Just how many species native to grassland and dryland habitats are threatened has not been calculated by either the 1994 or 1996 *IUCN Red List*. Only for birds have such analyses been made. BirdLife International, in *Birds to Watch 2: The World List of Threatened Birds* (Collar *et al*. 1994), concluded 6.3 percent of all threatened birds were grassland species, and a slightly larger percentage, 9.3 percent, were native to shrub and desert. Thus, 15.6 percent of the world's 1,111 threatened birds (173 species) inhabit grassland, shrub or desert (Collar *et al*. 1994). This is a significant percentage of the world's birds, and it is evidence that these regions are under great siege from a variety of factors. In the *2000 IUCN Red List* (Hilton-Taylor 2000), only forest areas had more threatened birds than shrubland

(about 22 percent) and grassland (15 percent). Likewise, for 515 threatened mammals, grassland was the second most important type of habitat after forests, with approximately 18 percent of all threatened species. Some 8 percent inhabited a shrubland (Hilton-Taylor 2000), and semi-desert and desert provided key habitats for many other mammals.

Loss of habitat is the primary threat to the species, but other causes include decreasing water tables and desertification, competition for food with livestock, and mining or other activities that completely eliminate habitats. Hunting and persecution in these open habitats is another threat to grassland and dryland species**.** Large mammals of open grasslands and deserts are highly vulnerable to hunting and persecution by nomadic herders who consider them unwelcome competitors for grassland.

The introduction of exotic plants has destroyed many bird habitats because some species are dependent on a certain type of vegetation for food or cover. Some plants have been deliberately spread, and others were nursery and garden plants that spread to the wild. Such introductions have been catastrophic in some areas, when exotic species of grasses and shrubs overtake native vegetation. The latter type rarely provides habitat or food supply for resident wildlife. In some cases, birds rely on a very specific type of habitat, such as grassland with scattered shrubs of native species. Birds and other wildlife with such specialized requirements are highly vulnerable to disappearance due to human-caused changes.

Off-road vehicles driven on fragile desert soils have destroyed habitats for a wide range of species. They cause instant mortality to tortoises, lizards and other animals, crushing them under their wheels and destroying their underground burrows. These vehicles kill slow-growing plants that are easily uprooted from the sandy soil. Dryland plants anchor the soils and provide a lifeline of shelter and food for native wildlife. Desert soils have thin layers of lichen on the surface that prevents soil particles from being blown away by the wind. Trampling by livestock and crushing by vehicular traffic destroys this fragile soil cover, promoting erosion and devegetation. In many parts of the Sahara, the Saudi Arabian Peninsula and portions of American deserts, off-road vehicles have eliminated virtually all vegetation, causing local extinctions of native wildlife.

Building fences for livestock or agriculture has also proved lethal to millions of wild ungulates, preventing their natural migrations and causing mortality when they attempted to leap over them. In Africa, Australia and North America, millions of animals have crashed into fences, subsequently dying from the collisions, starvation or dehydration as they were prevented from reaching vegetation and water. Few governments have legislation or sufficient parkland to protect wildlife threatened by the great numbers of livestock now grazing throughout the world. Grassland that once stretched from horizon to horizon has been converted to pasture and farmland in nearly every region of the world, leaving only bits and pieces of the original ecosystems. As humans migrate into the last of this wild grassland, they are obliterating native plants and animals. Should these trends continue, almost no native wildlife will remain outside national parks (Simon 1995). Much ecological damage is being done to fragile ecosystems that were never ecologically suitable areas for livestock grazing and are unable to recover from overgrazing.

Drylands of the World: EURASIA: Page 1

The central Asia steppe represents the largest remaining expanse of grassland in the world, but even it has been greatly reduced. A few hundred years ago, it stretched from Eastern Europe and the Black Sea east to the west side of China, a distance of 3,200 miles. The steppe is dotted with lakes, rock outcroppings and woodland copses framed by distant snow-capped mountains. Desert, dryland and grassland all occur here; some recent films and books capture the stark, haunting beauty of this region. Until the 20th century, wonderful wildlife spectacles could be seen. Great herds of saiga (*Saiga tatarica*), antelope-like ungulates, darkened the plains in the millions. Asiatic asses (*Equus hemonius* and *E. kiang*), deer, antelope and gazelles lived among the saiga on both grassland and shrub, while wild yaks (*Bos mutus*) and Bactrian camels (*Camelus bactrianus*) were confined to desert areas. Grazing animals and rodents were preyed upon by a variety of foxes, brown bears (*Ursus arctos*) and gray wolves (*Canis lupus*). Many wild cats were widespread, including the lion (*Panthera leo*) and the cheetah (*Acinonyx jubatus*), both of which have been virtually exterminated.

Drylands of the World: EURASIA

Portions of Europe were grassland until fairly recently. In the late 19th century and post-World War II period, many Western European regions that had been used for livestock came into agricultural cultivation to revive their national economy (Goriup 1988). In France, 99 percent of the dry grassland of Champagne was turned into intensive

crop-growing fields after World War II, causing many bird species to disappear. This pattern has been repeated in many parts of the world where human populations are rising.

Drylands of the World: EURASIA: Page 2

Among the most dramatic examples of agriculture on grassland and dryland are the development projects of the former Soviet Union. The western edge of the Asian steppe on the Black Sea in the Ukraine was turned to farmland during the mid-19th century. German settlers arrived, then plowed the soil for farming and introduced large numbers of livestock. Military colonies of some 60,000 men were established by the Russian government by the 1840s (Stewart 1992). By the 1860s, the once fertile soils eroded, and droughts brought famines. A series of crop failures caused the deaths of 500,000 people in 1891-92 and droughts continued during the early years of the 20th century (Stewart 1992). These grasslands had provided habitat for large numbers of Saiga and other wildlife over thousands of years.

What remained of the fertile soils became the object of the Soviet Union's settlement and cultivation program, beginning in 1929 with the announcement of a five year plan: "We must discover and conquer the country in which we live– Our steppe will truly become ours only when we come with columns of tractors and ploughs to break the thousand-year virgin soil" (Ponting 1991). When the steppe was plowed, dust storms and erosion resulted in a parallel to the Dust Bowl of the Great Plains in the United States, occurring at about the same time. Dust storms in the Ukraine blew millions of tons of top soil away, but the program continued. Collectivization of farms by Communist leaders brought even more of this rich land under the plow, and in 1954, Soviet Leader Nikita Khrushchev ordered that 90 million acres be cultivated to feed the entire Russian population (Stewart 1992). Erosion then became so severe that large areas became wasteland; in the years since 1964, portions of the steppe have been closed off to plowing, and better agricultural methods came into use (Stewart 1992).

Yet another Soviet agricultural plan destroyed an additional area of steppe. Large portions of Kazakhstan and Uzbekistan, an area of 100 million acres, were plowed between 1954 and 1960 (Ponting 1991). Land became eroded and infertile at a rate of 3.5 million acres a year prior to 1963; by 1965, more than 40 million acres, half the area, were badly damaged (Ponting 1991). More than 1 million acres of farmland were abandoned every year from the mid-1960s on in this region (Ponting 1991).

The lands south and west of the Aral Sea were another target for the Soviet agriculture programs, and the Amu Darya, Murgab and Tedjen Rivers that fed this sea were redirected south to a manmade canal leading to the Caspian Sea (Sparks 1992). These waters irrigated Uzbekistan's deserts, where monocultures of cotton were grown. The soil became topped with salt, however, as often happens when fresh water is pumped into parched land, drawing saline to the surface (Sparks 1992). The salts and agricultural chemicals polluted the soil to the point that by the late 1980s, the region represented one of the worst cases of ecological despoliation in the world (Sparks 1992).

Drylands of the World: EURASIA: Page 3

One of the last vestiges of untouched Ukrainian steppe has been preserved in a magnificent reserve, the

Askaniya-Nova, which covers 27,500 acres. In fact, it is one of the last examples of virgin steppe in the world (Durrell and Durrell 1986). Established in 1878 by Friedrich Falz-Fein, a wealthy landowner and descendant of a German settler, the land was originally used as a sheep farm. Native wildlife species were gradually introduced into the steppe, and mounted shepherds guarded them (Stewart 1992). Bobac marmots, which have become rare on the steppe, live in the reserve in colonies, and many native reptiles and amphibians survive here Œ safe from the agricultural development that surrounds them. Some 450 species of plants grow in Askaniya-Nova's grasslands, turning the land into a blaze of color in the spring with the blooms of thousands of wildflowers (Durrell and Durrell 1986). The area is reintroducing the great bustard, one of the many species of birds that almost disappeared. (*Otis tarda*).

Covering 1.6 million square miles (4.5 million square kilometers) in a belt between 200 and 600 miles wide, the steppe to the east remained lightly grazed by domestic livestock, and uncultivated until the 20th century. The native grasses of the steppe formed a tough turf, mainly of wild oat, rye grasses, sedge and fescue (Sparks 1992). These grasslands date back to the Pliocene Era, 7 to 10 million years ago. In some areas, the soil, known as *Chernozem* or black earth, is more than 3 feet deep and extraordinarily rich (Stewart 1992). In the south, graceful feather grasses (Stipa) use felt-like down to trap a layer of air to reduce water loss because of evaporation (Stewart 1992). Wild tulips, crocuses, irises and hyacinths color the steppe in spring and summer. The famed Russian author, Nicolai Gogol, described it as a "green-gold ocean splashed with millions of different colored flowers" (Stewart 1992). Diversity in the wild steppe is high; some 80 species of plants grow in a single square meter (Sparks 1992). Scorching heat up to 104 degrees F in the summer has stimulated the evolution of drought-resistant grasses.

The saiga was the dominant animal in this ecosystem, ranging in herds numbering in the tens of millions, making it the ecological equivalent of the American bison. Its distribution during the Ice Ages nearly circled the world, extending from England across Europe and throughout the entire Asian continent to western North America, which the species reached by land bridge. Saiga became extinct in North America and western Europe thousands of years ago, but until recent centuries, they ranged through most of northern Eurasia, from Poland south to Romaina and the southern Carpathian mountains and east to Mongolia and western China. This animal is a zoological curiosity, seeming to be part goat, part sheep and part antelope. Scientists were at a loss for hundreds of years to classify it. It has now been placed in the Bovidae family with wild cattle, gazelles and antelope, in its own genus and subfamily. At about 5 feet long and 31 inches tall at the shoulder, saiga males weigh up to 152 pounds and have short, spiraled horns. Females lack horns and are slightly smaller. Both have a heavy wool-like, buff-colored coat. The most extraordinary characteristic of these animals is their bulbous noses, which have greatly developed and complicated bones (Nowak 1999). The humped nose contains a sac lined by mucous membranes, an adaptation for warming and moistening inhaled air in the freezing winter weather. In warmer parts of the year, the membranes filter out the fine grit carried on the wind in clouds of dust (Sparks 1992).

The arid, open grasslands provide an ideal habitat for saiga, which can subsist on plants that are bitter and even toxic to other wildlife. They are capable of surviving the brutal, howling winds of the Central Asian winter, where temperatures reach -20 degrees F, and even begin courtship rut when snow is still on the ground in December (Sparks 1992). After mating, the herds migrate north, traveling up to 930 miles from their breeding areas in groups of 100,000 (Sparks 1992). They are able to streak across the steppe at speeds up to 50 miles per hour, covering 75 miles in a day (Nowak 1999). In May, when they have arrived at lush grassland, the calves are born. By August, they move south to wintering quarters, forming large herds again. The gray wolf and saiga have had a close ecological relationship for thousands of years as interdependent predator and prey, but today both are threatened.

Saiga were exterminated in the Crimea as early as the 13th century, but survived in the southern Ukraine until the 1700s (Nowak 1999). In the mid-19th century, a massive slaughter of saiga commenced, concurrent with that of the American bison and pronghorn in North America. They were eliminated in the entire central portion of their range from Kazakhstan to western China, thousands of miles to the east. The near-extermination of the Saiga occurred for a frivolous purpose: to obtain their horns to be ground up into powder sold as an aphrodisiac. The multitudes of saiga were reduced to less than a thousand animals by the first decade of the 20th century (Nowak 1999). Extinction

appeared a likely prospect when the Soviet government banned all saiga hunting in Russia in 1919, and four years later extended the ban to Kazakhstan (Stewart 1992).

Their numbers began to climb, but saiga encountered other difficulties that pushed many of their populations closer to extinction. The animals have been blocked by fences constructed in the 20th century in many parts of the steppe. Thousands have died after crashing into them at night at great speed. On one state farm, 300 were found dead in a single day, piled up against the fences (Stewart 1992). They have also drowned in irrigation canals, though in recent years, efforts have been made to prevent such deaths (Stewart 1992). Killing round-ups still occur, however, and by some reports, helicopters were used to herd the saiga until they collapsed in exhaustion; they were then machine-gunned (Stewart 1992). However, they recovered to more than 1 million animals by the 1970s, when another killing spree began. High prices were offered for their horns in the Asian folk medicine market, and the collapse of the Soviet Union in the early 1990s ended anti-poaching controls. Their population in Kalmykia declined from 800,000 in the 1970s to 120,000 in the 1990s (Nowak 1999).

Contamination of their steppe habitat in Uzbekistan from manufacture of chemical weapons has also killed the saiga. In 1988, thousands dropped dead on the Ustgart Plateau south of the Aral Sea when the wind unexpectedly shifted during a test at a nearby chemical weapons plant (Miller 1999). The heart of this species' population is now in the region north of the Aral and Caspian Seas in Kazakhstan, where the nominate subspecies (*Saiga tatarica tatarica*) survives. The massive killing caused their numbers to drop from 1.2 million to less than 600,000 (Chan *et al*. 1995, Nowak 1999). The price of their horns declined in the mid-1990s, perhaps as a reaction to the listing of the species on the Convention on International Trade in Endangered Species.

Only two small, highly endangered populations of their second subspecies, *Saiga tatarica mongolica*, survive far to the east in northwestern Mongolia. According to the IUCN (1994), a herd in the Shargiin Gobi that numbered 1,600 in 1989 declined to between 300 and 1,000 by 1993, while the other in Har-Us-Nuur totaled only 36 animals in 1989. Dr. Ronald Nowak, author of *Walker's Mammals of the World*, estimates their population at only about 300 (Nowak 1999). In any case, the Mongolian saiga is extremely endangered and lacks a strong conservation program to ensure its recovery. Their numbers continue to decline from poaching, severe winters and summers and genetic isolation (IUCN 1994). Although legally protected from hunting, no reserve has been set aside for them and there are no patrols to prevent poaching (IUCN 1994). They represent the last of the eastern saiga herds that inhabited the desert regions of western China and Mongolia, and they have lost 80 percent of their range. Efforts are being made by nomad herders to reintroduce the species into the Great Gobi National Park in southwestern Mongolia; young saiga calves are placed with domestic goats who foster-parent them (Schaller 1990), a potentially dangerous method if the calves imprint on the goats, possibly resulting in saiga trying to mate with goats upon reaching sexual maturity.

Few people from Western Europe or North America have seen saiga in the wild, and they are extremely rare in captivity. The late Gerald Durrell, a British zoologist and founder of Jersey Wildlife Preservation Trust, visited a Russian reserve called Kalmyk in the 1980s. He described the terrain as flat and dry, covered with golden grasses the exact color of the saiga's coat (Durrell and Durrell 1986). Lovely demoiselle cranes (*Anthropoides virgo*) fed in the grasses, and after a seven hour drive on the steppe, having passed only one village, they saw a huge herd of saiga grazing. "They were a magnificent sight as they moved slowly across the steppe with the colored sky and the sinking sun as a backdrop, the young giving strange, harsh, rattling bleats to be answered in deeper tones by their mothers" (Durrell and Durrell 1986). The next day, they found even bigger herds "until the ground seemed to be a sea of saiga." They filmed with great difficulty because the saiga were still wary and shy, but finally succeeded in driving a herd toward the camera. The film was shown on the series fiDurrells in Russiafl (see Video, Regional, Eurasia).

Another native ungulate came close to total extinction. Przewalski's horses (*Equus przewalskii*) Œ stocky and wild Š once ranged throughout the steppe. Some experts believe they evolved 150,000 to 250,000 years ago in the region, while others consider them to be a strain of the domestic horse (Nowak 1999). These sturdy, robust horses are uniformly tan with a stiff black mane, long black tail and black lower legs. For thousands of years they survived harsh climates, as long as grass and water were available. Their original range encompassed steppe from Kazakhstan, east

through Mongolia to Sinkiang, China, and possibly to southern Siberia (Nowak 1999). Soon after their discovery by Western scientists in 1879, they suffered steep declines from heavy hunting, and were crowded out of much of their habitat by growing numbers of livestock; by 1950, they had become confined to southwestern Mongolia and adjacent China (Nowak 1999). These last horses died out sometime after 1969, the year they were last seen, and subsequent searches for them proved fruitless (Nowak 1999).

Fortunately, some Przewalski's horses were taken into captivity and shipped to Europe early in the 20th century. The captive horses bred, providing animals to restock their original habitat. Many zoos now have small numbers of these horses, with a total captive population of about 1,000 (Nowak 1999). During the late 1990s, about 100 horses, now in their 13th to 15th generation in captivity, were released in the Hustain Nuruu Reserve southwest of Mongolia's capital city, Ulan Bator (Possehl 1995). They are being heavily guarded by herders, and despite some anxiety that they would not be able to adjust to living in the wild, they have shown every sign of adapting to their new environment. Stallions immediately began competing for harems of mares, and they seem to be exhibiting the natural traits of other wild horses.

Drylands of the World: EURASIA: Page 4

To the southeast, many of Pakistan's high plateaus and Himalayan foothills have become overgrazed and denuded of vegetation, leaving a desolate landscape. The Indus Plain and Karchat Hills have become a stony wasteland with stunted acacias scattered about; thin goats scour the terrain for blades of grass and people cut what few trees remain for firewood (Schaller 1980). In his book about the Himalayas, *Stones of Silence*, Dr. George Schaller (1980) imagined the land as it had once been: "Had man not misused this land for thousands of years, I would be driving through woodland, with wild asses standing in the broad-crowned shade of acacias and cheetah stalking unsuspecting Indian gazelles through swords of golden grass. Perhaps down by the river a pride of lions would be resting after the night's hunt. The forests are gone now, the rivers dry except after a downpour, and the lion, cheetah and asses are dead. Only a few gazelle remain. No wonder the land seems lonely as one drives toward the distant hills, trailing a funnel of red dust made incandescent by the sun."

Two types of wild asses are native to the steppe. Asiatic wild asses (*Equus hemionus*) once ranged from the Arabian Peninsula to Manchuria and even western India (Nowak 1999). These elegant wild equines have variable coloration, some populations with broad, dark dorsal stripes and black legs, and others uniformly tan without black markings. All have stiff black manes. They have disappeared from much of their range and are now endangered. Only a few hundred to a few thousand survive in Iran, Turkmenistan and India; in southern Mongolia and neighboring China, they are more numerous, with more than 8,000 animals (Schaller 1998). Its total population may not exceed 10,000; it is listed as endangered by the US Endangered Species Act and as vulnerable by the *2000 IUCN Red List*. The latter publication also lists six subspecies in various degrees of threat, including one, the Syrian, as extinct, with races in Iran and India as endangered (see Appendix).

The kiang (*Equus kiang*) is native to the Himalayan region, Tibet and adjacent regions of west-central China (Nowak 1999). These striking wild equines are bright russet in summer and have thick brown coats in the winter; their backs have a black dorsal stripe, and their bellies, legs, muzzle and neck are white (Nowak 1999). They prefer high elevations, up to 5,000 meters, where they forage on grasses and other vegetation. Considered abundant and secure until the mid-20th century, they began a steep decline after the Chinese occupation of Tibet in 1950. Large numbers of Chinese immigrants hunted them and displaced them with agriculture and livestock (Nowak 1999). One race native to western China and adjacent Tibet and India, E.k.polyodon, was thought extinct until a herd of 74 to 120 animals was discovered in Sikkim, China; elsewhere they remain much reduced from former numbers.

Grassland still covers much of Mongolia and Tibet, but vast numbers of domestic animals, yaks, sheep, goats and

camels graze in this fragile, arid land. Mongolia has a human population of 2.5 million, and 28 million livestock inhabit its 604,800 square miles. Livestock graze in the Gobi Desert's more verdant portions, which are a mosaic of drifting, bare sands, shrub, grassland characterized by tall tussock grass and arid mountains. Saiga once roamed here, and many extraordinary creatures cling to their existence.

Most of the world's remaining wild Bactrian camels survive in Mongolia's Great Gobi National Park. These camels differ from their domestic counterparts, which have large, misshapen humps, in being slender with trim, conical humps, sandy coats and sparse wool (Schaller 1990). Once widespread and abundant, this species is near extinction, as it is crowded out by hordes of livestock, including domestic camels, and often shot on sight by nomads and professional hunters. Their young have had low survival rates in recent years, and little is known of their reproductive biology that would explain this mortality (Schaller 1998). Herd size has also declined since the 19th century, when numbers in the dozens up to a hundred were seen. This may affect their vulnerability to predators, such as wolves. They are further threatened by interbreeding with domestic Bactrian camels; Gobi Park personnel have shot several hybrids in recent years (Schaller 1998).

Despite their large reserves, human activity is threatening the last of these superbly adapted wild camels. A 1994 film by Survival Anglia, fiMountains of the Snow Leopard,fl gauged their total population at only about 300. An aerial survey of the park in March 1997 recorded 314 camels and estimated total park population at 900 animals (Schaller 1998). In the Taklimakan Desert to the west, several other populations survive. One herd near Lop Nur, a lake dried up by irrigation diversion, had an estimated 200 animals in 1985, but they declined to only 80 to 100 in 1995 after a period of heavy hunting (Schaller 1998). Further west, a road built through their habitat near the Tarim River, combined with oil development, reduced the wild camels to only 50 to 80 animals (Schaller 1998). The total world population of these progenitors of domestic Bactrian camels is only about 1,500, while at least 2.5 million domestic camels inhabit central Asia (Schaller 1998).

An extremely rare predator, the Gobi bear (*Ursus (arctos) gobiensis*), is also resident in the Great Gobi National Park. Schaller (1998) and others consider it to be so distinct that it is a separate species from the brown bear (*Ursus arctos*). If recognized as so, it would be the rarest carnivore in the world, numbering only about 30 animals in a population isolated from other brown bears by hundreds of miles. They have apparently been separated for a very long time. Its closest relative, the endangered Himalayan brown or red bear (*Ursus arctos isabellinus*), occurs to the west of the Gobi with a range that extends to Nepal. Populations in Mongolia are listed on Appendix I of CITES, but Gobi bears have yet to be recognized by CITES, the *IUCN Red List* or the US Endangered Species Act. Fortunately, they receive protection in their sole remaining range within this park. They are the world's only true desert bears, and they subsist in extremely arid conditions, feeding on scarce tubers and wild plants. Yellowish-brown or reddish with dark legs, Gobi Bears are relatively small and lanky, weighing less than 200 pounds, about one-tenth the weight of their cousins in Alaska and Russia's Kamchatka Peninsula. fiMountains of the Snow Leopardfl (see above and in Video Section) is the first film record of Gobi Bears ever made. A female was filmed with her half-grown cub, scratching in the sand for wild rhubarb.

The bears to the west on the Tibetan Plateau are quite different in their appearance. Shaggy rather than thin-coated, they often have a conspicuous white collar, dark brown to black coats and rusty faces. Their black ears appear to be adorned with tassels (Schaller 1998). They are known as Tibetan bears (*Ursus arctos pruinosus*), listed as endangered by the US Endangered Species Act. Extremely rare on the steppe, they survive only in mountainous terrain, and have disappeared from the alpine meadows near the Yellow River where they were once common (Schaller 1998). They are severely persecuted by Tibetans, who usually kill them on sight (Schaller 1998).

A rare and dazzling resident of the Great Gobi National Park is the Houbara bustard (*Chlamydotis undulata*), a threatened relative of the great bustard. The bustard family, Otididae, with 25 species, occurs in Africa and Eurasia. These stocky, long-legged birds are distant relatives of cranes and are declining from loss of their grassland habitats and hunting. In the dryer steppe, where vegetation is brown and shrubby, the male Houbara bustard stands out dramatically, dashing about and displaying a long chest ruff of white Ostrich-like feathers surrounded by jet black

quills that he jerks as he dances a high-stepping strut. His erected white head feathers resemble a puffy hat.

To the southeast, the graceful Tibetan gazelle (*Procapra picticauda*) is endemic to the Tibetan Plateau, which abuts southern Siberia and western China. Early in the century, the grasslands at the headwaters of the Yellow River in eastern Qinghai, China, presented a great spectacle with enormous herds of these gazelles and other ungulates. The area is dotted with lakes and was home to wild yaks, kiangs and other wildlife (Schaller 1998). In the 1950s, roads were built, and livestock now grazes at densities of 40 head per square kilometer, displacing wildlife (Schaller 1998). Wild yaks disappeared, and kiangs and Tibetan gazelles have become rare and sparsely distributed in the region. As Schaller (1998) remarked, "One can traverse these grasslands for hours and seldom glimpse a gazelle." These gazelles and other ungulates are avidly hunted. Despite their extraordinary swiftness and great leaping ability, they cannot escape gunfire in this open habitat. Tibetan gazelles number 100,000 at most throughout their enormous range (Schaller 1998).

The influx of herders and farmers into these grasslands has been a result of an official Chinese government program which encouraged people from crowded urban areas to enter frontier regions of the west to settle. These new residents converted the steppe into farms and grazing land (Hsu 1988). Three-quarters of these steppe, 266 million hectares (657 million acres) of a total 358 million hectares (885 million acres), had become grazing or farmland by 1988 (Hsu 1988). Since then, this trend has accelerated. These wilderness areas are officially classified by the Chinese government as "wastelands" (Hsu 1988). Other types of wildlife are being eliminated, as well as hoofed animals. Rodent control programs poison pikas and ground squirrels. Some reserves have been set aside which protect at least a portion of the Chinese steppe. The Xianghai Nature Reserve, for example, covers 100,000 hectares (247,000 acres), but livestock and hunting are allowed in these reserves.

In 1993, the Chinese government established the Chang Tang Nature Reserve, an area of Tibetan steppe with breathtaking scenery of distant mountains and steppe dotted with icy lakes, larger than the state of New Mexico. Dr. George Schaller and his organization, the Wildlife Conservation Society, played an important role in the establishment of this reserve, which provides habitat for some of the steppe's most endangered species. His 1997 book, *Tibet's Hidden Wilderness: Wildlife and Nomads of the Chang Tang Reserve*, is illustrated with photographs of this magnificent region and its wildlife. Stunning mountains covered in snow, grassland oases and beautiful gazelles and antelope distinguish this wilderness. A companion book by Schaller, *Wildlife of the Tibetan Steppe*, provides more scientific detail on the biology, ecology and status of the wildlife of the entire region (Schaller 1998).

Chang Tang Reserve allows large numbers of pastoral people to graze their livestock, and approximately 22,000 people live in the reserve, with 1.4 million livestock Œ most of which are sheep (Schaller 1997). The livestock have displaced many wild herds, which now number only about 103,000 animals, 10 percent as numerous as the domestic animals. The huge numbers of livestock give an indication of the vast numbers of wildlife that once occurred on the steppe (Schaller 1997). Although quotas have been established, with maximum numbers of livestock per family at 486 animals per household in one part of the reserve, they are so generous that they leave little habitat for native wild sheep, gazelles, antelope and other wild ungulates, which are in steep decline (Schaller 1997).

A few wild yak (*Bos grunniens mutus*) herds inhabit Chang Tang. These extremely imposing animals are far larger and more massive than their domestic counterparts, with humps on their shoulders and shaggy black coats that nearly reach the ground. They survive in a few scattered herds, a result of heavy hunting. In the Aru Basin in the reserve, where a Pleistocene-like panorama of wild herds of many species existed as recently as 1990, yak numbers have been halved by hunting and the introduction of livestock and permanent settlements (Schaller 1997). Only about 15,000 of these magnificent animals remain, the majority surviving in three reserves on the Tibetan Plateau (Schaller 1998).

Tibetan antelope (*Panthops hodgsoni*) are native to this extremely harsh Tibetan steppe, which is swept by howling winds throughout the long winters. The male has long, straight horns that rise almost vertically from its head and bend forward at the tip. Their faces and front legs are black. Males weigh only about 100 pounds. Females are smaller and lack the male's horns. Both have buff coloration that blends into the pale tans of the steppe. Although

considered antelope, recent DNA studies have determined they are more closely related to goats; they retain some ancestral characteristics of both antelope and gazelles (Schaller 1997). Chiru have unusual physical adaptations to cope with the high-altitude environment Œ such as an extremely fine fur Œ which has made them the target of hunters, an enlarged nasal cavity to draw in the thin air on their long migrations, and high-crowned teeth to grind the tough vegetation.

Chiru were abundant until the 20th century. In 1897, a British military officer came upon enormous herds: "As far as the eye could reach, were thousands upon thousands of doe antelope and their young...there could not have been less than 15,000 or 20,000 visible at one time" (Schaller 1996). Heavy hunting for its fine wool, Shahtoosh, has been a major cause of its decline throughout this century. This wool is extremely valuable, and has reached luxury markets in western countries in recent decades (see Trade Chapter). At present, chiru still migrate in long lines for great distances over the windswept steppe, but their total population is estimated at less than 75,000. Although it is officially protected, illegal hunting continues, even by Tibetan government officials.

The native deer of the steppe occupy various habitats, from scattered woodlands to open grasslands. The largest species, the red deer (*Cervus elaphus*), known as elk in North America, has been severely overhunted and crowded out of its habitat. A race from Tibet known as the shou, *Cervus elaphus wallichi*, was thought extinct until a small population of 200 was discovered recently in an area east of Lhasa (Nowak 1999). Another subspecies from the steppe of western China, the Yarkand deer (*Cervus elaphus yarkandenis*), once thought extinct, numbers about 5,000 in central Sinkiang, China, with another 6,000 farmed animals (Nowak 1999). The Bactrian deer (*Cervus elaphus bactrianus*) of Central Asia nearly became extinct, reduced to only 300 to 400 animals in the 1960s from overhunting and loss of habitat to agriculture and livestock; it now numbers 900 (Nowak 1999). All three are listed as endangered on the US Endangered Species Act.

White-lipped deer (*Cervus albirostris*), found only on the Tibetan Plateau, prefer far more open habitat than most deer, especially alpine meadows; stags can weigh up to 230 kilograms and stand up to 140 centimeters at the shoulder, with large, white antlers (Schaller 1998). Heavy hunting and competition for forage with livestock have made them rare in most parts of their range, with scattered, discontinuous populations; they are common only where protected, such as in the vicinity of monasteries (Schaller 1998). Total numbers of this deer, which was once far more abundant, are estimated at approximately 50,000 to 100,000 (Schaller 1998).

A high diversity of small wild cats inhabits the steppe and deserts of Asia. Some are tiny, the size of a small house cat, and others range up to 3 feet in body length. Many have become endangered after their steppe habitat and natural prey were displaced by agriculture or livestock. Some are killed for their fur. The Turkmenian caracal (*Caracal caracal michaelis*), a sandy brown cat with long tufts on its ears, has disappeared from most of its habitat in the western steppe. Another shy and rare feline, Pallas' cat (*Otocolobus manul*), ranges from Iran to Siberia and China on rocky steppe and desert up to 4,000 meters in elevation (Nowak 1999). Having the longest, densest fur of any wild cat, this species inhabits the high-altitude rocky mountainsides and cold deserts of central Asia (Sleeper 1995). It has become very rare throughout its distribution from hunting for the fur trade and persecution by livestock owners. Weighing only 5 to 8 pounds, Pallas' cats have a thick muff-like tail they wrap around their feet for insulation in the snow (Sleeper 1995).

The magnificent Snow Leopard (*Uncia uncia*) is the largest and most endangered wild cat of this rugged region. Pursued by hunters throughout its range, which encompasses more than 2 million square kilometers of mountain ranges that extend over 12 countries, it has disappeared from the majority of its original distribution. The natural prey of these cats, wild goats and sheep, have been overhunted and crowded out of their natural habitats by livestock, forcing Snow Leopards to take livestock in some areas. The combined effects of fur hunting, persecution and loss of their natural prey are pushing the species close to extinction. Only in the past few decades have conservation programs begun to turn this downward trend around. One biologist, J. Fox, estimated total populations for the species at between 4,500 and 7,350 in 1994; in western China, they may number about 2,000, while in Kyrgystan, there may be 1,000 to 2,000; in Mongolia, approximately 1,000; India about 500; with scattered numbers in the Himalayan

countries of Nepal, Pakistan and Afghanistan (Fox 1994, Schaller 1998). For a growing number of countries, these beautiful wild cats have become a valuable asset to attract tourists and an important part of their natural heritage. Work by outside biologists and conservation organizations to persuade herdsmen not to kill them, but rather to protect their herds properly instead, is beginning to take hold in Pakistan and other parts of the Himalayas.

Drylands of the World: NORTH AMERICA

Just 200 years ago, North America's magnificent grasslands preserved the largest population of hoofed mammals in the world. Herds of American Bison totaled an estimated 60 million animals, almost 60 times the number of wildebeests that now inhabit East Africa. A mosaic of grasslands of various types stretched from the Midwest to the Pacific Ocean, merging into deserts in the Southwest. Some grassland habitats also existed in the Northeastern United States, a mixture of grassland and heath, either of natural origin or maintained by annual burns set by Native Americans. Grasslands, shrub and desert covered about one-third of the United States prior to settlement (Petty 1973). Grassland occupied approximately 17 percent; shrublands and deserts 8 percent each. Many parts of the latter areas are mixed habitats with grassland-shrub and shrub-desert communities. Grasslands once covered far more area in the Southwest prior to settlement, but today many of these have turned to desert after centuries of cattle grazing.

Drylands of the World: NORTH AMERICA: Page 1

In the early 1800s when Lewis and Clark explored the West for President Thomas Jefferson, short and tallgrass prairies occurred in a wide north-south expanse from southern Canada to the Gulf of Mexico, covering at least 1.5 million square kilometers (945,000 square miles) (Knopf 1988). Tallgrass prairie, requiring a moist environment, with 50 to 100 centimeters of rain per year, grew in the eastern section, extending in a wide north-south band from southern Canada to southeast Texas and southwestern Louisiana, and from Illinois in the east to eastern Oklahoma and North Dakota in the west. Tallgrass prairie once covered 577,500 square kilometers (365,825 square miles) (Knopf 1988). Named for the grass species within this ecosystem that reach up to 12 feet in height, it grows in thick, luxuriant stands (Brown 1985). Early settlers considered this habitat to be an impediment to farming and plowed millions of acres. Soon after European colonization, the eastern grasslands were plowed into prime farmland. Today, tallgrass prairie is reduced to less than 1 percent of its original expanses.

-

The tough, compacted shortgrass of the Great Plains further west required a heavy steel plow to break it apart, which was invented late in the 19th century, opening up additional millions of acres to cultivation (Ponting 1991). The United States government encouraged settlement by giving away plots of 160 acres of land to anyone who laid claim. Settlers and professional hunters killed off the vast herds of American Bison, Black-tailed and White-tailed Deer, Elk,

and Pronghorn Antelope, as described in Chapter One. Much of what shortgrass prairie remains is federally owned.

Settlers who plowed native grasslands did not appreciate the fragility of this environment, with its low rainfall and soil anchored by grasses. The topsoil was extremely deep, 5 inches or more, perhaps the world's richest soil. It had built up over hundreds of thousands of years from grassland vegetation dying and enriching the soil, along with dung from untold numbers of bison and other ungulates. Settlers deep-plowed this virgin prairie, reaping bumper crops for a few years. They enlarged their farm acreage by removing windbreak strips of vegetation and cutting tree groves. The eradication of natural vegetation, especially trees, lowered the ambient humidity because of the massive amounts of water vapor they had emitted, reducing rainfall. The lack of contour plowing encouraged erosion, as did the removal of the vegetation that held the soil in place.

This set the stage for major droughts which began in the early 1930s, and windstorms blew millions of tons of precious topsoil off the land. The plains of Oklahoma were the first to experience massive dust storms, forcing thousands of farmers to abandon the region. The phenomenon came to be known as the Dust Bowl. Topsoil disappeared from plowed fields in Kansas, Colorado, western Texas, New Mexico, Nebraska and the Dakotas (Ponting 1991). Winds swept away an estimated 350 million tons of topsoil in a single storm in May 1934, and blinding dust storms continued throughout the 1930s, darkening skies hundreds of miles away, as far east as New York City (Peck 1990). By 1938, 10 million acres had lost 5 inches of topsoil, and another 13.5 million acres lost the top 2.5 inches (Ponting 1991). An estimated 850 million tons of soil were being lost a year by the end of the 1930s, and the United States government began a program to restore the soil (Ponting 1991). Throughout the prairies, approximately 18 million acres turned into shrub desert during the decade of the 1930s (Peck 1990).

Drylands of the World: NORTH AMERICA: Page 2

Conservation practices improved after government programs were launched to control erosion, and agricultural subsidies have been paid to farmers ever since. Unfortunately, the ecological effects of these subsidies have been extremely destructive to topsoil and wildlife conservation on the 294 million acres farmed in the country. After extensive debate in Congress, a 1996 law, the Freedom to Farm Act, authorized the phasing out of subsidies, with the eventual goal of ending them altogether.

Erosion damage is even visible from space through satellite photography (Manning 1995). Statistics in 1997 showed that conservation tillage is being practiced on 37 percent of America's farmland, while conventional deep plowing is still carried out on 107 million acres, and reduced- or no-till farming was employed on 77 million acres (AP 1998). Erosion of topsoil continues at a rate estimated to be 17 times faster than new soil is formed (TPP 2000). Farming tends to eliminate wildlife, which can be mitigated by the planting of hedgerows, woodland and other natural habitat areas.

Water supplies for prairie farmers have also been overtaxed. Many natural waterways have been diverted for irrigation, drying up wetlands. Beneath the Great Plains lie underground aquifers, fed for thousands of years by water seepage. In the 20th century, farmers and ranchers in the dryer parts of the prairie region have been over-drawing water from the Ogallala Aquifer, a subterranean lake which is due to run dry in 60 years (Stolzenburg 1996).

Of the original grasslands, more than 90 percent of prairies are now gone, plowed into agricultural fields or mowed for cattle pasture. Nearly all the free-flowing rivers and streams that water prairies and drylands have been altered forever. Government programs have straightened and drained countless natural streams and wetlands through channelization, which removes streamside vegetation, straightens the bends in these waterways and excavates straight

ditches in their place. Hundreds of miles of western rivers have been covered in stones to prevent flooding of homes on the river, but these stones destroyriparian and river ecosystems.

Drylands of the World: NORTH AMERICA: Page 3

Ecological studies of the remnants of tallgrass prairie reveal them to be extremely rich in plant diversity, with up to 500 different species (Madson 1993). Of these, at least 150 species are grasses, with about 10 dominant kinds (Madson 1993). In the eastern portions, savannah with islands of forest, or grassland surrounded by forest, dominated (Brown 1985). Further west, isolated trees or groves, primarily oaks and hickories, replaced forest islands.

In Illinois, at the eastern edge of the original tallgrass prairie, only seven hundredths of one percent remains (.07 percent); this pitiful remnant makes a mockery of the state's nickname, "The Prairie State" (Stevens 1995). The original 21 million acres of Illinois tallgrass disappeared rapidly under the plow, leaving about 2,500 acres (Line 1997), of which only 11.2 acres of untouched prairie savannah exists (Stevens 1995). Even these remnants are so fragmented and poor in species that scientists can only guess at the original components of this ecosystem.

One of the rarest tallgrass birds is Henslow's Sparrow (*Ammodramus henslowii*), a small brown-and-black striped songbird, which breeds from the Northeast west to South Dakota and Kansas and south to North Carolina. This bird prefers fairly tall native grass species with scattered shrubs and woody growth, and requires a range of at least 500 acres (Line 1997). It was first listed on the National Audubon Society's annual Blue List of declining species in 1974, and by 1986, it was reported very rare or absent in many parts of the Northeast, Appalachia and the Great Lakes region (Ehrlich *et al*. 1992). The disappearance of tallgrass prairie is directly responsible for the decline of this sparrow, and it cannot survive in the tiny fragments that persist. Henslow's Sparrow may soon qualify for listing on the Endangered Species Act. The Fish and Wildlife Service (FWS) appraised its rate of decline at 93 percent since 1966, one of the most drastic for any North American breeding bird (Line 1997). FWS considers it a Migratory Nongame Bird of Management Concern; although a 1996 status survey found the species to be greatly reduced, the Service has not designated it an endangered species (Line 1997).

Historical records indicate that Henslow's Sparrows were abundant in the Midwest, from Wisconsin through Illinois, during the 19th century. Today, these birds are so rare that birdwatchers travel for hundreds of miles to see one. Their song is very unsparrow-like, a short staccato "se-LICK" which can be mistaken for an insect's call. Only four areas in the country still contain colonies of Henslow's Sparrows with populations of 400 or more nesting pairs: Missouri; The Nature Conservancy's Tallgrass Prairie Preserve in Oklahoma; Fort Riley, an army base in Kansas; and Jefferson Proving Ground in southern Indiana (Line 1997). Fort Riley is home to other rare grassland birds such as the Grasshopper Sparrow (*Ammodramus savannarum*), which has declined 66 percent overall, and has suffered a 96 percent decline in New York State since 1966 (Line 1997). Grasshopper Sparrows prefer shortgrass and open habitats devoid of brush and weeds and prosper when grasslands are mowed annually rather than burned, leaving seeds and insects (Swengel and Swengel 1997). The Sedge Wren (*Cistothorus platensis*), a state-listed species also resides on Jefferson Proving Ground (Pruitt 1997). Almost half the base, including all the grasslands, is off-limits to human access because of an estimated 1.5 million rounds of unexploded ordnance (Pruitt 1997), a fact which may work to the benefit of these rare species since large numbers of people can disturb these birds, causing them to desert ideal habitat. The future of these birds depends on the success of various efforts to protect and restore tallgrass prairie east of the Mississippi River.

The colorful Bobolink (*Dolichonyx oryzivorus*), a member of the blackbird family, Icteridae, nested in large numbers in overgrown fields and native grassfields until the last few decades. These birds migrate in immense flocks, wintering in South America. In recent years, however, they have become rare in many areas, as more and more hay fields are mowed during their nesting periods, or plowed for agriculture. They have also lost wintering habitat to

agriculture. Bobolinks have incurred an average of 90 percent decline in the Midwest, according to results from bird censuses conducted in the early 1990s, as analyzed by the Biological Resource Division of the U.S. Geological Survey. In one New York study, hay mowing caused the loss of 94 percent of Bobolink nests, while in undisturbed fields, 80 percent of the chicks survived (Line 1997). Conservationists and ornithologists have launched education programs to convince farmers to delay mowing their fields until late summer when these birds have finished nesting.

The largest remaining area of untilled tallgrass prairie, totaling about 60,000 acres, is found in the Flint Hills of Kansas and in the Osage Hills of Oklahoma; these grasslands were not plowed because both lie atop rugged limestone rock formations and have a comparatively thin topsoil. A national tallgrass prairie park was first proposed decades ago. Private owners of the land in the Flint Hills opposed federal legislation first introduced in 1962 to create such a park and, for more than 30 years, refused to sell or donate virgin prairie that stretches for about 100 miles (Madson 1993). Finally in 1996, after decades of lobbying by conservationists, the United States Congress authorized a national tallgrass prairie park and President Bill Clinton signed the bill into law, the first federal protection for this extraordinary habitat. The new Tallgrass Prairie National Preserve in the Flint Hills of east-central Kansas covers 10,894 acres. Disputes continue with neighboring cattle ranchers opposing the preserve and recommending that the land continue as a cattle ranch, legally possible under the Preserve designation, a less stringent category than National Park. Ecologists, however, have proposed restoring the original plant life, which has become less diverse after generations of cattle grazing. The preservation of this land is a great victory for environmentalists who have long worked toward this goal. Only with time will the enmities and differences be settled, hopefully on the side of the natural environment.

In Iowa and Minnesota, the Fish and Wildlife Service is planning to establish the Northern Tallgrass Prairie Habitat Preservation Area. Through purchases of land and easements, the area will cover come 70,000 acres (Line 1997). In Wisconsin, the International Crane Foundation has reestablished prairie on its land. An innovative program in the state allows dairy farmers to set aside one third of their pasture for grassland birds, mowing or grazing it after the nesting season (Line 1997).

A substantial unplowed section of tallgrass prairie was acquired by a private conservation organization. The Nature Conservancy obtained 30,000 acres in Oklahoma's Osage Hills, a former cattle ranch, in the early 1990s. It plans to restore the original plant life, and 300 bison have already been released in the prairie (Madson 1993). This sanctuary is sizeable enough to harbor a natural tallgrass ecosystem, which ecologists have calculated should encompass at least 16,500 acres, have a population of 500 bison, and a complete watershed (Madson 1993). The new preserve is being biologically inventoried prior to reintroduction of native species.

Drylands of the World: NORTH AMERICA: Page 4

Pronghorn Antelope, once numbering in the millions in grasslands from southern Canada to northern Mexico, have disappeared from much of their former range. They have rebounded from near extinction in the Great Plains, but are rare or endangered in the desert grasslands of the Southwest and northwestern Mexico. Two subspecies are listed as endangered by the U.S. Endangered Species Act: the Peninsular Pronghorn (*Antilocapra antilocapra peninsularis*) of Baja California, Mexico, and the Sonoran Pronghorn (*Antilocapra antilocapra sonoriensis*) of the Sonoran Desert of southern Arizona, southeastern California and adjoining Mexico. These two races have become endangered by a loss of grassland to overgrazing and agriculture and by overhunting. Sonoran Pronghorn number only between 125 and 250 animals in Arizona, and an equal number are estimated to survive in neighboring Mexico (Turbak 1995). Remnant populations of this subspecies reside in the Cabeza Prieta National Wildlife Refuge, the Organ Pipe National Monument, and on an Air Force gunnery range. Smaller than the prairie races of Pronghorn, they can survive in extreme conditions of heat, aridity and sparse vegetation. It is thought that they are able to live without ever drinking water, according to *Pronghorn: Portrait of the American Antelope* (Turbak 1995). Their habitat has been severely

damaged, and most of the original grassland range of the Pronghorn in the Southwest has been lost to agriculture or has become totally barren after centuries of heavy livestock grazing.

Sonoran Pronghorn inhabiting the Luke Air Force Base in Arizona number only about 100 animals, and some have been killed by low-level flight training, air-to-ground live fire and other military activities (Stauble 1997). Since the Endangered Species Act prohibits federal agencies from harming listed animals, these activities were illegal. Defenders of Wildlife sued the Fish and Wildlife Service for allowing these lethal activities, and new monitoring procedures resulted in the cancellation of three scheduled bombings in 1997 because Pronghorn were in the vicinity (Stauble 1997).

The Peninsular Pronghorn is even more endangered, numbering only about 100 to 250 animals in the Vizcaino Desert of the central Baja California peninsula of Mexico (Turbak 1995). At one time, they were far more numerous and common in this arid region of northwestern Mexico, but they have been crowded out by development and livestock and decimated by overhunting.

The Mexican or Chihuahuan Pronghorn (*Antilocapra americana mexicana*) was once native to southeast Arizona, Mexico, and portions of Texas and New Mexico. In Texas a small population remains near the town of Marathon in Brewster County, but the Arizona Pronghorn disappeared altogether by about 1920 as a result of uncontrolled hunting, agricultural development and livestock grazing (Turbak 1995). In the 1980s, 400 Chihuahuan Pronghorn were moved from Texas to five sites in Arizona, mainly in the center of the state, and these animals are doing well, having increased to 500 (Turbak 1995). Their long-term future is not rosy, however, because of the rampant urban and suburban growth taking place in central Arizona (Turbak 1995). These skittish and extremely high strung animals do not do well in captivity, and no captive herds of either subspecies are being bred in zoos.

Three of the five native prairie dog species are imperiled. The Utah Prairie Dog (*Cynomys parvidens*) has been driven to near extinction by rodent control programs and the loss of habitat to livestock and agriculture. Listed on the U.S. Endangered Species Act, this species has a restricted range in southwest Utah. A population estimated at 95,000 animals in 1920 fell to only 3,300 in 1972 (Nowak 1991). Through protection accorded by the Endangered Species Act, Utah Prairie Dogs began to rebound, and by 1984, the species was downgraded from endangered to threatened on the Endangered Species Act. Counts of Utah Prairie Dogs in the early 1990s ranged from 6,400 in the fall to 24,000 after they had pups in the spring (Nowak 1991). The Fish and Wildlife Service began transplanting prairie dogs from private to public lands (Turbak 1993). Initially, many of the released prairie dogs failed to survive, and not until they began releasing males in the spring, who industriously spent the summer excavating burrows to accommodate other prairie dogs released in the fall, did transplants succeed (Turbak 1993).

In southern Coahuila and northern San Luis Potos, Mexico, the Mexican Prairie Dog (*Cynomys mexicanus*) has become endangered from poisoning and shooting campaigns by ranchers and farmers (Nowak 1991). They have lost a great deal of their habitat to agriculture and huge cattle ranches. The species is listed as Endangered by the U.S. Endangered Species Act as well as by the *1996 IUCN Red List Animals*.

The Black-tailed Prairie Dog (*Cynomys ludovicianus*) numbered in the billions at the time of Lewis and Clark in the early 19th century. Its range covered the millions of acres of shortgrass prairie. This species has been decimated by conversion of the land to agriculture and poison campaigns, causing declines of 98 to 99 percent (Wuerthner 1996). The Biodiversity Legal Foundation in Colorado filed a petition in October 1994 to list this species as a Category 2 species under the Endangered Species Act, a category just below threatened. Although the Fish and Wildlife Service's own biologists supported this listing, the petition was denied after political pressure from ranchers and South Dakota's Senator Thomas Daschle (Wuerthner 1996).

Conservation biologists have expressed concern that the remaining prairie dog towns are so small and fragmented that this may cause the prairie town social system to slowly disintegrate (Stevens 1995b). For a healthy prairie dog ecosystem, reserves of at least several million acres are needed for these animals to recover their natural role in the

prairies (Wuerthner 1996). Some biologists who have studied this situation think that such reserves might be established by purchasing privately owned inholdings in public lands and consolidating portions of BLM land and national grasslands.

The image of the prairie dog as a pest to be exterminated is still dominant in the American West among ranchers, and through their influence, almost all public land except National Parks and some National Wildlife Refuges is managed for livestock, with control programs to eliminate prairie dogs. Poisoning even takes place in a few National Parks that border ranches (Wuerthner 1996). The fragmentation of their populations may be encouraging outbreaks of disease in the prairie dog colonies. Sylvatic plague, a disease that was introduced to North America from Asia in the early 1900s, has swept through many prairie dog towns, wiping out entire colonies in a matter of days (Matchett 1997). The disease is carried by fleas, and prairie dogs have no immunity to the disease (Wuerthner 1996).

As prairie dog towns disappeared, so, too, did a species that is entirely dependent on them. The Black-footed Ferret (*Mustela nigripes*) exists in no other habitat. With such a complete dependence on these rodents and their burrows, the species was extremely vulnerable to declines. Even prior to the poison campaigns, these black-masked members of the weasel family, Mustelidae, had been considered rare, and it is amazing that they survive at all. Ferrets resemble their close relatives, the weasels, in being long-bodied and slim with short legs, well designed to slip into prairie dog burrows. Rodent control campaigns killed ferrets directly when they fed on the bodies of poisoned prairie dogs (see Persecution and Hunting chapter).

A population of Black-footed Ferrets discovered in a South Dakota Indian Reservation in the 1960s died out after poison control programs were implemented. Thought extinct, none was seen until 1979, when two skulls that appeared to be from recently killed ferrets were found in Wyoming. No living animals were found, however. Then in 1981, a rancher found a dead Black-footed Ferret killed by his dog, and gave it to a Wyoming taxidermist to stuff and mount. Although the rancher did not recognize the species, the taxidermist realized that the animal was an endangered Black-footed Ferret. Fish and Wildlife Service biologists came to the property, located more Black-footed Ferrets and began field research. A young male Black-footed Ferret was live-trapped and fitted with a tiny radio transmitter so that researchers could track his movements. After that, more ferrets were seen in the same part of Wyoming. Dr. Tim Clark and his associates counted 58 animals, of which 36 were born in 1982 in this population.

This newly discovered population almost died out as well, however, when canine distemper, apparently spread by a pet dog in 1985, killed the majority of the 127 Black-footed Ferrets known to exist (Godbey and Biggins 1994). Only 19 animals survived of this population, and they were taken into captivity. In 1992, sylvatic plague struck the White-tailed Prairie Dog town inhabited by the ferrets, killing most of the town.

Prior to these events, an extraordinary film, fiThe Mysterious Black-footed Ferret,fl was made by the National Audubon Society in the Wyoming prairie dog town, revealing an enchanting creature (see Video Section, Mammals). They were filmed darting rapidly about in the early morning and at night, often engaging in high-speed chases of one another, zooming in and out of prairie dog burrows and leaping in graceful figure eights. Arching their bodies in an "S" shape, they danced in circles around one another. They often seemed to be playing tag. When an unfamiliar sound that might be a hawk or owl was heard, their black-masked faces appeared suddenly at burrow entrances, and they emitted excited yipping sounds of warning. They were able to back into burrows at high speed, shuffling backwards so quickly that they were gone in the blink of an eye.

Fortunately for the species, the captive-breeding program succeeded. Breeding cages were built in Wyoming, and the project was supervised by the Fish and Wildlife Service. Most of the captive Black-footed Ferrets are housed in units with a den on a lower level connected by plastic pipe to an upper level. They apparently find the pipes satisfactory substitutes for burrows, zipping rapidly between levels, with several ferrets to each unit. Gradually, other captive-breeding centers were established, with many zoos taking ferrets. The captive population rose to 118 animals by September 1989 (DeBlieu 1993) and to 250 breeding adults by 1994 (Godbey and Biggins 1994). Between 1995 and 1997, 400 kits were produced (Line 1997b). Genetically, however, the population is in danger of being inbred,

because the entire population is descended from only 19 animals.

No further signs of Black-footed Ferrets have been found in other parts of the West, and had other populations existed, they would probably by now have been poisoned by the prairie dog campaigns that continue. The Animal Damage Control division (part of the U.S. Department of Agriculture) uses federal funds to poison prairie dogs on millions of acres of federal lands. After the species was listed by the U.S. Endangered Species Act of 1973, federal employees were required to look for signs of the ferrets, such as tracks in the dirt, prior to poisoning prairie dog towns. These signs are not always present, however, and it is very likely that many ferrets have been killed by the United States government even after their supposed protection on the Act.

The present goal of the Endangered Species recovery program for Black-footed Ferrets is to establish new populations in various parts of the West by reintroducing captive-bred ferrets into existing prairie dog colonies. This goal has been difficult to attain, however, because the majority of prairie dog towns remaining in the West, most of which are on federal land, are still being poisoned. Tim Clark commented on this situation: "Prairie dogs figure prominently in the ecology of this continent. Does it make sense to try to eliminate prairie dogs and then turn around and declare ferrets endangered and spend of a lot of money attempting to restore them? We'd never think of burning a museum, yet when it comes to our biological heritage, we don't hesitate to bulldoze it, burn it, or plow it under...To avoid that, we should be protecting prairie dog habitat" (Long 1998).

Black-footed Ferrets require a large territory and, therefore, a sizeable prairie dog town. In 1991, after much searching, a release site was found north of Laramie, Wyoming, and 49 ferrets were set free; by the following spring, two of the females had produced litters (DeBlieu 1993). High mortality marked the first releases because these animals had not been conditioned to cope with natural predators. In 1992, another 90 animals were released, after a period of training in which they were kept in an outdoor pen with prairie dogs; this greatly improved the survival of released animals. Experiments in which ferrets are born and raised in dirt-filled pens with prairie dog burrows and live prairie dogs have produced the most successful adaptations to the wild of all (Matchett 1997). Disease still presents a danger: Of 228 ferrets released in Wyoming's Shirley Basin, only about six animals survived after plague broke out (Line 1997b).

The recovery programs have been conducted with the cooperation of state, federal, local and private concerns, and include education campaigns. Prior to the release of ferrets, local ranchers and others were consulted, and fears that prohibitions of the Endangered Species Act might cause problems if any ferrets were accidentally killed were allayed by the ferrets' designation as "nonessential experimental populations," which allows accidental killing without penalties.

In 1993 and 1994, more Black-footed Ferrets were released in the 1.1 million-acre Charles M. Russell National Wildlife Refuge in Montana in Black-tailed Prairie Dog towns; six of the 12 ferrets were killed by predators, but five of the 1994 releases survived, according to the Fish and Wildlife Service. Additional releases in 1995 and 1996 totaled 119 ferrets (Matchett 1997). Only about 30 ferrets were known to survive from these releases. Since sylvatic plague has been detected among the prairie dogs on the Charles M. Russell Refuge, Fish and Wildlife Service biologists have attempted to control its spread by spraying flea power dust into burrows (Matchett 1997). Over 65,000 individual prairie dog burrows were dusted, a major undertaking which may prevent an outbreak that will decimate these animals, and extirpate the introduced Black-footed Ferrets (Matchett 1997). Only 10 percent of young survive their first winter after leaving their mothers, and habitat that is free of prairie dog control programs is extremely limited.

For the future, however, the number of potential release sites in prairie dog towns that are not being poisoned or bulldozed is limited, and funds for ferret breeding and release may dry up completely (Line 1997b). Federal biologists working on the ferret recovery program have expressed dismay at the lack of public interest in the return of these delightful animals to the wild and believe this will translate into a termination of the program (Line 1997b). The Fish and Wildlife Service hopes that one of the release sites, probably in South Dakota, may have self-sustaining

populations in the future, allowing capture of wild-born young for release elsewhere, rather than supplying captive-bred ferrets at great expense.

Both prairie dogs and Black-footed Ferrets could be major tourist attractions, adding to public knowledge about them and support for their conservation. Prairie dog towns provide constant interest as the little dogs chatter and hug and kiss one another in greeting. Other wildlife, from rare Burrowing Owls to hawks, snakes, tortoises, butterflies and some 170 species, find refuge there. Tourists would likely find the night spotlighting research of biologists studying the ferrets to be fascinating and often extremely lively.

America's largest bird, the California Condor (*Gymnogyps californianus*), once soared over the grasslands of the West, feeding on carrion. Centuries of persecution by hunters and egg collectors nearly caused the bird's extinction. In the 1980s, the last few birds were removed from the wild, where they were dying from accidental poisoning from lead shot in deer carcasses and strychnine from rodent-control programs. A captive-breeding program has been extremely successful, allowing for the release into the wild in southern California and near Arizona's Grand Canyon of young condors from the population of some 169 birds. With a 9.5-foot wingspan, these magnificent birds may again soar over wilderness areas of the West, but there have been problems with released birds approaching people™s homes and even entering them, colliding with power lines and ingesting lead shot. Release of adults, especially some of the original condors, to guide the young, which under natural conditions remain with their parents for several years, may be the only answer to a successful reintroduction.

Fifty-five grassland animals and plants are now listed as endangered or threatened species in the United States (West 1997). Grassland birds have declined more drastically than birds from any other habitat, according to studies by the Fish and Wildlife Service (Pruitt 1997). The wild and beautiful prairies and western shrubland have lost many species of plants, insects and vertebrates. Even where the land has not been plowed, but heavy grazing has occurred, species diversity has declined, and many exotic species of grasses have become established (Peck 1990). In fact, of all North America's grassland birds, only 10 percent have stable or growing populations, according to the North American Breeding Bird Survey (Line 1997). About 260 species of birds are known to breed in the Great Plains, of which 32 are endemic; settlement and agriculture had very adverse effects on most of these species (Knopf 1988). At least 13 species of native grassland birds exhibited downward trends in their populations between 1966 and 1995 (Line 1997). Many of these are among the most familiar and, until recent times, most abundant grassland birds. Meadowlarks, five species of sparrows, prairie chickens and several birds of prey are among these.

Even the bits and pieces of grassland that these birds and other grassland wildlife occupy are swept by pesticides, herbicides and other chemicals used by modern farmers. Crops planted in huge monocultures of one type only, such as corn, create an ecosystem lacking diversity. The introduction in the 1940s of chemical pesticides, fungicides and other chemicals for widespread use was heralded by chemical companies as the ultimate answer to insect and weed pests and a boon to mankind. Farmers wage constant battles on insects, but each year, more species of insects become immune to certain pesticides, and some insects have become immune to all known pesticides. Pesticides kill beneficial as well as pest insects, upsetting ecological balances. Many of the long-lived pesticides of the chlorinated hydrocarbon family, including DDT and dieldrin, enter water tables, persisting in the bodies of animals throughout the food chain. Annual pesticide application in the United States is estimated at 750 million pounds, while the percentage of crops lost to pests has increased from 7 percent in the 1940s to an estimated 37 percent today.

Bird kills began to be documented from DDT use in the late 1940s, and water birds suffered mortality and reproductive failure. DDT and its toxic relatives concentrate in aquatic plants, which are then consumed by small fish, and carnivorous fish accumulated extremely high doses. Birds of prey at the top of their food chains who fed on these

fish or waterfowl suffered complete reproductive failure, and several species, such as the Peregrine Falcon (*Falco peregrinus*) and the Bald Eagle (*Haliaeetus leucocephalus*), suffered population collapses in areas of high pesticide use.

Seventy percent of the United States grain production is fed to livestock; 45.5 million cattle are grazed in the Great Plains (Manning 1995). Many of them graze in the 19 grasslands of the National Grasslands system administered by the Forest Service, which encompass 1,600,000 hectares (3,953,600 acres); 17 are located on the Great Plains, and two are in the Far West (Knopf 1988). They are used primarily as grazing land for livestock, but native wildlife, including endangered species, persists there. The Bureau of Land Management (BLM) and the U.S. Forest Service's National Grasslands are the major landowners in these areas, and both operate under legislation which mandates multiple use or, according the needs of wildlife and conservation, an equal consideration with those of humans. The National Wildlife Refuge System also controls millions of acres of grasslands and drylands harboring endangered species. Livestock grazing and exploitation for oil and minerals takes place on these refuges and, in many cases, they have not been managed in such a way as to preserve natural habitats and threatened species.

Drylands of the World: NORTH AMERICA: Page 6

The United States has set aside sizeable portions of its deserts as national parks, national monuments and national wildlife refuges, as well as vast acreage administered by the Bureau of Land Management. Lands that are administered by the National Park Service as parks, preserves or monuments are far better preserved than the national wildlife refuges or the BLM land. Death Valley National Monument, for example, an enormous area in southern California, protects a huge area with its native vegetation, and the unique oases harboring endangered pupfish as well as other endangered species such as Bighorn Sheep (*Ovis canadensis*). Organ Pipe Cactus National Monument in Arizona and Big Bend National Park in west Texas protect endangered endemic cactuses and other rare species of the Sonoran Desert. Both are scenically breathtaking, with backdrops of jagged mountains. The newly created Mojave National Preserve in southern California covers 1.4 million acres and was the result of decades of lobbying to preserve this unique area. Some cattle grazing and some other types of potentially destructive activities will still be allowed (Wilkinson 1996), but they are gradually being phased out of this preserve, as well as Death Valley National Park (Wilkinson 2000).

Outside the protected areas, however, the Sonoran Desert, with its great diversity of flora and fauna, is gradually being destroyed by residential and urban development. The city of Phoenix, Arizona, for example, has grown dramatically, now numbering 1 million people and spreading more than 469 square miles (Egan 1996a). It is using up precious water reserves through diversion projects. One, the Central Arizona Project, diverted water from the Colorado and dried up other rivers where Bald Eagles (*Haliaeetus leucocephalus*) once nested, eliminating entire riparian ecosystems for the sake of the new city-dwellers and cotton agribusiness. Endemic cactuses fall to the bulldozer, and many wildlife species have become threatened by the new development. The *Arizona Republic* newspaper began a series, "An Acre an Hour," on the disappearance of the Sonoran Desert in 1993, and in the following three years, it documented the destruction of 25,000 acres of this fragile habitat (Egan 1996a).

Grazing is allowed at about 36 national parks and preserves, causing conflicts between wildlife conservation and private interests (Wilkinson 2000). Livestock is allowed to graze as a result of heavy pressure from western Congressmen (Wilkinson 2000). Riparian, or riverside environments, are crucial to the wildlife of these regions, and this type of habitat has been obliterated in hundreds of miles of western waterways after heavy trampling by cattle and sheep. Cottonwood and willow tree groves provide food and shelter for wildlife, and their shade cools the water for trout and other cold-water fish. These streamside trees should be zealously protected. The upper San Pedro River in south-central Arizona contains the largest surviving expanse of broadleaf riparian forest in the Southwest (Christensen 1999). It represents a beautiful oasis in surrounding desert, home to rare Willow Flycatchers (*Empidonax traillii*),

warblers, hawks, and kingfishers; a pair of beavers has been released into the river in the hopes that they would create a marshy pond of willow thickets that the flycatchers prefer. In spite of careful management of this first riparian national conservation area by the Bureau of Land Management, including fencing to keep cattle away, the entire habitat is drying up from over-pumping of water for nearby towns and an Army base (Christensen 1999). Cottonwoods and willows are already starting to die, and within the next decade, half the trees along the river are expected to die. Since Arizona does not regulate its water, which is cheap and available, there may be no way to keep this patch of green from disappearing.

At least eight state fish in the West are endangered as a result of grazing. Overall, grazing threatens some 340 species (Wilkinson 2000), and its effects are even more pronounced in land controlled by the Bureau of Land Management. Forest Service land is used to graze cattle and sheep as well, resulting in many battles between ranchers and environmentalists who try to limit the number of livestock or remove them altogether. Some ranchers are responding to the environmental complaints and are restoring damaged rangeland, allowing grassland to rest and providing alternate water supplies for livestock. New Mexico and Colorado have "grass bank" programs to restore grazing land, a program applauded by scientists as well as conservationists (Blakeslee 2000).

Some ranchers are uncooperative, however, and some environmental organizations believe that grazing is antithetical to proper range management and forest health (Blakeslee 2000). Two conservation organizations have sued to stop all grazing on public lands until federal officials can prove that endangered species are being protected from the destruction of their habitats (Blakeslee 2000). Over the past few decades, small-scale ranching has ceased to be profitable in spite of grazing fees set so low that the parks spend many times more money to maintain the grazing allotments than they receive in fees (Wilkinson 2000).

Ranchers have even received permission to erect fences within the borders of some national parks, blocking wildlife migration routes. The United States Congress is considering taking conservation easements on private ranchland adjoining national parks to protect wildlife in Grand Teton National Park (Wilkinson 2000).

When many of these parks were established, grazing was considered a legitimate use of the parks by Congress, and they were gazetted under these conditions. In spite of this, National Park Service personnel have been able to invoke various laws, including the Endangered Species Act and the National Environmental Policy Act, to force withdrawal of cattle; in some cases, ranchers are compensated for their allotments. The National Park Service is sponsoring a report on park grazing issues that may form the basis for a management policy to reestablish the parks in their primary purpose of protecting the land intact for future generations.

Drylands of the World: NORTH AMERICA: Page 7

One of the most characteristic birds of shortgrass prairie is the Greater Prairie Chicken (*Tympanuchus cupido*). These spectacular birds measure about 16 to 18 inches long, with elegant brown-and-white striated plumage. Males have a large yellow comb of bare skin above the eyes and, during a courtship display for the drab female, he expands bright yellowish-orange skin pouches or sacs on the sides of his neck and raises horn-like feathers on the top of his head, while stamping his feet. The pouches amplify his vocalizations, a series of booming calls; he simultaneously snaps his tail in fanning movements (Johnsgard 1983). Groups of male prairie chickens gather on bare ground, known as a "lek" area, and display for the benefit of females; males also "flutter-jump," leaping off the ground with wings spread out, often while whooping, cackling or issuing whining calls. Their courtship displays are among the most dramatic prairie spectacles. Greater Prairie Chickens have disappeared from the majority of their original range, with one subspecies extinct and two others highly endangered.

