundreds of thousands of Sandhill Cranes migrate in the Midwest, bugling, calling and courtship displays, which resemble minuets.

"Gentle Giants of the Pacific: Humpback Whales" 1 hour. Sierra Club Series.
Wood Knapp Video. The amazing songs of these whales are heard in this film.

"In the Company of Whales" 90 minutes. Discovery Channel. (VHS & CD•ROM.)
1992. Following great whales and hearing their sounds with zoologist Roger Payne and other experts, insights are given on whale behavior and biology.

"Jaguar. Year of the Cat." 1 hour. Nature (PBS). Telenova Productions. 1995.
Filmed in the rainforests of Belize, the daily life of Jaguars is seen in remarkable close-ups accompanied by the sounds these cats make as they walk in the forest or lap water in a stream, with insect and bird songs in the background.

"National Audubon Society's Video Guides to North American Birds." Five one-hour cassettes. National Audubon Society. These videos show and record all species in the United States and Canada for which photo documentation exists. Audiocassettes of almost all the native breeding birds are available from this organization.

"Wild Wolves." 1 hour. BBC. NOVA. PBS. 1997. This film examines the true nature of wolves, their behavior and ecology and lets us listen to their howling.

Lawns

Project Summary

Many biologists and conservationists are now questioning the use of green lawns in yards, in front of public buildings and along highways. In general, green lawns have to be maintained through use of chemicals that can pollute the groundwater and kill beneficial plants and insects; use noisy, gas-guzzling mowers and leaf-blowers; and fail to preserve native plants. This project involves examination of the effects of these lawns on the environment and human health, as well as the use of energy and water to maintain them.

Background

Most biologists consider grass lawns to be ecological deserts because of their lack of diversity. In many areas, grass lawns cover a large percentage of land in villages and suburbs. Golf courses are increasing in number. Lawns are replacing natural habitats, such as woodlands, grasslands, shrub and desert and, in the process, wildlife and natural landscapes retreat. The Eastern Box Turtle has lost a large percentage of its original long grass, shrubby habitat to green lawns, and the species has declined dramatically. These slow-moving reptiles are also badly injured or killed by lawn mowers, which smash their shells (see Stevens 1994). Migratory birds and butterflies return in the spring to find

their natural habitats converted to green lawns, depriving them of feeding and breeding sites. In general, lawns provide little or no habitat for wildlife.

To keep them green, herbicides, pesticides and chemical fertilizers are sprayed or spread in vast quantities. More than 67 million pounds of chemicals are placed on US lawns annually (see Wasowski 2001). These chemicals kill useful native animals, such as pollinating insects, birds that disperse seeds and consume insects, burrowing rodents, and earthworms that aerate the soil. They also contaminate the groundwater. Some of these poisons are so powerful that they have caused sickness and death in humans. Early in 2001, the city of Halifax, Nova Scotia, Canada, became the first in North America to order a ban on all insecticides, herbicides and fungicides used on lawns. The ban was primarily intended to protect human health, especially children who are most vulnerable to pesticides (see Nickerson 2001). Fifty-five other communities across Canada are considering similar bans. Opposition to grass lawns and frequent mowing along public highways is also growing. One citizen of Orleans, Massachusetts, objected to the *The Boston Globe* when mowers destroyed carefully planted native wildflowers growing along a major highway in this Cape Cod area. The flowers, planted by volunteers (one as old as 85), of the New England Wild Flower Society, had been clearly posted not to be mowed.

Green lawns require constant care and use enormous amounts of energy for mowing, edging and removing leaves. Most lawn mowers and leaf blowers consume gasoline and pollute the air with fumes, while also creating noise pollution. Mowers also damage tree trunks or kill above-ground tree roots, especially of old trees, and frequently-applied fertilizer can harm older trees, which need slow-release enrichment of the soil (see Stocker 2001). For these reasons, gardeners recommend that no large tree be within 2 feet of a lawn. Another threat to trees is lawn watering during droughts; an insufficient amount of water reaches the tree roots, while the lawn absorbs most of the water (see Stocker 2001).

Lawns are also extremely costly. The American Nursery and Landscape Association estimated that Americans spent $17.4 billion on their lawns in 1999 (see Schembari 2001). The Lawn Institute, based in Illinois, estimates that the lawn care industry for North America is worth more than $25 billion (see Nickerson 2001). By planting perennial native grasses, shrubs, trees and flowers, homeowners could save literally billions of dollars.

The grass used for lawns in the United States is composed of various European turf species, which, unlike most native American grasses, require large amounts of water, often as much as a third of local water supplies. Householders use 40 to 60 percent of their water on their lawns in the summer. Erroneously called "Kentucky Blue Grass," this and other commercially distributed grass seed needs cool, damp climates for healthy growth. The grass quickly turns brown in the heat of summer or when not watered enough. In dry seasons, many towns mandate water rationing because lawn watering has depleted local supplies. The average lawn will use up to 10,000 gallons of water of a summer and 10 times the amount of pesticides as an acre of farmland (see Egan 2001).

Communities being built in dry areas, such as southwestern deserts, tend to plant green lawns because their owners have come from areas where they were typically used. In desert areas, green lawns can only be maintained through diversion of water that dries up rivers or alters the ecology of these regions. In Arizona, for example, several rivers have been reduced to dry beds by diversion for the burgeoning developments surrounding Phoenix and Tucson. Cities of the Southwest and California use enormous amounts of their water supplies to water green lawns. In the process, several pairs of endangered Bald Eagles that nested on one of these rivers, along with thousands of other forms of life, disappeared. One new resident of Phoenix, an architect, planted native plants in his garden instead of grass, defying local developers**,** who remove all native vegetation and cover the land with gravel. His yard was soon filled with wild marigolds, creosote bushes and other plants that seeded themselves in his beautiful, no-maintenance back yard. In Glendale, Arizona, homeowners receive a $100 rebate for converting 50 percent or more of their grass to shrubs or plants. Studies from Las Vegas found that a city could save 40 percent of its water by converting to non-grass alternatives. With the world facing increasing water shortages, the grass lawn, especially of non-native species of grasses, has become a luxury that is wasting this precious resource.

Green lawns can be grown with native grasses that do not require artificial watering and chemicals, and by using the cut grass as mulch. Fertilizers and herbicides are not necessary for these lawns, which can be mowed with electric or old-fashioned, human-powered mowers. Also, smaller areas can be planted. Instead of dominating the yard, lawns can become a minor part. Planting native vegetation, including wildflowers, shrubs and trees, in back yards and city lots is a preferable alternative to the green lawn. In shady, moist areas, mosses can be planted that never require mowing and stay green year-round (see reference list below). Perennial plants do not need replanting each year and require almost no maintenance. Trees provide shade, erosion control and habitat for wildlife. Planting a garden with native American plants can also aid in the conservation of ecosystems and rare species. By not using chemicals, groundwater and wildlife are protected.

Activities

Consult the books listed below before beginning the following project:

o Select two small land plots (each about 200 square feet) each distanced from one another by at least 100 feet. Prior to planting, take samples of soil and examine them under a microscope to determine the diversity of plants and animals, whether there are earthworms to aerate the soil, and other life forms. Measure the acidity. Describe the soil's texture, whether rich loam, clay or sand, and whether it is dry and crumbly or moist. Are there birds that feed in the grass or evidence of small mammals, such as tunnels? In one half of the plot, plant non-native grass and use the chemicals recommended by the grass seed company. Water and mow the lawn, if needed. On the other half of the lawn, dig up the soil and spread natural compost from leaves and other vegetation throughout, to a level of 2 feet. Sow seeds of native grasses**,** such as buffalograss (sold in many nurseries). Water this portion until the seeds are established, but not afterward. Do not apply any artificial fertilizers or other chemicals. Mow with electric or hand mower only. After one month, take soil samples from both areas and examine them under a microscope to determine the diversity of microbes and the moisture content in the two soil samples. Note whether the organic wildlife area has above-ground evidence of wildlife such as butterflies, small mammals, reptiles, amphibians and birds. Identify them by species. Did the organic grass survive without artificial watering? Compare the two soils, their moisture content, invertebrate species diversity, water usage, environmental effects and the cost to maintain each one. A third alternative is described in the next project, fiLiving with Nature,fl focusing on conversion of the lawn to native wildflowers, bushes and trees, which requires even less water and labor.

o As a study project, select a suburban area of approximately one city block and measure the acreage in green lawns, calculating the cost in use of chemicals, as well as gasoline for lawn mowers and leaf blowers. Estimate water consumption and the percentage of this that must be artificially applied through hosing or sprinklers. What is the water source? Ask the local water department how much water is used in your area for watering lawns each year. Contact the Environmental Protection Agency in Washington, DC, for information on contamination of groundwater by lawn chemicals and their effects on wildlife and human health.

Living with Nature

Project Summary

This project focuses on planting a garden with native plants and creating natural habitats that will attract wildlife and provide breeding and feeding areas for a wide variety of species. If an area for planting is not available, the principles of a natural garden can be learned. Also, the project discusses means of avoiding any lethal methods to control insects or animals with which one can come into contact in one's home or back yard, including Raccoons in garbage pails, deer munching shrubbery or moles burrowing in garden plots.

Background

The ecological problems presented by green lawns (see previous project) have brought many people to realize that many gardens and yards tend to reflect a lack of ecological knowledge and concern, and fail to preserve a natural environment and maintain wildlife habitat. This subject has resulted in many books and even garden magazine articles, but only a small minority of homeowners have abandoned the green lawn or reduced its size, making it a small part of one's yard rather than the dominant component. The long-term goal of converting lawns to natural environments is to provide wildlife with habitat it has lost in recent times, a period during which housing developments gobbled up millions of acres of woodland and pastures. Also, lack of tolerance for wildlife has increased, with homeowners moving into areas only recently converted to housing to be dismayed and often fearful when they find wildlife in the back yard. These animals were the original tenants of the land, and we are the invaders, but few homeowners seem to realize this fact and want nature to be tamed and non-invasive. Common sense approaches to this potential conflicts will be explored.

Activities

o Conversion of a yard from grass to natural vegetation can be done at once by digging up the entire lawn, excavating at least 2 feet to aerate and compost the soil, and replanting. A natural garden can also be planted gradually, plot by plot. The most important step is preparing the soil by enriching it with natural compost and organic fertilizers so that soil microorganisms and invertebrates, such as earthworms, can flourish and plants will have a better likelihood of surviving. Acidity testing is important to create a soil condition to which the type of plants used will adjust. Conifers, mountain laurel, rhododendron and related plants require high acidity, while grasslands and meadows tend to be more alkaline. Use no pesticides or artificial chemicals. Also to be avoided are bug zappers. These electric units that hang outside and electrocute insects have been shown to kill thousands of useful insects, such as moths, but almost no mosquitoes, for which they are intended (see *Wildlife Conservation* magazine, July/August 1997). A school class can utilize a plot of land of varying size according to the amount of time and effort it can expend. Many of the books listed below provide clear guidelines to follow in establishing a garden with native plants. Plan the garden to conform to the regional ecosystems, and use only plants native to the area. Some of the suggestions made in various books and articles include planting non-native plants to attract butterflies or birds. This should be avoided, and such plants should be removed. Consult guides to native plants to determine whether a species is indigenous. The best sources for native plants are organizations, such as the New England Wild Flower Society in Framingham, Massachusetts, that propagate all plants sold and recommend that no wild plants be dug up from woodlands or other natural habitats. The

most coveted and delicate species, such as damp woodland trilliums and lady slippers, will almost surely die if transplanted from the wild, as they live in a symbiosis with fungi. Moreover, they require many years to mature and are rare in the wild. The habitat established--whether a woodland, small pond with water plants, prairie with wildflowers, desert landscape with cacti or marsh--should be compatible with local vegetation. It might consist of recreating a habitat destroyed by developers on the very site. If the lot is completely open without shade trees or even bushes, it is not possible to establish a woodland environment immediately. The planting will have to be transitional, using species that would naturally seed in such areas, such as birch and ground cover plants in northern and mountainous areas. Whichever habitat is chosen, carefully record which plants are introduced and their survival on a regular basis.

o If you are creating a butterfly garden, follow instructions such as provided in the booklet, "Butterfly Gardening in New England," to establish shrub plants for the larvae, fragrant flowers to provide nectar for adults, a damp area for moisture and mineral feeding, and tangles of vegetation for the caterpillars. Keep in mind the locality. Host plants differ in each region of the country. In an open environment, a field of native goldenrod, milkweed and a diverse selection of plants would have the best likelihood of survival and attract butterflies of many species. Many butterflies specialize in a particular type of host plants, and only these can be planted. Flowers that attract many species of butterflies are a good introduction to such a project. When the flowers have appeared, spend an hour each sunny afternoon recording the species and numbers of butterflies that come to feed. Later in the season, try to find eggs, chrysalids and caterpillars among the vegetation. A good source for more information on this subject is *A World for Butterflies*. Photograph them. Note also other types of wildlife that come, whether birds, small rodents or other species. Write a report on the project, recording the successes and failures from beginning to end. The flowers may be left indefinitely, as they are perennials.

o Animals such as Raccoons, squirrels, deer, skunk, moles and rabbits are often seen as pests to be eliminated if they cause damage, eat prize plants or vegetables, or create burrows in the soil. What seems to be a major problem that can only result in trying to eliminate the animals can be solved or attitudes changed so that wildlife is better tolerated. *Living With Wildlife*, a book published by the Sierra Club, is based on the experiences of the California Center for Wildlife, a wildlife rehabilitation and education center with more than 200 volunteers and a professional staff. They receive more than 12,000 calls a year from people who have problems dealing with animal nuisances. Many problems, such as animals eating garden vegetables, can be solved with fencing, having garbage cans that cannot be opened by animals or are placed behind barriers, and spraying bushes and vegetation with substances and odors that repel animals. For example, to "raccoon-proof" a garbage can, fasten the lid securely with rope, bungee cords, chain or even weights. Secure the handle to a metal or wooden stake driven into the ground to prevent it from being rolled around. Store cans in wooden bins or in a locked shed or garage. Certain smells, such as ammonia, repel animals and can be sprayed on bushes or garbage cans. This book gives specific advice as well as encouraging a tolerant and positive attitude toward wildlife, reflecting the knowledge that we have entered *their* territory, not the opposite. If one's home has destroyed important habitat for wildlife, it is important to consider recreating it by allowing brush and shrubs to grow, instead of neat flower beds, to provide habitat for turtles, rabbits and groundhogs to share the property. Consider that a graceful deer in one's yard is a privilege to see. To protect special trees or fruit, spray them with repellants that contain milk, and hang bags of human hair. Most people choose to share their yards with deer and other wildlife, planting vegetation for them. It is also important to be tolerant of predators, such as bear, Cougar, Coyote and wolves, while staying far away from them. These predators, especially Cougar and Wolves, play an important role in regulating populations and maintaining the strength of deer and other ungulates. The overpopulation of deer in many parts of the country can be blamed on direct persecution of large predators. These predators should never be fed or approached, however, but allowed to exist as vital components in ecosystems. Few people are aware that Coyotes and foxes are important consumers of mice. A key factor in developing tolerance of wildlife is to understand their need to survive and to learn about and respect their natural behavior.

Lifestyles and Citizen Action

Through small changes in our lifestyle, we can reduce our use of energy, our pollution, our unnecessary consumption of material goods and help wildlife and the natural world. By launching programs within our community and making other contributions to conservation, we can have an even greater impact. This project will examine some examples of each conservation approach and encourage activism to preserve nature and endangered species. It will make recommendations about purchases that can either aid or damage the environment and wildlife.

Activism on the part of individuals and governments is crucial to reversing the trends that are extinguishing species and habitats at an unprecedented rate. The natural world is a place of beauty that provides a cornucopia of medicines, food and inspiration. The majority of scientific discoveries lie in the future. Preserving these treasures should be the most important goal of society. Future generations will not forgive us if we extinguish this precious heritage, upon which we depend for our very lives.

The majority of people on Earth are too occupied with survival to understand and act on the need to preserve species and natural environments, especially wilderness areas. Those people who can teach means of sustainable living without harming nature should become far more active to prevent further extinctions and erosions of natural ecosystems. On the whole, we have failed to treat the environment and our fellow creatures with the respect needed to prevent further losses to our natural heritage. Never before, however, have we known so much about the components and functioning of ecosystems, nor have we had the technology and the will with which to remedy past errors in order to live in harmony with the Earth.

Lifestyles and Citizen Action: Land Protection

Background

One can contribute to the preservation of biological diversity worldwide in many ways. Land protection is key to species' preservation. In foreign countries, biological diversity is at great risk, with extinctions occurring on a daily basis. Through support of international organizations, vital tracts of land can be purchased or the government convinced to designate them as national parks. In the United States, bogs, vernal ponds and other temporary wetlands, longleaf pine forests, old-growth cedar forests, tallgrass prairies and desert springs are some examples. They are vital to the survival of countless species, but receive little or no state or federal protection from destruction, and harbor many endangered species. Making a project of protecting a threatened habitat and/or species could spell the difference between survival and extinction for a particular plant or animal species, a very worthwhile project.

Activities

o Support organizations that specialize in setting aside land. This is key to saving the wildest, most pristine and important habitats before they are ruined. By obtaining issues of past magazines and press releases of organizations, such as The Nature Conservancy or Conservation International, learn what land they have protected that provided important habitat for endangered species and how they work to identify and protect biologically important areas in need of conservation. Help an organization that is raising money for land that harbors rare or endangered species in a foreign country. One class raised more than $100,000 to purchase a sizeable rainforest tract, teeming with beautiful tropical birds, in Costa Rica. Far less funds per acre are needed to acquire land in many countries where biodiversity is high than in the United States or Europe.

o On a local basis, a class could save an endangered species by helping to purchase its habitat. Information on a state-by-state basis on endangered species and habitats can be obtained from the Natural Heritage Programs connected with each Environment or Wildlife Department. These programs identify rare, endemic and declining species and their habitats, including those in need of protection. Also, national, state and local organizations and government departments can help in identifying land in need of protection. In some cases, an organization that specializes in a particular type of animal, such as frogs, cranes or turtles, will know of such areas and may already be raising money to purchase them. The class can choose an area in need of fund-raising and begin to aid in a fund-raising campaign. It would be more feasible to choose land that is not so expensive or large that many years would be needed to purchase it. The Nature Conservancy or another organization may be preserving the land. Another option is to launch a campaign to convince a town, state or federal agency to designate an area as protected. A field trip should be taken to the site, guided by a biologist familiar with the habitat--its plants and animals. Someone in the class could be designated to photograph the site, while others would take notes on what the guide says for a report and write letters to the editors of local newspapers. The site may preserve one or more endangered species, as well as an endangered habitat. Once successful, contact local newspapers to publicize the event, and write up the achievement in terms of how the goal was attained and what biological treasures were protected.

Lifestyles and Citizen Action: Sustainable Living

Background

A growing number of organizations are providing people around the world with alternatives to destroying forests and other natural habitats to clear land, obtain firewood or raise livestock. In tropical areas, land cleared of rainforest can be farmed for only a few years because of poor soil. Organizations are now helping these farmers survive in ecologically friendly ways through donation of solar cookers and heaters, aid in establishing small farms that utilize bio-gas (methane obtained from manure and sewage), and promotion of self-sustaining farming methods that do not destroy the environment. In Madagascar, primatologist Patricia Wright protected the forest home of endangered lemurs by convincing the government to establish a large national park. It provided many jobs for local people. She then raised money for the construction of schools and clinics. Deforestation has virtually stopped as a result, and the people have become protective of the forest after learning how it prevented mudslides. Providing this type of help for people in poor areas of the world will be a major project of Conservation International, which plans to integrate this approach with its land protection and biodiversity studies, through a donation it received of more than $1 billion.

Activities

o Select one or more threatened habitats that are being destroyed as a result of over-grazing, deforestation or other means by people in developing countries. Many examples are given in the main text of this book. In classroom discussion, explore the ways in which these areas are being destroyed. What habitats and threatened species are disappearing as a result? What do you think should be done to prevent this situation from continuing and to help the people at the same time? For example, in Central Asia, so many sheep, yak, horses and other livestock are grazed by nomadic people that they are ruining the grasslands, leaving little food or habitat for native gazelles, wild camels, antelope and wild horses. Native predators, such as wolves, bears and Snow Leopards, are killed as potential threats to the livestock. Make specific suggestions that would provide for the basic needs of the people by alterations in their lifestyle and simple technology, while preserving the ecosystem.

o Consult the Internet and other sources for organizations that distribute solar cookers and simple technology, as well as agricultural advice. Contact them with suggestions for areas to donate that harbor many endangered species and habitats. Ask which countries are the recipients of this aid. Find out which parts of the world are not receiving international aid and, if these areas are environmentally threatened, suggest that they receive aid.

Lifestyles and Citizen Action: Internet Solutions

Background

Internet websites provide a new avenue to protect the planet through programs like "click-to-donate." Merely by clicking onto the Internet site, one activates funding for wilderness, endangered species and environmental protection from corporate pledges. EcologyFund (www.ecologyfund.com) is one such website that receives more than 100,000 visitors each month. In exchange for ad exposure, the fund donates sponsors' money to protect wilderness, plant trees and reduce pollution. Threatened wilderness land in the United States, Canada, Mexico, Africa, the Amazon Basin, Patagonia and Scotland has been preserved, and the fund claims to protect 187 square feet of land and save 2 pounds of carbon dioxide per visitor every day. Care2 (www.care2.com) also has a "click-to-donate" program focusing on endangered species and rainforest protection. One of its programs, "Race for Big Cats," has protected 16,000 square miles of key habitat for endangered Tigers, Jaguars and Snow Leopards, in conjunction with the Wildlife Conservation Society. In cooperation with the Nature Conservancy, Care2 has purchased large tracts of rainforest.

A related approach to preserving wildlife and funding conservation work consists of Internet sites that tune into live videocameras located in national parks or other natural areas, sending signals to satellites. Some websites are free, while others charge a small fee. Cameras set up in South African national parks (www.africam.com) focus on wild animal lairs, waterholes and other wildlife spots. They have generated large sums of needed money for the park

system. In the United States, television cameras have been trained on Peregrine Falcon and Bald Eagle nests and transmitted to a cable station that plays the picture. Solar-powered videocameras have been designed that can be placed in the most remote wilderness with no need for batteries or outside electric power sources. This concept has great educational potential, simultaneously raising money for endangered species and wilderness protection, while educating as well. Such websites can provide important information on these subjects while providing exciting views of wildlife and wild places. As an alternative to eco-travel for those of lesser means or those unable to travel, such websites could offer tours, such as tree-top views of rainforests and their abundant wildlife, or close-ups of seabird colonies or coral reefs. They have the added benefit of protecting delicate ecological areas from the effects of too many tourists. Such websites should provide a portion of the funds to local people as an incentive to preserve the land and wildlife. If significant funds were generated, countries faced with choices such as whether to allow corporate logging, commercialization of wildlife, dams and other projects needed to repay national debts, might consider these cameras to be a better alternative. If successful, such websites would encourage countries to maintain large areas of wilderness. Videocameras also have a scientific potential in giving a 24-hour view of areas harboring wildlife, often difficult to observe through other means.

Activities

o Click onto several videocamera sites to see the various types of wildlife spectacles offered. Some examples: seemorebears.com (Alaskan bears feeding on salmon in season); www.african.com (see above); www.world-stream.com (views of ancient species of fish, the Coelacanth); zooatlanta.org (Giant Pandas). What threatened species or habitat would you like to see on a videocamera placed in the wild? Would you also like the views to be part of a menu offering information on the species and the habitat? What ideas do you have about the applications and potentials of these live videocams linked to the Internet and television cameras broadcasting to cable television stations?

o Select a country that is suffering high levels of environmental destruction
but also has beautiful scenery and many endangered species. Discuss the potential of proposing alternatives to such a country, i.e. placing videocameras as income producers versus commercial logging, a short-term destruction versus a long-term investment. What scenery and wildlife would you think would attract Internet users in this country?

Lifestyles and Citizen Action: Purchasing Power

Background

Developed countries consume 80 percent of the world's natural resources. If not for consumers in these countries, no market would exist for many luxury products, such as mahogany, teak and rosewood. The deforestation taking place to harvest these woods pushes many species of animals closer to extinction. Loggers take the largest and oldest trees. These are the ones most valuable as wildlife habitat, oxygen producers, carbon dioxide absorbers, soil stabilizers and water retainers. In spite of some programs meant to encourage "green" forestry practices, even selective logging, in which only a few trees are taken per acre, all types of logging have negative effects on pristine old-growth forests and their wildlife. (See Forests chapter). Many species are directly endangered through loss of habitat and hunting. People enter previously impassable forest on logging roads to kill Gorillas, chimpanzees, elephants, rare antelopes, birds and other wildlife for bushmeat markets and animal products for Traditional Medicine. (See Forests chapter). Old-growth forests in some parts of the world have been growing undisturbed, harboring the same types of trees for hundreds of millions of years. These forests are irreplaceable repositories of biodiversity and living pharmacies, precious for their scientific value as extraordinarily rich ecosystems. Scientific knowledge of the functioning of these forests and an inventory of their species has only just begun. Cutting one tree can kill a dozen that come crashing down as jungle vines entwine whole groups of trees and branches that stretch for long distances knock down neighboring trees. In the process, many animals lose their lives and habitats. Nest holes for birds, mammals, reptiles and insects, loose bark under which forest bats roost, tall canopies for eagles' nests--all are lost. The logs obtained are

not essential for human survival, but are sold as raw material for coffee tables, wall paneling and lawn furniture for the wealthy. Thousands are cut merely to manufacture shipping cartons or chopsticks, used once and discarded. more than 80 percent of these old-growth rainforests have been logged in the last century, greatly reducing the production of oxygen, water vapor and absorption of carbon dioxide. Certain products, such as Brazil and cashew nuts, can be extracted from tropical forests without harm. Ecotourism has great potential as a means of income. If profits are shared with the people who gather them, they will have an incentive to protect these trees. Other products that damage forests, especially tropical forests, are wooden carved boxes and tourist knick-knacks made from scarce woodlands in India, Indonesia and other countries where forests have been decimated.

Coffee was once grown in the shade of tall forest trees, but with the development of new strains of coffee plants, forests are being cleared to grow coffee in the sun (see the Forests chapter). Coffee grown in the shade is far more ecologically-friendly, since large trees are preserved. Many North American birds migrate to the tropics and winter in coffee plantations. The sun-grown coffee has deprived wildlife of this habitat. A campaign to return to shade-grown coffee, especially if grown without pesticides, was launched by the Smithsonian Institution a few years ago. Some commercial importers have provided a market for this shade-grown coffee, enlisting coffee farmers in many parts of the world to protect forests and grow coffee as an understory. Now this coffee is available in many US stores, marketed as "Shade-grown," "Bird-friendly" or "Shade-grown--Organic." Many of these coffees are comparable in price to, or only slightly higher than, sun-grown commercial coffee grown using pesticides. They have the added advantage of being healthier, since they contain no dangerous chemicals. Likewise, most bananas are grown with massive amounts of pesticides and herbicides, but many growers are now producing bananas organically. Ask your local grocery store to stock them and be aware that purchasing them helps the environment. A similar problem exists with the growing of chocolate from the cacao plant in tropical areas. Its great popularity in the United States has encouraged the clearance of forests for large-scale plantations that grow the plants in the sun, using fertilizer, fungicides and pesticides (see Khamsi 2001). Diseases have broken out in the large plantations, requiring heavy use of pesticides, fungicides and other chemicals to control them. Organic Commodity Products (OCP), a supplier in Cambridge, Massachusetts, promotes the growing of cacao in shade without artificial chemicals. Fortunately, 85 percent of the world's cacao is shade-grown. Some 6million small farmers who cannot afford pesticides provide this crop. Several chocolate companies are now marketing organic chocolate to promote environmentally friendly agriculture (see Khamsi 2001).

Caviar from sturgeon native to Russia and the Caspian Sea is one of the most valuable wildlife products. Sales in the United States and other importing countries have pushed virtually all Eurasian sturgeon species close to extinction. Even famous French chefs, including Jacques Pepin, recommend a boycott of Beluga, the most valuable caviar, which comes from the most endangered sturgeon species. Many other fisheries products come from species that have declined 90 percent or more in the past decade from overfishing. Atlantic Cod, Orange Roughy, Chilean Bass, Atlantic Bluefin Tuna, sharks of many species and swordfish have been seriously overfished. Many of these fish, such as sharks, are slow-reproducing, not having young until they are as old as 20 years. It is likely that their populations will never be able to sustain a commercial take. Pollack is a white fish from Alaskan waters that is being overfished to manufacture artificial crabmeat. The pollack fishery endangers Steller's Sea Lions, depriving them of a major food source. Shrimp from the Gulf of Mexico and many other tropical areas endanger sea turtles, which drown by the thousands in shrimp nets, which also catch millions of tons of unwanted fish that are discarded. Some shrimp is caught using nets that allow sea turtles and other non-target species to escape the net through turtle excluders, and these shrimp are often labeled "turtle-safe." Farmed shrimp and salmon involve environmental destruction. Mangroves are being cut in tropical countries around the world to construct shrimp farms, which emit large amounts of pollution. Farmed salmon are kept in off-shore pens, but many escape to breed with wild salmon, endangering the latter. The pens also contribute large amounts of pollution to the ocean.

Likewise, mining operations devastate entire ecosystems to obtain gold for jewelry and other minerals. The United States provides an enormous market for gold, the majority of which is made into jewelry. Even national parks in Indonesia are now permanently scarred, with large areas of land and rivers devegetated and poisoned with cyanide, which is used to separate the gold from ore. This country has the highest number of threatened species in the world, a

majority of which are found only here. Orangutans are being driven from their forest homes in Indonesian Borneo and Sumatra by loggers and gold miners, their populations now facing extinction in the wild. It is such activities that are fostered by the market for gold. Diamond extraction can destroy wildlife habitat and river bottoms, as well as causing human rights violations when used as currency by dictatorial governments who torture their citizens. Pearl cultivation damages American aquatic ecosystems. Pieces of mussel shell are inserted into living oysters, which causes the oyster to exude pearl material to surround the mussel shell. The mussel shells used for this cultivation come, for the most part, from the United States. Millions of tons of these shells are dug out of riverbeds, threatening some species.

As discussed in the Trade chapter and the previous project, millions of wild animals are captured for the pet trade and specialty collectors in wealthy countries. Parrots, cockatoos, macaws, turtles, tropical fish, snakes, lizards--and even frogs--are plucked from their tropical homes to be sold in pet stores. Some species have been driven to the edge of extinction by the wild pet trade, which also treats these animals inhumanely. The United States bans the import of most wild birds, but many species are still permitted under the Wild Bird Conservation Act. Also smuggling, a multi-billion dollar activity, funnels thousands of animals into pet stores where they are represented as legally taken or even captive-bred. Only 10 percent of shipments entering the United States are inspected for wildlife. For the majority of wild animals in the pet trade, little protection exists. Although the US Endangered Species Act and the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) have helped limit trade, strict controls exist for only a small minority of the most endangered species. Since the United States is the world's largest wildlife importer, the effect on wildlife has been catastrophic.

Lizard, snake and crocodile handbags, shoes and luggage; ivory; feathers and other wildlife products are part of a trade that has endangered hundreds of species. Even if the product was not made from an animal on the US Endangered
Species List, it may be threatened by trade or inhumanely captured or killed. At present, for example, the reptile product trade is killing millions of snakes and lizards for leather products, causing many species to become threatened. Yet almost no controls have been placed on the trade, and what controls there are contain loopholes making them ineffective.

Many plants are endangered by harvesting for collectors. Rare cacti, delicate woodland and wetland species such as Venus Flytraps, Yellow Lady Slippers and other orchids, South African protea and a long list of other plants are being plundered in the wild. Many of these plants cannot be raised in captivity and have been illegally dug up in the wild.

Activities

o Write a report on the effects that American consumers have on old-growth tropical rainforests and their wildlife.

o Ask local stores if they carry shade-grown and organic coffees and, if not, would they stock them? Several grocery store chains and many health food stores sell these coffees. In restaurants and coffeehouses where coffee is served in large quantities, ask them to purchase at least a portion of their coffee as shade-grown, organic. Write the Smithsonian Institution's Ornithology Department for more information on the effect of sun-grown coffee on birds and other wildlife, and write a report on the subject.

o Select one of the jewelry materials mentioned, such as gold. Read the Forests chapter in this book and other references to the mining of gold in South America, Africa and Asia and its effect on the environment and wildlife. Write a short report on the mining operations in a particular country and their effects on wildlife and the environment. If purchasing jewelry, choose artificial diamonds, pearls and gold. These items can hardly be distinguished from the genuine ones because of advances in simulation technology. Other types of gem and metal mining also damage the environment.

o Discuss the general reasons for boycotting wild pets; fur coats; reptile products; feathers; caviar; threatened fish; turtle meat;, Traditional Medicine remedies made from wild animals, such as snakes, bear, seahorses and other

animals; other wildlife products and rare plants that you have seen in stores. Select one species (or group of species, such as sharks) and write a report on how the trade is threatening it and how to publicize the need to boycott its products.