Attwater's Prairie Chicken (*Tympanuchus cupido attwateri*), native to coastal prairies of eastern Texas and

southwestern Louisiana, verges on extinction; in spite of recovery efforts that began in the 1970s, these birds total less than 68 in the wild (Anon. 1995). Historically, their population may have numbered 1 million birds in this region, but grasslands in this area have been destroyed by agriculture and development since the early 1900s. Efforts by the Fish and Wildlife Service to increase populations have included the establishment of Attwater's Prairie Chicken National Wildlife Refuge and, more recently, the 3,000-acre Galveston Bay Coastal Prairie Preserve in east Texas, which will be co-administered by the Fish and Wildlife Service and The Nature Conservancy (Anon. 1995). As recently as 1993, 456 Attwater's Prairie Chickens survived, but declines were noted at that time (Anon. 1993). Captive-breeding populations at four sites totaled 35 adults and 65 young in 1995, and some were released at the Attwater's Prairie Chicken National Wildlife Refuge.

The remaining subspecies of the Greater Prairie Chicken, *Tympanuchus cupido pinnatus*, is extinct, or nearly so, in 15 U.S. states and Canadian provinces, but legally hunted in four states. These birds suffered great declines in the past from market hunting, and hunting can decimate populations. In the 20th century, these birds lost much of their habitat to agriculture, and pesticides kill their chicks. Their distribution has become localized and fragmented, along with the undisturbed prairie which is their prime habitat.

Two grouse of the prairies have been listed as Special Concern by the National Audubon Society. The Sharp-tailed Grouse (*Tympanuchus phasianellus*), a close relative of the prairie chicken, resembles them except the male has a purple air sac in display and lacks the horn-like head feathers. This bird has a more northerly range than the latter species, living in brushy prairies, open bogs, or abandoned farmland from Illinois and Kansas north to Alaska (Farrand 1983). It has disappeared from much of the southern portion of its range as a result of overhunting, overgrazing, and conversion of native grasslands to agriculture (Ehrlich *et al*. 1992).

Drylands of the World: NORTH AMERICA: Page 8

Sage-juniper shrubland once covered much of many western states in a north-south band from southern Canada to Mexico. This habitat made optimum use of the low rainfall of the region while sheltering an array of wildlife. Pronghorn antelope, deer, foxes, jackrabbits, Coyotes and a great variety of small mammals, birds and reptiles were native. The Bureau of Land Management and private ranchers acquired much of this region and attempted to turn it into grazing land. To eradicate the native plants, herbicides were used, and in many areas, the vegetation was chained: Battleship anchor chains strung between bulldozers are dragged through the sage and other native plants, pulling them out by their roots and leaving bare earth. This eliminated large portions of this habitat, threatening a host of native species. Chaining has been opposed by conservationists and Native Americans, but little action was taken until a 1997 lawsuit by the Paiute Indian Tribe of Utah and the Southern Utah Wilderness Alliance halted work in the area. The tribe claimed that chaining disturbed archeological sites, and the conservation group opposed it on environmental grounds. Chaining continues in Utah and elsewhere. The destruction of sage-juniper shrubland has allowed an invasion of exotic weeds, from tumbleweed to Eurasian Cheatgrass (*Bromus tectorum*), an extremely flammable plant that has spread over an estimated 100 million acres across the West. Native wildlife, such as Mule Deer, Sage Grouse and jackrabbits, which thrive in sagebrush, disappear when Cheatgrass takes over. Cheatgrass does not provide good forage for livestock because it is green only briefly in the spring and fall. Massive rangeland fires have broken out, scorching the ground and bringing about the collapse of entire ecosystems, according to Jayne Belnap, an ecologist with the U.S. Geological Survey. Herbicides are being used to eradicate Cheatgrass with varying success, and a fungus may be introduced which kills the grass. Federal officials are attempting to restore native plants and grasses to portions of Utah to replace Cheatgrass and other exotic weeds such as Russian knapweed. Restoration of the original sage-juniper habitat may never occur, however.

One species that has suffered from loss of sagebrush habitat is the Sage Grouse (*Centrocercus urophasianus*), the largest grouse in North America. Weighing from 5 to 7 pounds, this bird is native to sage rangelands from southern

Saskatchewan south to Utah, Colorado and eastern California. The displaying male expands large white air sacs which are surrounded by a huge mass of fluffy white feathers encircling his head and covering his belly, making him look double his actual size. He folds his dark brown wings to frame the white chest plumage and spreads his brown spotted tail in a fan of long spikes. While displaying, the male makes a bubbling sound as air is released from his air sacs, and the female, in sombre brown and white plumage, cackles (Farrand 1983). Millions of acres of this spectacular bird's habitat have been converted to agriculture and grazing. Sagebrush, which comprises this species' entire diet, has been destroyed to create grazing land for cattle (Ehrlich *et al*. 1992). Western populations of the Sage Grouse may be listed on the Endangered Species Act, having been officially classified as a Category 2 species by the Fish and Wildlife Service, indicating a species that may be in jeopardy unless current trends are reversed. The full species has been listed by the National Audubon Society as a bird of "Special Concern" (Ehrlich *et al*. 1992). The Sage Grouse is extinct in British Columbia and New Mexico (Farrand 1983).

The destruction of sage shrubland did not result in seas of grass for cattle because of the climate and soil factors. Instead of forage, exotic grasses took hold, and today the Bureau of Land Management claims that one of these, the Eurasian weed cheatgrass (*Bromus tectorum*), has become the foremost environmental problem in the country. It has infested an estimated 100 million acres of what was once sage and native grasses. The BLM itself laid the way for this invasive weed, which is extremely flammable and spreads in uncontrolled wildfire once ignited. The United States government is planning to introduce a fungus native to Eurasia that kills the grass, and other scientists are testing an herbicide to kill it. Cheatgrass does not provide good forage for livestock because it is green only briefly in the spring and fall. Ranges that burned only once a century now catch fire every three or four, and cheatgrass has come to dominate the ecosystem. Some research scientists are cultivating native grasses in laboratories to replace cheatgrass. Chaining is planned to rid the range of cheatgrass.

West of the Rocky Mountains, large stretches of prairie, known as intermountain grasslands, occur from eastern Washington through Nevada and Utah. Only 1 percent or less of California's grasslands remain (Mittermeier *et al*. 1999). Once they covered 9 million hectares (more than 22 million acres), dominating the Sacramento and San Joaquin valleys, known as the Central Valley (Mittermeier *et al*. 1999). This valley is now almost entirely agricultural fields, livestock grazing area and urban development. Many species of plants and animals were probably lost since these grasslands were plowed before botanical and zoological studies were made (Knopf 1988). The vernal pools, or temporary wetlands, that once provided habitat for wildlife, including spawning places for turtles and frogs, are also nearly gone (Mittermeier *et al*. 1999).

In California's southwestern coastal region, a unique mosaic of ecosystems of sage giving way in parts to oak woodlands, dunes, conifers and riparian vegetation, once covered millions of acres (Boucher 1995). This natural environment is under extreme threat from development by the burgeoning populations of San Diego and a string of towns and cities that stud the coast and inland areas north to Los Angeles. Unrestricted building of homes, golf courses, highways and industries have consumed hundreds of thousands of acres here since the 1970s. The areas along river and streams, or riparian regions, are the most endangered habitats. The virtual explosion of development has squeezed wildlife into pockets of their original ranges and threatened the survival of hundreds of species.

The Fish and Wildlife Service lists 77 species of animals and plants that are dependent on the coastal sage ecosystem on the Endangered Species Act, and almost 400 more species as candidates (Mann and Plummer 1995). Among these is the California Gnatcatcher (*Polioptila californica*), a small black-capped songbird, first listed on the U.S. Endangered Species Act as Threatened in 1993 after the State of California bowed to developers and refused to list it on the state endangered legislation. The statewide population totals only a few thousand birds. Another endangered bird, Least Bell's Vireo (*Vireo bellii pusillus*), is restricted to shrub and scattered woodlands in this same region. The state of California has listed many other threatened resident species of the region, halting many developments. Since this is some of the most valuable real estate in the country, with real estate lots selling for between $200,000 and $3 million an acre, conflicts arose (Mann and Plummer 1995). The human population of Southern California quintupled between 1940 and 1995, a rate that exceeded Bangladesh's rate of increase (Mann and Plummer 1995). A consortium of 40 California conservation groups fought to save these songbirds and their habitat

and, in the process, curb the smog, traffic, pollution and housing developments that are taking over the state.

The high-pitched battle included developers, the business community, residents, local and state legislators, federal government authorities, conservationists and scientists, all at odds over the fate of this beautiful region and its wildlife. The coastal sage shrub ecosystem has been reduced to about 6,000 square miles of disconnected patches south of Los Angeles, with one of the largest preserved areas being the U.S. Marine Corps' Camp Pendleton (Mann and Plummer 1995). The California Resources Agency chose this habitat to test its Natural Communities Conservation Planning (NCCP) program, dividing it into 13 subregions; the city of San Diego had its own program to cover 12 habitat types over 900 square miles (Mann and Plummer 1995).

A complex alliance of organizations and interests finally agreed to a federal-state master plan for the conservation of two counties, with the objective of preserving the major part of what remains of the already fragmented ecosystem. Although far preferable to uncontrolled development, the Endangered Species Act's Habitat Conservation Plan (HCP) for San Diego and Riverside counties allowed massive growth of housing and highways to occur in endangered species habitat. Because the California Gnatcatcher is listed as Threatened under the Endangered Species Act rather than the more restrictive category of Endangered, development can continue under Fish and Wildlife Service regulations, which allow up to 5 percent of its coastal sage shrub habitat to be destroyed (Boucher 1995). Also, the listing of this bird had been conditional, based on the success of the NCCP plan under an obscure rule of the Endangered Species Act (Boucher 1995). The plan created a system of large protected reserves linked with corridors of similar habitat. Developers can build on habitat outside the reserves. The sizes of the reserves, which also include habitats of some or all of about 80 additional species threatened with extinction, are critically important. Scientists appointed to some review panels for the HCPs have found that, rather than producing specific guidelines, they were asked only for general ones, and considering that 90 percent of the coastal sage shrub has already been destroyed, there is little room for error. In Orange County, development companies own the majority of sage shrub, and their consultants have demanded that scientists prove their case concerning the amount of area needed for reserves, causing one environmentalist to conclude, "The county is the lead agency in name only. It's basically a branch of the real-estate industry there" (Boucher 1995).

In spite of the apparent success of some of these agreements, some scientists have expressed uncertainty as to whether the reserves will be adequate to prevent extinction of the California Gnatcatcher and other species (Boucher 1995). These conflicts are occurring in other parts of the country as well, pitting environmentalists against developers. Unless the careening, out-of-control development and the geometric population growth slow, thousands of species and their unique habitats will be lost in the process, no matter how careful the planning.

Drylands of the World: NORTH AMERICA: Page 9

Kangaroo rats are other species caught up in land battles. Native to shrub and desertland in the Southwest and Far West, several species are highly endangered. Their name might conjure up images of enormous, menacing rodents, but these little animals are, in fact, very attractive, with huge dark eyes. They have been named for their jumping ability. Ranging from 4 to almost 8 inches, depending on the species, they have long tails, equal in length to their body, ending in fluffy tufts (Nowak 1999). Weighing only between 1.2 to 6.3 ounces (35-180 grams), they are able to leap almost 7 feet on their outsized hindlegs (Nowak 1999).

A recent acoustical research study found that kangaroo rats communicate various messages, such as danger, by drumming their feet on the ground in different cadences. Twenty-one species of kangaroo rats occur in North America, living in colonies in shrublands and shortgrass prairies (Nowak 1999). Four species and subspecies of kangaroo rats live in California's San Joaquin Valley, north of Los Angeles, and each has lost at least 95 percent of its original habitat to agriculture and urbanization; all of the latter have been listed on the Endangered Species Act

(Nowak 1999). The original range of the Tipton Kangaroo Rat (*Dipodomys niatoides nitratoides*), a terrain of iodinebush, saltbush, Red Sage and other shrub plants, once covered nearly 2 million acres of the southern San Joaquin Valley, but today, only 1 percent of this rodent's population remains, almost all in the 4,000-acre LoKern Preserve, which protects a last remnant of this habitat. The Giant Kangaroo Rat (*Dipodomys ingens*), another endangered species of this valley, is the largest of all kangaroo rats; a population of this species lives in the LoKern Preserve (Peterson 1993). The Giant Kangaroo Rat is considered the most endangered of all kangaroo rats, classified as Critical by the *1996 IUCN Red List Animals* (Baillie and Groombridge 1996). This status designation is accorded to species in imminent danger of extinction. Kangaroo rats are extremely vulnerable to poisoning programs aimed at ground squirrels, and without reserves where poisoning is banned, they have disappeared.

Kit Foxes (*Vulpes macrotis*) are now rare throughout their range in the West, and one subspecies, the San Joaquin Kit Fox (*Vulpes macrotis mutica*), is listed on the U.S. Endangered Species Act as Endangered. Only 2,000 to 6,000 animals remain (Begley 1997). Some of these tiny foxes live in reserves, while others survive on the outskirts of cities built on their original habitat. Bakersfield, California is an urban area where a small and beleaguered population of these little foxes survives. Weighing only 5 pounds, the kit foxes in Bakersfield make their dens in vacant city lots, vulnerable to injury from broken glass and predation by dogs (Begley 1997). Cars and trucks kill and injure them. One lame Kit Fox with an injured back leg was given handouts of doughnuts and scraps by a night shift mechanic at a city maintenance yard until the animal was struck and killed by a vehicle (Begley 1997). In a bizarre accident, two kit foxes died after becoming entangled in soccer nets at California State University (Begley 1997).

San Joaquin Kit Foxes are also illegally shot for sport and poisoned by ranchers in the mistaken idea that they pose threats. They have been forced into the last vestiges of their once vast range, which becomes smaller each year. Construction crews have bulldozed them in their dens, and pairs, who mate for life, have been forced into unnatural habitats, digging dens beneath fuel storage tanks and in other exposed areas (Begley 1997). They have natural enemies as well, preyed upon by Coyotes and eagles. A recent escapee from fur farms, the eastern Red Fox, now roams the San Joaquin Valley and occasionally kills these little foxes (Begley 1997). Few of their 1-pound pups survive to adulthood. Only in the Carrizo Plain and portions of western Kern County do sizeable pieces of habitat remain. In all, they have lost over three-fourths of their original habitat, and these graceful, agile little foxes may disappear unless efforts are made to link fragmented populations and set aside more habitat.

This fox became a pawn in the battle over the U.S. Endangered Species Act, which has pitted commercial interests against conservationists. Congressman Richard Pombo, a California Republican, proposed legislation in 1994 to replace the Endangered Species Act. It would have made species preservation an optional matter to be weighed against potential economic losses that could result if the habitat were set aside, and would have required the federal government to pay property owners for the value lost on land subject to restrictions on behalf of endangered species. Congressman Pombo's district, the San Joaquin Valley, has very little undeveloped land left, and the land value has escalated. His family owns a large real estate firm which has profited from the land boom in the valley. San Joaquin Kit Foxes inhabit the ranch next door to Congressman Pombo, and his neighbor, Mark Connolly, does not share his views. Mr. Connolly likes open space as well as the foxes, and he sold the development rights on his property to a nature conservation organization, allowing him to protect the foxes along with the land (Egan 1996b). Congressman Pombo's proposed legislation, which fortunately, did not become law, would not have given special protection for the remaining San Joaquin Kit Foxes in his district without massive infusion of public money to repay landowners.

Private organizations, such as The Nature Conservancy, have been acquiring millions of acres of grassland and desert to protect endangered habitat. Educational programs on the importance of saving grassland and desert habitats and returning them to their original states will increase in the future as governmental entities and private organizations produce more publications, films and other materials. Students are also becoming involved in preserving these habitats by propagating the seeds of rare plants and restoring degraded prairie. American deserts are among the most stunning and colorful in the world, yet they are the subject of fewer conservation projects and educational publications than grasslands. They are under assault from developers, miners, livestock and highway builders. A growing number of conservationists are defending them, however, and designation of new national parks in the deserts of Utah and

southern California stopped planned developments and mining.

Drylands of the World: NORTH AMERICA: Page 10

So thorough has been the destruction of eastern savannah that reestablishing the native species has involved a detective investigation of early natural history documents. Conservationist Steve Packard found old botanical references on Illinois' native plants and gradually pieced together what species must have once lived in Vestal Grove; he then set about to find seeds, especially of rare plants that were threatened with extinction (Stevens 1995). Botanists and volunteers from the Sierra Club and The Nature Conservancy scoured the few places not plowed or developed still harboring rare Illinois prairie plants-- strips of land next to railroads, for example (Stevens 1995). Remarkably, many rare plants have been found, their seeds obtained, and, after long trial and error, methods of restoring this ecosystem developed. Controlled fires need to be set annually to burn off some types of aggressive shrubs. Before they were driven from the land, Native Americans lit these fires to maintain grasslands. This project is part of a far more ambitious plan in which 3,000 volunteers will replant 17,000 acres of tallgrass savannah on 142 sites in the Chicago area; ultimately, 100,000 acres will be restored, as described in *Miracle Under the Oaks*, a book by William K. Stevens (1995).

In another area near Chicago, the Forest Service has established the Midewin National Tallgrass Prairie on the site of the former Joliet Army Ammunition Plant; 5,000 acres will be restored to native grasses and wildflowers, and Elk and American Bison will be reintroduced (Line 1997).

The Fish and Wildlife Service is participating in a project to restore some 77,000 acres of grasslands in 85 counties of western Minnesota and northwestern Iowa, designated as the Northern Tallgrass Prairie Habitat Preservation Area (West 1997). In Minnesota and Iowa, less than 1 percent of the original 25 million acres of this habitat remains (West 1997). The project will involve individuals, organizations and various state and county governments as well, all working to restore the biological diversity and plants of these grasslands.

North Dakota, likewise, has less than 1 percent of its original tallgrass prairie. Parcels that remain are being acquired by the Department of the Interior, and some damaged land is being restored. A federally listed threatened flower, the exquisite Western Prairie Fringed Orchid (*Platanthera praeclara*), has a population in the Sheyenne National Grassland in southeastern North Dakota. Managed by the Custer National Forest under a conservation plan, its habitat is being preserved (Sieg 1997). This plant, although once widespread through the tallgrass prairie west of the Mississippi River, has become reduced to two main populations, one of which is the Sheyenne National Grassland. These orchids do not flower every year, but when they do, the white fringed flowers produce a fragrance that attracts hawkmoths that come at night to pollinate it (Sieg 1997). The species' life history is poorly understood, and efforts to germinate its seeds in greenhouse conditions have not been successful. Botanists suspect that a fungus might be needed to promote absorption of nutrients for germination, and it seems to require unusual conditions of soil moisture (Sieg 1997). These orchids live at least 10 years, and study is proceeding on individually marked plants to learn more about their ecology. In addition to loss of habitat, the plant is threatened by a noxious weed, Leafy Spurge (*Euphorbia esula*), which is spreading within its limited range(Sieg 1997).

Drylands of the World: NORTH AMERICA: Page 11

Contamination of water and soil in the United States Midwest is a growing problem. A major reason for the continued high use of pesticides is the planting of hybrid seeds bred to produce high yields. First introduced in the 1960s and 1970s, these seeds were touted as bringing about a "Green Revolution" which would feed the world. Massive applications of petroleum-based nitrogen fertilizers, toxic herbicides, insecticides and fungicides are required

to grow these weakened, seed-heavy plants (Ehrenfeld 1997). The costs of these chemicals and the giant machines needed to sow, apply pesticides and reap crops are so prohibitive that farmers become indebted, often losing their farms when crops fail (Ehrenfeld 1997). Green Revolution programs started and failed in many Third World countries, yet are still widespread. India, southeastern Asian countries and many Latin American nations experienced high yields at first, which later dropped, and incurred heavy debts from both the cost of the seed and the chemicals needed to grow these crops.

A more recent approach to insect and weed pests is the creation of genetically engineered versions of crop plants to resist certain diseases and pests. Genes from one plant resistant to disease are implanted in another, with only the disease-resistance trait passing on in theory. In practice, genes have many traits with the potential of being introduced, creating a plant with uncontrollable characteristics that might become established in the wild, overwhelming native plants (Ehrenfeld 1997). Genetically engineered versions of many food plants are grown on millions of acres in the United States. Some of these genetically engineered seeds have been implanted with the genes of animals, including fish, to impart various qualities such as resistance to cold (Feder 2000). The dangers of such manipulations are great, and many biologists have expressed serious reservations about these new man-made creations. *The Last Harvest. The Genetic Gamble That Threatens to Destroy American Agriculture* (Raeburn 1995) examines the potential threats.

One dangerous trend in genetic engineering of crop plants is the development of soybeans and other crop plants that are immune to the effects of herbicides, encouraging farmers to broadcast large amounts of these toxic chemicals, which are associated with human illness, including lymphoma (Ehrenfeld 1997). A leader in bio-engineering of crop plants is Monsanto, which also manufactures the herbicide Roundup, a product that has experienced unprecedented high sales in recent years due to the growth in sales of genetically engineered seeds. Rutgers University biology professor, David Ehrenfeld (1997), considers the genetic engineering trend to be a "Techno-pox upon the Land," whose approach ignores the "great complexity of living organisms and the consequences of tampering with them." Monsanto has funded a center at the famed Missouri Botanical Garden for research, which has angered many who are opposed to both genetic engineering and the toxic agricultural chemicals (Jackson 1998). For many Americans and the majority of Western Europeans, food produced in this manner is "Frankenfood" or Frankenstein-like creations that might harm people as well as the environment. Although European countries and many U.S. food processors reject genetically engineered grains, their use, as well as other crops with genes implanted from a wide variety of organisms from nuts to trout, is widespread in hundreds of products. Other countries, such as China, are eagerly introducing bioengineered crops.

Genetically engineered crops also present dangers to wild plants and animals, many of which are endangered, living in remnant prairies, roadsides and pastures. These areas provide vital habitat and feeding grounds for grassland birds, butterflies and other wildlife. Many bioengineered crops containing pesticide genes threaten these prairie vestiges. Monarch Butterflies are the most familiar butterflies in North America, ranging throughout the continent, their black-and-orange wings brightening gardens and fields as they migrate in spring and fall. Scientists recently found, however, that genetically engineered corn implanted with Bt, thought to be a fairly benign and natural pesticide, could spread pollen that was toxic to these beautiful butterflies and other beneficial insects (Feder 2000). Although conservationists and organic food advocates have campaigned against the use of this corn, the highly profitable bioengineering industry fought back with studies that concluded that the corn was not a threat to the butterflies. The United States government has no laws governing the effects on the environment of such crops, or even extensive field testing, prior to their use.

Far more ecologically benign is organic farming. Using natural fertilizers such as manure and plant material, rotating crops to enrich the soil and enhancing habitat for natural pest controllers, including birds and predatory insects, are all age-old farming methods. Those farmers who have used these methods have kept land fertile and yields high indefinitely. Within the past few decades, the pendulum has begun to swing away from synthetic pesticides, herbicides and fertilizers back to the natural approach to farming in the United States and elsewhere in the world. More and more American farms are returning to this method. Sales of organic food are rising in the United

States at a phenomenal rate, fed by a market willing to pay more for chemical-free food. This farming does not contaminate ground water, eliminate native plants and invertebrates with herbicides and fungicides, or kill wildlife with pesticides.

Drylands of the World: SOUTH AMERICA

The majority of South America's grasslands, from low altitudes to Andean meadows, have suffered desertification from livestock similar to that seen in other parts of the world. Agriculture has taken over large portions of tropical grasslands. Brazil's Emas National Park is an ecological island covering 131,868 hectares (325,846 acres) of grassland with some gallery and dry forest in the center of thousands of square miles of cultivated grain fields. This vestige of the original Brazilian grasslands has a rich variety of birds and several endangered mammals, including Giant Anteaters (*Myrmecophaga tridactyla*) and the beautiful Maned Wolf (*Chrysocyon brachyurus*). The once widespread grasslands of the region is threatened by pesticide use, erosion and other destructive practices in surrounding plantations. Conservation International and a local environmental group working to protect the Emas are attempting to reduce these threats and develop environmental education and ecotourism in this park (Fonseca *et al*. 1999). This park and its wildlife are seen in fiEmas: High Plains of Brazil,fl a 1985 film that shows many of the endangered species; aerial views show the island-like isolation of this national park (see Video, Regional, Latin America).

The endangered Maned Wolf was formerly widespread on the savannahs, northern pampas and chaco regions of central and eastern Brazil, Argentina and Uruguay (Nowak 1999). This longer-legged canid is designed to hunt in the savannah, able to peer high above the tall grass for rodents, birds, frogs and insects; it also feeds on fruit, especially that of a shrub known as *fructa de lobo (Solanum grandiflorum*), a member of the potato family (Dorst 1967). Its head and body are about 4 feet long, with shoulder height of 2.4 feet, making it a fairly large animal, but it weighs only 20 to 23 kilograms (44-50.6 lbs) (Nowak 1999). Looking somewhat like a Red Fox on stilts, its stick-like black legs contrast with long, shaggy, reddish-yellow body fur. The fur on its back and nape stands up stiffly, giving it the appearance of a large and stocky animal, while in reality, it is slight and wiry. The Maned Wolf does not closely resemble any other canid, and has been placed in a genus of its own. These wolves have been killed and persecuted under the false impression that they are a threat to livestock and have suffered from habitat loss, the annual burning of grasslands and live capture for zoos. Classified as Near-threatened by the IUCN (Baillie and Groombridge 1996), the Maned Wolf is Endangered on the U.S. Endangered Species Act, and on Appendix I of CITES.

Native deer of three species inhabit South America's grassland, wet savannah and shrub woodland. Two of these have become endangered by loss of their natural habitats to livestock, agriculture and overhunting. Pampas Deer (*Ozotoceros bezoarticus*) were once abundant in grasslands from southern Brazil to eastern Bolivia, Paraguay, Uruguay and northern and central Argentina (Nowak 1999). In spite of an enormous original distribution, these deer have undergone steep declines and now survive only in tiny remnants of their range. The species has been listed on Appendix I of CITES and as Endangered on the U.S. Endangered Species Act. Three subspecies of the Pampas Deer are listed in the *1996 IUCN Red List Animals* (Baillie and Groombridge 1996). These lovely deer inhabit a wide variety of grassland habitats, all at low elevations, including flood plains, rolling hills and grass tall enough to completely conceal a standing deer (Nowak 1999). Four hundred years ago, before the arrival of Europeans, these deer were abundant, especially on the pampas of Argentina and Uruguay (Nowak 1999). Native Indians had a relationship with the Pampas Deer similar to that of the Plains Indians with the American Bison in North America, relying on it for their livelihood. The Indians were expert horsemen who hunted the deer for subsistence purposes, but when Europeans settled, they killed them for commercial trade (Nowak 1999). More than 2 million skins were exported in the decade 1860-70 from Argentina, and others were taken in neighboring countries (Thornback and Jenkins 1982).

In spite of this slaughter, Pampas Deer remained widespread until the grasslands were settled. Cattle, sheep, exotic Sika and Fallow Deer, and European Hare were introduced, and the land was plowed for crops (Thornback and Jenkins 1982). Domestic livestock transmitted disease to the deer, further decimating them, and hunting continued in an uncontrolled manner (Nowak 1999). In Argentina, only a few remnant herds survive, totaling about 500 animals (Nowak 1999), while the population in southeastern Brazil is nearly extinct (Rizzini *et al*. 1988). In Uruguay only about 1,000 Pampas Deer remain in nine isolated sites (Nowak 1999). Populations in central Brazil, Bolivia, Paraguay and part of northern Argentina are low and declining (Nowak 1999).

The Cerrado of eastern Brazil is a wilderness of savannah, woodland/savannah and dry forest. Until recently, it had not been recognized for its biological wealth, either internationally or by the government of Brazil (Mittermeier *et al*. 1999). Now it is receiving the attention of conservation organizations within Brazil and has been a focus of the recent book, *Hotspots* (Mittermeier *et al*. 1999), describing these high-diversity areas. Action is being taken to preserve portions of this area, home to a wide variety of unusual plants and animals. The Private Natural Heritage Reserve system is similar to the conservation easements, or agreements not to develop land, that have been taken on privately owned land in the United States. Private conservation organizations in Brazil, especially FUNATURA, have been active in establishing these areas in the Cerrado, and to date over 20 of these wildlife sanctuaries have been established (Fonseca *et al*. 1999). Such land can receive tax deductions and legal protection provided by the Brazilian state. A book on the biology and wildlife of the area was published in 1993 (Pinto 1993), and in 1995, a major conference was convened on the conservation of the Cerrado and Pantanal, drawing 215 experts from Brazil and international participants (Fonseca *et al*. 1999). It identified 70 priority areas within the Cerrado for conservation and made suggestions for legislation to create incentives to preserve biodiversity and the environment (Fonseca *et al*. 1999).

A large national park was established in the Cerrado in 1989 covering 84,000 hectares (207,564 acres) of a 13-million-hectare region along the Sao Francisco River threatened by agricultural plantations and charcoal production (Fonseca *et al*. 1999). It is the first and only debt-for-nature swap ever approved for Brazil, signed by FUNATURA and The Nature Conservancy, providing some $2 million in government bonds whose interest would fund conservation within the park over the next 20 years (Fonseca *et al*. 1999).

Drylands of the World: SOUTH AMERICA: Atacama Desert

Patagonia, a vast wilderness of grasslands, shrub and desert, is home to a diverse array of unique animals, from endangered members of the camel family to deer and large rodents. Over the past few hundred years, this wildlife has been displaced by livestock, which are overgrazing and desertifying the region. The Guanaco (*Lama guanaco*), a wild relative of the domestic Llama, was once the characteristic animal of Patagonia's grasslands in populations estimated at between 30 and 50 million prior to the arrival of Europeans (Nowak 1999). In the past 400 years, they have been crowded out of prime habitat by the millions of sheep grazed by ranchers. Only about 571,000 Guanacos survive, and their numbers continue to decline (Nowak 1999). In some areas, ranchers kill Guanacos, considering them competitors with sheep for grass. The species has been eliminated from most of eastern and lowland grasslands, from southern Peru to eastern Argentina south to Tierra del Fuego (Nowak 1999). In their vast Patagonian range, no large protected areas have been set aside for them (Uhart and Baldi 2000). One of the few places where one can see these statuesque animals in Argentine Patagonia is the 2,500-acre Cabo Dos Bahias Provincial Reserve on the coast; it is surrounded by ranch land used for sheep grazing (Uhart and Baldi 2000). In the summer of 2000, 350 to 500 Guanacos were found dead in this small reserve, including entire families with newborn young. A team of veterinarians from the Wildlife Conservation Society (WCS) flew from New York to determine the cause (Uhart and Baldi 2000). Preliminary examination of carcasses indicated that the Guanacos had slowly starved to death as a result of being confined to a too-small reserve that was poorly managed and allowed to become overgrazed and desertified; managers had even allowed sheep to graze within the reserve (Uhart and Baldi 2000). WCS urgently recommended

that the reserve be enlarged.

Guanaco family groups are headed by a male who leads four to ten females and young under 15 months (Nowak 1999). At certain times of the year, groups form herds that may number as many as 100 animals (Dorst 1967). Males act as sentinels and warn of danger, allowing the herd to escape at high speed, up to 56 km per hour, outrunning a man on horseback (Dorst 1967). Guanacos are listed on Appendix II of CITES, since their pelt and fur are in commercial demand.

Its close relative, the graceful and beautiful Vicuña (*Vicugna vicugna*), inhabits hill and steppe grasslands at high altitudes of the Andes in Peru, Bolivia, northwestern Argentina and northern Chile (Nowak 1999). Heavily hunted for its extremely valuable fur, it nearly became extinct several times during the 20th century. The Incan people had traditionally captured Vicuñas alive, shearing them for their wool and releasing them. Prior to the arrival of the Spanish, these animals numbered an estimated 1 to 1.5 million (Nowak 1999). From the 17th century onward, the Spanish killed them by the hundreds of thousands, replacing them with domestic livestock in much of their original range. By the 1950s, only 400,000 Vicunas remained, declining to only 6,000 in 1965 (Nowak 1999). Since then, conservation measures have brought them back to about 200,000. Herds are rounded up under current laws, and their wool is sheared. The soft wool is marketed on a quota basis under CITES regulations from several countries, primarily Peru, but some illegal killing occurs (see Trade chapter). The populations of Vicuña need to be guarded very carefully to prevent further decimation of their numbers.

The Chaco, a mixed savannah-woodland region of Paraguay, Bolivia and Argentina, covers 100,000 square miles wedged between the Pantanal wetlands of southern Brazil, the semi-tropical forests of eastern Paraguay, the Argentine pampas and the Andes to the west. Prior to the arrival of Europeans, the grasslands were maintained by native peoples who burned vegetation periodically, limiting woodland growth (Bucher and Nores 1988). Ranches were allocated to European immigrants by the governments of Paraguay and Argentina, and the new immigrants cut woodlands and plowed the grassland for agriculture. This region, once a wildlife paradise with more mammal species per square mile than the Amazon basin, according to some zoologists' estimates, has become ravaged by misuse (Thigpen 1996). More than 400 species of birds were native to the thorny brushlands, marshes, forests of ancient oaks, grasslands and deserts (Thigpen 1996).

In Argentina and portions of Paraguay, overgrazing by livestock has turned savannah into shrub, and agriculture has destroyed more of the Chacoan ecosystem. This has threatened many species of native wildlife. The few parks in the region lack adequate staffing to prevent destruction by activities such as illegal grazing. In recent decades, bird trappers have felled tens of thousands of old oaks and other trees, used by Blue-fronted Amazons (*Amazona aestiva*) for nesting, in order to obtain the young chicks for the pet trade. This trade was ended in the early 1990s after undercover investigations and films by the Environmental Investigation Agency documented this cruel and destructive trade, and the United States banned importation of these birds. Public opinion and the catastrophic decline in wild populations of these parrots forced the Argentine government to stop exports, but in many areas of Argentina, old trees with nesting cavities have now disappeared. Forests have also been felled to make way for agriculture, which has threatened many kinds of parrots and other hole-nesting birds, such as woodpeckers and the Great Horned Owl (*Bubo virginianus*) (Bucher and Nores 1988). Eucalyptus has been planted in many parts of the Argentine Chaco, and this exotic tree has had a deleterious effect on native plants and wildlife.

Drylands of the World: AFRICA
Page 1 (Sahara Desert)
Page 2 (Serengeti)
Page 3 (Horn of Africa)

Drylands of the World: AFRICA: Page 1

The Sahara Desert represents an extreme case of grassland destruction by humans. African Elephants (*Loxodonta africana*) lived in the Central Saharan highlands 10,000 years ago, and until 6,000 years ago, much of the Sahara was a vast grassland, interspersed with lakes and rivers. People inhabiting this region at that time recorded the wildlife in paintings on mountainous cliff faces and on cave walls. Massive petroglyphs of larger-than-life-size Giraffes (*Giraffa camelopardalis*) have been found in Niger's Sahara (Clottes 1999). The male Giraffe is almost 20 feet long in a striking, deep engraving delineating each patterned blotch, crafted some 8,000 years ago (Clottes 1999). Drawings of antelope, ibex, Brown Bears (*Ursus arctos*), Lions, Cheetahs, elephants, gazelles and Black (*Diceros bicornis*) and White Rhinoceroses (*Ceratotherium simum*) froze in time an environment that gradually vanished. Five thousand years ago, Egyptians began cultivating grasslands for crops, overhunting wildlife and draining marshland bordering the Nile for agriculture (Ponting 1991). Ancient Egyptian paintings show the panorama of wildlife that once flourished in the grasslands and marshes in the Nile River region. Large and small wild cats were common, as were Giraffes, rhinoceroses, Hippopotamuses (*Hippopotamus amphibius*) and other large mammals. By the Old Kingdom period (2950-2350 B.C.), the African Elephant, rhinoceroses and Giraffes had disappeared from the Nile Valley (Ponting 1991). The Cheetah disappeared from northeastern Africa at an early period. These graceful cats had been domesticated by the Egyptians and appeared in their paintings, but were gradually killed off or over-captured in the wild. Misuse of the land, which ended in turning grasslands into sand dunes and destroying the fertility of the seasonal flood plains and marshes, was the major cause of the demise of the Egyptian civilization (Ponting 1991). Desert sands have interred many of the monuments and pyramids of this once flourishing culture.

Following the decline of the Egyptian civilization, the Sahara became a crossroads of nomadic peoples and their livestock. Over the centuries, grasslands turned to shrub and isolated patches of vegetation from overgrazing, resulting in a drying of the climate and a decline in large mammals. Sand dunes now dominate this enormous region, and the majority of grassland species have been eliminated. Only those animals able to subsist in extreme heat and desert-like conditions survive here today, and even these have been restricted to the few remaining pockets of vegetation and near oases. These green spots in the Sahara are fed by springs and were once havens for wildlife and plants. Humans have gradually taken them over for livestock, agriculture and human habitation. Until recently, camels transported salt across the Sahara, traveling in caravans of as many as 20,000, which required vast amounts of vegetation for fodder. Nomadic tribes such as the Tuareg continue to herd large flocks of sheep and goats consuming what vegetation manages to survive in this arid environment. Shrubs and trees are cut for firewood, further desertifying the region. During the 1970s and 1980s, severe droughts and an expanding desert resulted in the deaths of many domestic camels (Onishi 2001). As a result of desertification and consequent loss of vegetation, especially in Niger and Mali, many of these nomads are finally giving up their lifestyle and becoming farmers near oases (Onishi 2001).

During the 20th century, Saharan wildlife came under intensified pressure from increased numbers of livestock and hunting from all-terrain vehicles equipped with machine guns (see Persecution and Hunting chapter). By the 1970s, virtually all large ungulates had become endangered or disappeared altogether. Smaller species, such as gazelles, became rare.

Deterioration of the Sahara during the 20th century resulted in the expansion of its boundaries by about 250,000

square miles along its southern edge between 1925 and 1975; in parts of the Sudan, the desert boundary moved south by 120 miles in the years from 1958 to 1975 (Ponting 1991). The Sahara now covers an area equal to that of the United States, or 8 percent of the land area on the planet. Lacking vegetation other than on the far-flung oases, the landscape is marked by dune fields, gravel plains, rocky plateaus with deep gorges and stark mountains (Allan and Warren 1993).

Scimitar-horned Oryx (*Oryx dammah*) originally lived in arid grasslands from Morocco and Senegal east to Egypt and the Sudan, an immense range. In historic times, herds of 100 animals were commonly seen, increasing to 1,000 or more during wet season migrations (Nowak 1991). Their populations and range gradually shrank with hunting, overgrazing and agricultural encroachment on natural grasslands. The species disappeared from Egypt and Senegal in the 1950s, and by the 1970s, about only 6,000 animals remained in the wild (Nowak 1991). The *1996 IUCN Red List Animals* listed this species as Critical, Extinct in Algeria, Egypt, Libya, Mauritania, Senegal, and Western Sahara, and probably extinct in Burkina Faso, Chad, Mali, Niger, Sudan and Tunisia. Four years later, the *2000 IUCN Red List Species* listed the Scimitar-horned Oryx as Extinct in the wild. It now survives only in zoos and animal parks.

Another large antelope, the Addax (*Addax nasomaculatus*), once ranged from Western Sahara and Mauritania to Egypt and Sudan. It is now nearly extinct in the wild as a result of heavy hunting combined with loss of its grassland and shrubland habitat to agriculture and competition with livestock. Perfectly adapted to life in the desert, Addax are able to spend their lives without drinking water, deriving moisture from plants on which they feed (Nowak 1991). The *1996 IUCN Red List Animals* listed the Addax as Endangered, Extinct in Algeria, Egypt, Libya, and probably Sudan, and surviving only in Chad, Mali, Mauritania, possibly Niger and as a reintroduced population in Tunisia. Its status declined over the next four years, and in the *2000 IUCN Red List Species*, the Addax is listed as Critical, the most endangered category.

Small gazelles have also declined drastically in the Sahara. The Slender-horned Gazelle or Rhim (*Gazella leptoceros*), native to North Africa, is now extinct in Western Sahara, and endangered throughout its range, according to the *2000 IUCN Red List Species*. The endangered Dama Gazelle (*Gazella dama*), also a heavily hunted species, is extinct in Algeria, Libya, Mauritania, Morocco and Western Sahara; it has been reintroduced into Senegal, and populations are now confined to Chad, Mali, Niger and Sudan (Baillie and Groombridge 1996). Cuvier's Gazelle (*Gazella cuvieri*), another North African species, is extinct in the Western Sahara and survives in endangered populations in Algeria, Morocco and Tunisia, according to the IUCN. Gazelles in the Saudi Peninsula and Near East have suffered similar declines, with several races of gazelle, the Acacia (*Gazella gazella acaciae*) and Muscat (*Gazella gazella muscatensis*), now in the Critical category (Hilton-Taylor 2000). The Saudi Gazelle (*Gazella saudiya*) is now considered Extinct in the wild by the IUCN.

Large herds of Wild Asses (*Equus africanus*) ranged throughout the Sahara in prehistoric times. Over the centuries, they gradually disappeared as a result of hunting and loss of habitat. The species is now Critical, verging on extinction. The Asian Wild Ass (*Equus hemionus*) declined or disappeared in the Near East and Central Asia from the same causes. The Syrian race (*Equus hemionus hemippus*) became extinct in the wild, and other races are now endangered or highly threatened (Hilton-Taylor 2000). Likewise, their close relatives, zebras, have suffered similar fates. Burchell's Zebra (*Equus burchellii burchellii*) is now extinct, and the finely striped Grevy's Zebra (*Equus grevyi*) of East Africa is considered Endangered by the *2000 IUCN Red List Species*.

The southern boundary of the Sahara, the Sahel, is 100 miles closer to the Equator than it was 100 years ago. Somewhat more verdant than the Sahara, the Sahel was a mosaic of grassland and shrubland until recent times. Its decline into desert occurred rapidly. In the late 1970s, an elderly Upper Volta native, Chief Issoufi Alimonzo, recalled: fiThere were once elephants and giraffes and lions here. The father of my father saw them. When his forefathers came to this place 300 years ago, there were so many trees you couldn't see the lake" (Gore 1979). Today, the region is bare of the trees harvested to sell as fuel in the cities of the area, and surrounding countries of the Sahel are experiencing similar devegetation (Gore 1979). Rainfall is now too scarce to permit agricultural crops. Each year, the climate has grown dryer.

Drylands of the World: AFRICA: Page 2

The Serengeti, the great East African savannah, is considered the gem of the African continent. White-bearded Wildebeests (*Connochaetes taurinus*), the keystone animals of the Serengeti, have increased over the past few decades to some 1.5 million, recovering from heavy hunting and habitat modification (Nowak 1999). They are protected by large reserves and national parks in Tanzania and Kenya during the majority of their giant migratory path that takes them in a large circle, returning to the same grasslands each year to have their young. This spectacle was in great danger of disappearing in the mid-20th century when there were plans to carve up the region for private ranches and farms. Conservationist Bernhard Grzimek and others wrote of the international treasure that the Serengeti represented and the importance of preventing its loss in a moving book, *Serengeti Shall Not Die*. Years of work resulted in the protection of much of this grassland. The conditions that prevailed permitting such a disaster to occur were described in the foreword to the book: "One can protest that there is a moral duty to preserve this last of the great natural congregations of wild animals left in existence...But none of this seems to make any difference. The African authorities, both black and white, are decided that the interests of human beings are paramount, and that wherever human beings are in conflict with wild life it is the wild life that must go" (Grzimek and Grzimek 1961). These words proved prophetic for the wildlife of southern Africa described below. Today, it is inconceivable that the Serengeti might be destroyed intentionally, having become a major attraction for scientists and tourists from around the world, but it is being whittled away none the less.

Growing human populations in Kenya and Tanzania have usurped much of the land outside reserves for farmland, and Europeans have long owned large cattle ranches. Animals straying outside the parks are being killed as pests or for bushmeat markets. These savannahs are being fragmented by development up to the very edges of reserves. Wildlife populations have become isolated in protected areas.

Elephants have ancestral migratory routes for food and to obtain minerals from salt licks and caves. The parks often lack sufficient forage for them, and yet when they leave for food, they trample the crops of local farmers or feed in their fields. Many are killed for this, although Kenyan wildlife authorities have tried to prevent such deaths in the late 1990s by protecting farms and relocating elephant families to areas where they are absent as a result of the almost disastrous killing for ivory during the 1970s and 1980s. In spite of this, large animals, including Lions and other predators, are in steep decline in the Serengeti. Just since 1977, an estimated 412,000 large herd animals have disappeared from Kenya's savannahs, some species declining by more than 50 percent (McKinley 1998). National parks encompass only portions of habitats and migratory paths of many species (McKinley 1998). The trend accelerates as the overall population of Kenya is growing at a fast rate, with families having an average of six children. From 5 million in 1946, Kenya's people have increased to more than 28 million today.

Drylands of the World: AFRICA: Page 3

To the east lie the now desertified lands of the Horn of Africa, bordering the Red Sea. The countries of Somalia, Djibouti, Eritrea and Ethiopia occupy this region. Ancient civilizations have risen and fallen here. The Axumites, a Semitic people who conquered the natives of Ethiopia in the 5th century A.D., became a major trading partner with the Greeks and Romans, exporting elephant ivory, rhinoceros horn and Hippopotamus hides. This trade and land abuse may have been responsible for the disappearance of these animals from this area by an early date.

Highland savannahs covered much of the Horn of Africa until the late 19th and early 20th centuries. This region is noted for the high number of highly unusual, endemic species, especially large mammals. Antelope and wild goats,

unlike any in the world, and a beautiful fox-like canid, the Ethiopian or Simien Wolf (*Canis simensis*), are native. During the 1880s and 1890s, the large herds of hartebeest, oryx, antelope, gazelles and zebra that grazed these grasslands were devastated by disease brought by the influx of millions of livestock. Rinderpest, a cattle disease, killed 90 percent of the cattle and then spread to wildlife. In a rampant epidemic in the first years of the 20th century, millions of wild ungulates native to the Eritrean region were decimated (Simon 1995). Even today, the wildlife has not recovered because cattle, sheep and goats have replaced them, turning grasslands into shrub and desert. Many of these unique animals now teeter on the brink of extinction.

Drylands of the World: AFRICA: Page 4

The shrubland and deserts of today's Ethiopia, Somalia and southern Sudan are the product of overpopulation of people and livestock, combined with poor agricultural practices. Famines have killed millions of people in this region during the 20th century, and the destruction of the land has caused massive suffering through hunger and disease. International aid organizations, with the best intentions, supply emergency food and encourage farming and livestock rearing in these damaged areas during each crisis. They often replace livestock after droughts and have failed to educate the people on how to survive without damaging their environment; nor have they provided birth control information. Within a few years of these famines, human populations have risen dramatically, with resultant overgrazing of land by livestock purchased for them by aid organizations, thus repeating the cycle. Funding from these organizations has been crisis-oriented, and famines recur ever more frequently, causing the desert to expand while inflicting great human hardship on these peoples.

Families are encouraged to have large herds of livestock, especially the ecologically devastating goat, and some international aid programs specialize in supplying livestock to people around the world. Within 15 years of deviating famines in the mid-1980s that killed hundreds of thousands of people, drought struck again in 2000, threatening the lives of 16 million people in Ethiopia and neighboring countries (Fisher 2000). A typical family in the area has six to nine children, 200 goats and 60 cattle. In late 1999, after three years without rain, livestock died in huge numbers and families trekked to towns for aid (Fisher 2000). By December, 1999, 7.8 million people faced food shortages, and food shipments were sent by the European Union and aid groups (Fisher 2000).

Neither international aid organizations nor the Ethiopian government have placed a priority on saving the environment and preventing future famines by conservation programs and family planning services. The inhabitants of the region have unknowingly overexploited this dry land, through overgrazing, deforestation and plowing away the topsoil, rendering most of the land area infertile and barren. Ethiopia is a country three times the size of California and, prior to this relatively recent misuse of the land, was one of the most beautiful and wildlife-rich countries in the world. Neighboring Somalia, Eritrea and Djibouti have suffered similar declines in their environment from abuse of the land. There is an urgent need to protect these fragile and beautiful ecosystems and their fauna and flora while helping their people survive in ecologically benign ways. International aid groups and governments should consider projects which help both people and the environment.

Drylands of the World: AFRICA: Page 5

Another arid region, the Kalahari Desert and surrounding grasslands of Botswana, was the scene of a great wildlife catastrophe and massive ecological damage. Early in the 20th century, there may have been almost as many White-bearded Wildebeests in the southern herd as now survive in the Serengeti. The herds numbered at least 272,000 in Botswana (Owens and Owens 1984). Wildebeest from throughout southern Botswana traditionally came together during migration in long, single-file lines, headed toward their ancestral feeding area of lakes, shady

woodlands and grasslands north of the Central Kalahari Game Reserve (Owens and Owens 1984). Over the eons, the wildebeests had adapted to this hot, dry climate and semi-arid grassland. Vast numbers of Beisa Oryx, Giraffe, zebra and other ungulates were a part of this ecosystem.

Europeans, mainly from South Africa, took over enormous tracts of land to raise cattle. Fencing of livestock began in Botswana in the 1950s to control hoof-and-mouth, also known as foot-and-mouth disease. It was thought that this disease was endemic in wild ungulates such as antelope, who spread it to domestic livestock. In fact, there is no proof of this, and it is likely that the disease was introduced to Africa by domestic livestock. The disease may be airborne and, moreover, vaccinations have controlled it in many countries (Owens and Owens 1984). Ranchers, however, had been told by their European sponsors that the beef would be rejected when exported unless fences were built. With subsidies from the World Bank and European countries, they constructed a fence 800 miles long to separate the wildebeests, oryx, gazelles and other wild ungulates from cattle (Owens and Owens 1992). These ranches produced more beef at first than could be easily marketed, creating a huge surplus of beef in Europe and little profit to the ranchers.

The water and grasslands crucial to the survival of the herds were blocked by the fences. The wildebeests walked for days along the fences, hungrier and thirstier every day; they were joined by Giraffe, Gemsbok and zebras whose masses measured 3 miles wide and 5 miles long (Owens and Owens 1984). In 1961 and 1964, 80,000 wildebeests died near the fence, and during these years, an observer estimated that 10 percent of their population died every five days; in 1970, a massive die-off decimated the herds (Owens and Owens 1984). By the early 1990s, the once great southern wildebeest herd had been reduced to fewer than 30,000 animals (Nowak 1999). At least 250,000 wildebeests were killed between 1970 and 1984 (Owens and Owens 1984). The deaths of at least 1.5 million large animals have been called the worst wildlife slaughter of the 20th century (Owens and Owens 1992).

The wildlife die-offs had not been publicized to the world until two American biologists, Mark and Delia Owens, came to the Kalahari in 1974 to study Lions and the threatened Brown Hyenas (*Hyaena brunnea*), native to southern Africa. These hyenas, found only in portions of southern Africa, have been exterminated over much of their range by ranchers; they are continuing to decline and occupy only about half their original distribution after centuries of trapping and poisoning (Kingdon 1997).

The Owenses radio-tracked Brown Hyenas from a small airplane, and in 1979, Mark Owens happened to fly over the tragic spectacle of the dying wildebeest herd. The wildebeests had continued their disastrous migration year after year because no other source of grass and water existed in this parched environment. Mark Owens witnessed hundreds of animals collapsing from hunger, fatigue and thirst. A Giraffe that could have stepped over the fence was so weakened that he got caught in the wire and pitched forward, breaking his leg. His hind legs became ensnared, and he pawed the ground helplessly until he died (Owens and Owens 1984). The main fence north of the Central Kalahari Reserve cut off all but 2 miles of riverine and grassland habitat, and by the time the wildebeests found the end of the fence and saw the lake in the distance, many were so exhausted that they collapsed before reaching it (Owens and Owens 1984). Others, having finally reached Lake Xau, were so weakened that they drowned. In their path were domestic cattle, herded by local people, who had stripped the area of every blade of grass, leaving a concrete-like surface covered with grey powder. Here, even the strongest, prime wildebeests died, their knees buckling and muzzles sinking into the dust. In 1983, 60,000 wildebeests died near Lake Xau (Owens and Owens 1992). Armed men employed by the ranchers patrolled the fences, killing any wild animal that came near. These crews made a business of selling the meat in the country's capital, Gaborone. One of the owners of Safari South had a photograph of a pile of antelope bones "as large as a two-story house" taken near a fence (Owens and Owens 1992). On one occasion, Mark saw the stragglers attempt to reach Lake Xau in the distance, when a truck full of men drove into the herd, killing many under their wheels. Then the men let their dogs attack the wildebeests, hamstringing and disemboweling them, before coming in with knives to finish them off (Owens and Owens 1984). Owens buzzed the men, flying just over their heads to frighten them, and over the next days continued making flights, which apparently succeeded in stopping this slaughter.

The wildebeest die-offs were just the tip of the iceberg. Sixty miles south, up to 10,000 Red Hartebeests (*Alcelaphus buselaphus*) died each year, along with uncounted Gemsbok, Giraffes, Springbok and other desert antelope (Owens and Owens 1992). The decline in the southern herds continued in spite of reports submitted by Owens to the Botswana government on the catastrophic situation. They discovered, in fact, that the government's own wildlife department was well aware of the effects of the fencing and had earlier reports of huge wildlife mortalities in their files (Owens and Owens 1984).

The large ranches of the Kalahari had been drawing water from fossil aquifers which ran dry. Ranchers then moved on, with World Bank loans, to new areas, leaving in their wake "sterile wastelands covered with coils of fence wire and piles of bleached skeletons, the remains of tens of thousands of antelope whose migrations to water had been blocked" (Owens and Owens 1992). The ranchers ran out of wilderness and appealed to the Botswana government to dissolve the Central Kalahari Game Reserve, the second or third largest wildlife preserve in the world, so that they could graze additional cattle. They did not succeed in this goal, but the Owenses (1992) saw livestock 20 miles inside the reserve™s boundaries in 1987.

Unable to stop this slaughter officially or through appeals to major conservation organizations, the Owenses wrote a book, *Cry of the Kalahari*, published in 1984, which outlined the situation and their recommendations to remove fencing, stop human settlements along Lake Xau, and reestablish the wildlife corridor. Excerpts were printed in Life magazine. They noted that the United Kingdom (UK) government had annually donated 14.5 million British pounds to Botswana as a subsidy to the beef industry, and suggested that the money should instead be used to promote ecotourism and wildlife-related industries (Owens and Owens 1984). A filmmaker, Rick Lamba, made a documentary of the slaughter in the early 1980s entitled fiFrightened Wilderness,fl which was shown on the Turner cable networks and to the United States Congress.

Finally, the World Bank funds for these cattle projects ended. They had proved a financial debacle as well as an ecological one, with ranchers never repaying their loans, and the beef sold at 10 percent of what it cost to produce it (Owens and Owens 1992). In the intervening years, the wildebeest herd continued to decline. Between 1979 and 1994, this herd dropped 94 percent, and the hartebeest population fell 83 percent (Boffey 1997). Outside criticism finally resulted in a few improvements. A freeze was put on new settlements along Lake Xau's shores, and the Kalahari Conservation Society was founded, which is monitoring the situation (Owens and Owens 1992). Poaching and harassment of the wildebeest has continued, however, and they are shot, speared and clubbed in their migration, which is likely to end altogether without more dramatic changes in policy. Although World Bank funding has ended, cattle ranches and fences remain, decimating the remaining wildfire.

The Kuke cordon fence that separates the Central Kalahari Game Reserve from areas to the north has been expanded, worsening the plight of this wildlife. Beginning in late 1995, Botswana constructed three new fences in the northwest to prevent a cattle lung disease from spreading from Namibian cattle (Boffey 1997). Two parallel fences of electrified steel wire were built on the northern border with Namibia, extended to meet the border fence, effectively sealing off this area to migrating herds (Boffey 1997). In August 1997, a small plane flying over the area documented antelope attempting to find a way through the fence, and well-worn animal tracks indicating that many others had also tried in vain (Boffey 1997).

The Owenses (1992) describe the changes that took place in this desert: "The Kalahari was teeming with wildlife whose migrations had adapted them to long droughts and sparse grasslands. Large-scale commercial ranchers in the Kalahari killed off hundreds of thousands of wild animals, overgrazed the desert, and depleted the water from fossilized aquifers. They left a wasteland that was good for neither wild nor domestic stock." Along with the wildebeests and other ungulates went the once large populations of Lions, Leopard, and Brown Hyenas.

Drylands of the World: AFRICA: Page 6

In neighboring Namibia, Europeans also exterminate native ungulates and predators in vast areas in order to make room for cattle and agriculture. The wildlife of Namibia has declined almost as rapidly as that of the other two countries. A few national parks, such as the Namib, have prevented total extinction for some species. One of the largest protected areas, however, has been reduced to one-fourth its original size as a result of pressure from livestock owners. The Etosha Game Reserve of southern Namibia covered 38,427 square miles, equaling the Okavango Delta and Tanzania's Serengeti Plains, a region of great wildlife diversity and abundance (Simon 1995). Although designated a national park, it covers only 8,598 square miles, the rest having been given over to livestock and agricultural interests (Simon 1995). This park is a lifeline for the remaining wildlife, with waterholes even during the dry season that attract herds of Plains Zebra, wildebeest, hartebeest, Gemsbok, Kudu, Springbok, Giraffe and others (Simon 1995). In its dry woodlands, elephants graze. During the 1990s, anthrax swept Ethosha, introduced by livestock, and 30 Cheetahs died, nearly the entire population in the reserve, along with elephants, zebra and other ungulates.

The Mountain Zebra (*Equus zebra*), native to Angola and Namibia, was once abundant in the high country of the eastern Namib and deep into the desert as far west as the coast (Simon 1995). Today, the species is listed as Endangered by the *2000 IUCN Red List Species*. Superbly adapted to the dry environment, this zebra scrapes holes in dry river beds, allowing water to seep in. In this way, it creates waterholes for many other animals (Simon 1995). The Hartmann's Mountain Zebra (*Equus zebra hartmannae*), a very large race of the Mountain Zebra, numbered an estimated 50,000 to 75,000 in the 1950s (Nowak 1999). Competition with domestic livestock and persecution from farmers settling the region reduced them to only about 8,000 (Nowak 1999). Listed as Threatened by the U.S. Endangered Species Act and on Appendix II of CITES, Hartmann's Mountain Zebras are still being illegally killed, with about 500 to 1,000 skins a year taken by poachers (Nowak 1991). The Cape Mountain Zebra (*Equus zebra zebra*), the other race of Mountain Zebra, was originally common in the grassy highlands of Cape Province, South Africa. European settlers killed these zebra indiscriminately, virtually wiping them out, along with many other species of ungulates. As early as 1742, these zebra were considered threatened and were given official protection (Kingdon 1997). This hunting ban was ignored, however, reducing them to 11 animals, protected on the farm of Henry Lombard, who prevented their extinction (Kingdon 1997). A 1937 census found only 45 Cape Mountain Zebra, although a few more persisted in remote mountain areas (Nowak 1991). The Mountain Zebra National Park was established to preserve them, and their numbers rose to 474 in the 1980s, half of which lived in the park (Nowak 1991). They increased to about 700 in six reserves in the mid-1990s, all descended from seven females (Kingdon 1997). This race is listed as Endangered by U.S. Endangered Species Act, the IUCN, and is on Appendix I of CITES.

Drylands of the World: AFRICA: Page 7

In South Africa, herds of Black Wildebeest (*Connochaetes gnou*) have also been nearly exterminated by ranchers and farmers. Fewer than 10,000 survive in government and private preserves (Nowak 1999).

South Africa's heath and grasslands harbor hundreds of species of rare plants, and European settlement pushed many of these close to extinction. Vast areas have been plowed for agriculture, and entire families of endemic plants have been threatened. Proteas are among the most endangered of these endemic plants. These plants have beautiful flowers, and one highly endangered species, *Protea odorata*, has a white, lily-like bloom contrasting with red-rimmed, narrow leaves. This plant declined from a population of more than 1,000 plants in five populations in the early 1980s,

to a few plants by the mid-1990s (Hilton-Taylor and Paterson-Jones 1996). *Protea odorata* had a limited range of only 30 square kilometers on the Western Cape lowlands, growing in water-logged, gravelly, clay soil (Hilton-Taylor and Paterson-Jones 1996).

The Cape's heathland is highly threatened by farming, and even the untilled portions are being grazed by sheep and cattle. This plant regenerates from seed after fires that must be at intervals of from 7 to 12 years to allow the plants to grow, flower and produce seed (Hilton-Taylor and Paterson-Jones 1996). The site of the last three wild plants of *Protea odorata* was a privately owned piece of land near Joostenberg; the owner of the land, in full knowledge of the illegality of his action, cleared the site and planted oats (Hilton-Taylor and Paterson-Jones 1996). He has been charged, but South African law allows only a minor fine to be levied. Fortunately, this plant has been cultivated at Kirstenbosch National Botanical Garden, and seedlings will be reintroduced in Riverlands Nature Reserve where it once occurred (Hilton-Taylor and Paterson-Jones 1996).

European settlement has pushed many of these plants and the native wildlife close to extinction. The statuesque Bontebok antelope (*Damaliscus dorcas dorcas*) was once abundant in the region, but settlers nearly caused their xtinction. Today, a national park and some private land protect a population total of about 2,000 animals (Cowling and Pierce 1999).*

Drylands of the World: AFRICA: Footnote

*Proteas are featured in two beautiful film, fiFlower from the Flamesfl (BBC), showing their pollination by iridescent sunbirds and ecology in coastal South Africa, and fiNamaqualand. Diary of a Desert Gardenfl (Nature, PBS), which also shows the superb wildflower displays in this desert of southwest and western South Africa and its wildlife. These ecosystems are described in detail and illustrated with color photographs in *Wild South Afria* (MIT Press, 1998), a book in a series that focus on the biodiversity, reserves and conservation of various parts of the world.

Only about 51 percent of the original 74,000 square kilometers of habitat remains in its natural state, and only half of this is in a pristine state. Moreover, certain portions of the ecosystem exist only in isolated fragments among pesticide-treated farmland (Cowling and Pierce 1999). Farmers have even planted tea crops in mountain habitats, displacing native plants (Cowling and Pierce 1999). Sheep and cattle grazing is a major problem as well. Remnant habitat patches are also being invaded by the Australian tree, *Acacia saligna*, which is replacing native vegetation in many areas. Other exotic plants from the Mediterranean and a pine from California have also taken over as much as 36 percent of the habitat, depleting scarce water supplies (Cowling and Pierce 1999). All these factors combine to threaten 1,406 plant species listed by the *IUCN Red List*, of which nearly 300 are close to extinction and 29 are already extinct in the wild; added to this, six species of butterflies, seven fish, five amphibians, five reptiles, 12 birds and 21 mammals of the region are threatened with extinction (Cowling and Pierce 1999).

A change in attitude toward nature in South Africa has resulted in the establishment of 244 nature reserves and parks covering 14,060 sq. km, but 95 percent of this land is in mountain areas which are among the least threatened (Cowling and Pierce 1999). Less than 5 percent of lowlands is conserved, and the government has insufficient funds to buy critical areas (Cowling and Pierce 1999). However, in recent developments, alien plants are being removed to restore the water and habitat, with 48,043 hectares (118,714 acres) already cleared of exotics. New protected areas have been declared, including the Cape Peninsula National Park, the Cape Agulhas National Park and the West Coast Biosphere Reserve, and $6 million has been donated for plant conservation (Cowling and Pierce 1999). This rugged region may also become a tourist attraction, especially the habitat closest to Cape Town, with its spectacular ocean views and growing populations of native animals such as the Jackass Penguin colonies.

Africa has the greatest diversity of hoofed mammals in the world, the majority of which inhabit grasslands, shrub,

shrubland and desert. This superb variety is under threat throughout the continent, as habitat disappears, even in national parks. The Table, fiThreatened Mammals of Africa's Savannahs and Deserts,fl lists the startling count from the *2000 IUCN Red List Species*, encompassing all but a very few grazing and predatory mammals of these habitats. The 84 mammals, 41 of which are in higher categories of threat, have evolved over thousands of years in intricate adaptations to various food sources, habitats and climates. Within each habitat many species coexist, each exploiting a different habitat niche, such as tall plants or shrubs, grasses or woody vegetation. Predator and prey have evolved together, each benefiting the other. Grazing animals vary from the tiny Silver Dikdik, only a few feet tall, to the Giant Eland, rhinoceroses, and the largest, the African Elephant, weighing several tons. Some can scramble up vertical cliffs, and others leap in 30-foot arches over the savannah. Cheetahs, Leopards, hyenas and foxes are among the declining predators. One of the biggest surprises of the *2000 IUCN Red List Species* was that even species that are relatively common, such as the White-bearded Wildebeest, Giraffe, Lion, many gazelles, zebras and antelope, have become Conservation Dependent, surviving only through conservation programs or in national parks. Should all these animals fade to near-extinction or totally disappear, they will represent an enormous loss similar to the mass extinctions of large mammals of the Pleistocene. Imaginative solutions are needed to conserve these beautiful animals in the face of expanding agriculture and livestock grazing, which daily usurp more and more of their territory. The value of ecotourism to economies, especially when spread throughout neighboring communities, is one solution that is being adopted in a growing number of places. The teaching of better farming methods that consume less land, and environmental education, are other solutions. As in many parts of the world, the wildlife that is taken for granted by local peoples in Africa as uninteresting and not worth saving, is considered a great biological treasure by biologists and naturalists around the world.

Threatened Ungulates & Predators of African Drylands
Extinct in the Wild
Critical
Endangered
Vulnerable
Near-Threatened
Data Deficient
Conservation Dependent
AUSTRALIA

Threatened Ungulates & Predators of African Drylands: Extinct in the Wild
Known only to survive in captivity or as a population outside its original range after exhaustive surveys in the wild have failed to record any individuals.

-
Scimitar-horned Oryx *(Oryx dammah*)

Threatened Ungulates & Predators of African Drylands: Critical
Species or subspecies face an extremely high risk of extinction in the wild in the immediate future

-

Addax (*Addax nasomaculatus*)
African Ass (*Equus africanus*)
Black Rhinoceros (*Diceros bicornis*)
Ethiopian Wolf (*Canis simensis*)
Giant Sable Antelope (*Hippotragus niger variani*)
Hunter's Hartebeest or Hirola (*Damaliscus hunteri*)
North African Leopard (*Panthera pardus panthera*)
Northern White Rhinoceros (*Cerototherium simum cottoni*)
Walia Ibex (*Capra walie*)

Threatened Ungulates & Predators of African Drylands: Endangered
Species or subspecies face a very high risk of extinction in the wild in the near future.

African Elephant (*Loxodonta africana*)
African Wild Dog (*Lycaon pictus*)
Cuvier's Gazelle (*Gazella cuvieri*)
Dama Gazelle (*Gazella dama*)
Grevy's Zebra (Equus grevyi)
Mountain Nyala (*Tragelaphus buxtoni*)
Mountain Zebra (*Equus zebra*)
Northwestern African Cheetah (*Acinonyx jubatus hecki*)
Nubian Ibex (*Capra nubiana*)
Slender-horned Gazelle (*Gazella leptoceros*)
Swayne's Hartebeest (*Alcelaphus buselaphus swaynei*)
Tora Hartebeest (*Alcelaphus buselaphus tora*)
Western Giant Eland (*Taurotragus derbianus derbianus*)
Western Klipspringer (*Oreotragus oreotragus porteousi*)
Western Mountain Reedbuck (*Redunca fulvorufula adamariae*)

Threatened Ungulates & Predators of African Drylands: Vulnerable
Although not Critical or Endangered, facing a high risk of extinction in the medium-term future.

Barbary Sheep (*Ammotragus lervia*)
Beira Antelope (*Dorcatragus megalotis*)
Black-faced Impala (*Aepyceros melampus petersi*)
Bontebok (*Damaliscus pygargus pygargus*)
Cheetah (*Acinonyx jubatus*)
Clarke's Gazelle (*Ammodorcas clarkei*)
Dorcas Gazelle (*Gazella dorcas*)
Gerenuk (*Litocranius walleri*)
Haggard's Oribi (*Ourebia ourebi haggardi*)
Lion (*Panthera leo*)
Puku (*Kobus vardonii*)
Red-fronted Gazelle (*Gazella rufifrons*)

Silver Dikdik (*Madoqua piacentinii*)
Soemmerring's Gazelle (*Gazella soemmerringii*)
Somali Warthog (*Phacochoerus aethiopicus delamerei*)
Speke's Gazelle (*Gazella spekei*)

Threatened Ungulates & Predators of African Drylands: Near-Threatened
Species or subspecies which is close to qualifying for Vulnerable.