Films

"Affluenza." America's materialism affects the world's environment, destroying forests and other environments. Solutions to the out-of-control consumerism are offered in "Escape from Affluenza."

"Cultivating Opportunity. Self-Help Solutions to Poverty in the U.S. and Africa" focuses on small-scale farmers forming cooperatives to protect themselves against corporations taking over their land.

"Mountains of Gold" tells the story of Brazil's gold rush and the thousands of prospectors who pan and dredge gold in the rainforest.

"Secrets of the Choco" explores the survival of the Choco tribe in Colombia and its rainforest, threatened by highways and non-sustainable development. Six world experts on tropical ecology and sustainable development discuss the region's future.

"Super-Companies" concerns the operations of multinational corporations in terms of raw materials and how they are affecting the needs of people and the global environment.

Projects

Profile of an Endangered Species

Project Summary

Select a species threatened with extinction from the lists of endangered species in the Appendix of *The Endangered Species Handbook*, the *2000 IUCN List of Threatened Species* or another list mentioned below. Using the list of numbered information below as a guide, list its common name, scientific name and other information in that order. Not all of the questions listed below can be answered from available sources, but give an overview with as much information as possible.

Background

Species threatened with extinction may be classified in categories such as Critical, Endangered, Threatened, Vulnerable or Imperiled on various lists such as the US Endangered Species Act, the International Union for the Conservation of Nature and Natural Resources' (IUCN) *2000 Red List of Threatened Species*, publications of The Nature Conservancy or other organizations listed in the Organizations list in the Appendix. (For definitions of the US Endangered Species Act and the IUCN categories, see the list of Endangered and Threatened Species of Mammals, Birds, Reptiles and Amphibians in the Appendix.) This project seeks to describe species in decline or those on the verge of extinction. The number of plants and animals in these categories has increased in the past few decades. Of the many causes threatening species, the disappearance of wild habitats is the most important overall. But for many species, rampant trade and introductions of non-native species are the primary causes. Pollution, pesticides and other toxic chemicals, thinning of the ozone layer and other environmental problems play roles as well. For some species, several of these factors contribute to their decline.

The attitudes of people toward the environment and wildlife in areas where these species are found are often of extreme importance in deciding whether habitats are conserved, laws passed to prevent killing and trade and other conservation measures taken. In some countries, such as Bhutan in the Himalayas, wildlife is held in high regard, and heavy penalties are exacted for destroying the natural landscape or killing animals. In others, high population pressures, faltering economies and political chaos result in destruction of forests and wildlife for commercial purposes, in spite of protective laws and many concerned citizens. In the United States, the US Endangered Species Act is supported by the majority of people, but opposed by a large segment, who see it as politically and economically intrusive. Thus, the conservation status of species threatened with extinction is a complicated picture.

Legal protection, if not enforced, can leave the species open to poaching, even in protected reserves. In spite of strict laws, the Tiger, for example, has been killed in national parks and reserves throughout its range, as a result of high prices paid for its body parts in Traditional Medicine. Thus, a species must receive many types of protection, from habitat to hunting and sale restrictions, combined with a strong protective attitude by people living within its range and elsewhere. Also, funding for research and habitat protection is a major factor that is often lacking for the less charismatic species, such as invertebrates and many plants. The reports generated in this project may consist of only a page or a long report, depending on the wishes of the teacher, student or individual participating in this project.

Methods

Answering as many of the questions listed below as possible concerning an individual species selected is the purpose of the project. It might be easiest to select a native species of animal or plant on the US Endangered Species Act or listed by state Natural Heritage Programs for information that is readily available, or a species about which books or reports have been written, such as the Gray Wolf, the Tiger or the Whooping Crane. One can contact the state Natural Heritage offices in care of each state capital, the US Endangered Species Office in Washington, DC, for federally listed species or the regional offices of the US Fish and Wildfire Service. The US Fish and Wildlife Service has a website as well (see the Organizations list in the Appendix). For information on birds threatened with extinction worldwide, *Threatened Birds of the World*, by BirdLife International, published in 2000 by Lynx Edicions, Barcelona, provides status and other background information, illustrations and references on more than 1,000 species of birds. *Mammals of the World*, by Ronald M. Nowak (1999, Sixth Edition, Johns Hopkins University Press), is another reference providing much of the information listed below. The *2000 IUCN Red List of Threatened Species*, available in CD-ROM disk and on the Internet (www.redlist.org), lists animals and plants of the world in various categories of threat along with basic background information. It is published by The Red List Programme Officer, 219c

Huntingdon Road, Cambridge CB3 0DL, UK; e-mail redlist@ssc-uk.org. Additional books and articles can be found in the Books and Publications Section of the Appendix of this book and in reference lists following each chapter. Within the text of *The Endangered Species Handbook* are many case histories that might provide background information as well. Read Traits of Vulnerable Species in Chapter 2, Vanishing Species**,** to better understand the importance of many of the following questions.

Activities

Answer the following questions with the best available information.

Part I. Description and Characteristics of the Species

1. Species common name, scientific name
2. Class and Family
3. Past range: in recent years and historically
4. Present range: country or countries, region or location
   Does the species have a small breeding range, but a large wintering range?
5. Is the species endemic to a restricted area or region**,** such as an island?
6. What type of habitat does the species inhabit? (For example, oceans, undammed rivers, lakes, old-growth forests, grasslands, mixed habitat.)
7. What is the approximate size of its territory? For example, Siberian Tigers may require 500 square miles per animal, while a small gazelle might survive in an area of only a few square miles. The territorial needs of a species are crucial to its conservation.
8. Does the species require a specialized habitat or diet? Is it adaptable to a variety of habitats or diets?
9. Does the species show altruism, or the unselfish care for members of its own kind?
10. What is the species longevity, if known?
11. What is the species rate of reproduction? (How many young or seeds does it produce, at what intervals and what is their survival?)
12. What is the species rate of natural mortality? (Does the species have few natural enemies or causes of mortality or do large numbers of the species die each year?)
13. Is the species a flightless bird or slow•moving animal? How does this affect its ability to defend itself against predators--human and animal?
14. Is this a large or small animal? The term is relative and denotes size that humans consider large, such as elephants, and other large ungulates, such as antelope, giraffes or rhinoceros, as opposed to small gazelles; for predators, Tigers are large as compared to Ocelots or Margays.
15. Does the species breed in colonies or require large numbers of its own kind for protection, to locate food sources or for other means of survival?

Part B. Status and Conservation

1. Status: What are the threats to this species' survival? (For example, habitat loss, effects of exotic species, trade or other causes.) Describe them in detail.
2. Population numbers, where known, past (historic) and present. (In most cases this would be general information, such as common and widespread

in the past, and small population numbers at present.)

3. Current situation: Is the species in steep decline, making its status Critical, or in gradual decline, making its status Vulnerable. Is its population stable, but threatened because of very small numbers?
4. If in decline, does the present rate of decline exceed annual recruitment by reproduction? If so, by how much?
5. Legal status: Is the species legally protected from killing, capture, sale and harm in all or a portion of its range? If a species is found in many countries, provide as much information as possible. If protected, is the protection enforced?
6. Status of habitat: Are there reserves or national parks protecting the habitat? Is the habitat being destroyed, or is land use compatible with the needs of the species?
7. What are the attitudes of most people who live in the range of the species toward it? Are they aware of its presence and status? If so, do they support its protection or are they neutral or even negative, persecuting it?
8. Adequacy of existing conservation: What is being done, either by governmental or private conservation organizations or individuals, to help the species survive? Is the present program effective? Is adequate funding available for its protection? What would be needed to better ensure its survival?
9. What are the potential threats to the species, such as future habitat destruction from expanding human settlements and government policies of land development? For example, the wildlife of India will be under increasing pressure as the population increases and wild habitat is destroyed. Government policies, such as resettlement of people or development of grassland or rivers for human use, can present major threats to wildlife. China, for example, is gradually resettling millions of people into the steppe grasslands of its far west who are having a negative effect on native wildlife and the environment. Through data in almanacs on the rate of human population growth**,** calculate the threat of habitat loss in the future.
10. Can you think of something that needs to be done for the species, such as research; publicity in the form of articles or a film about its status; increased commitment from government or organizations to its conservation; or a website on the Internet asking for more information and suggestions? Can you think of a way you or your class could help the species?

Biodiversity

Project Summary

Biodiversity is a term used to describe the numbers of species, families and other biological divisions of life forms on Earth. Studies of this subject in various parts of the world will be discussed. Certain regions and countries in the world harbor very large numbers of plant and animal species, yet these same areas are threatened by habitat destruction. What is being done to preserve such areas will be explored. The importance of preserving biodiversity to

human society and environmental balance is a major purpose of the project. A related topic integral to the study of biodiversity is the variety of ecosystems and environments that provide habitats for the great diversity of life on Earth and their protection.

Background

As studies of the natural world have blossomed over the past century, scientists have documented Earth's amazing array of plants and animals, each species interrelated with others in its environment. Although life exists even in inhospitable environments, such as frigid mountain tops and hot springs, certain ecosystems, primarily tropical forests and coral reefs, harbor the greatest diversity of species. Research on the species of plants and animals in these areas is just beginning, but remarkable findings have emerged. In a single tree in Peru, for example, Dr. Edward O. Wilson, a famed biodiversity expert and entomologist, found 43 species of ants, a number equal to all the species of ants found in the British Isles.

Studies of biodiversity have increased in recent years, and one country, Costa Rica, is now carrying out a biological inventory of all its species, a massive and important task that may take a century. A study that has gone on since the building of the Panama Canal measures the decline in the number of species living on Barro Colorado Island as the waters of the Panama Canal rose around it. It has documented the loss of many wide-ranging species as the range grew smaller. Such studies add to the understanding of habitat requirements for various species and how the loss of some affects ecosystems as a whole. A study in the Brazilian Amazon measured the biodiversity of an extensive rainforest prior to cutting it into parcels of varying size to determine the effects on species (see Lovejoy *et al.* 1984). As a result of extensive deforestation, especially in tropical countries, many studies of forest fragmentation and its effects on biological diversity are taking place, finding that losses of even a few species can result in major ecological damage (see Laurance and Bierregaard 1997 and description in the Forests chapter). Biodiversity studies known as RAPs, or Rapid Assessment Programs, last only a few days and seek to identify areas of high diversity that are in danger of being destroyed. "Environmental S.W.A.T Team" is a film about biologists who conduct one of these RAPS, inventorying a tropical forest for Conservation International, an organization which was able to convince the country's government to protect a threatened region based on the results of the study (see Video section).

Brazil's Atlantic Forest, one of the world's most diverse environments, which once covered millions of square miles along the southern coast and well inland, has been reduced by 92 percent. Remnants of this forest have been found to harbor the greatest diversity of trees in the world: 476 species in a plot of only 2.5 acres. By contrast, a plot of similar size in a North American temperate forest has fewer than 80 species of trees. This is known as a "hotspot," or an area of great biological diversity. Others include forests in the Andes, Madagascar and Indonesia (see Mittermeier *et al.* 1999). A vast array of plants and animals can be found in the hot spots, including many extremely unusual and unique examples of evolution that are in imminent danger of extinction. New Caledonia, for example, an island in the southwestern Pacific Ocean, is home to a variety of plants and animals of ancient origin. It is a small portion of Gondwana, the southern supercontinent that broke up into pieces some 140 million years ago at the dawn of the age of birds. The ancestors of the most primitive avian families originated in Gondwana, and the Kagu, a bird still resident on New Caledonia, is a direct descendant (see Cracraft 2001). Related to cranes, rails and bustards, the elegant, gray Kagu is flightless, with a stunning pattern of wing and head crest feathers. It possesses characteristics so unusual that it has been placed in its own avian family. The Kagu is threatened with extinction along with scores of other ancient species on New Caledonia, many of which had survived for millions of years (see *Threatened Birds of the World*). This hotspot is in grave danger of losing diversity to nickel mining, feral dogs that kill the Kagus and other wildlife, and deforestation.

The huge growth in human population over the past century, now totaling some 6.5 billion, is responsible for colonization of previously remote wilderness areas and for providing a market for the decimation of ancient forests and rare wildlife for commercial purposes. Land is being cleared for grazing livestock and farming, while mining, industry, corporate logging and other development are obliterating species throughout the world. Forests have the largest number of threatened species of any habitat, although the oceans have scarcely been explored for biodiversity. Tropical forests throughout the world harbor about half the world's plants and animals on only 7 percent of the planet's

land area. Hot spots also exist in temperate regions, such as the Appalachian mountains of the eastern United States, which have more types of salamanders than exist anywhere in the world, now threatened by pollution and logging. Rivers and waterways of the southeastern United States have the greatest number of mussel species in the world, but government dam and water projects have caused hundreds of extinctions. Grasslands, where only a century ago wild antelope, bison and other ungulates roamed in untold millions, have been converted into farms or pastureland for livestock, the wildlife killed off or driven away. In Earth's history, mass extinctions have occurred on at least five occasions, nearly obliterating the majority of life forms. These were natural events, but the present catastrophic situation is considered the sixth mass extinction, one that may end in destroying or seriously damaging the remaining rainforests, coral reefs and other precious centers of biodiversity within the next century (see Wilson 1988, Leakey and Lewin 1995). By some estimates, half of the estimated 5 million animals and plants that now exist, only a fraction of which have been scientifically identified, could be gone within a century.

Just as the diversity and ecological roles of species are beginning to be seen as components of an immense and beautiful living tapestry, the strands of this tapestry are unraveling. The disappearance of even a single species can result in extinctions of others dependent on it. For example, elephants and hornbills are the primary dispersers of many forest plant seeds, upon which a host of animals rely. Both are now in danger of extinction, threatening entire ecosystems. Thus, biodiversity is not an abstract concept, but a blueprint of the Earth's life forms. It is vital that its many parts be preserved. Once destroyed, many ecosystems, such as old-growth forests and other key environments, may never regenerate. In most such cases, our knowledge of diverse systems is inadequate to gauge just how many species--or which species--could disappear from an ecosystem before it collapses. Nor do we know how much genetic diversity a species can lose through loss of individuals before it can no longer adapt to changes in its environment. Drastic changes caused by human activities are outpacing research on such situations. The healthy functioning of ecosystems is key to human survival. Although the majority of biologists consider the loss of biodiversity to be the greatest problem facing humanity, few members of the public are even aware of this critical situation. Ignoring these experts' opinions of the precarious status of our planet's health, upon which our lives depend, is the equivalent of ignoring the opinion of a team of eminent doctors recommending urgent action to remedy an emergency medical condition.

Steps are being taken to preserve many critically important regions. Through acquisition of habitats and reintroductions of species, entire ecosystems are being saved. In a growing trend, countries are setting aside large new national parks and reserves. Suriname, for example, has established a national park that encompasses the central core of the country, covered in virgin rainforest and teeming with wildlife. Bolivia has set aside massive parks in areas with high biodiversity and unusual types of forests. Brazil, with the help of conservationists from around the world, is now working to save the last 8 percent of its Atlantic Forest in the southeast. Several countries in southern Africa are establishing international parks that greatly enlarge protected areas and allow migratory species, such as African Elephants and other ungulates, to move freely across borders. Corridors for wildlife to move from one area to another are also being established in the Americas. These prevent isolation of small populations of animals that would likely dwindle to extinction. Education is key to the future of preserving biodiversity, which is vital in maintaining the planet's ecological stability. Studies on this and related subjects are now being taught in an increasing number of high schools and colleges so that future generations will not squander the planet's true wealth, its natural heritage. Appreciation of the sheer beauty of the natural world and its wealth of species is an important facet of this project.

Activities

o **Biodiversity study.** Organize a group of students or interested persons to conduct biodiversity studies in your area. Ecosystems should range from low to high diversity. To study forest diversity, for example, you might select: (1) a small city park; (2) a suburban back yard or tree farm, and 3. a woodland, preferably old-growth. To study aquatic ecosystems, you might select: (1) a city creek or river; (2) a suburban pond, and (3) a sizeable natural wetland. The complexity of the project will depend on the experts available for identifying and recording species. The object will be to list as many species as possible from each area and provide a general description of the habitat. If there are rare, threatened or endangered species in any of the areas, these should be described and, if seen, carefully

noted. Invite employees of the state's Natural Heritage Program to help in selection of sites and, if possible, accompany the group. A biodiversity day in the Boston area attracted many scientists, including botanists, ornithologists, herpetologists and mammalogists, who educated interested members of the public at various sites. Experts in birds do not have to be ornithologists but can be proficient bird-watchers, knowledgeable in bird song as well as sight identification. If the field trip is taken during bird migration, note which species breed in the area and which are migrating through. Mammals, reptiles, amphibians and fish (if in an aquatic environment) are less readily seen, and specialists in the latter animals might demonstrate methods of live-trapping or locating these animals by turning over rocks or netting. The identification of trees and plants, including ferns, mosses and lichens, will provide basic information about the habitat. If experts in some or all of these fields are available, or the team leaders are able to provide basic information, the group can be divided into subgroups, each of which will choose a type of life form, such as plants, invertebrates, birds or mammals. Once back in the classroom or environmental center, the various groups can meet and provide lists of the species they have seen in each area. Any rare, endemic or endangered species will be singled out and described in detail. This one-day project will not provide a complete picture of the biodiversity of an area but can give a general picture that is valuable. The effects that development has on nature and the need to protect wilderness and natural areas will become apparent through such a study. In general, biological diversity increases the farther one gets from large cities and suburban areas. Keep in mind, however, that some extremely rare species, especially plants and insects, have managed to survive in small pockets of wild habitat in unexpected places. Weedy growth next to railroads, for example, has been found to harbor many rare plants and insects. Such areas, never cleared for development, have remained natural. Open space, even with low biological diversity, is preferable to asphalt, and students may contribute ideas on making city parks and suburban backyards more diverse by planting trees and shrubs and allowing brushy areas to grow. More advanced students can participate in the CD-ROM biodiversity study listed below (see Wilson and Perlman 1999).

o **Bird feeding.** Another project involves appreciation of biodiversity with the potential for making a contribution to ornithology. Backyard bird feeders can provide an eye-opening education in biodiversity that is also extremely enjoyable. Bird feeders attract many common seed-eating birds. Adding suet and fruit can bring woodpeckers, orioles and other fruit-eating birds. The number of species that come to bird feeders is related to the habitat and surrounding area. Feeders in remote habitats or located on bird migratory flyways will attract more species than those placed in the city, which are likely to attract pigeons, sparrows and starlings, all European in origin. Sometimes, a rare species comes to the bird feeder to feed or is attracted as a predator on the birds. Bird feeders can provide important data on bird diversity and population trends. Cornell's Laboratory of Ornithology (159 Sapsucker Woods Road, Ithaca, NY 14850-1999 (Tel: 607-254-2473) conducts a program that enrolls volunteers to keep track of the birds that visit their feeders. By providing a wide variety of seed and other food, one can learn much about diets, how the birds feed, their behavior and plumage changes throughout the year. Books about bird feeding are sold in most book stores, and local chapters of the National Audubon Society provide information on feeders and feed. Television advice is given by Don and Lillian Stokes in their PBS series.

o **Bird-watching.** Bird-watching trips are important in learning about the majority of species that do not come to bird feeders or live in suburban backyards. Insect-eaters, such as warblers, flycatchers, vireos and other songbirds, can be seen only on migration or in their natural environments. During migration, especially in the spring, the beauty of these colorful birds, called "living jewels" by many naturalists, can be appreciated by using binoculars. Excursions to various habitats to see birds will also teach the diversity of environments, threats to them, and which types harbor the greatest diversity of birds. Local bird clubs, National Audubon Society chapters and naturalist clubs are sources of information on the best birding spots and times of year when one is likely to see the greatest number of birds. Many of these organizations conduct birding trips, both in the United States and in foreign countries. Declines in avian diversity and in population numbers will become evident after participation in several of these trips. Sources of information on such trends include trip guides who have been conducting tours or breeding bird surveys of the US Fish and Wildlife Service or the National Audubon Society over a period of years in the same habitat. Ask them for information on species that have declined or disappeared altogether as a result of environmental changes, pollution or other causes. Note the species of birds seen on the trip and find out from the guide or other authority, such as the US Fish and Wildlife Service or National Audubon Society, whether these species have declined over recent years. For

example, shorebirds seen on coastlines or in the Mississippi River region have suffered dramatic losses of up to 90 percent in some species over the past 30 years. The causes are diverse, from overfishing of food sources, disturbance of beach nesting areas, loss of habitat in wintering or nesting grounds to killing on their wintering grounds. On the list of species seen, note population trends and their causes in the area visited.

o **Worldwide perspective.** Learning about biodiversity from a worldwide perspective is key to understanding the subject. Dr. Edward O. Wilson of Harvard University coined the word "biodiversity" in the 1988 book of that title that he edited. His other book on the subject is also a primary resource. Both give overviews of the world's wealth of species and risks to them. Another important basic reference, *Conserving Biological Diversity*, by Jeff McNeely and other authors, is a 1990 overview of the problem, with key species and regions described. This leads to *Hotspots*, written a decade later in 2000 by Dr. R.A. Mittermeier and others. This book identifies hotspots as the world's most endangered high-biodiversity areas and discusses each in terms of geography; habitat; which species are native, especially those that are found only that in particular area (endemic species); statistical biodiversity for each area; threats to the area; and what is being done to conserve them. Clive Ponting's *A Green History of the World* helps explain why past civilizations have died out as a result of ignorance and overexploitation of their environment and the native wildlife upon which they depended. Michael J. Novacek of the American Museum of Natural History edited a 2001 book, *The Biodiversity Crisis. Losing What Counts*, a collection of essays by prominent scientists and conservationists who discuss the increasing rate of extinctions and give case history examples of areas at risk and what strategies are working to help protect them. The other references listed below provide additional information.

- Write an essay on the problem of the loss of biodiversity, emphasizing the reasons why it is important to the future of human society, as well as for the sake of conservation.
- List ways that consumers in the United States who buy tropical hardwoods and other goods, use large amounts of non-renewable energy and produce greenhouse gases, affect the loss of biodiversity.
- Choose a country or area that has high biodiversity, such as Colombia, Madagascar or Indonesia, and describe the geography, climate, type(s) of biological diversity, threats, unique species of plants and animals, conservation programs, and whether they are successful. Calculate the losses of species should the present rate of deforestation or other destruction continue, using references such as *Hotspots* and *Threatened Birds of the World.*

o **Species in danger.** Learning about threatened plants, birds, mammals and other species will provide in-depth knowledge of what is at stake. *Threatened Birds of the World* examines the 1,100 species whose future survival is in danger. This book illustrates each species with range maps, status and other background information. Many of these birds are illustrated in *The Life of Birds,* a book by David Attenborough, and in a 10-hour film series based on it seen on PBS. The Video section describes other films about threatened species. Other threatened animals and plants surveyed by the *2000 IUCN Red List of Threatened Species* are not described in depth by the International Union for the Conservation of Nature and Natural Resources (IUCN), which sponsors this list. The IUCN no longer publishes "Red Data Books," which gave background information on each species. The Internet site (www.redlist.org) provides some information, such as distribution and basic status category, but few listings give causes of the status and other related data. Such information gaps are filled in part by publications such as *Walker's Mammals of the World,* a two-volume, in-depth examination of mammals by Dr. Ronald Nowak, regularly updated and last issued in 1999. The IUCN Species Survival Commission sponsors many individual specialist groups that gather information on elephants, rhinos, whales, primates and many other categories. These groups issue newsletters and have websites. (Contact the SSC Red List Programme Officer, 219c Huntingdon Road, Cambridge CB3 0DL, UK; e-mail redlist@ssc-uk.org). Select a group of species, such as salamanders, frogs or orchids, and describe their general status. How many species are threatened? What are the general causes? What areas of the world do they inhabit? What will be the effect on other animals or plants in their ecosystems should they disappear? What should be done to preserve them?

Biodiversity: Video

"Biodiversity: The Variety of Life" explains what biodiversity is and why we should protect it. This film uses maps,

diagrams and examples to introduce new terms and concepts, including fragmentation, linkage, and viable population, to explain how ecosystems are dynamic and varied. It focuses on the North Cascades ecosystem, but presents general concepts.

"State of the Planet" is a 3-hour BBC Bristol film on the biodiversity crisis made for Discovery Communications in 2000. It examines the rise in extinctions and endangered species and causes such as "islandization" or isolation of habitat surrounded by development; it profiles Hawaii as leading the world in extinct and endangered species, its beautiful natural heritage being destroyed by exotic species and disappearance of native forests. The final hour of this film series, "The Future of Life," makes clear that if we do not act soon, great natural treasures will be lost.

"Natural Connections," produced by Howard Rosen for PBS in 2000, is a one-hour examination of the failure of the United States and other developed countries to protect nature. It links extravagant and unthinking lifestyles with the loss of biodiversity and proposes changes that will have direct effects in terms of preserving species.

Bats: Ecologically Important Mammals

Project Summary

Learning about bats and threats to them is the major purpose of this project, as well as understanding the importance of bats to the environment as pollinators, seed dispersers and insect-eaters. An endangered bat species will be selected as the subject of a report. Conservation of bats through the protection of their habitats and building of bat houses will be an important facet of this project.

Background

Bats comprise almost one-fourth of all mammals--nearly 1,000 species--yet they have not received the attention and credit they deserve as major insect-controllers and pollinators in ecosystems worldwide. Many species are becoming endangered, and others are declining from destruction of their nesting caves, direct persecution from ignorance, closure of mines which many bats had colonized, and indiscriminate use of pesticides.

Until recently, bats were routinely poisoned by commercial pest control companies in the mistaken idea that all bats pose the threat of rabies transmission. Only one-half of 1 percent of bats contract rabies. Over the past 45 years, only 20 people in the United States and Canada have contracted the disease from bats, according to Bat Conservation International, an organization dedicated to the conservation of bats and education about their ecological roles. Most problems involve people carelessly picking up obviously sick bats found out in the open or on the ground in the daytime. These should always be avoided, according to Dr. Merlin D. Tuttle, Founder and Executive Director of Bat Conservation International. Pest control companies in the United States are now adopting new and more informed policies regarding the removal of unwanted bats from buildings. The journal *Pest Management,* in its May 1992 edition, published several articles on how to "bat-proof" buildings without use of lethal means, and the usefulness of bats in controlling insects.

A single Brown Bat, one of North America's most common species, is capable of capturing 600 mosquitoes in an hour (see Tuttle and Smith referenced below). One colony of 20 million Mexican Free-tailed Bats in central Texas eats a quarter of a million pounds or more of insects each night, according to Bat Conservation International. Repercussions have occurred when bats have been destroyed. In Israel, a campaign to eradicate fruit bats instead killed almost 90 percent of the country's insectivorous bats; moths that were formerly controlled by the bats proliferated and became major agricultural pests (Tuttle and Smith). To control these pests, huge amounts of pesticides were used, further eliminating natural predators of insects and beneficial insects.

Nectar-feeding and fruit bats pollinate more than 130 genera of plants. The co-evolution of many bats and plants, the

latter evolving prominent, odoriferous large flowers blooming at night with copious nectar and pollen, and the former specialized tongues and muzzles for flower-feeding and acute senses of sight and smell, is a fascinating study in itself. The statuesque Century Plant of southwestern deserts has co-evolved with a pollinating bat, and this plant blooms at rare intervals, using nectar to attract its pollinator (see Howell referenced below). Among plants that bats pollinate are valuable fruits, nuts and spices: plantain, bananas, breadfruit, mangos, guavas, avocados, almonds, cashews, cloves, vanillin, carob and figs. In Southeast Asia, a bat that pollinates the Durian tree, which produces fruit marketed for $120 million per year, is being killed for food and its caves quarried for limestone. Few people in the region are aware of its economic importance and the need to conserve it. Fruit bats throughout the world are killed for food, and a growing number are becoming endangered.

Many US bats are listed on the US Endangered Species Act as Endangered or Threatened or on the *2000 IUCN Red List of Threatened Species*. The Indiana Bat's entire population winters in only a few caves in the United States. Approximately 95 percent of the entire known Gray Bat population hibernates in only nine caves with more than half in a single cave in northern Alabama. The threatened Rafinesques Big-eared Bat is found only in Indiana, but it receives no federal protection from the US Endangered Species Act. The Nature Conservancy and many state Natural Heritage Programs have been instrumental in purchasing numerous caves to protect these species.

The following bats are either listed on the US Endangered Species Act or on the *2000 IUCN Red List of Threatened Species*. Some experts estimate that approximately 40 percent of US bats are declining or already endangered. Many species recognized by mammalogists as threatened or endangered and listed by the IUCN as Vulnerable, a high category of risk, have not been listed on the US Endangered Species Act.

Threatened United States Bats
(Includes territories)

Key:
E = Endangered
NT = Near Threatened
T = Threatened
V = Vulnerable
X = Extinct

For definitions of these categories, see the list of Endangered and Threatened Mammals, Birds, Reptiles and Amphibians in the Appendix of this book.

Species	Distribution	US ESA	IUCN Red List
Big Long-nosed Bat *Leptonycteris nivalis*	US, Mexico, Guatemala	E	E
Brazilian Free-tailed Bat *Tadarida brasiliensis*	sw US to S. America		NT
California Leaf-nosed Bat *Macrotus californicus*	US, Mexico		V
Gray Bat *Myotis grisecens*	c. & se US	E	E
Hairy-legged Vampire Bat *Diphylla ecaudata*	US, Mexico to Peru		NT
Hawaiian Hoary Bat *Lasiurus cinereus semotus*	US (Hawaii)	E	

Hog-nosed Bat *Choeronycteris mexicana*	US, Mexico, C. America		NT
Indiana Bat *Myotis sodalis*	e. & Midwest US	E	E
Lesser Long-nosed Bat *Leptonycteris curasoae*	US to S. America		V
Sanborn's *L.c. yerbabuenae*		E	
Little Mariana Flying Fox *Pteropus tokudae*	Guam	E	X
Marianas Flying-fox *Pteropus mariannus*	SW Pacific		E
Guam *P.m.mariannus*		E	
Mexican Long-nosed Bat, see Big Long-nosed Bat			
Rafinesque's Big-eared Bat *Plecotus rafinesquii*	US (Indiana)		V
Townsend's Big-eared Bat *Plecotus townsendii*	US		V
Ozark *Plecotus townsnedii ingens*		E	
Virginia *Plecotus townsendii virginia*		E	
Underwood's Mastiff Bat *Eumops underwoodi*	US to Central America		NT

In addition, each state Natural Heritage Program has a list of threatened or rare mammals, many of which include bats. The major threats to bats in North America are similar to those in foreign countries. They include the cutting of old-growth forests that provide habitat, pesticide use, deliberate poisoning and destruction of caves where many bats winter.

Activities

o Find out which bats live in your area. For distribution information, consult guide books such as *North American Mammals*, published by the National Audubon Society. Use reference books such as *Bats*, by M. Brock Fenton (1992), *America's Neighborhood Bats*, by Merlin D. Tuttle (1988), and *Walker's Mammals of the World*, by Ronald Nowak. Bat Conservation International has published a beautiful brochure, "Bats: Gentle Friends, Essential Allies," and a fact sheet, "Important Bat Facts." Different species of bats can occupy the same general area, yet have different diets and habitats. How do the bats in your area differ in these ways? What do they eat? Contact the Natural Heritage Program of your state and ask them if there are important bat habitats, such as caves, that are endangered and how your class or local organization can help save these habitats.

o Select a threatened species of bat and write a report on its status, life history, threats and what is being done for its conservation. Consult the references below and your state's Natural Heritage Program.

o Discuss the ecological importance of bats. What fruits and other plants important to humans are pollinated by

bats? What would be the effect on insect populations if bats disappeared? *Bats in Question*, by Don E. Wilson, listed below, is a very useful book for information on this subject.

o Help dispel the image of bats as dangerous, rabid creatures who should be eliminated. Humane means of keeping bats from entering buildings exist, and local animal control officials and public health officials should be provided with such information, available from Bat Conservation International. Also, letters to the editor of your local newspaper can be helpful, especially if an article about rabies or vampire bats has been printed. Point out that bats are extremely beneficial and vital to the survival of many plants.

o Build a bat house as a class project. The instructions for construction and placement are given in "The Bat House Builder's Handbook" from Bat Conservation International and a video that gives instructions and general information. This pattern prevents mortality to bats from improper design, materials and placement. Once constructed, calculate the number and species of bats that will occupy the house(s) and the number of insects they will consume.

o Bats have many highly unusual characteristics. Many have echo-location sonar far more sensitive than that designed by humans. Others are able to hunt unusual prey, such as fish or frogs. Their abilities are so finely developed that they are only beginning to be understood. They also are intelligent and devoted to one another. They are among the few species who aid one another during the birthing process, as "animal midwives." Consult the books and films listed below and write a paper on a particular trait that you find fascinating.