Brown Hyena (*Hyaena brunnea*)

Chanler's Mountain Reedbuck (*Redunca fulvorufula chanleri*)

Giant Eland (*Taurotragus derbianus*)

Mongalla Gazelle (*Gazella thomsonii albonotata*)

Nile Lechwe (*Kobus megaceros*)

Royal Antelope (*Neotragus pygmaeus*)

Sitatunga (*Tragelaphus spekeii*)

White-eared Kob (*Kobus kob leucotis*)

Threatened Ungulates & Predators of African Drylands: Data Deficient
Inadequate information exists to make a direct, or indirect, assessment of its risk of extinction because appropriate data on abundance and/or distribution is lacking. More information is needed, and there is a possibility that future research will show that Threatened classification is appropriate.

Barbary Hyena (*Hyaena hyaena barbara*)
Chapman's Zebra (*Equus burchellii chapmani*)
Crawshay's Zebra (*Equus burchellii crawshayi*)
Fennec Fox (*Fennecus zerda*)
Pale Fox (*Vulpes pallida*)
Rueppell's Fox (*Vulpes rueppelli*)
Upper Zambezi Zebra (*Equus burchellii zambeziensis*)

Threatened Ungulates & Predators of African Drylands: Conservation Dependent
Species which does not currently qualify as Critical, Endangered or Vulnerable, but must be the focus of a continuing conservation program, the cessation of which would result in its qualifying for one of the Threatened categories above.

African Buffalo (*Syncerus caffer*)
Black Wildebeest (*Connochaetes gnou*)
Blesbok (*Damaliscus pygargus*)
Bohor Reedbuck (*Redunca redunca*)
Cape Grysbok (*Raphicerus melanotis*)
Common Eland (*Taurotragus oryx*)
Common Hartebeest (*Alcelaphus buselaphus*)
Gemsbok (*Oryx gazella*)
Giraffe (*Giraffa camelopardalis*)
Grant's Gazelle (*Gazella granti*)
Greater Kudu (*Tragelaphus strepsiceros*)
Grey Rhebok (*Pelea capreolus*)
Klipspringer (*Oreotragus oreotragus*)
Kob (*Kobus kob*)
Lechwe (*Kobus leche*)
Lesser Kudu (*Tragelaphus imerbis*)
Lichtenstein's Hartebeest (*Alcelaphus lichtensteinii*)
Mountain Reedbuck (*Redunca fulvorofula*)
Nyala (*Tragelaphus angasii*)
Oribi (*Ourebia ourebi*)
Sable Antelope (*Hippotragus niger*)
Sharpe's Grysbok (*Raphicerus sharpei*)
Spotted Hyena (*Crocuta crocuta*)
Springbok (*Antidorcas marsupialis*)
Thomson's Gazelle (*Gazella thomsonii*)

Tsessebe (*Damaliscus lunatus*)
White Rhinoceros (*Cerototherium simum*)
White-bearded Wildebeest (*Connochaetes taurinus*)

Threatened Ungulates & Predators of African Drylands: AUSTRALIA

Australia has been ecologically devastated by a combination of factors over the past 200 years. A continent dominated by drylands, its great center is a vast desert. Dry shrub forest originally covered much of the rest of the country. Only in the east and the northeastern tip of Queensland did tropical or subtropical forests prevail. Its climate has become dryer over the past few centuries as a result of overgrazing by livestock and forest clearance. Deserts have grown in area, claiming an ever greater percentage of the continent. In many parts of the country, shrublands and grasslands have been replaced by desert, causing extinctions and endangering native animals. Settled by former British prisoners and immigrants, sheep and cattle ranching became the center of the Australian economy in the 19th century. Within 200 years, massive ecological destruction has resulted from their activities. Livestock were released into the delicate environment, overgrazing grasslands and other habitats. Australia is second only to China in the number of sheep grazed, some 123 million, producing wool worth $5 billion, but leaving the land devegetated (O'Neill 1997). Gordon Grigg, professor of zoology at the University of Queensland in Brisbane, estimates that 700,000 square miles of arid zone habitat, or over half of Australia, are so degraded from sheep grazing that they may become permanent desert (Grigg 2000).

Forests were cleared for grazing land, agriculture, construction of railway ties, charcoal making and fuel for factories. More than 70 percent of Australia™s native forests have been destroyed (Lines 1991). Two-thirds of all arable land has been degraded by agriculture and livestock activities; of the continent's 7,750 million square kilometers, only the remotest, unused desert areas of Western Australia have no degraded land (Lines 1991). The story of the destruction of Australia's native flora and fauna has been carefully chronicled in the book, *Taming the Great South Land. A History of the Conquest of Nature in Australia*, by William J. Lines (1991).

Added to the livestock and land clearing threats were a flood of non-indigenous animals released by Acclimatisation Societies to "increase Australian usefulness" (Lines 1991). Rabbits, foxes, cats, mice and rats, European birds, exotic plants and all manner of goats, camels, donkeys and horses multiplied without natural enemies. Mice, rats and rabbits reached plague proportions, consuming vegetation and crops. Cats and foxes preyed on native birds and mammals who had few defenses against them. Eurasian rats ate birds' eggs and even preyed on tiny mammals and their young.

The European Rabbit proved the most destructive introduction, proliferating into the billions. Had native mammal predators, such as hawks, eagles, Dingoes and marsupial carnivores, been protected, they might have kept the rabbits and other exotics in check. But they were driven out by hunting and habitat destruction (Kennedy 1990, Lines 1991). By 1880, rabbits had overrun vast areas of shrub, devouring leaves, branches and trunks, killing native trees and grasses (Lines 1991). In the first 8 months of 1887, 10 million rabbits were destroyed in New South Wales, but this had little effect on their numbers (Lines 1991). Fences were erected over stretches as long as 500 kilometers in Queensland, where thousands of rabbits, having stripped the land bare, piled up against the wire, starving to death in sight of the green on the other side (Lines 1991).

Australians moved into new areas, bringing the rabbits as a meat source, and by the early 20th century, rabbits had denuded most of Western Australia, including an extremely important biodiversity "hotspot" in the far southwest.

Diseases and poisons, traps and hunting, all failed to eliminate rabbits, whose populations continue to rise and fall in plague proportions. In the late 20th century, experimental distribution of a poison derived from a plant to which native animals were immune was broadcast over millions of acres. This poison is known as Compound 1080 in the United States, where it was widely used against Coyotes and other predators before being restricted. It kills domestic dogs and cats as well, who die a very slow death. It also has secondary effects, i.e., animals that eat meat from animals killed by 1080, can be poisoned. It stays in the environment for long periods, killing hawks, owls and many other animals. This has brought about the protests of many humane organizations in Australia, but use of the poison continues.

Native mammals began to vanish during the 19th century, with the rate of extinction rising during the early 20th century (see Appendix). Twenty-three native Australian mammals have become extinct in the past 200 years, the majority of which are dryland species (Kennedy 1990). Australia now has the dubious honor of having experienced more mammal extinctions than any other continent (Kennedy 1990). In fact, 33 percent of arid zone mammals are extinct, and 90 percent of all medium-sized desert mammals are either extinct or threatened with extinction (Kennedy 1990). Seventy-one species of vascular plants have also become extinct (Walter and Gillett 1998). Most of the latter are dryland species. In all, 35 Australian animals have become extinct, 483 are highly threatened and 248 are in lesser categories of threat (Baillie and Groombridge 1996). Of 15,638 native vascular plants, 2,245 species are threatened, a rate of 14.4 percent (Walter and Gillett 1998).

Australia's land mass is approximately the same size as the lower 48 U.S. states, but it has proportionately far more threatened species. Endemic marsupials, such as many types of wallabies and native rodents other than large kangaroos, have either disappeared altogether from territories that once covered thousands of square miles or cling to existence in tiny reserves on small islands off the coasts where non-native animals are absent. With such limited ranges, many will probably die out. In fact, the majority of once wide-ranging species have been squeezed into small areas, a fraction of their original ranges. A wave of extinctions among species that are now endangered will probably occur within the next 50 years, according to some scientists. The majority of Australia's threatened species exist outside national parks and nature reserves, which contributes to a pessimistic view of their long-term survival.

The wildlife that inhabited Australia prior to European settlement included the most diverse marsupial fauna in the world. The majority inhabited dryland regions and have strange-sounding names that reflect their total uniqueness, resembling no other mammals on Earth. Quolls, wallabies, wombats, koalas, pademelons, potoroos, and bettongs are among these fascinating creatures. Almost all are now either extinct or in various states of endangerment. Each evolved over hundreds of thousands or millions of years to occupy an individual ecological niche, adapting to a variety of arid environments.

One of the rarest and strangest is the Bilby, or Rabbit-eared Bandicoot (*Macrotis lagotis*). A small burrowing animal, it has large ears, a long, pointed snout, and soft blue-grey fur washed with pinkish-brown, ending in a black-and-white crested tail, carried like a stiff banner while it canters along (Strahan 1995). The Bilby male can reach over 21 inches, while the female is only 11 inches long (Nowak 1999). Their burrow, which they can dig very rapidly with their clawed front feet, is spiral and up to 6 feet deep and 10 feet long, affording them protection from the searing heat of their desert habitat (Berra 1998). Sheltering during the day in their burrow, they do not lie down to sleep, but squat on their hind legs and tuck their muzzle between their forelegs with their long ears folded forward over the eyes (Nowak 1999). At night, they emerge to feed on insects, small vertebrates, seeds and fungi. Able to survive in the driest and hottest of Australian deserts, Bilbies once occupied all of central, western and southern Australia (Kennedy 1990). Their preferred habitat of hummock grasslands and acacia shrublands with spinifex and tussock grass has been degraded by cattle and rabbits (Kennedy 1990), and they have been trapped and preyed on by cats and foxes (Strahan 1998, Nowak 1999). Close to extinction, Bilbies survive only in a few isolated colonies in Western Australia, the Northern Territory and southwestern Queensland (Nowak 1999). The species is listed as endangered by the U.S. Endangered Species Act and Vulnerable by IUCN. Captive-breeding programs have been successful, and reintroduction programs are attempting to bring the species back to portions of its former range (Kennedy 1990).

A similar species, the Lesser Bilby (*Macrotis leucura*), inhabited the deserts of South Australia and Northern Territory until the early 20th century when it became extinct. Last seen in 1931, this delicate marsupial was eliminated by the same factors that have endangered the Bilby (Nowak 1999).

The Eastern Barred Bandicoot (*Perameles gunnii*), a close relative of Bilbies, inhabits heath, grassland and dunes in southern Victoria and Tasmania. With smaller ears than the Bilby, it also has soft, grey fur, but its back is barred with horizontal stripes of white. It has nearly disappeared from mainland Australia in the southeast and remains only in Hamilton in southwest Victoria, surviving in suburban gardens, nearby grasslands and a car dump site; three new captive colonies have been established elsewhere in Victoria (Kennedy 1990, Strahan 1998). Foxes and other introduced predators, as well as habitat destruction, are blamed for its perilous status. In Tasmania, where foxes are absent, it is more widely distributed, but it is declining here, too (Nowak 1999, Strahan 1998). Total population was estimated at only 633 in 1985, declining to 236 in 1988 and less than 100 in 1992 (Nowak 1999). Its counterpart, the Western Barred Bandicoot (*Perameles bougainville*), once ranged from central New South Wales west to the Indian Ocean. Today, this species' entire habitat consists of two small, predator-free islands--Bernier and Dorre Islands--off the central coast of Western Australia (Kennedy 1990). Native to a semi-arid habitat of shrub and open plains, its decline to near-extinction went unchronicled but is assumed to have been caused by habitat destruction, competition for food with rabbits and predation by foxes, cats and domestic dogs (Nowak 1999).

Two other members of the genus are now extinct: the Desert Bandicoot, *Perameles eremiana* of southern Northern Territory, northern South Australia and southeastern Western Australia, was last seen in 1931; a close relative, *Perameles fasciata*, disappeared about 1867. Yet another species, the Pig-footed Bandicoot (*Chaeropus ecaudatus*), the sole member of its genus but very closely related to the species above, became extinct in 1907 (see Extinct Species List in Appendix). Such devastation of entire groups of endemic species, mirrored in the fate of many other native Australian marsupials, has no parallel in recent history.

Another extraordinary family of marsupials is in steep decline. Wombats are heavy, up to 5 feet long, with thick bodies, very short legs, and tiny eyes; they weigh up to 77 pounds (Nowak 1991). In spite of their ungainly appearance, they are able to achieve speeds as high as 40 miles per hour for short distances (Nowak 1999). Endemic to Australia, there are three species in the Vombatidae family. Prior to European settlement, they were found throughout the continent in open grasslands and savannah with scattered trees and woodlands. Quite timid, they spend most of their time during the day, especially in hot climates, in extensive burrows which they excavate with their long, sharp claws, venturing out at night to feed on grasses, roots, bark and fungi (Nowak 1999). Their complex of tunnels leads to underground chambers so intricate that they are called cities. Sometimes several wombats occupy them, encountering one another only during breeding season, yet there is only one entrance.

All wombats have suffered declines from persecution by farmers who fear cattle will become injured by falling into the burrows, and many have been accidentally poisoned and gassed in rabbit-control programs because the latter animals seek shelter in wombat burrows (Nowak 1999). Ranchers routinely fill wombat holes (O'Neill 1997). Destruction of grasslands from overgrazing and agriculture has also eliminated populations (Kennedy 1990).

In spite of their somewhat imposing appearance, wombats are extremely gentle and playful in captivity (Nowak 1999). During a rash of forest fires in 1993 in New South Wales, many Common Wombats (*Vombatus ursinus*) became burned when they left their burrows to forage. Their paws were scorched by hot, smoldering soils, and they were unable to move; local people rescued many of the burned and frightened animals and nursed them back to health in their homes. Even though traumatized and shy of people, wild wombats could be carried about like huge puppies, submitting docilely to veterinary treatments.

Two of the three wombat species are listed in *Australia's Endangered Species* (Kennedy 1990). The most endangered is the Northern Hairy-nosed Wombat (*Lasiorhinus krefftii*), which is on the brink of extinction. Gone from New South Wales and southeastern Queensland, this wombat is confined to a tiny area of 15.5 square kilometers

in Epping Forest National Park, east-central Queensland (Kennedy 1990, Nowak 1999). Once native to open savannah and eucalypt woodland in New South Wales and Queensland, this species' total population has been reduced to only about 70 individuals (Nowak 1999). This wombat has been classified as Critical by the *1996 IUCN Red List* (Baillie and Groombridge 1996). These wombats are being studied by biologist Andrew Woolnough.

The Southern Hairy-nosed Wombat (*Lasiorhinus latifrons*) has declined in numbers and distribution from its original wide range from southeastern Western Australia to New South Wales, the entire southern half of the continent. Still fairly common in some areas, this species occupies a more arid habitat of near-desert conditions and has declined because of land clearance, overgrazing, and persecution by farmers, many of whom shoot this animal on sight (Kennedy 1990) based on mistaken beliefs that wombats damage fences and compete with livestock for grazing (Nowak 1999).

Australian grasslands have been severely degraded by livestock grazing. Once covered in perennial grasses that formed erosion-resistant mats, what vegetation remains is dominated by annual grasses (Fitzherbert and Baker-Gabb 1988). During the 19th century, untold millions of sheep and cattle grazed Australia's grasslands and deserts, and the damage they did to the soil and vegetation may be irreparable. Native saltbush has been eliminated on some steppe lands, and the diversity of native plants has been greatly reduced. Only since the 1940s have large private ranch holdings been broken up, and Australian ranchers have developed a greater awareness of the negative effects of livestock on the land (Fitzherbert and Baker-Gabb 1988).

Sheep ranchers have nearly eliminated many native animals by constructing a 3,307-mile fence across southeastern Australia to prevent Dingoes from entering southern areas where sheep are raised (O'Neill 1997). This fence prevents natural migrations of kangaroos and Emus, who can be seen running along the fence for miles, seeking an opening to cross (O'Neill 1997). Many die in collisions with the fence or from dehydration after trying for days to enter an area with grazing and water. The fence has not succeeded in keeping Dingoes, which number about 1 million in the country, out of sheep territory (O'Neill 1997). Dingoes are savagely persecuted in sheep country, poisoned, trapped in steel jaw leghold traps, shot and hung from fence posts (O'Neill 1997).

Australia's birds have also suffered from desertification and other activities of European immigrants. Ten Australian parrot species are listed in various degrees of threat by BirdLife International, and one is now considered extinct (Collar *et al*. 1994). The Paradise Parrot (*Psephotus pulcherrimus*) was last seen in 1927 (Greenway 1967). This beautiful parrot of central eastern Australia's grasslands was probably never very common; it lived in grassy woodlands and river valleys, the very habitat that was usurped by cattle ranchers (Fitzherbert and Baker-Gabb 1988). These were technicolor birds. The male was a dazzling combination of turquoise and emerald green on his breast, cheek and flank feathers, set off by black on wings, head and tail; he had large splashes of red on his wings, belly and forehead and his dark eyes were encircled by yellow. The female was a slightly paler version of the male. Their habitat degraded in the 19th century with heavy livestock grazing, and by 1915, these birds had become very rare (Forshaw 1989). Great beauty and relatively small size--11 inches in length including the tail-- made it attractive as a cage bird. Paradise Parrots were tame, feeding in pairs on the ground, and so were easily trapped for the cage bird trade, which pushed the already rare birds to extinction.

The rarest grassland parrot is the 9-inch Night Parrot (*Geopsittacus occidentalis*), whose greenish-yellow plumage mottled with dark brown, black and yellow allows it to blend into its spinifex grassland habitat (Forshaw 1989). This extremely mysterious species, seen in widely scattered localities of the arid interior of Australia, disappeared about 1912 and was thought extinct; then the species was sighted in 1979 in South Australia when several Night Parrots were flushed from underneath bushes (Forshaw 1989). These parrots spend most of their time on the ground and are thought to be nomadic. More recently, they have been seen in Western Australia, and a dead Night Parrot was found in 1990 (Collar *et al*. 1994). Grazing by livestock and the threat from introduced predators, such as foxes and cats, have contributed to their decline (Collar *et al*. 1994). They are so rare that no studies have been carried out on their diet or life history, but it is presumed to be nocturnal.

The greatest threat to Australia's grassland plants, preventing many of them from germinating, is heavy grazing by sheep, cattle, rabbits, goats, horses and donkeys (Kennedy 1990). One outspoken conservationist and landowner, John Wamsley, has established a sanctuary for native wildlife and plants. He excludes all livestock, foxes, rabbits, cats and other exotics with strong fences. He claims that the Australian government lacks resolve in protecting endangered species and their habitats, and with more fences and sanctuaries similar to his own, he believes that native wildlife could reoccupy habitats and recover their numbers. He has enlarged his preserve to over 100,000 acres. This may be the only area in mainland Australia where native mammals are increasing.

Endangered Species Handbook

Aquatic Ecosystems:

Aquatic Ecosystems

http://www.endangeredspecieshandbook.org/aquatic_preserving.php

Introduction

The marshes, lakes and seas of the world are host to a great diversity of life. In Asian wetlands, brightly colored storks step through reeds while scanning the shallow water for tiny fish. Marsh deer leap gracefully on their wide hooves through mud and spongy vegetation in Brazil's Pantanal. Great flocks of sandhill cranes darken the skies over North American rivers and bogs, emitting their haunting, hoarse cries as they circle to land. Otters, native to all continents except Australia, cavort on river banks, squealing to one another as they leap into the water. Eurasian and American beavers dam rivers, creating ponds where dragonflies, fish, frogs and aquatic mammals thrive. Papyrus swamps line many great rivers in Africa, home to strange shoebill storks, lechwe antelope, crocodiles and hippopotamuses. These aquatic habitats are a lifeline to hundreds more species of birds and mammals who come to drink and bathe. Freshwater ecosystems occupy a tiny fraction of the Earth's surface, unlike saltwater habitats, which cover three-fourths of the planet. Along tropical coasts, mangroves shelter tiny shrimp, crabs and fish. Manatees glide slowly in these quiet waters. A dazzling array of coral grows in fantastic shapes in tropical waters, inhabited by fish, anemones and starfish in every imaginable color, pattern and shape. Throughout the world's seas, whales, dolphins and seals leap above the waves and communicate with one another in complex musical sounds. Bizarre, deep-sea creatures inhabit sulphur-spewing hot vents or lightless sea floors. Wondrous habitats and their wildlife have undergone massive degradation caused by human activity. Many have disappeared altogether over the past few centuries and an even greater number are being destroyed or are losing many native species.

Benefits of Aquatic Ecosystems

Water, the basis of life on Earth, is the most precious of all natural resources. Freshwater and coastal wetlands cover only about 6 percent of the Earth's surface (Lean and Hinrichsen 1992), but produce three-fourths of the world's fish. Coastal marshes and mangroves play a major role in supporting diversity in the oceans by serving as spawning grounds and nurseries for two-thirds of the saltwater fish and shellfish caught for commercial purposes worldwide (Lean and Hinrichsen 1992). Wetlands perform a major role in preventing floods by retaining rainwater for slow release during the year and absorbing large amounts of rainfall, runoff and snowmelt. Wetlands also filter out contaminants. Some communities in the United States now construct wetlands for the purpose of filtering treated sewage water.

In a new approach to nature conservation, "Earth's Worth" scientists have begun calculating the dollar values of services performed by nature. Traditional economics value natural ecosystems only by practical use to human economies in short-term projects, such as real estate development or resource extraction. For example, how much a wetland is worth is a reflection of tax assessments, which are based on development possibilities and resale values. A boggy woodland might be appraised at a fairly low rate because it is difficult to develop for housing or other buildings. For this reason, such habitats are often bought at low prices and destroyed by development. By contrast, when one considers the ecological services rendered by that aquatic ecosystem, its values are far greater. It absorbs rainwater, thus preventing floods, provides a nursery area for aquatic wildlife and preserves woodland, which produces oxygen. The clean water supplied worldwide by natural filtration by marshes and mollusks that filter water was estimated by a group of ecologists to be valued at a minimum of $1.7 trillion (Stevens 1997). Estuaries and coastal wetlands are nurseries for multi-billion-dollar fisheries and shell fisheries, while they are also valuable in preventing floods. Yet such wetlands, which are often seen as ideal locations for ports and cities, are routinely filled for development. Scientists at the University of California at Berkeley calculated that the remaining wetlands in that state, 91 percent of which have been destroyed, are worth $10 billion annually in ecosystem services (Williams

1996). These ecosystems are usually considered virtually worthless by developers and industry.

The beautiful salt marshes of Georgia were under threat a few decades ago when it was discovered that large deposits of phosphate, which commercial interests wanted to mine for use as fertilizer, lay beneath them. Dr. Eugene Odum, who founded the science of ecology (Odum 1971) and taught at the University of Georgia, was able to prove to the state legislature that the long-term gain from these marshes as nurseries for the valuable shrimp and fish industries far exceeded the short-term profits that would accrue from permanently destroying them by mining. They received legal protection, an important precedent that recognized the economic value of wetlands. Since then, coastal marshes and other wetlands have attracted millions of tourists who come to see the wildlife and beautiful vistas that these habitats provide. Such visitors provide more income to the localities involved than extraction of minerals or development, since ecotourism is permanent.

The reason coastal wetlands and mangroves provide such important nurseries lies in the supply of nutrients they receive from ocean tides and freshwater runoff and rivers. Delta wetlands are especially rich in these nutrients brought by inland rivers and the tides. These floods bring nitrates, nitrites and minerals that nourish the vegetation of the wetlands. This rich habitat was eloquently described in Rachel Carson's *The Edge of the Sea* (1955). Among the grasses and reeds, microscopic life and invertebrates feed a great diversity of fish, shrimp, crabs, mammals, reptiles, amphibians and birds. Bivalves filter the water of aquatic ecosystems, keeping it clear and free of silt and pollutants. Freshwater marshes, lakes and ponds are breeding areas for crustaceans, mollusks and many vertebrates. Millions of waterfowl breed in the seasonal sloughs and potholes of North America prairies. Temporary wetlands, such as the vernal pools or wet season ponds, provide important habitat and breeding areas for frogs, toads, turtles, birds and a rich variety of invertebrates and plants.

Ancient peatlands and sphagnum bogs can be found on every continent except Antarctica. These wetlands absorb vast amounts of rainwater and store it year-round. Their soils tend to be poor in nutrients, but a wide variety of plant life has adapted to these habitats, from mosses and carnivorous plants such as Venus Flytraps and sundews to sedges and exquisite orchids (Rezendes 1996).

Swamp forests, often lining rivers, were once extensive in many parts of the world, providing habitat for water birds, mammals, amphibians and other wildlife, while preventing floods. In the United States, such forests once covered the shorelines of the Mississippi River and millions of acres in southern states. Deposits of soil from flooded rivers provide nutrients and anchoring for trees and plants. Most of these swamp forests were cut and replaced with agriculture by settlers, and today the region is plagued by floods.

Migratory aquatic animals need several types of habitats during the year. Salmon live in the open ocean but spawn and die in freshwater streams and rivers where the next generation hatches. Cranes and other water birds feed and breed in both salt and freshwater marshes, while using other types of wetlands during migration. Wetlands and surrounding ecosystems, such as woodlands, interact to provide habitat for many types of wildlife. When trees bordering wetlands are cut, this can adversely affect the water flow and wildlife living in wetlands. Some kinds of toads, for example, need both wetlands, such as ponds or lakes where they lay their eggs, and woodlands, where they seek out damp areas to spend most of the year. Thus, when considering the protection of wetlands, the neighboring environments must also be preserved.

Salt marshes in the tropics produce great quantities of plant matter. A reed marsh can produce many times more vegetation than the most fertile grasslands, and some can out-produce an average American wheat field by eightfold (Lean and Hinrichsen 1992).

Mangroves line almost 75 percent of the world's tropical shores (Mydans 1996). They are important in creating conditions for sea grass and coral reefs that are extremely productive ecosystems. Some 50 species of mangroves and related salt-tolerant trees and shrubs grow in silt-laden coastal waters in tropical latitudes (Ripple 1995). Mangroves are pioneer species Œ they create new land. By setting down shoots into the sand or mud, they gradually trap sediment

and create soil. These trees' ability to survive in saltwater allows them to colonize coastal areas where no other type of land tree can live. Anchored by roots in mud, they absorb oxygen through breathing roots that grow in the open air above the mud, enabling them to survive in soils devoid of oxygen.

As they grow, they produce new rootlets at successively higher levels above the high tide level (Collins 1990). Old mangrove trees have huge, above-water roots that form a network of hanging branches, and their trunks grow from the new land created. Their fallen leaves decay and provide food for fish and shrimp. The hanging roots become overgrown with an array of algae, sponges, barnacles and mussels, providing shelter for crabs, fish and shrimp, while the upper branches are used by water birds for perching and nesting. Alligators, crocodiles, manatees, young sea turtles and dolphins find refuge here. Sediments are held in place by mangroves, preventing clouding and silting of waters farther offshore so that dense mats of sea grass can flourish, providing shelter for fish, crabs and other marine life. These, in turn, further stabilize the sediment and allow formation of coral beds in clear water further offshore (Luoma 1993). These three ecosystems--mangroves, sea grass and coral reefs Œ often exist together, each helping create an environment for the other. Mangrove forests also buffer coasts from wave action, preventing inland floods. Bangladesh and other countries that have cut their mangroves have been inundated by disastrous floods, causing great loss of human life and property.

Oceans are vital in recycling important elements that represent the basic building blocks of living organisms: carbon, nitrogen, oxygen, phosphorus and sulphur (Daily 1997). Phytoplankton living in marine environments produces between 33 and 50 percent of the world's oxygen supply while absorbing vast amounts of carbon dioxide (Brown 1994). Oceans are the most important factor affecting the world's weather patterns. In turn, they are affected by changes in world temperatures, such as global warming, which create extreme weather from droughts to torrential rainfalls on land. This vast realm is of vital importance to human survival, yet we are only beginning to learn about its role in preserving life on Earth and its ecology, life forms and ecosystems. We have found an increasing use for many of its species for medicine and industry, and each year, new, useful compounds are isolated from marine animals and plants. Although the biological diversity of the ocean is known to be great, research is poorly funded and lags far behind the research on possible life forms on Mars, for example. The latter project consumes billions of dollars while oceanic creatures are fading into extinction prior even to being named.

Corals are among the oldest ecosystems, with a residence on Earth of at least 450 million years (Wells and Hanna 1992). Many reefs have been growing in the same place for millions of years. Glovers Reef off the Belize coast in the Caribbean rises 6,000 feet from the sea floor and began developing about 20 million years ago (Carter 1997). Coral reefs occur in a band approximately 30 degrees north and 30 degrees south of the Equator. Reefs buffer shorelines from ocean waves and in turn prevent erosion, as well as provide quiet waters for sea grasses to grow closer to shore. These grasses, in turn, are fed on by endangered manatees, sea turtles, fish and shellfish. Species diversity, a key to ecological stability on Earth, is very rich in coral reefs, rivaling that of tropical rainforests (Wells and Hanna 1992). The diversity, beauty and productivity of coral reefs make them vital ecosystems to conserve, yet they are in extreme danger of disappearing within the next century. They are the most endangered aquatic ecosystem on Earth.

Coral reefs cover 360,000 square miles, an area equal to only 0.3 percent of the world's oceans and smaller than British Columbia, yet an estimated 25 percent of the world's marine fish species live here (Chadwick 1999, Zuckoff 2000b). The greatest diversity of coral grows in the Pacific and Indian Oceans, in the Indonesian-Australian region where at least 450 species are found (Doubilet 1999). Corals have evolved into many forms. Among the many forms of coral, brain coral is nearly round, while elkhorn grows great branches, and delicate black coral forms thin strands in deep water. Surrounding most mainland and island masses in these regions, corals also populate shallow areas far offshore, as in the Red Sea. The world's largest coral reef, Australia's Great Barrier Reef, runs for 1,400 miles along the northeastern coast of that continent. Up to 3,000 species of plants and animals inhabit a typical Asian coral reef, and more than 1,000 live in Caribbean reefs (Wells and Hanna 1992). They are an oasis of life in warm waters which, in contrast to cold waters, are often poor in nutrients (Doubilet 1999).

Some coral has been found to be 800 to 1,000 years old, based on annual growth rings (Wells and Hanna 1992).

Growing very slowly, often less than 1 inch a year, the coral communities are made up of thousands of individual animals. Hard coral secretes calcium carbonate, a substance that becomes as hard as concrete (Doubilet 1999). When corals die, another generation grows on their skeletons, creating gigantic underwater structures that can grow for millions of years.

About 2,000 species of fish inhabit Southeast Asian reefs, and worldwide, between 4,000 and 5,000 fish species have been found in coral reefs so far (Wells and Hanna 1992), including starfish, sea urchins, sea cucumbers, crustaceans and mollusks in an incredible array of forms and colors, some resembling feathery anemones, others boldly striped to warn of poison. Many squeeze into crevices in the corals, creating a tapestry of textures and hues. On the Great Barrier Reef alone, some 4,000 species of mollusks are found, including sea slugs, clams, snails and hundreds of species of cones, trumpet shells, cowries and scallops (Wells and Hanna 1992).

Coral reefs provide habitat for many endangered species. Sea turtles find food and shelter here. The now endangered Hawksbill Turtle (*Eretmochelys imbricata*) was once commonly seen in coral reefs around the world, feeding on sponges and invertebrates (Wells and Hanna 1992). Large numbers of sea birds live on the fish produced in coral reefs, and many sea birds nest on islands around the world that are surrounded by coral reefs. In recent years, coral reef ecotourism has increased. Tourists now gaze at the reef wonders through glass-bottomed boats and scuba masks, generating a new source of income for many countries. Tourism accounts for 55 percent of the Gross National Product of the Bahamas and is playing an increasingly important role in other tropical countries. Tourism is a major incentive for countries to enact strict legislation protecting their marine environments.

Ocean creatures have proven valuable to medical research, supplying compounds that treat inflammations, asthma, heart disease, tumors, infections, viruses and pain (Chadwick 1999). Sea animals, such as cone shells, sea snakes and stonefish, contain some of the most toxic poisons in nature. Such compounds are offering non-addictive solutions to the treatment of pain and other medical problems. Some chemicals in sponges and sea slugs may be useful as insecticides, and coral itself is being investigated for possible use in bone grafts (Chadwick 1999). Glucosamine, a compound found in the shells of crabs and related animals, has proven to be extremely effective in treating osteoarthritis, controlling both pain and the progression of the disease which destroys cartilage. It seems to be a building block for cartilage and has been used safely in Europe for generations. This nutritional supplement has been tested by the Arthritis Foundation in clinical trials, after which it endorsed the use of Glucosamine for osteoarthritis. Finding new treatments for disease, and substances that can be used as glues obtained from barnacles, are among other ocean-based useful products. Future discoveries will depend on a healthy ocean that maintains its diversity.

Likewise, other types of sea and coastal ecosystem tourism have prospered in recent years. Whale watching has become a $1 billion industry worldwide, according to a 2000 study by the International Fund for Animal Welfare (BG 2000). At least 87 countries sponsor whale watching trips in 500 communities, allowing 9 million people to view these great mammals in 1998 (BG 2000). Cruises to Alaska, sport fishing, bird watching, hiking and other activities in non-tropical and freshwater destinations have also become far more important sources of income than resource extraction in many areas. The effects of the latter industries, including oil pollution, sedimentation from logging and pollution from mining, have decreased their income potential while destroying these precious ecosystems.

Destruction of Aquatic Ecosystems

As aquatic habitats are destroyed bit by bit, countless creatures and plants disappear. Crystalline bodies of water that furnished ample water to wildlife and people alike only a few centuries ago have become polluted or dried up. Growing human populations and development consume millions of acres of ecologically important coastal marshes and mangrove swamps to make way for airports, urban development, seaports, shrimp farms and resorts. More subtle changes are occurring from ozone depletion, acid rain and global warming caused by chemical pollutants in the

atmosphere. These may end in far-reaching ecological changes and extinctions that are only beginning to be chronicled.

Less than 3 percent of the Earth's water is fresh, and two-thirds of it is frozen in glaciers and ice caps. The remaining 0.5 percent is contained in aquifers, rivers, marshes, other wetlands and in the atmosphere (Barlow 1999). Global population growth is expected to outpace freshwater supplies by 56 percent by 2025 unless patterns of use change radically (Barlow 1999). Water use has grown at more than twice the rate of population increase in the 20th century, according to the United Nations (Barlow 1999). Almost 70 percent of the world's population lives in areas bordering bodies of water such as rivers, coastlines and lakes, where civilizations have traditionally arisen (Dugan 1993). The United Nations reports some 80 countries, 40 percent of the world's population, are already facing water shortages (Lewis 1996). At least 20 percent of the world's peoples do not have clean water for drinking, according to a 1997 conference of Earth Summit Plus (Grossfeld 1997). Cities have been increasing in size, and the United Nations predicts that within a decade, most of the world's peoples will live in cities for the first time in the human history. Currently, 2.6 billion people live in urban areas; this total is expected to rise to 3.3 billion by 2005 (Lynch 1996). By 2025, 5 billion people, or almost all people now living on Earth, are expected to be city-dwellers, the vast majority in poor countries without effective pollution control or sufficient water supply, by UN estimates.

The United Nations believes that by 2025, the world's population will number 8.3 billion, with two-thirds living in conditions of serious water shortage and one-third suffering from severe water scarcity (Barlow 1999). Growing urban populations require more and more fresh water. Rivers and lakes have been dammed, diverted and channeled to supply these cities, often with disastrous consequences for wildlife. Since all portions of a river are part of the same ecosystem, when it is dammed or altered, the river and its wildlife and plants are affected throughout its length, which may extend over 1,000 miles. Wetlands at the mouth of a river can be drained by the construction of a dam hundreds of miles inland. Likewise, channeling at the mouth of a river, increasing flow for ship navigation, can drain wetlands and alter flow for the entire length of the river, eliminating native wildlife and plants. The Missouri River, for example, was once a shallow, sandy-bottomed river lined with trees and swamps. When Lewis and Clark explored the region in the early 19th century, they saw great numbers of sturgeon, trout and other fish, aquatic mammals, and vast flocks of cranes, waterfowl and shorebirds. During the 20th century, multiple dams were built, and the river was channeled to accommodate ship traffic, radically altering the Missouri's ecosystem. The shallow-water feeding grounds for birds were drowned, and migratory sturgeon and trout found their routes blocked, endangering many species. After much opposition from barge operators and farmers, Congress funded a program in October 2000 to partially restore the flow to accommodate the needs of native wildlife by altering water releases from dams for a few months each year. Many conservationists are working to save even more of this original ecosystem.

Underground aquifers contain water that has been accumulating for thousands of years**.** Only in recent decades have they been exploited, and many are being over-pumped for city water supplies or agriculture. The High Plains Ogallala aquifer in the Great Plains of the United States stretches from South Dakota to Texas; pumping is depleting it eight times faster than it can be replenished naturally (Barlow 1999). This story is being repeated around the world, especially in desert regions such as North Africa, northern China and the Saudi Arabian peninsula, where fossil aquifers are being over-pumped for agriculture, industry and household use (Barlow 1999). This is resulting in their gradual depletion, contributing to a future "water bankruptcy" (Barlow 1999). Countries in arid regions are already competing for scarce water supplies. The Euphrates River has been dammed by Turkey, turning its flow to a trickle by the time it reaches Iraq. The latter country has become increasingly arid over the past few thousand years as grassland and bountiful water supplies deteriorated to desert as a result of over-use of water and drainage of wetlands.

Trade treaties, such as the North American Free Trade Agreement (NAFTA) signed between the United States, Canada and Mexico and the World Trade Organization (WTO), whose members include the majority of countries, override national water rights, assigning them to corporations and other commercial interests. Water is now being bought and sold as a commodity. One large company, the US Global Water Corporation, has signed an agreement with Sitka, Alaska, to transport 18 billion gallons of glacier water per year to China, where it will be bottled and sold

(Barlow 1999). A California company was denied the ability to purchase water from British Columbia and, under the principles of NAFTA, sued the government of Canada for $220 million (Barlow 1999). Environmental and species preservation are not considered in these global transactions. By treating water as a commodity to be traded to the highest bidder, ecosystems will be devastated. The International Forum on Globalization of San Francisco outlines many of these issues that point toward future catastrophes for the environment and human society alike in its report, *Blue Gold*. It concludes that only if water is considered to be commonly shared by humans and all species, and water diversion, damming, pollution, sale and bartering are halted, can there be hope for the future (Barlow 1999).

In the United States, only the onset of droughts brings about restrictions on water usage. Agriculture and livestock use an estimated 65 percent of the country's water supplies, households 10 percent and industry 25 percent. Much of the water used for agriculture comes from diverted rivers in irrigation programs which return it to water tables contaminated with large amounts of pesticides, herbicides and artificial fertilizers. An American family of four uses 300 gallons a day, far more than the average in most of the rest of the world. This profligacy has been at the expense of natural ecosystems. As human populations grow, water use will result in ever more strain on water supplies. Cities have sprung up in near-desert regions in the United States, requiring water diversion from other areas. One of the most dramatic examples of this is Los Angeles. The major flows from several rivers and lakes have been diverted to supply the needs of Los Angeles (Reisner 1986). Only with artificial water supplies has this city been able to grow to metropolis size. Its denizens waste their water supply to grow green lawns, and an enormous amount is used by local industry and agriculture. Los Angeles' water has been supplied at the expense of wildlife and plant species native to the diverted and drained water bodies, many of which are now endangered (Reisner 1986). Salmon and other fish have become endangered in the source rivers and lakes used to supply Los Angeles. Las Vegas, Phoenix and other western cities also tap the scarce water resources of the West. The diversion of water from natural rivers and lakes for large cities and massive agriculture projects is destroying aquatic oases in dry areas and drying up entire rivers in deserts, endangering species as diverse as tortoises, Bald Eagles (*Haliaeetus leucocephalus*) and songbirds.

Half of the people in developing countries suffer from illnesses associated with contaminated water, such as chronic diarrhea (Grossfeld 1997), and more than 5 million people, most of them children, die every year from these illnesses (Barlow 1999). Conflicts over water resources between countries and states are increasing, and in the future, wars may be fought over dwindling water supplies.

Although marshes are able to filter limited amounts of nutrient-laden water, raw, untreated sewage dumped into waterways can turn them into fetid, oxygenless mires. Ninety percent of the sewage in the swelling cities of poor countries is untreated, having had none of the solid matter removed, according to the World Resources Institute in Washington, DC. Some rivers, such as the Ganges and Brahmaputra River systems, are so polluted that the native dolphin, the endangered Ganges River Dolphin (*Platanista gangetica*), struggles to survive in the contaminated water. Fish are killed by the pollution, leaving the dolphins without food, and the high bacteria counts may be killing these dolphins directly. The Ganges has become so sewage-laden that it presents major health risks to the people who drink from and bathe in its water. This is especially ironic because this river is a holy river to the millions of Hindus who come to anoint themselves in its water. India has more than 3,000 towns and cities, but only eight of these have sewage treatment plants (Crossette 1996). Even sewage treatment systems can overflow during heavy rains, spilling toxic chemicals and oily runoff from roads, as well as untreated sewage. Since almost half of the world's population lives in cities, this is one of the world's most serious environmental problems.

The failure to conserve forests and vegetation has become a major factor in destroying natural aquatic ecosystems around the world. Besides causing mud slides and floods, the cutting of trees bordering rivers and streams also results in a rise in water temperature that affects the local climate and kills fish eggs and other wildlife. Clear-cut logging also causes siltation of rivers and lakes, smothering fish and wildlife. Salamanders, who require damp, undisturbed forest floors, are often eliminated by clear-cut logging. James Petranka of the University of North Carolina estimates that in the national forests of North Carolina, 14 million salamanders are wiped out every year by clear-cutting (Stolzenburg 1997). Extreme deforestation causes streams, springs, ponds and rivers to dry up and the regional climate to become more arid.

Oceans were once thought resilient to heavy pollution and the dumping of all types of debris. We are learning, however, that the combined effects of overfishing, killing of coral reefs and toxic contamination are turning them into aquatic deserts, according to Dr. Sylvia Earle, an eminent oceanographic scientist, and conservationist-author, Carl Safina (Earle and Henry 1999, Safina 1997). The oceans have also become crowded with commercial ships, fishing boats and pleasure craft, all of which are causing problems for wildlife. These ships discard plastics and other material and pose a threat of collision. Several cruise lines have been indicted and fined in recent years for dumping illegal materials overboard, including plastics, large amounts of waste oil and other toxic substances.

Coral reefs have proven very delicate and vulnerable to die-offs. Pollution, overfishing, cyanide poisoning and dynamiting to obtain tropical fish for the aquarium and Asian restaurant trades, or corals for the curio trade have all contributed to severe losses in the 70 million square miles of coral reef around the world.

Natural, unpolluted aquatic environments are fast disappearing around the world. Approximately 50 percent of the world's wetlands have been lost in historic times, according to *Wetlands in Danger: A World Conservation Atlas* (Dugan 1993). In the past, wetlands were destroyed primarily for agricultural development. Although this remains a major threat, programs such as dam construction and irrigation projects financed by the World Bank and the International Monetary Fund are becoming the major threat to pristine aquatic environments around the world. Unfortunately, the effects of these losses are usually appreciated too late, when species disappear and water ecologies are damaged.

Soils in many dryland areas have become polluted by salinization caused by irrigation schemes. Irrigation water flowing onto drylands brings to the surface substratum minerals and salts, which render the soil unfit for agriculture or almost any natural vegetation. Regions covering at least 150,000 square miles worldwide have become too saline to farm after irrigation programs (Dugan 1993).

Threatened Species

Approximately 41.4 percent of the 5,435 animals listed by the 2000 IUCN Red List, 2,251 species, are native to aquatic environments. Many more are in lower categories of threat such as near threatened or possibly threatened. Of these, 88 percent are native to inland or freshwater. At least 790 species of fish are threatened with extinction, 627 of these native to freshwater. This is an indication of the effects of dams, pollution and introductions of non-native fish that out-compete native species. Reptiles, totaling 111 species, are threatened by habitat destruction through wetland drainage and pollution, as well as demands of the pet, meat and skin trades that are pushing a growing number of turtles, crocodiles, chameleons and other lizards toward extinction. The threats to amphibians, especially frogs and toads, have grown dramatically in recent years, with environmental factors, such as UV radiation from ozone thinning, pesticide use, wetland destruction and pollution, playing important roles.

(Higher Categories of Threat)

	Marine	**Inland Water**	**Total**
Mammals	25	31	56
Birds	105	78	183
Reptiles	9	111	120

Total Animals	320	1,931	2,251
Plants	0	14	14
Grand Totals	320	1,945	2,265

Based on 2000 IUCN Red List of Threatened Species Compiled by Craig Hilton-Taylor. International Union for the Conservation of Nature and Natural Resources, Gland, Switzerland, Cambridge, U.K.

The number of threatened whales, dolphins, porpoises, manatees and seals has greatly increased in recent years. Moreover, many species have been upgraded in status to more endangered categories. Pollution, killing for meat and drowning in fishing nets play roles, but clearly more research needs to be carried out as to whether there is sufficient food for the large whales, such as the Blue, Fin, Sei, Gray and Northern Right Whales, none of which has recovered from past whaling. In the early 1980s, the IUCN, in its various Red Data Books, listed only three species of dolphins and six whales as threatened. In the 2000 IUCN Red List, 25 dolphins, six porpoises and 35 whales are listed in various categories, a dramatic increase. Marine ecological systems are becoming imbalanced as a result of overfishing. Gray whales have been washing ashore dead in unprecedented numbers on the North American Pacific coast. Many are thin and appear to have died of starvation, either from overfishing of their food supply or effects of changes in ocean temperatures brought about by El Nino or La Nina, which can greatly alter the types of fish remaining in an area. Destruction of sea beds is caused by fishing trawlers who rake sea beds for scallops and groundfish, obliterating entire communities of anemones, starfish, sea grass and habitats for a variety of fish and invertebrates.

A major increase in the number of threatened sea birds has also occurred. The number of threatened albatross has risen from two in the early 1980s to 20 in recent years. Similarly, only two species of penguins were threatened in the early 1980s, while 12 were listed in 2000. Petrels, small nocturnal sea birds that were once abundant, had 12 threatened species in the 1980s, mainly from disturbance of their nesting islands. At present, more than 40 species of petrels and storm-petrels are threatened with extinction. A major cause is long-line fishing for tuna, swordfish and other billfish, with baited hooks that attract albatross and petrels. Sea birds and birds that live along coastlines, lakes and rivers have been endangered by marsh drainage and pollution, human encroachment on their nesting habitats and invasions by exotic species of plants and animals.

The vast majority of threatened fish listed by the IUCN are freshwater species, but this may be an indication of our ignorance about the status of marine fish. The 1990 IUCN Red List included 751 species of fish in various categories (WCMC 1990). That number rose to 979 in 1994 (WCMC 1993), and in the 1996 IUCN Red List, 1,091 species were listed in all categories. The compilers of the 1996 edition of the IUCN Red List noted that only a small portion of the world's fish have been evaluated in terms of their status, and almost no marine species have been researched (Baillie and Groombridge 1996). The 2000 IUCN Red List listed 752 species in its three highest categories, an increase of 18 species from 1996. Worldwide, the status of the majority of fish has not been appraised. Ignorance of marine fish populations has contributed to their depletion in commercial fisheries, which are pushing many species toward extinction (see Trade chapter).

North American freshwater fish are perhaps the best known in terms of the status of the world's fish because of long-term biological studies and the state Natural Heritage Programs, which have a data bank of rare, endemic, declining and imperiled species. Two reports compiled by The Nature Conservancy, 1997 Species Report Card: The State of US Plants and Animals (Stein and Flack 1997) and the book Precious Heritage: The Status of Biodiversity in the United States (Stein et al. 2000), were based on data from the Natural Heritage Programs in all 50 states. The organization found that 16 species of United States fish have become extinct in recent times, and one species is possibly extinct; 93 species are critically imperiled, 88 species are imperiled and 116 are vulnerable. This total of 314 species comprises 36.1 percent of all American fish, which makes for an extremely high rate of endangerment (Stein and Flack 1997).

A major threat to native fish in the United States is the introduction of non-native species, usually game fish such as exotic trout, by state fish departments. Rainbow trout, for example, have been introduced in areas where they are not native, and have out-competed and endangered native cutthroat trout in the West, as well as introduced disease caught in fish hatcheries. Few other countries have undertaken such detailed studies of endangered native wildlife, but in countries where freshwater ecosystems have been greatly altered by channeling, diversion, dams and pollution, research would likely find similar rates of endangerment. In China, 80 percent of major rivers are so degraded they no longer support fish (Barlow 1999).

Frogs and toads represent the most dramatic rise in threatened species of any vertebrate. Their plight may be indicative of the serious environmental threats facing the Earth. Because of their thin, porous skin, frogs are extremely sensitive to environmental contaminants. Within the past few decades, a large number of frog and toad species have disappeared all over the world. Many have been found with grotesque deformities and diseases. What is happening to the frogs appears to be an early warning of serious threats to the Earth's aquatic ecosystems and to its atmosphere. The scale of the recent disappearance of frogs around the world has not been seen since mass extinctions that occurred millions of years ago. The ecological effects will be significant because of their important role in consuming insects and as food items for a large number of animals, from birds to reptiles.

In the 1979 IUCN Red Data Book of Threatened Animals, a world review found 18 species of frogs and toads to be in various categories of peril; in the 1990, the number of threatened frogs and toads had almost doubled to 35, and in 1994, 130 species were listed Œ more than triple the previous total (WCMC 1993). The 141 species in various categories in the 1996 IUCN Red List represented a fourfold increase since 1990 and an almost eightfold increase since 1979. This total grew to 173 frogs and toads in all categories in the 2000 IUCN Red List, with 112 in the three highest categories of threat. Thus, threatened frogs and toads have increased 10 times in number from 1979, a trend not seen in any other large group of vertebrates since such studies began.

The threats to these amphibians are not regional. Frogs are threatened wherever they exist, declining in 140 countries, with status research continuing (Stolzenburg 1997). A worldwide phenomenon is occurring, endangering amphibians and causing extinctions at a spiraling rate. Among the first to disappear were two newly discovered and highly unusual frog species that had been acclaimed as remarkable by scientists around the world. These frogs came from the rainforests of Australia and had astounded the scientific world with their breeding biology. Their life history was so extraordinary that the man who first described it had his paper rejected by a prestigious journal for being implausible. Michael J. Tyler, associate professor of Zoology at the University of Adelaide, discovered these species, known as gastric brooding frogs (Rheobatrachus silus and Rheobatrachus vitellinus), and was beginning research on potential applications of their amazing ability to turn off gastric acids to the treatment of human stomach ailments. These frogs were filmed before their disappearance, which documented that they swallow fertilized eggs that grow in the female's stomach and emerge six weeks later as tiny froglets when she opens her mouth (Yoffe 1992). In 1980, only a few years after their discovery, this species and others in the area vanished; they have not been seen since (Yoffe 1992).

The dazzling golden toad (Bufo periglenes) also disappeared suddenly. Jay M. Savage of the University of Miami

came upon this species, native to the cloud forests of Costa Rica, in 1964 in Monteverde Cloud Forest Reserve, witnessing large gatherings of males during the breeding season (Phillips 1994). National Geographic Society filmmakers, in making the film, fiRainforest,fl recorded the assemblages of hundreds of these colorful toads perched on rocks among misty streams, and also filmed their far less flamboyant mates. Less than 2 inches long, male golden toads were bright, shiny orange, in contrast to the slightly larger females who were dark olive to black with spots of red encircled by yellow (Phillips 1994). Depicted on tourist posters and protected in its reserve, the Golden Toad's future seemed assured. No studies were carried out to discover its haunts during the rest of the year, however (Phillips 1994). Tourists flocked to Monteverde, many drawn to see the beautiful toads. In 1987, an American biologist, Martha Crump, witnessed the last breeding group of golden toads. "They've been described as little jewels on the forest floor, and that's really the impression you get," she recalled years later (Phillips 1994). With a grant from the National Geographic Society, she returned in 1988 for two seasons of research (Phillips 1994). In 1988, only 10 toads were seen, and only one male was in the breeding area; in 1989, only one toad was seen (Phillips 1994). None have been seen since (Yoffe 1992); the protected area was enlarged to 26,000 acres in the early 1990s to preserve as much forest as possible.

Two other inhabitants of this cloud forest, a species of translucent glass frog (Yoffe 1992) and an endemic harlequin frog (Stolzenburg 1997) have become very rare. A total of 20 other frog species are also missing from this region, based on a survey of Monteverde by a University of Miami biologist in 1996 (Blakeslee 1997). In Ecuador's high Andes, an estimated 50 species of frogs have disappeared since 1990. In Puerto Rico's rainforests, 12 of 18 endemic frogs are extinct or nearly so (Stolzenburg 1997).

The first World Congress of Herpetology, for the study of reptiles and amphibians, convened in 1989, and many of the 1,300 participants began comparing notes on the shocking fact that the subjects of their research were disappearing from under their very eyes. A comprehensive study was undertaken under the guidance of the IUCN's Declining Amphibian Populations Task Force (DAPTF) (www.open.ac.uk/daptf) to standardize methods of study of amphibian population changes and the environmental factors that may be affecting amphibian reproduction and survival (Stebbins and Cohen 1995). The 1989 conference inspired a symposium the following year that addressed this problem, recruiting 1,000 researchers in 40 countries. The reports from these researchers are published in a bulletin known as the Froglog, published by DAPTF on its website.

What is happening to the world's frogs? Many of the traditional causes still contribute to declines in amphibian populations. Marshlands and boggy areas continue to be filled in and polluted; pesticides, herbicides and other toxic chemicals are entering aquatic ecosystems, causing mortality and mutations. Introduced predatory fish and even exotic frogs have eliminated some frog populations (Yoffe 1992). Trade in frogs for the gourmet food market and for high school biology dissections has also played a role in the declines of some species. Some tropical frogs are known to have succumbed to a protozoan, which kills many and weakens the immune systems of others, making them vulnerable to a host of other pathogens (Blakeslee 1997). The disappearing frogs are not all from polluted areas. Some are native to remote wilderness areas, national parks and other pristine areas. The most surprising possible cause for their disappearance is the increased ultraviolet (UV) radiation resulting from the thinning of the ozone layer. This has been the subject of much research. The thinning of the Earth's ozone layer is caused by Chlorofluorocarbons (CFCs), chemicals used as coolants, aerosol propellants and for other industrial purposes. When released into the atmosphere, they turn into chlorine and destroy the thin-but-vital layer of ozone that shields the Earth from harmful UV radiation. Chlorine-based solvents have also had this effect. First noticed in the 1970s and early 1980s when holes appeared in the ozone layer at the Earth's poles, many years passed until the cause was proven. Those who discovered this phenomenon were awarded the 1995 Nobel Prize in Chemistry, marking the first time this prize was ever awarded for achievement in environmental science. The recipients were Dr. F. Sherwood Rowland of the University of California, Dr. Mario Molina of the Massachusetts Institute of Technology and Dr. Paul Crutzen of the Max Planck Institute for Chemistry in Germany.

Holes and thinning of the protective ozone layer have allowed an increase in the amount of injurious ultraviolet rays reaching the Earth, which has brought about a dramatic rise in the number of human skin cancer cases, as well as

declines in amphibian populations. Although the use of CFCs has been banned in new appliances and air conditioners in the United States, the chemical is still used in older cars and refrigerators, escaping to the air from malfunctioning units and improper disposal of these appliances. Illegal CFC imports into the United States have been documented, and some countries still allow their use. CFCs will take at least a century to disappear from the upper atmosphere, according to scientists.

In 1996, Yale University researchers made a discovery that may help stem the breakdown in the ozone layer. A chemical extract obtained from rhubarb and related plants, sodium oxalate, can chemically break down CFCs when heated to 520 degrees F. (Sharkey 1997). The practical use of this discovery is years away, but it may prove to be effective in controlling this lethal phenomenon.

As ancient bridges between land and sea, amphibians were named from the Greek words amphi and bio, meaning living a double life, indicating they were both aquatic and terrestrial. Frogs and salamanders are the only two major groups of amphibians, and they form an evolutionary link between fish and reptiles. First emerging in the Triassic period 200 million years ago, frogs have outlasted dinosaurs, and until recently, most biologists considered them hardy and adaptable species (Yoffe 1992). The vast majority of the approximately 4,100 species live in tropical areas. They must hibernate to survive cold, temperate winters, and relatively few species have evolved this adaptation.

The breeding biology of frogs and toads is a fascinating study in variety. There are frogs that develop marsupial pouches like tiny kangaroos to carry their fertilized eggs, and species in which the males incubate tadpoles in their vocal sacs until they emerge (Stebbins and Cohen 1995). The parent of one tropical frog hops across the forest floor carrying a single tadpole sticking with a mucus to its back; it climbs a tree and steps into a bromeliad plant, placing the tadpole into a tiny amount of water (Roberts 1996). The female returns to lay unfertilized eggs for the tadpoles to eat; she must remember which bromeliads, of the thousands in the area, contain her tadpoles. When the female enters the bromeliad containing her tadpole, it instinctively wriggles, causing vibrations in the water which stimulate the mother to lay eggs for it to eat (Roberts 1996). Wendy Roberts, a biologist who has studied the many reproductive methods used by tropical frogs, believes that as long as frog populations do not continue to disappear, more discoveries of the extraordinary variety of their reproductive biology, parental care and behavior will be made (Roberts 1996). Some toads have even adapted to desert mud holes by burying themselves and entering a torpor-like state until it rains again.

The decline of North America's frogs and toads afflicts fully one-third of the 86 species (Yoffe 1992). Their disappearance in wilderness areas was documented as early as the 1970s. David Bradford, a biologist now with the Environmental Protection Agency, studied the Yosemite toad (Bufo canorus) and Mountain yellow-legged frog (Rana muscosa) in Yosemite National Park in the 1970s at 26 sites. When he returned in 1989 and visited each site, he found frogs had disappeared from all but one site (Yoffe 1992). A 1992 survey concluded that three of the eight toads and frogs native to the Yosemite region have nearly disappeared: the red-legged frog (Rana aurora), which has since been listed on the US Endangered Species Act; the Foothill yellow-legged frog (Rana boylei); and the Great Basin spadefoot (Scaphiopus intermontanus) (Yoon 1996). The Yosemite toad declined or disappeared at nine of the 13 original sites where a 1915 survey had found them abundant (Yoon 1996). Because of the longevity of toads, some living to be 35 years old, declines may go unnoticed as long as adults are alive, even though all their offspring may be dying year after year. Stebbins and Cohen (1995) documented declines in a number of once-common species in their text, A Natural History of Amphibians. Northern leopard frogs (Rana pipiens) and nine other species have become rare or absent in former haunts (Tyning 1995). The latter species has been dissected by the millions in high school biology classes, many of which require the students to kill the frogs, often by cruel means.

Dr. Andrew Blaustein, a herpetologist at Oregon State University, studied the Western toad in lakes in the Cascades Range at 4,000 feet for many years. By the mid-1980s, he found that these toads were becoming rare, yet in the same habitat, Pacific tree frogs (Hyla regilla) seemed to be thriving (Blaustein 1994). Female Western toads produce 12,000 eggs in long strips that are laid in unshaded ponds, and then they disappear into the forest, leaving the eggs to hatch in the shallow water (Blaustein 1994). Dr. Blaustein began to find eggs that did not develop properly, turning white, and

then dying and leaving a fetid, viscous mass (Blaustein 1994). Other amphibians of these mountains, the Cascades frog (Rana cascadae) and the red-legged frog, had also disappeared completely from most of their range (Blaustein 1994).

Dr. Blaustein and a colleague decided to conduct outdoor and indoor experiments to test the reactions of frog eggs to ultraviolet radiation. Trays of frog and toad eggs in water were placed outdoors, and some were exposed to UV rays; others screened from UV-B rays, the most harmful type of radiation; still more eggs were brought into the lab and kept in darkened conditions (Blaustein 1994). Ninety percent of the eggs raised indoors, as well as those screened from UV rays outdoors, developed normally, while 40 percent of the unscreened eggs exposed to UV rays died (Blaustein 1994). Here was proof of the effect of present levels of UV rays. Dr. Blaustein and other biologists have concluded acid rain is combining with UV radiation in some areas to kill frogs and toads (Yoon 1996).

Some frogs and toads are dying of unknown causes. One biologist studying the Western toad (Bufo canorus) in a wilderness area in Colorado in the 1970s came upon dozens of dying toads, barely able to move because of their puffy red legs (Yoffe 1992). She took several of them to a veterinarian and was told their immune systems had collapsed, making them vulnerable to infection (Yoffe 1992). Biologists in Massachusetts have found wood frog (Rana sylvatica) tadpoles dying of disease outbreaks in three of four recent years (Knight 1995).

Grotesquely deformed frogs have been discovered recently in many parts of the United States. In 1995, a biology class found frogs with shocking malformations near Henderson, Minn. Some were missing both hind legs; others had as many as six legs, and at least one had an eye growing in its mouth. Another had a leg growing from its stomach. Many had only one leg, one eye, four tangled hind legs, misshapen limbs and tails, missing or shrunken eyes and small sex organs (Associated Press 1996). These deformed frogs were shown on national television news programs throughout the country. Researchers found similar frogs in 1996 and 1997 in California, South Dakota, Wisconsin, Vermont and Massachusetts, as well as in Quebec, Canada. Up to 35 percent of frogs in these areas may be deformed. Within a year, deformed frogs were seen in 54 of 87 counties in Minnesota. A herpetologist from the University of Minnesota at Morris examined 10,000 frogs in the summer of 1996, finding the greatest number of abnormalities in frogs that spent the majority of their lives in water, rather than coming to water only to lay eggs. Vermont's leopard frogs had a 45 percent deformity rate, and for the first time, deformed salamanders were found. Three five-legged salamanders were found in Massachusetts, an ominous sign this phenomenon is spreading to another type of amphibian.

At the Scripps Institute in California, laboratory tests on frogs produced similar deformities when they were exposed to the commonly used mosquito pesticide, methaprine. This chemical affects growth hormones, causing them to malfunction. In September 1997, officials of the Minnesota Pollution Control Agency announced they reproduced the deformities when frog eggs were raised in tap water from areas with deformed frogs. They issued a public health alert based on this research, providing bottled water to people living in these areas. One Minnesota biologist found internal and external abnormalities in these frogs. EPA studies found deformities when frogs were exposed to ultraviolet rays as well. These findings indicate certain pesticides and UV radiation present major threats to amphibians. Other studies have shown parasites can also cause deformities (Yoon 1999).*

North American researchers have organized the Great Lakes Declining Amphibians Working Group, as well as the North American Amphibian Monitoring Program, maintained by the US Geological Survey of the Department of the Interior. The FROGWATCH USA website gives advice to concerned citizens to learn more about aiding this situation. The US Fish and Wildlife Center provides information about the population status of various amphibians, as does AmphibiaWeb, run by noted herpetologist, Dr. George B. Rabb.

The disappearance of frogs and toads may seem insignificant to many people. From an ecological point of view, however, these animals play an important role in controlling insect populations. After frogs were nearly extinguished in Bangladesh to supply gourmet tables in France with frog legs, mosquito numbers and the incidence of malaria skyrocketed (Yoffe 1992). Frogs themselves are a major food item for a wide variety of animals, from storks to

raccoons. They are an important link in the food chain, and their extinctions may have a major effect on a wide variety of other species and even evolution itself (Yoffe 1992).

From a human health point of view, frogs and toads have proven to be the source of many valuable medical compounds. Dart-poison frogs of Central and South America are more terrestrial than species that spend their lives in water, and to protect themselves, they have developed some extremely potent poisons that they excrete through their skin. Natives have used these chemicals on the tips of their arrows for hundreds of years to kill prey as large as monkeys. These tiny, brightly colored frogs are being studied by the National Institutes of Health for the alkaloid compounds found in their skin, which are used in research on nerve and muscle function, and as anti-convulsants and anti-arthritics (Sharp 1995). Another compound found in the skin of an Ecuadorian dart-poison frog has 200 times the pain-killing power of morphine (Sharp 1995).

Preserving Aquatic Ecosystems

Only recently have some aquatic environments received protection in some parts of the world. New marine sanctuaries that protect coral reefs and other sea life have been set aside in a growing number of countries. In 1994, Australia, the United States and six other nations founded the International Coral Reef Initiative to encourage preservation of reefs endangered by pollution, overfishing and other causes. In the future, sanctuaries and international agreements will provide major means of conserving these ecosystems. Unfortunately, many of these sanctuaries allow commercial fishing and the collection of mollusks. The value of aquatic ecosystems in preserving biodiversity is only beginning to be appreciated, aided by the growing popularity of bird-watching, scuba diving and coral reef tourist visits that are educating many people about the importance of protecting these fragile ecosystems.

Private organizations and universities are playing important roles in monitoring and conserving delicate aquatic habitats. The International Marine life Alliance, based in the Philippines, is convincing fishermen to catch fish in hand nets, rather than poison or dynamite reefs. The Global Coral Reef Alliance is investigating diseases that are afflicting reefs through scientific research, and Greenpeace International has been active in conducting worldwide surveys of the deterioration of coral reefs. Depletion of species by overfishing and consequent imbalances in reef ecosystems and biodiversity are being undertaken in various parts of the world. A Canadian researcher, Amanda Vincent, who documented a dramatic decline in seahorses as a result of over-harvest for Chinese Traditional Medicine, has been working with Philippine fishermen to limit catch and set aside sanctuaries where stocks can increase. Woods Hole and Scripps Oceanographic Institutes are conducting important research in marine environments, studying subjects as diverse as the effects of US Navy sonar testing on whale behavior and deep- sea environments. Small and maneuverable submarines are now exploring deep- sea ecosystems, taking samples of new species and filming these extraordinary habitats. Almost all such research is funded by non-governmental organizations, since governments have yet to realize the importance of funding such research.

International efforts began as early as 1973 to control Marube debris and pollution when the International Maritime Organization, a United Nations agency responsible for shipping, formed an agreement known as MARPOL. This agreement regulated the disposal of oil and hazardous chemicals. In 1978, it was amended to include annexes on the disposal of hazardous materials, sewage, fishing nets, ropes, bags and trash. In 1988, the Marine Plastics Pollution Research and Control Act was enacted by Congress, prohibiting United States ships from dumping plastic items into the sea, and prohibiting foreign ships from disposing of plastics within 200 miles of the United States. Plastics include such items as nylon fishing nets. As of 1994, all US government-owned ships had to comply with all regulations, disposing of plastic waste at port. The National Oceanic and Atmospheric Administration (NOAA) has an interagency task force on marine debris, which has attempted to coordinate other federal agencies to reduce marine debris. The Environmental Protection Agency, with the Center for Marine Conservation, and NOAA coordinate

annual beach cleanups, which are now being carried out in some European countries as well as in the Middle Eastern country of Bahrain. Thousands of tons of plastic bags and fishing lines that might have washed back out to sea have been removed by these cleanups. The Marine Entanglement Research Program was established by NOAA in 1984 to study this problem.

As a result of international concern about the disappearance of irreplaceable wetlands, the Ramsar Convention was adopted in 1971. Each member country designates and accords legal protection for at least one wetland to be included in the *List of Wetlands of International Importance*. More than 600 Ramsar sites have been designated, covering 100 million acres. Some of these wetlands, in spite of designation, are threatened by government-sponsored plans. The Acheloos Delta in southwestern Greece may be diverted to produce electricity, and a huge flood-control plan threatens Lake Utonai in Japan. The Ramsar Convention has been instrumental, however, in protecting wetlands through international cooperation. The Wadden Sea, a wetland on the coasts of the Netherlands, Germany and Denmark with up to 12 million birds wintering, breeding or migrating through its land, is being protected through cooperative agreements among the three countries (Dugan 1993). These wetlands are not in their natural state after centuries of diking, filling and other man-made changes, but efforts are being made to maintain large areas of marshland and other wetland habitat.

The North American Wetlands Conservation Act of 1989 created funding to preserve wetlands in Canada, the United States and Mexico; since 1989, hundreds of projects have protected more than 1 million acres of wetland ecosystems in the United States and Canada alone. A prime area preserved by this act is Cheyenne Bottoms, the last sizeable wetland in Kansas, designated as a "Wetland of International Importance" by the Ramsar Convention, a Hemispheric Reserve by the Western Hemisphere Shorebird Network, and Critical Habitat for the endangered whooping crane (*Grus americana*). To date, 6,000 acres have been protected, 35,000 restored and another 13,000 acres of Cheyenne Bottoms enhanced (Graziano 1994).

Another important aquatic environment, the lagoons of Baja California, has been designated a Biosphere Preserve. Under great threat from a proposed salt factory to be constructed by Mitsubishi Corporation in the prime wintering lagoons of gray whales, conservationists succeeded in stopping the project in late 2000. This preserve also shelters sea turtles, many sea birds and other marine mammals. Mexico's laws did not permit such damage to an officially declared Biosphere Preserve, but it nevertheless took years of legal wrangling and the participation of many conservation organizations to achieve this victory.

National anti-pollution legislation in many countries is making some progress in bringing back rivers and wetlands that had become lifeless from heavy pollution. International treaties have also been negotiated for individual rivers. The Danube River flows 1,770 miles from its source in Germany to the Black Sea, and along its entire length, it has been diked, dammed and channeled to accommodate barge traffic (Cowell 1995). In Hungary, the river inspired the famous waltz of that name and has been severely damaged by dams and diversion on the Slovak side, which have shunted most of the water from one of Europe's wildlife havens. This 200 square mile area is one of Europe's last wetlands, sheltering some 5,000 species of flora and fauna, and Hungary continues to negotiate its return.

The Danube Delta on the Black Sea lies mainly in Romania and is considered one of the world's great wetlands, covering 2,200 square miles (Simons 1997). In the mid-1980s Romania's dictator, Nicolae Ceausescu, decreed that the entire delta be transformed into grain fields (Simons 1997). He succeeded in destroying about one-fourth of the delta, or 240,000 acres, converting the land into wheat and rice fields. Not only was massive wildlife habitat lost, but his men shot pelicans and cormorants because they were eating too many fish (Simons 1997). The drainage plan did not succeed because the delta soil was not conducive to these crops, and by the time Ceausescu was executed by firing squad in 1989, it had been abandoned (Simons 1997).

In 1991 the Danube Delta was declared a Biosphere Preserve, and a conservation plan was set in place; as a first act, dikes and dams were breached, allowing the flooding of more than 9,000 acres (Simons 1997). As a feeding and resting area for millions of migratory birds of 325 species, the delta is of global importance (Simons 1997). It is also a

major nesting area for many threatened birds, including the Dalmatian pelican (*Pelecanus crispus*), a bird that was once abundant throughout Western Europe (Hoyo *et al*. 1992). Today, it is confined to eastern Europe and east-central Asia, with approximately 4,000 to 5,000 breeding pairs; fortunately, as a result of strong conservation programs, massive declines have been stopped or slowed (BI 2000).

An ecotourist industry has sprung up in the Danube Delta, helping to fund further restoration (Simons 1997). Anti-pollution work will be needed to cleanse the waters of an overload of contaminants poured into the river by the eight countries through which it flows (Simons 1997). This is the world's first example of the restoration of a delta and is founded on the philosophy that land valuable as flood protection and wildlife conservation is worth more in its natural state than converted for human use (Simons 1997). Experts involved in Mississippi and Rhine River restoration have been interested in the Danube restoration, which may herald a new approach to this crucial habitat.

Sections of rivers have received protection under the Wild and Scenic Rivers Act. This law and the actions private organizations such as American Rivers have succeeded in altering the pro-dam and channeling viewpoint that long has dominated America. The International Rivers Network has also worked to oppose dams around the world, often with great success. On the local scene, River Network, an organization founded in 1988, works at a grassroots level to encourage citizens to help clean up and preserve rivers and watersheds. Its book, *How to Save a River: A Handbook for Citizen Action* (Bolling 1994), provides a blueprint for individual conservationists. The Water Keeper Alliance, first launched to save the Hudson River from heavy pollution, works on many rivers in the United States to test water for pollution and works through activists and lawyers to stop pollution problems (Cronin and Kennedy 1997). Teachers and their students in countless school districts have adopted streams and rivers, removing trash and debris, and restoring them to their original states, even reintroducing native fish.

Progress is also being made in the United States in restoring wetland ecosystems. The Everglades is America's largest wetland. It was a vast, unspoiled marsh, a wilderness of sawgrass, groves of Bald Cypress trees and vegetated hillocks until only a century ago. Fresh water flowed through the 7 million acre Everglades from the enormous, 733 square mile Lake Okeechobee and its feeder rivers to the north, ending in Florida Bay (Levin 1996). During the dry season, rivers threaded their way through the wetland, and in spring wet seasons, the entire region would turn into a shallow river of grass. At one time, more wading birds nested here than anywhere else in the country. Four hundred species of birds, 60 species of amphibians and reptiles, and 25 species of mammals have been recorded in the southern Everglades alone, and at least 120 species of trees and 1,000 species of seed-bearing plants are native (Rex 1996).

Giant century-old alligators (*Alligator mississippiensis*) prey on a diversity of fish, turtles and snakes. River otters (Lutra canadensis) and tiny white-tailed deer (*Odocoileus virginianus seminola*) are also native. The round-tailed muskrat (*Neofiber alleni*) is found nowhere else. This rodent, dependent on shallow, freshwater marshes, has been affected by the invasion of exotic plants that have taken over much of the Everglades (Layne 1978). The Everglades mink (*Mustela vison evergladensis*) lives south of Lake Okeechobee, far from other races of mink. These animals are aquatic, utilizing much the same type of habitat as the round-tailed muskrat, although they are far more restricted in range (Layne 1978). Both species have declined as a result of development, water pollution and reduction of acreage of the freshwater marshes (Layne 1978).

Settlers arriving in Florida in the 19th century saw only a "pestilence-ridden swamp." The US government drained the entire wetland for development and agriculture, building the first federal canal in 1881 with enthusiastic state support. In 1905, the Governor of Florida vowed to wring the last drop of water out of the Everglades, and state drainage programs supplemented federal projects. Congress passed legislation in 1947 that authorized a massive program to control the flow of the Everglades, ostensibly to prevent flooding; 1,400 miles of canals, dikes and levees were built to straighten and channel the meandering Kissimmee River, the major feeder of Lake Okeechobee, in order to divert water for sugar growers south of the lake (Levin 1996). Four canals drained the lake and lowered water level by 5 feet; 3 to 4 million acres of its water were diverted toward the Atlantic every year, water that once fed the Everglades (Levin 1996). South of the lake, 500,000 acres were drained for agriculture. The same year this project was authorized, a strong-willed newspaper reporter, Marjory Stoneman Douglas (1947), wrote *The Everglades: River*

of Grass, pleading for the preservation of this great wetland. She carefully researched the conservation importance of the Everglades and documented the folly of destroying it to appease the growing agriculture industry. The book remains a classic, and not until the 1990s did the country realize that the drainage project was a terrible mistake.

Half the wetlands that once made up the Everglades are gone, now replaced by farms, suburban housing, agriculture and highways (Levin 1996). Ninety percent of the water birds and most of the native mammals have disappeared. The southern Everglades have become increasingly saline from an influx of sea water, causing the disappearance of many species unable to adapt. Some of the overflow from canals during heavy rains has been pumped into the Micaseekee Indian Reservation, which is located in the Everglades, flooding buildings and drowning hundreds of deer. In 1990, outflows drowned 90 percent of the entire deer population in the Everglades. Entire forests of bald cypress trees have died (Dugan 1993).

Wood storks once nested in colonies of 10,000 or more in the swamps northwest of the national park in the Corkscrew Swamp Sanctuary (Toops 1989). This 10,560-acre National Audubon Society sanctuary now protects 400 or fewer pairs of these birds; storks require shallow, freshwater pools that concentrate fish, especially during nesting season, to feed their young. Because of the drainage of the agricultural area and the lowering of water levels, wood storks died out and their chicks starved in the nest (Toops 1989). During the 1930s, at least 75,000 wood storks bred in Florida, but by 1975 there were only 12,000 (Kale 1978). They continued to decline, and in 1980, only 5,000 pairs remained (Lucas 1996). In 1984, the US Fish and Wildlife Service added the US population of wood storks to the Endangered Species Act.

The loss of water in the Everglades has had dramatic effects on alligators. They grow at abnormally slow rates, are underweight for their age and more anemic than alligators in other parts of the South. Research on the diet of these reptiles in 1997 revealed they were malnourished. The once-abundant populations of fish have disappeared, and alligators are forced to scavenge carcasses and feed on small mammals and snakes.

Federal protection was accorded to the southernmost 1.5 million acres of the Everglades by establishment of the Everglades National Park, but its ancient water flow pattern has been so disrupted by channeling, diversion and drainage that the ecosystem is a shadow of its former self. Adjoining the park to the northwest is Big Cypress National Preserve, an area of 570,000 acres also under the jurisdiction of the National Park Service, but with less restrictions; hunting, fishing and even mining are allowed in National Preserves under certain circumstances.

After 50 years of declining wildlife and proposals to restore the Everglades, Congress passed the Everglades Forever Act of 1994 (Cushman 1996a). Forty miles of the Kissimmee River, whose huge oxbows and curves through marshy pineland were turned into a diked canal by the US Army Corps of Engineers, will be returned to natural bends by this same agency. The cost of repairing the damage is an estimated $500 million, 14 times what it cost to obliterate the river's original curves (Levin 1996). Diking and channeling shortened the river from 103 miles to 56 miles, and a wet prairie where a million ducks wintered was drained (Levin 1996). A recent survey of the area found a total of eight ducks, and droughts in the region have increased (Levin 1996). Some local ranchers oppose the plan, but it has received the support of conservationists and, after intense lobbying, of President Bill Clinton. The nearby National Audubon Society's Kissimmee Prairie Preserve nearby, protects 8,000 acres of the original 30,000-square-mile flood plain of this river (Levin 1996).

Under the 1994 Everglades Forever Act, 40,000 acres of the agricultural lands will also be restored to marsh. A 3-mile-wide flow-way from Lake Okeechobee into the Everglades is another facet of the restoration plan. This would revive marshes below the lake. Sugar farmers have protested government acquisition and resent the proposed controls on the amounts of fertilizers and pesticides that can be released into the water system. The sugar industry in Florida receives $1.4 billion per year in federal tax breaks, and it has balked at any loss in its economic status. Added to the loss of acreage, the industry was angered by a proposed "sugar tax" that would have raised $245 million over a seven years to restore the Everglades (Levin 1996). Political contributions of more than $15 million from the sugar industry to presidential and other politicians™ campaigns to represent their case have stymied efforts to restore this

internationally important wetland. The funding was dealt a severe blow in November 1996 when Florida voters rejected the sugar tax plan on the Presidential ballot.

Funding by the Congress, which voted $7.8 billion for the Everglades Restoration Fund in 2000, permitted the project to go forward (Schmitt 2000). Florida will pay half of this sum over the next 40 years to redirect 80 percent of water now diverted back to the Everglades through an untested system of quarries and aquifers, and by removal of dikes and barriers (Schmitt 2000). The plan may not succeed in its goal of restoring the original ecosystem, but water flow will be improved, allowing wildlife to recover some of their populations. In another positive decision, plans that called for turning Homestead Air Force Base at the edge of the Everglades near Miami into an international commercial airport with hotels, development and new roads were canceled in early 2001 by the Clinton Administration (Canedy 2001).

Cleaning up Florida Bay and returning the sea grass to dead areas is another project that began in the 1990s, but it lacks the funding of the Everglades restoration. Its western portion is now saturated with algae, and the native turtle grass has disappeared from large areas (Stevens 1997). The tourist industry centered on snorkeling and diving is in decline as a result. A lack of fresh water has caused increased salinity and a resultant influx of water laden with agricultural chemicals. This aggravates the growth of algal blooms, such as red tide. Endangered sea turtles inhabit Florida Bay, and the coral reefs are home to a great diversity of fish and invertebrates, all of which are in steep decline.

The tourist industry brings $13 billion to Florida each year, a large percentage from Everglades tourists and others who come to appreciate the coral reefs and wildlife. This should impact decisions made to save the Everglades National Park, surrounding wetlands and Florida Bay.

The restoration of the Everglades represents an about-face for the historical approach to wetlands in the United States, and it may be copied in other parts of the country. Wetlands legislation still includes certain concepts such as "mitigation," a legal loophole allowing destruction of one marsh or wetland if another is preserved or created. Many ecologists consider that the natural wetland is far more complex and irreplaceable than the man-made one, and they should not be considered equal under the law (Daily 1997, Williams 1996). These man-made wetlands often fail to function naturally, and the concept of allowing such wetlands to be constructed when natural wetlands are destroyed is flawed. Developers often construct new wetlands in unnatural blocks without proper natural hydrology or native plants and animals.

Non-governmental organizations, such as The Nature Conservancy and the International Crane Foundation (ICF), have played a significant role in preserving many threatened wetland habitats for birds. The demilitarized zone between North and South Korea is a major refuge for cranes, white-tailed sea eagles and other water birds. Rare white-nape cranes (*Grus vipio*) were discovered feeding in the Han River estuary just south of the zone prior to the diking of these marshes for rice production. Dr. George Archibald, co-founder of ICF, and Korean ornithologist Kim Hon Kyu, convinced the South Korean government to set aside this marsh. Other key wildlife wetlands under threat have been preserved through the diplomacy of these conservation organizations and cooperation between biologists and governments that have bridged old enmities.

The problem of sewage and runoff from roadways, agricultural fields and suburban housing areas will only grow in the future. A US government project to deal with this problem has used natural solutions that could be imitated elsewhere. The project constructed shallow basins to capture runoff that then flows through grass, which removes solids and nutrients, and then to a cattail marsh for further cleansing. The last step is a deep pond with fish and mussels, which filter the water. Ten of these systems have been installed in Maine at a very small cost of $14,000 to $35,000, and similar structures have been built in New Jersey, New York and Massachusetts (Williams 1996). A new treatment process, vermifiltration, in which earthworms in soil filters extract nutrients and suspended matter from sewage, produces an effluent free of pathogens and ideal for irrigation. Several towns and cities in California have created marshes to filter sewage that has been given secondary treatment. These have become wildlife havens and

even tourist attractions. By contrast, Boston constructed a 9-mile pipe to carry treated sewage into Cape Cod Bay, where over 300 million gallons will be dumped each day, posing a threat to fisheries and other wildlife. Its cost was $390 million. Some cities have tapped sewage for methane gas to power city facilities.

Scientists are now attempting to address th**e** problem of soil salinization with salt-resistant plants. Department of Agriculture research has also found river reeds that turn toxic chemical runoff into water and carbon dioxide, poplar trees that absorb pollutants from groundwater, and grains and grasses that absorb fertilizer and herbicides, breaking down the toxins (Howe 1997). Prevention and care to avoid such pollution before it happens is even more important for the future.

The facilities for the 2000 Olympic Games at Sydney were designed to be environmentally sensitive. Recycled storm water was used for toilet flushing, and sewage effluent was filtered and recycled (Zuckoff 2000a). A degraded creek was restored to its former state, and when the rare Bell frog (*Litoria aurea*), was discovered on the site of the tennis center, special tunnels were built to allow these frogs to move through it unharmed (Zuckoff 2000a). This center did not create oily residue from automobiles on asphalt parking lots because these were the first Olympic Games to ban all internal combustion cars, requiring travel by trains that connected facilities and solar cars built for the games (Zuckoff 2000a).

Conservationists in the future will need to overcome the effects of a global economy spurred by corporate profits and politicians pushing destructive water projects through legislatures, only to repay financial contributions made to their campaigns or political favors done for them. Extraordinary wildlife habitats can be destroyed with the stroke of a pen. The Copper River Delta of Alaska is a large wetland vital to millions of waterfowl, shore birds and marine mammals, but politicians have proposed construction of a road through it for the benefit of loggers who want to remove timber.

With the warming of the global climate, ship traffic through the Arctic Ocean will increase, and the vast river deltas and waterfowl habitat in northern Canada will soon be threatened by oil tankers and construction of gas pipelines and roads. This region is vital habitat for a large percentage of the continent's waterfowl and shore birds, polar bears (*Ursus maritimus*), whales, seals, walrus and fish. Diamond mining and other development are already encroaching on this pristine area.

The extent of our interference with natural ecosystems is undoubtedly adversely affecting evolution. Nature has evolved superb adaptations in aquatic species**,** survivors for millennia within their habitats. We are just beginning to appreciate and understand the great diversity in aquatic ecosystems and the awe-inspiring beauty here. It is vital that this new understanding be used to protect, not destroy.

Rivers: Dams, Canals and Channeling

More than half of all accessible water is diverted for use by humans (Barlow 1999). Large-scale dam projects on major rivers have increased worldwide from 5,000 in 1950 to 38,000 by the end of the 20th century (Barlow 1999). More than 100 major dam projects are planned in West Africa alone, and conservationists predict crashes in fisheries and flood plain crops as a result (Dugan 1993). Many giant dams have ruined wilderness areas in order to produce electricity for which no demand existed. Wild and beautiful rivers in Indonesia, Brazil, India, Zambia and elsewhere have become fetid lakes, with an enormous loss in wildlife and plants. Many of the tributaries of the Amazon, the world's largest river and home to the greatest diversity of freshwater fish in the world, have been dammed over the past 50 years. In the process, hundreds of species of plants became extinct, drowned by the dam's rising waters.

Rivers: Dams, Canals and Channeling: Page 1

Between 1973 and 1983, Brazil borrowed $30 billion Brazil from international funds, such as the World Bank, to construct these dams (Lanz 1995). Huge debts are incurred by poor countries borrowing money from international funds to pay for dams. The real profits from dams accrue to companies that construct them and industries that directly benefit (Lanz 1995). Yet the rationale for dams has traditionally been to benefit the population as a whole. Numerous extinctions of native wildlife and plants have resulted from dam construction. This makes the real cost of such cheap electricity far more expensive, yet such calculations are not considered when nations endorse dams.

Until the 20th century, all but a few of the world's major rivers were pure. Today, the opposite is true. Unpolluted, un-dammed rivers are the exception, and even the great diversity of the mighty Amazon River is now threatened by dam construction on its tributaries. These dams have endangered countless species of wildlife. The majority of species evolved to live in rivers are unable to adapt to conditions created by artificial barriers such as dams and resultant changes in water temperature and current. In the United States, only 2 percent of rivers remain free-flowing and undeveloped (Barlow 1999). All major European rivers have been dammed, diked or channeled. After dam construction, reservoirs, which often cover hundreds of square miles, gradually fill, drowning untold thousands of animals in the process. Even those able to swim to dry land rarely survive because territories are already occupied by members of their own species. In tropical forests, threatened monkeys, armadillos, rodents, snakes and other animals drown, and rare plants and trees die under hundreds of feet of water. Dam gates cause wildlife mortality as well. Endangered West African manatees (*Trichechus senegalensis*) have been crushed to death when caught in the giant gates of these dams, or left high and dry when water levels were lowered (Reynolds and Odell 1991).

Dams upriver from coastal marshes disrupt the flow of water, which can cause crashes in breeding fish populations. Dammed rivers that empty into coastal deltas experience reduced freshwater flow, which creates an influx of saltwater into freshwater marshes (Lanz 1995). This devastates fisheries adapted to low salinity, such as many species of shrimp and crayfish. An extreme case is in Louisiana; its entire marsh coastline and its $700 million-per-year fishery-based economy have collapsed over the past few decades as saltwater has crept into freshwater marshes, drowning 1 million acres a year. Dikes and levees built for shipping traffic on the Mississippi River and its tributaries have decreased the freshwater flow into the marshes, causing this disaster. Another negative effect of dams on coastal ecosystems is the blockage of silt and sand that enriches delta marshes and maintains sandy beaches. Dams generally have to be abandoned within about 50 years because they fill up with silt and can no longer function efficiently. The serious environmental damage caused far outweighs these short-term economic benefits.

Migratory fish, from salmon to sturgeon and shad, find their paths blocked by dams. They leap in vain at the concrete barriers, and most fail to negotiate fish ladders on those dams that have installed these devices. The young of salmon that manage to hatch upstream from dams are crushed and torn to bits in the dams' massive turbines, which kill 90 percent of salmon young each year in the Pacific Northwest of the United States. Virtually every species of the seven salmon native to this region is threatened with extinction, and 214 stocks are threatened; 106 populations have already disappeared (Stein *et al*. 2000). These salmon and steelhead trout have also suffered from siltation caused by logging and agriculture, which has clouded the clear streams needed for spawning. The loss of these salmon, which numbered in the billions when Lewis and Clark entered the region in the early 19th century, has affected the livelihoods of hundreds of fishermen and wildlife that depended on these fish. Bald eagles, black and grizzly bears, river otters and many bird species rely on these fish as a vital food resource. Each fall, bears eat large quantities of fish, especially fatty fish like salmon, to fatten up prior to their winter hibernations. Without these fatty stores, many

bears do not survive the winter.

The outflow from dams is regulated by opening of gates, resulting in flows ranging from trickles to torrents. Wildlife requiring a certain water level can be eliminated when it changes radically. Rare trumpeter swans (*Cygnus buccinator*) wintering in eastern Idaho died in large numbers in 1989 when the reservoir on the Henry's Fork tributary of the Snake River was closed during a drought. The water downstream had previously remained unfrozen in winter, providing vital habitat. In February 1989 when the water froze as much as 4 feet below the surface, more than 50 swans froze or starved. The surrounding community became so concerned they raised $30,000 to purchase 4 billion gallons of reservoir water to be released. *Life* magazine photographer Glenn Oakley documented locals picking up and carrying the surviving swans to indoor areas; some were even warmed in nearby bathtubs. These swans were then transferred to a rehabilitation center where they were kept throughout the rest of the winter, and grain was supplied to the weakened swans remaining in the wild (Life April, 1989). In the words of a rescue coordinator from the Idaho Department of Fish and Game, "I guess nobody ever told these swans they should have filed for water rights."

Even more tragic events took place in Canada, where a massive dam project has inundated some 4,000 square miles of forest land and riverine habitat in Quebec and Labrador. These dams have had major effects on both people and wildlife since the 1970s. They impeded the ancestral migration route of caribou and caused 10,000 of these animals to drown in a torrent of water from one of the new dams in 1990 (Verhovek 1992). Chief Matthew Coon-Come of the Grand Council of the Crees appealed to conservationists to assist tribes in stopping any further work on the dam system. "For 5,000 years we did not leave a trace of our having been in James Bay. What we had came from the land and went back to the land. The land is sacred to us. This land holds the graves of our ancestors. But now, Hydro-Quebec is destroying our sacred land and our way of life. If you were to fly with me today in a Cessna, starting from the first James Bay dam, we'd fly for four and a half hours, and all you'd see is land drowned by water, three major rivers destroyed" (Coon-Come 1993). Chief Coon-Come first began fighting the dam projects in 1972 when he was 16 years old, and in 1994, at the age of 38, he was honored as the first North American recipient of a Goldman Environmental for his achievements in stopping the second phase of the James Bay project.

The Indus River dolphin or Susu (*Platanista minor*) of Pakistan and the Ganges dolphin, which also inhabits the Brahmaputra River system, are highly endangered. These dolphins appear to be blind, but have deeply set eyes that can receive light at an angle, perhaps when they surface (Nowak 1999). Of the two, the Indus River species is more endangered and considered to be on the brink of extinction (Leatherwood and Reeves 1983). It is considered endangered. This dolphin's entire range lies within the Pakistani provinces of Sind and Punjab where, despite of legal protection, it has declined, mainly as a result of a series of dams on the Indus that isolate populations, along with accidental drowning in fish nets and pollution (NGS 1995). Its population has been estimated at only about 400 animals between two dams in the Sind Province, and perhaps 150 more in small subpopulations farther north in the Punjab Province (Nowak 1999). The Ganges River dolphin inhabits a larger range and is found in western India, Bangladesh and Nepal. Pollution, boat traffic, fragmentation of populations by dams, accidental capture in fishing gear and hunting all threaten this species (Nowak 1999). 4,000 to 5,000 Ganges dolphins survive, and the species has disappeared from the Karnaphuli River to the east of the Ganges at the very least (Nowak 1999). In Nepal, dams have blocked portions of the dolphins™ range, trapping them in portions of river too small to ensure their survival (Leatherwood and Reeves 1983).

Fish and mollusks are especially vulnerable to disappearance when their habitats are radically changed by dams. The conditions created in the reservoir usually end in the destruction of aquatic vegetation, bottom-dwelling mollusk fauna, and the fish, turtles, birds and mammals that are part of free-flowing rivers. Sediment soon covers the mollusks and bottom vegetation and kills them, and water currents no longer bring food to the gills of mollusks and keep water clear. Caddis and stone flies, upon which trout and other fish feed, disappear when their larvae do not hatch in reservoir conditions (Lanz 1995). These insects are the primary food for trout and many other fish. Cold temperatures of swift-flowing, tree-lined rivers in temperate areas that teem with trout and salmon become warm, pond-like areas, to which these species cannot adapt.

Rivers: Dams, Canals and Channeling: Page 2

With a total of 297 species, North America has the world's greatest diversity of freshwater mussels, though they have suffered dramatic declines as a result of dams (Neves 1996). Free-flowing rivers and streams have been turned to ponds, and to compound the damage, the dam builders usually channel rivers downstream. Using machines with revolving chopping blades, natural, curving rivers and streams are converted into straight ditches. Stream edges are cleared of vegetation, and river bottoms are dredged, depositing mollusks and crustaceans in piles along the banks. What is left is a sea of mud in a ditch devoid of life. Malacologist Dr. George M. Davis (1977) concludes these projects, combined with acid drainage from strip mining, erosion and pesticide runoff from agriculture, have been the major causes for the near-extinction of much of the continent's native mollusk fauna (Davis 1977). At least 102 species are considered threatened in the United States, 97 percent of these from habitat loss or degradation (Stein *et al*. 2000).

Prior to the devastation of their habitats, mussels clustered in vast numbers on river bottoms throughout the major rivers and their tributaries in the Midwest and southeastern United States. These rivers meandered through forests that provided cool shade. River otters, muskrats and mink denned among tangled tree roots and in banksides. Water quality remained clear as a result of the forests and the filtering actions of the mussels. River snails fed on the detritus and algae of the mussel shoal, further cleansing the water. The mussel shells formed large, reef-like piles on river bottoms, providing habitat for fish, crayfish, water plants and large river snails. Turtles, aquatic birds and mammals fed on the fish, mussels, snails and crayfish in this ecosystem.

A major center of diversity for these mussels is Alabama, which has more than 235,000 miles of waterways and three major river basins left untouched by Pleistocene glaciers, preserving a great diversity of species (Stein and Flack 1997). Having survived the Ice Age, many species of mussels, fish and crayfish became extinct or endangered when water projects began destroying their habitats in the 1920s. The richest of all known beds, Mussel Shoals, located in the Tennessee River of Alabama, once had a diversity of approximately 70 mussel species. The Wilson Dam, completed in 1924, submerged Mussel Shoals and covered them with 15 to 20 feet of mud, causing the extinction of at least half the mussel species and five of the seven large river snails (Davis 1977). Experts at the University of Alabama in Tuscaloosa report 69 percent of mussel species are extinct, endangered, threatened or of special concern in the rivers and streams of the state (Cushman 1995b).

Many mussel species need small fish to complete their reproductive cycles. One threatened mollusk, the orange-nacre mucket (*Lampsilis perovalis*) of the Mobile River basin, produces larvae that resemble tiny fish; they anchor to the adult mussel with a long, wavy mucous strand that acts as a lure to tiny fish; when a fish attempts to eat this larva, however, it breaks away and attaches to the fish's body (Hartfield and Butler 1996). The fish carries the mussel larvae to a new area. Other mussels have different reproductive strategies. In some cases, fish congregating around the beds are parasitized by embryonic mussels who cling to their fins or gills and become enclosed in a cyst. The larvae absorb nutrients from the fish for two or three weeks, growing into juvenile mussels, and in the process, they are transported to new areas, where they detach and colonize stream beds (Hartfield and Butler 1996).

The orange-nacre mucket is one of many species that have disappeared from most major rivers, and only small streams and creeks now afford suitable habitats for the creature (Hartfield and Butler 1996). The host species for many mussels are darters. These fish exhibit a rainbow of iridescent hues in a multitude of patterns. Many of their names are evocative of their color or origin: Amber (*Percina antesella*), Bayou (*Etheostoma rubrum*), Goldline (*Percina aurolineata*), Slackwater (*Etheostoma boschungi*), Watercress (*Etheostoma nuchale*) and Okaloosa Darters (*Etheostoma okaloosae*). All the latter species are listed on the Endangered Species Act.

The most famous of these little fish is the 3-inch snail darter (Percina tanasi). Named after the river snails upon which it feeds, this species was discovered on the Little Tennessee River in 1973 above the Tellico Dam site after construction of this major dam by the Tennessee Valley Authority (TVA) had begun. Construction continued after the TVA was able to reverse preliminary injunctions to delay the dam brought by conservationists and irate Tennessee residents being evicted from their land. By the time the snail darter was scientifically described, proposed and listed under the Endangered Species Act, the dam was nearly complete. There is evidence that construction was hastened when word of the fish's discovery became known, in order to prevent conservationists from stopping the dam. The snail darter's survival is due to transplants into other parts of the Little Tennessee River and a few of its tributaries and its discovery in 1980 on a new site in Tennessee™s South Chickamauga Creek, by Dr. David Etnier of the University of Tennessee, who originally discovered the species. The snail darter is now known to exist in Alabama and Georgia, as well as Tennessee. It has been reclassified as threatened under the Endangered Species Act. It does not owe its existence to the TVA, however, which destroyed its only known habitat with a dam, nor to Congress, which rewrote the Endangered Species Act to sanction the extinction of this and other species that might impede "development."

Over three hundred types of crayfish are found in the United States; these species make up 61 percent of the 525 crayfish species found worldwide (Stein *et al*. 2000). Most species live in rivers, streams and waterways in the southeast (Clancy 1997). These crustaceans share many of the same ecosystems inhabited by mussels, darters and snails, and about half the species are threatened with extinction (Stein and Flack 1997). Hiding in crevices, under rocks and buried in sand, crayfish attempt to escape herons, raccoons, river otters and predatory fish (Clancy 1997). A 1996 study by the American Fisheries Society found 65 species of crayfish living in a single river drainage (Clancy 1997). They are usually only 3 or 4 inches long, and like lobsters and shrimp, females carry fertilized eggs attached to the underside of their abdomen. Even after hatching, she allows them to cling to her abdomen for several weeks before they become independent (Clancy 1997).

Native crayfish have declined along with mussels and fish in the altered environments created by dams and channeling. Only four crayfish species out of more than 150 species considered imperiled by The Nature Conservancy are listed on the Endangered Species Act, and almost nothing has been done for their preservation (Clancy 1997). The Nature Conservancy has programs to educate people to protect the land around streams from pollution from cattle, and it is building partnerships with local, rural organizations and conservation groups. The goal of their programs is to preserve the habitats of native crayfish and hundreds of other species by arresting water pollution and other misuses of waterways. This benefits the local economies in the process.

Mussels, crayfish and darters are important indicators of environmental quality because of their great sensitivity to changes in water quality. Scientists have warned a mass extinction of American mussels and crayfish is imminent. Public interest is sparse for these endangered species, lacking the popularity of the bald eagle, the gray wolf or even the black-footed ferret. Yet they are critical to the healthy functioning of southeastern aquatic ecosystems and represent a precious source of diversity on the continent.

The damming of southern rivers continued in the 1960s and 1970s. By 1967, there were nine dams on the Tennessee River, leaving only 22 miles free-flowing. The last un-dammed river in Tennessee, the Duck River, was dammed in 1975. It contained the greatest diversity of snail species left in the Tennessee-Ohio River system (Davis 1977). The Fish and Wildlife Service listed seven species of endangered mollusks native to the Duck River on the Endangered Species Act when the Columbia Dam was under construction. In retaliation, the TVA brought an unsuccessful lawsuit against the Department of the Interior (FWS 1979). Besides the biological impoverishment resulting from destruction of natural rivers and streams, many potential food sources for humans are lost, such as mussels, crayfish and fish.

For fish of rivers in the US West, the opposite conditions prevailed. Flowing through desert landscapes, these rivers tend to be warm and turbid from eroded soil. The Colorado River evolved an extremely rich, endemic fish diversity adapted to this water type. During the 20th century it was dammed throughout its course. Dam operators of the 49 dams on this river occasionally release water from these reservoirs. Coming from the bottom of the reserves,

the icy, cold water inundates ecosystems below, creating habitats that endanger native fish. Among these endangered fish are the humpback chub (*Gila cypha*), the Colorado squawfish (*Ptychocheilus lucius*) and razorback sucker (*Xyrauchen texanus*). The Colorado squawfish, a large fish reaching 6 feet, was once an important food fish for natives and settlers. None of these species have been able to adjust to the cold, clear waters of the dammed Colorado River, which prevented their free movement. The Fish and Wildlife Service has artificially maintained these and other endangered fish in hatcheries, and some populations survive in un-dammed tributaries. Dams on the Colorado River have also inundated precious riverside habitats of small marshes where rare water birds bred. The delta of the Colorado River was once a vast marsh in northern Mexico, a wildlife haven which harbored millions of waterfowl and fish. It was the life blood of the Cocopa tribe. As a result of the dams and diversion of its water to Los Angeles and for local agriculture, the delta is now a mere trickle. The silt that was once deposited on banks and in the delta is now retained upstream, depriving ecosystems downstream of nutrients.

Although the rate at which natural rivers are being dammed has slowed considerably in recent years, for many species the damage has been done. A growing number of organizations and individuals have been urging the removal of dams, especially those causing extinctions. The McPherri Dam on a tributary of the Sacramento River, which once had one of the largest salmon runs in the state, was demolished in 1998, and a few days later, another dam in Medford, Ore., was breached (Egan 1998). A dam on Maine's Kennebec River was removed in 1999, allowing salmon and other fish to return to former haunts. This required the work of many conservationists for more than a decade, and many politicians and others in the state opposed its removal. The 75,000 US dams were often built at huge public expense. Congressional representatives have pushed these projects through Congress for decades, promoted without real analysis of need, economic benefit or environmental effect. Some of the larger dams may be more difficult to remove. The dams on the lower Snake River in the Northwest, for example, have eliminated the millions of salmon that once spawned here, affecting wildlife and local economies. A major effort to breach these dams to allow passage of salmon is gaining momentum, but many barge operators and farmers who transport their grain to market on the barges are strongly opposing the breaching of these dams. In the future, dams may be regarded with less respect as naturally flowing rivers become better appreciated. As former Secretary of the Interior Bruce Babbitt said while commencing the destruction of a dam: "Dams are not like the pyramids of Egypt that stand for eternity. They are instruments that should be judged by the health of the rivers to which they belong" (Egan 1998). Breaching is a compromise to removal of dams that may be more acceptable to dam defenders.

Rivers: Dams, Canals and Channeling: Page 3

The Aral Sea, 300 miles to the east of Siberia's Lake Baikal, is ancient in origin. This was once the fourth-largest lake in the world, covering 25,000 square miles (Kinzer 1997). Two giant dams were constructed in the 1960s on its two feeder tributaries, the Amu Darya and Syr Darya. The diverted water was sent to the south to produce cotton (Filipov 1997). This crop requires great amounts of water and is unsuitable for the arid steppe region. The loss of its feeder rivers caused the Aral to shrink over the next 30 years from 25,675 square miles to 14,090 square miles, and its shores receded up to 50 miles (Stewart 1992). By 1997, it covered only 12,000 square miles, and it continues to shrink (Kinzer 1997). This once rich lake in the midst of the dry plains of Central Asia is expected to completely dry up by 2010 (Filipov 1997). As it dried up, the sediment from the Aral Sea's bed, which contained toxic chemicals, blew away, coating everything within hundreds of miles with 150 million tons of contaminated dust (Filipov 1997).

The wealth of diversity that once teemed in this desert sea has been lost. The destruction of this beautiful lake and its wildlife is without parallel anywhere in the world in recent history, an environmental catastrophe. The water that remains has become increasingly saline and polluted by unregulated industries (Filipov 1997). The collapse of the fishing industry has caused great financial hardship to the people who had lived along the shores of the Aral for centuries. In the 1950s, the Aral produced 40 to 50 tons yearly of sturgeon, pike and roach, among other species of fish; all of its 24 endemic fish are now extinct (Stewart 1992). The mayor of the town of Muynak, located at the

southern end of the lake, recalled, "Our fishing boats used to bring in 30,000 tons of fish each year." The town's population dropped from 45,000 in 1967 to 28,000 in the late 1990s (Kinzer 1997).

Of the Aral Sea region's 173 animal species, only 38 survived until the early 1990s (Stewart 1992). Almost all birds disappeared, along with the last of the fish, and only brackish pools remain along the shoreline (Filipov 1997). In March 1991, the Aral Sea was officially declared an ecological disaster area, and the Soviet government appealed to the United Nations Environmental Programme for help; an inter-republic commission was set up to reduce pollution, but with the dissolution of the USSR., the project was abandoned. In the years since the Soviet Union dissolved, destruction has continued unabated (Filipov 1997).

The five newly established Central Asian nations of the region, Kazakhstan, Uzbekistan, Krygyzstan, Tajikistan and Turkmenistan, are now competing for control of the water from its two feeder rivers to maintain their irrigation-fed agriculture (Filipov 1997). Although the leadership of these countries agree urgent action is required to save the Aral Sea, they are not ready to take drastic measures to conserve water (Kinzer 1997). Ironically, much of the diverted water is lost to evaporation and seepage because the irrigation canals were neither covered nor lined (Kinzer 1997). What water is left after heavy application of pesticides and other chemicals sprayed on cotton and rice fields becomes poisoned and trickles into the Aral, further contaminating it (Kinzer 1997). Cancers and other illnesses have struck the local people in Muynak (Kinzer 1997). An environmental organization, Aral-S-O-S, is attempting to reach agreements among the countries, but admits the countries' philosophy of considering water their national property may make the goal unattainable (Kinzer 1997). These nations continued discussions in 2000 without taking any action to prevent the impending loss of the Aral Sea.

In the majority of cases, dams are constructed with little or no knowledge of the ecosystems they are ruining. Likewise, the governments that authorize the dams rarely consider environmentally sound alternatives. In the 1940s, the Volga and Kama Rivers, 300 kilometers north of Moscow, were dammed to form an enormous reservoir that flooded 455,000 hectares (1,124,305 acres) of arable meadowland to produce a relatively small amount of electricity (Lanz 1995). Dams on the Volga impeded the natural migration of sturgeon from the Caspian Sea for their spawning, resulting in a catastrophic decline in the world's most valuable fish. Beluga caviar from the beluga sturgeon (Huso huso), an endangered species, is the most valuable fisheries product in the world, made more valuable by its continued decline in the Caspian. All the Caspian's species of sturgeon are endangered, as are species of the Amu-Dar and Syr-Dar Rivers feeding the Aral Sea.

The Three Gorges, a Yangtze River Dam project in China that will be completed in the next five years, will be the world's largest hydro-electric project. This dam, expected to cost up to $120 billion, will be 607 feet high, span over a mile and flood 400 miles of this major river, including 30 million acres of cultivated land (Carpenter 2001). The portion of the Yangtze River to be dammed is one of the most picturesque landscapes on Earth, its swift waters flowing through steep gorges and mountains enshrouded in mist. It has been painted by Chinese artists for centuries. The three gorges that will end up under water, the Qutang, Wu and Xiling Gorges, have tributaries and feeder streams that will also be adversely affected. One of these, north of the town of Wushan, the Daning River, is home to many ancient species of trees, such as the Dawn redwood (*Metasequoia glyptostroboides*), the dove tree (*Davidia involucrata*) and various ginkgoes (Hoh 1996). Forty-seven species of rare or endangered plants listed by the Chinese Academy of Science will be inundated when the dam waters rise; among these are many endemic medicinal plants (Hoh 1996). Funds are lacking to treat the 265 billion gallons a year of raw sewage and industrial waste that will flow into the impounded waters from the Three Gorges Dam (Tyler 1996). The project's managers admit there are no immediate solutions to the sewage and pollution problem, or to the impact of huge volumes of sediment that could clog the entire flow of the river (Tyler 1996).

The Yangtze River dolphin (*Lipotes vexillifer*) inhabits this part of the river and faces imminent extinction. Restricted to the Yangtze and portions of the Quiantang River, it has disappeared from much of its original range (Nowak 1999). This dolphin evolved in swift, muddy waters, preferring to live near large eddies. The sonar in its bulbous head is able to locate fish without vision. While this species is actually almost blind, these dolphins have

tremendous physical strength to negotiate strong currents. Boat travelers in the river 50 years ago saw hundreds of these dolphins leaping and swimming throughout its length, along with birds and other wildlife. Today, almost no wildlife can be seen. This species was endangered by other dams, collision with boats and ships, dynamiting for channel maintenance, pollution, accidental drowning in fishing nets and loss of food to over-fishing by humans, even prior to the Three Gorges dam construction (Nowak 1999). A large male found dead in January 1996 was examined by scientists; they determined he had died from an electric shock device used to kill fish in the Yangtze River (CNN 1996).

The lakes along the Yangtze once sheltered hundreds of dolphins, but sedimentation from agricultural runoff covered the lake bottom, and sewage polluted the water. It has disappeared from almost all its former strongholds. Surveys in 1986 found 300 animals, but in 1993, 200 or less were estimated to remain, and more recently only 9 individuals could be found (Nowak 1999). This species, adapted for millions of years to life in these rivers is now considered the most endangered of all cetaceans (Nowak 1999). The upper Yangtze will soon be awash in sewage and other pollution from the Three Gorges Dam, which will also block its movements, a habitat where these last dolphins are unlikely to survive. The sole native dolphin in captivity, Chichi, a male, has lived in a small concrete tank at the Institute of Hydrobiology in Wuhan since 1980 when fishermen snagged him on their hooks; he still has scars from these wounds. Pneumonia killed one young female placed with him, and several other females put in his tank in the hopes of captive breeding have died as well, according to a 1999 PBS documentary, "Great Wall Across the Yangtze."

Ocean Park Conservation Foundation in Hong Kong, in cooperation with the IUCN Cetacean Specialist Group and the Institute of Hydrobiology in Wuhan, China, have cooperated in a project to capture as many of the remaining animals as possible before the dam fills and move them to the Shishou Seminatural Reserve (Leatherwood and Genthe 1995). The reserve, a natural oxbow in the Yangtze, also harbors ten finless porpoises (*Neophocaena phocaenoides*) Œ a species that has lived in the river with the dolphins for thousands of years. Finless porpoises are also native to coastal waters west to Saudi Arabia, but their status is not well known. This solution is unlikely to protect more than a few members of the species, and it will almost certainly fade into extinction in the near future. Another species unlikely to survive the effects of this dam is the endemic, migratory Yangtze sturgeon (*Acipenser dabryanus*).

The dam will also affect the Yancheng Marshes, covering some 938 square miles on the north-central coast. Extending for 186 miles, they form a floodplain for the Yangtze River (Simon 1995). Over half a million water birds and shore birds winter here, including the highly endangered red-crowned crane (*Grus japonensis*), whose population in this wetland increased from 200 in 1981 to over 600 in 1987 (Simon 1995). The tidal flats of the Yangcheng are being reclaimed for agriculture, presenting another threat to this species, whose world population totals only about 2,200 birds (BI 2000). Another rare bird, Saunder's gull (*Larus saundersi*), has a world population of only 7,000 birds in decline (BI 2000), breeds in the Yancheng (Simon 1995). This marsh is of great importance to the 226 birds recorded here, since the vast majority of wetlands in China have been drained, polluted or are heavily hunted (Collar *et al*. 1994). For Pere David's deer (*Elaphurus davidianus*), the Yangcheng Marshes are a new home, one of several reintroduction sites for this species that became extinct in the wild and was rescued by captive breeding in England (Simon 1995).

Another water project, said to begin in two years, will divert water from just west of the Yangtze north to Tianjin, a city southeast of Beijing that is suffering water shortages (Eckholm 2000). Should this be carried out, the combined effect of this diversion and the Three Gorges Dam will decrease the flow of the Yangtze River so greatly that these marshes may dry up. Water from the Yangtze River west of the Three Gorges Dam will also be diverted north to the Yellow River, which has been overused and sometimes runs dry, and to mountain zones in the northwest and south (Eckholm 2000). Canals and reservoirs will be dug to carry this water in projects that will cost more than $12 billion (Eckholm 2000). The effects of these diversions on the remaining wildlife of this river will be devastating.

Rivers: Dams, Canals and Channeling: Page 4

Africa's rivers have also been dammed, eliminating wildlife. Most recently, a dam on Tanzania's Lower Kihansi River, costing $272 million, has blocked the flow of a beautiful waterfall, the sole habitat of a newly discovered toad, the Kinhansi spray toad (*Asperginus nectophrynoides*) (Donnelly 2001). This tiny, translucent toad is confined to a 10-acre marsh sprayed by the waterfall. The major source of funds, World Bank, was informed of the imminent extinction of the toad and the loss of the waterfall in 1997, but took no action until Friends of the Earth president Brent Blackwelder wrote the bank's president on the topic of the seriousness of the situation and need for corrective action (Donnelly 2001). An artificial spray system was installed for the toads, and 500 of the estimated 11,000 remaining toads were shipped to the Bronx Zoo and the Detroit Zoo. The toads have proven extremely difficult to maintain in captivity, although breeding did take place at the Bronx Zoo. Tiny, wingless insects must be hand-gathered for these toads, which weigh only two-tenths of a gram, and the majority of the zoo department's staff is occupied in caring for the toads. World Bank employees are considering a $5 million loan to manage the habitat around the Kihansi Gorge to prevent the species from becoming extinct (Donnelly 2001). It is remarkable that the World Bank has been forced to consider the survival of a tiny toad, but unfortunate that the entire ecosystem is being destroyed for electricity production that could have been generated in a less destructive fashion.

The amount of fresh water collected by dams worldwide has increased in the past 40 years by 10,000 cubic kilometers, or 10 trillion tons, an amount equivalent to all the moisture in the Earth's atmosphere (Browne 1996). Much of the water retained in reservoirs is lost to evaporation, especially in arid regions. Geophysicists calculate that dam building will continue until all sources of recoverable water have been exploited, a time that is expected to come in the next century (Browne 1996).

Wetland Drainage

The drainage of wetlands has caused extinctions in some parts of the world. The pink-headed duck (*Rhodonessa caryohphyllacea*), native to northeastern India, northern Myanmar (Burma) and central Nepal, was locally common during the 19th century in grassy wetlands, where it was heavily hunted by British colonials (Collar *et al*. 1994, Fuller 1987). The male had very unusual coloration, with a bright pink head and brownish plumage marked in pink and white spots. The female was a slightly less colorful version of the male. Males and females uttered different calls, having very different trachea: The male had a two-syllable metallic cry and the female a loud quack (Fuller 1987). Reduced by sport and market hunting, much of its habitat was gradually converted to agriculture, causing an apparent extinction (Fuller 1987). Although not seen in the wild since about 1936, this species is still listed by the IUCN as critical and there is some hope that it survives undetected (BI 2000, Collar *et al*. 1994).

At least five species of frogs have been extinguished by wetlands drainage. The Israel painted frog (*Discoglossus nigriventer*) was last seen in 1940 before its sole habitat, Lake Huleh, was drained for agriculture. Three species of frogs that inhabited the marshes and wetlands surrounding Mexico City disappeared after the city expanded and filled in wetlands for housing and industry and used others for dumping grounds. Leopard frogs of the genus *Rana: Rana johni* and *Rana pueblae* became extinct about 1979, and Tialoc's leopard frog (*Rana tlaloci*) was extinguished in 1990, according to D.M. Hillis, who wrote his Ph.D. Dissertation for the University of Kansas on the species.

Wetland Drainage: Page 1

South America's Pantanal, the world's largest wetland, is a vast network of tree-lined rivers, lakes, marshes, savannahs, palm groves and hillocks in southwestern Brazil, neighboring Paraguay and Bolivia (Simon 1995). Estimates of its size vary widely. Some are apparently based on the entire floodplain, and others on the wetland's size during the dry season. They range from 39,000 square miles (Dugan 1993) to 77,200 square miles, the size of South Dakota (Eckstrom 1996). By any definition, it is an immense region, having one of the most distinctive mosaics of vegetation and richest wildlife diversity in Latin America (Dugan 1993).* It is highly endangered by water diversion and drainage programs.

The Pantanal forms the upper waters of the Paraguay River system and is fed by the Cuiaba, Taquari and Miranda Rivers (Eckstrom 1996). During the rainy season, from December to June, the Pantanal drains the entire center of southern South America, fed by runoff from Bolivian highlands and the sources of the Paraguay River, forming a vast, shallow lake 7 feet deep with islands of vegetation (Eckstrom 1996). Amazonian fauna and flora meet with those of southern Chaco grasslands and pampas, creating a center of diversity: 3,500 plant species, 102 mammal species, 652 bird species, 177 reptile species, 40 amphibian species, at least 264 fish species and 1,132 butterfly species are native (EI 2001, Schemo 1996b). This huge wilderness is of vital importance to a host of animals that have disappeared from other parts of their ranges. They are threatened by the presence of 8 million cattle and the cattle management, which includes introduction of non-native grasses and clearing forest land monkeys and other terrestrial animals require (EI 2001). A new ecotourism industry is gaining ground in the Pantanal, and is bringing in funds to the region at a time when its natural treasures are most at risk (Schemo 1997).

Marsh deer (*Blastocerus dichotomus*) are South America's largest deer. They are superbly adapted to living in marshes and wet savannah. Their long, coarse coats repel water, and broad, webbed hooves prevent them from sinking into soft ground (Nowak 1999). Leaping over high grass, these deer move swiftly in this watery environment, using the hillocks and islands of vegetation to rest and have their young. Marsh deer formerly lived in the marshes along the Rio Parana and Rio Paraguay and perhaps as far north as the Amazon River (Nowak 1999). They are gone from Uruguay and have become very rare in Argentina, Bolivia, Peru and Paraguay (Nowak 1999). The Pantanal provides a last retreat for an estimated 7,000 deer, but even here they are declining (Nowak 1999). The species is listed as endangered in the Endangered Species Act, and as vulnerable on the *2000 IUCN Red List*. The estimated five million cattle who graze in the Pantanal (Eckstrom 1996) compete with these deer for habitat and forage. Moreover, cattle have spread brucellosis, which causes reproductive failure, to the deer (Nowak 1999, Thornback and Jenkins 1982). Cattle ranchers have persecuted these deer, and hunting, especially when these deer become stranded on islands during flooding, is another cause of decline (Nowak 1999, Thornback and Jenkins 1982). Dams and drainage for agriculture in the Parana River Delta on Brazil's coast have destroyed much of the once vast marshes there (Thornback and Jenkins 1982).

---

*A film that gives an excellent environmental and wildlife portrait of this wetland, fiPantanal: Prairie of the Great Waters,fl was made in 1986 (see Video, Regional, Latin America). It features many of the endangered species described here, along with views of the Pantanal in rainy and dry seasons. A book by Vic Banks (1991), *The Pantanal: Brazil's Forgotten Wilderness*, from the Sierra Club, also gives an overview.

The vast Pantanal is also the most important habitat for the engaging and highly endangered giant otter (*Pteroneura brasiliensis*), which is extinct in most of Brazil and absent from all the larger tributaries of the Amazon (Simon 1995). Killing for otter pelts has been a major factor their decline, and loss of prime habitat is another cause. Degradation of river banks needed for dens by illegal gold miners and cattle, deforestation that affects the water quality and fish with sedimentation and other changes to this wetland have resulted in declines in Giant Otter populations. These otters live in large family groups of up to 20 individuals and require large, high-quality ranges. They are among the noisiest of otter species, uttering a variety of squeals and screams to communicate with one another in the often murky water. This has attracted hunters, who have killed off families and eliminated the species in entire river systems. These otters depend on help from one another, such as loud warning calls about the presence of their major predator, caiman. Their fur is still valuable, although illegal in virtually every market in South America and elsewhere in the world (Nowak 1999).

South America's largest tropical mammal, the South American Tapir (*Tapirus terrestris*), is also native to the Pantanal. Young tapirs have striking white horizontal stripes and spots, which fade into a solid gray as they grow older. Tapirs find the wetlands and abundant vegetation of the Pantanal to be an ideal habitat, and they can be seen swimming in the ponds and bywaters with only their snouts above the water. Like the other three tapir species, the South American tapir has declined throughout its range from hunting and habitat destruction. The IUCN classifies it as near-threatened, and it is listed on the Endangered Species Act.

The Pantanal shelters the largest jaguar population (*Panthera onca*), a threatened species heavily hunted for its pelt and as a trophy. Even in the Pantanal, it was poached until recently, when anti-poaching programs and the Convention on International Trade in Endangered Species (CITES) ban on the sale of spotted cats destroyed the market for pelts and trophies. In this wilderness, jaguars prey on capybara, the world's largest rodent, various deer species and occasionally, domestic cattle. Once heavily persecuted by cattle ranchers, a growing number of cattle ranchers have opened their ranches to ecotourists and now protect jaguars as a prime attraction (Schemo 1997). If there were fewer cattle in the Pantanal, marsh deer, South American tapir and other large mammals would increase, creating a more balanced ecosystem with the jaguar as major predator. This may happen in the future, as the cattle industry is no longer as profitable as it once was (Schemo 1997).

The greatest concentration of water birds in Latin America resides in the Pantanal (Dugan 1993). The jabiru (*Jabiru mycteria*), a large and rare stork, is numerous here, building its great stick nests apart from other water birds. A colony of wood storks (*Mycteria americana*), a species that is endangered in Florida, may total 20,000 birds in the Pantanal. Egrets, herons and Roseate Spoonbills are abundant. Migrants on their way from southern South America to North America, such as the Arctic Tern (*Sterna paradisaea*), use the Pantanal as an important stopover place (Simon 1995), and three major flyways pass through it (Eckstrom 1996). Snail kites (*Rostrhamus sociabilis*), on the verge of extinction in the Everglades, are abundant here, feeding on the huge apple snails common in the Pantanal. This wetland's palm groves are an important food source and refuge for the largest parrot in the world, the magnificent and endangered blue-violet hyacinth macaw (*Anodorhynchus hyacinthinus*) (Sick 1993).

A zoologically important fish species that has been on Earth for 300 million years is also resident in the Pantanal. The South American lungfish (*Lepidosiren paradoxa*) is a member of a family with only six species remaining, all on other continents. Lungfish can breathe air with their single lung and are thought to be an evolutionary bridge between fish and land animals. At about 32 inches in length, this scaled, eel-like fish breathes at the surface when waters are high, and during the dry season, buries itself in the mud, breathing through a narrow tunnel leading to the surface, or entering a torpor-like state (Dorst 1967). Although not restricted to the Pantanal, this wetland provides ideal habitat for lungfish, and a large population is found here.

The Pantanal is decreasing in size as a result of drainage for agriculture, which has altered the flooding cycle (Dugan 1993). The major threat to this wetland is a 2,000-mile canal for shipping being dredged and channeled from the Paraguay-Parana Rivers, which link below the Pantanal. Five countries, Brazil, Bolivia, Paraguay, Argentina and

Uruguay, border these rivers and support this massive program, known as the Hidrovia Project (Schemo 1996b). The canal is intended to open up new markets for a growing agricultural trade for soybeans and sugar, as well as mining products from western Brazil (Brooke 1995). It will extend from Caceres, Brazil to Punta del Este, Uruguay, creating an inland seaport in Bolivia; construction involves blasting through rock formations, straightening and dredging rivers and controlling tributaries to allow year-round shipping (Schemo 1996). Although originally estimated to cost $1 billion, by the time the gates of the Porto Primavera Hydro Dam on the Parana River were closed in November 1998, costs had expanded far beyond the original estimate. At least $3 billion will be required for future maintenance (Eckstrom 1996).

A critic of the Hidrovia Project pointed out that an old railway crossing the southern Pantanal already exists, and new railways could be built to Sao Paulo (Eckstrom 1996). Biologists and ecologists are extremely worried that the basic hydrology of the Pantanal is not sufficiently understood to make such major changes, and the long-term effects of Hidrovia may be totally unforeseen, ending in destroying this wilderness (Eckstrom 1996).

Ignoring the delays imposed for completion of the $10.5 million environmental studies, Paraguay began work blasting through rock on the Paraguay River north of Asuncion in June 1996. The Inter-American Development Bank contributed $7.5 million in 1991 for feasibility studies, but the studies were carried out by the same company performing the engineering work, and they did not appraise the work as a whole. The United Nations Development Programme's ecological advisor on the project, Dr. Enrique Bucher, protested this approach: "In order to understand the hydrological response of the system, you have to analyze it in its globality" (Schemo 1996b). The Hidrovia Project, may result in draining the Pantanal, according to a study by Victor Ponce of San Diego State University (Schemo 1996b, 1997). The Pantanal acts like a vast sponge, releasing rainwater gradually and year-round into the Paraguay River; the dams and drainage of wetlands will expose down-river areas to flash flooding and start drying out this vast marshland (Brooke 1995)

Pantanal wildlife has already been impacted by the Porto Primavera Dam, the first of several dams in the Hidrovia Project, which drowned 300,000 acres of floodplain, forest and grasslands. The dam builders financed "rescue" of animals as the area filled with water in late 1998, filmed for the National Geographic Explorer program ("Paradise Lost," April 28, 1999). This "rescue" was marked by extreme mistreatment of animals and a low survival rate. Black howler monkeys were knocked from tree tops by ramming the tree trunks with motorboats, causing babies to fall off their mothers' backs. Many of the monkeys had just given birth and were separated from family members. Injuries such as broken tails occurred. The monkeys were treated so roughly that they panicked and thrashed about. To subdue them, they were put in bags for transport. One monkey in a bag was hung over the side of the boat into the water, where it must have drowned during the trip to a holding area. Surviving animals were unceremoniously dumped in enclosures and cages in the holding area. Many of the monkeys, armadillos, opossums, foxes, snakes and other wildlife were crated and transported out of the area for donation to zoos and research institutes. Caiman were also captured, apparently for their hides, since they were not at risk if left in the water. Marsh deer were caught in nets dropped from helicopters, placed in a net and sent by helicopter to their permanent new home in a concrete enclosure. Many died in the process. Only a few of the animals, including some of the monkeys, were released in woodland nearby. The rescuers admitted only about 5 percent of the wildlife was "saved."

Although gold mining has been banned in the Pantanal, illegal mining is fouling the rivers with mercury and other pollutants (EI 2001). Only two small areas in the Pantanal have received official protection (Dugan 1993). The Pantanal National Park protects less than 1 percent of this wetland, covering only 550 square miles, of which 53 square miles are dry land; most of the park has been underwater for the past 20 years (Eckstrom 1996). The Taiama Ecological Station covers 43 square miles (Emory 1990). Thus, well over 90 percent of the Pantanal is privately owned, mainly by cattle ranchers. Whether it will be possible to preserve large portions of the Pantanal remains to be seen. A budding ecotourism industry has begun, but the damage may already be done. By 2010, the Pantanal may have dried out, or its hydrology been so altered that only remnants of this once vast wetland will remain, as occurred in wetlands of the upper Nile River after the building of the Aswan Dam.

A biological diversity survey of the Pantanal is being carried out under the direction of Conservation International, an organization that specializes in such studies, using Brazilian and American scientists and volunteers from Earthwatch Institute, a group that helps fund scientific studies. Many individual projects will be carried out by various Conservation Research Centers, where scientists, educators and conservationists can cooperate to help preserve the Pantanal (EI 2001). One project on a 7,000-hectare ranch will study ecosystem components and create a series of corridors for the future management of the region (EI 2001). Another will study the avian diversity of the Rio Negro region. The fish of the Pantanal, their diversity, ecology and environmental needs, will be the subject of another study (CI 2001). Should the Pantanal begin to die as an ecosystem, a very real possibility in view of its threats, conservationists can use the data that these scientists are compiling of the great wealth of wildlife and plants and how they are affected by the downstream water projects in order to urge protection through alteration or even cancellation of water projects. As the planet's greatest wetland, interest in its conservation reaches around the world, and the better its functioning is understood, the more coherent will be its defense.

Wetland Drainage: Page 3

Africa's two largest wetlands are Botswana's Okavango Delta and the Sudd marshes of southern Sudan. Both are threatened by massive water projects that may result in draining them for agriculture. Civil war in Sudan has so far prevented the construction of the Jonglei Canal, which would drain large sections of the wetland. The Sudd, covering 6,370 square miles when flooded by the Nile, is a maze of lakes, rivers and papyrus swamps among lush grassland and woodland savannahs (Simon 1995). It has the richest diversity of birds of any African wetland. The extraordinary shoebill, or whale-billed stork (*Balaeniceps rex*), the sole member of its avian family, is resident. This stork-like bird, whose scientific name means "whale-headed king," resembles a creature imagined by Dr. Seuss, with an outsized head and huge primitive beak ending in a long hook. The papyrus swamps that are the bird™s habitat are being drained throughout their range, which extends from Sudan south to Zambia. Fires set in the swamp, civil wars and large numbers of cattle tramping vegetation and destroying nests in the Sudd and elsewhere have disrupted protected areas such as the Akagera National Park in Rwanda (BI 2000). Tanzania's population of 2,000 birds is one of the few stable ones, newly protected as the country's first Ramsar site (BI 2000). Large numbers are captured for zoos, which exhibit this bird as a curiosity (Hoyo *et al*. 1992). The total population of this unique species was estimated at about 11,000 to 15,000 birds and declining in the late 1990s (BI 2000).

In the Sudd's floodplains and grassland are enormous herds of two antelope, the kiang, a subspecies of the topi (*Damaliscus lunatus tiang*) and the white-eared kob (*Kobus kob leucotis*). Almost a million of these antelope migrate to take advantage of grassland, forming the second largest aggregation of large mammals remaining in Africa after the wildebeest (*Connochaetes taurinus*) of East Africa. A film about these spectacular animals, fiMysterious Herds of the Sudan: Migration of the White-eared Kobfl (see Video, Mammals), shows this landscape as well, a little-known corner of the Earth whose abundant wildlife may be decimated if the Jonglei Canal is constructed. Another threatened species that is found only in the Sudd and wetlands of adjacent Ethiopia is the Nile lechwe (*Kobus megaceros*), a wetland antelope with elongated hooves that spread the weight of its body to keep it from sinking and help it leap through shallow water in bounds. This black antelope has ridged horns that arch over its back and a goat-like appearance. The *2000 IUCN Red List* lists it as near-threatened. The Nile lechwe's population totals about 30,000, but its range is restricted, and should its habitat be destroyed by water projects, it will be threatened with extinction (Nowak 1999).

In the middle of the vast Kalahari Desert is a brilliant, blue gem, the 11,000-square-mile Okavango Delta wetlands. This extraordinary wildlife oasis is the world's largest inland delta, a magnificent watery wilderness of shallow lakes, papyrus swamps, meandering rivers, wet grasslands and woodlands. World renowned for its large populations of zebra, antelope, African elephant (*Loxodonta africana*) and Cape buffalo (*Syncerus caffer*), the Okavango attract tourists in large numbers. Waterfowl are abundant, and the African fish eagle (*Haliaeetus vocifer*),

which resembles the American bald eagle, is common. Fifteen species of marsh-dwelling antelope are native, many of which are unique to this region. One of these, the threatened red lechwe (Kobus leche), has a large portion of its population, some 30,000 animals, in the Okavango (Nowak 1999). A race of this antelope in the wetlands of Zambia, the Kafue lechwe (*Kobus leche kafuensis*), lost half its population of 100,000 in 1970 after the construction of two huge dams for hydroelectric power on the Kafue River, which radically altered the natural flooding and dried out much of its floodplain habitat (Nowak 1999). Another race of this species, *Kobus leche smithemani*, native to the Bangweulu Swamps of northern Zambia, fell from about 250,000 in the 1930s to around 30,000 today, as a result of hunting and disruption of water levels by human manipulation (Nowak 1999). Yet another race, *Kobus leche robertsi*, native to the Luongo and Luena River drainages of northwestern Zambia, is now extinct (Nowak 1999).

Cattle ranches have been carved out of portions of the Okavango, but until recently, this immense swamp remained nearly intact. Its precious water supply is now in decline. A major feeder of this swamp, the Kavango River, is now having much of its flow siphoned off by the Namibian government for agriculture and residential use. Botswana has objected strenuously to this project, but Namibia is determined to ease a severe water shortage caused by years of drought. The Boro River, which emerges from the delta, may be dredged and diverted for diamond mines (Postel 1997). These projects may end in draining the Okavango and destroying the enormously profitable tourist industry in Botswana (Hawker 1997). This wetland receives irregular rain which brings flocks of flamingos to nest and renews the water table, but should its feeder river be blocked, many of its unique wetland animals and sizeable herds of endangered African elephant may be lost.

Another threat to the Okavango Delta is the planned spraying of 7,180 square kilometers with the pesticide endosulphan, beginning in the winter of 2001 (Tyler 2001). The purpose is to destroy tsetse fly, the dreaded vector for sleeping sickness or trypanosomiasis (Tyler 2001). This pesticide is toxic to small fish and many other types of insects that are primary sources in the food chain for aquatic birds, such as herons and egrets. These birds breed during the winter months when the spraying is planned, and the threatened Slaty egret (*Egretta vinaceigula*), which breeds in the delta and has a world population of only 5,000 to 10,000 birds, is at serious risk (Tyler 2001). Ironically, the tsetse flies were being effectively controlled by the use of cloth baits soaked in insecticide and hung on poles, but they were not properly maintained by personnel, and stocks ran out (Tyler 2001). Conservation organizations are protesting to the Botswana government to stop the spraying and consider the environmental effects. Until recently, sleeping sickness was not an easily controlled disease, killing thousands of Africans. Native hoofed animals are immune to the disease. Recently, however, a new drug, DSMO, used in the United States to remove facial hair, has been found to be almost a miracle drug in awakening victims of this disease from their comatose states, without the side effects of available medications. One pharmaceutical company agreed in early 2001 to donate 3 years™ supply after pressure from various health organizations. This makes spraying toxic pesticides even more unnecessary.*

---

*fiOkavango. Jewel of the Kalahari,fl a series of three one-hour films by Partridge Films and the BBC, shows the great beauty and wealth of wildlife in this wetland. (See Video, Regional, Africa; see also the Book Section for several books about this swamp.)

Wetland Drainage: Page 4

Until the 20th century, wetlands covered large areas in Asia, from the swampy grasslands at the base of the Himalayas to the marshes and deltas of Thailand, Cambodia and Vietnam. With the growth in human populations and pressure to raise more crops, millions of acres were filled or converted to rice paddies. Thailand has lost virtually all

of its freshwater wetlands, and China, Laos and Vietnam have also incurred great losses. The majestic Sarus crane (*Grus antigone*) no longer nests in Thailand, and throughout Asia, cranes are threatened by loss of wetland habitat. Eight of the world's 15 crane species are found in Asia, and nearly all are considered endangered. They breed from high Tibetan reed lakes to coastal marshes, and all these habitats are being lost. The endangered black-necked crane (*Grus nigricollis*) breeds in high altitude sedge marshes and grasslands of the Tibetan plateau. Several of its important breeding marshes in western China have dried up as a result of intensive grazing and plowing of the steppe grasslands, and portions of its wintering wetlands in Bhutan are being drained (BI 2000). A dam planned on the Lhasa river also threatens wintering cranes. These beautiful cranes now number only 5,000 to 6,000 birds, and they are in decline (BI 2000).