Tuttle, Merlin D. and Eileen C. Smith. 1992. Bats: Nature's Own PCO. *Pest Management,* May, Vol. 11, No. 5, pages 10-13.
Wilson, Don E. 1997. *Bats in Question. The Smithsonian Answer Book*. Smithsonian Institution Press, Washington, DC. (Source book with questions and answers about bats and superb photography by Merlin D. Tuttle; addresses of organizations concerned with bat conservation are listed at the end of the book along with a list of all bats with their conservation status.)

Films

"Korup. An African Rain Forest." A Cameroon forest where bats are seen pollinating flowers at night.
"The Secret World of Bats." Overall view with the role of bats as pollinators and insect-eaters is stressed, and unusual species, such as fish-eating and threatened fruit bats, are seen.
"Wet Side Story." Central American rainforest with bats as a focal point. The sensitivity of their sonar is beautifully filmed.
"Private Life of Plants." Includes pollination by bats of several species of plants and describes how plants and bats co-evolved.
"Castaways of Sulawesi." An Indonesian island is the scene of cruel capture

of flying foxes for sale as food by young boys using hooks on kites that entangle them in flight.

The films above are described in detail in the Video section of this book.
In addition, other films that focus on bats include "Phantom of the Night" (bats of Central America); "Beneficial Bats" (Wild America series); "Land of the Giant Bats" (Comoros flying foxes); "Life Upside Down" (Quebec Government film emphasizing Canadian bats and their ecological role); "Night Stalkers" (bats of Belize--National Geographic Explorer TV program).

Slide Show
"Bats of America," by Bat Conservation International.

Conserving the Wood Thrush

Project Summary
Learn about the life history, distribution, ecology and conservation of the Wood Thrush, a songbird in steep decline. Using written materials and sources listed below, write a report on the threats it faces and what is needed to help it survive. For those who live in areas where the Wood Thrush is not native, select another declining songbird and follow the same suggestions.

Background
The Wood Thrush (*Catharus mustelinus*) is one of the most melodious songbirds in the world. Its beautiful, fluted song echoes through eastern North America's woodlands. In the words of Arthur Cleveland Bent, author of a series of authoritative life history studies of American birds: "The nature lover who has missed hearing the musical bell-like notes of the wood thrush, in the quiet woods of early morning or in the twilight, has missed a rare treat. The woods seem to have been transformed into a cathedral where peace and serenity abide. One's spirit seems truly to have been lifted by this experience."

The Wood Thrush is also useful to forest ecosystems, consuming vast amounts of insects. Unfortunately, its populations have declined in recent years from 40 to 80 percent, depending on the area. Major causes include the destruction of both its nesting and wintering forests, combined with parasitism on its nests by the Brown-headed Cowbird, a bird that lays its eggs in the nests of other birds. These eggs tend to be larger than the eggs laid by the Wood Thrush, and the aggressive chicks crowd out the thrush chicks. Wood Thrushes are closely related to the familiar American Robin, a common denizen of suburban yards and forests. Unlike the Robin, however, the Wood Thrush is not common in suburbs and backyards. Although the species was occasionally seen near homes and villages in the first half of the 20th century, today it breeds only in undisturbed forest tracts. Its forest habitats have become fragmented into smaller and smaller blocks, causing the species to disappear from many areas.
Wood Thrushes migrate to Mexico and Central America each winter. They seek out old-growth rainforests from southern Mexico through Panama. Within the past 40 years, their forests have been logged and often converted into

grazing land or agricultural fields. Researchers tracking these birds to their wintering grounds have discovered that they stay in the same area, even though it has been destroyed, and usually die within a short period from starvation or predation. The decline in this species' population was discovered through Breeding Bird Surveys conducted annually by the US Department of Interior. The Wood Thrush is close to endangered status, and conservation is critical to prevent its decline to extinction.

Other North American songbirds that migrate to tropical areas have declined as well. These birds, known as neotropical migrants, include tanagers, orioles, warblers, thrushes and vireos. These colorful birds brighten our forests and orchards, consume harmful insects and play important ecological roles. Almost all are in decline, some far more precipitously than others.

Activities

o Find out about the Wood Thrush, using the text in this book (see index), sources listed below and those available in your library and through computer on-line searches.

o Write a report answering as many of these questions as possible:
- What does the Wood Thrush look like?
- How large is it?
- Are males and females different in size or appearance?
- What is its diet?
- What type of woods does it prefer (for example, dry, old-growth forest or cool, damp forest near streams)?
- Does it build its nest on the ground, in bushes, or on tree branches?
- How large a territory does it establish?
- When does it sing? Describe its song (see reference on obtaining recording).
- How long does it live?
- What are its breeding and wintering ranges?
- How did early naturalists, such as John James Audubon, describe Wood Thrushes in the 19th century? (See Audubon and Coues book below.)
- How serious is the threat from Brown-headed Cowbirds who lay their eggs in Wood Thrush nests? (This was noted even in the 1930s by Bent (1964), and later by other authors such as Rappole *et al.* (1989), and Terborgh (1989.)
- How can people contribute to protecting both the breeding and wintering habitat of the Wood Thrush?

o Field study**:** If you live east of the Mississippi River in the range of this species, visit an area where Wood Thrushes live**.** First, listen to the recording of their songs (see below). Often they are more easily heard than seen. Do not approach a nest or disturb birds by playing recordings of their songs. Photograph the woodland setting where you hear the Wood Thrushes and try to observe them quietly from a distance. Describe what wildflowers, trees and other birds you see. If you live outside their range, see films listed below and listen to recordings or select another species of thrush or songbird found in your area that is in decline as a result of habitat loss, especially forests. Consult your local Audubon Society, the US Fish and Wildlife Service, your state's Natural Heritage Program or the bird count programs listed below.

o Conservation project**:** Find out if there is a woodland near your home where Wood Thrushes breed. The local National Audubon Society or birding organization can provide this information. If so, is it protected from logging? Can your class or school help in protecting a woodland where they breed?

o Participate in a survey of native birds through programs sponsored by local Audubon or birding organizations. The

American Birding Association publishes an annual guide, "Volunteer Opportunities for Birders," which lists day-long programs and more extensive studies. Available for $2 from Volunteer Directory, ABA Sales, P.O. Box 6599, Colorado Springs, CO 80934; 800-634-7736. For further ideas, see Nickens reference below.

o Why are some species rare and others common? Compare the Wood Thrush with the American Robin by answering the following questions: Does the Robin migrate? If so, where does it migrate? Are there dangers in its wintering ground, such as deforestation? Where does the Robin nest? Is there more habitat for American Robins or for Wood Thrushes? Explain why. Are there threats to the American Robin?

Books and Publications

Adams, George. 1994. *Birdscaping Your Garden. A Practical Guide to Backyard Birds and the Plants that Attract Them.* Rodale Press, Emmaus, PA. (On page 87, the Wood Thrush is profiled, providing information about migration, breeding range, nesting, feeding, garden bushes and fruiting plants that it will eat, as well as the woodland habitat it prefers.)

Audubon, Maria R. and Elliott Coues. 1986. *Audubon and His Journals*. Vols. I and II. Dover Publications, New York. (First published in 1897, Audubon's journals were collected by Maria Audubon with notes by the distinguished naturalist Elliott Coues. Wood Thrushes are mentioned many times.)

Bent, Arthur C. *Life Histories of North American Thrushes, Kinglets, and Their Allies.* First published in 1949 and reprinted by Dover Publications, New York, 1964, pages 101-122.

Bull, John and John Farrand, Jr. 1977. *The Audubon Society Field Guide to North American Birds. Eastern Region.* Alfred A. Knopf, New York. (A photo guide.)

Cherry, Lynne. 1997. *Flute's Journey. The Life of a Wood Thrush*. A Gulliver Green Book. Harcourt Brace and Company, San Diego, CA; New York.

DeGraaf, Richard M. and John H. Rappole. 1995. *Neotropical Migratory Birds. Natural History, Distribution, and Population Changes*. Comstock Press, Cornell University, Ithaca, NY. (This book has range maps of all North American breeding birds that migrate to Latin America and several pages of discussion of each species.)

Farrand, John Jr. (ed.). 1983. *The Audubon Society Master Guide to Birding.* (Has color photo of adult at nest with chicks and a color painting of the juvenile.)

Forbush, Edward Howe and John Bichard May. 1959. *A Natural History of a Bird of Eastern and Central North America*. Bramhall House, New York, pages 377-378.

Geffen, Alice M. 1978. *A Birdwatcher's Guide to the Eastern United States*. Barron's, Woodbury, NY. (This and the Pettingill book below list major parks, refuges and public lands by state; under each is a list of birds to be seen.)

Hagan, John M. III and David W. Johnston (eds.). 1992. *Ecology and Conservation of Neotropical Migrant Landbirds*. Smithsonian Institution Press, Washington, DC. (This book is not indexed. It is a collection of papers from a 1989 symposium, containing much information on the problems of songbirds, including the Wood Thrush, especially an article on destruction of its habitat in Veracruz, Mexico, on pages 337-344.)

Harrison, Colin. 1978. *A Field Guide to the Nests, Eggs and Nestlings of North American Birds.* The Stephen Greene Press, Brattleboro, VT; Lexington, MA. (This book describes the nest and nestlings and gives the nesting dates; a color photo shows the egg.)

Keast, Allen and Eugene S. Morton (eds.). 1980. *Migrant Birds in the Neotropics: Ecology, Behavior, Distribution and Conservation*. Smithsonian Institution Press, Washington, DC. (Papers submitted at a symposium. Many discuss the threats that migrant songbirds, including Wood Thrushes, face on their wintering range. The introduction gives an overview of the songbird decline.)

Kricher, John C. 1988. *A Field Guide to the Ecology of Eastern Forests. North America*. The Peterson Field Guide Series. Houghton Mifflin Co., Boston, MA. (This book contains information on hundreds of species of plants and animals, many of which are illustrated with color photos.)

National Audubon Society Nature Guides. *North American's Eastern Forests and Wetlands*. Alfred A. Knopf, New York.

Nickens, Eddie. 1997. Beyond the Life List. *Wildlife Conservation* magazine, July/August. (Wildlife Conservation Society, Bronx Zoo, Bronx, NY 10460.)
(This article describes the work of volunteers who participate in surveys, banding, birdfeeder studies and other projects relating to North American songbirds; it provides addresses and phone numbers of various organizations.)

Peterson, Roger Tory. *A Field Guide to the Birds. A Complete Guide to All the Birds of Eastern and Central North America*. Houghton Mifflin Co., Boston, MA. (This classic guide has excellent illustrations, breeding range map and descriptions.)

Pettingill, Olin Sewall, Jr. 1977. *A Guide to Bird Finding East of the Mississippi*. Oxford University Press, New York. (Although many of the areas described in this indexed book have changed since it was first written, many are protected sanctuaries, parks and reserves.)

Rappole, John H., Eugene S. Morton, Thomas E. Lovejoy III and James L. Ruos. 1983. *Nearctic Avian Migrants in the Neotropics*. US Fish and Wildlife Service and World Wildlife Fund, Washington, DC. (This publication is not indexed, but is a well-organized report on North American songbirds, their ecology and threats. Range maps show breeding range as well as wintering range of all migratory species.)

Sibley, David A. 2000. *The Sibley Guide to Birds*. Alfred A. Knopf, New York. (Considered one of most inclusive guides because it includes information on subspecies, varieties and other aspects not covered in most guides.)

Stokes, Donald and Lillian. 1996. *Stokes Field Guide to Birds. Eastern Region.* Little, Brown & Co., Boston, MA. (Color photos.)

Terborgh, John. 1989. *Where Have All The Birds Gone?* Princeton University Press, Princeton, NJ. (Many mentions in the text, see index; this is a landmark book on the decline in North American songbirds, exploring their problems on both the breeding and wintering grounds)

Yoon, C.K. 1994. More Than Decoration, Songbirds Are Essential to Forests' Health. *The New York Times*, Nov. 8.

Organizations and Governments

National Audubon Society, 700 Broadway, New York, NY 10003. (212-979-3000); or local chapters.

Conservation International, 1015 18th St., NW, Suite 1000, Washington, DC 20036.

Breeding Bird Survey, Biological Resources Division, US Geological Survey, Patuxent Wildlife Research Center, 12100 Beech Forest Rd., Laurel, MD 20708.
Fish and Wildlife Reference Service, 5430 Grosvenor Lane, Suite 110, Bethesda, MD 20814 (800-582-3421).

Recordings

The Peterson Field Guide Series. A Field Guide to Bird Songs of Eastern and Central North America, recorded by the Cornell Laboratory of Ornithology. 2nd edition. Houghton Mifflin Co., Boston, MA. 1983. Two tape cassettes. (Wood Thrush on Side 3, Band 4). Other recordings, such as the Stokes audio guides, are also available.

Films

"On a Wing and a Song." This Canadian Broadcasting Company film gives an overview of the songbird decline in Eastern North America, illustrating the vast areas of boreal forest where many of these birds nest in Canada, which has been logged. It addresses the loss of habitat in their tropical wintering grounds; the millions killed by colliding with skyscrapers and antennas during migration; and the parasitism by cowbirds.
"On a Wing and a Prayer." A similar title to the above film, this film focuses on an Illinois woodland and the decline in songbirds, primarily Wood Thrushes. The parasitism by cowbirds is dramatically shown: Wood Thrush chicks starve to death next to huge, fat cowbird chicks. This film also has a teacher's guide.
(See Video section for more detail and distributor list.)

North America in the Year 1400

Project Summary and Background

North America has changed radically since 1400, prior to the arrival of Europeans. It was then a continent without roads, skyscrapers, massive farms and other signs of modern life. This project involves research to discover what the country looked like at this early date, how areas such as the eastern forests, prairies and western forests have changed, and what species of animals and plants disappeared or became threatened as a result of changes to their environment or losses in their populations from other causes.

Activities

o Read the section in this book entitled "Epitaphs for North America's Lost Species and Environments" in Chapter 1.

o Using this and other sources mentioned in the reference list and in local libraries, select an area somewhere in North America. Some possible choices are the following: Cape Cod, Massachusetts; the Chesapeake Bay; eastern old-growth forests; long-grass prairies of the Midwest; short-grass prairies of the West; Sequoia or Redwood forests of

California; or the Mojave Desert in California. If there are parks in the area you choose, contact the park directors, conservation organizations and museums for natural history information.

- Describe the landscape as it was prior to the arrival of Europeans, without roads, modern buildings or other signs of the 20th century. What was the habitat like? Was it forest, mountain, grassland, desert, wetland, river or a combination of these? Were there beautiful vistas or dense woodlands with tangled vegetation? Describe a typical scene in the area you have chosen. For example, in a short-grass prairie, a herd of American Bison graze while, in the background, Pronghorn antelope run in close formation. On a distant hilltop, a pack of Gray Wolves watches the scene while a Grizzly Bear ambles through the low shrubs, looking for ripe berries. Overhead, flocks of Whooping Cranes soar, trumpeting to one another; and near a prairie dog town, grouse display in an open area, issuing booming calls.

- What species of mammals live here? If there are herds of deer, what species are they? Are there American Bison, Elk, Moose, Bighorn Sheep or Pronghorn? What kind of predators prey on these animals?

- Describe what bird species inhabit the area and whether they are abundant or rare. Are there Passenger Pigeons or Carolina Parakeets?

- What other kinds of animals are native? What reptiles, amphibians and fish, for example, inhabit the area? Apply the same questions about life history, habitats, reproduction and feeding.

- How do these animals interact ecologically? For example, if a western short-grass prairie were chosen, the prairie dog colony has abundant wildlife living underground in the burrows, including Black-footed Ferrets, Burrowing Owls, snakes and tortoises. Bison and other grazing animals feed on the grasses above, made greener by the cropping of the prairie dogs. Which species are the predators, and which the prey?

- Is there a tribe of Native Americans who live in this area? What is the name of the tribe? Are they nomadic, or have they established a permanent settlement? Are they hunters, fishers or farmers? What animals do they hunt or fish, or which crops are grown? What are their beliefs about the natural world and wildlife?

o Based on these descriptions of a past landscape, become acquainted with the present landscape and discuss the following:

- How has the natural environment changed? How does it appear today?

- What species no longer live here? Which ones are extinct altogether? (Check the list of extinct species in the Appendix and publications in the Books and Publications section on extinctions and extinct species accounts.)

- What do you think has been lost that should have been protected?

- Are there parts of this area that have not changed and remain as they were 600 years ago?

- Are there people or organizations working to preserve or restore parts of the original landscape and wildlife? How can you participate in this?

Note: This project can be applied to foreign countries or used by teachers outside of North America. As a general rule, it is easier if the area selected is local because information is easier to obtain. As a class project, students might divide into groups, each selecting a species or group of species, such as mammals. This project may be shortened and parts deleted if time is limited, concentrating, for example, on a single species of the region or the general changes in the landscape. It may also be broadened to explore, in detail, the plants and animals of the region by contacting the Natural Heritage Program of your state in the Wildlife Department.

Sources

"Epitaphs for North America's Lost Species and Environments" in Chapter 1 of this book has extensive references listed. Also the fiGrasslands, Shrublands and Deserts,fl fiAquatic Ecosystemsfl and fiForestsfl chapters provide details on these ecosystems and changes in them since settlement. See the fiPersecution and Huntingfl chapter for the treatment of native predators and the effect of their disappearance on ecological systems.

Books and Publications

The following list contains many out-of-print books that may be difficult to obtain, as well as many in-print editions, covering a wide variety of habitats and species of plants and animals. Conduct searches for these and other books in your library and through the Internet.

Forests

Project Summary

This project involves learning about the types of forests that grow on Earth and selecting one type of forest to describe in detail in terms of the climate, what types of trees grow there and what species of native plants and animals are threatened. It also involves learning about the ways in which this type of forest is being conserved or destroyed.

Background

As described in the Forests and Madagascar and Other Islands chapters, forests harbor the largest number of endangered species of all habitats. Uncontrolled logging, especially of old-growth forests, has threatened the survival of thousands of native plants and animals. Forests are a crucial factor in maintaining the planet's oxygen supply and supplying moisture to the atmosphere. By absorbing vast amounts of carbon dioxide, forests reduce pollution and global warming. Their roots also anchor soils, preventing erosion, and store moisture that gradually seeps into rivers and streams so that they flow year-round, even in droughts.

The world land area covered by forests has been retreating for centuries. Although there are still extensive boreal forests in northern Canada and Siberia, and tropical forest still covers most of the Amazon, forests are being logged at a fast pace. The increase in human populations has resulted in growing numbers of people cutting forests for firewood or to clear land for agriculture. In many parts of the world, forests with extraordinary diversity of life have been nearly eliminated or are in the process of being destroyed. Central Africa's ancient rainforests are being logged for the largest trees, hundreds of years old, and their wildlife, including endangered chimpanzees and Gorillas, is being slaughtered to sell in bushmeat markets. Tropical rainforests, especially those growing in lowland areas, are the most threatened type of forest. These forests harbor the largest diversity of wildlife and plants and are, therefore, most in need of protection. In the United States, entire forest ecosystems have become endangered, and many species of native trees have become threatened, some from diseases of foreign origin, others from logging and development. Examples of threatened forest ecosystems in North America are the native pine forests of the Southeastern United States, the old-growth temperate rainforests of the Northwest and the old-growth forests of the East.

Many species of trees, including the stately American Elm and the American Chestnut, have been decimated by exotic species of fungi. These trees once numbered in the billions. The American Elm has declined and disappeared from many parts of the East, and the American Chestnut is almost extinct throughout its range in eastern North America. It once made up a large portion of the eastern hardwood forests. The wildlife of these forests has lost much of its diversity, as the Gray Wolf, Red Wolf, Mountain Lion, and their prey, the Elk, Eastern Bison and, in northern woods, the Caribou were all hunted to the last animal. Rainforests of the Pacific Northwest, with their towering American Redwoods and Sequoias, Western Hemlock, Red Cedar and other conifers, have been reduced to about 5 to 10 percent of their original range as a result of logging and development. Their wildlife, likewise, is under siege, and many species, including the Grizzly Bear, Fisher, Lynx, Gray Wolf, Northern Spotted Owl and Marbled Murrelet, are absent or extremely rare.

Endangered trees and wildlife of temperate forests in South America include the massive Chilean Larch or Alerce, which can grow for 4,000 years and reach sizes almost as great as the Sequoias of California, the world's most massive trees. Alerces have been decimated, cut for their valuable wood, along with other trees in these forests--species which grew on Earth prior to the appearance of dinosaurs. Vast forests of beeches, for example, and primitive conifers covered millions of square miles in Chile and Argentina, but only a fraction remain, the rest logged to make way for agriculture and livestock. The wildlife of these forests, from the world's smallest deer, the Pudu, to the Andean Bear, is threatened. Likewise, the temperate rainforests of New Zealand and eastern Australia have been greatly reduced, threatening kiwis of several species and other unique wildlife.

Tropical forests of many types, from lowland rainforests to dry deciduous forests and, in higher elevations, montane cloud forests, grow in a belt around the Earth's tropical latitudes. They teem with millions of species of insects, birds, mammals, reptiles and amphibians. The last 5 percent of Brazil's Atlantic coastal forest harbors South America's greatest primate diversity, with species ranging in size from tiny lion marmosets, weighing only a few ounces, to the Muriqui, or Woolly Spider Monkey, the continent's largest primate. All are now threatened with extinction. Madagascar's tropical forests echo with the calls of 33 species of lemurs, charming and fascinating primates that exist nowhere else but in these forests that are being cut for farm plots and charcoal. In Amazonian and Indonesian rainforests, literally hundreds of kinds of colorful parrots fly in noisy flocks, each with its own ecological niche of food type and habitat. Almost one-third of all parrots are now threatened.

A large percentage of tropical forests have been destroyed over the past century, with some areas, such as the Philippines, Thailand, West Africa, Andean countries, the Caribbean and, most recently, parts of Indonesia, experiencing almost total deforestation. The losses here have been dramatic, as Orangutans, Tigers, rare birds and two species of primitive rhinos add to these countries' endangered lists. The countries with the largest numbers of endangered birds, Indonesia and Brazil, have lost, or are in the process of losing, large tracts of tropical rainforest. Entire ecosystems are collapsing in the process. The great variety of fig trees of Southeast Asia depend on hornbills to distribute their seeds, but these birds are fast disappearing. Pollinating species like bats, small primates and birds are also in sharp decline as the rainforests are destroyed. Many are found only in a limited area, surviving in the remnants of these forests.

On the positive side, many large preserves have been set aside in South America to protect this diversity, and conservationists are working in other parts of the world to protect parks and help establish new reserves to prevent massive extinctions in these forests. Paper recycling and using substitutes for wood-based products are also conserving trees.

Activities

o Examine as many of the books listed below, showing the great beauty and diversity of forests, as possible. These include *Jungles; The Rainforests*, *A Celebration; The Life and Mysteries of the Jungle*; *The Living Wild; Hotspots. Earth's Biologically Richest and Most Endangered Terrestrial Ecoregions*; *North America's Rainforest. The Endangered Paradise*; *Living Planet. Preserving Edens of the Earth*; *Ancient Forests. A Celebration of North America's Old-growth Wilderness*; and *The Enchanted Canopy*. *A Journey of Discovery to the Last Unexplored Frontier, the Roof of the World's Rainforests*. Also, read books on particular forest species, such as butterflies, birds, primates, bats or insects. Many are listed in the Books and Publications section. See films listed below and in the Video section of this book on forests, particularly threatened ones in Madagascar and other parts of the world, as well as films of endangered forest wildlife. This introduction is intended to create enthusiasm and curiosity as well as an appreciation of the wealth of plants and animals that are at stake as old-growth forests are destroyed.

o Select a forest from the list below to study its status and threatened trees and wildlife.
- United States southeastern Long-leaf Pine forests
- North American eastern hardwood forests
- North American temperate rainforests
- South American temperate rainforests
- Brazilian forests of Atlantic coast
- New Zealand or Australian temperate rainforests
- Madagascar tropical rainforest
- Hawaiian tropical rainforest
- Mascarene tropical forests
- West African tropical rainforests
- Andean tropical rainforests and cloud forests
- Central American cloud forests

- Colombian rainforests
- Caribbean tropical forests
- East African tropical forests
- Indonesian rainforests
- Philippine rainforests
- Indian montane forests of the Ghat region
- Himalayan forests
- Chinese tropical forests

o Read about this type of forest in *The Endangered Species Handbook* and in references listed in the Forests chapter and the Books and Publications section. Also consult the Internet.

o Describe the original extent of this forest several hundred years ago, and the present extent. (Collins 1990 and Mittermeier 1999a, cited below, are excellent references.) Explain how it has become threatened. For example, some forests have been gradually whittled away by cutting for firewood or land clearance, while others have been cut by corporate logging companies or government programs to establish large-scale agricultural farms. Still others have been officially conserved but, through failures in enforcement or misguided policies, their wildlife and trees have been lost.

o What species of wildlife and plants or trees have become endangered as a result of the destruction of these forests? Which species are unique to that forest region? Describe them.

o Select an animal or plant species that is threatened with extinction and write a short report about it, using the criteria in the project, "Profile of an Endangered Species." It can be a type of butterfly, orchid, ant, bird or mammal, for example. Write about the species in the context of its forest habitat, whether its habitat is being protected, and other threats to it that may include pollution, trade or competition with exotic species. As source material, consult this book, *Threatened Birds of the World, Walker's Mammals of the World*, and other references cited here or in the Books and Publications section of this book.

o By consulting books, such as *Hotspots* and other books listed below, list the threats to the forest you are describing and what is being done to protect the forest and its wildlife.

o Read the Forests chapter for information on the use of plants, such as kenaf, to make paper and building houses with little or no lumber. Discuss the role these measures could have in conserving forests. Write organizations, such as Earth Island Institute, for information.

Forests: Films
The films below are reviewed in the Video section, which gives information on their distributors and more detail on their content. Also, films on individual forest species, such as Tigers, are reviewed, along with additional films on many of the subjects and regions above.

General films on rainforests: "Rain Forest" and "Exploring the High Frontier," both by National Geographic Society.
Temperate rainforests in US: "Ancient Forests,fl fiLast Stands of the Giants"
Temperate pine forest of US southeast: "Remnants of a Forest"
US National Forests: "Our Vanishing Forests"
Regional: "Amazonia: A Burning Question;" "The Decade of Destruction" (Amazon rainforest); "Korup--An African Rain Forest" (Cameroon); "Spirits of the Forest" (Madagascar); "Forest Primeval" (Part 3 of "Heart of Africa") (Democratic Republic of the Congo & area); "Animalai, India's Elephant Mountain" about the Indian Ghats; "Monkeys on the Edge" (Brazil's Atlantic forest); "Song of Protest," "Land of the Kiwi," and "Mountains of Water" (New Zealand).

Grasslands
Project Summary
The purpose of this project is to learn about the wild grasslands of the world, their wildlife and threats to them. One particular region will be selected and its original extent, wildlife, and present status will be described. The ways in which this grassland is being conserved or destroyed will be a major focus.

Background
Just a century ago, grasslands covered much of central North America, from southern Canada through Texas to northern Mexico, and from west of the Rockies east to Midwestern and northeastern states. Tall-grass prairie, with grasses up to 12 feet in height, grew from Ohio west to the Mississippi River area. This savannah grassland had groves of oak and other trees. It had extremely rich soil and was plowed by American settlers into farmland. Today, less than 1 percent of the original extent remains, making it an extremely endangered natural ecosystem. West of the tall-grass prairies, a mixture of tallgrass and short-grass prairies existed, and further west, short-grass dominated. The short-grass and mixed prairies have also been plowed for crops, but some sizeable areas remain, primarily kept as pasture for cows. These grasslands have been greatly altered, leaving few examples of the original ecosystems. Vast herds of American Bison once grazed throughout these grasslands, with prairie dog towns covering millions of acres in the short-grass prairies.

The savannahs of East Africa, grazed by a great diversity of hoofed animals, represent a classic example of grasslands that are still in natural, intact condition. Although under stress from growing human populations, large reserves and national parks protect much of this region. By contrast, the dryer grasslands of southern Africa have been severely damaged by the introduction of large numbers of domestic cattle and the fencing off of wildlife from waterholes and prime grasslands to prevent the spread of hoof-and-mouth disease to cattle. This has resulted in a large decline in overall numbers of both herbivores and carnivores. This is a repetition of the overuse of the Sahara and Sahel regions

to the north, centuries before, by great herds of domestic camels and sheep, turning grasslands into sandy desert. Ethiopia, Somalia and countries to the north and east of the Serengeti in East Africa's horn were once covered in lush grasslands. Wildlife species found only in this region became threatened when Europeans introduced livestock, which infected wild ungulates with rinderpest and other diseases, causing massive mortalities.

In vast steppes that once stretched from the Black Sea to western China, livestock now far outnumber native ungulates, such as the Saiga antelope, a species that once thundered in herds of millions. Overgrazing and plowing of this dry land for crops has further degraded it, causing massive dust storms, similar to those that resulted from plowing the American prairie in the 20th century. South America has extensive grasslands in Venezuela and south-central Brazil, many of which become wetlands during rainy seasons. In Argentina and Chile's Patagonian grasslands, rheas, deer, Guanacos and other wildlife once abounded. After centuries of overgrazing by sheep and cattle, this wildlife has declined greatly, and the grasslands are turning to desert. Australia's grasslands have also been converted to use by livestock, displacing the varied marsupials and rodents that once thrived here.

Preservation of grasslands and their wildlife is now taking place in many parts of the world, including the United States, southern Africa and Australia. Reserves of remnant grasslands, with their great diversity of wildflowers, grasses and other plants, are being set aside and native wildlife reintroduced. This trend may spread to parts of Asia as well, but the pressures of human populations requiring farmland and grazing for livestock may prevent restoration in most areas.

Activities

o Read "Epitaph for America's Lost Species and Environments" in Chapter 1 to learn about the travels of Lewis and Clark through these prairies early in the 19th century, followed by the extermination of the great herds of bison, deer and Pronghorn. Read the Grasslands, Shrublands and Deserts chapter with references cited for more information on North American and other grasslands around the world and their endangered species. Write a short paper describing the changes in grasslands in North America since colonial times and the effects on wildlife.

o Select a grassland from the following list to study its wildlife and present status:

- North America's Tallgrass Prairie
- North America's Short-grass Prairie
- Central Asia's Steppes
- Australia's Grasslands and Drylands
- Saharan and Sahel Drylands
- East Africa's Serengeti
- Southern Africa's Grasslands
- Horn of Africa's Grasslands
- South America's Pampas
- South America's Patagonia

* What species of wildlife, plants or trees have become endangered as a result of the destruction of this region's grasslands or affected by related activities, such as grazing and meat hunting, by herdspeople? Which species are unique to that grassland region? Describe them.

* Select an animal or plant species native to this region that is threatened with extinction, and write a short report about it, using the criteria in the project, "Profile of an Endangered Species." It can be a type of wildflower, tortoise, butterfly, bird or mammal, for example. Write about the species in the context of its grassland habitat, whether its habitat is being protected, and other threats to it that may include pollution, trade or competition with exotic species. As source material, consult this book, *Threatened Birds of the World, Walker's Mammals of the World*, and other references cited here or in the Books and Publications section of this book.