Colorful Asian storks, once widespread, are now threatened with extinction as their habitat declines yearly. Seven species are now listed by BirdLife International in *Threatened Birds of the World* (BI 2000). They include the vulnerable milky stork (*Mycteria cinerea*), the endangered Storm's stork (Ciconia stormi), the vulnerable lesser adjutant (*Leptoptilos javanicus*), the endangered greater adjutant (Leptoptilos dubius), the endangered Oriental stork (*Ciconia boyciana*), the near-threatened painted stork (*Mycteria leucocephala*) and the near-threatened black-necked stork (*Ephippiorhynchus asiaticus*). Such a diversity of storks is found nowhere else on the planet. North America has only one species, the wood stork, and only the white stork is native to Europe. Some breed in the mangroves of Indonesia, and others, like the Oriental stork, which greatly resembles the white stork, winter in marshes in Japan, North Korea and Taiwan, where they face hunting, draining of wetlands, pesticides and pollution. The total world population of this bird is estimated at only 2,500 and declining (BI 2000).

Wetland Drainage: Page 5

In the United States, early American colonists began draining wetlands in the 17th century, and various laws encouraging this activity were enacted through the years. Over half of wetlands of all types, and some 70 percent of riparian, or riverside, wetlands in this country, have been destroyed (Rezendes 1996). Losses continue under the Clean Water Act's weak regulations that place the US Army Corps of Engineers in charge of issuing permits to developers who apply for permission to fill in wetlands. The Corps' major role has been the construction of dams and levees, dredging of ports, and other water projects responsible for causing numerous extinctions among the nation's wildlife. These regulations exempt small and temporary wetlands, such as vernal pools and prairie potholes, and the Corps has been less than vigilant in enforcing wetland protection (Williams 1996). Federal legislation should change the authority designated to oversee wetlands conservation from the US Army Corps of Engineers to the Department of the Interior. The United States may be the only country in the world to allow its dike and canal makers to oversee conservation of these ecosystems. Wetlands protection should be far stricter in both federal and state legislation to prevent further losses.

Unfortunately, these important wetlands are often not protected by law in the United States, or, in the case of states such as Massachusetts, are protected only by some towns and only if officially registered as vernal pools (Appel 1999). These pools are being destroyed, often intentionally, by developers and homeowners who fear that building on or near the pool would be restricted (Appel 1999). Even when the pool itself is not destroyed, its water supply can be cut off by building nearby. A prime area for wood frogs in Framingham, Mass., disappeared, even though registered as a vernal pool, because the surrounding 25 acres of woodland were cut to construct a cinema complex (Ridout 2000). The required 125-foot buffer area of woods that was left surrounding the pool did not supply enough runoff water; the vernal pool dried out and the frogs disappeared (Ridout 2000). The disappearance of turtles from many areas in the East has been blamed on the filling of these important habitats where they migrate to lay their eggs.

Many swamp forests in the East and in the Midwest, as well as potholes essential as breeding habitat for waterfowl and stopovers for the continent's shore birds, were drained with government subsidies. Iowa lost 98 percent of its

potholes; Minnesota, 75 percent; South Dakota, 35 percent; Montana, 27 percent and North Dakota, which had one-third of all these ecosystems, 49 percent (Williams 1996). The latter state's legislature discourages protection of the remaining potholes by requiring approval of conservation easements or purchase for conservation by an agricultural council (Williams 1996). This reflects the failure of federal and state governments to value wetlands for their ecological importance rather than for commercial purposes such as agriculture, construction or mining. In other parts of the world, similar attitudes prevail. The black-faced spoonbill (*Platalea minor*), a large white wading bird of Asia has been reduced to only about 700 birds (BI 2000). More than 200 of these birds winter in Taiwan's Chiku marsh, near the capital city, Tainan, now under great threat from development (WESPA 1994). A Taiwanese government official, when questioned about proposed drainage of the marsh, stated to CNN on January 6, 1994, "We can't stop our industrial progress for a few birds." Throughout the range of these endangered birds in east Asia's coastal wetlands, development has drained their habitats or converted them into aquaculture ponds (BI 2000).

Coral Reefs

The beautiful and diverse coral reefs of the world are today more threatened than they have been for many millions of years. A survey in the 1980s found that damage had occurred in coral reefs in 93 of the 109 countries where these rich ecosystems are found (Wells and Hanna 1992). At least 10 percent of coral reefs around the world had been damaged beyond repair, while 30 percent were in critical condition and expected to disappear within 10 to 20 years; another 30 percent were expected to die by 2050 (Carter 1997). Research in 1999 found further damage: one-third of all coral reefs were dead and 90 percent degraded to some extent.

In the Maldive Islands in the Indian Ocean, all the coral around inhabited islands has been excavated. This limestone material has been fashioned into houses. An estimated 95 percent of these reefs are dead or dying (Zuckoff 2000b). The result has been lowland flooding by the sea because these protective barriers were destroyed. Because of the growing numbers of tourists, tour boats, scuba divers and spear fishers, many ancient reefs are declining in species diversity or dying out altogether. In some areas, hotels are often built with inadequate pollution and erosion controls near coral reefs. Even touching a coral can harm the delicate outer layer, which can take 100 years to recover.

Dynamiting and poisoning reefs to obtain fish are methods banned throughout Asia, yet they regularly occur. David Doubilet (1999) has spent much of his life photographing coral reefs and has witnessed such activities. On one occasion while diving in the Philippines, he saw large areas of coral reefs reduced to white rubble. The cause was nearby boatmen who lobbed bottles of homemade explosives into the sea (Doubilet 1999). They were chased off by a marine official who fired a pistol round over the poachers' heads, but on inspecting the results in the coral reef, Doubilet saw fish spinning aimlessly in convulsions or belly-up amidst the craters of blast sites (Doubilet 1999). Beginning in the 1960s, Philippine fishermen pumped cyanide poison into 33 million coral heads at a rate of 330,000 pounds yearly (Chadwick 1999). Approximately 95 percent of the reefs of the Philippines have been destroyed from the combined effects of sewage pollution, dynamiting and the use of cyanide to obtain tropical fish for the pet trade (Chadwick 1999). These fish usually die within weeks from the cyanide (Wells and Hanna 1992). In the rich reefs surrounding Indonesia, a recent trade has begun for live fish which are kept in aquariums to be consumed in restaurants in Hong Kong and other major cities; the fish are stunned by small amounts of poison and the coral often dies after being sprayed (see Trade, Fisheries).

Seashell and pearl harvests have depleted many reefs of species important in controlling reef predators. The Crown-of-Thorns starfish of the western Pacific was once preyed on and kept in check by 12-inch giant triton mollusks, a species collected heavily for the shell trade. The fish that controlled populations of Crown-of-Thorns starfish have been killed off by fishing, further causing imbalance to reefs. Sewage or agricultural runoff promotes the growth of plankton that also encourages these starfish to multiply to pestilential levels, killing off large portions of coral (Chadwick 1999).

Siltation runoff from clear-cutting forests near shore and agricultural plowing has become major factors in the death of 95 percent of Philippine reefs and the dying of reefs in the Florida Keys and elsewhere. When silt comes to rest on live coral, the coral is smothered. Fertilizers and sewage encourage the growth of bacteria, viruses and diseases, such as aspergillosis, that have devastated hundreds of coral reefs in the Caribbean (Chadwick 1999).

Coral bleaching, in which colorful corals turn white and die, is affecting a growing number of reefs. Even a slight rise in ocean temperature can kill off the symbiotic algae living in the coral. The algae gives coral color and without it, the coral animals die. Global warming has been mainly responsible for gradually raising ocean temperatures, and should it continue, the majority of the world's reefs will die out. Household bleach, used by fishermen to stun fish, can also cause bleaching. UV radiation from ozone depletion may play a major role, as well by killing off the symbiotic algae (Chadwick 1999). In some cases, coral bleaching can be temporary, and corals can recover if water temperatures cool before too much time has passed or if the corals are not also being attacked by pollutants, pesticides or a different type of algae produced from fertilizer nutrients in the water.

The Great Barrier Reef has incurred die-offs of coral in many areas. This massive reef is considered one of the great natural wonders of the world, with a great diversity of fish and corals. Coral bleaching has killed various parts of the reef in recent years, and in 1998, the warmest year ever recorded, large sections of the reef died, leaving white skeletons in place of dazzling fish and colorful corals (Zuckoff 2000b). Some reefs recovered when temperatures cooled, but most did not. Scientists meeting at the fourth meeting of the International Coral Reef Symposium in 2000 warned that global warming and other threats must be stopped if the world's coral reefs are to be saved (Zuckoff 2000b). At the present rate of destruction, one scientist estimated that coral reefs will be gone in 30 to 50 years (Zuckoff 2000b). Global warming is not being arrested, however, as countries, led by the United States, the largest producer of greenhouse gases, continue to pollute the atmosphere.

Mangrove Destruction

In the Americas, mangroves grow as far north as southern Florida and the Florida Keys, throughout the Caribbean region; and in South America, they occur in a narrow band lining the Amazon River and on the coasts of French Guiana and northern Brazil. Mangroves are also abundant in river deltas of West Africa, portions of the Middle East, east to Malaysia, Papua New Guinea, northern Australia and on many western Pacific islands.

The Sundarban mangroves surround the Ganges Delta, extending along the coasts of eastern India and Bangladesh. They cover 2,300 square miles and penetrate far inland along the Ganges River, forming an intricate maze of rivers, creeks and canals that are flooded daily by ocean tides (Dugan 1993). Wildlife is abundant in these mangroves. At least 35 species of reptiles, 270 bird species and 42 mammal species are native (Dugan 1993). The most famous of these is the magnificent Bengal tiger (*Panthera tigris bengalus*), whose largest population may be found here. India has set aside a large reserve for tigers and other wildlife in its portion of the Sundarbans; as many as 350 to 400 tigers are present in Bangladesh's portion, with 250 to 300 in India's (Dugan 1993). Even in this maze of mangroves, however, tigers are under siege from poachers, and since the early 1990s, their numbers have declined even here from habitat loss, poaching and loss of prey animals to hunters.

The Sundarban mangroves are heavily exploited by the over 300,000 people who live here. Each year 9 million cubic metres of timber and pulpwood and 106,400 tons of fuel wood are cut by Bangladeshi and Indian natives (Dugan 1993). Overcutting has affected the fisheries habitat that provides about 150,000 tons of fish per year for the 10,000 fishermen in these mangroves (Dugan 1993). So many of the outer island mangroves have been destroyed that storm surges caused by cyclones now move much further inland, leaving destruction and loss of life in their wake (Hauser 1992). Fragile mangroves have been destroyed for a fishing jetty and prawn culture area inside the Indian

Bhitarkanika Sanctuary for endangered Olive Ridley Sea Turtles (*Lepidochelys olivacea*). These projects were funded by the World Bank. This prime wildlife area is vital to white-bellied sea eagles and threatened Indian smooth-coated otters of the same species as Maxwell's otter (see above). The Olive Ridley sea turtles experienced a major die-off in February 2000.

The cutting of mangroves in southeast Asia has destroyed thousands of acres to supply paper mills in Japan (Collins 1990). Prior to the Vietnam War, scientists estimate that at least 1,000 square miles of the Mekong Delta were mangrove and paperbark forest. Eleven million gallons of herbicide defoliants (known as Agent Orange) were sprayed during the war, destroying half the delta wetlands, or 480 square miles of mangrove and 100 square miles of paperbark (Dugan 1993). To compound the damage, the forests beyond the mangroves were burned and sprayed with herbicides, and canals were dug by the U.S. armed forces to drain the flooded areas (Dugan 1993). Much of this land remains poisoned and infertile 35 years after the end of the war; replanting is taking place on non-poisoned acreage. The human toll has been significant: thousands of Vietnamese died from the effects, and many children born since the war have had a high incidence of birth defects, serious skin disease and tumors; American soldiers exposed to these chemicals suffered a wide range of cancers and other major health problems. Only recently has the US government acknowledged the full range of the effects of these herbicides and paid compensation to ailing servicemen.

The Mekong River delta is native to 260 species of fish, 35 reptile species, 6 amphibian species, 386 bird species and 23 mammal species (Simon 1995). Among these are the endangered Estuarine crocodile (*Crocodylus porosus*), a species in decline throughout its southeast Asian range, and the threatened eastern Sarus crane (*Grus antigone*), which disappeared from Vietnam during the war but later returned (Simon 1995). One of the rarest birds in the world, the giant ibis (*Pseudibis gigantea*), is the largest of all ibises, a silvery-gray bird with pink legs. The Mekong Delta system in Cambodia was its stronghold in the 1920s, where it was commonly seen, but a 1994 survey found no giant ibis. Wetland drainage for agriculture, hunting and deforestation have pushed it to the edge of extinction. Extinct in Thailand, only two birds have been seen in southern Laos in recent years Œ in 1993 near a proposed protected area (Collar *et al*. 1994). Once native to the Mekong Delta in Vietnam, it was probably extinguished during the war. Cambodia has some lowland wetlands and may have undiscovered populations of giant ibis, but at present the estimated total world population is 50 birds and declining (BI 2000).

At present, the greatest threat to mangroves worldwide is the farmed shrimp industry. Mangroves are natural nurseries for shrimp, and this industry destroys the mangroves by cutting them in wide swaths to make room for artificial ponds. These ponds are closed off to prevent the shrimp from swimming back to the sea. Without the natural cleansing of the tides, the ponds soon become polluted and laden with chemicals added by the farmers. Although not all farmed shrimp are raised in this environmentally destructive manner, in some countries this type of farming predominates. The worldwide shrimp farm industry is worth at least $8 billion (Mydans 1996) and produces 783,200 tons of shrimp per year, about 30 percent of the world's shrimp production (Nixon 1996). Fifty countries now farm shrimp, many with aid from the World Bank. The governments of India and Ecuador have banned the further cutting of mangroves for shrimp farms, but in Ecuador, 85 square miles of mangroves were illegally cut after the ban. In the Philippines, 1,000 square miles of mangroves, 67 percent of the country's total, were destroyed between 1920 and 1980, most being converted to ponds for farming shrimp and milkfish (Dugan 1993).

Grassroots environmental organizations have recently appealed to international conservation groups and lending banks to stop funding the farmed shrimp industry and to the public to boycott all farmed shrimp. One such group, the Seattle-based Mangrove Action Project, has united with The Sierra Club of Canada and other organizations to lobby against tropical shrimp farms. The shrimp pond industry may die out on its own, however, because of disease outbreaks in the ponds. Various types of virus and bacterial infections have spread through shrimp ponds because of their stagnancy and the crowding of shrimp. More than 42,000 acres of ponds in Ecuador now lie fallow, having been swept by disease, and many fishermen and shrimp farmers now see the wisdom in protecting the mangroves because these trees are able to filter water and maintain a clean environment for shrimp far more efficiently than human-made holding ponds along the coasts (Nixon 1996). High-technology aquaculture buildings have been constructed that use aerated and filtered water and operate independently of natural ecosystems. Some of these facilities have been

constructed in Thailand and elsewhere. They are a far more environmentally friendly method of producing shrimp. A key element is the captive-breeding of shrimp in such a facility, rather than removal of wild larvae from the ocean.

Noise, Boat Collisions and Debris

The once quiet oceans now rumble with huge cargo, cruise and naval ships whose noisy engines drown out the delicate rumblings, and songs whales make to establish territory and communicate, as well as the myriad sounds other creatures emit in the ocean depths vital to their survival. The North Atlantic, Mediterranean and Baltic are especially busy shipping lanes. Wildlife now has new and lethal noises to cope with. The Navy has been testing anti-submarine sonar called Low Frequency Active. Powerful sonar waves are broadcast underwater to test a means of detecting quiet enemy submarines (White 2000a). These sonar waves can travel hundreds of miles and be extremely loud. Humpback whale (*Megaptera novaeangliae*) males emitting their complex, haunting songs to establish territory have become silent or moved away when these waves were broadcast. More ominously, testing in 1995 off the coast of Greece coincided with an unusual stranding of Cuvier's beaked whales (*Ziphius cavirostris*) resulting in the deaths of these seldom-seen whales. In March 2000, Ken Balcomb, a biologist from the Center for Whale Research who is familiar with sonar, was present when a stranding occurred while Navy tests were taking place nearby. Fifteen animals stranded, including dense beaked whales (*Mesoplodon densirostris*) and other species of beaked whales, a Minke whale (*Balaenoptera acutorostrata*) and a spotted dolphin (*Stenella frontalis*). All washed up on the shores of a Bahamian island; when pushed back into deep water, they were unable to remain upright, clearly unbalanced and disoriented, and nine died (White 2000a). Along with Harvard biologist Darlene Ketton, Ken Balcomb performed necropsies on several whales, finding their ears full of blood and, in one case, hemorrhages striped the lungs; further testing discovered that a whale had suffered a concussion, apparently the result of acute trauma from pressure (White 2000a). A press conference organized by the Animal Welfare Institute following these findings featured Ken Balcomb and other whale experts, who attested to the fact that the sonar is reckless, unnecessary and lethal to whales. Soon after, the Navy canceled testing of active sonar off New Jersey, as well as its scheduled tests on sperm whales in the Azores (White 2000). This technology fills the ocean with penetrating sound waves that greatly disturb or kill marine mammals, interfering with their own sonar and natural behavior.

A major cause of mortality for Florida manatees is collisions with boats. Manatees struck by motorboats or their propellers can be killed instantly, or may suffer slow, painful deaths from deep slashes and internal injuries. In some cases, these strikes have been intentional. CNN recently reported a case of a woman who witnessed a young man in a motorboat repeatedly driving over a mother manatee and her calf until both were dead. She called the state law enforcement division, but by the time officers arrived, the perpetrator was gone. Many calves are orphaned when their mothers are killed, and only if they are found within hours can they be rescued and cared for by Sea World or other aquariums in Florida. In the first half of 2000, the state determined that 61 deaths were caused by watercraft, just short of the all-time high of 67 for the entire year of 1999. These figures may be lower than the actual mortality, since some manatees may be struck and sink, while others, whose bodies are found, may show no outward sign of injury, having been struck by the bow or side of a boat. These collisions occur with such frequency that virtually all adult Florida manatees have propeller scars on their backs.

The present system of posting speed limits has not been effective in reducing collisions, since so many boaters refuse to obey them and enforcement is inadequate. Manatees swim long distances to find warm water during the winter, passing through shipping lanes and most of southern Florida's navigable waters. This creates a problem that the State of Florida and the Fish and Wildlife Service have not properly addressed, yet one that must be solved to preserve this species. Apparently, manatees do not hear motorboats coming. Research is taking place on the placement of some type of noisemaker attached to the underside of boats to warn them. Even this would not result in a halt to all manatee-boat collisions, however, because these animals are too slow-moving to avoid high-speed boats.

Boat propeller guards would also reduce manatee deaths and injuries, as well as human injuries caused by accidents with these sharp blades, but they have not been required by law. The number of pleasure craft in Florida has risen exponentially in recent years, with few laws and regulations governing those who propel them, such as strict regulations on sobriety and competence to handle the boats. Heavy boat traffic has also resulted in human fatalities and injuries from collisions.

Two lawsuits were filed in January 2000 on behalf of the Florida manatee. A coalition of 18 environmental and animal welfare groups, led by the Save the Manatee Club, sued the State of Florida, the US Army Corps of Engineers and the US Fish and Wildlife Service. The Animal Welfare Institute's companion organization, the Society for Animal Protective Legislation, has worked with the coalition's legislative team to obtain $500,000 from the Congress for manatee protection. The corps was sued for its repeated issuance of permits for development in manatee habitat without analyzing the cumulative effects of the permits on the species or its habitat. The suit charges the Fish and Wildlife Service with failure to properly enforce the Marine Mammal Protection Act of 1972 and the Endangered Species Act to prevent mortality and to conserve the species. The US Fish and Wildlife Service failed to designate adequate sanctuaries for manatees where boat traffic would be restricted, reducing its proposed list of sites from 150 in Florida to 10 to 15 (Daley 2001).

The second suit was filed against the Florida Fish and Wildlife Conservation Commission, which has not complied with the Florida Manatee Sanctuary Act of 1978, enforced speed limits, or taken other measures designed to protect these vulnerable animals. The mortality rate from all causes is far greater than the number born, pushing manatees toward extinction. Florida Governor Jeb Bush angered conservationists in late 2000 by allowing the licensing of more boat slips in Sarasota, although the county had not completed a required plan to protect manatees (Daley 2001).

The future is bleak for the approximately 3,000 surviving Florida manatees unless dramatic action is taken (Daley 2001). Their survival has become critical. Other causes of mortality, such as death from red tide, pollution or cold weather, add to the toll. In 2000, for example, 273 manatees died from all causes, close to 10 percent of the entire population (Daley 2001). Since manatees have a single young only every 5 to 7 years, they cannot sustain such losses. These gentle and affectionate animals have been on Earth for 45 million years, yet a lack of concern and willingness to alter our recreational boating habits may eliminate them in Florida. Elsewhere in the range of these manatees, far stricter regulations have been imposed on boat traffic. In Belize, for example, very few manatees have boat propeller scars because many areas are off-limits to all motorized boats, and tours are conducted in boats propelled by poles.

There are two major threats to whales and marine mammals causing their elimination in many areas. Fishing vessels throw out ropes, nets and other debris that entangle marine mammals, often lethally, and vessels of all types present the danger of mortality through collisions. One or more highly endangered North Atlantic right whales (*Eubalaena glacialis* die each year from rope and net entanglements or collisions with ships; their population is only at about 300. In 1995, a whale of this endangered species became wrapped in lobster line and died off the Rhode Island coast. In September 1997, another whale became hamstrung with nylon netting around his head, towing a 9-foot sea anchor near Nova Scotia; it took 8 1/2 hours to free him, after a 25-kilometer chase by a rescue team. A young blue whale (*Balaenoptera musculus*) was killed when a ship collided with it; the ship entered a Massachusetts port with the whale impaled on its bow. In early 2001, three dead fin whales (*Balaenoptera physalus*) washed ashore along the Atlantic coasts of the United States, killed by ship collisions. For North Atlantic right whales, such collisions may end in their extinction, unless means are found to prevent them. These whales have a single calf only once every five years and are dying at such a rate that scientists expect their extinction within less than a century.

Plastic bags and fishing gear have been found to strangle and suffocate endangered sea turtles, marine mammals and sea birds. Endangered albatross on Laysan Island are among the many species to have died after ingesting plastic materials. They also feed their chicks plastic items they mistake for food, unintentionally killing them. Sea turtles, dolphins, whales and sea lions around the world are drowning and strangling in fishing lines and nets. One endangered fin whale that washed ashore dead in Biscayne Bay, northern Spain, in 1997 was found to have ingested huge amounts of plastic sheeting and bags that clogged its digestive system. Each year millions of balloons are

released to the winds, and untold numbers end up floating in the oceans, a peril to wildlife. One young sperm whale (*Physeter catodon*) starved to death after swallowing a single balloon that blocked its intestine. Endangered sea turtles die after consuming plastic bags and balloons, mistaking them for jellyfish. Non-biodegradable plastics and nylon nets and ropes in the ocean will present lethal threats to wildlife for the indefinite future. Although international treaties have been signed that regulate such dumping, to date no national or international program has attempted to remove debris, such as plastic items, nets and fishing lines, from the oceans.

Toxic Chemicals

Some chemicals, such as Polychlorinated Biphenyls (PCBs) and pesticides, have entered aquatic systems, causing birth defects in water birds and other wildlife. PCBs, manufactured by General Electric, were used for decades in refrigerators and other industrial uses until it was discovered that when released to the environment, they had serious effects on wildlife. American bald eagles have been among the species affected by PCBs, producing chicks with crossed bills and other defects.

Toxic Chemicals: Page 1

Beluga whales (*Delphinapterus leucas*) in the St. Lawrence River have also been affected. Isolated from members of their species living further north for thousands of years, they have declined dramatically in recent years. Many of these beautiful whales, known for the lyrical songs they sing to one another, have been found dead with tumors, malformations and impairment of female reproductive organs. This river, which links Lake Erie to the Atlantic Ocean, has become severely polluted with chemical contaminants, resulting in declines in wildlife. American eels (*Anguilla rostrata*) accumulate high levels of toxins on their spring migration from the Great Lakes down the St. Lawrence River to the sea and contaminate the Belugas when they feed on them. A major source of PCBs in the river is a sunken barge in the Gulf of St. Lawrence, which has been oozing these toxins for more than 25 years; its cleanup is difficult because there is fear it will break apart either on its own or if moved (Nickerson 1996).

The St. Lawrence belugas numbered about 5,000 in the 1600s, but whaling, which went on until the 1940s, reduced their population to about 2,500 (Katona *et al*. 1993). Before they could fully recover, contaminants from industries surrounding the Great Lakes and St. Lawrence seaway took a tragic toll on them. Today, only 400 to 500 belugas remain in this river. A study by Dr. Pierre Beland of the St. Lawrence National Institute of Toxicology in Quebec found that 40 percent of all belugas necropsied had malignant tumors in their digestive systems, mouths, esophagi, intestines and respiratory systems. Two percent of the belugas found at the mouth of the Saguanay River were visibly deformed. PCBs, which cause malformations in mammals and birds, were found at levels up to 3,400

parts per million (ppm) in the milk of a lactating female beluga and up to 576 ppm in blubber (Katona *et al*. 1993). Fish is unfit for human consumption if it contains 2 ppm of PCBs.

In 1976, the United States banned the manufacture of PCBs, and other industrialized countries followed. But in the nearly 50 years that they were manufactured, an estimated 3.4 billion pounds had been produced, and they have become pervasive in the environment, spreading on air currents and through aquatic food chains. PCBs are now found in animals thousands of miles away from locations where these chemicals were used, in the blubber of whales and the milk of nursing polar bears (Colborn *et al*. 1996). Once PCBs are deposited in the fat of animals and humans, they remain indefinitely and do not biodegrade. These and related chemicals continue to cause birth defects and reproductive failure in wildlife (Colborn *et al*. 1996). Virtually all humans carry PCBs and other persistent chemicals in their body fat, and a nursing mother passes these chemicals on to her baby (Colborn *et al*. 1996). The higher the animal on the food chain, such as birds of prey, whales, seals and land predators, the higher the concentrations of PCBs and chlorinated hydrocarbons like DDT, multiplying up to 3 billion times as they move up the food chain from microorganisms to polar bears (Colborn *et al*. 1996).

PCBs have also contaminated killer whales (*Orcinus orca*) in the Pacific Northwest. The Institute of Ocean Sciences tested 47 of these giant dolphins living off the British Columbia coast, finding levels two to five times as high as belugas in the St. Lawrence River (NG 2000). Just to the south, the killer whales off the San Juan Islands of Washington State are in decline, with the highest PCB levels ever found in wildlife (White 2000b). Deformed polar bear cubs have been found in Norway's Svalbard Islands. Researchers in 1996 found seven cubs with both male and female sex organs (NG 1999). These islands receive three times the PCB exposure of northern Canada, where only one such case has been seen (NG 1999). Pesticides and PCBs are carried here by air and water from Europe, North America and Asia.

During the 1990s, bald eagles (*Haliaeetus leucocephalus*) feeding on seagulls near Lake Superior accumulated contaminants 20 times higher than fish-eating birds of the same area (Colborn *et al*. 1996). Bald eagle chicks hatched in the Great Lakes were found with severe birth defects, from crossed bills to missing eyes, clubbed feet and a wasting disease that causes chicks to weaken and die (Colborn *et al*. 1996). Scientists have detected high residues of contaminants such as dioxin, PCBs and furans in the eagles. PCBs are the most likely cause of these abnormalities, but several chemicals might interact with toxic effects (Colborn *et al*. 1996).

Almost the entire length of the Hudson River has been contaminated by PCB dumping and outflow from a General Electric plant. Seepage of PCBs continues from the plant foundations, even though the chemical is no longer produced here, rendering fish from the river commercially unmarketable. After decades of conservation, striped bass recovered from heavy fishing in the Hudson River, but they contain such high amounts of PCBs that if caught by sport fishermen, they cannot be sold, and pregnant women are warned not to eat them. The removal of these residues from the Hudson and other river bottoms has not been carried out because of the difficulty of containing them in such a way as to prevent their dispersal into the atmosphere. General Electric was ordered to dredge the PCB residues in 2000, but local communities along the Hudson River have expressed opposition, fearing that they would disperse throughout the river. These chemicals may be impossible to eliminate from the Earth.

Like PCBs, persistent types of pesticides and herbicides, even in minute quantities, can be stored in the tissues of aquatic organisms and accumulate in greater and greater amounts in the ascending food chain. These chemicals can accumulate to toxic levels, killing the animals or interfering with their production of eggs, a known effect of chlorinated hydrocarbon pesticides, primarily DDT, that nearly caused the extinction of the Peregrine falcon (*Falco peregrinus*) in North America and great declines in bald eagles and other birds. The most injurious of these, DDT, dieldrin and chlordane, have been banned in the United States for most uses, but are used in foreign countries and remain in many areas where they were manufactured.

Toxic Chemicals: Page 2

Although persistent pesticides of the DDT family have been banned in the United States, they are still manufactured here and exported for control of malaria to many tropical countries. DDT is still present in a 17 square mile dumping area in the coastal waters off California. Montrose Chemical Corporation and two other companies dumped some 100 tons of DDT between 1947 and 1971, when it was banned. These ocean residues continue to enter the food chain through fish and other organisms. This has affected birds who feed on these fish, including brown pelicans and bald eagles on the California coast, who still laid thin-shelled eggs as a result of DDT contamination of their food supply 30 years after the ban. Highly toxic pesticides banned in the United States are still being used around the world, killing large numbers of birds and other wildlife. Diazinon, a pesticide commonly used on golf courses in the United States, and highly toxic to geese and other birds, was recently banned in the United States, along with Dursban, a commonly used lawn chemical. Pesticides and related chemicals that kill and cause mutations in wildlife are indeed still being broadcast in the United States as well as in other parts of the world. Only with more oversight and strong legislation to limit use and export of these chemicals can wildlife and aquatic ecosystems be protected.

DDT and other pesticides contaminate entire ecosystems in tropical countries, and some North American birds winter in areas where these chemicals are still used. Between 1992 and 1994 alone, the United States exported at least 247 million pounds of banned or restricted pesticides to the rest of the world. DDT, for example, is widely used for malaria control in Africa and Asia. Virtually no laws restrict this trade, which has the potential of causing major wildlife declines and extinctions.

In agricultural areas in northern Florida, American alligators (*Alligator mississipiensis*) have been found with abnormalities and poor reproductive success thought to have been caused by pesticides in their food supply (Colborn *et al*. 1996). Many synthetic chemicals react on animals in a manner similar to hormones. Dicofol, a pesticide related to DDT, was widely used in the vicinity of Lake Apopka, finding its way into the waters and causing abnormalities in alligators. Males developed unusually small penises and defective testicles, and females had abnormal eggs and sex organs (Colborn *et al*. 1996). The male alligators in this lake had elevated levels of female hormones, equal to those in normal female alligators, and one-fourth the normal level of testosterone; females had estrogen levels double the norm (Colburn *et al*. 1996). The reproduction of alligators in the area has nearly ceased altogether, with almost no eggs hatching (Colburn *et al*. 1996). Red-eared turtles of Lake Apopka, considered unlikely to be affected by this pesticide since they are plant-eaters, surprised researchers by exhibiting reproductive difficulties as well. Many turtles discovered had not developed normally as either male or female (Colborn *et al*. 1996).

Toxic Chemicals: Page 3

Within the past few decades, an increasing toll of wildlife has been taken by toxic chemicals in aquatic environments. Massive seal kills have occurred in the North Sea, and in January 1996, the body of an endangered sperm whale (*Physeter catodon*) washed up on a Danish beach. Analyses of its tissues revealed dangerous levels of heavy metals Œ so much mercury and cadmium that the intestine had to be buried at a special dangerous waste site. The amount of toxic cadmium was 20 times higher and the quantity of mercury double that normally found in fish. The North Sea has become extremely polluted, laden with toxic chemicals from industry and untreated sewage.

Off the west coast of Mexico, a large number of dead dolphins and Gray Whales have washed ashore since 1997. Some were the apparent victims of cyanide poisoning. Drug traffickers use a cyanide-based chemical to mark ocean

drop-off sites, and this chemical is thought to be responsible for poisoning these and hundreds of other marine mammals and fish. Some Gray Whales that wash ashore may be suffering other maladies related to toxic chemicals or contamination, combined with a lack of food. Numbers have risen off U.S. coasts: 278 in 1999, more than 300 in the first half of 2000 (White 2000b). The number of Gray Whale calves also declined from 1,520 in 1997 to 282 in 1999 (White 2000b). Many of the dead whales were emaciated.

Very high levels of methyl mercury have been detected in the Everglades. A study by Greenpeace found that this highly toxic metal was emanating from trash incinerators operating on the East Coast. Endangered Florida Panthers (*Felis concolor coryi*) have been found dead with toxic levels of mercury in their bodies. These endangered cats, an unusual subspecies of the Cougar, are close to extinction, with a population of fewer than 30 animals. Mercury is also present in sewage sludge, much of which is spread on land as fertilizer. In one year alone, 1996, the state of New Hampshire spread 1.6 tons of mercury on land (Giordano 1998). Their dairy farms are among the users of sludge obtained from chemical treatment plants in Massachusetts and other states (Giordano 1998). Common Loons, known for their haunting cries once heard in virtually every one of New Hampshire's thousands of lakes, have declined precipitously in recent years, their bodies laden with very high levels of methyl mercury (Giordano 1998).

In spite of the clear danger presented by mercury, little has been done to limit its use and disposal. Only Vermont has passed legislation that bans disposal in landfills and requires labeling of products such as fluorescent light bulbs, light switches, batteries for hearing aids and watches and thermometers. Mercury is also used in dental fillings. Boston banned the sale of household mercury thermometers in 2000, and the ban is expected to be extended statewide in 2001 (Daley and Kremmer 2001). Several other states are considering legislation to require labeling of mercury-containing products and banning their disposal by flushing or placing in the trash. New York State proposed legislation in 2001 that would eliminate the use of mercury in such products beginning in 2004 (McKinley 2001). The Environmental Protection Agency and the New York Department of Environmental Conservation began to cooperate in regulating mercury sent into the air by incinerators five years ago, but coal-burning power plants, which emit about 30 percent of all mercury emissions, are not subject to any federal or state restrictions (McKinley 2001).

Toxic mercury residues from metals companies is often shipped out of the country to nations that accept them. Now, however, some countries are unwilling to allow such shipments. One cargo ship headed for Bombay, India, in January 2001, carrying 20 tons of mercury reclaimed from a Maine factory, set off a tempest of protests by environmentalists in that country who denounced the "toxic trade" (Daley and Kremmer 2001). At least 12 factories in the United States have stocks of tons of mercury, some of which is used in a chemical process to produce chlorine (Daley and Kremmer 2001). India is a major user of industrial mercury as well, but resents becoming a dumping ground for other countries (Daley and Kremmer 2001).

Toxic Chemicals: Page 4

Within the past decade, sea turtles in Florida Bay and the surrounding waters have shown signs of disease caused by toxic chemicals. Hundreds of turtles have been found dead or dying, some with massive tumor growths on their skin, covering their heads, necks and legs. It is thought that these growths are caused by a virus that attacked the turtles because of their lowered immunity system, which was in turn caused by pollution such as runoff from farmland or inadequate food when sea grasses died off. Some of these turtles have been saved by placing them in aquariums for months to build up their immune systems. Because of the increasing number of sick turtles seen, however, and the other problems that these sea turtles face, many scientists now believe that within 50 years, sea turtles will have disappeared from Southeastern waters.

Chemical runoff from agriculture in the reclaimed marshes of central Florida is thought responsible for the outbreaks of red tide organisms that killed hundreds of endangered Florida manatees (*Trichechus manatus latirostris*)

in 1996, devastating their populations. A total of 415 manatees died that year, a record number. Of these, a large percentage died from the toxins. The hundreds of dying manatees, who exhibited no symptoms prior to their deaths, caused great concern among scientists and conservationists who cooperated to discover the cause. Analyses of tissues carried out by the Florida Marine Research Institute and federal, state and private agencies finally concluded that red tide toxics produced by dinoflagellates were the cause. Some of the sick Florida manatees exhibited neuromuscular problems consistent with those previously described in manatees exposed to red tides and were taken to a rehabilitation facility at Lowry Park Zoo in Tampa (Turner 1996). Three females recovered over a period of three days, during which time they required assistance to stay afloat for breathing (Turner 1996).

Although red tide is a natural phenomenon, scientists believe that these tides, which have been occurring with greater frequency in recent years, are erupting as a result of effluents, such as sewage and agricultural fertilizers and pesticides (Broad 1996). The average number of Florida manatees that die each year was 100 or fewer prior to 1990, but since then, each year 200 or more die. The effects of pollutants may be a major factor in the doubling of their death rate at a time when toxic chemicals have become pervasive in Florida waters. Since a female manatee has only one young every five to seven years, this death rate is far greater than the recruitment rate.

Toxic Chemicals: Page 5

Pollution-caused mortality of wildlife was, until recently, rare, occurring in isolated areas in the world's oceans. Increasingly, however, these poisons are becoming widespread, and the effects on ecosystems and individual species have been serious. Red tides have affected the Chinese coast in recent years, causing massive fish kills and wiping out fish farms (Chu 2000). They are attributed to sewage dumping. In Hong Kong, where a red tide covered 2,000 square miles, 700,000 tons of sewage is dumped yearly into the nearby Bohai Sea (Chu 2000). Long-term dumping of sewage, toxic chemicals and fertilizer is killing all fish and sea life, creating "dead zones." A dead zone in the Gulf of Mexico off the delta of the Mississippi River covers 7,000 square miles, the size of New Jersey; it spreads west to the Texas coast (Yoon 1998). Caused by a lack of oxygen, 50 dead zones were found in oceans and seas throughout the world by 2000. Cruise ships now number in the thousands, and each one generates a million gallons of waste water, 200,000 gallons of sewage and 25,000 gallons of oil-contaminated water each week, according to the Bluewater Network (Johnston 2000). Even small motor boats are heavy polluters of the air and water, emitting toxic fumes and leaving trails of oil and gasoline in the water.

Toxic Chemicals: Page 6

The spectacled eider (*Somateria fischeri*), a beautiful duck of Alaska and arctic Russia, has incurred great declines that may be related to ingestion of toxic chemicals. The Iowa-sized Yukon-Yuskokwim Delta of western Alaska had 100,000 of these ducks breeding here in the 1970s, but beginning in 1986, they lost 14 percent of their population each year; 95 percent of their original numbers are now gone, leaving only about 5,000 birds (Dunkel 1997). In 1993, the species was listed as threatened on the Endangered Species Act, and a task force set about trying to discover the causes. They found that many of the birds had high levels of lead from Eskimo hunting with bird shot. Although 34 of the 42 Eskimo villages in the delta have passed resolutions in favor of using steel shot over lead shot, most natives apparently believe that the birds are dying out from being studied and handled by biologists (Dunkel 1997). One Fish and Wildlife Service biologist observed a spectacled eider dying of lead poisoning: "She was flopping along [on the ground] and couldn't lift her head . . . She died within an hour" (Dunkel 1997). Lead in sub-lethal concentrations can cause females to abandon nests and males to become infertile.

Lead poisoning has killed other wildlife as well. The magnificent and rare Steller's sea eagles of Russia's

Kamchatka Peninsula and northern Japan have been dying of lead poisoning from eating carcasses of deer killed by Japanese hunters (Garcelon 1999). Lead shot cannot be used by United States waterfowl hunters (other than native Americans) because of massive bird-kills in marshes where lead shot accumulated.

Until February 1995, the wintering area of spectacled eiders, where they spend 10 months of the year, was unknown. The Fish and Wildlife Service had attached radio transmitters to several of these ducks, only to find the signals fading during the winter. One radio, however, continued to send out signals which were detected and located by biologists flying over the Bering Sea in a small plane (Dunkel 1997). To their amazement, they saw flotillas of these ducks, gathered in dense flocks south of St. Lawrence Island off western Alaska. Packed close together, their body heat helped keep the ice open. DNA studies determined that these ducks comprised the entire world population of the spectacled eider, converged from Alaska's North Slope, the western Alaskan delta and arctic Russia. Each returns to the location where it hatched, and when one population declines, there is no recruitment from the others (Dunkel 1997). This makes the decline in the Yukon-Kuskokwim Delta population all the more serious. The Bering Sea has been found to contain cadmium, selenium, strontium and other contaminants in high concentrations, which might be another explanation for the decline in these ducks (Dunkel 1997). Their disappearance coincides with the downward population trends of Alaskan mammals that were abundant only a few decades ago. Harbor seals of the Bering Sea have plummeted 60 percent since the 1970s; fur seals, 20 to 40 percent and Steller's sea lions (*Eumetopias jubatus*), a disastrous 80 percent, pushing them to endangered status (Dunkel 1997). Overfishing may play a role in these declines, but since the spectacled eider feeds on mussels and other bivalves, as well as surface invertebrates, and has declined concurrently with the others, contaminants are apparently playing an important role.

Toxic Chemicals: Page 7

The rivers of Europe may be the most polluted and changed by diversion, dams and channeling in the world. The Rhine, considered the "great open sewer of Western Europe," has lost the majority of its native fish, but pollution control efforts are beginning to show results (Simons 1995). After an absence of 40 years, a single, stranded Atlantic salmon (Salmo salar) appeared after flooding of the Rhine in the Netherlands in the spring of 1995 (Simons 1995). Atlantic salmon are now being reintroduced to rivers of Europe where they have been absent for many decades. A recent report on the Rhine's cleanup status concluded, however, that although much improvement had been made, heavy metals, dioxin, chlorine compounds like PCBs, herbicides and animal manure remain in sediments and are still released along parts of the river. Common otters (*Lutra lutra*) in Germany have dangerous levels of toxins in their kidneys, livers and fat, and cormorants along the river are laying eggs with thin shells (Simons 1995). Every year in the European Union, 250 million tons of solid industrial waste are produced, most of which is deposited in landfills which can leech into the groundwater (Lanz 1995).

As a result of population and industrial growth, incidents of wildlife killed by pollution in Africa have become more frequent. Formerly pristine lakes in the Great Rift Valley of East Africa are breeding grounds for 80 percent of the world's flamingos. Greater and lesser flamingos by the millions nest and feed in high-altitude, briny lakes. Lakes Nakuru and Bogoria in Kenya have become polluted in recent decades by factories that emit heavy metals and other industrial wastes. People have built towns and cities along the shores that discharge large amounts of untreated sewage into the lakes. Since 1993, several mass die-offs of flamingos have occurred on these lakes. More than 50,000 flamingos died in 1993 and 1995, and two more die-offs in the summer of 1999 and early 2000 killed thousands more. There is a real possibility that the massive flocks of these beautiful pink birds, one of the Earth's great wildlife spectacles, might vanish.

Toxic Chemicals: Page 8

Acid rain is another threat posed to lakes, streams and ponds. Large power plants in Europe and the United States and, most recently, in China, which burn fossil fuels such as coal, have affected forests and aquatic systems hundreds and even thousands of miles away from the source of pollution. In the 1970s, tall stacks were mandated as pollution control to dispel soot particles, sulphur dioxide and nitrogen oxides. Rather than control the problem, they merely spread it by dispersing these pollutants vast distances on the wind. The pollutants combine with atmospheric water and fall to the ground hundreds or thousands of miles away as diluted sulphuric and nitric acids. Coal-fired power plants in England and central Europe have poisoned the lakes and rivers of Scandinavia, while plants in the US Midwest and southern Ontario, Canada, have rendered lakes in New England and Quebec lifeless. In Scandinavia, 20,000 lakes are now lifeless as a result of acid rain (Mason and Macdonald 1986), and in northeastern North America, thousands more have become totally barren (Durrell 1986). Acid rain increases acidity in water to levels toxic to many types of wildlife. In lakes with clear water and few nutrients, acid rain can eliminate all life forms. Acid rain's effects on aquatic species have been catastrophic, eliminating water birds, salamanders, otters, many types of fish, frogs and other temperate wildlife in entire regions.

Coal mines contribute to acidification of aquatic ecosystems as well by exuding acids that poison streams and rivers in their drainage. Thousands of streams in Appalachia in eastern North America have been rendered sterile from coal mines that continue to poison waterways, even when no longer being mined, until they are sealed off. In October 2000, a coal mine sludge retention pond in eastern Kentucky gave way, spilling 200 million gallons of toxic waste into streams feeding the Ohio River (NYT 2000). The state's governor declared a state of emergency in the northeast as water supplies for the entire region were threatened with contamination (NYT 2000).

Toxic Chemicals: Page 9

Air pollution regulations in the 1980s and 1990s mandated removal of the majority of sulphur dioxides prior to the release of emissions, and this has made a difference in the rate of acidification in North America and Europe. In parts of Europe, lime has been broadcast from small planes on some of these lifeless lakes to lower acidity. Usually, liming has to be frequently repeated and is not always effective. When pollution is decreased, however, life forms return, and air pollution controls have resulted in decreased acidification in some areas.

Dioxin, a chemical emitted by paper and plastic manufacturing plants and incinerators, has been found in aquatic ecosystems. It is toxic to many fish and their eggs, and is considered a cancer risk to humans. Dioxin residues in Lake Ontario, Canada, began killing the eggs of Lake Trout as early as the 1940s, and the species became extinct in the lake by the early 1950s (Colborn *et al*. 1996). Dioxin has been found in high concentrations in Eskimos of the Canadian arctic who eat caribou and seal meat; the latter animals consumed dioxins contained in their food from airborne dioxin generated by incinerators in the United States and Mexico (Hilts 2000).

Toxic Chemicals: Page 10

Chesapeake Bay is the largest expanse of saltwater estuary in the United States. Covering 64,000 square miles, its marshes are watered by its major feeders, the Potomac, Susquehanna, Rappahannock and Patuxent Rivers, along with countless smaller feeder streams from its Maryland and Virginia shores. More than 150 rivers and streams contribute to its 650-mile-wide watershed, which extends over portions of six states (White 1982). The Bay is bordered by 8,100 miles of shoreline, including its tributaries (White 1982). The growth of Washington, D.C. and Baltimore and Annapolis, Maryland, as well as other large cities and suburbs on Chesapeake Bay, and the growth of agriculture that leeches sediments and chemicals, have been responsible for destroying large portions of this great estuary. About 140

square miles of the watershed are built on every year. Urban and suburban growth, agriculture, overfishing and industrialization have all taken a toll on the water quality of Chesapeake Bay. The raising of chickens and hogs in factory farms in the region has increased over the past few decades, producing enormous quantities of fecal material that contaminate rivers and the Bay. During storms, containment ponds have overflowed, pouring pollutants into the waterways which have been implicated in outbreaks of red tide and bacterial disease (Broad 1996). Runoff of pesticides, herbicides, sewage, fertilizer and sedimentation have turned the once clear waters murky in many parts of the Bay. The fragile ecosystem of sea grasses and marshland is damaged.

Fisheries that once produced 28 million pounds of oyster meat and 55 million pounds of blue crab have plummeted. The disappearance of 90 percent of the sea grass from Chesapeake Bay, mainly as a result of chemical pollution and sedimentation, has brought about a crash in blue crab populations, with closures in fishing seasons. Crabs lay eggs and shelter in sea grass. Oyster harvests are now 1 percent of what they were a century ago. Their populations have plummeted, and only with their absence is the role that they play in the health of Chesapeake Bay becoming clear. Originally, the billions of oysters filtered the complete volume of water in the Bay in a three-day period, clarifying the water and removing pollutants (Daily 1997). Their ecological value far outweighed the revenue they produced for fishermen. Overfishing has played a role in the decline of oysters, but the major problem is the disintegration of this once-productive estuary through losses of sea grasses and sedimentation from development and pollution. Another casualty was the Maryland darter (*Etheostoma sellare*), known only from a creek in the northern tributaries of Chesapeake Bay. Not seen for many years, some authorities, including the International Union for the Conservation of Nature (IUCN), consider it extinct (Baillie and Groombridge 1996). The shortnose sturgeon (*Acipenser brevirostrum*) historically ranged throughout the Chesapeake Bay area, where thousands were caught annually. Dams, overfishing and pollution combined to eliminate this sturgeon, and spawning no longer occurs in any of the Chesapeake's feeder rivers. The species is threatened throughout its eastern range and is listed on the Endangered Species Act.

Decades after the Clean Water Act came into effect, the Environmental Protection Agency (EPA) announced in 1996 that only 40 percent of the country's waterways are suitable for swimming or fishing because of pollution from various sources. In 1997, residents of 47 US states were warned by EPA not to eat certain types of freshwater fish after issuance of some 2,200 fish consumption advisories, a new high. These advisories list 45 contaminants in lakes and rivers, including mercury, PCBs, chlordane, dioxin and DDT. In many parts of the United States, well water has been found to be contaminated with pesticides and herbicides. This is especially severe in the farm belt of the Midwest, where the majority of these chemicals are used. According to the EPA, 1.25 billion pounds of weed and pest killers were used throughout the United States in 1995, an all-time high. Pesticide and herbicide runoff from agricultural fields was found in half of more than 500,000 miles of rivers tested by the EPA in 1995. Homeowners pouring these chemicals on their green lawns are also contributing to the contamination of streams, rivers and water supplies. A new contaminant of groundwater is a gasoline additive, methyl tert-butyl ether (MTBE). This chemical was designed to reduce air pollution to allow gasoline to burn more cleanly, but because of leakage from gasoline tanks around the country, it has entered the groundwater in every state and has been detected in 5.4 percent of wells in a US Geological Survey study. Other solvents added to gasoline were found in 47 percent of urban wells and 14 percent of rural wells (Saar 1999). The drinking-water limits set by EPA were exceeded in many of these wells (Saar 1999). This chemical is suspected to be a carcinogen.

Contamination of aquatic ecosystems has occurred throughout the world. It has played a role in endangering one of the world's rarest birds, the crested ibis (*Nipponia nippon*). Unlike any other ibis in appearance, the bird has white or pearl gray plumage, a shaggy mane of feathers and salmon pink tail feathers, which contrast with bare red facial skin and carmine red legs. Only 66 birds remain, up from 22 birds in the early 1990s, with a captive population in two breeding centers of over 100 birds (BI 2000). These elegant birds once ranged from southeast Siberia, Manchuria and China to as far east as Korea and Japan. For centuries they were hunted for their long nuptial plumes, nearly causing their extinction (Schreiber *et al*. 1989). The Japanese population of the crested ibis declined until only the tiny Sado Island held the last population; the eggs and chicks were killed by crows and jays, and the last birds were taken into captivity (Schreiber *et al*. 1989). Extinct in Siberia in 1917 and thought extinct in China by 1958, a pair was found

nesting in Shaanxi Province in central China in 1981. This only remaining breeding population has slowly increased, but with fewer than 100 birds in the wild, it remains endangered (BI 2000).

Toxic Chemicals: Page 11

Crested ibises require large trees for nesting near marshes, and to protect these birds, China enacted emergency regulations prohibiting logging in the area. Their nest is a flimsy stick platform lined with small twigs, leaves and hay, built in tree branches at heights up to 25 meters (Hoyo *et al*. 1992). Hunting has also been banned, and the Chinese government accorded them official protection, but some wintering birds are still shot (BI 2000). These birds declined in Japan as a result of poisoning by mercury pesticides and other agricultural chemicals applied to rice paddies. Their feeding habits make them very susceptible to poisoning from pesticides because chemicals accumulate in the bodies of their aquatic prey of crabs, frogs, small fish, mollusk and insects. For this reason, pesticides have been banned in nearby rice paddies (BI 2000). The drainage of rice fields in the wintering habitat has reduced food supply, and 80 percent of birds found dead in the wild have starved to death (BI 2000).

Gold mining has become a major peril to rivers and aquatic ecosystems. The ore is treated with cyanide or mercury to remove the gold, and the toxic waste is either flushed into waterways or accumulates in holding ponds. Cyanide is one of the most toxic of all compounds, and it has caused irreparable harm to the pristine rivers of New Guinea, South America and other parts of the world. Cyanide spills have caused massive fish kills and river destruction in Guyana (Associated Press 1995). Brazilian gold miners have illegally polluted rivers in tribal reservations in remote Amazonian forests with cyanide, destroying the entire fish and aquatic fauna upon which tribes had depended for thousands of years.

In Papua (formerly known as Irian Jaya), the western portion of the island of New Guinea governed by Indonesia, the Grasberg Mine contains the world's largest known gold deposit, an estimated 22 million ounces (Bryce 1995). This mine sits atop a peak in the Sudirman Mountains, rising nearly 16,400 feet, and provides habitat for many unique species (Whitten and Whitten 1992). The Grasberg Mine has polluted the Aikwa River, which drains the region and flows to the southeastern coast, killing fish (Bryce 1995). The mine also contains 15 billion pounds of copper and 37 million ounces of silver, for a total value of $50 billion (Bryce 1995). These ores are being mined and transported through the world's longest slurry pipeline and down the world's longest single-span cable car track to a massive mill (Whitten and Whitten 1992). The entire mountain has already been stripped, reducing it to terraced ridges, and US-owned Freeport-McMoran Copper and Gold Inc., which owns the mine, plans to drill in 75 more sites (O'Neill 1996). The company has been given access to 9 million acres (1.5 times the size of Vermont) by the Indonesian government (O'Neill 1996). French surveyors are seeking uranium in the Vogelkop, or Bird's Head, Peninsula at the far western end of New Guinea, and Australians are searching for gold in the Korowa region in east-central Papua (O'Neill 1996).

New Guinea's great biological diversity is being threatened by this mining. Beautiful birds of paradise, bowerbirds, tree kangaroos and countless other species, ancient forests and wild rivers are gradually being destroyed by mining. At present, forests cover 85 percent of Papua, and clear, free flowing rivers drain the highlands (O'Neill 1996). Much of Papua is without roads, and many areas remain unexplored. New Guinea's extraordinary birdlife is rich in species, totaling 725, more than in all of North America (Beehler *et al*. 1986). Tim Flannery, an Australian mammalogist, is so concerned about the destruction of this island, and the effect on native peoples, that he dedicated his book on New Guinea's wildlife to Chief Executive Officers of mining companies "in the hope that, through reading it, they will understand a little better the people whose lives they so profoundly change" (Flannery 1998). Flannery discovered an extraordinary black and white species of tree kangaroo (*Dendrolagus mbaiso*) in a forest not far from the mine. The mine owners built a large, dam-like structure to contain the enormous amount of mine tailings, all of which are dumped into the headwaters of the Aikwa River. The sediment builds up and smothers the roots of

trees, causing vast tracts of forest to die and killing fish and mudcrabs along the coast (Flannery 1998). The tailings area will eventually be so large that it will be visible from space, and the mine has encouraged logging and other intrusions into the wilderness (Flannery 1998).

To the northwest, rivers of southern Borneo have been turned into "polluted deserts" by local people in search of gold. They clear away the rainforest, destroying banks with high-powered hoses (Mydans 1997). Mercury is used to extract the gold dust, contaminating the rivers with 100 times acceptable levels (Mydans 1997). These forests are home to endangered Orangutans and hundreds of animals and plants found nowhere else on Earth.
South America's river banks are also being ravaged by miners who use high- pressure water jets to blast apart the riversides, destroying all vegetation and habitat for endangered giant otters and water birds. Venezuela's largest mine, Minerven, near El Callao, dumps cyanide and metal particles into a man-made pond without liners or barriers to prevent seepage. Trees surrounding the pond have died, and the pond's surface has become so spongy and dense that one can walk on it (Schemo 1996a). Cyanide dumped into the waters is killing fish and poisoning manatees and other aquatic life.

Oil Spills

The interdependence of mangroves, sea grass and coral reefs can result in the decline of all three ecosystems when oil spills occur. After a 1986 oil spill on the Panamanian Caribbean coast, even minute effects could be measured because the mangrove ecology of this particular area had been studied in detail by scientists from the Smithsonian Institution since the 1970s. First the spill killed expanses of sea grasses and their root systems, along with 150 acres of mangrove trees and their roots in a thin strip along the coast (Luoma 1993). Following this, the waves were able to loosen and suspend the bottom sediments, and these mixed with oil particles which sank to the sea floor; each rainy season, the oil was stirred up and re-suspended (Luoma 1993). This annual flushing of the oil contaminated the entire ecosystem and gradually killed the coral reef (Luoma 1993). Up to 96 percent of corals on heavily polluted reefs died, and even at depths of 12 meters, 45 percent of corals perished; many of the surviving corals suffered toxic effects, being left with bleached and diseased patches (Wells and Hanna 1992). Effects on fish populations were more gradual, taking three or four years before stocks showed sharp declines as a result of destruction of their eggs. The Smithsonian™s Tropical Research Institute prepared a report on the effects of this spill, concluding that full recovery of the ecosystem might take as long as a century (Luoma 1993).

The worst oil spill in US history occurred on March 24, 1989 in Prince William Sound, Alaska, when the Exxon Valdez, an oil tanker fully loaded with crude oil from the Alaskan Oil Pipeline, foundered on a reef just miles from the port of Valdez. This southern coast teemed with wildlife. Fifty pairs of Bald Eagles nested within the Sound, and 2,500 more lived within the archipelago that extends 900 miles to the southwest. Millions of sea birds and waterfowl in vast colonies nested along the coasts, among them the very rare harlequin duck (*Histrionicus histrionicus*), which had a large breeding population. More than 20 million shore birds and other arctic species pass through the Sound while on migration, and in all, 219 bird species have been recorded in Prince William Sound (Browne 1989). The Exxon spill occurred only two weeks before spring migration.

Sea otters (*Enhydris lutris*) numbered at least 10,000 in Prince William Sound, the largest concentration in the world. Thousands of harbor seals used the islands for feeding and calving. Gray whales fed and migrated through the area, and killer whales had resident pods. Commercial fishermen caught vast catches of salmon, herring and other food fish. The coastline, one of the world's most spectacular, is lined with federal, state and native Alaskan protected lands. Kenai Fjords and Katmai National Parks, Kodiak National Wildlife Refuge and thousands of acres of state and native lands had, until the spill, preserved a magnificent environment almost intact. Rocky beaches alternated with marshes and sheer cliffs studded with sea bird nests.

The Exxon Valdez spilled more than 11 million gallons of crude oil. Almost no action to clean the spill took place for days, due to a lack of preparation on the part of the Exxon Corporation and state authorities, and a lack of agreement about whether to burn off the oil, which the state refused to allow, or to spread chemical dispersants that were feared to cause wildlife mortality. This delay allowed the heavy oil to sink to 90-foot depths and spread hundreds of miles along the coast. By April 10, it covered 3,000 square miles, having spread throughout the region's inlets and coves and southwest 500 miles to Kodiak Island, the haven for the massive Kodiak bear (Ursus arctos middendorffi). The amount of shoreline oiled equaled the distance from Boston to the Chesapeake Bay (Mitchell 1999). Surface oil was 18 inches thick, coating sea birds that landed in it with a lethal film. Many died and sank in open water. By the time the spill ceased spreading, it was found to have fouled 1,500 miles of shorelines and covered 10,000 square miles, an area the size of Vermont (Schneider 1994a).

When cleaning finally began days later, it consisted of high-pressure hosing and wiping rocks. This did not remove the tons of oil that sank deep into the sand, marshes and offshore shellfish beds. Only 15 percent of the oil was recovered through vacuum tubes and booms, while the sunken oil remained a decade later, preventing oxygen in mudflats and wetlands from entering with microorganisms that would break down the oil (Mitchell 1999). The rest has been dispersed by a decade of surf and ocean currents washing it away and has evaporated from the surface.

The toll on wildlife was immediate. Sea birds began washing up on the shore coated with thick oil, some still alive. Sea otters struggled ashore as well, trying to clean their coats while lying on oiled rocks. Crews employed by Exxon picked up dead birds and sea mammals, and by May 12, ABC News reported that 20 tons of dead animals had been collected along 550 miles of soiled beach, of which only two miles had been cleaned. Actual numbers of sea bird mortalities will never be known, but some biologists have estimated that up to 500,000 birds died. Species most affected were common and yellow-billed loons, horned grebes, Pacific cormorants, black-winged and white-winged scoters, common murres, pigeon guillemots and the threatened marbled murrelets (*Brachyramphus marmoratus*). The entire population of common murres in the Barren Islands in Prince William Sound apparently died (Senner 1989), and 40 percent of the region's murres died (Mitchell 1999). Oiled birds and sea otters were brought to special rescue centers, where survival tended to be low.

Sea otters incurred very high mortality and suffered for long periods before they died. Their extremely fine fur collected oil as they swam about the surface, unable to avoid the oil like seals and sea birds who submerged or flew away from the spill. At least 980 carcasses were recovered, but judging from counts carried out during the next few years, almost half the Sound's sea otters died during the spill or from its effects (Schneider 1994). People scouring the beaches for oiled animals often heard the otters before they saw them. The crude oil's toxic chemicals literally destroyed their livers and other internal organs within hours, causing such pain that they screamed as they died. Some were found dead with mouths wide open as if still screaming. An ABC news program filmed several of the otter pups that were rescued, doll-like balls of fluff who spent hours screeching for their dead mothers. Having no thick layer of body fat to keep them warm, sea otters rely on their dense, layered fur which they constantly groom so that it remains waterproof, with a layer of air to insulate against the cold. When they swam into oil, the otters groomed furiously but succeeded only in distributing oil over their bodies and into their gullets (Wheelwright 1994). Their clumped fur let icy water in, and the crude oil burned their stomachs, sometimes causing acute emphysema, with air bubbles bulging out under the skin of the otter's throat in a grisly necklace (Wheelwright 1994). Many succumbed to hypothermia and sank. When the dead otters were autopsied, a majority of females had near-term fetuses the size of plump rabbits; the western Sound where the oil spill occurred was a "female" area, and they outnumbered males in the otter morgue two to one, with more than 60 percent pregnant (Wheelwright 1994).

Of the several hundred sea otters brought to rescue centers, fewer lived than died, and only a tiny percentage of the total oiled animals were rescued. Most of the surviving pregnant females aborted or had stillborn cubs. Carolyn McCollum was one of the hundreds of volunteers who came from all parts of the country, and even from foreign countries, to help care for oiled animals. In an article for *Wildlife Conservation*, she described seeing these otters snuggling with towels, bunching them up for a pillow or using them to groom their faces. These intelligent animals have been documented as tool users: they use rocks as shell-openers when hand-held or as hard surfaces upon which

they bang open shells. Carolyn McCollum (McCollum 1990) took care of one female so ill she was unable to eat, wheezing with emphysema: "I could tell from her abdominal breathing that she was in great pain; her sad eyes followed my movements lethargically and I wished there was something more I could do. About 10:00 p.m. she fell asleep; as I felt her chest to make sure she was still breathing, she pressed my hand to her body with her short forearm and I let her hold it there. Ill and weak, the otters at the center behaved like small babies . . .I held my patient's paw until 4:15 the next morning when she stopped breathing. As the vet came to take her to be autopsied . . . I shuddered to think how many more animals would go through the same ordeal.fl

Long-term damage to Prince William Sound started to become apparent by 1994. Marine ecological systems had suffered serious effects. Some species of water birds, especially harlequin ducks, ceased to reproduce in the Sound (Schneider 1994a). Although salmon catches initially rose in 1990 and 1991, as did herring in 1991 and 1992, the catches later plummeted (Schneider 1994a). In the spring of 1994, Alaska officials closed the Sound's herring fishery because there were too few fish. The herring, which are the keystone species in Prince William Sound, fed on by sea birds, mammals and humans alike, died from disease which manifested in skin lesions, perhaps caused by sub-lethal effects of oil (Mitchell 1999). By 1999, herring had still not recovered, and a population estimated at 120,000 tons prior to the spill fell to 40,000 tons (Mitchell 1999). The oil remaining in the water has apparently affected a variety of wildlife, preventing the recovery of virtually every species except the Bald Eagle (Mitchell 1999). Populations of sea otters, harbor seals, killer whales, pink salmon, herring and many sea birds have not recovered. Harbor seals plummeted from 2,000 to only 900 in the Sound. For seals and other fish-eating marine mammals, there are apparently not enough fish to eat, and recovery of fish populations seems to have been slowed by the remaining oil, which kills young fish even at very low concentrations (Mitchell 1999). Fishermen were awarded $5 billion for their losses by a US District Court in 1994, when a jury decided that the captain of the Exxon Valdez had acted recklessly (Schneider 1994b), but they have yet to be paid by Exxon (Mitchell 1999). This company, now merged with Mobil Oil Company, continues to earn approximately $8 billion per year, yet it refuses to settle this claim, and fishermen now earn only half their pre-spill income.

The spectacular Steller's eider (*Polysticta stelleri*) was once an abundant bird of Alaskan and Russian arctic waters. These striking waterfowl formerly nested on the Alaskan Peninsula and the Yukon Delta to the Canadian border, but in recent years they have disappeared from Alaska except the western Arctic coastal plain. Worldwide, their population has declined 50 percent, and they have been listed on the Endangered Species Act as threatened. The oil from the Exxon Valdez and other spills may have spread throughout the region in miniscule amounts that gradually became lethal to these birds. Other oil spills have occurred in Alaska since 1989, including 100,000 gallons spilled in 1997. Some oil tankers have illegally dumped or spilled oil and oily ballast.

Some good came from this massive oil spill. The state of Alaska purchased 650,000 acres of land within the archipelago for wildlife protection with $900 million from the Exxon settlement. Old-growth forests, providing key habitat for threatened species, have been deeded by native corporations for permanent protection from logging in conservation easements, and 61 trout and salmon spawning streams will be purchased (Mitchell 1999). A fund of $140 million, which began in 1994 from Exxon payments, will be available for spending on research, monitoring, fisheries applications and habitat protection (Mitchell 1999). The corporation that monitors the movements of oil tankers through Prince William Sound has adopted new procedures and equipment for fighting future spills, but only three of 28 tankers that use the Sound have double hulls (Mitchell 1999). Double hulls, or an inner hull protected by an outer one, greatly reduce leakage in a collision. It is estimated that 60 percent or less of its oil would have spilled had the Exxon Valdez been equipped with double hulls (Mitchell 1999).

Other oil spills around the world have involved heavy wildlife mortality as well. Jackass or African penguins (*Spheniscus demersus*) once numbered more than 1 million birds in colonies along the coasts of South Africa and Namibia, but their numbers have been in decline for decades. They have declined to 180,000 birds Œ a result of multiple oil spills, destruction of breeding habitat for extraction of guano, food shortages as a result of overfishing by commercial purse seiners, feral cats on their nesting grounds and disturbance by humans causing them to abandon nests (BI 2000). In June 1994, a large spill near Cape Town killed thousands of these penguins (Associated Press

1994). The species was classified as near-threatened by BirdLife International in 1994 (Collar *et al*. 1994), and it has suffered population declines ever since. In Threatened Birds of the World, BirdLife International classifies the species as vulnerable, a more threatened category that indicates serious decline.

In the summer of 2000, a large oil spill occurred within feet of their prime breeding ground off Cape Town. Professional bird rescue organizations, experts and volunteers from around the world converged on the area within a few days. This was the most massive bird rescue in history and saved the lives of over 38,500 adult penguins by placing all adults that could be caught in a giant warehouse and holding area in Cape Town (Associated Press 2000a). Oiled birds were cleaned and fed, while oil-free birds were held to prevent them from becoming oiled in the spill. Most were caught on land attending to chicks and incubating eggs, as this was the height of the breeding season. More than 19,000 birds were shipped 500 miles up the coast and released (Associated Press 2000a). By the time they returned to Cape Town, a swim that was monitored on the Internet, the spill had been cleaned up. The rescuers claimed the unprecedented survival rate of 90 percent. The unfortunate casualties were abandoned chicks and eggs. In spite of the large numbers of birds saved, the entire generation of young were lost, and an unknown number of oiled adult birds died at sea.

In the Siberian tundra, a delicate frozen ecosystem with a thin layer of soil covering permanently frozen ground, known as permafrost, is extremely vulnerable to damage from oil spills. Oil exploitation over the past few decades has resulted in many spills that permanently scarred the land. The most recent, in the fall of 1994, spilled approximately 33 million gallons of oil, three times the total spilled in Alaska, polluting three major rivers. Long-term effects will not be measured for years, but the immediate effects have been massive fish kills in the Kolva, Pechora and Usa Rivers of the northeast (Filipov 1994).

Large oil spills, however dramatic, do not constitute the majority of oil spilled in oceans. They may make up only about 12 percent (Wells and Hanna 1992). Forty-five percent of the oil that is becoming pervasive in ocean ecosystems comes from the routine flushing of tanks and bilges of ships at sea, and one-third comes from regular leakages at land-based operations such as refineries (Wells and Hanna 1992). Floating tar balls and dissolved light oil continue to cause mortality and ecological damage, destroying the waterproofing of birds' feathers and settling on coral reefs. As marine biologist Dr. Sylvia Earle, former chief scientist of the National Oceanic and Atmospheric Administration (NOAA), noted in *Sea Change: A Message of the Oceans* (1995): "Nets dragged through the sea anywhere are likely to come up clogged with tar balls, beaches in the most remote areas are fringed with an oily scum or lined with sticky gobs of oil; over the surface of much of the ocean a rainbow-hued film glistens with deadly beauty at one time or another." Since 1970, 50 major spills the size of the *Exxon Valdez*'s have happened worldwide (Mitchell 1999).

The ingestion of lethal oil compounds, whether within days or weeks after a spill or from residues remaining years afterward which enter the food chain, is the key cause of mortality for the millions of sea creatures that die in oil spills. Research conducted by Dr. Daniel W. Anderson of the University of California at Davis revealed that only 12 to 15 percent of Brown Pelicans rescued in oil spills survived for two years (Kopytoff 1996). The greater the amount of oil ingested, the higher the death rate.

A remarkable discovery in the late 1990s has yet to be aggressively pursued as a means of cleaning up spilled oil. A barber who watched the news of the Exxon Valdez spill noted that the sea otters died in large numbers as a result of the extreme absorbency of their fur and their ingestion of oil while grooming. He began collecting human hair from his barbershop and testing it for absorption of oil. It proved remarkable in its ability to suck up large amounts of oil when contained in mesh nylon bags, leaving almost no oil in the water. He approached NOAA and showed them his findings. They tested the process and confirmed his results. Although this was widely publicized on television and in newspapers, little has apparently been done to place this very simple, low-tech process into real situations by encouraging oil tankers and land-based oil pollution teams to store large amounts of hair for this purpose. NOAA tests determined that the oil absorbed by the hair could easily be recovered by squeezing the bags into holding tanks.

In the wake of the Exxon Valdez spill, Congress enacted the Oil Pollution Act of 1990, which requires oil tankers operating in US waters to pay large penalties and carry massive insurance liability for spills. Civil penalties range up to $1,000 per barrel discharged. Within a month of the passage of this law, 20 oil companies created two new organizations: the Marine Spill Response Corporation and the Marine Preservation Association (Earle 1995).

The need for such protection from catastrophic spillage has been apparent since the early 1970s when these supertankers began to ply the world's oceans loaded with 200,000 tons of crude oil, built so cheaply they had virtually no protection against splitting apart if they ran aground. The dangers of these ships were dramatically portrayed in the 1974 book, *Supership* (Mostert 1974). More than 25 years of oil spills later, stringent regulations still have not become the rule of the sea. An international agreement requires all oil tankers built after July 1996 to have double hulls, but not all countries are complying. Congress put off the effective date of an amendment requiring replacement of single-hulled ships with environmentally sound double hulls to 2015**,** and even this date may be postponed.

Extinct Species
The Yangtze River (Baiji) Dolphin

The baiji, a freshwater dolphin species weighing 220 to 355 pounds, was historically found throughout the Yangtze River and its surrounding lakes and tributaries. Like other river dolphins, they had long, narrow beaks and poor vision. Because they lived in extremely muddy waters, baiji relied on echolocation to locate mates and food. This dependence kept the ancient species alive for over 20 million years, but recently, human exploitation took its toll. The last official baiji sighting was in 2004, when only two individuals were observed. Sadly, a 2006 expedition revealed no sightings, and the species was deemed fifunctionally extinct.fl

The exponential growth of the Chinese population posed a variety of threats to the survival of the baiji. In 1975, the species was first listed as a Protected Animal of the First Order by the Chinese government. Chinese officials designated protected areas for the baiji; however, the areas proved insufficient and did not encompass the full length of its habitat. Futile captive breeding efforts were also attempted for years.

In the 1990s, electrofishing killed a large number of the dolphins, and overfishing depleted their prey. Additionally, the lengthy construction of the Three Gorges Dam obstructed natural migration patterns, isolated groups of individuals, and impaired breeding opportunities. Along with this industrialization came more ship traffic, which increased the likelihood of dolphin collisions with boat propellers and ships.

Furthermore, the activity in the river created anthropogenic noise that impeded the baiji™s ability to locate food and mates. Water pollution and entanglement in fishing gear are also blamed for the species™ decline. The baiji, accustomed to a pristine and rich environment, was no match for the increasing pollution and congestion of its home.

While the baiji was listed as an endangered species under the US Endangered Species Act and as a critically endangered species on the IUCN Red List of Threatened Species, it was unable to recover due to a lack of information, growing threats and its small population size. Today, the Yangtze River has lost its top predator, which will have a devastating effect on local ecosystems.

Aquatic Ecosystems

Introduction

The marshes, lakes and seas of the world are host to a great diversity of life. In Asian wetlands, brightly colored storks step through reeds while scanning the shallow water for tiny fish. Marsh deer leap gracefully on their wide hooves through mud and spongy vegetation in Brazil's Pantanal. Great flocks of sandhill cranes darken the skies over North American rivers and bogs, emitting their haunting, hoarse cries as they circle to land. Otters, native to all continents except Australia, cavort on river banks, squealing to one another as they leap into the water. Eurasian and American beavers dam rivers, creating ponds where dragonflies, fish, frogs and aquatic mammals thrive. Papyrus swamps line many great rivers in Africa, home to strange shoebill storks, lechwe antelope, crocodiles and hippopotamuses. These aquatic habitats are a lifeline to hundreds more species of birds and mammals who come to drink and bathe. Freshwater ecosystems occupy a tiny fraction of the Earth's surface, unlike saltwater habitats, which cover three-fourths of the planet. Along tropical coasts, mangroves shelter tiny shrimp, crabs and fish. Manatees glide slowly in these quiet waters. A dazzling array of coral grows in fantastic shapes in tropical waters, inhabited by fish, anemones and starfish in every imaginable color, pattern and shape. Throughout the world's seas, whales, dolphins and seals leap above the waves and communicate with one another in complex musical sounds. Bizarre, deep-sea creatures inhabit sulphur-spewing hot vents or lightless sea floors. Wondrous habitats and their wildlife have undergone massive degradation caused by human activity. Many have disappeared altogether over the past few centuries and an even greater number are being destroyed or are losing many native species.

Benefits of Aquatic Ecosystems

Water, the basis of life on Earth, is the most precious of all natural resources. Freshwater and coastal wetlands cover only about 6 percent of the Earth's surface (Lean and Hinrichsen 1992), but produce three-fourths of the world's

fish. Coastal marshes and mangroves play a major role in supporting diversity in the oceans by serving as spawning grounds and nurseries for two-thirds of the saltwater fish and shellfish caught for commercial purposes worldwide (Lean and Hinrichsen 1992). Wetlands perform a major role in preventing floods by retaining rainwater for slow release during the year and absorbing large amounts of rainfall, runoff and snowmelt. Wetlands also filter out contaminants. Some communities in the United States now construct wetlands for the purpose of filtering treated sewage water.

In a new approach to nature conservation, "Earth's Worth" scientists have begun calculating the dollar values of services performed by nature. Traditional economics value natural ecosystems only by practical use to human economies in short-term projects, such as real estate development or resource extraction. For example, how much a wetland is worth is a reflection of tax assessments, which are based on development possibilities and resale values. A boggy woodland might be appraised at a fairly low rate because it is difficult to develop for housing or other buildings. For this reason, such habitats are often bought at low prices and destroyed by development. By contrast, when one considers the ecological services rendered by that aquatic ecosystem, its values are far greater. It absorbs rainwater, thus preventing floods, provides a nursery area for aquatic wildlife and preserves woodland, which produces oxygen. The clean water supplied worldwide by natural filtration by marshes and mollusks that filter water was estimated by a group of ecologists to be valued at a minimum of $1.7 trillion (Stevens 1997). Estuaries and coastal wetlands are nurseries for multi-billion-dollar fisheries and shell fisheries, while they are also valuable in preventing floods. Yet such wetlands, which are often seen as ideal locations for ports and cities, are routinely filled for development. Scientists at the University of California at Berkeley calculated that the remaining wetlands in that state, 91 percent of which have been destroyed, are worth $10 billion annually in ecosystem services (Williams 1996). These ecosystems are usually considered virtually worthless by developers and industry.

The beautiful salt marshes of Georgia were under threat a few decades ago when it was discovered that large deposits of phosphate, which commercial interests wanted to mine for use as fertilizer, lay beneath them. Dr. Eugene Odum, who founded the science of ecology (Odum 1971) and taught at the University of Georgia, was able to prove to the state legislature that the long-term gain from these marshes as nurseries for the valuable shrimp and fish industries far exceeded the short-term profits that would accrue from permanently destroying them by mining. They received legal protection, an important precedent that recognized the economic value of wetlands. Since then, coastal marshes and other wetlands have attracted millions of tourists who come to see the wildlife and beautiful vistas that these habitats provide. Such visitors provide more income to the localities involved than extraction of minerals or development, since ecotourism is permanent.

The reason coastal wetlands and mangroves provide such important nurseries lies in the supply of nutrients they receive from ocean tides and freshwater runoff and rivers. Delta wetlands are especially rich in these nutrients brought by inland rivers and the tides. These floods bring nitrates, nitrites and minerals that nourish the vegetation of the wetlands. This rich habitat was eloquently described in Rachel Carson's *The Edge of the Sea* (1955). Among the grasses and reeds, microscopic life and invertebrates feed a great diversity of fish, shrimp, crabs, mammals, reptiles, amphibians and birds. Bivalves filter the water of aquatic ecosystems, keeping it clear and free of silt and pollutants. Freshwater marshes, lakes and ponds are breeding areas for crustaceans, mollusks and many vertebrates. Millions of waterfowl breed in the seasonal sloughs and potholes of North America prairies. Temporary wetlands, such as the vernal pools or wet season ponds, provide important habitat and breeding areas for frogs, toads, turtles, birds and a rich variety of invertebrates and plants.

Ancient peatlands and sphagnum bogs can be found on every continent except Antarctica. These wetlands absorb vast amounts of rainwater and store it year-round. Their soils tend to be poor in nutrients, but a wide variety of plant life has adapted to these habitats, from mosses and carnivorous plants such as Venus Flytraps and sundews to sedges and exquisite orchids (Rezendes 1996).

Swamp forests, often lining rivers, were once extensive in many parts of the world, providing habitat for water birds, mammals, amphibians and other wildlife, while preventing floods. In the United States, such forests once

covered the shorelines of the Mississippi River and millions of acres in southern states. Deposits of soil from flooded rivers provide nutrients and anchoring for trees and plants. Most of these swamp forests were cut and replaced with agriculture by settlers, and today the region is plagued by floods.

Migratory aquatic animals need several types of habitats during the year. Salmon live in the open ocean but spawn and die in freshwater streams and rivers where the next generation hatches. Cranes and other water birds feed and breed in both salt and freshwater marshes, while using other types of wetlands during migration. Wetlands and surrounding ecosystems, such as woodlands, interact to provide habitat for many types of wildlife. When trees bordering wetlands are cut, this can adversely affect the water flow and wildlife living in wetlands. Some kinds of toads, for example, need both wetlands, such as ponds or lakes where they lay their eggs, and woodlands, where they seek out damp areas to spend most of the year. Thus, when considering the protection of wetlands, the neighboring environments must also be preserved.

Salt marshes in the tropics produce great quantities of plant matter. A reed marsh can produce many times more vegetation than the most fertile grasslands, and some can out-produce an average American wheat field by eightfold (Lean and Hinrichsen 1992).

Mangroves line almost 75 percent of the world's tropical shores (Mydans 1996). They are important in creating conditions for sea grass and coral reefs that are extremely productive ecosystems. Some 50 species of mangroves and related salt-tolerant trees and shrubs grow in silt-laden coastal waters in tropical latitudes (Ripple 1995). Mangroves are pioneer species Œ they create new land. By setting down shoots into the sand or mud, they gradually trap sediment and create soil. These trees' ability to survive in saltwater allows them to colonize coastal areas where no other type of land tree can live. Anchored by roots in mud, they absorb oxygen through breathing roots that grow in the open air above the mud, enabling them to survive in soils devoid of oxygen.

As they grow, they produce new rootlets at successively higher levels above the high tide level (Collins 1990). Old mangrove trees have huge, above-water roots that form a network of hanging branches, and their trunks grow from the new land created. Their fallen leaves decay and provide food for fish and shrimp. The hanging roots become overgrown with an array of algae, sponges, barnacles and mussels, providing shelter for crabs, fish and shrimp, while the upper branches are used by water birds for perching and nesting. Alligators, crocodiles, manatees, young sea turtles and dolphins find refuge here. Sediments are held in place by mangroves, preventing clouding and silting of waters farther offshore so that dense mats of sea grass can flourish, providing shelter for fish, crabs and other marine life. These, in turn, further stabilize the sediment and allow formation of coral beds in clear water further offshore (Luoma 1993). These three ecosystems--mangroves, sea grass and coral reefs Œ often exist together, each helping create an environment for the other. Mangrove forests also buffer coasts from wave action, preventing inland floods. Bangladesh and other countries that have cut their mangroves have been inundated by disastrous floods, causing great loss of human life and property.

Oceans are vital in recycling important elements that represent the basic building blocks of living organisms: carbon, nitrogen, oxygen, phosphorus and sulphur (Daily 1997). Phytoplankton living in marine environments produces between 33 and 50 percent of the world's oxygen supply while absorbing vast amounts of carbon dioxide (Brown 1994). Oceans are the most important factor affecting the world's weather patterns. In turn, they are affected by changes in world temperatures, such as global warming, which create extreme weather from droughts to torrential rainfalls on land. This vast realm is of vital importance to human survival, yet we are only beginning to learn about its role in preserving life on Earth and its ecology, life forms and ecosystems. We have found an increasing use for many of its species for medicine and industry, and each year, new, useful compounds are isolated from marine animals and plants. Although the biological diversity of the ocean is known to be great, research is poorly funded and lags far behind the research on possible life forms on Mars, for example. The latter project consumes billions of dollars while oceanic creatures are fading into extinction prior even to being named.

Corals are among the oldest ecosystems, with a residence on Earth of at least 450 million years (Wells and Hanna

1992). Many reefs have been growing in the same place for millions of years. Glovers Reef off the Belize coast in the Caribbean rises 6,000 feet from the sea floor and began developing about 20 million years ago (Carter 1997). Coral reefs occur in a band approximately 30 degrees north and 30 degrees south of the Equator. Reefs buffer shorelines from ocean waves and in turn prevent erosion, as well as provide quiet waters for sea grasses to grow closer to shore. These grasses, in turn, are fed on by endangered manatees, sea turtles, fish and shellfish. Species diversity, a key to ecological stability on Earth, is very rich in coral reefs, rivaling that of tropical rainforests (Wells and Hanna 1992). The diversity, beauty and productivity of coral reefs make them vital ecosystems to conserve, yet they are in extreme danger of disappearing within the next century. They are the most endangered aquatic ecosystem on Earth.

Coral reefs cover 360,000 square miles, an area equal to only 0.3 percent of the world's oceans and smaller than British Columbia, yet an estimated 25 percent of the world's marine fish species live here (Chadwick 1999, Zuckoff 2000b). The greatest diversity of coral grows in the Pacific and Indian Oceans, in the Indonesian-Australian region where at least 450 species are found (Doubilet 1999). Corals have evolved into many forms. Among the many forms of coral, brain coral is nearly round, while elkhorn grows great branches, and delicate black coral forms thin strands in deep water. Surrounding most mainland and island masses in these regions, corals also populate shallow areas far offshore, as in the Red Sea. The world's largest coral reef, Australia's Great Barrier Reef, runs for 1,400 miles along the northeastern coast of that continent. Up to 3,000 species of plants and animals inhabit a typical Asian coral reef, and more than 1,000 live in Caribbean reefs (Wells and Hanna 1992). They are an oasis of life in warm waters which, in contrast to cold waters, are often poor in nutrients (Doubilet 1999).

Some coral has been found to be 800 to 1,000 years old, based on annual growth rings (Wells and Hanna 1992). Growing very slowly, often less than 1 inch a year, the coral communities are made up of thousands of individual animals. Hard coral secretes calcium carbonate, a substance that becomes as hard as concrete (Doubilet 1999). When corals die, another generation grows on their skeletons, creating gigantic underwater structures that can grow for millions of years.

About 2,000 species of fish inhabit Southeast Asian reefs, and worldwide, between 4,000 and 5,000 fish species have been found in coral reefs so far (Wells and Hanna 1992), including starfish, sea urchins, sea cucumbers, crustaceans and mollusks in an incredible array of forms and colors, some resembling feathery anemones, others boldly striped to warn of poison. Many squeeze into crevices in the corals, creating a tapestry of textures and hues. On the Great Barrier Reef alone, some 4,000 species of mollusks are found, including sea slugs, clams, snails and hundreds of species of cones, trumpet shells, cowries and scallops (Wells and Hanna 1992).

Coral reefs provide habitat for many endangered species. Sea turtles find food and shelter here. The now endangered Hawksbill Turtle (*Eretmochelys imbricata*) was once commonly seen in coral reefs around the world, feeding on sponges and invertebrates (Wells and Hanna 1992). Large numbers of sea birds live on the fish produced in coral reefs, and many sea birds nest on islands around the world that are surrounded by coral reefs. In recent years, coral reef ecotourism has increased. Tourists now gaze at the reef wonders through glass-bottomed boats and scuba masks, generating a new source of income for many countries. Tourism accounts for 55 percent of the Gross National Product of the Bahamas and is playing an increasingly important role in other tropical countries. Tourism is a major incentive for countries to enact strict legislation protecting their marine environments.

Ocean creatures have proven valuable to medical research, supplying compounds that treat inflammations, asthma, heart disease, tumors, infections, viruses and pain (Chadwick 1999). Sea animals, such as cone shells, sea snakes and stonefish, contain some of the most toxic poisons in nature. Such compounds are offering non-addictive solutions to the treatment of pain and other medical problems. Some chemicals in sponges and sea slugs may be useful as insecticides, and coral itself is being investigated for possible use in bone grafts (Chadwick 1999). Glucosamine, a compound found in the shells of crabs and related animals, has proven to be extremely effective in treating osteoarthritis, controlling both pain and the progression of the disease which destroys cartilage. It seems to be a building block for cartilage and has been used safely in Europe for generations. This nutritional supplement has been tested by the Arthritis Foundation in clinical trials, after which it endorsed the use of Glucosamine for osteoarthritis.

Finding new treatments for disease, and substances that can be used as glues obtained from barnacles, are among other ocean-based useful products. Future discoveries will depend on a healthy ocean that maintains its diversity.

Likewise, other types of sea and coastal ecosystem tourism have prospered in recent years. Whale watching has become a $1 billion industry worldwide, according to a 2000 study by the International Fund for Animal Welfare (BG 2000). At least 87 countries sponsor whale watching trips in 500 communities, allowing 9 million people to view these great mammals in 1998 (BG 2000). Cruises to Alaska, sport fishing, bird watching, hiking and other activities in non-tropical and freshwater destinations have also become far more important sources of income than resource extraction in many areas. The effects of the latter industries, including oil pollution, sedimentation from logging and pollution from mining, have decreased their income potential while destroying these precious ecosystems.

Destruction of Aquatic Ecosystems

As aquatic habitats are destroyed bit by bit, countless creatures and plants disappear. Crystalline bodies of water that furnished ample water to wildlife and people alike only a few centuries ago have become polluted or dried up. Growing human populations and development consume millions of acres of ecologically important coastal marshes and mangrove swamps to make way for airports, urban development, seaports, shrimp farms and resorts. More subtle changes are occurring from ozone depletion, acid rain and global warming caused by chemical pollutants in the atmosphere. These may end in far-reaching ecological changes and extinctions that are only beginning to be chronicled.

Less than 3 percent of the Earth's water is fresh, and two-thirds of it is frozen in glaciers and ice caps. The remaining 0.5 percent is contained in aquifers, rivers, marshes, other wetlands and in the atmosphere (Barlow 1999). Global population growth is expected to outpace freshwater supplies by 56 percent by 2025 unless patterns of use change radically (Barlow 1999). Water use has grown at more than twice the rate of population increase in the 20th century, according to the United Nations (Barlow 1999). Almost 70 percent of the world's population lives in areas bordering bodies of water such as rivers, coastlines and lakes, where civilizations have traditionally arisen (Dugan 1993). The United Nations reports some 80 countries, 40 percent of the world's population, are already facing water shortages (Lewis 1996). At least 20 percent of the world's peoples do not have clean water for drinking, according to a 1997 conference of Earth Summit Plus (Grossfeld 1997). Cities have been increasing in size, and the United Nations predicts that within a decade, most of the world's peoples will live in cities for the first time in the human history. Currently, 2.6 billion people live in urban areas; this total is expected to rise to 3.3 billion by 2005 (Lynch 1996). By 2025, 5 billion people, or almost all people now living on Earth, are expected to be city-dwellers, the vast majority in poor countries without effective pollution control or sufficient water supply, by UN estimates.

The United Nations believes that by 2025, the world's population will number 8.3 billion, with two-thirds living in conditions of serious water shortage and one-third suffering from severe water scarcity (Barlow 1999). Growing urban populations require more and more fresh water. Rivers and lakes have been dammed, diverted and channeled to supply these cities, often with disastrous consequences for wildlife. Since all portions of a river are part of the same ecosystem, when it is dammed or altered, the river and its wildlife and plants are affected throughout its length, which may extend over 1,000 miles. Wetlands at the mouth of a river can be drained by the construction of a dam hundreds of miles inland. Likewise, channeling at the mouth of a river, increasing flow for ship navigation, can drain wetlands and alter flow for the entire length of the river, eliminating native wildlife and plants. The Missouri River, for example, was once a shallow, sandy-bottomed river lined with trees and swamps. When Lewis and Clark explored the region in the early 19th century, they saw great numbers of sturgeon, trout and other fish, aquatic mammals, and vast flocks of cranes, waterfowl and shorebirds. During the 20th century, multiple dams were built, and the river was channeled to accommodate ship traffic, radically altering the Missouri's ecosystem. The shallow-water feeding grounds for birds were drowned, and migratory sturgeon and trout found their routes blocked, endangering many

species. After much opposition from barge operators and farmers, Congress funded a program in October 2000 to partially restore the flow to accommodate the needs of native wildlife by altering water releases from dams for a few months each year. Many conservationists are working to save even more of this original ecosystem.

Underground aquifers contain water that has been accumulating for thousands of years**.** Only in recent decades have they been exploited, and many are being over-pumped for city water supplies or agriculture. The High Plains Ogallala aquifer in the Great Plains of the United States stretches from South Dakota to Texas; pumping is depleting it eight times faster than it can be replenished naturally (Barlow 1999). This story is being repeated around the world, especially in desert regions such as North Africa, northern China and the Saudi Arabian peninsula, where fossil aquifers are being over-pumped for agriculture, industry and household use (Barlow 1999). This is resulting in their gradual depletion, contributing to a future "water bankruptcy" (Barlow 1999). Countries in arid regions are already competing for scarce water supplies. The Euphrates River has been dammed by Turkey, turning its flow to a trickle by the time it reaches Iraq. The latter country has become increasingly arid over the past few thousand years as grassland and bountiful water supplies deteriorated to desert as a result of over-use of water and drainage of wetlands.

Trade treaties, such as the North American Free Trade Agreement (NAFTA) signed between the United States, Canada and Mexico and the World Trade Organization (WTO), whose members include the majority of countries, override national water rights, assigning them to corporations and other commercial interests. Water is now being bought and sold as a commodity. One large company, the US Global Water Corporation, has signed an agreement with Sitka, Alaska, to transport 18 billion gallons of glacier water per year to China, where it will be bottled and sold (Barlow 1999). A California company was denied the ability to purchase water from British Columbia and, under the principles of NAFTA, sued the government of Canada for $220 million (Barlow 1999). Environmental and species preservation are not considered in these global transactions. By treating water as a commodity to be traded to the highest bidder, ecosystems will be devastated. The International Forum on Globalization of San Francisco outlines many of these issues that point toward future catastrophes for the environment and human society alike in its report, *Blue Gold*. It concludes that only if water is considered to be commonly shared by humans and all species, and water diversion, damming, pollution, sale and bartering are halted, can there be hope for the future (Barlow 1999).

In the United States, only the onset of droughts brings about restrictions on water usage. Agriculture and livestock use an estimated 65 percent of the country's water supplies, households 10 percent and industry 25 percent. Much of the water used for agriculture comes from diverted rivers in irrigation programs which return it to water tables contaminated with large amounts of pesticides, herbicides and artificial fertilizers. An American family of four uses 300 gallons a day, far more than the average in most of the rest of the world. This profligacy has been at the expense of natural ecosystems. As human populations grow, water use will result in ever more strain on water supplies. Cities have sprung up in near-desert regions in the United States, requiring water diversion from other areas. One of the most dramatic examples of this is Los Angeles. The major flows from several rivers and lakes have been diverted to supply the needs of Los Angeles (Reisner 1986). Only with artificial water supplies has this city been able to grow to metropolis size. Its denizens waste their water supply to grow green lawns, and an enormous amount is used by local industry and agriculture. Los Angeles' water has been supplied at the expense of wildlife and plant species native to the diverted and drained water bodies, many of which are now endangered (Reisner 1986). Salmon and other fish have become endangered in the source rivers and lakes used to supply Los Angeles. Las Vegas, Phoenix and other western cities also tap the scarce water resources of the West. The diversion of water from natural rivers and lakes for large cities and massive agriculture projects is destroying aquatic oases in dry areas and drying up entire rivers in deserts, endangering species as diverse as tortoises, Bald Eagles (*Haliaeetus leucocephalus*) and songbirds.

Half of the people in developing countries suffer from illnesses associated with contaminated water, such as chronic diarrhea (Grossfeld 1997), and more than 5 million people, most of them children, die every year from these illnesses (Barlow 1999). Conflicts over water resources between countries and states are increasing, and in the future, wars may be fought over dwindling water supplies.

Although marshes are able to filter limited amounts of nutrient-laden water, raw, untreated sewage dumped into waterways can turn them into fetid, oxygenless mires. Ninety percent of the sewage in the swelling cities of poor countries is untreated, having had none of the solid matter removed, according to the World Resources Institute in Washington, DC. Some rivers, such as the Ganges and Brahmaputra River systems, are so polluted that the native dolphin, the endangered Ganges River Dolphin (*Platanista gangetica*), struggles to survive in the contaminated water. Fish are killed by the pollution, leaving the dolphins without food, and the high bacteria counts may be killing these dolphins directly. The Ganges has become so sewage-laden that it presents major health risks to the people who drink from and bathe in its water. This is especially ironic because this river is a holy river to the millions of Hindus who come to anoint themselves in its water. India has more than 3,000 towns and cities, but only eight of these have sewage treatment plants (Crossette 1996). Even sewage treatment systems can overflow during heavy rains, spilling toxic chemicals and oily runoff from roads, as well as untreated sewage. Since almost half of the world's population lives in cities, this is one of the world's most serious environmental problems.

The failure to conserve forests and vegetation has become a major factor in destroying natural aquatic ecosystems around the world. Besides causing mud slides and floods, the cutting of trees bordering rivers and streams also results in a rise in water temperature that affects the local climate and kills fish eggs and other wildlife. Clear-cut logging also causes siltation of rivers and lakes, smothering fish and wildlife. Salamanders, who require damp, undisturbed forest floors, are often eliminated by clear-cut logging. James Petranka of the University of North Carolina estimates that in the national forests of North Carolina, 14 million salamanders are wiped out every year by clear-cutting (Stolzenburg 1997). Extreme deforestation causes streams, springs, ponds and rivers to dry up and the regional climate to become more arid.

Oceans were once thought resilient to heavy pollution and the dumping of all types of debris. We are learning, however, that the combined effects of overfishing, killing of coral reefs and toxic contamination are turning them into aquatic deserts, according to Dr. Sylvia Earle, an eminent oceanographic scientist, and conservationist-author, Carl Safina (Earle and Henry 1999, Safina 1997). The oceans have also become crowded with commercial ships, fishing boats and pleasure craft, all of which are causing problems for wildlife. These ships discard plastics and other material and pose a threat of collision. Several cruise lines have been indicted and fined in recent years for dumping illegal materials overboard, including plastics, large amounts of waste oil and other toxic substances.

Coral reefs have proven very delicate and vulnerable to die-offs. Pollution, overfishing, cyanide poisoning and dynamiting to obtain tropical fish for the aquarium and Asian restaurant trades, or corals for the curio trade have all contributed to severe losses in the 70 million square miles of coral reef around the world.

Natural, unpolluted aquatic environments are fast disappearing around the world. Approximately 50 percent of the world's wetlands have been lost in historic times, according to *Wetlands in Danger: A World Conservation Atlas* (Dugan 1993). In the past, wetlands were destroyed primarily for agricultural development. Although this remains a major threat, programs such as dam construction and irrigation projects financed by the World Bank and the International Monetary Fund are becoming the major threat to pristine aquatic environments around the world. Unfortunately, the effects of these losses are usually appreciated too late, when species disappear and water ecologies are damaged.

Soils in many dryland areas have become polluted by salinization caused by irrigation schemes. Irrigation water flowing onto drylands brings to the surface substratum minerals and salts, which render the soil unfit for agriculture or almost any natural vegetation. Regions covering at least 150,000 square miles worldwide have become too saline to farm after irrigation programs (Dugan 1993).

Threatened Species

Approximately 41.4 percent of the 5,435 animals listed by the 2000 IUCN Red List, 2,251 species, are native to aquatic environments. Many more are in lower categories of threat such as near threatened or possibly threatened. Of these, 88 percent are native to inland or freshwater. At least 790 species of fish are threatened with extinction, 627 of these native to freshwater. This is an indication of the effects of dams, pollution and introductions of non-native fish that out-compete native species. Reptiles, totaling 111 species, are threatened by habitat destruction through wetland drainage and pollution, as well as demands of the pet, meat and skin trades that are pushing a growing number of turtles, crocodiles, chameleons and other lizards toward extinction. The threats to amphibians, especially frogs and toads, have grown dramatically in recent years, with environmental factors, such as UV radiation from ozone thinning, pesticide use, wetland destruction and pollution, playing important roles.

(Higher Categories of Threat)

	Marine	Inland Water	Total

Plants	0	14	14
Grand Totals	320	1,945	2,265

Based on 2000 IUCN Red List of Threatened Species Compiled by Craig Hilton-Taylor. International Union for the Conservation of Nature and Natural Resources, Gland, Switzerland, Cambridge, U.K.

The number of threatened whales, dolphins, porpoises, manatees and seals has greatly increased in recent years. Moreover, many species have been upgraded in status to more endangered categories. Pollution, killing for meat and drowning in fishing nets play roles, but clearly more research needs to be carried out as to whether there is sufficient food for the large whales, such as the Blue, Fin, Sei, Gray and Northern Right Whales, none of which has recovered from past whaling. In the early 1980s, the IUCN, in its various Red Data Books, listed only three species of dolphins and six whales as threatened. In the 2000 IUCN Red List, 25 dolphins, six porpoises and 35 whales are listed in various categories, a dramatic increase. Marine ecological systems are becoming imbalanced as a result of overfishing. Gray whales have been washing ashore dead in unprecedented numbers on the North American Pacific coast. Many are thin and appear to have died of starvation, either from overfishing of their food supply or effects of changes in ocean temperatures brought about by El Nino or La Nina, which can greatly alter the types of fish remaining in an

area. Destruction of sea beds is caused by fishing trawlers who rake sea beds for scallops and groundfish, obliterating entire communities of anemones, starfish, sea grass and habitats for a variety of fish and invertebrates.

A major increase in the number of threatened sea birds has also occurred. The number of threatened albatross has risen from two in the early 1980s to 20 in recent years. Similarly, only two species of penguins were threatened in the early 1980s, while 12 were listed in 2000. Petrels, small nocturnal sea birds that were once abundant, had 12 threatened species in the 1980s, mainly from disturbance of their nesting islands. At present, more than 40 species of petrels and storm-petrels are threatened with extinction. A major cause is long-line fishing for tuna, swordfish and other billfish, with baited hooks that attract albatross and petrels. Sea birds and birds that live along coastlines, lakes and rivers have been endangered by marsh drainage and pollution, human encroachment on their nesting habitats and invasions by exotic species of plants and animals.

The vast majority of threatened fish listed by the IUCN are freshwater species, but this may be an indication of our ignorance about the status of marine fish. The 1990 IUCN Red List included 751 species of fish in various categories (WCMC 1990). That number rose to 979 in 1994 (WCMC 1993), and in the 1996 IUCN Red List, 1,091 species were listed in all categories. The compilers of the 1996 edition of the IUCN Red List noted that only a small portion of the world's fish have been evaluated in terms of their status, and almost no marine species have been researched (Baillie and Groombridge 1996). The 2000 IUCN Red List listed 752 species in its three highest categories, an increase of 18 species from 1996. Worldwide, the status of the majority of fish has not been appraised. Ignorance of marine fish populations has contributed to their depletion in commercial fisheries, which are pushing many species toward extinction (see Trade chapter).

North American freshwater fish are perhaps the best known in terms of the status of the world's fish because of long-term biological studies and the state Natural Heritage Programs, which have a data bank of rare, endemic, declining and imperiled species. Two reports compiled by The Nature Conservancy, 1997 Species Report Card: The State of US Plants and Animals (Stein and Flack 1997) and the book Precious Heritage: The Status of Biodiversity in the United States (Stein et al. 2000), were based on data from the Natural Heritage Programs in all 50 states. The organization found that 16 species of United States fish have become extinct in recent times, and one species is possibly extinct; 93 species are critically imperiled, 88 species are imperiled and 116 are vulnerable. This total of 314 species comprises 36.1 percent of all American fish, which makes for an extremely high rate of endangerment (Stein and Flack 1997).

A major threat to native fish in the United States is the introduction of non-native species, usually game fish such as exotic trout, by state fish departments. Rainbow trout, for example, have been introduced in areas where they are not native, and have out-competed and endangered native cutthroat trout in the West, as well as introduced disease caught in fish hatcheries. Few other countries have undertaken such detailed studies of endangered native wildlife, but in countries where freshwater ecosystems have been greatly altered by channeling, diversion, dams and pollution, research would likely find similar rates of endangerment. In China, 80 percent of major rivers are so degraded they no longer support fish (Barlow 1999).

Frogs and toads represent the most dramatic rise in threatened species of any vertebrate. Their plight may be indicative of the serious environmental threats facing the Earth. Because of their thin, porous skin, frogs are extremely sensitive to environmental contaminants. Within the past few decades, a large number of frog and toad species have disappeared all over the world. Many have been found with grotesque deformities and diseases. What is happening to the frogs appears to be an early warning of serious threats to the Earth's aquatic ecosystems and to its atmosphere. The scale of the recent disappearance of frogs around the world has not been seen since mass extinctions that occurred millions of years ago. The ecological effects will be significant because of their important role in consuming insects and as food items for a large number of animals, from birds to reptiles.

In the 1979 IUCN Red Data Book of Threatened Animals, a world review found 18 species of frogs and toads to be in various categories of peril; in the 1990, the number of threatened frogs and toads had almost doubled to 35, and in

1994, 130 species were listed Œ more than triple the previous total (WCMC 1993). The 141 species in various categories in the 1996 IUCN Red List represented a fourfold increase since 1990 and an almost eightfold increase since 1979. This total grew to 173 frogs and toads in all categories in the 2000 IUCN Red List, with 112 in the three highest categories of threat. Thus, threatened frogs and toads have increased 10 times in number from 1979, a trend not seen in any other large group of vertebrates since such studies began.

The threats to these amphibians are not regional. Frogs are threatened wherever they exist, declining in 140 countries, with status research continuing (Stolzenburg 1997). A worldwide phenomenon is occurring, endangering amphibians and causing extinctions at a spiraling rate. Among the first to disappear were two newly discovered and highly unusual frog species that had been acclaimed as remarkable by scientists around the world. These frogs came from the rainforests of Australia and had astounded the scientific world with their breeding biology. Their life history was so extraordinary that the man who first described it had his paper rejected by a prestigious journal for being implausible. Michael J. Tyler, associate professor of Zoology at the University of Adelaide, discovered these species, known as gastric brooding frogs (Rheobatrachus silus and Rheobatrachus vitellinus), and was beginning research on potential applications of their amazing ability to turn off gastric acids to the treatment of human stomach ailments. These frogs were filmed before their disappearance, which documented that they swallow fertilized eggs that grow in the female's stomach and emerge six weeks later as tiny froglets when she opens her mouth (Yoffe 1992). In 1980, only a few years after their discovery, this species and others in the area vanished; they have not been seen since (Yoffe 1992).

The dazzling golden toad (Bufo periglenes) also disappeared suddenly. Jay M. Savage of the University of Miami came upon this species, native to the cloud forests of Costa Rica, in 1964 in Monteverde Cloud Forest Reserve, witnessing large gatherings of males during the breeding season (Phillips 1994). National Geographic Society filmmakers, in making the film, fiRainforest,fl recorded the assemblages of hundreds of these colorful toads perched on rocks among misty streams, and also filmed their far less flamboyant mates. Less than 2 inches long, male golden toads were bright, shiny orange, in contrast to the slightly larger females who were dark olive to black with spots of red encircled by yellow (Phillips 1994). Depicted on tourist posters and protected in its reserve, the Golden Toad's future seemed assured. No studies were carried out to discover its haunts during the rest of the year, however (Phillips 1994). Tourists flocked to Monteverde, many drawn to see the beautiful toads. In 1987, an American biologist, Martha Crump, witnessed the last breeding group of golden toads. "They've been described as little jewels on the forest floor, and that's really the impression you get," she recalled years later (Phillips 1994). With a grant from the National Geographic Society, she returned in 1988 for two seasons of research (Phillips 1994). In 1988, only 10 toads were seen, and only one male was in the breeding area; in 1989, only one toad was seen (Phillips 1994). None have been seen since (Yoffe 1992); the protected area was enlarged to 26,000 acres in the early 1990s to preserve as much forest as possible.

Two other inhabitants of this cloud forest, a species of translucent glass frog (Yoffe 1992) and an endemic harlequin frog (Stolzenburg 1997) have become very rare. A total of 20 other frog species are also missing from this region, based on a survey of Monteverde by a University of Miami biologist in 1996 (Blakeslee 1997). In Ecuador's high Andes, an estimated 50 species of frogs have disappeared since 1990. In Puerto Rico's rainforests, 12 of 18 endemic frogs are extinct or nearly so (Stolzenburg 1997).

The first World Congress of Herpetology, for the study of reptiles and amphibians, convened in 1989, and many of the 1,300 participants began comparing notes on the shocking fact that the subjects of their research were disappearing from under their very eyes. A comprehensive study was undertaken under the guidance of the IUCN's Declining Amphibian Populations Task Force (DAPTF) (www.open.ac.uk/daptf) to standardize methods of study of amphibian population changes and the environmental factors that may be affecting amphibian reproduction and survival (Stebbins and Cohen 1995). The 1989 conference inspired a symposium the following year that addressed this problem, recruiting 1,000 researchers in 40 countries. The reports from these researchers are published in a bulletin known as the Froglog, published by DAPTF on its website.

What is happening to the world's frogs? Many of the traditional causes still contribute to declines in amphibian populations. Marshlands and boggy areas continue to be filled in and polluted; pesticides, herbicides and other toxic chemicals are entering aquatic ecosystems, causing mortality and mutations. Introduced predatory fish and even exotic frogs have eliminated some frog populations (Yoffe 1992). Trade in frogs for the gourmet food market and for high school biology dissections has also played a role in the declines of some species. Some tropical frogs are known to have succumbed to a protozoan, which kills many and weakens the immune systems of others, making them vulnerable to a host of other pathogens (Blakeslee 1997). The disappearing frogs are not all from polluted areas. Some are native to remote wilderness areas, national parks and other pristine areas. The most surprising possible cause for their disappearance is the increased ultraviolet (UV) radiation resulting from the thinning of the ozone layer. This has been the subject of much research. The thinning of the Earth's ozone layer is caused by Chlorofluorocarbons (CFCs), chemicals used as coolants, aerosol propellants and for other industrial purposes. When released into the atmosphere, they turn into chlorine and destroy the thin-but-vital layer of ozone that shields the Earth from harmful UV radiation. Chlorine-based solvents have also had this effect. First noticed in the 1970s and early 1980s when holes appeared in the ozone layer at the Earth's poles, many years passed until the cause was proven. Those who discovered this phenomenon were awarded the 1995 Nobel Prize in Chemistry, marking the first time this prize was ever awarded for achievement in environmental science. The recipients were Dr. F. Sherwood Rowland of the University of California, Dr. Mario Molina of the Massachusetts Institute of Technology and Dr. Paul Crutzen of the Max Planck Institute for Chemistry in Germany.

Holes and thinning of the protective ozone layer have allowed an increase in the amount of injurious ultraviolet rays reaching the Earth, which has brought about a dramatic rise in the number of human skin cancer cases, as well as declines in amphibian populations. Although the use of CFCs has been banned in new appliances and air conditioners in the United States, the chemical is still used in older cars and refrigerators, escaping to the air from malfunctioning units and improper disposal of these appliances. Illegal CFC imports into the United States have been documented, and some countries still allow their use. CFCs will take at least a century to disappear from the upper atmosphere, according to scientists.

In 1996, Yale University researchers made a discovery that may help stem the breakdown in the ozone layer. A chemical extract obtained from rhubarb and related plants, sodium oxalate, can chemically break down CFCs when heated to 520 degrees F. (Sharkey 1997). The practical use of this discovery is years away, but it may prove to be effective in controlling this lethal phenomenon.

As ancient bridges between land and sea, amphibians were named from the Greek words amphi and bio, meaning living a double life, indicating they were both aquatic and terrestrial. Frogs and salamanders are the only two major groups of amphibians, and they form an evolutionary link between fish and reptiles. First emerging in the Triassic period 200 million years ago, frogs have outlasted dinosaurs, and until recently, most biologists considered them hardy and adaptable species (Yoffe 1992). The vast majority of the approximately 4,100 species live in tropical areas. They must hibernate to survive cold, temperate winters, and relatively few species have evolved this adaptation.

The breeding biology of frogs and toads is a fascinating study in variety. There are frogs that develop marsupial pouches like tiny kangaroos to carry their fertilized eggs, and species in which the males incubate tadpoles in their vocal sacs until they emerge (Stebbins and Cohen 1995). The parent of one tropical frog hops across the forest floor carrying a single tadpole sticking with a mucus to its back; it climbs a tree and steps into a bromeliad plant, placing the tadpole into a tiny amount of water (Roberts 1996). The female returns to lay unfertilized eggs for the tadpoles to eat; she must remember which bromeliads, of the thousands in the area, contain her tadpoles. When the female enters the bromeliad containing her tadpole, it instinctively wriggles, causing vibrations in the water which stimulate the mother to lay eggs for it to eat (Roberts 1996). Wendy Roberts, a biologist who has studied the many reproductive methods used by tropical frogs, believes that as long as frog populations do not continue to disappear, more discoveries of the extraordinary variety of their reproductive biology, parental care and behavior will be made (Roberts 1996). Some toads have even adapted to desert mud holes by burying themselves and entering a torpor-like state until it rains again.

The decline of North America's frogs and toads afflicts fully one-third of the 86 species (Yoffe 1992). Their disappearance in wilderness areas was documented as early as the 1970s. David Bradford, a biologist now with the Environmental Protection Agency, studied the Yosemite toad (Bufo canorus) and Mountain yellow-legged frog (Rana muscosa) in Yosemite National Park in the 1970s at 26 sites. When he returned in 1989 and visited each site, he found frogs had disappeared from all but one site (Yoffe 1992). A 1992 survey concluded that three of the eight toads and frogs native to the Yosemite region have nearly disappeared: the red-legged frog (Rana aurora), which has since been listed on the US Endangered Species Act; the Foothill yellow-legged frog (Rana boylei); and the Great Basin spadefoot (Scaphiopus intermontanus) (Yoon 1996). The Yosemite toad declined or disappeared at nine of the 13 original sites where a 1915 survey had found them abundant (Yoon 1996). Because of the longevity of toads, some living to be 35 years old, declines may go unnoticed as long as adults are alive, even though all their offspring may be dying year after year. Stebbins and Cohen (1995) documented declines in a number of once-common species in their text, A Natural History of Amphibians. Northern leopard frogs (Rana pipiens) and nine other species have become rare or absent in former haunts (Tyning 1995). The latter species has been dissected by the millions in high school biology classes, many of which require the students to kill the frogs, often by cruel means.

Dr. Andrew Blaustein, a herpetologist at Oregon State University, studied the Western toad in lakes in the Cascades Range at 4,000 feet for many years. By the mid-1980s, he found that these toads were becoming rare, yet in the same habitat, Pacific tree frogs (Hyla regilla) seemed to be thriving (Blaustein 1994). Female Western toads produce 12,000 eggs in long strips that are laid in unshaded ponds, and then they disappear into the forest, leaving the eggs to hatch in the shallow water (Blaustein 1994). Dr. Blaustein began to find eggs that did not develop properly, turning white, and then dying and leaving a fetid, viscous mass (Blaustein 1994). Other amphibians of these mountains, the Cascades frog (Rana cascadae) and the red-legged frog, had also disappeared completely from most of their range (Blaustein 1994).

Dr. Blaustein and a colleague decided to conduct outdoor and indoor experiments to test the reactions of frog eggs to ultraviolet radiation. Trays of frog and toad eggs in water were placed outdoors, and some were exposed to UV rays; others screened from UV-B rays, the most harmful type of radiation; still more eggs were brought into the lab and kept in darkened conditions (Blaustein 1994). Ninety percent of the eggs raised indoors, as well as those screened from UV rays outdoors, developed normally, while 40 percent of the unscreened eggs exposed to UV rays died (Blaustein 1994). Here was proof of the effect of present levels of UV rays. Dr. Blaustein and other biologists have concluded acid rain is combining with UV radiation in some areas to kill frogs and toads (Yoon 1996).

Some frogs and toads are dying of unknown causes. One biologist studying the Western toad (Bufo canorus) in a wilderness area in Colorado in the 1970s came upon dozens of dying toads, barely able to move because of their puffy red legs (Yoffe 1992). She took several of them to a veterinarian and was told their immune systems had collapsed, making them vulnerable to infection (Yoffe 1992). Biologists in Massachusetts have found wood frog (Rana sylvatica) tadpoles dying of disease outbreaks in three of four recent years (Knight 1995).

Grotesquely deformed frogs have been discovered recently in many parts of the United States. In 1995, a biology class found frogs with shocking malformations near Henderson, Minn. Some were missing both hind legs; others had as many as six legs, and at least one had an eye growing in its mouth. Another had a leg growing from its stomach. Many had only one leg, one eye, four tangled hind legs, misshapen limbs and tails, missing or shrunken eyes and small sex organs (Associated Press 1996). These deformed frogs were shown on national television news programs throughout the country. Researchers found similar frogs in 1996 and 1997 in California, South Dakota, Wisconsin, Vermont and Massachusetts, as well as in Quebec, Canada. Up to 35 percent of frogs in these areas may be deformed. Within a year, deformed frogs were seen in 54 of 87 counties in Minnesota. A herpetologist from the University of Minnesota at Morris examined 10,000 frogs in the summer of 1996, finding the greatest number of abnormalities in frogs that spent the majority of their lives in water, rather than coming to water only to lay eggs. Vermont's leopard frogs had a 45 percent deformity rate, and for the first time, deformed salamanders were found. Three five-legged salamanders were found in Massachusetts, an ominous sign this phenomenon is spreading to another type of

amphibian.

At the Scripps Institute in California, laboratory tests on frogs produced similar deformities when they were exposed to the commonly used mosquito pesticide, methaprine. This chemical affects growth hormones, causing them to malfunction. In September 1997, officials of the Minnesota Pollution Control Agency announced they reproduced the deformities when frog eggs were raised in tap water from areas with deformed frogs. They issued a public health alert based on this research, providing bottled water to people living in these areas. One Minnesota biologist found internal and external abnormalities in these frogs. EPA studies found deformities when frogs were exposed to ultraviolet rays as well. These findings indicate certain pesticides and UV radiation present major threats to amphibians. Other studies have shown parasites can also cause deformities (Yoon 1999).*

North American researchers have organized the Great Lakes Declining Amphibians Working Group, as well as the North American Amphibian Monitoring Program, maintained by the US Geological Survey of the Department of the Interior. The FROGWATCH USA website gives advice to concerned citizens to learn more about aiding this situation. The US Fish and Wildlife Center provides information about the population status of various amphibians, as does AmphibiaWeb, run by noted herpetologist, Dr. George B. Rabb.

The disappearance of frogs and toads may seem insignificant to many people. From an ecological point of view, however, these animals play an important role in controlling insect populations. After frogs were nearly extinguished in Bangladesh to supply gourmet tables in France with frog legs, mosquito numbers and the incidence of malaria skyrocketed (Yoffe 1992). Frogs themselves are a major food item for a wide variety of animals, from storks to raccoons. They are an important link in the food chain, and their extinctions may have a major effect on a wide variety of other species and even evolution itself (Yoffe 1992).

From a human health point of view, frogs and toads have proven to be the source of many valuable medical compounds. Dart-poison frogs of Central and South America are more terrestrial than species that spend their lives in water, and to protect themselves, they have developed some extremely potent poisons that they excrete through their skin. Natives have used these chemicals on the tips of their arrows for hundreds of years to kill prey as large as monkeys. These tiny, brightly colored frogs are being studied by the National Institutes of Health for the alkaloid compounds found in their skin, which are used in research on nerve and muscle function, and as anti-convulsants and anti-arthritics (Sharp 1995). Another compound found in the skin of an Ecuadorian dart-poison frog has 200 times the pain-killing power of morphine (Sharp 1995).

Preserving Aquatic Ecosystems

Only recently have some aquatic environments received protection in some parts of the world. New marine sanctuaries that protect coral reefs and other sea life have been set aside in a growing number of countries. In 1994, Australia, the United States and six other nations founded the International Coral Reef Initiative to encourage preservation of reefs endangered by pollution, overfishing and other causes. In the future, sanctuaries and international agreements will provide major means of conserving these ecosystems. Unfortunately, many of these sanctuaries allow commercial fishing and the collection of mollusks. The value of aquatic ecosystems in preserving biodiversity is only beginning to be appreciated, aided by the growing popularity of bird-watching, scuba diving and coral reef tourist visits that are educating many people about the importance of protecting these fragile ecosystems.

Private organizations and universities are playing important roles in monitoring and conserving delicate aquatic habitats. The International Marine life Alliance, based in the Philippines, is convincing fishermen to catch fish in hand nets, rather than poison or dynamite reefs. The Global Coral Reef Alliance is investigating diseases that are

afflicting reefs through scientific research, and Greenpeace International has been active in conducting worldwide surveys of the deterioration of coral reefs. Depletion of species by overfishing and consequent imbalances in reef ecosystems and biodiversity are being undertaken in various parts of the world. A Canadian researcher, Amanda Vincent, who documented a dramatic decline in seahorses as a result of over-harvest for Chinese Traditional Medicine, has been working with Philippine fishermen to limit catch and set aside sanctuaries where stocks can increase. Woods Hole and Scripps Oceanographic Institutes are conducting important research in marine environments, studying subjects as diverse as the effects of US Navy sonar testing on whale behavior and deep- sea environments. Small and maneuverable submarines are now exploring deep- sea ecosystems, taking samples of new species and filming these extraordinary habitats. Almost all such research is funded by non-governmental organizations, since governments have yet to realize the importance of funding such research.

International efforts began as early as 1973 to control Marube debris and pollution when the International Maritime Organization, a United Nations agency responsible for shipping, formed an agreement known as MARPOL. This agreement regulated the disposal of oil and hazardous chemicals. In 1978, it was amended to include annexes on the disposal of hazardous materials, sewage, fishing nets, ropes, bags and trash. In 1988, the Marine Plastics Pollution Research and Control Act was enacted by Congress, prohibiting United States ships from dumping plastic items into the sea, and prohibiting foreign ships from disposing of plastics within 200 miles of the United States. Plastics include such items as nylon fishing nets. As of 1994, all US government-owned ships had to comply with all regulations, disposing of plastic waste at port. The National Oceanic and Atmospheric Administration (NOAA) has an interagency task force on marine debris, which has attempted to coordinate other federal agencies to reduce marine debris. The Environmental Protection Agency, with the Center for Marine Conservation, and NOAA coordinate annual beach cleanups, which are now being carried out in some European countries as well as in the Middle Eastern country of Bahrain. Thousands of tons of plastic bags and fishing lines that might have washed back out to sea have been removed by these cleanups. The Marine Entanglement Research Program was established by NOAA in 1984 to study this problem.

As a result of international concern about the disappearance of irreplaceable wetlands, the Ramsar Convention was adopted in 1971. Each member country designates and accords legal protection for at least one wetland to be included in the *List of Wetlands of International Importance*. More than 600 Ramsar sites have been designated, covering 100 million acres. Some of these wetlands, in spite of designation, are threatened by government-sponsored plans. The Acheloos Delta in southwestern Greece may be diverted to produce electricity, and a huge flood-control plan threatens Lake Utonai in Japan. The Ramsar Convention has been instrumental, however, in protecting wetlands through international cooperation. The Wadden Sea, a wetland on the coasts of the Netherlands, Germany and Denmark with up to 12 million birds wintering, breeding or migrating through its land, is being protected through cooperative agreements among the three countries (Dugan 1993). These wetlands are not in their natural state after centuries of diking, filling and other man-made changes, but efforts are being made to maintain large areas of marshland and other wetland habitat.

The North American Wetlands Conservation Act of 1989 created funding to preserve wetlands in Canada, the United States and Mexico; since 1989, hundreds of projects have protected more than 1 million acres of wetland ecosystems in the United States and Canada alone. A prime area preserved by this act is Cheyenne Bottoms, the last sizeable wetland in Kansas, designated as a "Wetland of International Importance" by the Ramsar Convention, a Hemispheric Reserve by the Western Hemisphere Shorebird Network, and Critical Habitat for the endangered whooping crane (*Grus americana*). To date, 6,000 acres have been protected, 35,000 restored and another 13,000 acres of Cheyenne Bottoms enhanced (Graziano 1994).

Another important aquatic environment, the lagoons of Baja California, has been designated a Biosphere Preserve. Under great threat from a proposed salt factory to be constructed by Mitsubishi Corporation in the prime wintering lagoons of gray whales, conservationists succeeded in stopping the project in late 2000. This preserve also shelters sea turtles, many sea birds and other marine mammals. Mexico's laws did not permit such damage to an officially declared Biosphere Preserve, but it nevertheless took years of legal wrangling and the participation of many

conservation organizations to achieve this victory.

National anti-pollution legislation in many countries is making some progress in bringing back rivers and wetlands that had become lifeless from heavy pollution. International treaties have also been negotiated for individual rivers. The Danube River flows 1,770 miles from its source in Germany to the Black Sea, and along its entire length, it has been diked, dammed and channeled to accommodate barge traffic (Cowell 1995). In Hungary, the river inspired the famous waltz of that name and has been severely damaged by dams and diversion on the Slovak side, which have shunted most of the water from one of Europe's wildlife havens. This 200 square mile area is one of Europe's last wetlands, sheltering some 5,000 species of flora and fauna, and Hungary continues to negotiate its return.

The Danube Delta on the Black Sea lies mainly in Romania and is considered one of the world's great wetlands, covering 2,200 square miles (Simons 1997). In the mid-1980s Romania's dictator, Nicolae Ceausescu, decreed that the entire delta be transformed into grain fields (Simons 1997). He succeeded in destroying about one-fourth of the delta, or 240,000 acres, converting the land into wheat and rice fields. Not only was massive wildlife habitat lost, but his men shot pelicans and cormorants because they were eating too many fish (Simons 1997). The drainage plan did not succeed because the delta soil was not conducive to these crops, and by the time Ceausescu was executed by firing squad in 1989, it had been abandoned (Simons 1997).

In 1991 the Danube Delta was declared a Biosphere Preserve, and a conservation plan was set in place; as a first act, dikes and dams were breached, allowing the flooding of more than 9,000 acres (Simons 1997). As a feeding and resting area for millions of migratory birds of 325 species, the delta is of global importance (Simons 1997). It is also a major nesting area for many threatened birds, including the Dalmatian pelican (*Pelecanus crispus*), a bird that was once abundant throughout Western Europe (Hoyo *et al*. 1992). Today, it is confined to eastern Europe and east-central Asia, with approximately 4,000 to 5,000 breeding pairs; fortunately, as a result of strong conservation programs, massive declines have been stopped or slowed (BI 2000).

An ecotourist industry has sprung up in the Danube Delta, helping to fund further restoration (Simons 1997). Anti-pollution work will be needed to cleanse the waters of an overload of contaminants poured into the river by the eight countries through which it flows (Simons 1997). This is the world's first example of the restoration of a delta and is founded on the philosophy that land valuable as flood protection and wildlife conservation is worth more in its natural state than converted for human use (Simons 1997). Experts involved in Mississippi and Rhine River restoration have been interested in the Danube restoration, which may herald a new approach to this crucial habitat.

Sections of rivers have received protection under the Wild and Scenic Rivers Act. This law and the actions private organizations such as American Rivers have succeeded in altering the pro-dam and channeling viewpoint that long has dominated America. The International Rivers Network has also worked to oppose dams around the world, often with great success. On the local scene, River Network, an organization founded in 1988, works at a grassroots level to encourage citizens to help clean up and preserve rivers and watersheds. Its book, *How to Save a River: A Handbook for Citizen Action* (Bolling 1994), provides a blueprint for individual conservationists. The Water Keeper Alliance, first launched to save the Hudson River from heavy pollution, works on many rivers in the United States to test water for pollution and works through activists and lawyers to stop pollution problems (Cronin and Kennedy 1997). Teachers and their students in countless school districts have adopted streams and rivers, removing trash and debris, and restoring them to their original states, even reintroducing native fish.

Progress is also being made in the United States in restoring wetland ecosystems. The Everglades is America's largest wetland. It was a vast, unspoiled marsh, a wilderness of sawgrass, groves of Bald Cypress trees and vegetated hillocks until only a century ago. Fresh water flowed through the 7 million acre Everglades from the enormous, 733 square mile Lake Okeechobee and its feeder rivers to the north, ending in Florida Bay (Levin 1996). During the dry season, rivers threaded their way through the wetland, and in spring wet seasons, the entire region would turn into a shallow river of grass. At one time, more wading birds nested here than anywhere else in the country. Four hundred species of birds, 60 species of amphibians and reptiles, and 25 species of mammals have been recorded in the southern

Everglades alone, and at least 120 species of trees and 1,000 species of seed-bearing plants are native (Rex 1996).

Giant century-old alligators (*Alligator mississippiensis*) prey on a diversity of fish, turtles and snakes. River otters (Lutra canadensis) and tiny white-tailed deer (*Odocoileus virginianus seminola*) are also native. The round-tailed muskrat (*Neofiber alleni*) is found nowhere else. This rodent, dependent on shallow, freshwater marshes, has been affected by the invasion of exotic plants that have taken over much of the Everglades (Layne 1978). The Everglades mink (*Mustela vison evergladensis*) lives south of Lake Okeechobee, far from other races of mink. These animals are aquatic, utilizing much the same type of habitat as the round-tailed muskrat, although they are far more restricted in range (Layne 1978). Both species have declined as a result of development, water pollution and reduction of acreage of the freshwater marshes (Layne 1978).

Settlers arriving in Florida in the 19th century saw only a "pestilence-ridden swamp." The US government drained the entire wetland for development and agriculture, building the first federal canal in 1881 with enthusiastic state support. In 1905, the Governor of Florida vowed to wring the last drop of water out of the Everglades, and state drainage programs supplemented federal projects. Congress passed legislation in 1947 that authorized a massive program to control the flow of the Everglades, ostensibly to prevent flooding; 1,400 miles of canals, dikes and levees were built to straighten and channel the meandering Kissimmee River, the major feeder of Lake Okeechobee, in order to divert water for sugar growers south of the lake (Levin 1996). Four canals drained the lake and lowered water level by 5 feet; 3 to 4 million acres of its water were diverted toward the Atlantic every year, water that once fed the Everglades (Levin 1996). South of the lake, 500,000 acres were drained for agriculture. The same year this project was authorized, a strong-willed newspaper reporter, Marjory Stoneman Douglas (1947), wrote *The Everglades: River of Grass*, pleading for the preservation of this great wetland. She carefully researched the conservation importance of the Everglades and documented the folly of destroying it to appease the growing agriculture industry. The book remains a classic, and not until the 1990s did the country realize that the drainage project was a terrible mistake.

Half the wetlands that once made up the Everglades are gone, now replaced by farms, suburban housing, agriculture and highways (Levin 1996). Ninety percent of the water birds and most of the native mammals have disappeared. The southern Everglades have become increasingly saline from an influx of sea water, causing the disappearance of many species unable to adapt. Some of the overflow from canals during heavy rains has been pumped into the Micaseekee Indian Reservation, which is located in the Everglades, flooding buildings and drowning hundreds of deer. In 1990, outflows drowned 90 percent of the entire deer population in the Everglades. Entire forests of bald cypress trees have died (Dugan 1993).

Wood storks once nested in colonies of 10,000 or more in the swamps northwest of the national park in the Corkscrew Swamp Sanctuary (Toops 1989). This 10,560-acre National Audubon Society sanctuary now protects 400 or fewer pairs of these birds; storks require shallow, freshwater pools that concentrate fish, especially during nesting season, to feed their young. Because of the drainage of the agricultural area and the lowering of water levels, wood storks died out and their chicks starved in the nest (Toops 1989). During the 1930s, at least 75,000 wood storks bred in Florida, but by 1975 there were only 12,000 (Kale 1978). They continued to decline, and in 1980, only 5,000 pairs remained (Lucas 1996). In 1984, the US Fish and Wildlife Service added the US population of wood storks to the Endangered Species Act.

The loss of water in the Everglades has had dramatic effects on alligators. They grow at abnormally slow rates, are underweight for their age and more anemic than alligators in other parts of the South. Research on the diet of these reptiles in 1997 revealed they were malnourished. The once-abundant populations of fish have disappeared, and alligators are forced to scavenge carcasses and feed on small mammals and snakes.

Federal protection was accorded to the southernmost 1.5 million acres of the Everglades by establishment of the Everglades National Park, but its ancient water flow pattern has been so disrupted by channeling, diversion and drainage that the ecosystem is a shadow of its former self. Adjoining the park to the northwest is Big Cypress National Preserve, an area of 570,000 acres also under the jurisdiction of the National Park Service, but with less

restrictions; hunting, fishing and even mining are allowed in National Preserves under certain circumstances.

After 50 years of declining wildlife and proposals to restore the Everglades, Congress passed the Everglades Forever Act of 1994 (Cushman 1996a). Forty miles of the Kissimmee River, whose huge oxbows and curves through marshy pineland were turned into a diked canal by the US Army Corps of Engineers, will be returned to natural bends by this same agency. The cost of repairing the damage is an estimated $500 million, 14 times what it cost to obliterate the river's original curves (Levin 1996). Diking and channeling shortened the river from 103 miles to 56 miles, and a wet prairie where a million ducks wintered was drained (Levin 1996). A recent survey of the area found a total of eight ducks, and droughts in the region have increased (Levin 1996). Some local ranchers oppose the plan, but it has received the support of conservationists and, after intense lobbying, of President Bill Clinton. The nearby National Audubon Society's Kissimmee Prairie Preserve nearby, protects 8,000 acres of the original 30,000-square-mile flood plain of this river (Levin 1996).

Under the 1994 Everglades Forever Act, 40,000 acres of the agricultural lands will also be restored to marsh. A 3-mile-wide flow-way from Lake Okeechobee into the Everglades is another facet of the restoration plan. This would revive marshes below the lake. Sugar farmers have protested government acquisition and resent the proposed controls on the amounts of fertilizers and pesticides that can be released into the water system. The sugar industry in Florida receives $1.4 billion per year in federal tax breaks, and it has balked at any loss in its economic status. Added to the loss of acreage, the industry was angered by a proposed "sugar tax" that would have raised $245 million over a seven years to restore the Everglades (Levin 1996). Political contributions of more than $15 million from the sugar industry to presidential and other politicians™ campaigns to represent their case have stymied efforts to restore this internationally important wetland. The funding was dealt a severe blow in November 1996 when Florida voters rejected the sugar tax plan on the Presidential ballot.

Funding by the Congress, which voted $7.8 billion for the Everglades Restoration Fund in 2000, permitted the project to go forward (Schmitt 2000). Florida will pay half of this sum over the next 40 years to redirect 80 percent of water now diverted back to the Everglades through an untested system of quarries and aquifers, and by removal of dikes and barriers (Schmitt 2000). The plan may not succeed in its goal of restoring the original ecosystem, but water flow will be improved, allowing wildlife to recover some of their populations. In another positive decision, plans that called for turning Homestead Air Force Base at the edge of the Everglades near Miami into an international commercial airport with hotels, development and new roads were canceled in early 2001 by the Clinton Administration (Canedy 2001).

Cleaning up Florida Bay and returning the sea grass to dead areas is another project that began in the 1990s, but it lacks the funding of the Everglades restoration. Its western portion is now saturated with algae, and the native turtle grass has disappeared from large areas (Stevens 1997). The tourist industry centered on snorkeling and diving is in decline as a result. A lack of fresh water has caused increased salinity and a resultant influx of water laden with agricultural chemicals. This aggravates the growth of algal blooms, such as red tide. Endangered sea turtles inhabit Florida Bay, and the coral reefs are home to a great diversity of fish and invertebrates, all of which are in steep decline.

The tourist industry brings $13 billion to Florida each year, a large percentage from Everglades tourists and others who come to appreciate the coral reefs and wildlife. This should impact decisions made to save the Everglades National Park, surrounding wetlands and Florida Bay.

The restoration of the Everglades represents an about-face for the historical approach to wetlands in the United States, and it may be copied in other parts of the country. Wetlands legislation still includes certain concepts such as "mitigation," a legal loophole allowing destruction of one marsh or wetland if another is preserved or created. Many ecologists consider that the natural wetland is far more complex and irreplaceable than the man-made one, and they should not be considered equal under the law (Daily 1997, Williams 1996). These man-made wetlands often fail to function naturally, and the concept of allowing such wetlands to be constructed when natural wetlands are destroyed is

flawed. Developers often construct new wetlands in unnatural blocks without proper natural hydrology or native plants and animals.

Non-governmental organizations, such as The Nature Conservancy and the International Crane Foundation (ICF), have played a significant role in preserving many threatened wetland habitats for birds. The demilitarized zone between North and South Korea is a major refuge for cranes, white-tailed sea eagles and other water birds. Rare white-nape cranes (*Grus vipio*) were discovered feeding in the Han River estuary just south of the zone prior to the diking of these marshes for rice production. Dr. George Archibald, co-founder of ICF, and Korean ornithologist Kim Hon Kyu, convinced the South Korean government to set aside this marsh. Other key wildlife wetlands under threat have been preserved through the diplomacy of these conservation organizations and cooperation between biologists and governments that have bridged old enmities.

The problem of sewage and runoff from roadways, agricultural fields and suburban housing areas will only grow in the future. A US government project to deal with this problem has used natural solutions that could be imitated elsewhere. The project constructed shallow basins to capture runoff that then flows through grass, which removes solids and nutrients, and then to a cattail marsh for further cleansing. The last step is a deep pond with fish and mussels, which filter the water. Ten of these systems have been installed in Maine at a very small cost of $14,000 to $35,000, and similar structures have been built in New Jersey, New York and Massachusetts (Williams 1996). A new treatment process, vermifiltration, in which earthworms in soil filters extract nutrients and suspended matter from sewage, produces an effluent free of pathogens and ideal for irrigation. Several towns and cities in California have created marshes to filter sewage that has been given secondary treatment. These have become wildlife havens and even tourist attractions. By contrast, Boston constructed a 9-mile pipe to carry treated sewage into Cape Cod Bay, where over 300 million gallons will be dumped each day, posing a threat to fisheries and other wildlife. Its cost was $390 million. Some cities have tapped sewage for methane gas to power city facilities.