* By consulting books such as those listed below, describe the threats to the particular grassland or dryland you have selected, and discuss what is being done to protect the natural habitat and its wildlife?

o Use this project as a model to study the status of shrublands and deserts, as described in the Grasslands, Shrublands and Desert chapter of this book, with the emphasis on desertification of drylands into desert through grazing, firewood gathering and other activities. See the reference list of the latter chapter for further reading.

o If you live within the range of these habitats, participate in a project to restore native plants to a grassland. Grassland birds have undergone drastic declines in the past decade, mainly through loss of habitat. Identify the grassland birds in your area and help in a project to obtain habitat for them, improve existing habitat or grow seeds of native plants for planting. Several source books supply information on mail-order nurseries that sell native plants and seeds. *Noah's Garden* has chapters entitled, "In Respect of Grass" and "To Plant A Prairie," which give very specific information about these habitats. The National Wildflower Research Center (2600 FM 973 North, Austin, TX 78725) supplies native plant bibliographies for each region and lists native plant associations. A book written by Lady Bird Johnson, who founded this center, and Carlton B. Lees, *Wildflowers Across America*, is a dazzling showcase of native wildflowers as well as an excellent source of information on these ecosystems. If you live near a shrubland or desert, plant native flowers and plants in your garden instead of grass to restore the ecosystem and conserve water. See the list of books below for instructions on planting desert and dryland gardens.

o If you live in an area where grasslands are mowed for hay, begin a public relations campaign to convince farmers to wait until after bird nesting season is over to mow. This would be in late July or August for most species of grassland birds. Consult reference books to determine the nesting times of grassland birds in your area. Such measures would be of great help to certain birds that have lost most of their natural grassland habitat. Make up posters that illustrate one or more of the following birds, and text describing their decline and need for undisturbed nesting habitat. In the East, the Bobolink, Grasshopper and Henslow's Sparrows and Bluebird, among others, will benefit. In the West, various species of Lesser and Greater Prairie Chicken, Sage Grouse and other bird species mentioned in the Grasslands, Shrublands and Deserts chapter are among these. Ask farmers and landowners to help preserve these birds and other wildlife by mowing practices. Have signs made that landowners could post on their property saying, for example, "Grassland Birds Protected Here." Publicize the campaign through letters to the local newspapers and speeches at local organizational meetings.

o Construct nesting boxes for Bluebirds and Purple Martins to be donated to landowners in grassland with scattered trees or bordered by woods. Instructions on how to make and maintain Bluebird houses can be obtained from the North America Bluebird Society, P.O. Box 6295, Silver Spring, MD 20906. *The Complete Birdhouse Book*, by Don and Lillian Stokes, also gives instructions on building and upkeep for both the Bluebird and Purple Martin houses. Films made by Don and Lillian Stokes include advice on planting for birds by species, such as hummingbirds and grassland birds; advice on how to construct, place and maintain bird nesting boxes is also given (CPTV Offer, P.O. Box 82, Hopkinton, MA 01748). The placement and maintenance of bird nest boxes should be long-term so that they may provide permanent nesting homes. It is important to keep records on the occupancy and breeding success of each box.

o Help native butterflies by planting wildflowers of species that are needed for their life cycle. The Monarch Butterfly, for example, requires Milkweed plants for feeding and laying its eggs. Learn about the species of butterflies and other pollinating insects in grasslands in your area, especially those in decline. For species listed on the US Endangered Species Act, all conservation projects should be coordinated with the US Fish and Wildlife Service and your state Natural Heritage Program (affiliated with the Department of Game or Wildlife in each state). Roadsides next to highways or in median strips and along country roads or railroads provide important habitat for butterflies, especially in areas where grasslands are disappearing. Contact your state and local transportation departments to obtain permission to plant wildflowers in these areas. The North American Butterfly Association (909 Birch St., Baraboo, WI 53913) provides information about helping butterfly habitat and butterfly watching, a new and fascinating activity for which there are guide books. *A World for Butterflies. Their Lives, Behavior and Future*, by

Phil Schappert, is a primary source of information about butterfly life histories, habitats, conservation and threats. It also contains beautiful photography of hundreds of butterfly species worldwide. More information can be obtained from Dr. Schappert via the Internet: www.aworldforbutterflies.com. *Butterfly Gardening: Creating Summer Magic in Your Garden*, published by the Sierra Club, was compiled by the Xerces Society, a conservation organization for native American butterflies, in cooperation with the Smithsonian Institution. Be careful not to use commercial wildflower seed mixes that include species not native to your area or even to the United States. Certain exotic wildflowers, such as Purple Loosestrife, a European plant, are spreading in the United States, drying up marshes and crowding out native wildflowers.

Grasslands: Films

All films mentioned below are reviewed in the Video section.

"Crane River" is a celebration of the huge flocks of Sandhill Cranes that migrate across North American prairies.
"Durrell in Russia" is a 12-part series which includes films on the Saiga, European Bison and grasslands of Russia.
"Emas. High Plain of Brazil" centers on this large grassland, surrounded almost entirely by agriculture that serves as an island for Brazil's unique grassland animals, including the Giant Anteater and Maned Wolf.
"Grasslands," a Canadian Broadcasting Company documentary, describes the biodiversity and ecology of North American grasslands and their destruction.
"Land of the Eagle," a series, concerns North America as it was prior to settlement by Europeans, with segments on the prairies and their wildlife.

"Mysterious Black-footed Ferret" focuses on this extraordinary and highly endangered prairie native, filming its graceful, sinuous movements and rapid leaps while hunting prairie dogs.
"Nature of Australia" explores the natural history of the continent in six parts, from its grasslands to drylands, how native wildlife has been affected and what ecological harm has been done by humans.
"The Saiga of Kazakhstan" chronicles the decline in the herds that numbered more than 1 million animals as a result of hunting, fencing off of grasslands and loss of habitat. They have disappeared from the center of their original range in Central Asia.
"Sea of Grass" (segment of "The Living Planet") is one of the parts to this BBC series that describes the evolution of various ecosystems of the Earth.
"The Tiny Carnivores" introduces one to Australia's small marsupials, many of which are nocturnal and endangered, driven from their habitats in grassland, savannah and desert by human activity.
"Vanishing Prairie," a Disney classic, shows the inside of a prairie dog burrow and the wildlife that teems in this habitat.
"Varmints" documents the decline of prairie dogs in the American West through systematic poisoning programs by federal, state and local authorities, placing them in endangered status, and explains their important role in prairie ecosystems.
"Wildebeest Race for Life" follows the trail of 1 million of these odd-looking ungulates as they migrate in a large circle around the Serengeti.

Aquatic Ecosystems

Project Summary

Aquatic ecosystems are the most varied of all ecosystems, ranging from freshwater ponds to rivers, lakes, saltmarshes, coasts, mangroves and coral reefs to open ocean. Although a single type of ecosystem will be chosen for the project, it is hoped that the reports will be presented to the class to acquaint students with the characteristics of as many of these habitats as possible. The project will consist of selecting a particular type of aquatic ecosystem that is threatened in a geographical area listed below. This ecosystem, the threats to it--whether through pollution, damming, diversion or other activity--will be described, including its wildlife. Also certain aquatic species that are in sharp decline will be among the subjects listed for special attention. The ways in which this aquatic ecosystem, species or group of species is being conserved or destroyed will be a major focus.

Background

The aquatic ecosystems of the world have never been more stressed and degraded. The rise in human population to more than 6 billion people by the end of the 20th century placed strains of overuse and pollution on the limited supplies of fresh water, leaving billions of people without adequate clean water supplies and creating rising tensions over water rights. In these conflicts, wildlife pays a high price, losing pristine habitat and becoming contaminated with toxic chemicals and oil spills that are killing wildlife around the world. Dams have endangered numerous fish by impeding their migrations, and developing countries have been damming their rivers at an increasing rate. Rivers that flowed swiftly become still ponds after damming, an alteration to which many fish cannot adjust. Many of these fish are also declining as a result of the introduction of non-native fish, which are out-competing them. The Nile Perch was introduced as a food fish in Lake Victoria, and it has virtually eliminated hundreds of species of native cichlid fish, colorful and ancient species. The Colorado River of the US west has many dams on it, which have totally altered

the river's flow patterns and temperature, endangering many fish that had evolved in the swift-flowing, silt-laden water. The most dramatic example of a dam endangering a wide variety of plants and animals, and dislocating 1 million people, is the Three Gorges Dam being built on the Yangtze River of China. It will almost certainly result in the extinction of the Yangtze River Dolphin, a very ancient freshwater species, the Yangtze Sturgeon and numerous plants that will be inundated by the waters. Although far upstream, it will also have the effect of drying up wetlands downriver and at the delta. With inadequate provision for sewage treatment for the millions of people and industry living alongside the new lake formed by the dam, the Yangtze is expected to become extremely polluted. Large dams inundate vast areas, displacing thousands of people from their homes and drowning rare trees, plants and wildlife.

Diversion of rivers for agriculture or water supply has left many riverbeds and deltas dry, causing entire ecosystems to collapse. An increasing problem with rising temperatures has been violent storms which cause severe flooding of rivers, made worse by the deforestation that robs hillsides and riverbanks of protective trees that absorb rainfall throughout the year and hold the soil in place. Lakes and spring ponds that dry up in the summer are also being filled in by developers and government projects, eliminating habitat for myriad aquatic creatures, from frogs and salamanders to turtles and water birds.

Overfishing, pollution and destruction of ocean environments have reached crisis proportions, with 70 percent of all fish caught commercially in depleted status or worse, including some of the most ecologically important species--sharks, tuna and others at the top of their food chain. Toxic chemical pollution has increased, especially in colder waters, where whales and other cetaceans are dying from massive build-ups of chemicals such as PCBs (Polychlorinated Biphenyls), pesticides, heavy metals and other toxins. Along the pristine coast of Washington state, Killer Whales are dying from these toxic chemicals, as are white Beluga Whales in the St. Lawrence River. A Sperm Whale that died recently of toxic chemicals had to be disposed of as highly toxic waste. Other waste in the oceans is killing wildlife. Abandoned driftnets drown thousands of birds, seals, sea lions and sharks, and fishing line entangles endangered Northern Right Whales and other wildlife, drowning them. Plastic sheeting, balloons, plastic from six-packs and other trash are killing seabirds, such as the long-lived and declining albatross, which unknowingly feed this trash to their chicks, killing them, or swallow the items themselves, later dying of blocked intestines. Collisions with ships and motor boats are causing large numbers of deaths in Florida Manatees and whales.

Coral reefs, the most beautiful and biologically diverse ocean ecosystems, are dying from many threats. Dynamite and cyanide used to kill and capture fish destroy the entire reef. Overfishing, pollution and silt that washes off nearby lands from agriculture and development can combine to kill a reef. Global warming causes coral bleaching that is affecting a growing number of reefs. More than one-third of all coral reefs are now dead or dying.

Wetlands have declined in the United States by 50 percent. This has resulted in more destructive floods and losses in fisheries production. Wetlands filter pollutants, and their reduction has lowered water quality. Elsewhere in the world, similar declines have taken place. Both fresh and saltwater marshes provide important benefits in cleaning water through a natural filtration system. In fact, the worldwide value of this benefit to the Earth and human society has been calculated at $1.7 trillion. Marshes also provide important flood controls by absorbing large amounts of water from nearby sources or rainfall, as well as a multi-billion dollar benefit of serving as nurseries for fish, shellfish and other wildlife. Traditionally, however, they are filled in for development, airports, seaports and other commercial uses which are considered to be far more beneficial to society. It is important to reexamine such an approach, especially in view of the tremendous costs of flooding in human lives and property and the decline in fish and shellfish harvests.

An atmospheric phenomenon caused, apparently, by CFCs, or chlorofluorocarbons, chemicals used in refrigeration and for other industrial purposes, is thinning the ozone layer, a protective shield that filters the sun's rays before they strike Earth. Large holes have developed over the Poles, especially the South Pole, allowing huge amounts of ultraviolet rays from the sun to enter the atmosphere, causing many cases of skin cancer in humans and having unforeseen effects on animals with sensitive skin like frogs and salamanders. Frog species are disappearing at a catastrophic rate, especially those that lay their eggs in the open, exposed to the ultraviolet rays of the sun. Frogs are

also suffering grotesque birth defects, which may be caused by pesticides or virus outbreaks. Frogs™ decline may be a warning sign that serious problems exist in the aquatic ecosystems of the world that will soon begin to affect human beings.

Activities

o Read the Aquatic Ecosystems chapter, which describes many of these problems in detail and parts of the world where large numbers of animals and plants are endangered. The references cited will provide more information.

o Select a species of wildlife or plant that has become endangered as a result of the destruction of aquatic ecosystems or related activities. Describe its status, threats to its habitat and what--if anything--is being done to prevent its extinction.

o Select an aquatic area from the following list to study its wildlife and present status:

- United States™ Colorado River
- Florida's Everglades swamp
- Rivers and wetlands of the US East and Southeast
- Russia's Lake Baikal
- Central Asia's Aral Sea
- East Africa's Lake Victoria
- Southern Africa's Okavango Delta
- Brazil's Pantanal wetlands
- Amazon River and its dams
- China's Yangtze River
- Australia's Great Barrier Reef
- Mississippi River Delta and adjacent waters

All are described in the Aquatic Ecosystems chapter. See also Video and Books and Publications sections.

o The following wildlife has become endangered as a result of the destruction of these aquatic ecosystems or related activities. Select one and discuss threats, species involved and conservation programs:

- albatross and other large seabirds
- frogs
- whales and dolphins
- sharks
- sea turtles
- penguins

o Select an aquatic animal or plant species that is threatened with extinction and write a short report about it, using the criteria in the project, "Profile of an Endangered Species." It can be a type of fish, frog, turtle, aquatic insect (such as a dragonfly), bird or mammal, for example. Write about the species in the context of its aquatic habitat, whether its habitat is being protected, and other threats to it, which may include pollution, trade or competition with exotic species. As source material, consult this book, *Threatened Birds of the World, Walker's Mammals of the World* and other references cited here or in the Books and Publications section of this book.

o Make comparisons between natural means of flood control, including marshes, beaver ponds and heavily forested stream and riversides, and artificial means, such as levees, dikes and canals. *Water, A Natural History*, listed below, is helpful in pointing out the differences. Compare the cost and success of natural means of controlling pollution, such as sewage through marshes that filter waste, and artificial means through sewage plants. Individual homes in

suburban and rural areas use septic tanks and cesspools to store sewage. In times of heavy rain, however, they often overflow into rivers, as do urban sewage plants. In many parts of the world, no sewage treatment exists, causing rivers and waterways near cities to become severely polluted. Some cities in California and elsewhere have constructed artificial marshes to filter sewage water, creating, in the process, wildlife havens. New types of toilets, known as compost toilets, are another less-polluting innovation. Read Chapter 9, "Aqueducts and Toilet Bowls" in *Water, A Natural History*, and write a short report on improvements needed in the present systems.

o Grassroots organizations throughout the world have been successful in restoring rivers and other aquatic ecosystems. Using a book, such as *How to Save a River. A Handbook for Citizen Action*, select a river, wetland, pond (including beaver ponds), lake or vernal pool (temporary wetland that dries up in the summer) to help preserve or clean up from pollution. Small projects can be of importance in conservation. For example, some high school classes in the Midwest sampled a nearby marsh for the types of frogs found there and discovered that the majority were deformed, having five or more legs, misplaced eyes or other grotesque malformations. The situation was given publicity, and research began on the causes. Pesticide contamination was considered the most likely cause, since water from the marsh used to grow frogs in captivity produced similar deformities. One organization, The Riverlands Conservancy, has helped purchase river habitat in Oregon, Missouri and Washington totaling 17,174 acres since 1993. Measuring pollution in local waterways is an excellent class project that can lead to environmental action on the part of state or federal authorities. Save Our Streams program, run by The River Network, headquartered in Portland, Oregon, and its sister organization, The River Clearinghouse, provide information to activists throughout the country on an 800 "hot line," using a database of volunteer experts who provide advice. The River Watch Network has been instrumental in helping communities monitor water quality in order to restore and protect rivers. (See *How to Save a River. A Handbook for Citizen Action* for more information and other organizations, which include American Rivers, the International Rivers Network and Riverkeepers, working to preserve aquatic ecosystems.) Using these examples, propose a class project to help conserve a local aquatic ecosystem**.**

Aquatic Ecosystems: Films

All films mentioned below are reviewed in the Video section.

General: "Acid Rain. Clouds with a Sulphur Lining" discusses the severe problem of acidification of rainwater caused by air pollution and its effect on forests and other environments. "Dead Ahead: The Exxon Valdez Disaster" is an examination of the 1989 oil spill in Alaska from many aspects. "Pollution: World at Risk" is a general look at various types of pollution and toxic chemicals and their environmental effects. "Vanishing Wetlands," produced by the Canadian Broadcasting Company, explains the ecological benefits of wetlands and threats to them. "The Wasting of a Wetland" focuses on the Everglades but describes the abuse of wetlands as it affects wildlife**.**

Ocean environments: "Cities of Coral"; "Coral Reefs. Rainforests of the Sea"; and "Jewels of the Caribbean Sea" all center on coral reefs. They show the great beauty and diversity as well as the threats to them. "Creatures of the Mangroves" and "Margins of the Land" (segment of "The Living Planet") treat the shoreline areas, and "Messages from the Birds" concerns the decline in shorebirds in North America. "The Open Ocean" (segment in "The Living Planet") explores the evolution of this habitat on Earth. "The Mirage of the Sea" discusses the overfishing and exploitation based on the assumption that there would always be plenty of fish. "Blue Whale: Largest Animal on Earth" is the first film to follow these giants in the ocean. "Desert Whales" are the Gray Whales that winter off Baja California, Mexico. "The Forgotten Mermaids" is a film about Florida Manatees. "Sperm Whales: The Real Moby Dick" gives glimpses into these deep-diving whales and discusses the fact that they have not recovered from whaling, with large males still very rare. "Colony Z" is about the very rare Yellow-eyed Penguin of the New Zealand region. "Whales Down Under" focuses on a population of newly discovered Southern Right Whales east of New Zealand, following them for a long period.

Freshwater environments: "Sweet Fresh Water" (segment in "The Living Planet") is an in-depth look at the planet's limited supply of water and the creatures who inhabit these environments. "Giant Otters" follows a boisterous group of these largest of otters in South America, discussing the causes for their decline. "Journey to Save a Crane" describes a project of the International Crane Foundation to preserve the endangered Siberian Crane through delicate negotiations with Chinese and Russian authorities. "White Water, Blue Duck" is a film about this threatened New Zealand duck and its remarkable adaptation to a very swift-flowing river. "Jewel of the Rift" (segment in "Heart of Africa" series) concerns Lake Victoria, its geology and the amazing, colorful fish native to it, which are now being eliminated by the Nile Perch. "Okavango: Jewel of the Kalahari" explores this huge wetland, second largest in Africa, set in the middle of a desert. "Amazon. Land of the Flooded Forest" illustrates how the flooding of the Amazon River each year nourishes a diverse ecosystem of fish, freshwater dolphins, fruits and trees. "Journey to the Sacred Sea" travels to Lake Baikal, where the unique fish and seals inhabit an extremely ancient and deep lake threatened by pollution. "Cadillac Desert" is an expose of the diversion of lakes and rivers to supply Los Angeles with its water supply at the expense of wildlife and the environment. "Prairie Waters" visits the potholes of Midwestern North America, temporary ponds and lakes that provide breeding habitat for millions of ducks and other birds each spring, yet are routinely filled in by farmers. "The Wild Colorado" is a thorough look at the geology and ecology of the Colorado River and the effect of dams on its wildlife and ecology.

Trade

Project Summary

To better understand the international wildlife trade in live animals and animal products, focus will be placed on one or more major categories of the trade. The major categories are: whaling, fur, reptile skins, Traditional Medicine products, fisheries, wild pets (including cage birds, lizards, turtles, snakes and frogs). Selection by a student of a species, group of species or general subject under one of these categories allows an overview that can be thorough and involve much research, or result in a short report. A classroom project could involve a subject such as Traditional Medicine, in which groups of students would select individual species or groups of species, such as rhinos (killed for their horns), Tigers (killed for every part of their bodies), seahorses, snakes, turtles, monkeys and other primates and sharks. The reports would be presented together.

Background

Trade in live animals, plants and the products made from them has caused extinctions and has pushed many to the edge of extinction. At least 15 percent of highly threatened mammals and birds have declined as a result of trade, according to the International Union for the Conservation of Nature and Natural Resources (IUCN) (see Hilton-Taylor 2000). Internationally, billions of dollars are earned legally and illegally, and each year, more species become exploited. The trade is second only to the international drug trade in overall profits, worth an estimated $3 billion a year in protected live animals and animal products. As soon as one species becomes rare from exploitation and receives protection, the trade switches to a similar one, pushing it into threatened status. Much of this trade is for luxury products or to supply collectors and the wealthy who wish to own rare birds and other wildlife; wear the furs of endangered species, such as Snow Leopards or Cheetahs; purchase purses or clothes made from rare snakes or other reptiles; or consume luxury foods, such as endangered fish, whale and even Tiger meat. The wool of the Tibetan Antelope, the Chiru, ivory from elephants, the caviar of the endangered Beluga Sturgeon, rhinoceros horn and live Spix's Macaws, captured for collectors of rare animals, are worth far more than gold. The Traditional Medicine trade deals in a wide variety of animal products and plants and is a major factor pushing the Tiger, rhinoceros, seahorses and a host of other species toward extinction. For the majority of species exploited for this trade, substitutes exist or the products are not effective remedies. Ecological systems worldwide are being disrupted with the removal of predators and other keystone species, causing a loss of biodiversity.

This trade is taking place in spite of the landmark Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), enacted in the 1970s and now ratified by a majority of the countries in the world. It places animals at greatest risk of extinction on Appendix I, which prohibits commercial trade, and threatened species on Appendix II, which limits or controls trade on a species-by-species basis. CITES bans trade in species listed on either Appendix if the trade will be detrimental to the species' wild populations. In practice, many species that are threatened with extinction and listed on CITES Appendices are traded illegally or in countries which lack national legislation restricting wildlife trade. Although endangered spotted cat fur coats are no longer seen in New York City clothing stores, the fur trade continues to use the skins of rare cats and other wildlife, which are openly sold in many countries around the world. Enforcement funding is inadequate in the majority of countries, even the United States, where only 10 percent of shipments are inspected. Moreover, certain products, such as powdered rhino horn or Tiger bones, can be easily secreted in packaging while in transit. CITES has been an important deterrent to trade in endangered species, however, providing many threatened animals and plants with needed protection. Also, a growing number of countries have strict legislation prohibiting trade in protected species, including exports.

The methods used to capture and kill animals for the wildlife trade are often cruel in the extreme. Steel-jaw leghold traps and wire neck snares that cause great pain and injury produce pelts for the fur and bushmeat trades. Whales die from exploding harpoons thrust into their heads and bodies. Frightened live animals are crowded into cramped, dirty cages and transported to pet shops and laboratories, suffering high mortality along the way. Man's inhumanity to animals reaches an extreme in the wild animal trade.

Activities

o Read the Trade chapter in this book and other sources referenced.

o Select a subject among the following wildlife and plant trades for further study:
- fur trade
- whaling and sale of whale meat
- sea turtles--trade in eggs, meat, shell and stuffed curios
- fine wools--Shahtoosh from Tibetan Antelope and Vicuña
- bushmeat from endangered gorillas, chimpanzees, monkeys, turtles and other wildlife of Africa and Southeast Asia
- fisheries products--sharks for their fins and meat and caviar,

for example
- reptile products for luggage, handbags and other luxury goods
- wild bird pets
- reptile pets, such as lizards, snakes and turtles
- fish for aquariums
- butterflies for collectors
- plants, such as orchids and cacti, for collectors

After reading about these trades in this book and other sources, write a report that discusses the following aspects:
- How many animals or plants are estimated taken per year for this trade?
- What species are they? What is their status in the wild?
- Where are the animals and animal products sold? Are they killed or collected in one country where they are protected and then sold in another?
- What controls exist to protect threatened and endangered species traded? Are they listed on CITES or the US Endangered Species List? Are they protected in their country of origin with high penalties for illegal take or killing, or are the penalties so low that there is an incentive to capture the species illegally? In India, for example, wildlife smugglers and killers of Tigers and other protected wildlife almost never receive jail sentences or large fines, while in China, the death penalty can result from killing a Giant Panda.
- What profits can be earned from sale of these animals or animal products? Find out the prices of expensive goods, such as Beluga or other Russian caviar, Shahtoosh and other items.
- What are the potential ecological effects of the disappearance of these animals? African and Asian Elephants are keystone species, distributing tree seeds, creating water holes and forest openings that benefit their ecosystems. Their disappearance from many areas has already had ecological effects. Find other examples, such as Tigers, which are at the top of their food chain; monkeys and other primates who pollinate flowers or distribute seeds; birds caught for zoos and collectors, such as hornbills, who distribute fig seeds; or animals that are important food items for wildlife.

o Traditional Medicine trade--a group project. Based on the information in the Trade chapter and the references below, divide the class into groups and have each group select from the various species used in this trade, such as Tigers and other wild cats, rhinoceros, monkeys, seahorses, musk and other types of deer, snakes, pangolins, bears of all species and rare plants. The information for each group to gather is the following:

- What is the extent of this trade? Are animals and plants being collected throughout the world to supply the trade?
- What percentage is sold in China, other parts of Asia or in Asian pharmacies in other parts of the world?
- What prices are obtained for these animals at the level of the captor, the local markets, exporter, importer and retail sales?

What effect is this having on the species? Will it become extinct if the trade continues at its present level?
- Is the trade legal in the animal's country of origin? Is the species listed on CITES or banned from importation or exportation? Is the species openly sold in some markets? Where and when?
- Are there education programs that are trying to stop the killing, marketing and purchase of these species or the over-harvesting of rare plants? What governments or organizations are trying to help these species through protection of habitat, bans on commerce or enactment of strong legislation to protect them?

o Enforcement of existing legislation is crucial to protecting threatened and endangered animals and plants. What state and federal laws ban the sale, killing and purchase of endangered species? How is evidence gathered for wildlife crime cases? How does CITES work?

o Visit stores that sell animal products and live animals.
- Fur and department stores with furs: List the kinds of animals used to make the garments being sold. It is required by US law that the species of animal and country of origin be listed on the label. List the ranched animals, such as mink and chinchilla, and wild-trapped ones, such as lynx, beaver and raccoon. Write down the number of coats and other garments of each type of animal, the date, the store and its address. Neither ranched nor wild animals are humanely treated prior to their deaths. Learn about the methods of killing of wild animals (types of traps, number of animals killed per country and US state) and the numbers and species of animals farmed. Contact the Animal Welfare Institute, the Humane Society of the United States and PETA for films that show the cruelty of trapping. Farmed animals are kept in tiny cages, where they become neurotic, and killing methods are unregulated.

- Visit department and shoe stores to determine whether reptile products are being sold. This trade kills millions of animals and threatens many species, as well as causing rats and other rodents they prey on to increase to pest proportions when too many snakes and other reptile predators are killed. List the species from which the item is made, if possible. Laws regarding labeling of reptile products are less strict than those regarding furs, and some do not list the species. If possible, determine if any endangered species are sold and how many items are being sold in your area.

- Visit pet stores to inventory reptile pets, such as iguanas, lizards, snakes and turtles. Find out how many are wild-caught, what species and whether threatened. Also visit pet stores to inventory their cage birds. Ask if the birds were taken from the wild or are captive-bred. In the United States, wild-caught parrot imports are allowed only for a few breeders, and parrots in pet stores should be captive-bred. Ask if the birds were bred in captivity. Many finches and other birds are also banned from importation. Obtain a copy of the Wild Bird Conservation Act and see if any of the species listed as fibannedfl are being sold. If so, tell the store owner and report this to the US Fish and Wildlife Service Law Enforcement Division. Contact the Environmental Investigation Agency (EIA)

for films that show the capture of wild birds in Senegal and Argentina and the cruelty involved in the cage bird trade. If any pet store is selling primates, find out the species. It may be endangered, as in the case of a Diana Monkey sold in a Long Island pet store a few years ago. Primates do not make good pets and should not be purchased. Many organizations receive unwanted primate pets to care for, after they have bitten their owners. Ask your local pet store to avoid sale of live animals. This is a trend in many pet stores that now sell only pet food, leashes, books and other non-living items. Patronize such stores. Contact your local humane society to learn of rejected wild pets and the difficulty in finding homes for them and recount these examples in a letter to your local newspaper, asking people not to buy wild-caught animals of any type.

o Attitudes are crucial to the protection of native wildlife by the people living within their habitat. Killing of animals for food and sale as pets has increased in recent years as international trade provides worldwide markets. It has become all the more important for wildlife to be valued and protected by people living in their range. Effective education is a key. A program in Saint Lucia, an island in the West Indies, is run by Paul Butler, working for the organization RARE. He has taught pride and appreciation of native wildlife and convinced the people living on the island to protect their native parrot, a species in high demand among collectors and numbering only a few hundred in the wild, as well as their forests and other wildlife (see reference below). The smuggling of the St. Lucia Parrot has virtually stopped as a result, and its forest is now protected as the habitat for this national bird. In the rainforests of the Congo, a Gorilla family being studied by a primatologist was filmed. In order to acquaint local people with these animals, the film was shown to them. They had considered these apes to be fierce, dangerous animals, worthy of being killed for the bushmeat market. When they saw the tender affection among family members and the playfulness of the young Gorillas, they were pleased and surprised, saying "They are like us!" They had the forest declared a protected reserve and now teach their children to protect these Gorillas. (This was filmed by Moses Films and shown on National Geographic Explorer, entitled "Living with Gorillas" in 2000.) Write a report about the need for similar programs and find out about others being conducted to educate people about their wildlife. Think of species that would benefit from such programs, and write a short summary of an education program you think would be effective for an individual species or group of species. For example, turtles are being heavily exploited for meat and the pet trade throughout the world, endangering many species. If they were better appreciated in their native lands, especially Southeast Asia, where tradition and folklore hold them in high esteem, their future might be brighter. Design a poster and educational brochure about Asian turtles that could be distributed in Viet Nam, Laos, China and other countries where turtles are being captured in enormous numbers.

o While great profits can be derived from the sale of wildlife, even greater ones can come from tourism. Elephants killed for their ivory bring the hunter a one-time profit of several thousand dollars, but tourism centered

around elephants can benefit local people throughout the long life of the elephant, a life of some 60 years, totaling $100,000 or more. The capture of rare parrots, likewise, is far less profitable than ecotourism, which is worth 100 times or more the value of their sale in the pet trade. Whale meat is far less valuable than live whales that are whale watched. Whale watching now earns $1 billion per year worldwide from the 9 million people who take part in excursions in almost 90 countries, according to the International Fund for Animal Welfare. Think of other examples of non-lethal or non-invasive programs that benefit wildlife and ones that might be started to provide local people with income without harming wildlife. Another form of non-lethal business concerning wildlife involves the placement of videocameras in wild habitats, connected with the Internet. Internet users pay a small fee to see live views of the animal or scene, or to access the website for more films and information. South Africa's national parks are profiting from such a system, and the potential is great for other such videocamera placements. Videocameras can be solar-powered, as engineered by Daniel Zatz in Alaska, who has placed these cameras near bear feeding areas, with the images sent to a museum in Washington state (seemorebears.com). They also have the advantage of not injuring or invading the habitat of shy species which might be disturbed by large numbers of tourists. Think of species that might benefit from videocameras in their habitats. Examples might be wild parrots at their nests or Tigers filmed in national parks along trails.

Trade: Films

All films are described in detail in the Video section.

General: "The Business of Extinction," produced in 1977, is a classic film on wildlife trade and is extremely hard-hitting, showing smuggling and animal cruelty in the wildlife trade. "The Rangers of Nepal" profiles the bravery and dedication of Nepalese rangers who protect Indian Rhinoceros, Tigers, Asian Elephants and other animals from poachers. "Wildlife for Sale. Dead or Alive" is a Canadian Broadcasting Company film documenting the multi-billion dollar trades--legal and illegal--in wildlife that endanger thousands of species worldwide.

Ivory trade: "Echo of the Elephants," "Elephant," "The Elephants of Tsavo" and "Daphne Sheldrick and the Orphans of Tsavo" all deal with the slaughter that elephants endured during the 1980s and the effects on their populations and behavior. These sensitive and intelligent animals are traumatized when a family member is killed. The last film concerns the orphan elephants, tiny victims of the killing for ivory, affectionately cared for by Daphne Sheldrick in Kenya.

Fur and Traditional Medicine Trade: "Empire of the Red Bear" is a series about Russian wildlife that includes the discovery of two dead Siberian Tiger cubs who starved to death when their mother was killed. "Tiger. Lord of the Wild" profiles many of the activists trying to stop the trade in Tiger pelts and body parts in India and elsewhere. "Giant Otters" was filmed in Guyana, one of the few places left where these animals can be seen because of their killing for fur throughout their South American range, which is discussed.