Scientists are now attempting to address th**e** problem of soil salinization with salt-resistant plants. Department of Agriculture research has also found river reeds that turn toxic chemical runoff into water and carbon dioxide, poplar trees that absorb pollutants from groundwater, and grains and grasses that absorb fertilizer and herbicides, breaking down the toxins (Howe 1997). Prevention and care to avoid such pollution before it happens is even more important for the future.

The facilities for the 2000 Olympic Games at Sydney were designed to be environmentally sensitive. Recycled storm water was used for toilet flushing, and sewage effluent was filtered and recycled (Zuckoff 2000a). A degraded creek was restored to its former state, and when the rare Bell frog (*Litoria aurea*), was discovered on the site of the tennis center, special tunnels were built to allow these frogs to move through it unharmed (Zuckoff 2000a). This center did not create oily residue from automobiles on asphalt parking lots because these were the first Olympic Games to ban all internal combustion cars, requiring travel by trains that connected facilities and solar cars built for the games (Zuckoff 2000a).

Conservationists in the future will need to overcome the effects of a global economy spurred by corporate profits and politicians pushing destructive water projects through legislatures, only to repay financial contributions made to their campaigns or political favors done for them. Extraordinary wildlife habitats can be destroyed with the stroke of a pen. The Copper River Delta of Alaska is a large wetland vital to millions of waterfowl, shore birds and marine mammals, but politicians have proposed construction of a road through it for the benefit of loggers who want to remove timber.

With the warming of the global climate, ship traffic through the Arctic Ocean will increase, and the vast river deltas and waterfowl habitat in northern Canada will soon be threatened by oil tankers and construction of gas pipelines and roads. This region is vital habitat for a large percentage of the continent's waterfowl and shore birds, polar bears (*Ursus maritimus*), whales, seals, walrus and fish. Diamond mining and other development are already encroaching on this pristine area.

The extent of our interference with natural ecosystems is undoubtedly adversely affecting evolution. Nature has evolved superb adaptations in aquatic species**,** survivors for millennia within their habitats. We are just beginning to appreciate and understand the great diversity in aquatic ecosystems and the awe-inspiring beauty here. It is vital that this new understanding be used to protect, not destroy.

Rivers: Dams, Canals and Channeling

More than half of all accessible water is diverted for use by humans (Barlow 1999). Large-scale dam projects on major rivers have increased worldwide from 5,000 in 1950 to 38,000 by the end of the 20th century (Barlow 1999). More than 100 major dam projects are planned in West Africa alone, and conservationists predict crashes in fisheries and flood plain crops as a result (Dugan 1993). Many giant dams have ruined wilderness areas in order to produce electricity for which no demand existed. Wild and beautiful rivers in Indonesia, Brazil, India, Zambia and elsewhere have become fetid lakes, with an enormous loss in wildlife and plants. Many of the tributaries of the Amazon, the world's largest river and home to the greatest diversity of freshwater fish in the world, have been dammed over the past 50 years. In the process, hundreds of species of plants became extinct, drowned by the dam's rising waters.

Rivers: Dams, Canals and Channeling: Page 1

Between 1973 and 1983, Brazil borrowed $30 billion Brazil from international funds, such as the World Bank, to construct these dams (Lanz 1995). Huge debts are incurred by poor countries borrowing money from international funds to pay for dams. The real profits from dams accrue to companies that construct them and industries that directly benefit (Lanz 1995). Yet the rationale for dams has traditionally been to benefit the population as a whole. Numerous extinctions of native wildlife and plants have resulted from dam construction. This makes the real cost of such cheap electricity far more expensive, yet such calculations are not considered when nations endorse dams.

Until the 20th century, all but a few of the world's major rivers were pure. Today, the opposite is true. Unpolluted, un-dammed rivers are the exception, and even the great diversity of the mighty Amazon River is now threatened by dam construction on its tributaries. These dams have endangered countless species of wildlife. The majority of species evolved to live in rivers are unable to adapt to conditions created by artificial barriers such as dams and resultant changes in water temperature and current. In the United States, only 2 percent of rivers remain free-flowing and undeveloped (Barlow 1999). All major European rivers have been dammed, diked or channeled. After dam construction, reservoirs, which often cover hundreds of square miles, gradually fill, drowning untold thousands of animals in the process. Even those able to swim to dry land rarely survive because territories are already occupied by members of their own species. In tropical forests, threatened monkeys, armadillos, rodents, snakes and other animals drown, and rare plants and trees die under hundreds of feet of water. Dam gates cause wildlife mortality as well. Endangered West African manatees (*Trichechus senegalensis*) have been crushed to death when caught in the giant gates of these dams, or left high and dry when water levels were lowered (Reynolds and Odell 1991).

Dams upriver from coastal marshes disrupt the flow of water, which can cause crashes in breeding fish populations. Dammed rivers that empty into coastal deltas experience reduced freshwater flow, which creates an

influx of saltwater into freshwater marshes (Lanz 1995). This devastates fisheries adapted to low salinity, such as many species of shrimp and crayfish. An extreme case is in Louisiana; its entire marsh coastline and its $700 million-per-year fishery-based economy have collapsed over the past few decades as saltwater has crept into freshwater marshes, drowning 1 million acres a year. Dikes and levees built for shipping traffic on the Mississippi River and its tributaries have decreased the freshwater flow into the marshes, causing this disaster. Another negative effect of dams on coastal ecosystems is the blockage of silt and sand that enriches delta marshes and maintains sandy beaches. Dams generally have to be abandoned within about 50 years because they fill up with silt and can no longer function efficiently. The serious environmental damage caused far outweighs these short-term economic benefits.

Migratory fish, from salmon to sturgeon and shad, find their paths blocked by dams. They leap in vain at the concrete barriers, and most fail to negotiate fish ladders on those dams that have installed these devices. The young of salmon that manage to hatch upstream from dams are crushed and torn to bits in the dams' massive turbines, which kill 90 percent of salmon young each year in the Pacific Northwest of the United States. Virtually every species of the seven salmon native to this region is threatened with extinction, and 214 stocks are threatened; 106 populations have already disappeared (Stein *et al*. 2000). These salmon and steelhead trout have also suffered from siltation caused by logging and agriculture, which has clouded the clear streams needed for spawning. The loss of these salmon, which numbered in the billions when Lewis and Clark entered the region in the early 19th century, has affected the livelihoods of hundreds of fishermen and wildlife that depended on these fish. Bald eagles, black and grizzly bears, river otters and many bird species rely on these fish as a vital food resource. Each fall, bears eat large quantities of fish, especially fatty fish like salmon, to fatten up prior to their winter hibernations. Without these fatty stores, many bears do not survive the winter.

The outflow from dams is regulated by opening of gates, resulting in flows ranging from trickles to torrents. Wildlife requiring a certain water level can be eliminated when it changes radically. Rare trumpeter swans (*Cygnus buccinator*) wintering in eastern Idaho died in large numbers in 1989 when the reservoir on the Henry's Fork tributary of the Snake River was closed during a drought. The water downstream had previously remained unfrozen in winter, providing vital habitat. In February 1989 when the water froze as much as 4 feet below the surface, more than 50 swans froze or starved. The surrounding community became so concerned they raised $30,000 to purchase 4 billion gallons of reservoir water to be released. *Life* magazine photographer Glenn Oakley documented locals picking up and carrying the surviving swans to indoor areas; some were even warmed in nearby bathtubs. These swans were then transferred to a rehabilitation center where they were kept throughout the rest of the winter, and grain was supplied to the weakened swans remaining in the wild (Life April, 1989). In the words of a rescue coordinator from the Idaho Department of Fish and Game, "I guess nobody ever told these swans they should have filed for water rights."

Even more tragic events took place in Canada, where a massive dam project has inundated some 4,000 square miles of forest land and riverine habitat in Quebec and Labrador. These dams have had major effects on both people and wildlife since the 1970s. They impeded the ancestral migration route of caribou and caused 10,000 of these animals to drown in a torrent of water from one of the new dams in 1990 (Verhovek 1992). Chief Matthew Coon-Come of the Grand Council of the Crees appealed to conservationists to assist tribes in stopping any further work on the dam system. "For 5,000 years we did not leave a trace of our having been in James Bay. What we had came from the land and went back to the land. The land is sacred to us. This land holds the graves of our ancestors. But now, Hydro-Quebec is destroying our sacred land and our way of life. If you were to fly with me today in a Cessna, starting from the first James Bay dam, we'd fly for four and a half hours, and all you'd see is land drowned by water, three major rivers destroyed" (Coon-Come 1993). Chief Coon-Come first began fighting the dam projects in 1972 when he was 16 years old, and in 1994, at the age of 38, he was honored as the first North American recipient of a Goldman Environmental for his achievements in stopping the second phase of the James Bay project.

The Indus River dolphin or Susu (*Platanista minor*) of Pakistan and the Ganges dolphin, which also inhabits the Brahmaputra River system, are highly endangered. These dolphins appear to be blind, but have deeply set eyes that can receive light at an angle, perhaps when they surface (Nowak 1999). Of the two, the Indus River species is more endangered and considered to be on the brink of extinction (Leatherwood and Reeves 1983). It is considered

endangered. This dolphin's entire range lies within the Pakistani provinces of Sind and Punjab where, despite of legal protection, it has declined, mainly as a result of a series of dams on the Indus that isolate populations, along with accidental drowning in fish nets and pollution (NGS 1995). Its population has been estimated at only about 400 animals between two dams in the Sind Province, and perhaps 150 more in small subpopulations farther north in the Punjab Province (Nowak 1999). The Ganges River dolphin inhabits a larger range and is found in western India, Bangladesh and Nepal. Pollution, boat traffic, fragmentation of populations by dams, accidental capture in fishing gear and hunting all threaten this species (Nowak 1999). 4,000 to 5,000 Ganges dolphins survive, and the species has disappeared from the Karnaphuli River to the east of the Ganges at the very least (Nowak 1999). In Nepal, dams have blocked portions of the dolphins™ range, trapping them in portions of river too small to ensure their survival (Leatherwood and Reeves 1983).

Fish and mollusks are especially vulnerable to disappearance when their habitats are radically changed by dams. The conditions created in the reservoir usually end in the destruction of aquatic vegetation, bottom-dwelling mollusk fauna, and the fish, turtles, birds and mammals that are part of free-flowing rivers. Sediment soon covers the mollusks and bottom vegetation and kills them, and water currents no longer bring food to the gills of mollusks and keep water clear. Caddis and stone flies, upon which trout and other fish feed, disappear when their larvae do not hatch in reservoir conditions (Lanz 1995). These insects are the primary food for trout and many other fish. Cold temperatures of swift-flowing, tree-lined rivers in temperate areas that teem with trout and salmon become warm, pond-like areas, to which these species cannot adapt.

Rivers: Dams, Canals and Channeling: Page 2

With a total of 297 species, North America has the world's greatest diversity of freshwater mussels, though they have suffered dramatic declines as a result of dams (Neves 1996). Free-flowing rivers and streams have been turned to ponds, and to compound the damage, the dam builders usually channel rivers downstream. Using machines with revolving chopping blades, natural, curving rivers and streams are converted into straight ditches. Stream edges are cleared of vegetation, and river bottoms are dredged, depositing mollusks and crustaceans in piles along the banks. What is left is a sea of mud in a ditch devoid of life. Malacologist Dr. George M. Davis (1977) concludes these projects, combined with acid drainage from strip mining, erosion and pesticide runoff from agriculture, have been the major causes for the near-extinction of much of the continent's native mollusk fauna (Davis 1977). At least 102 species are considered threatened in the United States, 97 percent of these from habitat loss or degradation (Stein *et al*. 2000).

Prior to the devastation of their habitats, mussels clustered in vast numbers on river bottoms throughout the major rivers and their tributaries in the Midwest and southeastern United States. These rivers meandered through forests that provided cool shade. River otters, muskrats and mink denned among tangled tree roots and in banksides. Water quality remained clear as a result of the forests and the filtering actions of the mussels. River snails fed on the detritus and algae of the mussel shoal, further cleansing the water. The mussel shells formed large, reef-like piles on river bottoms, providing habitat for fish, crayfish, water plants and large river snails. Turtles, aquatic birds and mammals fed on the fish, mussels, snails and crayfish in this ecosystem.

A major center of diversity for these mussels is Alabama, which has more than 235,000 miles of waterways and three major river basins left untouched by Pleistocene glaciers, preserving a great diversity of species (Stein and Flack 1997). Having survived the Ice Age, many species of mussels, fish and crayfish became extinct or endangered when water projects began destroying their habitats in the 1920s. The richest of all known beds, Mussel Shoals, located in the Tennessee River of Alabama, once had a diversity of approximately 70 mussel species. The Wilson Dam, completed in 1924, submerged Mussel Shoals and covered them with 15 to 20 feet of mud, causing the extinction of at least half the mussel species and five of the seven large river snails (Davis 1977). Experts at the University of

Alabama in Tuscaloosa report 69 percent of mussel species are extinct, endangered, threatened or of special concern in the rivers and streams of the state (Cushman 1995b).

Many mussel species need small fish to complete their reproductive cycles. One threatened mollusk, the orange-nacre mucket (*Lampsilis perovalis*) of the Mobile River basin, produces larvae that resemble tiny fish; they anchor to the adult mussel with a long, wavy mucous strand that acts as a lure to tiny fish; when a fish attempts to eat this larva, however, it breaks away and attaches to the fish's body (Hartfield and Butler 1996). The fish carries the mussel larvae to a new area. Other mussels have different reproductive strategies. In some cases, fish congregating around the beds are parasitized by embryonic mussels who cling to their fins or gills and become enclosed in a cyst. The larvae absorb nutrients from the fish for two or three weeks, growing into juvenile mussels, and in the process, they are transported to new areas, where they detach and colonize stream beds (Hartfield and Butler 1996).

The orange-nacre mucket is one of many species that have disappeared from most major rivers, and only small streams and creeks now afford suitable habitats for the creature (Hartfield and Butler 1996). The host species for many mussels are darters. These fish exhibit a rainbow of iridescent hues in a multitude of patterns. Many of their names are evocative of their color or origin: Amber (*Percina antesella*), Bayou (*Etheostoma rubrum*), Goldline (*Percina aurolineata*), Slackwater (*Etheostoma boschungi*), Watercress (*Etheostoma nuchale*) and Okaloosa Darters (*Etheostoma okaloosae*). All the latter species are listed on the Endangered Species Act.

The most famous of these little fish is the 3-inch snail darter (Percina tanasi). Named after the river snails upon which it feeds, this species was discovered on the Little Tennessee River in 1973 above the Tellico Dam site after construction of this major dam by the Tennessee Valley Authority (TVA) had begun. Construction continued after the TVA was able to reverse preliminary injunctions to delay the dam brought by conservationists and irate Tennessee residents being evicted from their land. By the time the snail darter was scientifically described, proposed and listed under the Endangered Species Act, the dam was nearly complete. There is evidence that construction was hastened when word of the fish's discovery became known, in order to prevent conservationists from stopping the dam. The snail darter's survival is due to transplants into other parts of the Little Tennessee River and a few of its tributaries and its discovery in 1980 on a new site in Tennessee™s South Chickamauga Creek, by Dr. David Etnier of the University of Tennessee, who originally discovered the species. The snail darter is now known to exist in Alabama and Georgia, as well as Tennessee. It has been reclassified as threatened under the Endangered Species Act. It does not owe its existence to the TVA, however, which destroyed its only known habitat with a dam, nor to Congress, which rewrote the Endangered Species Act to sanction the extinction of this and other species that might impede "development."

Over three hundred types of crayfish are found in the United States; these species make up 61 percent of the 525 crayfish species found worldwide (Stein *et al*. 2000). Most species live in rivers, streams and waterways in the southeast (Clancy 1997). These crustaceans share many of the same ecosystems inhabited by mussels, darters and snails, and about half the species are threatened with extinction (Stein and Flack 1997). Hiding in crevices, under rocks and buried in sand, crayfish attempt to escape herons, raccoons, river otters and predatory fish (Clancy 1997). A 1996 study by the American Fisheries Society found 65 species of crayfish living in a single river drainage (Clancy 1997). They are usually only 3 or 4 inches long, and like lobsters and shrimp, females carry fertilized eggs attached to the underside of their abdomen. Even after hatching, she allows them to cling to her abdomen for several weeks before they become independent (Clancy 1997).

Native crayfish have declined along with mussels and fish in the altered environments created by dams and channeling. Only four crayfish species out of more than 150 species considered imperiled by The Nature Conservancy are listed on the Endangered Species Act, and almost nothing has been done for their preservation (Clancy 1997). The Nature Conservancy has programs to educate people to protect the land around streams from pollution from cattle, and it is building partnerships with local, rural organizations and conservation groups. The goal of their programs is to preserve the habitats of native crayfish and hundreds of other species by arresting water pollution and other misuses of waterways. This benefits the local economies in the process.

Mussels, crayfish and darters are important indicators of environmental quality because of their great sensitivity to changes in water quality. Scientists have warned a mass extinction of American mussels and crayfish is imminent. Public interest is sparse for these endangered species, lacking the popularity of the bald eagle, the gray wolf or even the black-footed ferret. Yet they are critical to the healthy functioning of southeastern aquatic ecosystems and represent a precious source of diversity on the continent.

The damming of southern rivers continued in the 1960s and 1970s. By 1967, there were nine dams on the Tennessee River, leaving only 22 miles free-flowing. The last un-dammed river in Tennessee, the Duck River, was dammed in 1975. It contained the greatest diversity of snail species left in the Tennessee-Ohio River system (Davis 1977). The Fish and Wildlife Service listed seven species of endangered mollusks native to the Duck River on the Endangered Species Act when the Columbia Dam was under construction. In retaliation, the TVA brought an unsuccessful lawsuit against the Department of the Interior (FWS 1979). Besides the biological impoverishment resulting from destruction of natural rivers and streams, many potential food sources for humans are lost, such as mussels, crayfish and fish.

For fish of rivers in the US West, the opposite conditions prevailed. Flowing through desert landscapes, these rivers tend to be warm and turbid from eroded soil. The Colorado River evolved an extremely rich, endemic fish diversity adapted to this water type. During the 20th century it was dammed throughout its course. Dam operators of the 49 dams on this river occasionally release water from these reservoirs. Coming from the bottom of the reserves, the icy, cold water inundates ecosystems below, creating habitats that endanger native fish. Among these endangered fish are the humpback chub (*Gila cypha*), the Colorado squawfish (*Ptychocheilus lucius*) and razorback sucker (*Xyrauchen texanus*). The Colorado squawfish, a large fish reaching 6 feet, was once an important food fish for natives and settlers. None of these species have been able to adjust to the cold, clear waters of the dammed Colorado River, which prevented their free movement. The Fish and Wildlife Service has artificially maintained these and other endangered fish in hatcheries, and some populations survive in un-dammed tributaries. Dams on the Colorado River have also inundated precious riverside habitats of small marshes where rare water birds bred. The delta of the Colorado River was once a vast marsh in northern Mexico, a wildlife haven which harbored millions of waterfowl and fish. It was the life blood of the Cocopa tribe. As a result of the dams and diversion of its water to Los Angeles and for local agriculture, the delta is now a mere trickle. The silt that was once deposited on banks and in the delta is now retained upstream, depriving ecosystems downstream of nutrients.

Although the rate at which natural rivers are being dammed has slowed considerably in recent years, for many species the damage has been done. A growing number of organizations and individuals have been urging the removal of dams, especially those causing extinctions. The McPherri Dam on a tributary of the Sacramento River, which once had one of the largest salmon runs in the state, was demolished in 1998, and a few days later, another dam in Medford, Ore., was breached (Egan 1998). A dam on Maine's Kennebec River was removed in 1999, allowing salmon and other fish to return to former haunts. This required the work of many conservationists for more than a decade, and many politicians and others in the state opposed its removal. The 75,000 US dams were often built at huge public expense. Congressional representatives have pushed these projects through Congress for decades, promoted without real analysis of need, economic benefit or environmental effect. Some of the larger dams may be more difficult to remove. The dams on the lower Snake River in the Northwest, for example, have eliminated the millions of salmon that once spawned here, affecting wildlife and local economies. A major effort to breach these dams to allow passage of salmon is gaining momentum, but many barge operators and farmers who transport their grain to market on the barges are strongly opposing the breaching of these dams. In the future, dams may be regarded with less respect as naturally flowing rivers become better appreciated. As former Secretary of the Interior Bruce Babbitt said while commencing the destruction of a dam: "Dams are not like the pyramids of Egypt that stand for eternity. They are instruments that should be judged by the health of the rivers to which they belong" (Egan 1998). Breaching is a compromise to removal of dams that may be more acceptable to dam defenders.

Rivers: Dams, Canals and Channeling: Page 3

The Aral Sea, 300 miles to the east of Siberia's Lake Baikal, is ancient in origin. This was once the fourth-largest lake in the world, covering 25,000 square miles (Kinzer 1997). Two giant dams were constructed in the 1960s on its two feeder tributaries, the Amu Darya and Syr Darya. The diverted water was sent to the south to produce cotton (Filipov 1997). This crop requires great amounts of water and is unsuitable for the arid steppe region. The loss of its feeder rivers caused the Aral to shrink over the next 30 years from 25,675 square miles to 14,090 square miles, and its shores receded up to 50 miles (Stewart 1992). By 1997, it covered only 12,000 square miles, and it continues to shrink (Kinzer 1997). This once rich lake in the midst of the dry plains of Central Asia is expected to completely dry up by 2010 (Filipov 1997). As it dried up, the sediment from the Aral Sea's bed, which contained toxic chemicals, blew away, coating everything within hundreds of miles with 150 million tons of contaminated dust (Filipov 1997).

The wealth of diversity that once teemed in this desert sea has been lost. The destruction of this beautiful lake and its wildlife is without parallel anywhere in the world in recent history, an environmental catastrophe. The water that remains has become increasingly saline and polluted by unregulated industries (Filipov 1997). The collapse of the fishing industry has caused great financial hardship to the people who had lived along the shores of the Aral for centuries. In the 1950s, the Aral produced 40 to 50 tons yearly of sturgeon, pike and roach, among other species of fish; all of its 24 endemic fish are now extinct (Stewart 1992). The mayor of the town of Muynak, located at the southern end of the lake, recalled, "Our fishing boats used to bring in 30,000 tons of fish each year." The town's population dropped from 45,000 in 1967 to 28,000 in the late 1990s (Kinzer 1997).

Of the Aral Sea region's 173 animal species, only 38 survived until the early 1990s (Stewart 1992). Almost all birds disappeared, along with the last of the fish, and only brackish pools remain along the shoreline (Filipov 1997). In March 1991, the Aral Sea was officially declared an ecological disaster area, and the Soviet government appealed to the United Nations Environmental Programme for help; an inter-republic commission was set up to reduce pollution, but with the dissolution of the USSR., the project was abandoned. In the years since the Soviet Union dissolved, destruction has continued unabated (Filipov 1997).

The five newly established Central Asian nations of the region, Kazakhstan, Uzbekistan, Krygyzstan, Tajikistan and Turkmenistan, are now competing for control of the water from its two feeder rivers to maintain their irrigation-fed agriculture (Filipov 1997). Although the leadership of these countries agree urgent action is required to save the Aral Sea, they are not ready to take drastic measures to conserve water (Kinzer 1997). Ironically, much of the diverted water is lost to evaporation and seepage because the irrigation canals were neither covered nor lined (Kinzer 1997). What water is left after heavy application of pesticides and other chemicals sprayed on cotton and rice fields becomes poisoned and trickles into the Aral, further contaminating it (Kinzer 1997). Cancers and other illnesses have struck the local people in Muynak (Kinzer 1997). An environmental organization, Aral-S-O-S, is attempting to reach agreements among the countries, but admits the countries' philosophy of considering water their national property may make the goal unattainable (Kinzer 1997). These nations continued discussions in 2000 without taking any action to prevent the impending loss of the Aral Sea.

In the majority of cases, dams are constructed with little or no knowledge of the ecosystems they are ruining. Likewise, the governments that authorize the dams rarely consider environmentally sound alternatives. In the 1940s, the Volga and Kama Rivers, 300 kilometers north of Moscow, were dammed to form an enormous reservoir that flooded 455,000 hectares (1,124,305 acres) of arable meadowland to produce a relatively small amount of electricity (Lanz 1995). Dams on the Volga impeded the natural migration of sturgeon from the Caspian Sea for their spawning, resulting in a catastrophic decline in the world's most valuable fish. Beluga caviar from the beluga sturgeon (Huso huso), an endangered species, is the most valuable fisheries product in the world, made more valuable by its continued

decline in the Caspian. All the Caspian's species of sturgeon are endangered, as are species of the Amu-Dar and Syr-Dar Rivers feeding the Aral Sea.

The Three Gorges, a Yangtze River Dam project in China that will be completed in the next five years, will be the world's largest hydro-electric project. This dam, expected to cost up to $120 billion, will be 607 feet high, span over a mile and flood 400 miles of this major river, including 30 million acres of cultivated land (Carpenter 2001). The portion of the Yangtze River to be dammed is one of the most picturesque landscapes on Earth, its swift waters flowing through steep gorges and mountains enshrouded in mist. It has been painted by Chinese artists for centuries. The three gorges that will end up under water, the Qutang, Wu and Xiling Gorges, have tributaries and feeder streams that will also be adversely affected. One of these, north of the town of Wushan, the Daning River, is home to many ancient species of trees, such as the Dawn redwood (*Metasequoia glyptostroboides*), the dove tree (*Davidia involucrata*) and various ginkgoes (Hoh 1996). Forty-seven species of rare or endangered plants listed by the Chinese Academy of Science will be inundated when the dam waters rise; among these are many endemic medicinal plants (Hoh 1996). Funds are lacking to treat the 265 billion gallons a year of raw sewage and industrial waste that will flow into the impounded waters from the Three Gorges Dam (Tyler 1996). The project's managers admit there are no immediate solutions to the sewage and pollution problem, or to the impact of huge volumes of sediment that could clog the entire flow of the river (Tyler 1996).

The Yangtze River dolphin (*Lipotes vexillifer*) inhabits this part of the river and faces imminent extinction. Restricted to the Yangtze and portions of the Quiantang River, it has disappeared from much of its original range (Nowak 1999). This dolphin evolved in swift, muddy waters, preferring to live near large eddies. The sonar in its bulbous head is able to locate fish without vision. While this species is actually almost blind, these dolphins have tremendous physical strength to negotiate strong currents. Boat travelers in the river 50 years ago saw hundreds of these dolphins leaping and swimming throughout its length, along with birds and other wildlife. Today, almost no wildlife can be seen. This species was endangered by other dams, collision with boats and ships, dynamiting for channel maintenance, pollution, accidental drowning in fishing nets and loss of food to over-fishing by humans, even prior to the Three Gorges dam construction (Nowak 1999). A large male found dead in January 1996 was examined by scientists; they determined he had died from an electric shock device used to kill fish in the Yangtze River (CNN 1996).

The lakes along the Yangtze once sheltered hundreds of dolphins, but sedimentation from agricultural runoff covered the lake bottom, and sewage polluted the water. It has disappeared from almost all its former strongholds. Surveys in 1986 found 300 animals, but in 1993, 200 or less were estimated to remain, and more recently only 9 individuals could be found (Nowak 1999). This species, adapted for millions of years to life in these rivers is now considered the most endangered of all cetaceans (Nowak 1999). The upper Yangtze will soon be awash in sewage and other pollution from the Three Gorges Dam, which will also block its movements, a habitat where these last dolphins are unlikely to survive. The sole native dolphin in captivity, Chichi, a male, has lived in a small concrete tank at the Institute of Hydrobiology in Wuhan since 1980 when fishermen snagged him on their hooks; he still has scars from these wounds. Pneumonia killed one young female placed with him, and several other females put in his tank in the hopes of captive breeding have died as well, according to a 1999 PBS documentary, "Great Wall Across the Yangtze."

Ocean Park Conservation Foundation in Hong Kong, in cooperation with the IUCN Cetacean Specialist Group and the Institute of Hydrobiology in Wuhan, China, have cooperated in a project to capture as many of the remaining animals as possible before the dam fills and move them to the Shishou Seminatural Reserve (Leatherwood and Genthe 1995). The reserve, a natural oxbow in the Yangtze, also harbors ten finless porpoises (*Neophocaena phocaenoides*) Œ a species that has lived in the river with the dolphins for thousands of years. Finless porpoises are also native to coastal waters west to Saudi Arabia, but their status is not well known. This solution is unlikely to protect more than a few members of the species, and it will almost certainly fade into extinction in the near future. Another species unlikely to survive the effects of this dam is the endemic, migratory Yangtze sturgeon (*Acipenser dabryanus*).

The dam will also affect the Yancheng Marshes, covering some 938 square miles on the north-central coast. Extending for 186 miles, they form a floodplain for the Yangtze River (Simon 1995). Over half a million water birds and shore birds winter here, including the highly endangered red-crowned crane (*Grus japonensis*), whose population in this wetland increased from 200 in 1981 to over 600 in 1987 (Simon 1995). The tidal flats of the Yangcheng are being reclaimed for agriculture, presenting another threat to this species, whose world population totals only about 2,200 birds (BI 2000). Another rare bird, Saunder's gull (*Larus saundersi*), has a world population of only 7,000 birds in decline (BI 2000), breeds in the Yancheng (Simon 1995). This marsh is of great importance to the 226 birds recorded here, since the vast majority of wetlands in China have been drained, polluted or are heavily hunted (Collar *et al*. 1994). For Pere David's deer (*Elaphurus davidianus*), the Yangcheng Marshes are a new home, one of several reintroduction sites for this species that became extinct in the wild and was rescued by captive breeding in England (Simon 1995).

Another water project, said to begin in two years, will divert water from just west of the Yangtze north to Tianjin, a city southeast of Beijing that is suffering water shortages (Eckholm 2000). Should this be carried out, the combined effect of this diversion and the Three Gorges Dam will decrease the flow of the Yangtze River so greatly that these marshes may dry up. Water from the Yangtze River west of the Three Gorges Dam will also be diverted north to the Yellow River, which has been overused and sometimes runs dry, and to mountain zones in the northwest and south (Eckholm 2000). Canals and reservoirs will be dug to carry this water in projects that will cost more than $12 billion (Eckholm 2000). The effects of these diversions on the remaining wildlife of this river will be devastating.

Rivers: Dams, Canals and Channeling: Page 4

Africa's rivers have also been dammed, eliminating wildlife. Most recently, a dam on Tanzania's Lower Kihansi River, costing $272 million, has blocked the flow of a beautiful waterfall, the sole habitat of a newly discovered toad, the Kinhansi spray toad (*Asperginus nectophrynoides*) (Donnelly 2001). This tiny, translucent toad is confined to a 10-acre marsh sprayed by the waterfall. The major source of funds, World Bank, was informed of the imminent extinction of the toad and the loss of the waterfall in 1997, but took no action until Friends of the Earth president Brent Blackwelder wrote the bank's president on the topic of the seriousness of the situation and need for corrective action (Donnelly 2001). An artificial spray system was installed for the toads, and 500 of the estimated 11,000 remaining toads were shipped to the Bronx Zoo and the Detroit Zoo. The toads have proven extremely difficult to maintain in captivity, although breeding did take place at the Bronx Zoo. Tiny, wingless insects must be hand-gathered for these toads, which weigh only two-tenths of a gram, and the majority of the zoo department's staff is occupied in caring for the toads. World Bank employees are considering a $5 million loan to manage the habitat around the Kihansi Gorge to prevent the species from becoming extinct (Donnelly 2001). It is remarkable that the World Bank has been forced to consider the survival of a tiny toad, but unfortunate that the entire ecosystem is being destroyed for electricity production that could have been generated in a less destructive fashion.

The amount of fresh water collected by dams worldwide has increased in the past 40 years by 10,000 cubic kilometers, or 10 trillion tons, an amount equivalent to all the moisture in the Earth's atmosphere (Browne 1996). Much of the water retained in reservoirs is lost to evaporation, especially in arid regions. Geophysicists calculate that dam building will continue until all sources of recoverable water have been exploited, a time that is expected to come in the next century (Browne 1996).

Wetland Drainage

The drainage of wetlands has caused extinctions in some parts of the world. The pink-headed duck (*Rhodonessa*

caryohphyllacea), native to northeastern India, northern Myanmar (Burma) and central Nepal, was locally common during the 19th century in grassy wetlands, where it was heavily hunted by British colonials (Collar *et al*. 1994, Fuller 1987). The male had very unusual coloration, with a bright pink head and brownish plumage marked in pink and white spots. The female was a slightly less colorful version of the male. Males and females uttered different calls, having very different trachea: The male had a two-syllable metallic cry and the female a loud quack (Fuller 1987). Reduced by sport and market hunting, much of its habitat was gradually converted to agriculture, causing an apparent extinction (Fuller 1987). Although not seen in the wild since about 1936, this species is still listed by the IUCN as critical and there is some hope that it survives undetected (BI 2000, Collar *et al*. 1994).

At least five species of frogs have been extinguished by wetlands drainage. The Israel painted frog (*Discoglossus nigriventer*) was last seen in 1940 before its sole habitat, Lake Huleh, was drained for agriculture. Three species of frogs that inhabited the marshes and wetlands surrounding Mexico City disappeared after the city expanded and filled in wetlands for housing and industry and used others for dumping grounds. Leopard frogs of the genus *Rana: Rana johni* and *Rana pueblae* became extinct about 1979, and Tialoc's leopard frog (*Rana tlaloci*) was extinguished in 1990, according to D.M. Hillis, who wrote his Ph.D. Dissertation for the University of Kansas on the species.

Wetland Drainage: Page 1

South America's Pantanal, the world's largest wetland, is a vast network of tree-lined rivers, lakes, marshes, savannahs, palm groves and hillocks in southwestern Brazil, neighboring Paraguay and Bolivia (Simon 1995). Estimates of its size vary widely. Some are apparently based on the entire floodplain, and others on the wetland's size during the dry season. They range from 39,000 square miles (Dugan 1993) to 77,200 square miles, the size of South Dakota (Eckstrom 1996). By any definition, it is an immense region, having one of the most distinctive mosaics of vegetation and richest wildlife diversity in Latin America (Dugan 1993).* It is highly endangered by water diversion and drainage programs.

The Pantanal forms the upper waters of the Paraguay River system and is fed by the Cuiaba, Taquari and Miranda Rivers (Eckstrom 1996). During the rainy season, from December to June, the Pantanal drains the entire center of southern South America, fed by runoff from Bolivian highlands and the sources of the Paraguay River, forming a vast, shallow lake 7 feet deep with islands of vegetation (Eckstrom 1996). Amazonian fauna and flora meet with those of southern Chaco grasslands and pampas, creating a center of diversity: 3,500 plant species, 102 mammal species, 652 bird species, 177 reptile species, 40 amphibian species, at least 264 fish species and 1,132 butterfly species are native (EI 2001, Schemo 1996b). This huge wilderness is of vital importance to a host of animals that have disappeared from other parts of their ranges. They are threatened by the presence of 8 million cattle and the cattle management, which includes introduction of non-native grasses and clearing forest land monkeys and other terrestrial animals require (EI 2001). A new ecotourism industry is gaining ground in the Pantanal, and is bringing in funds to the region at a time when its natural treasures are most at risk (Schemo 1997).

Marsh deer (*Blastocerus dichotomus*) are South America's largest deer. They are superbly adapted to living in marshes and wet savannah. Their long, coarse coats repel water, and broad, webbed hooves prevent them from sinking into soft ground (Nowak 1999). Leaping over high grass, these deer move swiftly in this watery environment, using the hillocks and islands of vegetation to rest and have their young. Marsh deer formerly lived in the marshes

along the Rio Parana and Rio Paraguay and perhaps as far north as the Amazon River (Nowak 1999). They are gone from Uruguay and have become very rare in Argentina, Bolivia, Peru and Paraguay (Nowak 1999). The Pantanal provides a last retreat for an estimated 7,000 deer, but even here they are declining (Nowak 1999). The species is listed as endangered in the Endangered Species Act, and as vulnerable on the *2000 IUCN Red List*. The estimated five million cattle who graze in the Pantanal (Eckstrom 1996) compete with these deer for habitat and forage. Moreover, cattle have spread brucellosis, which causes reproductive failure, to the deer (Nowak 1999, Thornback and Jenkins 1982). Cattle ranchers have persecuted these deer, and hunting, especially when these deer become stranded on islands during flooding, is another cause of decline (Nowak 1999, Thornback and Jenkins 1982). Dams and drainage for agriculture in the Parana River Delta on Brazil's coast have destroyed much of the once vast marshes there (Thornback and Jenkins 1982).

---

*A film that gives an excellent environmental and wildlife portrait of this wetland, fiPantanal: Prairie of the Great Waters,fl was made in 1986 (see Video, Regional, Latin America). It features many of the endangered species described here, along with views of the Pantanal in rainy and dry seasons. A book by Vic Banks (1991), *The Pantanal: Brazil's Forgotten Wilderness*, from the Sierra Club, also gives an overview.

The vast Pantanal is also the most important habitat for the engaging and highly endangered giant otter (*Pteroneura brasiliensis*), which is extinct in most of Brazil and absent from all the larger tributaries of the Amazon (Simon 1995). Killing for otter pelts has been a major factor their decline, and loss of prime habitat is another cause. Degradation of river banks needed for dens by illegal gold miners and cattle, deforestation that affects the water quality and fish with sedimentation and other changes to this wetland have resulted in declines in Giant Otter populations. These otters live in large family groups of up to 20 individuals and require large, high-quality ranges. They are among the noisiest of otter species, uttering a variety of squeals and screams to communicate with one another in the often murky water. This has attracted hunters, who have killed off families and eliminated the species in entire river systems. These otters depend on help from one another, such as loud warning calls about the presence of their major predator, caiman. Their fur is still valuable, although illegal in virtually every market in South America and elsewhere in the world (Nowak 1999).

South America's largest tropical mammal, the South American Tapir (*Tapirus terrestris*), is also native to the Pantanal. Young tapirs have striking white horizontal stripes and spots, which fade into a solid gray as they grow older. Tapirs find the wetlands and abundant vegetation of the Pantanal to be an ideal habitat, and they can be seen swimming in the ponds and bywaters with only their snouts above the water. Like the other three tapir species, the South American tapir has declined throughout its range from hunting and habitat destruction. The IUCN classifies it as near-threatened, and it is listed on the Endangered Species Act.

The Pantanal shelters the largest jaguar population (*Panthera onca*), a threatened species heavily hunted for its pelt and as a trophy. Even in the Pantanal, it was poached until recently, when anti-poaching programs and the Convention on International Trade in Endangered Species (CITES) ban on the sale of spotted cats destroyed the market for pelts and trophies. In this wilderness, jaguars prey on capybara, the world's largest rodent, various deer species and occasionally, domestic cattle. Once heavily persecuted by cattle ranchers, a growing number of cattle ranchers have opened their ranches to ecotourists and now protect jaguars as a prime attraction (Schemo 1997). If there were fewer cattle in the Pantanal, marsh deer, South American tapir and other large mammals would increase, creating a more balanced ecosystem with the jaguar as major predator. This may happen in the future, as the cattle industry is no longer as profitable as it once was (Schemo 1997).

The greatest concentration of water birds in Latin America resides in the Pantanal (Dugan 1993). The jabiru (*Jabiru mycteria*), a large and rare stork, is numerous here, building its great stick nests apart from other water birds.

A colony of wood storks (*Mycteria americana*), a species that is endangered in Florida, may total 20,000 birds in the Pantanal. Egrets, herons and Roseate Spoonbills are abundant. Migrants on their way from southern South America to North America, such as the Arctic Tern (*Sterna paradisaea*), use the Pantanal as an important stopover place (Simon 1995), and three major flyways pass through it (Eckstrom 1996). Snail kites (*Rostrhamus sociabilis*), on the verge of extinction in the Everglades, are abundant here, feeding on the huge apple snails common in the Pantanal. This wetland's palm groves are an important food source and refuge for the largest parrot in the world, the magnificent and endangered blue-violet hyacinth macaw (*Anodorhynchus hyacinthinus*) (Sick 1993).

A zoologically important fish species that has been on Earth for 300 million years is also resident in the Pantanal. The South American lungfish (*Lepidosiren paradoxa*) is a member of a family with only six species remaining, all on other continents. Lungfish can breathe air with their single lung and are thought to be an evolutionary bridge between fish and land animals. At about 32 inches in length, this scaled, eel-like fish breathes at the surface when waters are high, and during the dry season, buries itself in the mud, breathing through a narrow tunnel leading to the surface, or entering a torpor-like state (Dorst 1967). Although not restricted to the Pantanal, this wetland provides ideal habitat for lungfish, and a large population is found here.

The Pantanal is decreasing in size as a result of drainage for agriculture, which has altered the flooding cycle (Dugan 1993). The major threat to this wetland is a 2,000-mile canal for shipping being dredged and channeled from the Paraguay-Parana Rivers, which link below the Pantanal. Five countries, Brazil, Bolivia, Paraguay, Argentina and Uruguay, border these rivers and support this massive program, known as the Hidrovia Project (Schemo 1996b). The canal is intended to open up new markets for a growing agricultural trade for soybeans and sugar, as well as mining products from western Brazil (Brooke 1995). It will extend from Caceres, Brazil to Punta del Este, Uruguay, creating an inland seaport in Bolivia; construction involves blasting through rock formations, straightening and dredging rivers and controlling tributaries to allow year-round shipping (Schemo 1996). Although originally estimated to cost $1 billion, by the time the gates of the Porto Primavera Hydro Dam on the Parana River were closed in November 1998, costs had expanded far beyond the original estimate. At least $3 billion will be required for future maintenance (Eckstrom 1996).

A critic of the Hidrovia Project pointed out that an old railway crossing the southern Pantanal already exists, and new railways could be built to Sao Paulo (Eckstrom 1996). Biologists and ecologists are extremely worried that the basic hydrology of the Pantanal is not sufficiently understood to make such major changes, and the long-term effects of Hidrovia may be totally unforeseen, ending in destroying this wilderness (Eckstrom 1996).

Ignoring the delays imposed for completion of the $10.5 million environmental studies, Paraguay began work blasting through rock on the Paraguay River north of Asuncion in June 1996. The Inter-American Development Bank contributed $7.5 million in 1991 for feasibility studies, but the studies were carried out by the same company performing the engineering work, and they did not appraise the work as a whole. The United Nations Development Programme's ecological advisor on the project, Dr. Enrique Bucher, protested this approach: "In order to understand the hydrological response of the system, you have to analyze it in its globality" (Schemo 1996b). The Hidrovia Project, may result in draining the Pantanal, according to a study by Victor Ponce of San Diego State University (Schemo 1996b, 1997). The Pantanal acts like a vast sponge, releasing rainwater gradually and year-round into the Paraguay River; the dams and drainage of wetlands will expose down-river areas to flash flooding and start drying out this vast marshland (Brooke 1995)

Pantanal wildlife has already been impacted by the Porto Primavera Dam, the first of several dams in the Hidrovia Project, which drowned 300,000 acres of floodplain, forest and grasslands. The dam builders financed "rescue" of animals as the area filled with water in late 1998, filmed for the National Geographic Explorer program ("Paradise Lost," April 28, 1999). This "rescue" was marked by extreme mistreatment of animals and a low survival rate. Black howler monkeys were knocked from tree tops by ramming the tree trunks with motorboats, causing babies to fall off their mothers' backs. Many of the monkeys had just given birth and were separated from family members. Injuries such as broken tails occurred. The monkeys were treated so roughly that they panicked and thrashed about. To

subdue them, they were put in bags for transport. One monkey in a bag was hung over the side of the boat into the water, where it must have drowned during the trip to a holding area. Surviving animals were unceremoniously dumped in enclosures and cages in the holding area. Many of the monkeys, armadillos, opossums, foxes, snakes and other wildlife were crated and transported out of the area for donation to zoos and research institutes. Caiman were also captured, apparently for their hides, since they were not at risk if left in the water. Marsh deer were caught in nets dropped from helicopters, placed in a net and sent by helicopter to their permanent new home in a concrete enclosure. Many died in the process. Only a few of the animals, including some of the monkeys, were released in woodland nearby. The rescuers admitted only about 5 percent of the wildlife was "saved."

Although gold mining has been banned in the Pantanal, illegal mining is fouling the rivers with mercury and other pollutants (EI 2001). Only two small areas in the Pantanal have received official protection (Dugan 1993). The Pantanal National Park protects less than 1 percent of this wetland, covering only 550 square miles, of which 53 square miles are dry land; most of the park has been underwater for the past 20 years (Eckstrom 1996). The Taiama Ecological Station covers 43 square miles (Emory 1990). Thus, well over 90 percent of the Pantanal is privately owned, mainly by cattle ranchers. Whether it will be possible to preserve large portions of the Pantanal remains to be seen. A budding ecotourism industry has begun, but the damage may already be done. By 2010, the Pantanal may have dried out, or its hydrology been so altered that only remnants of this once vast wetland will remain, as occurred in wetlands of the upper Nile River after the building of the Aswan Dam.

A biological diversity survey of the Pantanal is being carried out under the direction of Conservation International, an organization that specializes in such studies, using Brazilian and American scientists and volunteers from Earthwatch Institute, a group that helps fund scientific studies. Many individual projects will be carried out by various Conservation Research Centers, where scientists, educators and conservationists can cooperate to help preserve the Pantanal (EI 2001). One project on a 7,000-hectare ranch will study ecosystem components and create a series of corridors for the future management of the region (EI 2001). Another will study the avian diversity of the Rio Negro region. The fish of the Pantanal, their diversity, ecology and environmental needs, will be the subject of another study (CI 2001). Should the Pantanal begin to die as an ecosystem, a very real possibility in view of its threats, conservationists can use the data that these scientists are compiling of the great wealth of wildlife and plants and how they are affected by the downstream water projects in order to urge protection through alteration or even cancellation of water projects. As the planet's greatest wetland, interest in its conservation reaches around the world, and the better its functioning is understood, the more coherent will be its defense.

Wetland Drainage: Page 3

Africa's two largest wetlands are Botswana's Okavango Delta and the Sudd marshes of southern Sudan. Both are threatened by massive water projects that may result in draining them for agriculture. Civil war in Sudan has so far prevented the construction of the Jonglei Canal, which would drain large sections of the wetland. The Sudd, covering 6,370 square miles when flooded by the Nile, is a maze of lakes, rivers and papyrus swamps among lush grassland and woodland savannahs (Simon 1995). It has the richest diversity of birds of any African wetland. The extraordinary shoebill, or whale-billed stork (*Balaeniceps rex*), the sole member of its avian family, is resident. This stork-like bird, whose scientific name means "whale-headed king," resembles a creature imagined by Dr. Seuss, with an outsized head and huge primitive beak ending in a long hook. The papyrus swamps that are the bird™s habitat are being drained throughout their range, which extends from Sudan south to Zambia. Fires set in the swamp, civil wars and large numbers of cattle tramping vegetation and destroying nests in the Sudd and elsewhere have disrupted protected areas such as the Akagera National Park in Rwanda (BI 2000). Tanzania's population of 2,000 birds is one of the few stable ones, newly protected as the country's first Ramsar site (BI 2000). Large numbers are captured for zoos, which exhibit this bird as a curiosity (Hoyo *et al*. 1992). The total population of this unique species was estimated at about 11,000 to 15,000 birds and declining in the late 1990s (BI 2000).

In the Sudd's floodplains and grassland are enormous herds of two antelope, the kiang, a subspecies of the topi (*Damaliscus lunatus tiang*) and the white-eared kob (*Kobus kob leucotis*). Almost a million of these antelope migrate to take advantage of grassland, forming the second largest aggregation of large mammals remaining in Africa after the wildebeest (*Connochaetes taurinus*) of East Africa. A film about these spectacular animals, fiMysterious Herds of the Sudan: Migration of the White-eared Kobfl (see Video, Mammals), shows this landscape as well, a little-known corner of the Earth whose abundant wildlife may be decimated if the Jonglei Canal is constructed. Another threatened species that is found only in the Sudd and wetlands of adjacent Ethiopia is the Nile lechwe (*Kobus megaceros*), a wetland antelope with elongated hooves that spread the weight of its body to keep it from sinking and help it leap through shallow water in bounds. This black antelope has ridged horns that arch over its back and a goat-like appearance. The *2000 IUCN Red List* lists it as near-threatened. The Nile lechwe's population totals about 30,000, but its range is restricted, and should its habitat be destroyed by water projects, it will be threatened with extinction (Nowak 1999).

In the middle of the vast Kalahari Desert is a brilliant, blue gem, the 11,000-square-mile Okavango Delta wetlands. This extraordinary wildlife oasis is the world's largest inland delta, a magnificent watery wilderness of shallow lakes, papyrus swamps, meandering rivers, wet grasslands and woodlands. World renowned for its large populations of zebra, antelope, African elephant (*Loxodonta africana*) and Cape buffalo (*Syncerus caffer*), the Okavango attract tourists in large numbers. Waterfowl are abundant, and the African fish eagle (*Haliaeetus vocifer*), which resembles the American bald eagle, is common. Fifteen species of marsh-dwelling antelope are native, many of which are unique to this region. One of these, the threatened red lechwe (Kobus leche), has a large portion of its population, some 30,000 animals, in the Okavango (Nowak 1999). A race of this antelope in the wetlands of Zambia, the Kafue lechwe (*Kobus leche kafuensis*), lost half its population of 100,000 in 1970 after the construction of two huge dams for hydroelectric power on the Kafue River, which radically altered the natural flooding and dried out much of its floodplain habitat (Nowak 1999). Another race of this species, *Kobus leche smithemani*, native to the Bangweulu Swamps of northern Zambia, fell from about 250,000 in the 1930s to around 30,000 today, as a result of hunting and disruption of water levels by human manipulation (Nowak 1999). Yet another race, *Kobus leche robertsi*, native to the Luongo and Luena River drainages of northwestern Zambia, is now extinct (Nowak 1999).

Cattle ranches have been carved out of portions of the Okavango, but until recently, this immense swamp remained nearly intact. Its precious water supply is now in decline. A major feeder of this swamp, the Kavango River, is now having much of its flow siphoned off by the Namibian government for agriculture and residential use. Botswana has objected strenuously to this project, but Namibia is determined to ease a severe water shortage caused by years of drought. The Boro River, which emerges from the delta, may be dredged and diverted for diamond mines (Postel 1997). These projects may end in draining the Okavango and destroying the enormously profitable tourist industry in Botswana (Hawker 1997). This wetland receives irregular rain which brings flocks of flamingos to nest and renews the water table, but should its feeder river be blocked, many of its unique wetland animals and sizeable herds of endangered African elephant may be lost.

Another threat to the Okavango Delta is the planned spraying of 7,180 square kilometers with the pesticide endosulphan, beginning in the winter of 2001 (Tyler 2001). The purpose is to destroy tsetse fly, the dreaded vector for sleeping sickness or trypanosomiasis (Tyler 2001). This pesticide is toxic to small fish and many other types of insects that are primary sources in the food chain for aquatic birds, such as herons and egrets. These birds breed during the winter months when the spraying is planned, and the threatened Slaty egret (*Egretta vinaceigula*), which breeds in the delta and has a world population of only 5,000 to 10,000 birds, is at serious risk (Tyler 2001). Ironically, the tsetse flies were being effectively controlled by the use of cloth baits soaked in insecticide and hung on poles, but they were not properly maintained by personnel, and stocks ran out (Tyler 2001). Conservation organizations are protesting to the Botswana government to stop the spraying and consider the environmental effects. Until recently, sleeping sickness was not an easily controlled disease, killing thousands of Africans. Native hoofed animals are immune to the disease. Recently, however, a new drug, DSMO, used in the United States to remove facial hair, has been found to be almost a miracle drug in awakening victims of this disease from their comatose states, without the

side effects of available medications. One pharmaceutical company agreed in early 2001 to donate 3 years™ supply after pressure from various health organizations. This makes spraying toxic pesticides even more unnecessary.*

---

*fiOkavango. Jewel of the Kalahari,fl a series of three one-hour films by Partridge Films and the BBC, shows the great beauty and wealth of wildlife in this wetland. (See Video, Regional, Africa; see also the Book Section for several books about this swamp.)

Wetland Drainage: Page 4

Until the 20th century, wetlands covered large areas in Asia, from the swampy grasslands at the base of the Himalayas to the marshes and deltas of Thailand, Cambodia and Vietnam. With the growth in human populations and pressure to raise more crops, millions of acres were filled or converted to rice paddies. Thailand has lost virtually all of its freshwater wetlands, and China, Laos and Vietnam have also incurred great losses. The majestic Sarus crane (*Grus antigone*) no longer nests in Thailand, and throughout Asia, cranes are threatened by loss of wetland habitat. Eight of the world's 15 crane species are found in Asia, and nearly all are considered endangered. They breed from high Tibetan reed lakes to coastal marshes, and all these habitats are being lost. The endangered black-necked crane (*Grus nigricollis*) breeds in high altitude sedge marshes and grasslands of the Tibetan plateau. Several of its important breeding marshes in western China have dried up as a result of intensive grazing and plowing of the steppe grasslands, and portions of its wintering wetlands in Bhutan are being drained (BI 2000). A dam planned on the Lhasa river also threatens wintering cranes. These beautiful cranes now number only 5,000 to 6,000 birds, and they are in decline (BI 2000).

Colorful Asian storks, once widespread, are now threatened with extinction as their habitat declines yearly. Seven species are now listed by BirdLife International in *Threatened Birds of the World* (BI 2000). They include the vulnerable milky stork (*Mycteria cinerea*), the endangered Storm's stork (Ciconia stormi), the vulnerable lesser adjutant (*Leptoptilos javanicus*), the endangered greater adjutant (Leptoptilos dubius), the endangered Oriental stork (*Ciconia boyciana*), the near-threatened painted stork (*Mycteria leucocephala*) and the near-threatened black-necked stork (*Ephippiorhynchus asiaticus*). Such a diversity of storks is found nowhere else on the planet. North America has only one species, the wood stork, and only the white stork is native to Europe. Some breed in the mangroves of Indonesia, and others, like the Oriental stork, which greatly resembles the white stork, winter in marshes in Japan, North Korea and Taiwan, where they face hunting, draining of wetlands, pesticides and pollution. The total world population of this bird is estimated at only 2,500 and declining (BI 2000).

Wetland Drainage: Page 5

In the United States, early American colonists began draining wetlands in the 17th century, and various laws encouraging this activity were enacted through the years. Over half of wetlands of all types, and some 70 percent of riparian, or riverside, wetlands in this country, have been destroyed (Rezendes 1996). Losses continue under the Clean Water Act's weak regulations that place the US Army Corps of Engineers in charge of issuing permits to developers who apply for permission to fill in wetlands. The Corps' major role has been the construction of dams and levees, dredging of ports, and other water projects responsible for causing numerous extinctions among the nation's wildlife. These regulations exempt small and temporary wetlands, such as vernal pools and prairie potholes, and the

Corps has been less than vigilant in enforcing wetland protection (Williams 1996). Federal legislation should change the authority designated to oversee wetlands conservation from the US Army Corps of Engineers to the Department of the Interior. The United States may be the only country in the world to allow its dike and canal makers to oversee conservation of these ecosystems. Wetlands protection should be far stricter in both federal and state legislation to prevent further losses.

Unfortunately, these important wetlands are often not protected by law in the United States, or, in the case of states such as Massachusetts, are protected only by some towns and only if officially registered as vernal pools (Appel 1999). These pools are being destroyed, often intentionally, by developers and homeowners who fear that building on or near the pool would be restricted (Appel 1999). Even when the pool itself is not destroyed, its water supply can be cut off by building nearby. A prime area for wood frogs in Framingham, Mass., disappeared, even though registered as a vernal pool, because the surrounding 25 acres of woodland were cut to construct a cinema complex (Ridout 2000). The required 125-foot buffer area of woods that was left surrounding the pool did not supply enough runoff water; the vernal pool dried out and the frogs disappeared (Ridout 2000). The disappearance of turtles from many areas in the East has been blamed on the filling of these important habitats where they migrate to lay their eggs.

Many swamp forests in the East and in the Midwest, as well as potholes essential as breeding habitat for waterfowl and stopovers for the continent's shore birds, were drained with government subsidies. Iowa lost 98 percent of its potholes; Minnesota, 75 percent; South Dakota, 35 percent; Montana, 27 percent and North Dakota, which had one-third of all these ecosystems, 49 percent (Williams 1996). The latter state's legislature discourages protection of the remaining potholes by requiring approval of conservation easements or purchase for conservation by an agricultural council (Williams 1996). This reflects the failure of federal and state governments to value wetlands for their ecological importance rather than for commercial purposes such as agriculture, construction or mining. In other parts of the world, similar attitudes prevail. The black-faced spoonbill (*Platalea minor*), a large white wading bird of Asia has been reduced to only about 700 birds (BI 2000). More than 200 of these birds winter in Taiwan's Chiku marsh, near the capital city, Tainan, now under great threat from development (WESPA 1994). A Taiwanese government official, when questioned about proposed drainage of the marsh, stated to CNN on January 6, 1994, "We can't stop our industrial progress for a few birds." Throughout the range of these endangered birds in east Asia's coastal wetlands, development has drained their habitats or converted them into aquaculture ponds (BI 2000).

Coral Reefs

The beautiful and diverse coral reefs of the world are today more threatened than they have been for many millions of years. A survey in the 1980s found that damage had occurred in coral reefs in 93 of the 109 countries where these rich ecosystems are found (Wells and Hanna 1992). At least 10 percent of coral reefs around the world had been damaged beyond repair, while 30 percent were in critical condition and expected to disappear within 10 to 20 years; another 30 percent were expected to die by 2050 (Carter 1997). Research in 1999 found further damage: one-third of all coral reefs were dead and 90 percent degraded to some extent.

In the Maldive Islands in the Indian Ocean, all the coral around inhabited islands has been excavated. This limestone material has been fashioned into houses. An estimated 95 percent of these reefs are dead or dying (Zuckoff 2000b). The result has been lowland flooding by the sea because these protective barriers were destroyed. Because of the growing numbers of tourists, tour boats, scuba divers and spear fishers, many ancient reefs are declining in species diversity or dying out altogether. In some areas, hotels are often built with inadequate pollution and erosion controls near coral reefs. Even touching a coral can harm the delicate outer layer, which can take 100 years to recover.

Dynamiting and poisoning reefs to obtain fish are methods banned throughout Asia, yet they regularly occur. David Doubilet (1999) has spent much of his life photographing coral reefs and has witnessed such activities. On one

occasion while diving in the Philippines, he saw large areas of coral reefs reduced to white rubble. The cause was nearby boatmen who lobbed bottles of homemade explosives into the sea (Doubilet 1999). They were chased off by a marine official who fired a pistol round over the poachers' heads, but on inspecting the results in the coral reef, Doubilet saw fish spinning aimlessly in convulsions or belly-up amidst the craters of blast sites (Doubilet 1999). Beginning in the 1960s, Philippine fishermen pumped cyanide poison into 33 million coral heads at a rate of 330,000 pounds yearly (Chadwick 1999). Approximately 95 percent of the reefs of the Philippines have been destroyed from the combined effects of sewage pollution, dynamiting and the use of cyanide to obtain tropical fish for the pet trade (Chadwick 1999). These fish usually die within weeks from the cyanide (Wells and Hanna 1992). In the rich reefs surrounding Indonesia, a recent trade has begun for live fish which are kept in aquariums to be consumed in restaurants in Hong Kong and other major cities; the fish are stunned by small amounts of poison and the coral often dies after being sprayed (see Trade, Fisheries).

Seashell and pearl harvests have depleted many reefs of species important in controlling reef predators. The Crown-of-Thorns starfish of the western Pacific was once preyed on and kept in check by 12-inch giant triton mollusks, a species collected heavily for the shell trade. The fish that controlled populations of Crown-of-Thorns starfish have been killed off by fishing, further causing imbalance to reefs. Sewage or agricultural runoff promotes the growth of plankton that also encourages these starfish to multiply to pestilential levels, killing off large portions of coral (Chadwick 1999).

Siltation runoff from clear-cutting forests near shore and agricultural plowing has become major factors in the death of 95 percent of Philippine reefs and the dying of reefs in the Florida Keys and elsewhere. When silt comes to rest on live coral, the coral is smothered. Fertilizers and sewage encourage the growth of bacteria, viruses and diseases, such as aspergillosis, that have devastated hundreds of coral reefs in the Caribbean (Chadwick 1999).

Coral bleaching, in which colorful corals turn white and die, is affecting a growing number of reefs. Even a slight rise in ocean temperature can kill off the symbiotic algae living in the coral. The algae gives coral color and without it, the coral animals die. Global warming has been mainly responsible for gradually raising ocean temperatures, and should it continue, the majority of the world's reefs will die out. Household bleach, used by fishermen to stun fish, can also cause bleaching. UV radiation from ozone depletion may play a major role, as well by killing off the symbiotic algae (Chadwick 1999). In some cases, coral bleaching can be temporary, and corals can recover if water temperatures cool before too much time has passed or if the corals are not also being attacked by pollutants, pesticides or a different type of algae produced from fertilizer nutrients in the water.

The Great Barrier Reef has incurred die-offs of coral in many areas. This massive reef is considered one of the great natural wonders of the world, with a great diversity of fish and corals. Coral bleaching has killed various parts of the reef in recent years, and in 1998, the warmest year ever recorded, large sections of the reef died, leaving white skeletons in place of dazzling fish and colorful corals (Zuckoff 2000b). Some reefs recovered when temperatures cooled, but most did not. Scientists meeting at the fourth meeting of the International Coral Reef Symposium in 2000 warned that global warming and other threats must be stopped if the world's coral reefs are to be saved (Zuckoff 2000b). At the present rate of destruction, one scientist estimated that coral reefs will be gone in 30 to 50 years (Zuckoff 2000b). Global warming is not being arrested, however, as countries, led by the United States, the largest producer of greenhouse gases, continue to pollute the atmosphere.

Mangrove Destruction

In the Americas, mangroves grow as far north as southern Florida and the Florida Keys, throughout the Caribbean region; and in South America, they occur in a narrow band lining the Amazon River and on the coasts of French Guiana and northern Brazil. Mangroves are also abundant in river deltas of West Africa, portions of the Middle East,

east to Malaysia, Papua New Guinea, northern Australia and on many western Pacific islands.

The Sundarban mangroves surround the Ganges Delta, extending along the coasts of eastern India and Bangladesh. They cover 2,300 square miles and penetrate far inland along the Ganges River, forming an intricate maze of rivers, creeks and canals that are flooded daily by ocean tides (Dugan 1993). Wildlife is abundant in these mangroves. At least 35 species of reptiles, 270 bird species and 42 mammal species are native (Dugan 1993). The most famous of these is the magnificent Bengal tiger (*Panthera tigris bengalus*), whose largest population may be found here. India has set aside a large reserve for tigers and other wildlife in its portion of the Sundarbans; as many as 350 to 400 tigers are present in Bangladesh's portion, with 250 to 300 in India's (Dugan 1993). Even in this maze of mangroves, however, tigers are under siege from poachers, and since the early 1990s, their numbers have declined even here from habitat loss, poaching and loss of prey animals to hunters.

The Sundarban mangroves are heavily exploited by the over 300,000 people who live here. Each year 9 million cubic metres of timber and pulpwood and 106,400 tons of fuel wood are cut by Bangladeshi and Indian natives (Dugan 1993). Overcutting has affected the fisheries habitat that provides about 150,000 tons of fish per year for the 10,000 fishermen in these mangroves (Dugan 1993). So many of the outer island mangroves have been destroyed that storm surges caused by cyclones now move much further inland, leaving destruction and loss of life in their wake (Hauser 1992). Fragile mangroves have been destroyed for a fishing jetty and prawn culture area inside the Indian Bhitarkanika Sanctuary for endangered Olive Ridley Sea Turtles (*Lepidochelys olivacea*). These projects were funded by the World Bank. This prime wildlife area is vital to white-bellied sea eagles and threatened Indian smooth-coated otters of the same species as Maxwell's otter (see above). The Olive Ridley sea turtles experienced a major die-off in February 2000.

The cutting of mangroves in southeast Asia has destroyed thousands of acres to supply paper mills in Japan (Collins 1990). Prior to the Vietnam War, scientists estimate that at least 1,000 square miles of the Mekong Delta were mangrove and paperbark forest. Eleven million gallons of herbicide defoliants (known as Agent Orange) were sprayed during the war, destroying half the delta wetlands, or 480 square miles of mangrove and 100 square miles of paperbark (Dugan 1993). To compound the damage, the forests beyond the mangroves were burned and sprayed with herbicides, and canals were dug by the U.S. armed forces to drain the flooded areas (Dugan 1993). Much of this land remains poisoned and infertile 35 years after the end of the war; replanting is taking place on non-poisoned acreage. The human toll has been significant: thousands of Vietnamese died from the effects, and many children born since the war have had a high incidence of birth defects, serious skin disease and tumors; American soldiers exposed to these chemicals suffered a wide range of cancers and other major health problems. Only recently has the US government acknowledged the full range of the effects of these herbicides and paid compensation to ailing servicemen.

The Mekong River delta is native to 260 species of fish, 35 reptile species, 6 amphibian species, 386 bird species and 23 mammal species (Simon 1995). Among these are the endangered Estuarine crocodile (*Crocodylus porosus*), a species in decline throughout its southeast Asian range, and the threatened eastern Sarus crane (*Grus antigone*), which disappeared from Vietnam during the war but later returned (Simon 1995). One of the rarest birds in the world, the giant ibis (*Pseudibis gigantea*), is the largest of all ibises, a silvery-gray bird with pink legs. The Mekong Delta system in Cambodia was its stronghold in the 1920s, where it was commonly seen, but a 1994 survey found no giant ibis. Wetland drainage for agriculture, hunting and deforestation have pushed it to the edge of extinction. Extinct in Thailand, only two birds have been seen in southern Laos in recent years Œ in 1993 near a proposed protected area (Collar *et al*. 1994). Once native to the Mekong Delta in Vietnam, it was probably extinguished during the war. Cambodia has some lowland wetlands and may have undiscovered populations of giant ibis, but at present the estimated total world population is 50 birds and declining (BI 2000).

At present, the greatest threat to mangroves worldwide is the farmed shrimp industry. Mangroves are natural nurseries for shrimp, and this industry destroys the mangroves by cutting them in wide swaths to make room for artificial ponds. These ponds are closed off to prevent the shrimp from swimming back to the sea. Without the natural cleansing of the tides, the ponds soon become polluted and laden with chemicals added by the farmers.

Although not all farmed shrimp are raised in this environmentally destructive manner, in some countries this type of farming predominates. The worldwide shrimp farm industry is worth at least $8 billion (Mydans 1996) and produces 783,200 tons of shrimp per year, about 30 percent of the world's shrimp production (Nixon 1996). Fifty countries now farm shrimp, many with aid from the World Bank. The governments of India and Ecuador have banned the further cutting of mangroves for shrimp farms, but in Ecuador, 85 square miles of mangroves were illegally cut after the ban. In the Philippines, 1,000 square miles of mangroves, 67 percent of the country's total, were destroyed between 1920 and 1980, most being converted to ponds for farming shrimp and milkfish (Dugan 1993).

Grassroots environmental organizations have recently appealed to international conservation groups and lending banks to stop funding the farmed shrimp industry and to the public to boycott all farmed shrimp. One such group, the Seattle-based Mangrove Action Project, has united with The Sierra Club of Canada and other organizations to lobby against tropical shrimp farms. The shrimp pond industry may die out on its own, however, because of disease outbreaks in the ponds. Various types of virus and bacterial infections have spread through shrimp ponds because of their stagnancy and the crowding of shrimp. More than 42,000 acres of ponds in Ecuador now lie fallow, having been swept by disease, and many fishermen and shrimp farmers now see the wisdom in protecting the mangroves because these trees are able to filter water and maintain a clean environment for shrimp far more efficiently than human-made holding ponds along the coasts (Nixon 1996). High-technology aquaculture buildings have been constructed that use aerated and filtered water and operate independently of natural ecosystems. Some of these facilities have been constructed in Thailand and elsewhere. They are a far more environmentally friendly method of producing shrimp. A key element is the captive-breeding of shrimp in such a facility, rather than removal of wild larvae from the ocean.