Whaling**,** Sealing and Sea Turtle Killing: "The Great Whales," "Return of the Great Whales," "Blue Whale: Largest Animal on Earth," "Sperm Whales: The Real Moby Dick" and "Whales Down Under" all discuss the effects of whaling on the great whales. The latter film focuses on the Southern Right Whale, a species heavily hunted and only beginning to recover 50 years after receiving protection. "Sea of Slaughter" is based on Farley Mowat's history of the decimation of wildlife along the North Atlantic coasts. Walrus, whales, seals, sea mink, seabirds and other species that teemed in these waters in colonial times were killed for market sales--several species to extinction. "Long Live the Turtle" is part of a series on Japanese wildlife. "In the Shadow of Fujisan" discusses Japanese killing of sea turtles and their trade in these animals, as well as whaling and dolphin-killing. "Ancient Sea Turtles Stranded in a Modern World," by the Sea Turtle Restoration Project of Earth Island Institute, chronicles the many threats to sea turtles, especially drowning in shrimp nets, urging remedial effort to protect them.

Cage Birds: "Bird Traffic" is an excellent expose of the illegal capture of Salmon-crested Cockatoos at the roosts in Indonesia, showing the trauma and cruelty of their caging and shipment to Singapore and other Asian markets, endangering the species. "Caribbean Cool" is a film about the work of Paul Butler in St. Lucia and other Caribbean islands to protect the native parrot and its habitat. Children are taught about the parrots and dress in parrot costumes, singing songs about these birds and other wildlife of the island. The parrot is the national bird and is given much publicity and positive attention on the island.

Predator Prejudice

Project Summary

The purpose of this project is to research the general subject of predator prejudice and its effect on predators in various parts of the world. Read the material below and the Persecution and Hunting chapter in this book. The subject in general or a particular predator which has become endangered as a result of prejudice and persecution will be selected for a short report, including information on past and present distribution, control measures taken and the present status of the species.

Background

In the United States, Grizzly Bears, Gray and Red Wolves were eliminated from 98 percent of the country south of Canada by European settlers in control programs using poisons**,** guns and traps. Today, through natural recolonization and reintroduction, these predators are reoccupying small portions of their original ranges. Unfortunately, outside national parks, these animals are encountering prejudice. Local livestock owners, whose ranches surround the protected national parks and forests, oppose their presence. Livestock owners near one Gray Wolf reintroduction site in Yellowstone National Park in Montana attempted unsuccessfully through a lawsuit to have wolves removed from the park. Wildlife research over the past century has found that wolves rarely kill domestic livestock, and their predation on deer, elk and other ungulates keep these species strong and healthy. Grizzly Bears are mainly vegetarian, with occasional predation on small rodents or the calves or fawns of elk or deer, yet they have been hunted out of all but about 1 percent of their original range in the western United States south of Alaska.

Predator prejudice is common throughout the world wherever livestock is grazed in large numbers. In Ethiopia in East Africa, the Simien Wolf, a small canid that preys mainly on rodents, has been killed off by livestock owners who mistakenly believe them to present threats to their sheep and cattle. The species is near extinction. Likewise in South America, Europe and Asia, predators have been heavily persecuted, with wolves, bears, big cats and others eliminated from areas near human habitation and many wilderness areas.

Seals, sea lions and otters are also the object of prejudice from fishermen who believe that they take too many fish. In fact, they often prey on fish that are not taken for human consumption, many of which are predators of food fish. The Caribbean Monk Seal was persecuted to extinction, and its close relative, the Mediterranean Monk Seal, is now critically endangered as a result of killing by fishermen. Its remaining populations, numbering fewer than 1,000

animals, hide in caves along the coasts. Sea otters eat invertebrates that eat kelp and sea grass, thereby playing a key role in maintaining these ecosystems in which fish and shellfish flourish, but abalone fishermen consider them unwanted predators.

Birds of prey have also been persecuted as threats to livestock or because they competed for the same food as humans. The Bald Eagle was killed for a bounty in many parts of the United States because it fed on fish, causing fishermen to believe that it was an unwelcome competitor. Hawks and eagles around the world are shot and poisoned by ranchers and others, reducing many species to endangered status. In some areas, birds of prey are shot on sight. Legal protection for these birds has only recently been enacted in the United States, but many other countries fail to accord protection. They have an important ecological role to play by preventing rodents, snakes and other species from multiplying to pest proportions. The majority of species specialize in killing rodents, which helps farmers raising and storing grains.

Likewise, bats prey on insects and are important pollinators of plants, but they are persecuted in most parts of the world.

Snakes are also important predators of rodents, yet they, too, are routinely killed around the world. They are either considered pests or inspire great fear that they might present a threat to human beings. Snakes tend to be afraid of people, who are not their natural prey, and if left alone, will not attack.

Crocodiles perform a useful role in preying of overpopulated fish, yet they are killed as potential threats or for the leather trade. A majority of crocodile species are now endangered.

Activities

o Research: Using the sources listed in the Persecution and Hunting chapter, and others listed below, as well as those available in your library and through computer on-line searches, learn about the subject in general. Consider the following aspects of the issue:

1. Laws have been enacted since the Middle Ages in Europe encouraging the killing of predators and even punishing those who did not kill and deliver their hides to authorities. Many of these laws have been altered over the years and now remain in the form of bounties paid for pelts, and regulations permit and encourage persecution of predators. Are there state laws that allow persecution of predators, including endangered species? (Read the US Endangered Species Act and the Marine Mammal Protection Act to find examples of legalized killing of species considered predators of livestock or fish.)

2. What attitudes prevail in various parts of the world toward predators? While negative fears and hatred dominate in many areas, trends are changing in many countries. North American native tribes traditionally revere predators and incorporate them into their folklore. Europeans settling America had an opposing view, instituting predator control programs. What is unusual about the legal status and attitude toward the Gray Wolf in Italy? (See Persecution and Hunting chapter.) What happens to endangered Cheetahs when white ranchers who hate predators take over land in Namibia and South Africa? What education programs are taking place to change prejudices? The reintroduction in the United States of both Gray and Red Wolves was a result of this new view and the application of the US Endangered Species Act, but education programs have had mixed success. In some areas, such as Yellowstone National Park, however, tourists are coming in large numbers, spending money in local towns, and watching the Gray Wolves in an open environment considered the best "wolf watching" area in the world. Could tourism help save predators? The survival of predators depends entirely on attitudes of people living in their habitats.

3. Biological Studies: Studies on Gray Wolves in Alaska in the 1940s by Adolph Murie began a major change in knowledge of these animals and their relations with their natural prey that overturned previous misconceptions, many of which assumed that they were destructive to their prey. These studies have been augmented by other biologists on various predators throughout the world, confirming the important and positive role that predators play in ecosystems.

What studies can you find that examine the biological role of predators of various types, including birds, fish (such as sharks) and reptiles (such as snakes and crocodiles)?

4. Economic Damage: Control programs against predators are based on real or assumed damage to livestock or other property or assets, but they have rarely been based on fact. Exaggeration and fear have distorted estimates of actual losses to predators. Moreover, the ranchers or herders tend to release their livestock into the wild without guard dogs or other protection. When their animals are found dead, predators are blamed, when proof is often lacking. When livestock is guarded by dogs or fences, or housed in buildings or pens at night and when giving birth, mortality is usually very low. Unfortunately, US government programs, such as the Animal Damage Control (ADC) Division of the Department of Agriculture, routinely trap and poison hundreds of thousands of animals each year without proof of their predation on livestock. Contact the ADC and ask how many traps, how much poison and how many animals of all types have been killed in recent years. Also ask for the numbers and species of no-target animals, such as endangered Grizzly bears, Bald and Golden Eagles and other wildlife, taken in these programs. Ask the ADC how it avoids killing endangered animals? How much is spent on these programs per year, and what alternative programs could protect livestock in non-lethal ways, including guard dogs or other guard animals, such as llamas and donkeys, and by providing information on protecting livestock for far less money?

o Reports and Discussion: Select the subject of predator control in general for a report based on the information you have gathered in accordance with the categories above. Discuss this issue in class.

o Select a particular species that has been persecuted to endangered or threatened status by predator control programs. What was the original range of the species? What is its present range? What are the natural prey species of the animal and its habitat? When did control programs begin to eliminate the species and what were the reasons on which they were based? Was the species gradually, or rapidly, reduced in both numbers and range? Were control methods directed at adult animals only or on the young, such as killing pups in the den? What is the natural behavior of the animal in terms of its social nature with others of its kind, number of young, number of breeding adults in a group, whether it is solitary, and whether it can easily recover its population once control is stopped or tends to decline to extinction? What are the attitudes of the people who live within its habitat? What is being done to help the species? What do you think should be done to prevent its extinction?

o Conservation: Describe various means of protecting predators that are persecuted. For example, bats have been conserved through education programs in local communities and schools about their ecological role and how to bat-proof buildings. Ecotourism is another means of protecting bats, since their flights at dusk can be spectacular. The economic value of predators in controlling insects or rodents, for example, is an important argument in their favor. Many approaches are needed, depending on the attitudes held by the local people, the type of damage alleged and the economic factor. In some cases, the same species can be reviled in one part of the world and admired in another. The Gray Wolf is now a valued and protected predator in a growing number of countries, but in Russia and other countries, it is still tainted by folklore that bears no relation to fact. Make recommendations for the conservation of the Gray Wolf or another species in a country where it is persecuted. Write a brochure and design a poster for a species of your choice that would educate the public about why this species should not be persecuted.

Predator Prejudice: Films
All films are described in detail in the Video section.

Wolves: "Crying Wolf," "Wolf" (Spain), "Wild Wolves" (general), "Return of the Wolves" (Yellowstone National Park). All discuss the persecution, disappearance from large portions of its original range, and facts about the Gray Wolf's true ecological role and behavior. "Wild Dogs of Africa" is a sensitive portrayal of these endangered canids, including discussion of their persecution by ranchers, especially in southern Africa.

Bears: "Grizzly and Man--Uneasy Truce" (US persecution); "Grizzly Bears: Losing Ground" (British Columbia, Canada). These two films show the extreme ignorance and fear with which these bears are seen in North America, resulting in their killing for presumed threats and a lack of commitment on the part of the public and some officials to preserve the species.

Seals: "Orphans of Time" concerns the two surviving species of monk seals, the Mediterranean and the Hawaiian, both of which are highly endangered. "Seals--the Salmon Eaters," a film about seals in the Pacific Northwest (primarily Washington state) describes the intense hatred felt by fishermen toward seals and their desire to kill large numbers of them to increase the take of salmon.

Birds of Prey: "Anna and the Honey-Buzzards" is an inspiring film about a woman who has protected migrating birds of prey in southern Italy from being killed illegally by hunters who shot them from bunkers on hillsides. She has been joined by others who help her patrol the area since the film was made. "Eagles: The Majestic Hunters" is a beautiful film about these superb hunters and their life histories. It includes shocking footage of persecution of eagles in various parts of the world where they are killed and nailed to fences or poisoned.

Snakes**:** "Snake" is an excellent film to dispel irrational fears about snakes, 85 percent of which are harmless to humans, and to show their value in controlling rodents and other snakes.

Bats: See film list at end of "Bats: Ecologically Important Mammals" project.

Saving the American Elm and Chestnut Trees
Project Summary
This is an action-oriented project in which students or individuals obtain seedlings of these endangered trees and plant them to help restore the species, which were once widespread. For those living in areas outside the range of these species in Eastern North America, other threatened trees may be planted.

Background
Both the American Chestnut and the American Elm have been decimated by diseases brought to the United States on

wood or trees. Millions of these magnificent trees have died, but within the past decade, plant geneticists have produced disease-resistant types. The Elm Research Institute distributes seedlings grown from trees that have natural resistance to Dutch Elm Disease and have survived exposure to it. The tree that is cultivated by this institute is called the American Liberty Elm, and since 1983, more than 250,000 seedlings have been distributed to organizations, such as the Boy Scouts of America and others, who grow them from seedlings, then sell them to local towns, public parks and organizations for planting. The organization hopes to bring back the American Elm to Main Street America. The Elm Research Institute also provides advice on saving diseased elms. One teacher in Michigan organized local neighborhood groups who located diseased trees and succeeded in treating them to prevent their deaths.

The American Chestnut, a massive tree of eastern forests, made up about one-fourth of the original eastern forests in colonial times. It provided nuts that were fed on by populations of the now extinct Passenger Pigeon, American Turkeys, Black Bears, squirrels and other wildlife. These trees grew to heights of 100 feet or more and had deeply furrowed trunks, earning them the name "Eastern Redwood." Their near-extinction has been catastrophic to forest ecosystems. The Chestnut Blight that attacked them was first seen in 1904 on American Chestnut trees lining avenues near the Bronx Zoo, and apparently entered the country on another species of chestnut tree imported for botanical purposes. Like Dutch Elm Disease, this disease cuts off nutrients and water, gradually killing the trees. It has killed almost all American Chestnut trees in the east, and only a hundred or so remain in southern Canada. Some trees that were planted outside the natural range, such as in Oregon, survive. The stumps of American Chestnuts still produce sprouts that can grow up to 20 feet tall until they die from the disease.

Old-growth Longleaf Pine forests once covered millions of acres in the Southeast, with one of the world's richest diversity of forest floor plants and native wildlife, including the Ivory-billed Woodpecker. These forests have declined to 2 percent of their original size, and many of their former denizens are endangered or gone. The Southern Live Oak, a magnificent semi-evergreen tree that has a massive, spreading crown and twisted branches, has declined in many areas within its natural range. These native trees should be brought back through massive planting programs. In more Western areas, Redwood, native oaks and many types of pines and conifers have declined from former abundance and should be replanted.

Activities

o Help conserve endangered trees, such as the American Elm. Plant American Liberty Elms if you live in eastern North America. The Elm Research Institute will send an application to those who wish to receive 500 to 1,000 free elm seedlings. Teachers who wish to participate in the program must pledge several years commitment in order to care for the trees prior to their sale. The trees are guaranteed if properly maintained, and the Elm Research Institute will replace any trees that die. This is potentially a fund-raising program because the trees can be sold after a few years of care. The Elm Research Institute can be contacted at 1-800-FOR ELMS; Fax 603-358-6305; website: http://www.forelms.org.

o Plant American Chestnut trees if you live in the range of the east where this tree once grew. The American Chestnut Foundation was formed in 1983 to save this species through selective breeding of resistant strains. At present, they have succeeded in growing resistant trees and are developing seeds from these trees. They distribute kits of resistant seeds, which can be grown in one™s back yard, for $50. When they are old enough, they can be pollinated with pollen from blight-resistant trees being cultivated in Virginia. This is somewhat more complex than the growing of American Elms, but for a high school class, it would be an excellent way of learning about plant reproduction while helping to save an endangered native tree. A 17-year-old resident of Somerville, New Jersey, Timothy Van Vliet, is an enthusiastic supporter of the program and has grown a number of Chestnut trees in his back yard, one of which is 10 feet tall. With more people like Timothy Van Vliet, the American Chestnut may return to its former abundance. The American Chestnut Foundation can be contacted at P.O. Box 4044, Bennington, VT 05201, or telephoned at 1-802-447-0110. Membership in the organization is $40.

o Plant other threatened native trees. Those who live in western North America can help a rare or declining species of tree. Contact the Redwoods National Park (1111 Second St., Crescent City, CA 95531; and the Save-the-Redwoods

League (114 Sansome St., San Francisco, CA 94104) for information on obtaining seeds and seedlings. If one lives in the Pacific Northwest, native trees, such as Western Hemlock, Sitka Spruce and Western Red Cedar, have been reduced by 95 percent because of logging. Replanting these magnificent trees will help to bring back these forests and provide habitat for the threatened Northern Spotted Owl, Marbled Murrelet and other native species. Help protect the stands of these forests that remain by contacting organizations such as the Native Forest Council (P.O. Box 2190, Eugene, OR 97402); Save America's Forests, Washington DC (202-544-9219); and The Nature Conservancy (1815 N. Lynn St., Arlington, VA 22209; (703-841-5300).

Read "Smiles of Vanished Woods," Chapter 11 of *Noah's Garden. Restoring the Ecology of Our Own Backyards*, by Sara Stein, which discusses the importance of planting only native trees and the threat of exotic species, such as the Norway Maple, which can crowd out indigenous species. This book also stresses the importance of preserving old trees with hollow trunks and snags that wildlife can use and of planting understories of native bushes that hundreds of species of wild animals use for shelter and feeding.

Bees and Other Pollinators

Project Summary

Study the behavior of bees, using written materials, films and observations of actual beehives. Learn about plants that would become extinct without pollination by bees and what species of bees are indigenous to your area, especially those that are rare or declining. Learn what plants and habitats these species require and, if possible, plant their preferred flowers and erect a bee house.

Background

Many native bees in North America are important pollinators. A growing number are becoming rare as a result of pesticides, competition with non-native bee species and destruction of natural habitats. Very few types of bees sting humans. There are 500 species of native bees in New England, for example, but the most commonly seen bees are the European honeybees used to pollinate orchards and other crops. Some native bees are green, blue or red, and many are as small as flies. Others are twice the size of bumblebees. A few are nocturnal.

The communication system bees use to identify sources of nectar and pollen to one another was first discovered in

European Honeybees (*Apis mellifera*). When one bee locates a source of food, such as a flowering tree, it returns to the hive and through a complex series of movements with its feet, called dances, communicates to the other bees the location of the food source. The type of dance performed by the bee indicates the distance from the hive to the pollen and nectar. This system of communication involves a highly sophisticated integration of perceived and memorized information and was first discovered by an Austrian scientist, Karl von Frisch, a world-renowned animal behaviorist. He wrote two books on his discoveries: *Bees, Their Vision, Chemical Senses and Language*; and *The Dance Language and Orientation of Bees*. (See Reference list below.)

Methods

Learn about pollinators and their ecological importance and behavior. *The Natural History of Pollination*, by Michael Proctor, Peter Yeo and Andrew Lack, describes bee communication in terms of the extreme importance of bees as the pollinators of many native plants. Consult various reference books that describe bee behavior in detail. "Dancing the Good News" in the book, *Alien Empire. An Exploration of the Lives of Insects*, by Christopher O'Toole, clearly illustrates this remarkable phenomenon. This book is a companion to the excellent television series of the same name shown on Nature, the PBS program produced by WNET and filmed by BBC, which shows the dance of the honeybees as well as the behavior and ecology of many insect pollinators.

Activities

o Take a field trip to see a beehive. Teachers may contact local nature education centers, Audubon societies, state Natural Heritage Programs and US Department of Agriculture extension services to learn about local bee hives that could be visited.

o Contact the Natural Heritage Program connected with your state wildlife department, and find out which species of wild bees live in your area and which species are rare or declining. Discuss these species and what can be done to help them. What plants would become extinct if pollinating bees were to disappear? (*The Natural History of Pollination* is a good source of information for this subject.)

o Plant flowers and flowering trees that attract native bees. Find out which plants are preferred by bees in your area. Do not use pesticides or herbicides of any kind.

o Erect a beehouse in your back yard to attract native, stingless bees. A few holes drilled in scrap lumber and mounted under the eaves of a house, or some paper straws glued into a milk carton and placed on a tree branch, will entice native bees. To attract the large and colorful Bumblebees, build a house such as the one described in *Attracting Backyard Wildlife*, by Bill Merilees.

o Using *The Forgotten Pollinators*, by Stephen L. Buchmann and Gary Paul Nabhan, *The Natural History of Pollination* mentioned above, and other references on insects listed in the Books and Publications section of the Appendix of this book, select one or more pollinators, whether butterflies, ants or other insects, birds, bats or primates. Learn about these pollinators and which plants they pollinate, especially those that are threatened with extinction.

o By consulting the books mentioned above, the main text of *The Endangered Species Handbook*, and books listed in the Books and Publications section of this book, learn about the importance of pollinators in maintaining the world's ecosystems and how crucial it is to protect pollinating animals. Describe a pollinator or group of pollinators that are crucial to an ecosystem. For example, read the section in the Forests chapter in *The Endangered Species Handbook* concerning tiny wasps that pollinate a wide variety of figs which, in turn, nourish hundreds of species of wildlife. Learn about mammals, such as bats that pollinate many types of plants, through descriptions in this book and others listed in the project, "Bats, Useful Insectivores and Pollinators." Find an example of a species of plant that has lost its natural pollinator through extinction and now exists only through human intervention.

o The economic importance of pollinators has been calculated in several books and studies. In *Nature's Services:*

Societal Dependence on Natural Ecosystems, edited by Gretchen Daily, for example, the role of wild pollinators, such as insects and other animals, is valued at $117 billion worldwide. This means that the wild bees, ants and other species that pollinate commercial crops, such as fruit trees and wild plants, perform tasks that are worth $117 billion per year to the world's economy. The authors of *Forgotten Pollinators* estimate that pollinators save farmers in the United States an estimated $1.6 billion annually. Select a farm crop and find out from local US Department of Agriculture offices whether wild species of insects or other animals pollinate it. Through data from the US Department of Agriculture and almanacs, calculate the value of this crop and the losses to farmers should the wild pollinators disappear.

o Wild pollinators are in decline in many areas as a result of heavy pesticide use, which kills insects and other wildlife, and habitat loss, as in the cutting of forests, which causes declines in bats, tropical birds and insects. The Forests chapter discusses this in detail. Write a report on this problem, giving as many examples as possible of the loss in these essential species and the types of threats that pollinators face.

o Select a pollinator**,** such as a type of butterfly**,** and learn about what plants it pollinates. Does it pollinate a single species of plant or many species? Where does it live? What is its status? If threatened, how can it be helped?

"The Private Life of Plants." 1995. TBS/BBC. 6 hours. (Part 3, "The Birds and the Bees," concerns pollination.) Available from Discovery Channel School: 888-892-3484; www.discoveryschool.com.

Learning Animal Anatomy Without Dissection

Project Summary

Learn about animal anatomy in non-lethal ways. New communication technology may provide better knowledge about anatomy, through videos and virtual learning, than does dissection. Learn about these new resources and discuss their use in the classroom.

Background

In a growing trend, biology classes are being taught about the anatomy of frogs, cats and other animals from CD-ROM software, such as "Digital Frog and Cat Lab," rather than killing live animals for dissection or dissecting dead animals. An estimated 6 million vertebrates, half of which are frogs, are dissected each year by high school students, who are often so upset by the experience that they turn away from future science courses. Such school projects are inhumane, often requiring that frogs be killed by the student, for example. Moreover, frogs are in decline in the wild from a variety of causes, including the capture for such dissections. Their populations need protection. Many of the cats killed for use in high school dissection had been house pets that were illegally caught and sold to animal dealers in the United States and Mexico. Humane organizations have been promoting non-lethal substitutes for many years.

Activities

o Find out if your state's education department allows use of alternatives to animal dissection in classrooms.

o Review a copy of "Digital Frog and Cat Lab" or another software from the organizations below. The National Geographic Society sells various films, film-strips and other materials on animal anatomy. The lessons include function, taxonomy and structure. The Society's "Educational Services" catalog lists these products (P.O. Box 98019, Washington, DC 20090; 800-368-2728; www.nationalgeographic.org).

o Contact the American Anti-Vivisection Society (Suite 204 Noble Plaza, 801 Old York Rd., Jenkintown, PA 19046, 215-887-0816), which publishes the brochure "Animals in Education: An Outline for Student Activists" and distributes audio-visual materials. Also contact the American Fund for Alternatives to Animal Research (175 West 12th St., Suite 16G, New York, NY 10011, 212-989-8073) and the American Society for the Prevention of Cruelty to Animals (ASPCA) (441 East 92nd St., New York, NY 10128, 212-876-7700), which publishes the pamphlet, "ASPCA Guidelines for Student Experiments Involving Animals." The Animal Legal Defense Fund (1363 Lincoln Ave., San Rafael, CA 94901) has a "Dissection Hotline": 800-922-FROG, and publishes the brochure "Objecting to Dissection: A College Students' Handbook." The Humane Society of the United States (2100 L St., NW, Washington, DC 20037, 202-452-1100) publishes the brochure, "Does the Idea of Dissecting or Experimenting on Animals in Biology Class Disturb You?" Also, the National Anti-Vivisection Society (53 West Jackson Blvd., Suite 1550, Chicago, IL 60604, 312-427-6065) publishes "Reverence for Life: An Ethic for High School Biology Curricula" and "School Project Packet." The Student Action Corps for Animals (P.O. Box 15588, Washington, DC 20003, 202-543-8983) is dedicated to empowering young people in high school to work effectively for animal rights and acts as a communication network; it began the national "Say No to Dissection" campaign in 1984 and publishes *SACA News* and brochures such as "Say No to Dissection," "Suggestions for High School Student Animal Rights Groups" and "1-0-1 Non-Animal Biology Lab Methods."

Attitudes and Ethics

Project Summary

Examine the list of principles related to the treatment of animals entitled "An Animal Bill of Rights" (see below) and consider how these principles relate to declining and endangered species. Suggestions are given on how to use this document for classroom discussion or reports on endangered species.

Background

Our attitudes about animals have undergone radical changes in the past few decades. For most of human history, people have believed, like the philosopher René Descartes, that animals were merely machines, blindly obeying instincts. The opinions of many people have been greatly changed by the results of work with animals, for example, the intelligent Chimpanzees who make tools and exhibit many of the same emotions that humans have, such as fear, love, anger, joy and even despair. Elephants have also shown extraordinary qualities of altruism, and many examples

of their intelligence have been documented by zoologists. Whales and dolphins, too, have been shown to be intelligent and extremely devoted to one another.

Attitudes towards animals are also changing rapidly as a result of films and books and closer contacts with domestic cats and dogs. The popularity of house pets, with whom we form strong bonds, has encouraged a growing number of people to regard animals as having many of the same emotions as humans, and their friendship and loyalty toward us have been an inspiration to many. The popularity of nature films and books has educated the public to have a greater affection and respect for wild animals and a desire to protect and appreciate them. Still, many people treat animals as having neither sensitivities nor even the ability to feel pain. Fur trapping, research involving cruel experiments on animals, and baiting or attacking animals as an amusement are examples of a lack of compassion. A comment by a Canadian forester represents such a point of view that is, fortunately, disappearing: "Our instinctive attitude toward other species seems to range from indifference to antipathy . . . Concern for other species, particularly for those that have no immediate economic value to us, is a learned response, one we still struggle with" (Don Gayton, British Columbia Forest Service, "Terms of Endangerment" article in *Canadian Geographic*, May/June 1997).

Having a set of values and principles is a logical step in reevaluating how we treat animals--domestic and wild. The famed British zoologist Desmond Morris, in his book *The Animal Contract* (Warner Brothers, 1990), recommends 10 principles that human beings should adopt in their treatment of animals. This book discusses in detail the basis for the principles and gives many examples of our treatment and mistreatment of animals. He states that brutality to animals affects all our conduct and dealings with humans as well, and that a culture that is sympathetic to animals is a culture that is sensitive and caring in all respects. Moreover, he believes that a culture that feels a kinship with animals will be a culture that keeps faith with its roots in recognizing that humans are also animals, relatives of other species. These principles, as related to threatened species, are discussed below. They could also be used as interesting subjects for classroom discussions or for reports.

An Animal Bill of Rights

1. No animal should be endowed with imaginary qualities of good or evil to satisfy our superstitious beliefs or religious prejudices.

2. No animal should be dominated or degraded to entertain us.

3. No animal should be kept in captivity unless it can be provided with an adequate physical and social environment.

4. No animal should be kept as a companion unless it can adapt easily to the lifestyle of its human owner.

5. No animal species should be driven to extinction by direct persecution or further increases in the human population.

6. No animal should be made to suffer pain or distress to provide us with sport.

7. No animal should be subjected to physical or mental suffering for unnecessary experimental purposes.

8. No farm animal should be kept in a deprived environment to provide us with food or produce.

9. No animal should be exploited for its fur, its skin, its ivory or for any other luxury product.

10. No working animal should be forced to carry out heavy duties that cause it stress or pain.

Source: *The Animal Contract* by Desmond Morris. Warner Books. 1990.

Although many of these principles relate to domestic animals and can be discussed in another setting, others relate to our treatment of wildlife, including endangered species. Discuss the way in which these principles apply to threatened species.

Activities

o Principle number 1 could apply to wolves and bats, which are considered by many societies and individuals to be evil. Read the Persecution and Hunting chapter in this book for other such cases and consider the implications of such prejudices on the survival of many animals.

o Principle number 2 can also be applied to endangered species in that Lions (now considered Vulnerable species), Tigers, chimpanzees and elephants (all Endangered species) are trained to perform tricks in circuses that degrade them. Brown Bears used by gypsies in Europe and Asia are another example. They are dragged about by leashes attached to nose rings and trained to perform extremely unnatural acts, such as "dancing" on their hind legs. Discuss this principle and learn how circus animals are trained and how they are treated. Contact organizations such as PAWS (Performing Animal Welfare Society, P.O. Box 849, Galt, CA 95632) or the Animal Welfare Institute to learn more about this.

o Principle number 3 can apply to zoos that house endangered species. If the captive conditions do not allow the animals adequate physical and social environments, they would be considered to be violations of these principles. Examples might be the keeping of an elephant, a highly social species, by itself, in a small enclosure without water to bathe in or space to exercise. These animals are also chained at night in many zoos. Are there animals at your local zoo kept in such conditions?

o Principle number 4 can be applied to wild pets of many species that are kept in unnatural conditions. Tigers and other big cats, wild-caught parrots and many reptiles and amphibians are kept in peoples' back yards in cages or in indoor conditions that are highly unhealthy or psychologically traumatic for the animal. Many states ban various wild pets for this reason. Read the Trade chapter in this book for more information on wild pets and zoos. Find out the laws of your state or country regarding the keeping of exotic pets, especially endangered species.

o Principle number 5 is an extremely critical one in relation to endangered species. Although the US Endangered Species Act specifically addresses the issue of driving species to extinction as unacceptable, the law has been weakened by its opponents and faces further weakening. Moreover, only listed species receive such protection. Many threatened and endangered species that are not listed on the US Endangered Species Act receive no legal protection. In other countries of the world, such as Canada, no law prohibits driving a species to extinction or protects endangered species. Human overpopulation is a major cause driving species to extinction. This is an extremely important moral dilemma, one that is being faced by countries such as Indonesia, which has relocated people from overpopulated islands, such as Java, to areas still forested, such as Borneo and western New Guinea. These new immigrants are burning forests, with the encouragement of the Indonesian government, to create farms and grazing land for livestock. In the process, they are driving endangered species, such as the Orangutan, toward extinction. What should societies do in these circumstances, which will become more and more common in the future?

o Principle number 6 states that causing pain or distress in animals for our amusement is reprehensible and must not take place. Most examples of such cruelty involve domestic animals, such as steers in bull fights, roosters in cockfights and pit bulls in dog fights. Consider situations in which threatened or wild animals are used in such ways. For example, Asian bears are abused in street shows, and Tigers and elephants suffer in circuses. Hunting rare animals for sport might be considered to fall into this category, especially when it is carried out by means that do not usually kill quickly, such as by bow and arrow, and when it is not done for food, but for amusement.

o Principle number 7 concerns causing unnecessary pain for experimental purposes. Such experiments often involve the use of threatened animals. Chimpanzees and monkeys are involved in painful experiments to test drugs, in

simulated car crashes or other research. The use of these animals is justified by many research laboratories and others as being important because it can help human beings in various ways, such as finding cures to diseases. However, many experiments are unnecessary and repetitive of already published research. Does the treatment of these animals, especially long-lived chimpanzees who must spend a lifetime that can reach 60 or more years in sterile confinement, justify the research, or are there alternatives to using these animals? (Contact the Animal Welfare Institute for its published reports and articles on this subject.)

o Principle number 9 regards exploitation of animals for furs, skins and other luxury items. Many threatened species are legally traded for such purposes. All the wild cats that are listed on Appendix II of the Convention on International Trade in Endangered Species of Wild of Fauna and Flora (CITES) may be traded with export permits, for example. The trade in elephant ivory during the 1980s nearly caused the extinction of both the African and Asian species. In 1989 all ivory trade was banned by CITES. Today, many countries want to reopen trade in African ivory, claiming they have stockpiles and overpopulation of elephants in some areas. Discuss the ethics of killing animals for luxury goods and select a species that is threatened with extinction as a result of such killing. This principle could also apply to the trade in live wild pets that threatens many species. Read the Trade chapter in this book for more information.

Film

"The Animal Contract," based on the book by Desmond Morris. Garner MacLennan London and Lifetime Pictures in association with Island Visual Arts and G.C. Films, UK.

Wildlife Music

Project Summary.

People once thought that animals were "dumb" because they could not speak in human language or that the seas were silent because we were unable to hear their sounds. Many still think that birds sing for people. We now know that wild animals communicate with one another and other species in thousands of different sounds. This project will acquaint students and others with many of these sounds. They have definite purposes and can communicate a wide variety of messages, whether territorial, warnings to members of their own species, mating calls or other meanings we have yet to understand. Human activities are having negative effects on the communications of some animals, even causing mortality. This project will encourage appreciation of the great variety of animal sounds, especially those of disappearing species. Means of preventing interference with animal communication and working to reduce human-created noise will be explored.

Background

A chorus of bugles as flocks of Sandhill Cranes take flight, the eerie violin-like songs of Humpback Whales or the croaking of frogs can evoke emotion and deep appreciation. Human response to wildlife songs reflects the universality of music. Virtually all human societies have their own music (see Milius 2001). Just as we are drawn to the sounds of nature, animals have been attracted to human music. The now-extinct Laughing Owl of New Zealand would fly close to a person playing an accordion after dusk, remaining in the vicinity until the music stopped (see Fuller 2001). Researchers in the Pacific Northwest have dangled microphones playing music from their boats and found that dolphins and Killer Whales approached and listened for long periods. The mournful, musical howls of wolves caused fear in the superstitious medieval times, but today they are appreciated as true animal songs, each wolf contributing a slightly different melody. In fact, when a recording of wolf howls was released during the 1970s, the music critic of *The New York Times* judged the musical talent of each wolf singer. (Wolf Education and Research Center: www.wolfcenter.org provides information on howling.) Songs play an integral role in wildlife communication and survival. Endangered denizens of American grasslands, prairie dogs, also have complex languages, giving different calls to one another to warn of birds of prey, land predators, humans with guns and other threats. Some bird songs, like those of many birds of paradise, stunningly beautiful birds of New Guinea, are so loud and bizarre that they seem to have been electronically produced. They are designed to penetrate dense foliage for long distances. Bellbirds and howler monkeys of Latin America and gibbons of Asia also sing so loudly that the songs carry for miles in the rainforests. Gibbons mate for life and sing duets in whoops that echo through the forest. Many wildlife songs are used to defend territories or to find a mate. Beluga whales and Mountain Lions communicate with one another in bird-like chirps. Elephants are now known to emit deep sounds, inaudible to humans, which carry for great distances to elephant herds miles away (see Payne 1998). Likewise, bats and dolphins emit ultrasonic sounds to find their prey and to navigate. Some of these are audible to the human ear. Many of these species are now listed as Threatened, however (see Endangered and Threatened Species list in the Appendix).

As the world becomes filled with human-made noise, from the giant engines of ships, planes, trucks and earth-moving machines to jet skis, snowmobiles, snow blowers and chainsaws, wildlife songs and calls are being drowned out. Each Humpback Whale has its own individual song. The males vary the songs each year, and females seem to be attracted to the males who emit the most complex songs. Marine mammals emit a great variety of squeaks, hums, squeals and chirps to communicate with one another and echo-locate, but they can be drowned out by ships, motorboats, jet skis and other human-made sounds. It is critical for the survival of these marine mammals that they be able to communicate.

Some ship noises are even lethal to marine mammals. The US Navy has been testing an anti-submarine sonar called Low Frequency Active Sonar (LFAS). Powerful sonar waves are broadcast underwater to test a means of detecting quiet enemy submarines (see White 2000a). These sonar waves can travel hundreds of miles and be extremely loud. Humpback Whale males have stopped singing or moved away when these waves were broadcast. More ominously, testing in 1995 off the coast of Greece coincided with an unusual stranding of Cuvier's Beaked Whales, resulting in the deaths of these seldom-seen whales. In March 2000, Ken Balcomb, a biologist familiar with sonar, was present in the Bahamas when a stranding occurred at the same time Navy LFAS tests were taking place nearby. Fifteen whales stranded, including Dense Beaked Whales, a Minke Whale and a Spotted Dolphin. All washed up on the shores, and when pushed back into deep water, they were unable to remain upright, clearly unbalanced, disoriented and apparently in pain. Without their hearing, they cannot find their way in the ocean. Nine died. Along with Harvard biologist Darlene Ketton, Ken Balcomb performed necropsies on several whales, finding their ears full of blood. In one case, hemorrhages striped the lungs. Further testing revealed that a whale had suffered a concussion, apparently the result of acute trauma from pressure (White 2000a). A press conference organized by the Animal Welfare Institute following these findings featured Ken Balcomb of the Center for Whale Research and other whale experts, who attested to the fact that LFAS is reckless, unnecessary and lethal to whales. Soon after, the Navy canceled testing of active sonar off New Jersey and also its scheduled tests on Sperm Whales in the Azores (White 2000a). The Navy has not cancelled these tests altogether, however, claiming that more research by Woods Hole Oceanographic Institute is needed to reach a final conclusion.

Bird reproduction has also been affected by the sounds of highway or airplane traffic. Researchers have found that male birds living near such loud noises cannot hear their own songs or those of their rivals and, in a few generations, begin singing songs so different from their instinctive ones that other males do not respond, nor do females, preventing reproduction. Frogs living near highways have also been found to lose their natural calls in the din of traffic noise. It is not known whether these animals have suffered hearing damage or are simply unable to hear fellow creatures over the din. Much of the noise created by human machines could be reduced or eliminated with muffling devices. Design of machines that will not interfere with animal communication should become a priority.

Activities

o Listen to recordings, such as fiMusic of the Birds,**fl** listed below. Visit websites that play animal sounds and songs. One, intended for visually-impaired people, plays bird songs: www.nhest.org; and www.naturesongs.com has many types of natural music. The largest collection of natural sounds in the world is at the Macaulay Library of Natural Sounds at the Cornell Laboratory of Ornithology (www.birds.cornell.edu). It has 150,000 recordings. The British Library's national sound archive has more than 130,000 recordings: www.bl.uk/collections/sound-archive/wild.html). The Nature Sounds Society website (www.naturesounds.org) gives information on other sites. For an academic approach, consult the site of the World Forum for Acoustic Ecology: interact.uoregon.edu/MediaLit/wfae/home/. Watch wildlife films that include songs and calls, especially those of threatened and endangered species, such as birds of paradise, whales, wolves and elephants (see list below and Video section). Write an essay on the songs of one group of species, such as whales, or a particular species, describing the variety of the songs or calls.

o Compare the wildlife sounds heard in environments far from highways and airports with those near them. Take walks in several types of habitats with experts who can identify wildlife sounds, such as frog chirps and croaks, bird songs and insect noises. Tape record the sounds heard and count the number of species in a quiet habitat versus those heard near a busy highway or airplane flight path. Note that each species' song can be heard in normal conditions because of its own frequency and rhythm. Discuss the effect of noise on these species, and describe the various calls heard without interference.

o Learn about means of lessening human-created noise. Write the Environmental Protection Agency (EPA) in Washington, DC (see Organizations list, Teachers™ Aids section) for information on noise pollution and how existing engines can be muffled for quieter substitutes. For example, electric-powered lawn mowers and leaf blowers make far less noise than gas-powered ones. Airplane engines that are quieter than those currently in use have been designed,

but no strong government mandate has encouraged their manufacture. Automobile and truck engines can be made quieter, and certain road surfaces can decrease traffic sounds. Snowmobiles that emit far less noise have been manufactured, but without legislation mandating their use, there is little demand. Consult the Internet for organizations working actively to require that quieter machines be in use. Write a report on the need for noise pollution equipment.

o Research the effects of snowmobiles, jet skis and all-terrain vehicles on wildlife. Contacting various organizations, including the National Parks and Conservation Association (see Organizations list in Teachers™ Aids section) for information on their work to keep these vehicles out of the national parks because of the negative effects the noise has on wildlife. Find out the decibel levels of various vehicles that are allowed in wildlife areas and off-road wilderness parks and their effects on various species of wildlife.

o The US Navy testing of anti-submarine sonar, Low Frequency Active Sonar (LFAS), described above, has been shown to be extremely dangerous to some marine mammals and drives others away from their traditional migration and feeding areas. Write the Animal Welfare Institute for more information on this program and how to help stop it.

Films

The following represent only a few of the many films concerning animal calls and music. See the Video section of this book for further listings. Also, many audiocassettes are available with wildlife sounds of various types.

"Attenborough in Paradise." 1 hour. Nature (PBS). BBC. 1996.
David Attenborough visits New Guinea and describes the birds of paradise and

their extraordinary calls.
"Crane River." 1 hour. National Audubon Society. PBS Video. 1988. Hundreds of thousands of Sandhill Cranes migrate in the Midwest, bugling, calling and courtship displays, which resemble minuets.
"Gentle Giants of the Pacific: Humpback Whales" 1 hour. Sierra Club Series. Wood Knapp Video. The amazing songs of these whales are heard in this film.
"In the Company of Whales" 90 minutes. Discovery Channel. (VHS & CD•ROM.) 1992. Following great whales and hearing their sounds with zoologist Roger Payne and other experts, insights are given on whale behavior and biology.
"Jaguar. Year of the Cat." 1 hour. Nature (PBS). Telenova Productions. 1995. Filmed in the rainforests of Belize, the daily life of Jaguars is seen in remarkable close-ups accompanied by the sounds these cats make as they walk in the forest or lap water in a stream, with insect and bird songs in the background.
"National Audubon Society's Video Guides to North American Birds." Five one-hour cassettes. National Audubon Society. These videos show and record all species in the United States and Canada for which photo documentation exists. Audiocassettes of almost all the native breeding birds are available from this organization.
"Wild Wolves." 1 hour. BBC. NOVA. PBS. 1997. This film examines the true nature of wolves, their behavior and ecology and lets us listen to their howling.

Lawns

Project Summary

Many biologists and conservationists are now questioning the use of green lawns in yards, in front of public buildings and along highways. In general, green lawns have to be maintained through use of chemicals that can pollute the groundwater and kill beneficial plants and insects; use noisy, gas-guzzling mowers and leaf-blowers; and fail to preserve native plants. This project involves examination of the effects of these lawns on the environment and human health, as well as the use of energy and water to maintain them.

Background

Most biologists consider grass lawns to be ecological deserts because of their lack of diversity. In many areas, grass lawns cover a large percentage of land in villages and suburbs. Golf courses are increasing in number. Lawns are replacing natural habitats, such as woodlands, grasslands, shrub and desert and, in the process, wildlife and natural landscapes retreat. The Eastern Box Turtle has lost a large percentage of its original long grass, shrubby habitat to green lawns, and the species has declined dramatically. These slow-moving reptiles are also badly injured or killed by lawn mowers, which smash their shells (see Stevens 1994). Migratory birds and butterflies return in the spring to find their natural habitats converted to green lawns, depriving them of feeding and breeding sites. In general, lawns provide little or no habitat for wildlife.

To keep them green, herbicides, pesticides and chemical fertilizers are sprayed or spread in vast quantities. More than 67 million pounds of chemicals are placed on US lawns annually (see Wasowski 2001). These chemicals kill useful native animals, such as pollinating insects, birds that disperse seeds and consume insects, burrowing rodents, and earthworms that aerate the soil. They also contaminate the groundwater. Some of these poisons are so powerful that

they have caused sickness and death in humans. Early in 2001, the city of Halifax, Nova Scotia, Canada, became the first in North America to order a ban on all insecticides, herbicides and fungicides used on lawns. The ban was primarily intended to protect human health, especially children who are most vulnerable to pesticides (see Nickerson 2001). Fifty-five other communities across Canada are considering similar bans. Opposition to grass lawns and frequent mowing along public highways is also growing. One citizen of Orleans, Massachusetts, objected to the *The Boston Globe* when mowers destroyed carefully planted native wildflowers growing along a major highway in this Cape Cod area. The flowers, planted by volunteers (one as old as 85), of the New England Wild Flower Society, had been clearly posted not to be mowed.

Green lawns require constant care and use enormous amounts of energy for mowing, edging and removing leaves. Most lawn mowers and leaf blowers consume gasoline and pollute the air with fumes, while also creating noise pollution. Mowers also damage tree trunks or kill above-ground tree roots, especially of old trees, and frequently-applied fertilizer can harm older trees, which need slow-release enrichment of the soil (see Stocker 2001). For these reasons, gardeners recommend that no large tree be within 2 feet of a lawn. Another threat to trees is lawn watering during droughts; an insufficient amount of water reaches the tree roots, while the lawn absorbs most of the water (see Stocker 2001).

Lawns are also extremely costly. The American Nursery and Landscape Association estimated that Americans spent $17.4 billion on their lawns in 1999 (see Schembari 2001). The Lawn Institute, based in Illinois, estimates that the lawn care industry for North America is worth more than $25 billion (see Nickerson 2001). By planting perennial native grasses, shrubs, trees and flowers, homeowners could save literally billions of dollars.

The grass used for lawns in the United States is composed of various European turf species, which, unlike most native American grasses, require large amounts of water, often as much as a third of local water supplies. Householders use 40 to 60 percent of their water on their lawns in the summer. Erroneously called "Kentucky Blue Grass," this and other commercially distributed grass seed needs cool, damp climates for healthy growth. The grass quickly turns brown in the heat of summer or when not watered enough. In dry seasons, many towns mandate water rationing because lawn watering has depleted local supplies. The average lawn will use up to 10,000 gallons of water of a summer and 10 times the amount of pesticides as an acre of farmland (see Egan 2001).

Communities being built in dry areas, such as southwestern deserts, tend to plant green lawns because their owners have come from areas where they were typically used. In desert areas, green lawns can only be maintained through diversion of water that dries up rivers or alters the ecology of these regions. In Arizona, for example, several rivers have been reduced to dry beds by diversion for the burgeoning developments surrounding Phoenix and Tucson. Cities of the Southwest and California use enormous amounts of their water supplies to water green lawns. In the process, several pairs of endangered Bald Eagles that nested on one of these rivers, along with thousands of other forms of life, disappeared. One new resident of Phoenix, an architect, planted native plants in his garden instead of grass, defying local developers**,** who remove all native vegetation and cover the land with gravel. His yard was soon filled with wild marigolds, creosote bushes and other plants that seeded themselves in his beautiful, no-maintenance back yard. In Glendale, Arizona, homeowners receive a $100 rebate for converting 50 percent or more of their grass to shrubs or plants. Studies from Las Vegas found that a city could save 40 percent of its water by converting to non-grass alternatives. With the world facing increasing water shortages, the grass lawn, especially of non-native species of grasses, has become a luxury that is wasting this precious resource.

Green lawns can be grown with native grasses that do not require artificial watering and chemicals, and by using the cut grass as mulch. Fertilizers and herbicides are not necessary for these lawns, which can be mowed with electric or old-fashioned, human-powered mowers. Also, smaller areas can be planted. Instead of dominating the yard, lawns can become a minor part. Planting native vegetation, including wildflowers, shrubs and trees, in back yards and city lots is a preferable alternative to the green lawn. In shady, moist areas, mosses can be planted that never require mowing and stay green year-round (see reference list below). Perennial plants do not need replanting each year and require almost no maintenance. Trees provide shade, erosion control and habitat for wildlife. Planting a garden with

native American plants can also aid in the conservation of ecosystems and rare species. By not using chemicals, groundwater and wildlife are protected.

Activities

Consult the books listed below before beginning the following project:

o Select two small land plots (each about 200 square feet) each distanced from one another by at least 100 feet. Prior to planting, take samples of soil and examine them under a microscope to determine the diversity of plants and animals, whether there are earthworms to aerate the soil, and other life forms. Measure the acidity. Describe the soil's texture, whether rich loam, clay or sand, and whether it is dry and crumbly or moist. Are there birds that feed in the grass or evidence of small mammals, such as tunnels? In one half of the plot, plant non-native grass and use the chemicals recommended by the grass seed company. Water and mow the lawn, if needed. On the other half of the lawn, dig up the soil and spread natural compost from leaves and other vegetation throughout, to a level of 2 feet. Sow seeds of native grasses**,** such as buffalograss (sold in many nurseries). Water this portion until the seeds are established, but not afterward. Do not apply any artificial fertilizers or other chemicals. Mow with electric or hand mower only. After one month, take soil samples from both areas and examine them under a microscope to determine the diversity of microbes and the moisture content in the two soil samples. Note whether the organic wildlife area has above-ground evidence of wildlife such as butterflies, small mammals, reptiles, amphibians and birds. Identify them by species. Did the organic grass survive without artificial watering? Compare the two soils, their moisture content, invertebrate species diversity, water usage, environmental effects and the cost to maintain each one. A third alternative is described in the next project, fiLiving with Nature,fl focusing on conversion of the lawn to native wildflowers, bushes and trees, which requires even less water and labor.

o As a study project, select a suburban area of approximately one city block and measure the acreage in green lawns, calculating the cost in use of chemicals, as well as gasoline for lawn mowers and leaf blowers. Estimate water consumption and the percentage of this that must be artificially applied through hosing or sprinklers. What is the water source? Ask the local water department how much water is used in your area for watering lawns each year. Contact the Environmental Protection Agency in Washington, DC, for information on contamination of groundwater by lawn chemicals and their effects on wildlife and human health.

Living with Nature

Project Summary

This project focuses on planting a garden with native plants and creating natural habitats that will attract wildlife and provide breeding and feeding areas for a wide variety of species. If an area for planting is not available, the principles of a natural garden can be learned. Also, the project discusses means of avoiding any lethal methods to control insects or animals with which one can come into contact in one's home or back yard, including Raccoons in garbage pails, deer munching shrubbery or moles burrowing in garden plots.

Background

The ecological problems presented by green lawns (see previous project) have brought many people to realize that many gardens and yards tend to reflect a lack of ecological knowledge and concern, and fail to preserve a natural environment and maintain wildlife habitat. This subject has resulted in many books and even garden magazine articles, but only a small minority of homeowners have abandoned the green lawn or reduced its size, making it a small part of one's yard rather than the dominant component. The long-term goal of converting lawns to natural environments is to provide wildlife with habitat it has lost in recent times, a period during which housing developments gobbled up millions of acres of woodland and pastures. Also, lack of tolerance for wildlife has increased, with homeowners moving into areas only recently converted to housing to be dismayed and often fearful when they find wildlife in the back yard. These animals were the original tenants of the land, and we are the invaders, but few homeowners seem to realize this fact and want nature to be tamed and non-invasive. Common sense approaches to this potential conflicts will be explored.

Activities

o Conversion of a yard from grass to natural vegetation can be done at once by digging up the entire lawn, excavating at least 2 feet to aerate and compost the soil, and replanting. A natural garden can also be planted gradually, plot by plot. The most important step is preparing the soil by enriching it with natural compost and organic fertilizers so that soil microorganisms and invertebrates, such as earthworms, can flourish and plants will have a better likelihood of surviving. Acidity testing is important to create a soil condition to which the type of plants used will adjust. Conifers, mountain laurel, rhododendron and related plants require high acidity, while grasslands and meadows tend to be more alkaline. Use no pesticides or artificial chemicals. Also to be avoided are bug zappers. These electric units that hang outside and electrocute insects have been shown to kill thousands of useful insects, such as moths, but almost no mosquitoes, for which they are intended (see *Wildlife Conservation* magazine, July/August 1997). A school class can utilize a plot of land of varying size according to the amount of time and effort it can expend. Many of the books listed below provide clear guidelines to follow in establishing a garden with native plants. Plan the garden to conform to the regional ecosystems, and use only plants native to the area. Some of the suggestions made in various books and articles include planting non-native plants to attract butterflies or birds. This should be avoided, and such plants should be removed. Consult guides to native plants to determine whether a species is indigenous. The best sources for native plants are organizations, such as the New England Wild Flower Society in Framingham, Massachusetts, that propagate all plants sold and recommend that no wild plants be dug up from woodlands or other natural habitats. The most coveted and delicate species, such as damp woodland trilliums and lady slippers, will almost surely die if transplanted from the wild, as they live in a symbiosis with fungi. Moreover, they require many years to mature and are rare in the wild. The habitat established--whether a woodland, small pond with water plants, prairie with wildflowers, desert landscape with cacti or marsh--should be compatible with local vegetation. It might consist of recreating a habitat destroyed by developers on the very site. If the lot is completely open without shade trees or even bushes, it is not possible to establish a woodland environment immediately. The planting will have to be transitional, using species that would naturally seed in such areas, such as birch and ground cover plants in northern and

mountainous areas. Whichever habitat is chosen, carefully record which plants are introduced and their survival on a regular basis.

o If you are creating a butterfly garden, follow instructions such as provided in the booklet, "Butterfly Gardening in New England," to establish shrub plants for the larvae, fragrant flowers to provide nectar for adults, a damp area for moisture and mineral feeding, and tangles of vegetation for the caterpillars. Keep in mind the locality. Host plants differ in each region of the country. In an open environment, a field of native goldenrod, milkweed and a diverse selection of plants would have the best likelihood of survival and attract butterflies of many species. Many butterflies specialize in a particular type of host plants, and only these can be planted. Flowers that attract many species of butterflies are a good introduction to such a project. When the flowers have appeared, spend an hour each sunny afternoon recording the species and numbers of butterflies that come to feed. Later in the season, try to find eggs, chrysalids and caterpillars among the vegetation. A good source for more information on this subject is *A World for Butterflies*. Photograph them. Note also other types of wildlife that come, whether birds, small rodents or other species. Write a report on the project, recording the successes and failures from beginning to end. The flowers may be left indefinitely, as they are perennials.

o Animals such as Raccoons, squirrels, deer, skunk, moles and rabbits are often seen as pests to be eliminated if they cause damage, eat prize plants or vegetables, or create burrows in the soil. What seems to be a major problem that can only result in trying to eliminate the animals can be solved or attitudes changed so that wildlife is better tolerated. *Living With Wildlife*, a book published by the Sierra Club, is based on the experiences of the California Center for Wildlife, a wildlife rehabilitation and education center with more than 200 volunteers and a professional staff. They receive more than 12,000 calls a year from people who have problems dealing with animal nuisances. Many problems, such as animals eating garden vegetables, can be solved with fencing, having garbage cans that cannot be opened by animals or are placed behind barriers, and spraying bushes and vegetation with substances and odors that repel animals. For example, to "raccoon-proof" a garbage can, fasten the lid securely with rope, bungee cords, chain or even weights. Secure the handle to a metal or wooden stake driven into the ground to prevent it from being rolled around. Store cans in wooden bins or in a locked shed or garage. Certain smells, such as ammonia, repel animals and can be sprayed on bushes or garbage cans. This book gives specific advice as well as encouraging a tolerant and positive attitude toward wildlife, reflecting the knowledge that we have entered *their* territory, not the opposite. If one's home has destroyed important habitat for wildlife, it is important to consider recreating it by allowing brush and shrubs to grow, instead of neat flower beds, to provide habitat for turtles, rabbits and groundhogs to share the property. Consider that a graceful deer in one's yard is a privilege to see. To protect special trees or fruit, spray them with repellants that contain milk, and hang bags of human hair. Most people choose to share their yards with deer and other wildlife, planting vegetation for them. It is also important to be tolerant of predators, such as bear, Cougar, Coyote and wolves, while staying far away from them. These predators, especially Cougar and Wolves, play an important role in regulating populations and maintaining the strength of deer and other ungulates. The overpopulation of deer in many parts of the country can be blamed on direct persecution of large predators. These predators should never be fed or approached, however, but allowed to exist as vital components in ecosystems. Few people are aware that Coyotes and foxes are important consumers of mice. A key factor in developing tolerance of wildlife is to understand their need to survive and to learn about and respect their natural behavior.

Lifestyles and Citizen Action

Through small changes in our lifestyle, we can reduce our use of energy, our pollution, our unnecessary consumption of material goods and help wildlife and the natural world. By launching programs within our community and making other contributions to conservation, we can have an even greater impact. This project will examine some examples of each conservation approach and encourage activism to preserve nature and endangered species. It will make recommendations about purchases that can either aid or damage the environment and wildlife.

Activism on the part of individuals and governments is crucial to reversing the trends that are extinguishing species and habitats at an unprecedented rate. The natural world is a place of beauty that provides a cornucopia of medicines, food and inspiration. The majority of scientific discoveries lie in the future. Preserving these treasures should be the most important goal of society. Future generations will not forgive us if we extinguish this precious heritage, upon which we depend for our very lives.

The majority of people on Earth are too occupied with survival to understand and act on the need to preserve species and natural environments, especially wilderness areas. Those people who can teach means of sustainable living without harming nature should become far more active to prevent further extinctions and erosions of natural ecosystems. On the whole, we have failed to treat the environment and our fellow creatures with the respect needed to prevent further losses to our natural heritage. Never before, however, have we known so much about the components and functioning of ecosystems, nor have we had the technology and the will with which to remedy past errors in order to live in harmony with the Earth.

Land Protection
Sustainable Living
Internet Solutions
Purchasing Power

Lifestyles and Citizen Action: Land Protection

Background

One can contribute to the preservation of biological diversity worldwide in many ways. Land protection is key to species' preservation. In foreign countries, biological diversity is at great risk, with extinctions occurring on a daily basis. Through support of international organizations, vital tracts of land can be purchased or the government convinced to designate them as national parks. In the United States, bogs, vernal ponds and other temporary wetlands, longleaf pine forests, old-growth cedar forests, tallgrass prairies and desert springs are some examples. They are vital to the survival of countless species, but receive little or no state or federal protection from destruction, and harbor many endangered species. Making a project of protecting a threatened habitat and/or species could spell the difference between survival and extinction for a particular plant or animal species, a very worthwhile project.

Activities

o Support organizations that specialize in setting aside land. This is key to saving the wildest, most pristine and important habitats before they are ruined. By obtaining issues of past magazines and press releases of organizations, such as The Nature Conservancy or Conservation International, learn what land they have protected that provided important habitat for endangered species and how they work to identify and protect biologically important areas in need of conservation. Help an organization that is raising money for land that harbors rare or endangered species in a foreign country. One class raised more than $100,000 to purchase a sizeable rainforest tract, teeming with beautiful tropical birds, in Costa Rica. Far less funds per acre are needed to acquire land in many countries where biodiversity is high than in the United States or Europe.

o On a local basis, a class could save an endangered species by helping to purchase its habitat. Information on a state-by-state basis on endangered species and habitats can be obtained from the Natural Heritage Programs connected with each Environment or Wildlife Department. These programs identify rare, endemic and declining species and their habitats, including those in need of protection. Also, national, state and local organizations and government departments can help in identifying land in need of protection. In some cases, an organization that specializes in a particular type of animal, such as frogs, cranes or turtles, will know of such areas and may already be raising money to purchase them. The class can choose an area in need of fund-raising and begin to aid in a fund-raising campaign. It would be more feasible to choose land that is not so expensive or large that many years would be needed to purchase it. The Nature Conservancy or another organization may be preserving the land. Another option is to launch a campaign to convince a town, state or federal agency to designate an area as protected. A field trip should be taken to the site, guided by a biologist familiar with the habitat--its plants and animals. Someone in the class could be designated to photograph the site, while others would take notes on what the guide says for a report and write letters to the editors of local newspapers. The site may preserve one or more endangered species, as well as an endangered habitat. Once successful, contact local newspapers to publicize the event, and write up the achievement in terms of how the goal was attained and what biological treasures were protected.

Lifestyles and Citizen Action: Sustainable Living

Background

A growing number of organizations are providing people around the world with alternatives to destroying forests and other natural habitats to clear land, obtain firewood or raise livestock. In tropical areas, land cleared of rainforest can be farmed for only a few years because of poor soil. Organizations are now helping these farmers survive in ecologically friendly ways through donation of solar cookers and heaters, aid in establishing small farms that utilize

bio-gas (methane obtained from manure and sewage), and promotion of self-sustaining farming methods that do not destroy the environment. In Madagascar, primatologist Patricia Wright protected the forest home of endangered lemurs by convincing the government to establish a large national park. It provided many jobs for local people. She then raised money for the construction of schools and clinics. Deforestation has virtually stopped as a result, and the people have become protective of the forest after learning how it prevented mudslides. Providing this type of help for people in poor areas of the world will be a major project of Conservation International, which plans to integrate this approach with its land protection and biodiversity studies, through a donation it received of more than $1 billion.

Activities

o Select one or more threatened habitats that are being destroyed as a result of over-grazing, deforestation or other means by people in developing countries. Many examples are given in the main text of this book. In classroom discussion, explore the ways in which these areas are being destroyed. What habitats and threatened species are disappearing as a result? What do you think should be done to prevent this situation from continuing and to help the people at the same time? For example, in Central Asia, so many sheep, yak, horses and other livestock are grazed by nomadic people that they are ruining the grasslands, leaving little food or habitat for native gazelles, wild camels, antelope and wild horses. Native predators, such as wolves, bears and Snow Leopards, are killed as potential threats to the livestock. Make specific suggestions that would provide for the basic needs of the people by alterations in their lifestyle and simple technology, while preserving the ecosystem.

o Consult the Internet and other sources for organizations that distribute solar cookers and simple technology, as well as agricultural advice. Contact them with suggestions for areas to donate that harbor many endangered species and habitats. Ask which countries are the recipients of this aid. Find out which parts of the world are not receiving international aid and, if these areas are environmentally threatened, suggest that they receive aid.

Lifestyles and Citizen Action: Internet Solutions

Background

Internet websites provide a new avenue to protect the planet through programs like "click-to-donate." Merely by clicking onto the Internet site, one activates funding for wilderness, endangered species and environmental protection from corporate pledges. EcologyFund (www.ecologyfund.com) is one such website that receives more than 100,000 visitors each month. In exchange for ad exposure, the fund donates sponsors' money to protect wilderness, plant trees and reduce pollution. Threatened wilderness land in the United States, Canada, Mexico, Africa, the Amazon Basin, Patagonia and Scotland has been preserved, and the fund claims to protect 187 square feet of land and save 2 pounds of carbon dioxide per visitor every day. Care2 (www.care2.com) also has a "click-to-donate" program focusing on endangered species and rainforest protection. One of its programs, "Race for Big Cats," has protected 16,000 square miles of key habitat for endangered Tigers, Jaguars and Snow Leopards, in conjunction with the Wildlife Conservation Society. In cooperation with the Nature Conservancy, Care2 has purchased large tracts of rainforest.

A related approach to preserving wildlife and funding conservation work consists of Internet sites that tune into live videocameras located in national parks or other natural areas, sending signals to satellites. Some websites are free, while others charge a small fee. Cameras set up in South African national parks (www.africam.com) focus on wild animal lairs, waterholes and other wildlife spots. They have generated large sums of needed money for the park system. In the United States, television cameras have been trained on Peregrine Falcon and Bald Eagle nests and transmitted to a cable station that plays the picture. Solar-powered videocameras have been designed that can be placed in the most remote wilderness with no need for batteries or outside electric power sources. This concept has great educational potential, simultaneously raising money for endangered species and wilderness protection, while educating as well. Such websites can provide important information on these subjects while providing exciting views of wildlife and wild places. As an alternative to eco-travel for those of lesser means or those unable to travel, such

websites could offer tours, such as tree-top views of rainforests and their abundant wildlife, or close-ups of seabird colonies or coral reefs. They have the added benefit of protecting delicate ecological areas from the effects of too many tourists. Such websites should provide a portion of the funds to local people as an incentive to preserve the land and wildlife. If significant funds were generated, countries faced with choices such as whether to allow corporate logging, commercialization of wildlife, dams and other projects needed to repay national debts, might consider these cameras to be a better alternative. If successful, such websites would encourage countries to maintain large areas of wilderness. Videocameras also have a scientific potential in giving a 24-hour view of areas harboring wildlife, often difficult to observe through other means.

Activities

o Click onto several videocamera sites to see the various types of wildlife spectacles offered. Some examples: seemorebears.com (Alaskan bears feeding on salmon in season); www.african.com (see above); www.world-stream.com (views of ancient species of fish, the Coelacanth); zooatlanta.org (Giant Pandas). What threatened species or habitat would you like to see on a videocamera placed in the wild? Would you also like the views to be part of a menu offering information on the species and the habitat? What ideas do you have about the applications and potentials of these live videocams linked to the Internet and television cameras broadcasting to cable television stations?

o Select a country that is suffering high levels of environmental destruction
but also has beautiful scenery and many endangered species. Discuss the potential of proposing alternatives to such a country, i.e. placing videocameras as income producers versus commercial logging, a short-term destruction versus a long-term investment. What scenery and wildlife would you think would attract Internet users in this country?

Lifestyles and Citizen Action: Purchasing Power

Background

Developed countries consume 80 percent of the world's natural resources. If not for consumers in these countries, no market would exist for many luxury products, such as mahogany, teak and rosewood. The deforestation taking place to harvest these woods pushes many species of animals closer to extinction. Loggers take the largest and oldest trees. These are the ones most valuable as wildlife habitat, oxygen producers, carbon dioxide absorbers, soil stabilizers and water retainers. In spite of some programs meant to encourage "green" forestry practices, even selective logging, in which only a few trees are taken per acre, all types of logging have negative effects on pristine old-growth forests and their wildlife. (See Forests chapter). Many species are directly endangered through loss of habitat and hunting. People enter previously impassable forest on logging roads to kill Gorillas, chimpanzees, elephants, rare antelopes, birds and other wildlife for bushmeat markets and animal products for Traditional Medicine. (See Forests chapter). Old-growth forests in some parts of the world have been growing undisturbed, harboring the same types of trees for hundreds of millions of years. These forests are irreplaceable repositories of biodiversity and living pharmacies, precious for their scientific value as extraordinarily rich ecosystems. Scientific knowledge of the functioning of these forests and an inventory of their species has only just begun. Cutting one tree can kill a dozen that come crashing down as jungle vines entwine whole groups of trees and branches that stretch for long distances knock down neighboring trees. In the process, many animals lose their lives and habitats. Nest holes for birds, mammals, reptiles and insects, loose bark under which forest bats roost, tall canopies for eagles' nests--all are lost. The logs obtained are not essential for human survival, but are sold as raw material for coffee tables, wall paneling and lawn furniture for the wealthy. Thousands are cut merely to manufacture shipping cartons or chopsticks, used once and discarded. more than 80 percent of these old-growth rainforests have been logged in the last century, greatly reducing the production of oxygen, water vapor and absorption of carbon dioxide. Certain products, such as Brazil and cashew nuts, can be extracted from tropical forests without harm. Ecotourism has great potential as a means of income. If profits are shared with the people who gather them, they will have an incentive to protect these trees. Other products that

damage forests, especially tropical forests, are wooden carved boxes and tourist knick-knacks made from scarce woodlands in India, Indonesia and other countries where forests have been decimated.

Coffee was once grown in the shade of tall forest trees, but with the development of new strains of coffee plants, forests are being cleared to grow coffee in the sun (see the Forests chapter). Coffee grown in the shade is far more ecologically-friendly, since large trees are preserved. Many North American birds migrate to the tropics and winter in coffee plantations. The sun-grown coffee has deprived wildlife of this habitat. A campaign to return to shade-grown coffee, especially if grown without pesticides, was launched by the Smithsonian Institution a few years ago. Some commercial importers have provided a market for this shade-grown coffee, enlisting coffee farmers in many parts of the world to protect forests and grow coffee as an understory. Now this coffee is available in many US stores, marketed as "Shade-grown," "Bird-friendly" or "Shade-grown--Organic." Many of these coffees are comparable in price to, or only slightly higher than, sun-grown commercial coffee grown using pesticides. They have the added advantage of being healthier, since they contain no dangerous chemicals. Likewise, most bananas are grown with massive amounts of pesticides and herbicides, but many growers are now producing bananas organically. Ask your local grocery store to stock them and be aware that purchasing them helps the environment. A similar problem exists with the growing of chocolate from the cacao plant in tropical areas. Its great popularity in the United States has encouraged the clearance of forests for large-scale plantations that grow the plants in the sun, using fertilizer, fungicides and pesticides (see Khamsi 2001). Diseases have broken out in the large plantations, requiring heavy use of pesticides, fungicides and other chemicals to control them. Organic Commodity Products (OCP), a supplier in Cambridge, Massachusetts, promotes the growing of cacao in shade without artificial chemicals. Fortunately, 85 percent of the world's cacao is shade-grown. Some 6million small farmers who cannot afford pesticides provide this crop. Several chocolate companies are now marketing organic chocolate to promote environmentally friendly agriculture (see Khamsi 2001).

Caviar from sturgeon native to Russia and the Caspian Sea is one of the most valuable wildlife products. Sales in the United States and other importing countries have pushed virtually all Eurasian sturgeon species close to extinction. Even famous French chefs, including Jacques Pepin, recommend a boycott of Beluga, the most valuable caviar, which comes from the most endangered sturgeon species. Many other fisheries products come from species that have declined 90 percent or more in the past decade from overfishing. Atlantic Cod, Orange Roughy, Chilean Bass, Atlantic Bluefin Tuna, sharks of many species and swordfish have been seriously overfished. Many of these fish, such as sharks, are slow-reproducing, not having young until they are as old as 20 years. It is likely that their populations will never be able to sustain a commercial take. Pollack is a white fish from Alaskan waters that is being overfished to manufacture artificial crabmeat. The pollack fishery endangers Steller's Sea Lions, depriving them of a major food source. Shrimp from the Gulf of Mexico and many other tropical areas endanger sea turtles, which drown by the thousands in shrimp nets, which also catch millions of tons of unwanted fish that are discarded. Some shrimp is caught using nets that allow sea turtles and other non-target species to escape the net through turtle excluders, and these shrimp are often labeled "turtle-safe." Farmed shrimp and salmon involve environmental destruction. Mangroves are being cut in tropical countries around the world to construct shrimp farms, which emit large amounts of pollution. Farmed salmon are kept in off-shore pens, but many escape to breed with wild salmon, endangering the latter. The pens also contribute large amounts of pollution to the ocean.

Likewise, mining operations devastate entire ecosystems to obtain gold for jewelry and other minerals. The United States provides an enormous market for gold, the majority of which is made into jewelry. Even national parks in Indonesia are now permanently scarred, with large areas of land and rivers devegetated and poisoned with cyanide, which is used to separate the gold from ore. This country has the highest number of threatened species in the world, a majority of which are found only here. Orangutans are being driven from their forest homes in Indonesian Borneo and Sumatra by loggers and gold miners, their populations now facing extinction in the wild. It is such activities that are fostered by the market for gold. Diamond extraction can destroy wildlife habitat and river bottoms, as well as causing human rights violations when used as currency by dictatorial governments who torture their citizens. Pearl cultivation damages American aquatic ecosystems. Pieces of mussel shell are inserted into living oysters, which causes the oyster to exude pearl material to surround the mussel shell. The mussel shells used for this cultivation

come, for the most part, from the United States. Millions of tons of these shells are dug out of riverbeds, threatening some species.

As discussed in the Trade chapter and the previous project, millions of wild animals are captured for the pet trade and specialty collectors in wealthy countries. Parrots, cockatoos, macaws, turtles, tropical fish, snakes, lizards--and even frogs--are plucked from their tropical homes to be sold in pet stores. Some species have been driven to the edge of extinction by the wild pet trade, which also treats these animals inhumanely. The United States bans the import of most wild birds, but many species are still permitted under the Wild Bird Conservation Act. Also smuggling, a multi-billion dollar activity, funnels thousands of animals into pet stores where they are represented as legally taken or even captive-bred. Only 10 percent of shipments entering the United States are inspected for wildlife. For the majority of wild animals in the pet trade, little protection exists. Although the US Endangered Species Act and the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) have helped limit trade, strict controls exist for only a small minority of the most endangered species. Since the United States is the world's largest wildlife importer, the effect on wildlife has been catastrophic.

Lizard, snake and crocodile handbags, shoes and luggage; ivory; feathers and other wildlife products are part of a trade that has endangered hundreds of species. Even if the product was not made from an animal on the US Endangered
Species List, it may be threatened by trade or inhumanely captured or killed. At present, for example, the reptile product trade is killing millions of snakes and lizards for leather products, causing many species to become threatened. Yet almost no controls have been placed on the trade, and what controls there are contain loopholes making them ineffective.

Many plants are endangered by harvesting for collectors. Rare cacti, delicate woodland and wetland species such as Venus Flytraps, Yellow Lady Slippers and other orchids, South African protea and a long list of other plants are being plundered in the wild. Many of these plants cannot be raised in captivity and have been illegally dug up in the wild.

Activities

o Write a report on the effects that American consumers have on old-growth tropical rainforests and their wildlife.

o Ask local stores if they carry shade-grown and organic coffees and, if not, would they stock them? Several grocery store chains and many health food stores sell these coffees. In restaurants and coffeehouses where coffee is served in large quantities, ask them to purchase at least a portion of their coffee as shade-grown, organic. Write the Smithsonian Institution's Ornithology Department for more information on the effect of sun-grown coffee on birds and other wildlife, and write a report on the subject.

o Select one of the jewelry materials mentioned, such as gold. Read the Forests chapter in this book and other references to the mining of gold in South America, Africa and Asia and its effect on the environment and wildlife. Write a short report on the mining operations in a particular country and their effects on wildlife and the environment. If purchasing jewelry, choose artificial diamonds, pearls and gold. These items can hardly be distinguished from the genuine ones because of advances in simulation technology. Other types of gem and metal mining also damage the environment.

o Discuss the general reasons for boycotting wild pets; fur coats; reptile products; feathers; caviar; threatened fish; turtle meat;, Traditional Medicine remedies made from wild animals, such as snakes, bear, seahorses and other animals; other wildlife products and rare plants that you have seen in stores. Select one species (or group of species, such as sharks) and write a report on how the trade is threatening it and how to publicize the need to boycott its products.

Films

"Affluenza." America's materialism affects the world's environment, destroying forests and other environments. Solutions to the out-of-control consumerism are offered in "Escape from Affluenza."
"Cultivating Opportunity. Self-Help Solutions to Poverty in the U.S. and Africa" focuses on small-scale farmers forming cooperatives to protect themselves against corporations taking over their land.
"Mountains of Gold" tells the story of Brazil's gold rush and the thousands of prospectors who pan and dredge gold in the rainforest.
"Secrets of the Choco" explores the survival of the Choco tribe in Colombia and its rainforest, threatened by highways and non-sustainable development. Six world experts on tropical ecology and sustainable development discuss the region's future.
"Super-Companies" concerns the operations of multinational corporations in terms of raw materials and how they are affecting the needs of people and the global environment.

Teachers' Aids and Educational Materials

Teachers' Aids
The American Biology Teacher. Published by the National Association of Biology Teachers, 12030 Sunrise Valley Dr., Reston, VA 20191; www.nabt.org; Phone: 1-800-406-0775. Although not primarily concerned with endangered species, this magazine occasionally has information on this subject.

Bullfrog Films™ catalog includes an extensive collection of educational films on the environment and wildlife, many of which are thought provoking and could serve as the basis for discussion. The catalog lists recommended grade levels and awards, accreditation and other background information on each film along with descriptions of the content. Some of the films are reviewed in the video section. www.bullfrogfilms.com; Phone: 1-800-543-3764.

Discovery Channel School. fiDiscovery Channel School K-12 Catalogfl lists materials, such as CD-ROMs and videos, which are packaged together. For example, the Insects packet includes a CD-ROM, a student resource book, fiInsect Files,fl a Teachers™ A-Z Resource Guide on Insects, and an Internet site featuring electron microscope images of insects and fiB-Eye: The World Through the Eyes of a Beefl to show what a flower looks like to a bee. Other packets with CD-ROMs, teachers™ guides and student resource books include: fiPlants,fl fiReptiles,fl fiFish and Amphibians,fl fiInvertebrates,fl fiProtists and Fungi,fl fi Mammals,fl fiBirds,fl fiEvolutionfl and fiEcology.fl The latter title™s Internet link features suggestions on projects to save beaches, a global warming debate about coral reefs, and fiEarth Today.fl Each CD-ROM contains a long video as well as library searches of references, a digital lab and instructions for presentations of slides, text and sound effects to be created by the students. Among the selections in the fiEarth Sciencefl CD-ROM bundle is fiConservation of Natural Resources.fl The latter CD-ROM is also offered in a bundle along with a student resource book, a teacher™s guide and Internet links. Videos geared toward school classes have themes divided into segments. Titles for grades 6 to 12 include: fiFinite Oceansfl on the limits of oceans to absorb pollutants and provide resources; fiCoral Reefsfl explores the Red Sea, an extremely diverse coral ecosystem; fiUnderstanding Oceansfl explains their movements, tides, endangered creatures and experts; fiWater: To the Last Dropfl investigates the contamination and misuse that threatens the limited supplies of freshwater upon which we depend; www.discoveryschool.com.

Conserving Earth™s Biodiversity by Edward O. Wilson and Dan L. Perlman, 1999. Island Press, Covelo, CA (interactive CD-ROM teaching conservation biology and environmental science). Teachers can register for an examination copy and view a demo at: www.islandpress.org/wilsoncd. Senior author is Harvard University professor, author of *The Diversity of Life* and editor of *Biodiversity*, key books on the subject.

Earthwatch. This bimonthly periodical, published by Earthwatch, is available by subscription and is sold by many newsstands. Earthwatch sponsors research projects by scientists. Contributors, scholarship and fellowship students may accompany scientists on their expeditions. Projects have included studies of threatened plants and animals and their disappearing habitats in Australia, Brazil and Thailand; endangered sea turtle ecology in Baja California, Mexico; and Florida Manatees. A typical project is carried out by a scientist affiliated with a well-known university or institution. Volunteers pay to assist the scientists by making observations, taking photographs and performing miscellaneous duties for a period of about two weeks. Active participation in the study depends on the health, interests and abilities of the volunteer. Many teachers go on expeditions, taking copious notes and photos, and use the experience as a teaching outline for courses. Students may also be sponsored by their class or family. Volunteers must

be 16 years or older. For those unable to participate in research trips, project briefings are available for $15 each, written by the scientists heading each project, with background information and results as available. There are scholarships and fellowships offered to selected applicants. Earthwatch Institute, 3 Clock Tower Place, Suite 100, P.O. Box 75, Maynard, MA 01754-9928; Phone: 1-800-776-0188; www.earthwatch.org has more than 5,000 pages of background information on projects, a global classroom, an education site, and a virtual expedition. The site has won more than 25 awards for excellence.

Endangered Means There™s Still Time This free US Fish and Wildlife Service brochure explains the basic causes endangering species. The brochures, fiPlacing Animals and Plants on the List of Endangered and Threatened Speciesfl and fiESA Basicsfl explain the listing process, critical habitat and other facets of the US Endangered Species Act. fiWhy Save Endangered Species?fl presents strong arguments for the preservation of biodiversity as it benefits human health and agriculture and tells how animals can be barometers of environmental quality, warning us of the dangers of pesticides, for example. Other brochures include profiles of the Mexican Wolf, Red Wolf, Whooping Crane and others. fiConserving Borderline Species, A Partnership between the United States and Canadafl is a report describing the cooperative programs that have helped Whooping Cranes, Swift Foxes, Black-footed Ferrets and other wildlife and plants that inhabit both sides of the Canada/US border region. A poster entitled fiThe Road to Recoveryfl illustrates some of the species that, because of the Endangered Species Act, have increased in numbers from Near-extinction: the Grizzly Bear, Bald Eagle, Lange™s Metalmark Butterfly, Gray Whale and Greenback Cutthroat Trout. By calling the Publications Unit of the US Fish and Wildlife Service (304-876-7203) or the Office of Endangered Species, one can also request fact sheets on a selected number of US endangered species and copies of US Fish and Wildlife Service publications (USFWS, 4401 N. Fairfax Dr., Arlington, VA 22203; www.fws.gov/). Further information on US endangered species is available from www.natureserve.org, a private database providing legal status and general information on all species listed by The Nature Conservancy as Imperiled.

Environmental Vacations: Volunteer Projects to Save the Planet, by Stephanie Ocko, 2nd edition, John Muir Publications, 1992. Distributed by W.W. Norton & Co., 248 pages. This book describes ways in which nonscientists can assist experts in activities (such as monitoring the diversity of rainforests), observing animal behavior or other projects, giving particulars on the projects and how to become involved.

The Globe program for classrooms involves students from around the world who participate in ecology studies by gathering and analyzing data; ncdc.noaa.gov/GLOBE/globe.html. It is affiliated with the National Oceanic and Atmospheric Administration (NOAA).

Green Teacher, P.O. Box 1431, Lewiston, NY 14092; or in Canada, 95 Robert St., Toronto, Ontario M5S 2K5, Canada. Five issues per year, $27.00; sold on newsstands also. This magazine is very well done. It lists environmental projects and activities and has a humane orientation. Some articles are in both French and English.

Knowledge Unlimited, P.O. Box 52, Madison, WI 53701-0052; www.ku.com. This catalog lists videos, filmstrips, resource guides, classroom posters, books and other educational materials under major categories, including Science, which has many listings on endangered species and environmental topics.

National Geographic Society. The Educational Services department of the National Geographic Society provides material, films and filmstrips on general science and biology, including endangered species and habitats. Its free catalog, fiSchool Publishing,fl for Grades K-12 offers a wide variety of environmental books, videos, CD-ROMs and

other visual material accompanied by teachers™ guides. An Internet site designed for teachers gives further detail: www.nationalgeographic.com/education. One learning packet centers on the Tiger. The teaching guide includes lessons on habitat, populations, adaptation, predator/prey relationships, conservation and scientific studies, accompanied by two videos the society produced on the species, slides, posters and student handouts. Another teaching unit describes The Jason Project Expeditions, sponsored in part by the National Geographic Society. Each centers on a part of the world. These kits combine studies of a variety of disciplines centered on an area or country: biology, climate study, geology and others.

Students learn how to measure pollutants and study endangered species™ diets. These lessons are also shown on the new National Geographic television channel. An interactive encyclopedia CD-ROM on Mammals, for Grades 2-12, allows students to see and hear more than 200 mammals through photos, range maps, acoustics, facts on endangered species, mystery games that test powers of deduction, and a lesson plan booklet. Videos made for the classroom on many subjects include a series on bioscience, showing life cycles of various insects, a trout river ecosystem, and other themes for various grade levels. Each includes a teacher™s guide and is described in the Teacher Store page or in the Video and Media Catalog. Anatomy of frogs and other animals are included in material that teaches function, taxonomy and structure. For the growing number of teachers and students who would rather find another means of learning about frog or mammal anatomy rather than dissection, especially in view of the declining status of frogs, this material provides a solution. (Also see the Projects Section in this book, fiLearning Animal Anatomy Without Dissection.fl)

*Rainforest Teacher™s Packet.*Rainforest Action Network, 221 Pine St., Suite 500, San Francisco, CA 94104. Educational materials listed on www.ran.org; Phone: 415-398-4404. Students and others may sign up for fiaction alertsfl on issues affecting the world™s rainforests.

The Rainforest Book. How you can save the world™s rainforests, by Scott Lewis with the Natural Resources Defense Council, Living Planet Press, 1990. Aimed toward students, the text has chapters on the importance of rainforests, both tropical and US temperate rainforests, how they can be saved and how individuals can help with specific examples of aiding organizations, encouraging local businesses not to buy rainforest products, visiting rainforests, adopting an acre of rainforest, and further reading, films and other information sources.

Save America™s Forest. Citizen Action Guide The activist organization, Save America™s Forests, has published a 51-page how-to guide for citizens and/or students to work within communities to educate others on the decline of America™s forests from clearcutting and over-harvesting. It is available online at www.saveamericasforestsfund.org. Also available from this organization, a slide show, fiClearcuts Coast to Coastfl (purchase or rental); an annotated bibliography on forests; and the award-winning video, fiThe Last Ancient Forestsfl (11 minutes, purchase $7). Save America™s Forests, 4 Library Ct., SE, Washington, DC 20003; www.saveamericasforests.org; Phone: 202-544-9219.

Science Teacher. National Science Teachers Association, 1840 Wilson Blvd., Arlington, VA 22201-3000; Phone: 703-243-7100; www.nsta.org. Published nine times a year, this is a valuable periodical, aiding teachers of environmental subjects.

Teacher™s Guide to World Resources and Biodiversity(ISBN 0-7872-4259-4), 2001. This guide provides economic, ecological, ethical and esthetic reasons why we should care that species are becoming extinct. Students explore the root causes of biodiversity loss and strategies for conservation. Cost is $9.99. Published and distributed by Kendall Hunt, it can be ordered online through their Web site. The site also includes fiEndangered Forestsfl and many other

titles on the environment. Discounts are given to teachers who order in bulk. Web site: www.kendallhunt.com; Phone: 1-800-542-6657.

fiUnderstanding Biodiversity.fl Encyclopedia Britannica™s 19-minute video is aimed at high school students. It stresses the need for ecosystems to have diverse life forms and the important roles different types of scientists play in biodiversity preservation. The cloud forests of Venezuela are the background for teaching this subject. A Teacher™s Guide is included, listing objectives and suggestions for classroom discussion topics. Encyclopedia Britannica Educational Corporation (1-800-554-9862).

fiBritannica. Electronic Media Catalogfl descries many videos (without teachers™ guides) on the environment and wildlife. It also offers a fiGuide to Dissection,fl in which a video software package with four parts shows dissections of a rat, frog, pigeon and dogfish. Using software, the student can do a virtual dissection with a computer mouse.

Video Project. Free catalog of educational environmental videos for use in schools and libraries. Video Project, P.O. Box 77188, San Francisco, CA 94107; Phone: 1-800-4-PLANET; www.videoproject.net.

The Wild Ones. The Wildlife Trust (formerly the Wildlife Preservation Trust) is a sister organization to the Durrell Conservation Trust in the United States, founded by Gerald Durrell, noted author and conservationist, which works on environmental and endangered species programs throughout the world. For students, the organization sponsors fiThe Wild Onesfl (www.thewildones.org), which includes a newsletter, *The Wild Ones*, and accompanying fiTeacher Connection,fl both of which can be downloaded from its Web site. The latter enrolls classes and provides suggestions for curriculum activities involving conservation, endangered species, natural history and related topics that complement the newsletter. *The Wild Ones* is also published in other countries, such as Mexico, translated into Spanish, with added topics pertaining to that country™s environment and wildlife.

Letters and artwork from students around the world are published on the site. Through the Web site, students can write the scientists working on various projects for the organization. The newsletter for the general membership, *On the Edge*, often focuses on particular endangered species; recent issues may be accessed through the Web site under fiField Notes,fl with the year of publication. The organization in the United Kingdom, which publishes the newsletter *The Dodo Dispatch* (ages 7-16), and the Canadian sister organization can be reached through the Web site as well. The Wildlife Trust, 61 Route 9W, Palisades, NY 10964-8000; Phone: 845-365-8337; www.wildlifetrust.org.

Wildlife Review Abstracts, National Information Services Corporation, 3100 St. Paul St., Suite 806, Baltimore, MD 21218. Formerly a quarterly report published by the US Fish and Wildlife Service, these annotated bibliographies are now a privately run database system with 514,000 entries of publications on wildlife and the environment, indexed by species, subject and geographical areas. Abstracts from wildlife, fisheries, ornithological, ecological and forestry journals are sold through a yearly subscription for $1,045. The data is available on CD-ROM and is compiled from many sources. The Wildlife Species Information Library at the site includes data on habitats in states from a DOS-based CD-ROM or 45,000 pages of online species™ profiles. Phone: 410-243-0797; www.nisc.com.

Teachers' Aids and Educational Materials

Teachers' Aids
The American Biology Teacher. Published by the National Association of Biology Teachers, 12030 Sunrise Valley Dr., Reston, VA 20191; www.nabt.org; Phone: 1-800-406-0775. Although not primarily concerned with endangered species, this magazine occasionally has information on this subject.

Bullfrog Films™ catalog includes an extensive collection of educational films on the environment and wildlife, many of which are thought provoking and could serve as the basis for discussion. The catalog lists recommended grade levels and awards, accreditation and other background information on each film along with descriptions of the content. Some of the films are reviewed in the video section. www.bullfrogfilms.com; Phone: 1-800-543-3764.

Discovery Channel School. fiDiscovery Channel School K-12 Catalogfl lists materials, such as CD-ROMs and videos, which are packaged together. For example, the Insects packet includes a CD-ROM, a student resource book, fiInsect Files,fl a Teachers™ A-Z Resource Guide on Insects, and an Internet site featuring electron microscope images of insects and fiB-Eye: The World Through the Eyes of a Beefl to show what a flower looks like to a bee. Other packets with CD-ROMs, teachers™ guides and student resource books include: fiPlants,fl fiReptiles,fl fiFish and Amphibians,fl fiInvertebrates,fl fiProtists and Fungi,fl fi Mammals,fl fiBirds,fl fiEvolutionfl and fiEcology.fl The latter title™s Internet link features suggestions on projects to save beaches, a global warming debate about coral reefs, and fiEarth Today.fl Each CD-ROM contains a long video as well as library searches of references, a digital lab and instructions for presentations of slides, text and sound effects to be created by the students. Among the selections in the fiEarth Sciencefl CD-ROM bundle is fiConservation of Natural Resources.fl The latter CD-ROM is also offered in a bundle along with a student resource book, a teacher™s guide and Internet links. Videos geared toward school classes have themes divided into segments. Titles for grades 6 to 12 include: fiFinite Oceansfl on the limits of oceans to absorb pollutants and provide resources; fiCoral Reefsfl explores the Red Sea, an extremely diverse coral ecosystem; fiUnderstanding Oceansfl explains their movements, tides, endangered creatures and experts; fiWater: To the Last Dropfl investigates the contamination and misuse that threatens the limited supplies of freshwater upon which we depend; www.discoveryschool.com.

Conserving Earth™s Biodiversity by Edward O. Wilson and Dan L. Perlman, 1999. Island Press, Covelo, CA (interactive CD-ROM teaching conservation biology and environmental science). Teachers can register for an examination copy and view a demo at: www.islandpress.org/wilsoncd. Senior author is Harvard University professor, author of *The Diversity of Life* and editor of *Biodiversity*, key books on the subject.

Earthwatch. This bimonthly periodical, published by Earthwatch, is available by subscription and is sold by many

newsstands. Earthwatch sponsors research projects by scientists. Contributors, scholarship and fellowship students may accompany scientists on their expeditions. Projects have included studies of threatened plants and animals and their disappearing habitats in Australia, Brazil and Thailand; endangered sea turtle ecology in Baja California, Mexico; and Florida Manatees. A typical project is carried out by a scientist affiliated with a well-known university or institution. Volunteers pay to assist the scientists by making observations, taking photographs and performing miscellaneous duties for a period of about two weeks. Active participation in the study depends on the health, interests and abilities of the volunteer. Many teachers go on expeditions, taking copious notes and photos, and use the experience as a teaching outline for courses. Students may also be sponsored by their class or family. Volunteers must be 16 years or older. For those unable to participate in research trips, project briefings are available for $15 each, written by the scientists heading each project, with background information and results as available. There are scholarships and fellowships offered to selected applicants. Earthwatch Institute, 3 Clock Tower Place, Suite 100, P.O. Box 75, Maynard, MA 01754-9928; Phone: 1-800-776-0188; www.earthwatch.org has more than 5,000 pages of background information on projects, a global classroom, an education site, and a virtual expedition. The site has won more than 25 awards for excellence.

Endangered Means There™s Still Time This free US Fish and Wildlife Service brochure explains the basic causes endangering species. The brochures, fiPlacing Animals and Plants on the List of Endangered and Threatened Speciesfl and fiESA Basicsfl explain the listing process, critical habitat and other facets of the US Endangered Species Act. fiWhy Save Endangered Species?fl presents strong arguments for the preservation of biodiversity as it benefits human health and agriculture and tells how animals can be barometers of environmental quality, warning us of the dangers of pesticides, for example. Other brochures include profiles of the Mexican Wolf, Red Wolf, Whooping Crane and others. fiConserving Borderline Species, A Partnership between the United States and Canadafl is a report describing the cooperative programs that have helped Whooping Cranes, Swift Foxes, Black-footed Ferrets and other wildlife and plants that inhabit both sides of the Canada/US border region. A poster entitled fiThe Road to Recoveryfl illustrates some of the species that, because of the Endangered Species Act, have increased in numbers from Near-extinction: the Grizzly Bear, Bald Eagle, Lange™s Metalmark Butterfly, Gray Whale and Greenback Cutthroat Trout. By calling the Publications Unit of the US Fish and Wildlife Service (304-876-7203) or the Office of Endangered Species, one can also request fact sheets on a selected number of US endangered species and copies of US Fish and Wildlife Service publications (USFWS, 4401 N. Fairfax Dr., Arlington, VA 22203; www.fws.gov/). Further information on US endangered species is available from www.natureserve.org, a private database providing legal status and general information on all species listed by The Nature Conservancy as Imperiled.

Environmental Vacations: Volunteer Projects to Save the Planet, by Stephanie Ocko, 2nd edition, John Muir Publications, 1992. Distributed by W.W. Norton & Co., 248 pages. This book describes ways in which nonscientists can assist experts in activities (such as monitoring the diversity of rainforests), observing animal behavior or other projects, giving particulars on the projects and how to become involved.

The Globe program for classrooms involves students from around the world who participate in ecology studies by gathering and analyzing data; ncdc.noaa.gov/GLOBE/globe.html. It is affiliated with the National Oceanic and Atmospheric Administration (NOAA).

Green Teacher, P.O. Box 1431, Lewiston, NY 14092; or in Canada, 95 Robert St., Toronto, Ontario M5S 2K5, Canada. Five issues per year, $27.00; sold on newsstands also. This magazine is very well done. It lists environmental projects and activities and has a humane orientation. Some articles are in both French and English.

Knowledge Unlimited, P.O. Box 52, Madison, WI 53701-0052; www.ku.com. This catalog lists videos, filmstrips, resource guides, classroom posters, books and other educational materials under major categories, including Science, which has many listings on endangered species and environmental topics.

National Geographic Society. The Educational Services department of the National Geographic Society provides material, films and filmstrips on general science and biology, including endangered species and habitats. Its free catalog, fiSchool Publishing,fl for Grades K-12 offers a wide variety of environmental books, videos, CD-ROMs and other visual material accompanied by teachers™ guides. An Internet site designed for teachers gives further detail: www.nationalgeographic.com/education. One learning packet centers on the Tiger. The teaching guide includes lessons on habitat, populations, adaptation, predator/prey relationships, conservation and scientific studies, accompanied by two videos the society produced on the species, slides, posters and student handouts. Another teaching unit describes The Jason Project Expeditions, sponsored in part by the National Geographic Society. Each centers on a part of the world. These kits combine studies of a variety of disciplines centered on an area or country: biology, climate study, geology and others.

Students learn how to measure pollutants and study endangered species™ diets. These lessons are also shown on the new National Geographic television channel. An interactive encyclopedia CD-ROM on Mammals, for Grades 2-12, allows students to see and hear more than 200 mammals through photos, range maps, acoustics, facts on endangered species, mystery games that test powers of deduction, and a lesson plan booklet. Videos made for the classroom on many subjects include a series on bioscience, showing life cycles of various insects, a trout river ecosystem, and other themes for various grade levels. Each includes a teacher™s guide and is described in the Teacher Store page or in the Video and Media Catalog. Anatomy of frogs and other animals are included in material that teaches function, taxonomy and structure. For the growing number of teachers and students who would rather find another means of learning about frog or mammal anatomy rather than dissection, especially in view of the declining status of frogs, this material provides a solution. (Also see the Projects Section in this book, fiLearning Animal Anatomy Without Dissection.fl)

Rainforest Teacher™s Packet.Rainforest Action Network, 221 Pine St., Suite 500, San Francisco, CA 94104. Educational materials listed on www.ran.org; Phone: 415-398-4404. Students and others may sign up for fiaction alertsfl on issues affecting the world™s rainforests.

The Rainforest Book. How you can save the world™s rainforests, by Scott Lewis with the Natural Resources Defense Council, Living Planet Press, 1990. Aimed toward students, the text has chapters on the importance of rainforests, both tropical and US temperate rainforests, how they can be saved and how individuals can help with specific examples of aiding organizations, encouraging local businesses not to buy rainforest products, visiting rainforests, adopting an acre of rainforest, and further reading, films and other information sources.

Save America™s Forest. Citizen Action Guide The activist organization, Save America™s Forests, has published a 51-page how-to guide for citizens and/or students to work within communities to educate others on the decline of America™s forests from clearcutting and over-harvesting. It is available online at www.saveamericasforestsfund.org. Also available from this organization, a slide show, fiClearcuts Coast to Coastfl (purchase or rental); an annotated bibliography on forests; and the award-winning video, fiThe Last Ancient Forestsfl (11 minutes, purchase $7). Save America™s Forests, 4 Library Ct., SE, Washington, DC 20003; www.saveamericasforests.org; Phone: 202-544-9219.

Science Teacher. National Science Teachers Association, 1840 Wilson Blvd., Arlington, VA 22201-3000; Phone: 703-243-7100; www.nsta.org. Published nine times a year, this is a valuable periodical, aiding teachers of

environmental subjects.

Teacher™s Guide to World Resources and Biodiversity(ISBN 0-7872-4259-4), 2001. This guide provides economic, ecological, ethical and esthetic reasons why we should care that species are becoming extinct. Students explore the root causes of biodiversity loss and strategies for conservation. Cost is $9.99. Published and distributed by Kendall Hunt, it can be ordered online through their Web site. The site also includes fiEndangered Forestsfl and many other titles on the environment. Discounts are given to teachers who order in bulk. Web site: www.kendallhunt.com; Phone: 1-800-542-6657.

fiUnderstanding Biodiversity.fl Encyclopedia Britannica™s 19-minute video is aimed at high school students. It stresses the need for ecosystems to have diverse life forms and the important roles different types of scientists play in biodiversity preservation. The cloud forests of Venezuela are the background for teaching this subject. A Teacher™s Guide is included, listing objectives and suggestions for classroom discussion topics. Encyclopedia Britannica Educational Corporation (1-800-554-9862).

fiBritannica. Electronic Media Catalogfl descries many videos (without teachers™ guides) on the environment and wildlife. It also offers a fiGuide to Dissection,fl in which a video software package with four parts shows dissections of a rat, frog, pigeon and dogfish. Using software, the student can do a virtual dissection with a computer mouse.

Video Project. Free catalog of educational environmental videos for use in schools and libraries. Video Project, P.O. Box 77188, San Francisco, CA 94107; Phone: 1-800-4-PLANET; www.videoproject.net.

The Wild Ones. The Wildlife Trust (formerly the Wildlife Preservation Trust) is a sister organization to the Durrell Conservation Trust in the United States, founded by Gerald Durrell, noted author and conservationist, which works on environmental and endangered species programs throughout the world. For students, the organization sponsors fiThe Wild Onesfl (www.thewildones.org), which includes a newsletter, *The Wild Ones*, and accompanying fiTeacher Connection,fl both of which can be downloaded from its Web site. The latter enrolls classes and provides suggestions for curriculum activities involving conservation, endangered species, natural history and related topics that complement the newsletter. *The Wild Ones* is also published in other countries, such as Mexico, translated into Spanish, with added topics pertaining to that country™s environment and wildlife.

Letters and artwork from students around the world are published on the site. Through the Web site, students can write the scientists working on various projects for the organization. The newsletter for the general membership, *On the Edge*, often focuses on particular endangered species; recent issues may be accessed through the Web site under fiField Notes,fl with the year of publication. The organization in the United Kingdom, which publishes the newsletter *The Dodo Dispatch* (ages 7-16), and the Canadian sister organization can be reached through the Web site as well. The Wildlife Trust, 61 Route 9W, Palisades, NY 10964-8000; Phone: 845-365-8337; www.wildlifetrust.org.

Wildlife Review Abstracts, National Information Services Corporation, 3100 St. Paul St., Suite 806, Baltimore, MD 21218. Formerly a quarterly report published by the US Fish and Wildlife Service, these annotated bibliographies are now a privately run database system with 514,000 entries of publications on wildlife and the environment, indexed by species, subject and geographical areas. Abstracts from wildlife, fisheries, ornithological, ecological and forestry journals are sold through a yearly subscription for $1,045. The data is available on CD-ROM and is compiled from many sources. The Wildlife Species Information Library at the site includes data on habitats in states from a DOS-based CD-ROM or 45,000 pages of online species™ profiles. Phone: 410-243-0797; www.nisc.com.

Teachers' Aids and Educational Materials

Teachers' Aids
The American Biology Teacher. Published by the National Association of Biology Teachers, 12030 Sunrise Valley Dr., Reston, VA 20191; www.nabt.org; Phone: 1-800-406-0775. Although not primarily concerned with endangered species, this magazine occasionally has information on this subject.

Bullfrog Films™ catalog includes an extensive collection of educational films on the environment and wildlife, many of which are thought provoking and could serve as the basis for discussion. The catalog lists recommended grade levels and awards, accreditation and other background information on each film along with descriptions of the content. Some of the films are reviewed in the video section. www.bullfrogfilms.com; Phone: 1-800-543-3764.

Discovery Channel School. fiDiscovery Channel School K-12 Catalogfl lists materials, such as CD-ROMs and videos, which are packaged together. For example, the Insects packet includes a CD-ROM, a student resource book, fiInsect Files,fl a Teachers™ A-Z Resource Guide on Insects, and an Internet site featuring electron microscope images of insects and fiB-Eye: The World Through the Eyes of a Beefl to show what a flower looks like to a bee. Other packets with CD-ROMs, teachers™ guides and student resource books include: fiPlants,fl fiReptiles,fl fiFish and Amphibians,fl fiInvertebrates,fl fiProtists and Fungi,fl fi Mammals,fl fiBirds,fl fiEvolutionfl and fiEcology.fl The latter title™s Internet link features suggestions on projects to save beaches, a global warming debate about coral reefs, and fiEarth Today.fl Each CD-ROM contains a long video as well as library searches of references, a digital lab and instructions for presentations of slides, text and sound effects to be created by the students. Among the selections in the fiEarth Sciencefl CD-ROM bundle is fiConservation of Natural Resources.fl The latter CD-ROM is also offered in a bundle along with a student resource book, a teacher™s guide and Internet links. Videos geared toward school classes have themes divided into segments. Titles for grades 6 to 12 include: fiFinite Oceansfl on the limits of oceans to absorb pollutants and provide resources; fiCoral Reefsfl explores the Red Sea, an extremely diverse coral ecosystem; fiUnderstanding Oceansfl explains their movements, tides, endangered creatures and experts; fiWater: To the Last Dropfl investigates the contamination and misuse that threatens the limited supplies of freshwater upon which we depend; www.discoveryschool.com.

Conserving Earth™s Biodiversity by Edward O. Wilson and Dan L. Perlman, 1999. Island Press, Covelo, CA (interactive CD-ROM teaching conservation biology and environmental science). Teachers can register for an examination copy and view a demo at: www.islandpress.org/wilsoncd. Senior author is Harvard University professor, author of *The Diversity of Life* and editor of *Biodiversity*, key books on the subject.

Earthwatch. This bimonthly periodical, published by Earthwatch, is available by subscription and is sold by many newsstands. Earthwatch sponsors research projects by scientists. Contributors, scholarship and fellowship students may accompany scientists on their expeditions. Projects have included studies of threatened plants and animals and their disappearing habitats in Australia, Brazil and Thailand; endangered sea turtle ecology in Baja California, Mexico; and Florida Manatees. A typical project is carried out by a scientist affiliated with a well-known university or institution. Volunteers pay to assist the scientists by making observations, taking photographs and performing miscellaneous duties for a period of about two weeks. Active participation in the study depends on the health, interests and abilities of the volunteer. Many teachers go on expeditions, taking copious notes and photos, and use the experience as a teaching outline for courses. Students may also be sponsored by their class or family. Volunteers must be 16 years or older. For those unable to participate in research trips, project briefings are available for $15 each, written by the scientists heading each project, with background information and results as available. There are scholarships and fellowships offered to selected applicants. Earthwatch Institute, 3 Clock Tower Place, Suite 100, P.O. Box 75, Maynard, MA 01754-9928; Phone: 1-800-776-0188; www.earthwatch.org has more than 5,000 pages of background information on projects, a global classroom, an education site, and a virtual expedition. The site has won more than 25 awards for excellence.

Endangered Means There™s Still Time This free US Fish and Wildlife Service brochure explains the basic causes endangering species. The brochures, fiPlacing Animals and Plants on the List of Endangered and Threatened Speciesfl and fiESA Basicsfl explain the listing process, critical habitat and other facets of the US Endangered Species Act. fiWhy Save Endangered Species?fl presents strong arguments for the preservation of biodiversity as it benefits human health and agriculture and tells how animals can be barometers of environmental quality, warning us of the dangers of pesticides, for example. Other brochures include profiles of the Mexican Wolf, Red Wolf, Whooping Crane and others. fiConserving Borderline Species, A Partnership between the United States and Canadafl is a report describing the cooperative programs that have helped Whooping Cranes, Swift Foxes, Black-footed Ferrets and other wildlife and plants that inhabit both sides of the Canada/US border region. A poster entitled fiThe Road to Recoveryfl illustrates some of the species that, because of the Endangered Species Act, have increased in numbers from Near-extinction: the Grizzly Bear, Bald Eagle, Lange™s Metalmark Butterfly, Gray Whale and Greenback Cutthroat Trout. By calling the Publications Unit of the US Fish and Wildlife Service (304-876-7203) or the Office of Endangered Species, one can also request fact sheets on a selected number of US endangered species and copies of US Fish and Wildlife Service publications (USFWS, 4401 N. Fairfax Dr., Arlington, VA 22203; www.fws.gov/). Further information on US endangered species is available from www.natureserve.org, a private database providing legal status and general information on all species listed by The Nature Conservancy as Imperiled.

Environmental Vacations: Volunteer Projects to Save the Planet, by Stephanie Ocko, 2nd edition, John Muir Publications, 1992. Distributed by W.W. Norton & Co., 248 pages. This book describes ways in which nonscientists can assist experts in activities (such as monitoring the diversity of rainforests), observing animal behavior or other projects, giving particulars on the projects and how to become involved.

The Globe program for classrooms involves students from around the world who participate in ecology studies by gathering and analyzing data; ncdc.noaa.gov/GLOBE/globe.html. It is affiliated with the National Oceanic and Atmospheric Administration (NOAA).

Green Teacher, P.O. Box 1431, Lewiston, NY 14092; or in Canada, 95 Robert St., Toronto, Ontario M5S 2K5, Canada. Five issues per year, $27.00; sold on newsstands also. This magazine is very well done. It lists environmental projects and activities and has a humane orientation. Some articles are in both French and English.

Knowledge Unlimited, P.O. Box 52, Madison, WI 53701-0052; www.ku.com. This catalog lists videos, filmstrips, resource guides, classroom posters, books and other educational materials under major categories, including Science, which has many listings on endangered species and environmental topics.

National Geographic Society. The Educational Services department of the National Geographic Society provides material, films and filmstrips on general science and biology, including endangered species and habitats. Its free catalog, fiSchool Publishing,fl for Grades K-12 offers a wide variety of environmental books, videos, CD-ROMs and other visual material accompanied by teachers™ guides. An Internet site designed for teachers gives further detail: www.nationalgeographic.com/education. One learning packet centers on the Tiger. The teaching guide includes lessons on habitat, populations, adaptation, predator/prey relationships, conservation and scientific studies, accompanied by two videos the society produced on the species, slides, posters and student handouts. Another teaching unit describes The Jason Project Expeditions, sponsored in part by the National Geographic Society. Each centers on a part of the world. These kits combine studies of a variety of disciplines centered on an area or country: biology, climate study, geology and others.

Students learn how to measure pollutants and study endangered species™ diets. These lessons are also shown on the new National Geographic television channel. An interactive encyclopedia CD-ROM on Mammals, for Grades 2-12, allows students to see and hear more than 200 mammals through photos, range maps, acoustics, facts on endangered species, mystery games that test powers of deduction, and a lesson plan booklet. Videos made for the classroom on many subjects include a series on bioscience, showing life cycles of various insects, a trout river ecosystem, and other themes for various grade levels. Each includes a teacher™s guide and is described in the Teacher Store page or in the Video and Media Catalog. Anatomy of frogs and other animals are included in material that teaches function, taxonomy and structure. For the growing number of teachers and students who would rather find another means of learning about frog or mammal anatomy rather than dissection, especially in view of the declining status of frogs, this material provides a solution. (Also see the Projects Section in this book, fiLearning Animal Anatomy Without Dissection.fl)

*Rainforest Teacher™s Packet.*Rainforest Action Network, 221 Pine St., Suite 500, San Francisco, CA 94104. Educational materials listed on www.ran.org; Phone: 415-398-4404. Students and others may sign up for fiaction alertsfl on issues affecting the world™s rainforests.

The Rainforest Book. How you can save the world™s rainforests, by Scott Lewis with the Natural Resources Defense Council, Living Planet Press, 1990. Aimed toward students, the text has chapters on the importance of rainforests, both tropical and US temperate rainforests, how they can be saved and how individuals can help with specific examples of aiding organizations, encouraging local businesses not to buy rainforest products, visiting rainforests, adopting an acre of rainforest, and further reading, films and other information sources.

Save America™s Forest. Citizen Action Guide The activist organization, Save America™s Forests, has published a 51-page how-to guide for citizens and/or students to work within communities to educate others on the decline of America™s forests from clearcutting and over-harvesting. It is available online at www.saveamericasforestsfund.org. Also available from this organization, a slide show, fiClearcuts Coast to Coastfl (purchase or rental); an annotated bibliography on forests; and the award-winning video, fiThe Last Ancient Forestsfl (11 minutes, purchase $7). Save America™s Forests, 4 Library Ct., SE, Washington, DC 20003; www.saveamericasforests.org; Phone: 202-544-9219.

Science Teacher. National Science Teachers Association, 1840 Wilson Blvd., Arlington, VA 22201-3000; Phone: 703-243-7100; www.nsta.org. Published nine times a year, this is a valuable periodical, aiding teachers of environmental subjects.

Teacher™s Guide to World Resources and Biodiversity(ISBN 0-7872-4259-4), 2001. This guide provides economic, ecological, ethical and esthetic reasons why we should care that species are becoming extinct. Students explore the root causes of biodiversity loss and strategies for conservation. Cost is $9.99. Published and distributed by Kendall Hunt, it can be ordered online through their Web site. The site also includes fiEndangered Forestsfl and many other titles on the environment. Discounts are given to teachers who order in bulk. Web site: www.kendallhunt.com; Phone: 1-800-542-6657.

fiUnderstanding Biodiversity.fl Encyclopedia Britannica™s 19-minute video is aimed at high school students. It stresses the need for ecosystems to have diverse life forms and the important roles different types of scientists play in biodiversity preservation. The cloud forests of Venezuela are the background for teaching this subject. A Teacher™s Guide is included, listing objectives and suggestions for classroom discussion topics. Encyclopedia Britannica Educational Corporation (1-800-554-9862).

fiBritannica. Electronic Media Catalogfl descries many videos (without teachers™ guides) on the environment and wildlife. It also offers a fiGuide to Dissection,fl in which a video software package with four parts shows dissections of a rat, frog, pigeon and dogfish. Using software, the student can do a virtual dissection with a computer mouse.

Video Project. Free catalog of educational environmental videos for use in schools and libraries. Video Project, P.O. Box 77188, San Francisco, CA 94107; Phone: 1-800-4-PLANET; www.videoproject.net.

The Wild Ones. The Wildlife Trust (formerly the Wildlife Preservation Trust) is a sister organization to the Durrell Conservation Trust in the United States, founded by Gerald Durrell, noted author and conservationist, which works on environmental and endangered species programs throughout the world. For students, the organization sponsors fiThe Wild Onesfl (www.thewildones.org), which includes a newsletter, *The Wild Ones*, and accompanying fiTeacher Connection,fl both of which can be downloaded from its Web site. The latter enrolls classes and provides suggestions for curriculum activities involving conservation, endangered species, natural history and related topics that complement the newsletter. *The Wild Ones* is also published in other countries, such as Mexico, translated into Spanish, with added topics pertaining to that country™s environment and wildlife.

Letters and artwork from students around the world are published on the site. Through the Web site, students can write the scientists working on various projects for the organization. The newsletter for the general membership, *On the Edge*, often focuses on particular endangered species; recent issues may be accessed through the Web site under fiField Notes,fl with the year of publication. The organization in the United Kingdom, which publishes the newsletter *The Dodo Dispatch* (ages 7-16), and the Canadian sister organization can be reached through the Web site as well. The Wildlife Trust, 61 Route 9W, Palisades, NY 10964-8000; Phone: 845-365-8337; www.wildlifetrust.org.

Wildlife Review Abstracts, National Information Services Corporation, 3100 St. Paul St., Suite 806, Baltimore, MD 21218. Formerly a quarterly report published by the US Fish and Wildlife Service, these annotated bibliographies are now a privately run database system with 514,000 entries of publications on wildlife and the environment, indexed by species, subject and geographical areas. Abstracts from wildlife, fisheries, ornithological, ecological and forestry journals are sold through a yearly subscription for $1,045. The data is available on CD-ROM and is compiled from many sources. The Wildlife Species Information Library at the site includes data on habitats in states from a

DOS-based CD-ROM or 45,000 pages of online species™ profiles. Phone: 410-243-0797; www.nisc.com.

Television Series

Over the past decade, more and more nature programs are being produced for television. The interest shown by the public in these programs is growing. Some of these programs are described below, and special films on wildlife are reviewed in the Films section.

Discovery Communications Inc., which sponsors the Discovery Channel, Animal Planet, and other channels, shows many hours of natural history films each week. Animal Planet shows animal programs exclusively, some of which deal with endangered species. The channel has been very successful, and the new National Geographic channel has many wildlife and environmental documentaries. Other than the occasional National Geographic Society special aired on NBC, major networks do not have regular prime-time programs on the environment or wildlife. By contrast, PBS airs regular programs on these subjects. These programs, including Nature, NOVA, David Attenborough's Natural World and others, have been shown for decades, as PBS led the way in airing high quality, informative and beautiful programs on wildlife and natural history.

Animal Rescue. Syndicated.
This one-half hour weekly program gives many examples of people helping animals or, in some cases, animals helping other animals through various crises. Moose and deer that have fallen into freezing water are pulled to safety, oiled birds, injured turtles and starving sea lions are rescued and rehabilitated, and there are many stories about help for stranded or injured pets and domestic animals. Veterinary care is described, and much interesting information is given about positive examples of humane treatment of animals. At the end of the program, ARK gives general tips about helping animals

Assignment Discovery. Discovery Channel.
On weekdays during the school year, this one•hour program is shown between 9 and 10 a.m., with a format designed especially for teachers to tape for use throughout the year. At least once a week, a program is dedicated to natural science. Commercials have been removed and the programs contain highlights from prime-time programs. Web page: www.discovery.com. There are also species sites such as "Lizards!": www.discovery.com/exp/lizards/lizards.html

National Geographic Explorer. MSNBC.
This weekly two-hour program highlights films by the National Geographic Society, as well as those of other film producers. Many of these films deal with endangered species and wildlife conservation. Some are distributed commercially by the National Geographic Society, but the majority is not commercially available. This program has an Internet page for more information on specials and programs shown: www.nationalgeographic.com

Nature. PBS.
One of the finest wildlife and natural history programs on television, Nature has high•quality photography, well-written and interesting narrative, and often, unusual subject material. Produced by WNET, the PBS station in New York, films produced by the British Broadcasting Co. (BBC), Survival Anglia, Partridge Films, Wolfgang Bayer and other producers are shown. The weekly one-hour programs are repeated. See reviews below. They are available from PBS (see Distributors list).

NOVA. PBS.
Produced by WGBH in Boston, MA, these one-hour films have garnered many awards. Programs relate to wildlife conservation, astronomy, sociology and many other subjects. Some NOVA films have centered on endangered species and habitats, such as the Great Barrier Reef and condors. They may be taped for classroom use within seven

days of broadcast. Videocassettes of the programs are available. NOVA teacher's guide, a semi•annual publication, presents discussions of the programs with quizzes and lesson plans. This may be subscribed to at www.pbs.org/nova/teachers/guidesubscribe.htmp or viewed on line at http://main/wgbh.org/wgbh/learn/teacherscenter. This site provides major projects, partner schools, professional development workshops and favorite links. The printed copy can be ordered from WGBH, 125 Western Avenue, Boston, MA 02134. Videocassettes can be ordered from: WGBH NOVA Videos, P.O. Box 2284, South Burlington, VT 05407•2284.

Today. National Geographic Channel.
This daily, hour-long program reviews natural history news, including some longer reports on endangered species and programs to aid them as well as environmental items of interest. The program also has items that are reflective of its magazine content, such as profiles of native tribes, country highlights and geography. It is the only such program on television since "Earth Matters," CNN's excellent weekly environmental news program, was cancelled.

Films as Educational Aids

Video involving endangered animals and plants is now of amazing quality and interest, an exciting trend. Films on disappearing wildlife are no longer focused on zoo animals, but on animals in the wild. This is extremely important in educating and motivating the public, as well as students, to preserve these vanishing treasures and their beautiful--but fragile--environments. As wildlife films grow in popularity, filmmakers are tackling ever more unusual challenges to find extremely rare animals or remote habitats, spending years to obtain magnificent footage. Some animals being captured on film have only just been described scientifically and have never before been filmed. The results are sometimes dazzling, with imaginative presentation. For the viewer and student, such fascinating subjects are not only educational, but provide a free trip to beautiful parts of the world where wildlife can be seen in natural habitats, exhibiting natural behavior not seen in zoo animals. Many endangered animals inhabit magnificent landscapes, from alpine meadows framed by snowy mountains in New Zealand to remote rainforests in Brazil or Madagascar. The best of these films have been made by cinematographers with a great deal of natural history knowledge or guidance, showing distinctive features of animals and plants, as well as threats to their survival and habitats. To see a Harpy Eagle, the largest eagle in the world, at close range at its nest more than 100 feet above the forest floor, caring for chicks and arriving with prey as large as sloths, is an exciting spectacle that will also encourage the preservation of this endangered species.

Some classic films combine information with an artistic eye and a narrative that provides viewers with a new perspective. Among these are "Baobab: Portrait of a Tree;" "Korup--An African Rainforest;" "The Living Planet" series; "Among the Wild Chimpanzees;" "Reflections on Elephants;" and "The Private Life of Plants." Such films provide eloquent and intelligent lessons that teach not only basic information about the habitats and species focused upon, but argue strongly in favor of their conservation. Saving wild places and habitats is the most important tool in preventing extinctions, and these films make this clear. Some films also show the tragic slaughter of rare animals and destruction of habitats, the better to call attention to why these activities must be stopped and to make real the plight of nature. Lessons about biological diversity are an intrinsic part of many films as well, although this has often been more intimated than stressed openly.

The viewer who sees the final product rarely imagines the hardships and imaginative use of technology that went into the film's production. "Wildfilm," a 1995 documentary (Partridge Film Ltd. and Television New Zealand Natural History Productions, shown on PBS), describes how natural history films are made, with many delightful encounters between filmmakers and animals. It divulges many of the secrets used, such as a remote-controlled miniature helicopter equipped with a camera that provides aerial views of mountainous terrains and night filming of difficult

subjects. Difficulties included cameras freezing while filming Emperor Penguins at 60 degrees below zero F. Technological advances now permit microphotography by film producers, such as Oxford Films, of natural worlds invisible to the naked eye. Superb underwater photography is also capturing coral reef creatures and the fantastic animals that live in deep-sea habitats. Another innovation is the approach used in IMAX films, projecting many cameras on giant screens, giving the viewer a dramatic sense of entering into the film. They are shown at some 20 specialized theaters, most of which are in science museums.

In some cases, filmmakers risk their lives to obtain their final products. In 1993, one of the greatest wildlife and nature cinematographers, Dieter Plage, fell to his death from a film platform 150 feet up a tropical forest tree. The dangers of this vocation also include attacks by wild animals, accidents, tropical diseases, and even clashes with local people. Many of these filmmakers are dedicated conservationists, and their portrayals of wildlife contribute to conservation efforts. Several organizations convene wildlife film festivals, awarding prizes in various categories, and occasionally, Academy Awards are presented to wildlife filmmakers. Many of the reviews below give credit to the filmmakers, the best of whom must combine qualities from intellectual curiosity to artistry of presentation, along with physical endurance.

Some filmmakers have been criticized in the past for staging dramatic scenes for wildlife movies, often harming or killing animals in the process. Such criticism was sometimes justified, and stricter permit regulations on the part of various countries have reduced some of the more flagrant examples of past abuses. In other cases, filmmakers are witness to extreme suffering by animals because of accidents, disease or starvation. Many national parks prohibit human intervention. However, in some situations, people created the crises.

One tragic case involved a group of Cheetahs in Namibia. First, a Lion killed a finanny,fl or non-breeding female Cheetah, in this group, who helped watch the cubs; then the breeding female died soon after of anthrax. Three of the five cubs quickly died of starvation, being too young to hunt alone, and the two surviving male cubs set out alone on the sunbaked desert. One emaciated cub collapsed, while the other tried desperately and unsuccessfully to catch a Bat-eared Fox. The weaker cub was filmed as it tried valiantly to raise itself from the ground when jackals arrived, who had sensed his condition. Unable to remain standing, the cub's hindquarters gave way, and he fell to the ground, his eyes wild and unfocused. The filmmakers, nose to the ground, recorded his death.

Cheetahs are highly endangered and declining throughout their range, persecuted in southern Africa by ranchers whose careless management of livestock caused the deaths of a mother and her cubs. Intervention in this case was warranted. They could have easily captured the skeletally thin and weak Cheetah cubs. There are two rescue centers in Namibia for these endangered and beleaguered wild cats. This film, "Etosha, Africa's Untamed Wilderness," is part of Reader's Digest's Living Edens series, produced in 1997 by ABC/Kane Productions, and filmed by Adrian Warren and Justin Maguire. A code of ethics for wildlife filmmakers should include interventions in such cases.

Although more and more filmmakers are traveling to record the diversity of Borneo, Madagascar, Costa Rica and other species-rich environments, too many films are still being made of large East African mammals, such as wildebeest and their predators. Many fascinating areas have not been visited by cinematographers. Rainforest birds, for example, are rarely filmed, with a few exceptions, nor are the endangered temperate forests of Australia or South America. Many of the "hot spots" of biological diversity, such as Madagascar, Mauritius, New Zealand and southwestern India, have been the subjects of films, but other areas, including the Philippines, South Africa, New Caledonia, and the Ecuadorian highlands, have almost never been seen in nature films. Yet these areas are teeming with extraordinary wildlife and plants that would fascinate viewers.

Rare trees and plants are also being ignored, to their detriment. Many of the most unusual trees of the world, from the Monkeypod Tree of South America to the towering Kauris and their relatives of New Zealand, Australia and New Caledonia, are highly endangered, and visually stunning. The latter are survivors of the supercontinent Gondwana, as are the rare protea flowering plants of South Africa. Yet many of these plants are on the verge of extinction, being logged, overcollected or otherwise destroyed. A film about these fragments that have lived on Earth for 100 million

years or more, some pre-dating the dinosaurs, would be extremely interesting and important for their conservation by raising awareness of their plight. The value of trees in producing oxygen, holding the soil in place, preventing floods and providing habitat for wildlife is of vital importance, yet the last of the old-growth forests, the richest in species of all forests, are being cleared for agriculture and wood products. This subject--as well as the crucial role that invertebrates play in symbiotic relationships with plants, pollination and other ecological roles--needs far more attention from filmmakers. Catastrophes such as floods and landslides are often the result of wetland filling and forest clearing, yet films on these subjects usually dwell on the sensational aspects, stressing the dramatic footage of houses and vehicles destroyed and survival stories. Nature's great value to human society is not understood by the majority of people, and several fascinating books have been written to explain and even place a monetary value on natural ecosystems vs. the value of exploited natural resources. Such studies would make fascinating films and provide logical arguments to oppose the constantly accelerating trend toward commercial exploitation and destruction of the environment worldwide.

The value of films in providing a record of endangered species was made clear in the film, "Rain Forest," by the National Geographic Society. The brilliant Golden Toads of Costa Rica, seen in their mating gatherings, disappeared a few years later and have not been seen since. Video of the great African Elephant herds prior to the 1980s slaughters represents another example of wildlife spectacles that may never return because of the increase in human population and development of wildlife habitat. As wilderness areas shrink, films should be made of these regions, both aerially and at ground level, to record these precious remnants of the entire planet as it once appeared, to argue for their protection and to inventory their native wildlife and plants.

For many films, especially those shown on PBS, companion books and teaching guides that provide additional information have been written. Books and articles on endangered species become all the more interesting and relevant after seeing films on the same subject. By combining films and literature on endangered species, both students and the public in general can grasp the essentials of the major threats to endangered species and the many fascinating and unique species that are in imminent danger of disappearing.

A learning program on Madagascar, for example, can be brought to life when seeing films of the delightful lemurs and other native wildlife, accompanied by books such as Ken Preston-Mafham's 1991 book, *The Natural History of Madagascar*, and other references on the subject in the Books and Publications section. (See descriptions of Madagascar and its wildlife in the Madagascar and Other Islands chapter of this book.) Many films on Madagascar and its wildlife are reviewed below.

The last wilderness retreats of numerous endemic and rare species are in danger from logging, livestock and other exotic species, mining and other destruction. Some are so breathtakingly beautiful that it is difficult to comprehend that for many people, these regions and their fragile wildlife and plants are without value or importance. The majority of people on Earth are struggling to survive and do not understand that the loss of these places can affect them. As ecosystems become unbalanced, food supplies are threatened by droughts, and poverty increases. Much needs to be done to aid these people to live in harmony with nature and to provide them with financial aid. Some of these films address these issues and provide solutions. Films can be of great importance in teaching people around the world about the crises that are facing us as the last old-growth forests are cut down, and the loss of biological diversity, which stabilizes nature, will cause a myriad of other ecological disasters. Films reviewed here show the complexity, beauty and majesty of many types of forests--cloud, temperate and tropical rain, and deciduous--and their importance in absorbing carbon dioxide and producing oxygen, as well as providing habitat for untold numbers of animals. For nearly every ecological crisis now facing us, a film explains the problem--at least its basics--and, above all, illustrates what is being lost because of ignorance and greed.

Films can also show the endearing sides of wildlife that touch the heart, the devotion of elephants for one another, the gentle affection between lemurs, chimpanzees and other animals. Their intelligence, athleticism and other qualities can amaze the viewer. Our compassion is aroused when we see films of animals dying in traps, harpooned, shot, orphaned or otherwise suffering. The many films shown in North America about the Gray Wolf have inspired a

public interest in the species' conservation and sparked a new ecotourism around the reintroduced wolves of Yellowstone National Park. Although some people, primarily livestock ranchers, remain prejudiced against wolves, they have become a minority. This contrasts dramatically with the situation in other parts of the world where wolves are being driven to extinction because of misunderstandings about their ecological importance and their supposed threats to humans and livestock. Many films have shown the loyalty and devotion wolves display to one another, even at the risk of their lives. These qualities are the very ones esteemed in dogs, who were descended from wolves.

Without a film record of animal behavior, such as that of the wolf, the qualities described by observers and scientists might be treated with more skepticism, as they were in the past. It is difficult, for example, for those who have portrayed the wolf as a vicious and dangerous animal, to maintain this view in the face of film documentation that provides a fact-based view. For this reason, films can be a more powerful and influential educational tool than the written word.

Endangered Species Lists
Note that the US Endangered Species Act legally protects species listed, Convention on International Trade in Endangered Species (CITES)-listed species are internationally controlled legally, while IUCN Red List species do not necessarily have legal protection.

U.S. Endangered and Threatened Wildlife and Plants, 50 CFR 17.11 & 17.12, Sept. 1993, *Federal Register*.

Also now available through Internet, updated lists of the Endangered Species Act, copies of the Act as amended, species maps and candidate listings. E-mail should use R9IRMLIB@mail.fws.gov

World Conservation Monitoring Center. 1994. *1994 IUCN Red List of Threatened Animals*. IUCN Species Survival Commission, 286 pages. (Red Data Book species only.)

World Conservation Monitoring Centre. 1993. *World Checklist of Threatened Amphibians and Reptiles.* WCMC and Joint Nature Conservation Committee, Cambridge, UK, 991 pages (with bibliography). (CITES and Red Data Book species.)

World Conservation Monitoring Centre. 1993. *World Checklist of Threatened Birds*. WCMC and Joint Nature Conservation Committee, Cambridge, UK, 308 pages (with bibliography). (CITES and Red Data Book species.)

World Conservation Monitoring Centre. 1993. *World Checklist of Threatened Mammals*. WCMC and Joint Nature Conservation Committee, Cambridge, UK, 150 pages (with bibliography). (CITES and Red Data Book species.)

World Conservation Monitoring Centre. 1993. *Checklist of Fish and Invertebrates listed in the CITES Appendices*. WCMC, 183 pages.

Note: For individual country red data lists, see Regional Section, this list. For state endangered lists, contact state wildlife departments.

Zoos, Captive Breeding, Recovery and Reintroduction