Noise, Boat Collisions and Debris

The once quiet oceans now rumble with huge cargo, cruise and naval ships whose noisy engines drown out the delicate rumblings, and songs whales make to establish territory and communicate, as well as the myriad sounds other creatures emit in the ocean depths vital to their survival. The North Atlantic, Mediterranean and Baltic are especially busy shipping lanes. Wildlife now has new and lethal noises to cope with. The Navy has been testing anti-submarine sonar called Low Frequency Active. Powerful sonar waves are broadcast underwater to test a means of detecting quiet enemy submarines (White 2000a). These sonar waves can travel hundreds of miles and be extremely loud. Humpback whale (*Megaptera novaeangliae*) males emitting their complex, haunting songs to establish territory have become silent or moved away when these waves were broadcast. More ominously, testing in 1995 off the coast of Greece coincided with an unusual stranding of Cuvier's beaked whales (*Ziphius cavirostris*) resulting in the deaths of these seldom-seen whales. In March 2000, Ken Balcomb, a biologist from the Center for Whale Research who is familiar with sonar, was present when a stranding occurred while Navy tests were taking place nearby. Fifteen animals stranded, including dense beaked whales (*Mesoplodon densirostris*) and other species of beaked whales, a Minke whale (*Balaenoptera acutorostrata*) and a spotted dolphin (*Stenella frontalis*). All washed up on the shores of a Bahamian island; when pushed back into deep water, they were unable to remain upright, clearly unbalanced and disoriented, and nine died (White 2000a). Along with Harvard biologist Darlene Ketton, Ken Balcomb performed necropsies on several whales, finding their ears full of blood and, in one case, hemorrhages striped the lungs; further testing discovered that a whale had suffered a concussion, apparently the result of acute trauma from pressure (White 2000a). A press conference organized by the Animal Welfare Institute following these findings featured Ken Balcomb and other whale experts, who attested to the fact that the sonar is reckless, unnecessary and lethal to whales. Soon after, the Navy canceled testing of active sonar off New Jersey, as well as its scheduled tests on sperm whales in the Azores (White 2000). This technology fills the ocean with penetrating sound waves that greatly disturb or kill marine mammals, interfering with their own sonar and natural behavior.

A major cause of mortality for Florida manatees is collisions with boats. Manatees struck by motorboats or their

propellers can be killed instantly, or may suffer slow, painful deaths from deep slashes and internal injuries. In some cases, these strikes have been intentional. CNN recently reported a case of a woman who witnessed a young man in a motorboat repeatedly driving over a mother manatee and her calf until both were dead. She called the state law enforcement division, but by the time officers arrived, the perpetrator was gone. Many calves are orphaned when their mothers are killed, and only if they are found within hours can they be rescued and cared for by Sea World or other aquariums in Florida. In the first half of 2000, the state determined that 61 deaths were caused by watercraft, just short of the all-time high of 67 for the entire year of 1999. These figures may be lower than the actual mortality, since some manatees may be struck and sink, while others, whose bodies are found, may show no outward sign of injury, having been struck by the bow or side of a boat. These collisions occur with such frequency that virtually all adult Florida manatees have propeller scars on their backs.

The present system of posting speed limits has not been effective in reducing collisions, since so many boaters refuse to obey them and enforcement is inadequate. Manatees swim long distances to find warm water during the winter, passing through shipping lanes and most of southern Florida's navigable waters. This creates a problem that the State of Florida and the Fish and Wildlife Service have not properly addressed, yet one that must be solved to preserve this species. Apparently, manatees do not hear motorboats coming. Research is taking place on the placement of some type of noisemaker attached to the underside of boats to warn them. Even this would not result in a halt to all manatee-boat collisions, however, because these animals are too slow-moving to avoid high-speed boats. Boat propeller guards would also reduce manatee deaths and injuries, as well as human injuries caused by accidents with these sharp blades, but they have not been required by law. The number of pleasure craft in Florida has risen exponentially in recent years, with few laws and regulations governing those who propel them, such as strict regulations on sobriety and competence to handle the boats. Heavy boat traffic has also resulted in human fatalities and injuries from collisions.

Two lawsuits were filed in January 2000 on behalf of the Florida manatee. A coalition of 18 environmental and animal welfare groups, led by the Save the Manatee Club, sued the State of Florida, the US Army Corps of Engineers and the US Fish and Wildlife Service. The Animal Welfare Institute's companion organization, the Society for Animal Protective Legislation, has worked with the coalition's legislative team to obtain $500,000 from the Congress for manatee protection. The corps was sued for its repeated issuance of permits for development in manatee habitat without analyzing the cumulative effects of the permits on the species or its habitat. The suit charges the Fish and Wildlife Service with failure to properly enforce the Marine Mammal Protection Act of 1972 and the Endangered Species Act to prevent mortality and to conserve the species. The US Fish and Wildlife Service failed to designate adequate sanctuaries for manatees where boat traffic would be restricted, reducing its proposed list of sites from 150 in Florida to 10 to 15 (Daley 2001).

The second suit was filed against the Florida Fish and Wildlife Conservation Commission, which has not complied with the Florida Manatee Sanctuary Act of 1978, enforced speed limits, or taken other measures designed to protect these vulnerable animals. The mortality rate from all causes is far greater than the number born, pushing manatees toward extinction. Florida Governor Jeb Bush angered conservationists in late 2000 by allowing the licensing of more boat slips in Sarasota, although the county had not completed a required plan to protect manatees (Daley 2001).

The future is bleak for the approximately 3,000 surviving Florida manatees unless dramatic action is taken (Daley 2001). Their survival has become critical. Other causes of mortality, such as death from red tide, pollution or cold weather, add to the toll. In 2000, for example, 273 manatees died from all causes, close to 10 percent of the entire population (Daley 2001). Since manatees have a single young only every 5 to 7 years, they cannot sustain such losses. These gentle and affectionate animals have been on Earth for 45 million years, yet a lack of concern and willingness to alter our recreational boating habits may eliminate them in Florida. Elsewhere in the range of these manatees, far stricter regulations have been imposed on boat traffic. In Belize, for example, very few manatees have boat propeller scars because many areas are off-limits to all motorized boats, and tours are conducted in boats propelled by poles.

There are two major threats to whales and marine mammals causing their elimination in many areas. Fishing

vessels throw out ropes, nets and other debris that entangle marine mammals, often lethally, and vessels of all types present the danger of mortality through collisions. One or more highly endangered North Atlantic right whales (*Eubalaena glacialis* die each year from rope and net entanglements or collisions with ships; their population is only at about 300. In 1995, a whale of this endangered species became wrapped in lobster line and died off the Rhode Island coast. In September 1997, another whale became hamstrung with nylon netting around his head, towing a 9-foot sea anchor near Nova Scotia; it took 8 1/2 hours to free him, after a 25-kilometer chase by a rescue team. A young blue whale (*Balaenoptera musculus*) was killed when a ship collided with it; the ship entered a Massachusetts port with the whale impaled on its bow. In early 2001, three dead fin whales (*Balaenoptera physalus*) washed ashore along the Atlantic coasts of the United States, killed by ship collisions. For North Atlantic right whales, such collisions may end in their extinction, unless means are found to prevent them. These whales have a single calf only once every five years and are dying at such a rate that scientists expect their extinction within less than a century.

Plastic bags and fishing gear have been found to strangle and suffocate endangered sea turtles, marine mammals and sea birds. Endangered albatross on Laysan Island are among the many species to have died after ingesting plastic materials. They also feed their chicks plastic items they mistake for food, unintentionally killing them. Sea turtles, dolphins, whales and sea lions around the world are drowning and strangling in fishing lines and nets. One endangered fin whale that washed ashore dead in Biscayne Bay, northern Spain, in 1997 was found to have ingested huge amounts of plastic sheeting and bags that clogged its digestive system. Each year millions of balloons are released to the winds, and untold numbers end up floating in the oceans, a peril to wildlife. One young sperm whale (*Physeter catodon*) starved to death after swallowing a single balloon that blocked its intestine. Endangered sea turtles die after consuming plastic bags and balloons, mistaking them for jellyfish. Non-biodegradable plastics and nylon nets and ropes in the ocean will present lethal threats to wildlife for the indefinite future. Although international treaties have been signed that regulate such dumping, to date no national or international program has attempted to remove debris, such as plastic items, nets and fishing lines, from the oceans.

Toxic Chemicals

Some chemicals, such as Polychlorinated Biphenyls (PCBs) and pesticides, have entered aquatic systems, causing birth defects in water birds and other wildlife. PCBs, manufactured by General Electric, were used for decades in refrigerators and other industrial uses until it was discovered that when released to the environment, they had serious effects on wildlife. American bald eagles have been among the species affected by PCBs, producing chicks with crossed bills and other defects.

Beluga whales (*Delphinapterus leucas*) in the St. Lawrence River have also been affected. Isolated from members of their species living further north for thousands of years, they have declined dramatically in recent years. Many of these beautiful whales, known for the lyrical songs they sing to one another, have been found dead with tumors, malformations and impairment of female reproductive organs. This river, which links Lake Erie to the Atlantic Ocean, has become severely polluted with chemical contaminants, resulting in declines in wildlife. American eels (*Anguilla rostrata*) accumulate high levels of toxins on their spring migration from the Great Lakes down the St. Lawrence River to the sea and contaminate the Belugas when they feed on them. A major source of PCBs in the river is a sunken barge in the Gulf of St. Lawrence, which has been oozing these toxins for more than 25 years; its cleanup is difficult because there is fear it will break apart either on its own or if moved (Nickerson 1996).

The St. Lawrence belugas numbered about 5,000 in the 1600s, but whaling, which went on until the 1940s, reduced their population to about 2,500 (Katona *et al*. 1993). Before they could fully recover, contaminants from industries surrounding the Great Lakes and St. Lawrence seaway took a tragic toll on them. Today, only 400 to 500 belugas remain in this river. A study by Dr. Pierre Beland of the St. Lawrence National Institute of Toxicology in Quebec found that 40 percent of all belugas necropsied had malignant tumors in their digestive systems, mouths, esophagi, intestines and respiratory systems. Two percent of the belugas found at the mouth of the Saguanay River were visibly deformed. PCBs, which cause malformations in mammals and birds, were found at levels up to 3,400 parts per million (ppm) in the milk of a lactating female beluga and up to 576 ppm in blubber (Katona *et al*. 1993). Fish is unfit for human consumption if it contains 2 ppm of PCBs.

In 1976, the United States banned the manufacture of PCBs, and other industrialized countries followed. But in the nearly 50 years that they were manufactured, an estimated 3.4 billion pounds had been produced, and they have become pervasive in the environment, spreading on air currents and through aquatic food chains. PCBs are now found in animals thousands of miles away from locations where these chemicals were used, in the blubber of whales and the milk of nursing polar bears (Colborn *et al*. 1996). Once PCBs are deposited in the fat of animals and humans, they remain indefinitely and do not biodegrade. These and related chemicals continue to cause birth defects and reproductive failure in wildlife (Colborn *et al*. 1996). Virtually all humans carry PCBs and other persistent chemicals in their body fat, and a nursing mother passes these chemicals on to her baby (Colborn *et al*. 1996). The higher the animal on the food chain, such as birds of prey, whales, seals and land predators, the higher the concentrations of PCBs and chlorinated hydrocarbons like DDT, multiplying up to 3 billion times as they move up the food chain from microorganisms to polar bears (Colborn *et al*. 1996).

PCBs have also contaminated killer whales (*Orcinus orca*) in the Pacific Northwest. The Institute of Ocean Sciences tested 47 of these giant dolphins living off the British Columbia coast, finding levels two to five times as high as belugas in the St. Lawrence River (NG 2000). Just to the south, the killer whales off the San Juan Islands of Washington State are in decline, with the highest PCB levels ever found in wildlife (White 2000b). Deformed polar bear cubs have been found in Norway's Svalbard Islands. Researchers in 1996 found seven cubs with both male and female sex organs (NG 1999). These islands receive three times the PCB exposure of northern Canada, where only one such case has been seen (NG 1999). Pesticides and PCBs are carried here by air and water from Europe, North America and Asia.

During the 1990s, bald eagles (*Haliaeetus leucocephalus*) feeding on seagulls near Lake Superior accumulated contaminants 20 times higher than fish-eating birds of the same area (Colborn *et al*. 1996). Bald eagle chicks hatched in the Great Lakes were found with severe birth defects, from crossed bills to missing eyes, clubbed feet and a wasting disease that causes chicks to weaken and die (Colborn *et al*. 1996). Scientists have detected high residues of contaminants such as dioxin, PCBs and furans in the eagles. PCBs are the most likely cause of these abnormalities, but several chemicals might interact with toxic effects (Colborn *et al*. 1996).

Almost the entire length of the Hudson River has been contaminated by PCB dumping and outflow from a General Electric plant. Seepage of PCBs continues from the plant foundations, even though the chemical is no longer

produced here, rendering fish from the river commercially unmarketable. After decades of conservation, striped bass recovered from heavy fishing in the Hudson River, but they contain such high amounts of PCBs that if caught by sport fishermen, they cannot be sold, and pregnant women are warned not to eat them. The removal of these residues from the Hudson and other river bottoms has not been carried out because of the difficulty of containing them in such a way as to prevent their dispersal into the atmosphere. General Electric was ordered to dredge the PCB residues in 2000, but local communities along the Hudson River have expressed opposition, fearing that they would disperse throughout the river. These chemicals may be impossible to eliminate from the Earth.

Like PCBs, persistent types of pesticides and herbicides, even in minute quantities, can be stored in the tissues of aquatic organisms and accumulate in greater and greater amounts in the ascending food chain. These chemicals can accumulate to toxic levels, killing the animals or interfering with their production of eggs, a known effect of chlorinated hydrocarbon pesticides, primarily DDT, that nearly caused the extinction of the Peregrine falcon (*Falco peregrinus*) in North America and great declines in bald eagles and other birds. The most injurious of these, DDT, dieldrin and chlordane, have been banned in the United States for most uses, but are used in foreign countries and remain in many areas where they were manufactured.

Toxic Chemicals: Page 2

Although persistent pesticides of the DDT family have been banned in the United States, they are still manufactured here and exported for control of malaria to many tropical countries. DDT is still present in a 17 square mile dumping area in the coastal waters off California. Montrose Chemical Corporation and two other companies dumped some 100 tons of DDT between 1947 and 1971, when it was banned. These ocean residues continue to enter the food chain through fish and other organisms. This has affected birds who feed on these fish, including brown pelicans and bald eagles on the California coast, who still laid thin-shelled eggs as a result of DDT contamination of their food supply 30 years after the ban. Highly toxic pesticides banned in the United States are still being used around the world, killing large numbers of birds and other wildlife. Diazinon, a pesticide commonly used on golf courses in the United States, and highly toxic to geese and other birds, was recently banned in the United States, along with Dursban, a commonly used lawn chemical. Pesticides and related chemicals that kill and cause mutations in wildlife are indeed still being broadcast in the United States as well as in other parts of the world. Only with more oversight and strong legislation to limit use and export of these chemicals can wildlife and aquatic ecosystems be protected.

DDT and other pesticides contaminate entire ecosystems in tropical countries, and some North American birds winter in areas where these chemicals are still used. Between 1992 and 1994 alone, the United States exported at least 247 million pounds of banned or restricted pesticides to the rest of the world. DDT, for example, is widely used for malaria control in Africa and Asia. Virtually no laws restrict this trade, which has the potential of causing major wildlife declines and extinctions.

In agricultural areas in northern Florida, American alligators (*Alligator mississipiensis*) have been found with abnormalities and poor reproductive success thought to have been caused by pesticides in their food supply (Colborn *et al*. 1996). Many synthetic chemicals react on animals in a manner similar to hormones. Dicofol, a pesticide related to DDT, was widely used in the vicinity of Lake Apopka, finding its way into the waters and causing abnormalities in alligators. Males developed unusually small penises and defective testicles, and females had abnormal eggs and sex organs (Colborn *et al*. 1996). The male alligators in this lake had elevated levels of female hormones, equal to those in normal female alligators, and one-fourth the normal level of testosterone; females had estrogen levels double the norm (Colburn *et al*. 1996). The reproduction of alligators in the area has nearly ceased altogether, with almost no eggs hatching (Colburn *et al*. 1996). Red-eared turtles of Lake Apopka, considered unlikely to be affected by this pesticide since they are plant-eaters, surprised researchers by exhibiting reproductive difficulties as well. Many turtles

discovered had not developed normally as either male or female (Colborn *et al*. 1996).

Toxic Chemicals: Page 3

Within the past few decades, an increasing toll of wildlife has been taken by toxic chemicals in aquatic environments. Massive seal kills have occurred in the North Sea, and in January 1996, the body of an endangered sperm whale (*Physeter catodon*) washed up on a Danish beach. Analyses of its tissues revealed dangerous levels of heavy metals Œ so much mercury and cadmium that the intestine had to be buried at a special dangerous waste site. The amount of toxic cadmium was 20 times higher and the quantity of mercury double that normally found in fish. The North Sea has become extremely polluted, laden with toxic chemicals from industry and untreated sewage.

Off the west coast of Mexico, a large number of dead dolphins and Gray Whales have washed ashore since 1997. Some were the apparent victims of cyanide poisoning. Drug traffickers use a cyanide-based chemical to mark ocean drop-off sites, and this chemical is thought to be responsible for poisoning these and hundreds of other marine mammals and fish. Some Gray Whales that wash ashore may be suffering other maladies related to toxic chemicals or contamination, combined with a lack of food. Numbers have risen off U.S. coasts: 278 in 1999, more than 300 in the first half of 2000 (White 2000b). The number of Gray Whale calves also declined from 1,520 in 1997 to 282 in 1999 (White 2000b). Many of the dead whales were emaciated.

Very high levels of methyl mercury have been detected in the Everglades. A study by Greenpeace found that this highly toxic metal was emanating from trash incinerators operating on the East Coast. Endangered Florida Panthers (*Felis concolor coryi*) have been found dead with toxic levels of mercury in their bodies. These endangered cats, an unusual subspecies of the Cougar, are close to extinction, with a population of fewer than 30 animals. Mercury is also present in sewage sludge, much of which is spread on land as fertilizer. In one year alone, 1996, the state of New Hampshire spread 1.6 tons of mercury on land (Giordano 1998). Their dairy farms are among the users of sludge obtained from chemical treatment plants in Massachusetts and other states (Giordano 1998). Common Loons, known for their haunting cries once heard in virtually every one of New Hampshire's thousands of lakes, have declined precipitously in recent years, their bodies laden with very high levels of methyl mercury (Giordano 1998).

In spite of the clear danger presented by mercury, little has been done to limit its use and disposal. Only Vermont has passed legislation that bans disposal in landfills and requires labeling of products such as fluorescent light bulbs, light switches, batteries for hearing aids and watches and thermometers. Mercury is also used in dental fillings. Boston banned the sale of household mercury thermometers in 2000, and the ban is expected to be extended statewide in 2001 (Daley and Kremmer 2001). Several other states are considering legislation to require labeling of mercury-containing products and banning their disposal by flushing or placing in the trash. New York State proposed legislation in 2001 that would eliminate the use of mercury in such products beginning in 2004 (McKinley 2001). The Environmental Protection Agency and the New York Department of Environmental Conservation began to cooperate in regulating mercury sent into the air by incinerators five years ago, but coal-burning power plants, which emit about 30 percent of all mercury emissions, are not subject to any federal or state restrictions (McKinley 2001).

Toxic mercury residues from metals companies is often shipped out of the country to nations that accept them. Now, however, some countries are unwilling to allow such shipments. One cargo ship headed for Bombay, India, in January 2001, carrying 20 tons of mercury reclaimed from a Maine factory, set off a tempest of protests by environmentalists in that country who denounced the "toxic trade" (Daley and Kremmer 2001). At least 12 factories in the United States have stocks of tons of mercury, some of which is used in a chemical process to produce chlorine (Daley and Kremmer 2001). India is a major user of industrial mercury as well, but resents becoming a dumping ground for other countries (Daley and Kremmer 2001).

Toxic Chemicals: Page 4

Within the past decade, sea turtles in Florida Bay and the surrounding waters have shown signs of disease caused by toxic chemicals. Hundreds of turtles have been found dead or dying, some with massive tumor growths on their skin, covering their heads, necks and legs. It is thought that these growths are caused by a virus that attacked the turtles because of their lowered immunity system, which was in turn caused by pollution such as runoff from farmland or inadequate food when sea grasses died off. Some of these turtles have been saved by placing them in aquariums for months to build up their immune systems. Because of the increasing number of sick turtles seen, however, and the other problems that these sea turtles face, many scientists now believe that within 50 years, sea turtles will have disappeared from Southeastern waters.

Chemical runoff from agriculture in the reclaimed marshes of central Florida is thought responsible for the outbreaks of red tide organisms that killed hundreds of endangered Florida manatees (*Trichechus manatus latirostris*) in 1996, devastating their populations. A total of 415 manatees died that year, a record number. Of these, a large percentage died from the toxins. The hundreds of dying manatees, who exhibited no symptoms prior to their deaths, caused great concern among scientists and conservationists who cooperated to discover the cause. Analyses of tissues carried out by the Florida Marine Research Institute and federal, state and private agencies finally concluded that red tide toxics produced by dinoflagellates were the cause. Some of the sick Florida manatees exhibited neuromuscular problems consistent with those previously described in manatees exposed to red tides and were taken to a rehabilitation facility at Lowry Park Zoo in Tampa (Turner 1996). Three females recovered over a period of three days, during which time they required assistance to stay afloat for breathing (Turner 1996).

Although red tide is a natural phenomenon, scientists believe that these tides, which have been occurring with greater frequency in recent years, are erupting as a result of effluents, such as sewage and agricultural fertilizers and pesticides (Broad 1996). The average number of Florida manatees that die each year was 100 or fewer prior to 1990, but since then, each year 200 or more die. The effects of pollutants may be a major factor in the doubling of their death rate at a time when toxic chemicals have become pervasive in Florida waters. Since a female manatee has only one young every five to seven years, this death rate is far greater than the recruitment rate.

Toxic Chemicals: Page 5

Pollution-caused mortality of wildlife was, until recently, rare, occurring in isolated areas in the world's oceans. Increasingly, however, these poisons are becoming widespread, and the effects on ecosystems and individual species have been serious. Red tides have affected the Chinese coast in recent years, causing massive fish kills and wiping out fish farms (Chu 2000). They are attributed to sewage dumping. In Hong Kong, where a red tide covered 2,000 square miles, 700,000 tons of sewage is dumped yearly into the nearby Bohai Sea (Chu 2000). Long-term dumping of sewage, toxic chemicals and fertilizer is killing all fish and sea life, creating "dead zones." A dead zone in the Gulf of Mexico off the delta of the Mississippi River covers 7,000 square miles, the size of New Jersey; it spreads west to the Texas coast (Yoon 1998). Caused by a lack of oxygen, 50 dead zones were found in oceans and seas throughout the world by 2000. Cruise ships now number in the thousands, and each one generates a million gallons of waste water, 200,000 gallons of sewage and 25,000 gallons of oil-contaminated water each week, according to the Bluewater Network (Johnston 2000). Even small motor boats are heavy polluters of the air and water, emitting toxic fumes and leaving trails of oil and gasoline in the water.

Toxic Chemicals: Page 6

The spectacled eider (*Somateria fischeri*), a beautiful duck of Alaska and arctic Russia, has incurred great declines that may be related to ingestion of toxic chemicals. The Iowa-sized Yukon-Yuskokwim Delta of western Alaska had 100,000 of these ducks breeding here in the 1970s, but beginning in 1986, they lost 14 percent of their population each year; 95 percent of their original numbers are now gone, leaving only about 5,000 birds (Dunkel 1997). In 1993, the species was listed as threatened on the Endangered Species Act, and a task force set about trying to discover the causes. They found that many of the birds had high levels of lead from Eskimo hunting with bird shot. Although 34 of the 42 Eskimo villages in the delta have passed resolutions in favor of using steel shot over lead shot, most natives apparently believe that the birds are dying out from being studied and handled by biologists (Dunkel 1997). One Fish and Wildlife Service biologist observed a spectacled eider dying of lead poisoning: "She was flopping along [on the ground] and couldn't lift her head . . . She died within an hour" (Dunkel 1997). Lead in sub-lethal concentrations can cause females to abandon nests and males to become infertile.

Lead poisoning has killed other wildlife as well. The magnificent and rare Steller's sea eagles of Russia's Kamchatka Peninsula and northern Japan have been dying of lead poisoning from eating carcasses of deer killed by Japanese hunters (Garcelon 1999). Lead shot cannot be used by United States waterfowl hunters (other than native Americans) because of massive bird-kills in marshes where lead shot accumulated.

Until February 1995, the wintering area of spectacled eiders, where they spend 10 months of the year, was unknown. The Fish and Wildlife Service had attached radio transmitters to several of these ducks, only to find the signals fading during the winter. One radio, however, continued to send out signals which were detected and located by biologists flying over the Bering Sea in a small plane (Dunkel 1997). To their amazement, they saw flotillas of these ducks, gathered in dense flocks south of St. Lawrence Island off western Alaska. Packed close together, their body heat helped keep the ice open. DNA studies determined that these ducks comprised the entire world population of the spectacled eider, converged from Alaska's North Slope, the western Alaskan delta and arctic Russia. Each returns to the location where it hatched, and when one population declines, there is no recruitment from the others (Dunkel 1997). This makes the decline in the Yukon-Kuskokwim Delta population all the more serious. The Bering Sea has been found to contain cadmium, selenium, strontium and other contaminants in high concentrations, which might be another explanation for the decline in these ducks (Dunkel 1997). Their disappearance coincides with the downward population trends of Alaskan mammals that were abundant only a few decades ago. Harbor seals of the Bering Sea have plummeted 60 percent since the 1970s; fur seals, 20 to 40 percent and Steller's sea lions (*Eumetopias jubatus*), a disastrous 80 percent, pushing them to endangered status (Dunkel 1997). Overfishing may play a role in these declines, but since the spectacled eider feeds on mussels and other bivalves, as well as surface invertebrates, and has declined concurrently with the others, contaminants are apparently playing an important role.

Toxic Chemicals: Page 7

The rivers of Europe may be the most polluted and changed by diversion, dams and channeling in the world. The Rhine, considered the "great open sewer of Western Europe," has lost the majority of its native fish, but pollution control efforts are beginning to show results (Simons 1995). After an absence of 40 years, a single, stranded Atlantic salmon (Salmo salar) appeared after flooding of the Rhine in the Netherlands in the spring of 1995 (Simons 1995). Atlantic salmon are now being reintroduced to rivers of Europe where they have been absent for many decades. A recent report on the Rhine's cleanup status concluded, however, that although much improvement had been made, heavy metals, dioxin, chlorine compounds like PCBs, herbicides and animal manure remain in sediments and are still

released along parts of the river. Common otters (*Lutra lutra*) in Germany have dangerous levels of toxins in their kidneys, livers and fat, and cormorants along the river are laying eggs with thin shells (Simons 1995). Every year in the European Union, 250 million tons of solid industrial waste are produced, most of which is deposited in landfills which can leech into the groundwater (Lanz 1995).

As a result of population and industrial growth, incidents of wildlife killed by pollution in Africa have become more frequent. Formerly pristine lakes in the Great Rift Valley of East Africa are breeding grounds for 80 percent of the world's flamingos. Greater and lesser flamingos by the millions nest and feed in high-altitude, briny lakes. Lakes Nakuru and Bogoria in Kenya have become polluted in recent decades by factories that emit heavy metals and other industrial wastes. People have built towns and cities along the shores that discharge large amounts of untreated sewage into the lakes. Since 1993, several mass die-offs of flamingos have occurred on these lakes. More than 50,000 flamingos died in 1993 and 1995, and two more die-offs in the summer of 1999 and early 2000 killed thousands more. There is a real possibility that the massive flocks of these beautiful pink birds, one of the Earth's great wildlife spectacles, might vanish.

Toxic Chemicals: Page 8

Acid rain is another threat posed to lakes, streams and ponds. Large power plants in Europe and the United States and, most recently, in China, which burn fossil fuels such as coal, have affected forests and aquatic systems hundreds and even thousands of miles away from the source of pollution. In the 1970s, tall stacks were mandated as pollution control to dispel soot particles, sulphur dioxide and nitrogen oxides. Rather than control the problem, they merely spread it by dispersing these pollutants vast distances on the wind. The pollutants combine with atmospheric water and fall to the ground hundreds or thousands of miles away as diluted sulphuric and nitric acids. Coal-fired power plants in England and central Europe have poisoned the lakes and rivers of Scandinavia, while plants in the US Midwest and southern Ontario, Canada, have rendered lakes in New England and Quebec lifeless. In Scandinavia, 20,000 lakes are now lifeless as a result of acid rain (Mason and Macdonald 1986), and in northeastern North America, thousands more have become totally barren (Durrell 1986). Acid rain increases acidity in water to levels toxic to many types of wildlife. In lakes with clear water and few nutrients, acid rain can eliminate all life forms. Acid rain's effects on aquatic species have been catastrophic, eliminating water birds, salamanders, otters, many types of fish, frogs and other temperate wildlife in entire regions.

Coal mines contribute to acidification of aquatic ecosystems as well by exuding acids that poison streams and rivers in their drainage. Thousands of streams in Appalachia in eastern North America have been rendered sterile from coal mines that continue to poison waterways, even when no longer being mined, until they are sealed off. In October 2000, a coal mine sludge retention pond in eastern Kentucky gave way, spilling 200 million gallons of toxic waste into streams feeding the Ohio River (NYT 2000). The state's governor declared a state of emergency in the northeast as water supplies for the entire region were threatened with contamination (NYT 2000).

Toxic Chemicals: Page 9

Air pollution regulations in the 1980s and 1990s mandated removal of the majority of sulphur dioxides prior to the release of emissions, and this has made a difference in the rate of acidification in North America and Europe. In parts of Europe, lime has been broadcast from small planes on some of these lifeless lakes to lower acidity. Usually, liming has to be frequently repeated and is not always effective. When pollution is decreased, however, life forms return, and air pollution controls have resulted in decreased acidification in some areas.

Dioxin, a chemical emitted by paper and plastic manufacturing plants and incinerators, has been found in aquatic ecosystems. It is toxic to many fish and their eggs, and is considered a cancer risk to humans. Dioxin residues in Lake Ontario, Canada, began killing the eggs of Lake Trout as early as the 1940s, and the species became extinct in the lake by the early 1950s (Colborn *et al*. 1996). Dioxin has been found in high concentrations in Eskimos of the Canadian arctic who eat caribou and seal meat; the latter animals consumed dioxins contained in their food from airborne dioxin generated by incinerators in the United States and Mexico (Hilts 2000).

Toxic Chemicals: Page 10

Chesapeake Bay is the largest expanse of saltwater estuary in the United States. Covering 64,000 square miles, its marshes are watered by its major feeders, the Potomac, Susquehanna, Rappahannock and Patuxent Rivers, along with countless smaller feeder streams from its Maryland and Virginia shores. More than 150 rivers and streams contribute to its 650-mile-wide watershed, which extends over portions of six states (White 1982). The Bay is bordered by 8,100 miles of shoreline, including its tributaries (White 1982). The growth of Washington, D.C. and Baltimore and Annapolis, Maryland, as well as other large cities and suburbs on Chesapeake Bay, and the growth of agriculture that leeches sediments and chemicals, have been responsible for destroying large portions of this great estuary. About 140 square miles of the watershed are built on every year. Urban and suburban growth, agriculture, overfishing and industrialization have all taken a toll on the water quality of Chesapeake Bay. The raising of chickens and hogs in factory farms in the region has increased over the past few decades, producing enormous quantities of fecal material that contaminate rivers and the Bay. During storms, containment ponds have overflowed, pouring pollutants into the waterways which have been implicated in outbreaks of red tide and bacterial disease (Broad 1996). Runoff of pesticides, herbicides, sewage, fertilizer and sedimentation have turned the once clear waters murky in many parts of the Bay. The fragile ecosystem of sea grasses and marshland is damaged.

Fisheries that once produced 28 million pounds of oyster meat and 55 million pounds of blue crab have plummeted. The disappearance of 90 percent of the sea grass from Chesapeake Bay, mainly as a result of chemical pollution and sedimentation, has brought about a crash in blue crab populations, with closures in fishing seasons. Crabs lay eggs and shelter in sea grass. Oyster harvests are now 1 percent of what they were a century ago. Their populations have plummeted, and only with their absence is the role that they play in the health of Chesapeake Bay becoming clear. Originally, the billions of oysters filtered the complete volume of water in the Bay in a three-day period, clarifying the water and removing pollutants (Daily 1997). Their ecological value far outweighed the revenue they produced for fishermen. Overfishing has played a role in the decline of oysters, but the major problem is the disintegration of this once-productive estuary through losses of sea grasses and sedimentation from development and pollution. Another casualty was the Maryland darter (*Etheostoma sellare*), known only from a creek in the northern tributaries of Chesapeake Bay. Not seen for many years, some authorities, including the International Union for the Conservation of Nature (IUCN), consider it extinct (Baillie and Groombridge 1996). The shortnose sturgeon (*Acipenser brevirostrum*) historically ranged throughout the Chesapeake Bay area, where thousands were caught annually. Dams, overfishing and pollution combined to eliminate this sturgeon, and spawning no longer occurs in any of the Chesapeake's feeder rivers. The species is threatened throughout its eastern range and is listed on the Endangered Species Act.

Decades after the Clean Water Act came into effect, the Environmental Protection Agency (EPA) announced in 1996 that only 40 percent of the country's waterways are suitable for swimming or fishing because of pollution from various sources. In 1997, residents of 47 US states were warned by EPA not to eat certain types of freshwater fish after issuance of some 2,200 fish consumption advisories, a new high. These advisories list 45 contaminants in lakes and rivers, including mercury, PCBs, chlordane, dioxin and DDT. In many parts of the United States, well water has been found to be contaminated with pesticides and herbicides. This is especially severe in the farm belt of the Midwest, where the majority of these chemicals are used. According to the EPA, 1.25 billion pounds of weed and

pest killers were used throughout the United States in 1995, an all-time high. Pesticide and herbicide runoff from agricultural fields was found in half of more than 500,000 miles of rivers tested by the EPA in 1995. Homeowners pouring these chemicals on their green lawns are also contributing to the contamination of streams, rivers and water supplies. A new contaminant of groundwater is a gasoline additive, methyl tert-butyl ether (MTBE). This chemical was designed to reduce air pollution to allow gasoline to burn more cleanly, but because of leakage from gasoline tanks around the country, it has entered the groundwater in every state and has been detected in 5.4 percent of wells in a US Geological Survey study. Other solvents added to gasoline were found in 47 percent of urban wells and 14 percent of rural wells (Saar 1999). The drinking-water limits set by EPA were exceeded in many of these wells (Saar 1999). This chemical is suspected to be a carcinogen.

Contamination of aquatic ecosystems has occurred throughout the world. It has played a role in endangering one of the world's rarest birds, the crested ibis (*Nipponia nippon*). Unlike any other ibis in appearance, the bird has white or pearl gray plumage, a shaggy mane of feathers and salmon pink tail feathers, which contrast with bare red facial skin and carmine red legs. Only 66 birds remain, up from 22 birds in the early 1990s, with a captive population in two breeding centers of over 100 birds (BI 2000). These elegant birds once ranged from southeast Siberia, Manchuria and China to as far east as Korea and Japan. For centuries they were hunted for their long nuptial plumes, nearly causing their extinction (Schreiber *et al*. 1989). The Japanese population of the crested ibis declined until only the tiny Sado Island held the last population; the eggs and chicks were killed by crows and jays, and the last birds were taken into captivity (Schreiber *et al*. 1989). Extinct in Siberia in 1917 and thought extinct in China by 1958, a pair was found nesting in Shaanxi Province in central China in 1981. This only remaining breeding population has slowly increased, but with fewer than 100 birds in the wild, it remains endangered (BI 2000).

Toxic Chemicals: Page 11

Crested ibises require large trees for nesting near marshes, and to protect these birds, China enacted emergency regulations prohibiting logging in the area. Their nest is a flimsy stick platform lined with small twigs, leaves and hay, built in tree branches at heights up to 25 meters (Hoyo *et al*. 1992). Hunting has also been banned, and the Chinese government accorded them official protection, but some wintering birds are still shot (BI 2000). These birds declined in Japan as a result of poisoning by mercury pesticides and other agricultural chemicals applied to rice paddies. Their feeding habits make them very susceptible to poisoning from pesticides because chemicals accumulate in the bodies of their aquatic prey of crabs, frogs, small fish, mollusk and insects. For this reason, pesticides have been banned in nearby rice paddies (BI 2000). The drainage of rice fields in the wintering habitat has reduced food supply, and 80 percent of birds found dead in the wild have starved to death (BI 2000).

Gold mining has become a major peril to rivers and aquatic ecosystems. The ore is treated with cyanide or mercury to remove the gold, and the toxic waste is either flushed into waterways or accumulates in holding ponds. Cyanide is one of the most toxic of all compounds, and it has caused irreparable harm to the pristine rivers of New Guinea, South America and other parts of the world. Cyanide spills have caused massive fish kills and river destruction in Guyana (Associated Press 1995). Brazilian gold miners have illegally polluted rivers in tribal reservations in remote Amazonian forests with cyanide, destroying the entire fish and aquatic fauna upon which tribes had depended for thousands of years.

In Papua (formerly known as Irian Jaya), the western portion of the island of New Guinea governed by Indonesia, the Grasberg Mine contains the world's largest known gold deposit, an estimated 22 million ounces (Bryce 1995). This mine sits atop a peak in the Sudirman Mountains, rising nearly 16,400 feet, and provides habitat for many unique species (Whitten and Whitten 1992). The Grasberg Mine has polluted the Aikwa River, which drains the region and flows to the southeastern coast, killing fish (Bryce 1995). The mine also contains 15 billion pounds of copper and 37 million ounces of silver, for a total value of $50 billion (Bryce 1995). These ores are being mined and transported

through the world's longest slurry pipeline and down the world's longest single-span cable car track to a massive mill (Whitten and Whitten 1992). The entire mountain has already been stripped, reducing it to terraced ridges, and US-owned Freeport-McMoran Copper and Gold Inc., which owns the mine, plans to drill in 75 more sites (O'Neill 1996). The company has been given access to 9 million acres (1.5 times the size of Vermont) by the Indonesian government (O'Neill 1996). French surveyors are seeking uranium in the Vogelkop, or Bird's Head, Peninsula at the far western end of New Guinea, and Australians are searching for gold in the Korowa region in east-central Papua (O'Neill 1996).

New Guinea's great biological diversity is being threatened by this mining. Beautiful birds of paradise, bowerbirds, tree kangaroos and countless other species, ancient forests and wild rivers are gradually being destroyed by mining. At present, forests cover 85 percent of Papua, and clear, free flowing rivers drain the highlands (O'Neill 1996). Much of Papua is without roads, and many areas remain unexplored. New Guinea's extraordinary birdlife is rich in species, totaling 725, more than in all of North America (Beehler *et al*. 1986). Tim Flannery, an Australian mammalogist, is so concerned about the destruction of this island, and the effect on native peoples, that he dedicated his book on New Guinea's wildlife to Chief Executive Officers of mining companies "in the hope that, through reading it, they will understand a little better the people whose lives they so profoundly change" (Flannery 1998). Flannery discovered an extraordinary black and white species of tree kangaroo (*Dendrolagus mbaiso*) in a forest not far from the mine. The mine owners built a large, dam-like structure to contain the enormous amount of mine tailings, all of which are dumped into the headwaters of the Aikwa River. The sediment builds up and smothers the roots of trees, causing vast tracts of forest to die and killing fish and mudcrabs along the coast (Flannery 1998). The tailings area will eventually be so large that it will be visible from space, and the mine has encouraged logging and other intrusions into the wilderness (Flannery 1998).

To the northwest, rivers of southern Borneo have been turned into "polluted deserts" by local people in search of gold. They clear away the rainforest, destroying banks with high-powered hoses (Mydans 1997). Mercury is used to extract the gold dust, contaminating the rivers with 100 times acceptable levels (Mydans 1997). These forests are home to endangered Orangutans and hundreds of animals and plants found nowhere else on Earth.
South America's river banks are also being ravaged by miners who use high- pressure water jets to blast apart the riversides, destroying all vegetation and habitat for endangered giant otters and water birds. Venezuela's largest mine, Minerven, near El Callao, dumps cyanide and metal particles into a man-made pond without liners or barriers to prevent seepage. Trees surrounding the pond have died, and the pond's surface has become so spongy and dense that one can walk on it (Schemo 1996a). Cyanide dumped into the waters is killing fish and poisoning manatees and other aquatic life.

Oil Spills

The interdependence of mangroves, sea grass and coral reefs can result in the decline of all three ecosystems when oil spills occur. After a 1986 oil spill on the Panamanian Caribbean coast, even minute effects could be measured because the mangrove ecology of this particular area had been studied in detail by scientists from the Smithsonian Institution since the 1970s. First the spill killed expanses of sea grasses and their root systems, along with 150 acres of mangrove trees and their roots in a thin strip along the coast (Luoma 1993). Following this, the waves were able to loosen and suspend the bottom sediments, and these mixed with oil particles which sank to the sea floor; each rainy season, the oil was stirred up and re-suspended (Luoma 1993). This annual flushing of the oil contaminated the entire ecosystem and gradually killed the coral reef (Luoma 1993). Up to 96 percent of corals on heavily polluted reefs died, and even at depths of 12 meters, 45 percent of corals perished; many of the surviving corals suffered toxic effects, being left with bleached and diseased patches (Wells and Hanna 1992). Effects on fish populations were more gradual, taking three or four years before stocks showed sharp declines as a result of destruction of their eggs. The Smithsonian™s Tropical Research Institute prepared a report on the effects of this spill, concluding that full recovery

of the ecosystem might take as long as a century (Luoma 1993).

The worst oil spill in US history occurred on March 24, 1989 in Prince William Sound, Alaska, when the Exxon Valdez, an oil tanker fully loaded with crude oil from the Alaskan Oil Pipeline, foundered on a reef just miles from the port of Valdez. This southern coast teemed with wildlife. Fifty pairs of Bald Eagles nested within the Sound, and 2,500 more lived within the archipelago that extends 900 miles to the southwest. Millions of sea birds and waterfowl in vast colonies nested along the coasts, among them the very rare harlequin duck (*Histrionicus histrionicus*), which had a large breeding population. More than 20 million shore birds and other arctic species pass through the Sound while on migration, and in all, 219 bird species have been recorded in Prince William Sound (Browne 1989). The Exxon spill occurred only two weeks before spring migration.

Sea otters (*Enhydris lutris*) numbered at least 10,000 in Prince William Sound, the largest concentration in the world. Thousands of harbor seals used the islands for feeding and calving. Gray whales fed and migrated through the area, and killer whales had resident pods. Commercial fishermen caught vast catches of salmon, herring and other food fish. The coastline, one of the world's most spectacular, is lined with federal, state and native Alaskan protected lands. Kenai Fjords and Katmai National Parks, Kodiak National Wildlife Refuge and thousands of acres of state and native lands had, until the spill, preserved a magnificent environment almost intact. Rocky beaches alternated with marshes and sheer cliffs studded with sea bird nests.

The Exxon Valdez spilled more than 11 million gallons of crude oil. Almost no action to clean the spill took place for days, due to a lack of preparation on the part of the Exxon Corporation and state authorities, and a lack of agreement about whether to burn off the oil, which the state refused to allow, or to spread chemical dispersants that were feared to cause wildlife mortality. This delay allowed the heavy oil to sink to 90-foot depths and spread hundreds of miles along the coast. By April 10, it covered 3,000 square miles, having spread throughout the region's inlets and coves and southwest 500 miles to Kodiak Island, the haven for the massive Kodiak bear (Ursus arctos middendorffi). The amount of shoreline oiled equaled the distance from Boston to the Chesapeake Bay (Mitchell 1999). Surface oil was 18 inches thick, coating sea birds that landed in it with a lethal film. Many died and sank in open water. By the time the spill ceased spreading, it was found to have fouled 1,500 miles of shorelines and covered 10,000 square miles, an area the size of Vermont (Schneider 1994a).

When cleaning finally began days later, it consisted of high-pressure hosing and wiping rocks. This did not remove the tons of oil that sank deep into the sand, marshes and offshore shellfish beds. Only 15 percent of the oil was recovered through vacuum tubes and booms, while the sunken oil remained a decade later, preventing oxygen in mudflats and wetlands from entering with microorganisms that would break down the oil (Mitchell 1999). The rest has been dispersed by a decade of surf and ocean currents washing it away and has evaporated from the surface.

The toll on wildlife was immediate. Sea birds began washing up on the shore coated with thick oil, some still alive. Sea otters struggled ashore as well, trying to clean their coats while lying on oiled rocks. Crews employed by Exxon picked up dead birds and sea mammals, and by May 12, ABC News reported that 20 tons of dead animals had been collected along 550 miles of soiled beach, of which only two miles had been cleaned. Actual numbers of sea bird mortalities will never be known, but some biologists have estimated that up to 500,000 birds died. Species most affected were common and yellow-billed loons, horned grebes, Pacific cormorants, black-winged and white-winged scoters, common murres, pigeon guillemots and the threatened marbled murrelets (*Brachyramphus marmoratus*). The entire population of common murres in the Barren Islands in Prince William Sound apparently died (Senner 1989), and 40 percent of the region's murres died (Mitchell 1999). Oiled birds and sea otters were brought to special rescue centers, where survival tended to be low.

Sea otters incurred very high mortality and suffered for long periods before they died. Their extremely fine fur collected oil as they swam about the surface, unable to avoid the oil like seals and sea birds who submerged or flew away from the spill. At least 980 carcasses were recovered, but judging from counts carried out during the next few years, almost half the Sound's sea otters died during the spill or from its effects (Schneider 1994). People scouring the

beaches for oiled animals often heard the otters before they saw them. The crude oil's toxic chemicals literally destroyed their livers and other internal organs within hours, causing such pain that they screamed as they died. Some were found dead with mouths wide open as if still screaming. An ABC news program filmed several of the otter pups that were rescued, doll-like balls of fluff who spent hours screeching for their dead mothers. Having no thick layer of body fat to keep them warm, sea otters rely on their dense, layered fur which they constantly groom so that it remains waterproof, with a layer of air to insulate against the cold. When they swam into oil, the otters groomed furiously but succeeded only in distributing oil over their bodies and into their gullets (Wheelwright 1994). Their clumped fur let icy water in, and the crude oil burned their stomachs, sometimes causing acute emphysema, with air bubbles bulging out under the skin of the otter's throat in a grisly necklace (Wheelwright 1994). Many succumbed to hypothermia and sank. When the dead otters were autopsied, a majority of females had near-term fetuses the size of plump rabbits; the western Sound where the oil spill occurred was a "female" area, and they outnumbered males in the otter morgue two to one, with more than 60 percent pregnant (Wheelwright 1994).

Of the several hundred sea otters brought to rescue centers, fewer lived than died, and only a tiny percentage of the total oiled animals were rescued. Most of the surviving pregnant females aborted or had stillborn cubs. Carolyn McCollum was one of the hundreds of volunteers who came from all parts of the country, and even from foreign countries, to help care for oiled animals. In an article for *Wildlife Conservation*, she described seeing these otters snuggling with towels, bunching them up for a pillow or using them to groom their faces. These intelligent animals have been documented as tool users: they use rocks as shell-openers when hand-held or as hard surfaces upon which they bang open shells. Carolyn McCollum (McCollum 1990) took care of one female so ill she was unable to eat, wheezing with emphysema: "I could tell from her abdominal breathing that she was in great pain; her sad eyes followed my movements lethargically and I wished there was something more I could do. About 10:00 p.m. she fell asleep; as I felt her chest to make sure she was still breathing, she pressed my hand to her body with her short forearm and I let her hold it there. Ill and weak, the otters at the center behaved like small babies . . .I held my patient's paw until 4:15 the next morning when she stopped breathing. As the vet came to take her to be autopsied . . . I shuddered to think how many more animals would go through the same ordeal.fl

Long-term damage to Prince William Sound started to become apparent by 1994. Marine ecological systems had suffered serious effects. Some species of water birds, especially harlequin ducks, ceased to reproduce in the Sound (Schneider 1994a). Although salmon catches initially rose in 1990 and 1991, as did herring in 1991 and 1992, the catches later plummeted (Schneider 1994a). In the spring of 1994, Alaska officials closed the Sound's herring fishery because there were too few fish. The herring, which are the keystone species in Prince William Sound, fed on by sea birds, mammals and humans alike, died from disease which manifested in skin lesions, perhaps caused by sub-lethal effects of oil (Mitchell 1999). By 1999, herring had still not recovered, and a population estimated at 120,000 tons prior to the spill fell to 40,000 tons (Mitchell 1999). The oil remaining in the water has apparently affected a variety of wildlife, preventing the recovery of virtually every species except the Bald Eagle (Mitchell 1999). Populations of sea otters, harbor seals, killer whales, pink salmon, herring and many sea birds have not recovered. Harbor seals plummeted from 2,000 to only 900 in the Sound. For seals and other fish-eating marine mammals, there are apparently not enough fish to eat, and recovery of fish populations seems to have been slowed by the remaining oil, which kills young fish even at very low concentrations (Mitchell 1999). Fishermen were awarded $5 billion for their losses by a US District Court in 1994, when a jury decided that the captain of the Exxon Valdez had acted recklessly (Schneider 1994b), but they have yet to be paid by Exxon (Mitchell 1999). This company, now merged with Mobil Oil Company, continues to earn approximately $8 billion per year, yet it refuses to settle this claim, and fishermen now earn only half their pre-spill income.

The spectacular Steller's eider (*Polysticta stelleri*) was once an abundant bird of Alaskan and Russian arctic waters. These striking waterfowl formerly nested on the Alaskan Peninsula and the Yukon Delta to the Canadian border, but in recent years they have disappeared from Alaska except the western Arctic coastal plain. Worldwide, their population has declined 50 percent, and they have been listed on the Endangered Species Act as threatened. The oil from the Exxon Valdez and other spills may have spread throughout the region in miniscule amounts that gradually became lethal to these birds. Other oil spills have occurred in Alaska since 1989, including 100,000 gallons spilled in

1997. Some oil tankers have illegally dumped or spilled oil and oily ballast.

Some good came from this massive oil spill. The state of Alaska purchased 650,000 acres of land within the archipelago for wildlife protection with $900 million from the Exxon settlement. Old-growth forests, providing key habitat for threatened species, have been deeded by native corporations for permanent protection from logging in conservation easements, and 61 trout and salmon spawning streams will be purchased (Mitchell 1999). A fund of $140 million, which began in 1994 from Exxon payments, will be available for spending on research, monitoring, fisheries applications and habitat protection (Mitchell 1999). The corporation that monitors the movements of oil tankers through Prince William Sound has adopted new procedures and equipment for fighting future spills, but only three of 28 tankers that use the Sound have double hulls (Mitchell 1999). Double hulls, or an inner hull protected by an outer one, greatly reduce leakage in a collision. It is estimated that 60 percent or less of its oil would have spilled had the Exxon Valdez been equipped with double hulls (Mitchell 1999).

Other oil spills around the world have involved heavy wildlife mortality as well. Jackass or African penguins (*Spheniscus demersus*) once numbered more than 1 million birds in colonies along the coasts of South Africa and Namibia, but their numbers have been in decline for decades. They have declined to 180,000 birds Œ a result of multiple oil spills, destruction of breeding habitat for extraction of guano, food shortages as a result of overfishing by commercial purse seiners, feral cats on their nesting grounds and disturbance by humans causing them to abandon nests (BI 2000). In June 1994, a large spill near Cape Town killed thousands of these penguins (Associated Press 1994). The species was classified as near-threatened by BirdLife International in 1994 (Collar *et al*. 1994), and it has suffered population declines ever since. In Threatened Birds of the World, BirdLife International classifies the species as vulnerable, a more threatened category that indicates serious decline.

In the summer of 2000, a large oil spill occurred within feet of their prime breeding ground off Cape Town. Professional bird rescue organizations, experts and volunteers from around the world converged on the area within a few days. This was the most massive bird rescue in history and saved the lives of over 38,500 adult penguins by placing all adults that could be caught in a giant warehouse and holding area in Cape Town (Associated Press 2000a). Oiled birds were cleaned and fed, while oil-free birds were held to prevent them from becoming oiled in the spill. Most were caught on land attending to chicks and incubating eggs, as this was the height of the breeding season. More than 19,000 birds were shipped 500 miles up the coast and released (Associated Press 2000a). By the time they returned to Cape Town, a swim that was monitored on the Internet, the spill had been cleaned up. The rescuers claimed the unprecedented survival rate of 90 percent. The unfortunate casualties were abandoned chicks and eggs. In spite of the large numbers of birds saved, the entire generation of young were lost, and an unknown number of oiled adult birds died at sea.

In the Siberian tundra, a delicate frozen ecosystem with a thin layer of soil covering permanently frozen ground, known as permafrost, is extremely vulnerable to damage from oil spills. Oil exploitation over the past few decades has resulted in many spills that permanently scarred the land. The most recent, in the fall of 1994, spilled approximately 33 million gallons of oil, three times the total spilled in Alaska, polluting three major rivers. Long-term effects will not be measured for years, but the immediate effects have been massive fish kills in the Kolva, Pechora and Usa Rivers of the northeast (Filipov 1994).

Large oil spills, however dramatic, do not constitute the majority of oil spilled in oceans. They may make up only about 12 percent (Wells and Hanna 1992). Forty-five percent of the oil that is becoming pervasive in ocean ecosystems comes from the routine flushing of tanks and bilges of ships at sea, and one-third comes from regular leakages at land-based operations such as refineries (Wells and Hanna 1992). Floating tar balls and dissolved light oil continue to cause mortality and ecological damage, destroying the waterproofing of birds' feathers and settling on coral reefs. As marine biologist Dr. Sylvia Earle, former chief scientist of the National Oceanic and Atmospheric Administration (NOAA), noted in *Sea Change: A Message of the Oceans* (1995): "Nets dragged through the sea anywhere are likely to come up clogged with tar balls, beaches in the most remote areas are fringed with an oily scum or lined with sticky gobs of oil; over the surface of much of the ocean a rainbow-hued film glistens with deadly beauty

at one time or another." Since 1970, 50 major spills the size of the *Exxon Valdez*'s have happened worldwide (Mitchell 1999).

The ingestion of lethal oil compounds, whether within days or weeks after a spill or from residues remaining years afterward which enter the food chain, is the key cause of mortality for the millions of sea creatures that die in oil spills. Research conducted by Dr. Daniel W. Anderson of the University of California at Davis revealed that only 12 to 15 percent of Brown Pelicans rescued in oil spills survived for two years (Kopytoff 1996). The greater the amount of oil ingested, the higher the death rate.

A remarkable discovery in the late 1990s has yet to be aggressively pursued as a means of cleaning up spilled oil. A barber who watched the news of the Exxon Valdez spill noted that the sea otters died in large numbers as a result of the extreme absorbency of their fur and their ingestion of oil while grooming. He began collecting human hair from his barbershop and testing it for absorption of oil. It proved remarkable in its ability to suck up large amounts of oil when contained in mesh nylon bags, leaving almost no oil in the water. He approached NOAA and showed them his findings. They tested the process and confirmed his results. Although this was widely publicized on television and in newspapers, little has apparently been done to place this very simple, low-tech process into real situations by encouraging oil tankers and land-based oil pollution teams to store large amounts of hair for this purpose. NOAA tests determined that the oil absorbed by the hair could easily be recovered by squeezing the bags into holding tanks.

In the wake of the Exxon Valdez spill, Congress enacted the Oil Pollution Act of 1990, which requires oil tankers operating in US waters to pay large penalties and carry massive insurance liability for spills. Civil penalties range up to $1,000 per barrel discharged. Within a month of the passage of this law, 20 oil companies created two new organizations: the Marine Spill Response Corporation and the Marine Preservation Association (Earle 1995).

The need for such protection from catastrophic spillage has been apparent since the early 1970s when these supertankers began to ply the world's oceans loaded with 200,000 tons of crude oil, built so cheaply they had virtually no protection against splitting apart if they ran aground. The dangers of these ships were dramatically portrayed in the 1974 book, *Supership* (Mostert 1974). More than 25 years of oil spills later, stringent regulations still have not become the rule of the sea. An international agreement requires all oil tankers built after July 1996 to have double hulls, but not all countries are complying. Congress put off the effective date of an amendment requiring replacement of single-hulled ships with environmentally sound double hulls to 2015**,** and even this date may be postponed.

Extinct Species
The Yangtze River (Baiji) Dolphin

The baiji, a freshwater dolphin species weighing 220 to 355 pounds, was historically found throughout the Yangtze River and its surrounding lakes and tributaries. Like other river dolphins, they had long, narrow beaks and poor vision. Because they lived in extremely muddy waters, baiji relied on echolocation to locate mates and food. This dependence kept the ancient species alive for over 20 million years, but recently, human exploitation took its toll. The last official baiji sighting was in 2004, when only two individuals were observed. Sadly, a 2006 expedition revealed no sightings, and the species was deemed fifunctionally extinct.fl

The exponential growth of the Chinese population posed a variety of threats to the survival of the baiji. In 1975, the species was first listed as a Protected Animal of the First Order by the Chinese government. Chinese officials designated protected areas for the baiji; however, the areas proved insufficient and did not encompass the full length of its habitat. Futile captive breeding efforts were also attempted for years.

In the 1990s, electrofishing killed a large number of the dolphins, and overfishing depleted their prey. Additionally, the lengthy construction of the Three Gorges Dam obstructed natural migration patterns, isolated groups of individuals, and impaired breeding opportunities. Along with this industrialization came more ship traffic, which increased the likelihood of dolphin collisions with boat propellers and ships.

Furthermore, the activity in the river created anthropogenic noise that impeded the baiji™s ability to locate food and mates. Water pollution and entanglement in fishing gear are also blamed for the species™ decline. The baiji, accustomed to a pristine and rich environment, was no match for the increasing pollution and congestion of its home.

While the baiji was listed as an endangered species under the US Endangered Species Act and as a critically endangered species on the IUCN Red List of Threatened Species, it was unable to recover due to a lack of information, growing threats and its small population size. Today, the Yangtze River has lost its top predator, which will have a devastating effect on local ecosystems.

Endangered Species Handbook

Madagascar and other Islands:

Madagascar and other Islands

Madagascar

Imagine an island more than 1,000 miles long in a blue tropical ocean. Forests cover vast areas, interspersed with swamps where crocodiles 8 meters long lie in wait to prey on pygmy hippopotamuses. Thousands of giant tortoises with shells 4 feet across lumber about. In the forests and in dryer parts of the island live some of the strangest primates to have ever existed on Earth. Some 45 species of these lemurs live throughout the island and range in size from the world's smallest primate, weighing about 1 ounce, to a lemur the size of a Gorilla (Tattersall 1993).

Huge white birds plod along forest trails and through savannah grasses. Many kinds of these birds inhabit the island. The largest resembles an Ostrich, but is far more massive in build, weighing 1,000 pounds (Feduccia 1996). It stands 10 feet tall and lays 20-pound eggs, 13 inches long (Feduccia 1996, Greenway 1967). More than 100 other kinds of tropical birds that exist nowhere else fly in forests and deserts and wade in still marshes.

Primitive hedgehog-like mammals, called tenrecs, scurry in forest underbrush. One type of tenrec lives in cold mountain streams, swimming with webbed feet and flattened tail, while another has spines like a porcupine and stripes down its back like a skunk. It communicates with its young by vibrating its spines.

Hundreds of kinds of amphibians and reptiles inhabit forests, aquatic environments, savannahs and drylands. Frogs of every imaginable color and pattern leap in green shadows. Chameleons, some brilliantly colored, and others shades of mottled brown, creep invisibly about. The largest, 2 feet long, can capture mice and birds, while the smallest, measuring only 1.5 inches, feeds on insects (Amos 1980). Tortoises with shells adorned in delicate yellow sunburst patterns inhabit shrub and deserts.

Plants exist in unparalleled variety, a botanical paradise. Relicts of species long-extinct on mainland areas--tall tree ferns, palms, red-flowered flame trees, massive deciduous and rainforest trees, giant tamarinds and aloes, desert oddities, and baobabs of many sizes--grow in even the driest parts of the island. Orchids in a rainbow of colors bloom among the deep green rainforests. Waterfalls abound, cascading down tall cliffs into rivers and lakes. Along the west coast, a dry deciduous forest stretches the length of the island**.** The central highlands are a mosaic of woodland and savannah, while the eastern regions are covered in dense, humid rainforest. In the extreme south, a desert environment prevails, harboring *Didierea*, strange cactus-resembling plants that form long, spiny, twisted shafts rising 30 feet into the air. An impenetrable wilderness of limestone spikes and sharp rocks dominates the far north. Rare birds and lemurs find refuge in this craggy landscape and feed in oases watered by meandering streams.

Flightlessness, fearlessness, gigantism, dwarfism, and survival of ancient species all occurred in this evolutionary laboratory. That such a large land mass went uninhabited by humans for so long is truly remarkable. Nowhere else on the planet has such a large land area remained isolated for such a prolonged period, allowing a flowering of diverse life forms to flourish and adapt to the island's many habitats and terrains in this mild, tropical climate. Such is the history of the island from Madagascar in 400 A.D., a century before the arrival of the Malagasy people of Asia. Had humans reached Madagascar earlier, it might not have evolved its diverse, yet vulnerable, fauna and flora.

How such an extraordinary diversity of animals and plants inhabits Madagascar is tied to its geological history. Some 160 million years ago, when Africa, Australia, New Zealand and South America were united in the super-continent Gondwana, Madagascar was attached to eastern Africa and what is now peninsular India. Dinosaurs, giant turtles, crocodiles, primitive mammals, reptilian birds and lizards roamed on this massive land mass. Gondwana gradually broke apart as a result of movements of tectonic plates covering the Earth's crust. For many millions of years, India and Madagascar formed a mini-continent. Then, about 88 million years ago, they split along Madagascar's east coast, and peninsular India moved northward toward Asia (Garbutt 1999, Tyson 2000).

Paleontologists have only recently discovered that Madagascar was home to dinosaurs and other primitive animals quite unlike those found in other parts of the world. The oldest known species of dinosaur, dating back 227 million years, may be the ancestor of all dinosaurs (Flynn 2000). One dinosaur had teeth that were clove-shaped (Stenzelt and Thiessen 2000). Seven species of crocodiles inhabited Madagascar from the Cretaceous period onward, including a pug-nosed vegetarian species (Flynn 2000). About 65 million years ago, the last dinosaurs died out, concurrent with their extinction throughout the world. Some native plants and animals survived from the time when Madagascar was part of Gondwana. Giant tortoises, crocodiles, boas, tenrec ancestors and possibly an early form of elephant birds may have lived on the super-continent, although most ornithologists are certain that the ancestor of the elephant bird flew to the island and became flightless (Feduccia 1996). Plants of many kinds, virtually unchanged from their ancient forms, grow on the island.

Immigrant animals arrived during the millennia from many sources. Because Madagascar separated from India and Gondwana long before the evolution of the prosimians that were the ancestors of the lemurs, these primates must have come from mainland Africa, where their close relatives, bush babies and galagos, survive today. Some scientists believe they might have traveled over a land connection that existed between Africa and Madagascar at some point (Tyson 2000). Others dispute that there ever was such a land bridge and maintain that they arrived by sea, perhaps sheltering on large mats of floating vegetation or clinging to uprooted tree trunks that swept down mainland rivers to the sea and washed up on Madagascar's shores. Few modern mammals of Africa, whether baboons, monkeys, gazelles, antelope or other hoofed mammals, reached Madagascar. The hippopotamuses must have originated in Africa, but how they came to the island is another mystery.

Over many millennia, a blossoming of evolution occurred in this mild, tropical climate of Gondwandan and immigrant species, radiating into entire new families and creating a flora and fauna of great diversity unlike any in the world. Birds, bats and insects flew or were blown to the island by wind currents and storms from Africa and Asia. No large carnivores arrived, however. The largest mammal predators are relatives of mongooses, primitive viverrids. Grazing and browsing roles were filled by hippopotamuses, land tortoises, lemurs and elephant birds.

Human Settlers Invade Paradise

About 500 A.D., immigrant people from Asia, most probably Indonesia or Malaysia, arrived on Madagascar's shores in hand-hewn canoes, bringing domestic animals with them. They began clearing forests and burning them for farmland, and turned lakes and wetlands into rice paddies. Cleared land produced crops for only a few years until the thin soil became sterile. Farmers then moved on to other parts of the forest, in this slash-and-burn agriculture. At some point, African herdsmen colonized the island, bringing zebu cattle, which crowded out wildlife (Tyson 2000). Gradually, abuse of the land eroded the soil in the central highlands to bare earth, pocketed and gouged by deep gullies and cavernous holes. This region had harbored a great variety of lemurs, along with a wealth of birds, reptiles and unique plants. Throughout the island, wildlife declined as habitats disappeared, isolating animals in smaller and smaller patches of forest and wetlands. The large lemurs, tortoises and elephant birds were avidly hunted.

Within 600 years of the arrival of the Malagasy, extinctions claimed many native animals. Several elephant bird species, the larger lemurs and many native plants vanished. Two kinds of pygmy hippos inhabited the island. The Madagascar Hippopotamuses (*Hippopotamus lemerlei*), an amphibious species, and *Hippopotamus madagascariensis*, a forest species, were both about 6.5 feet long and 2.5 feet tall, smaller than the Common Hippopotamus of Africa, which is about 10 feet long (Tyson 2000). From genetic and anatomical analysis, both seem to have evolved from the latter species (Tyson 2000). The hippos had been widely distributed and very common prior to the arrival of the Malagasy (Dewar 1984). Their bones have been found with marks indicating that they had been butchered (Tyson 2000). Both died out long before Europeans arrived. The native crocodile, whose large bones have been found, is

believed by some scientists to represent large specimens of Nile Crocodiles, the species native today (Tyson 2000). It is thus possible that the crocodile survived. A large mongoose-like viverrid, *Cryptoprocta spelea*, and a very unusual aardvark-like animal, *Plesiorycteropus madagascariensis*, died out at an early date (Dewar 1984).

Prior to the arrival of humans, elephant birds had been abundant in most parts of the island, as attested by the prevalence of their bones. There were two genera, and from six to 12 species of these birds (Tyson 2000). It is likely that the flightless birds fell prey to the primitive weapons of the Malagasy and were crowded out of their habitats by livestock (Tyson 2000). The last to die out was the Great Elephant Bird (*Aepyornis maximus*), which may have survived until recent times by retreating to remote swamps. Dr. Alexander Wetmore of the Smithsonian Institution examined bones of a Great Elephant Bird unearthed in archeological excavations in the 1960s. He was amazed by their size: "The incredible femur, or thighbone, of this ponderous bird is by far the largest I have ever seen" (Wetmore 1967). Estimated to weigh at least 1,000 pounds, more than three times the weight of an Ostrich, it produced eggs larger than any dinosaur's, with a capacity of 2 gallons (equivalent to seven Ostrich eggs), 180 chicken eggs or 12,000 hummingbird eggs (Bradbury 1919, Fuller 1987). When one was X•rayed, the bones of an embryo three•fourths developed were revealed (Wetmore 1967). Something had interrupted the embryo's growth and frozen it within the eggshell for hundreds and perhaps thousands of years (Wetmore 1967).

Despite its fearsome size, the Great Elephant Bird lacked a hooked beak for tearing prey and was plainly not a predator (Wetmore 1967). Its large, clawed feet may have helped it defend itself against the small native predators but were not enough to protect it from Malagasy arrows. Its short legs prevented it from running as fast as its relative, the Ostrich, but it may have been quite agile when chased. This vegetarian bird browsed and cropped plants, able to reach with its long neck to the lower branches of trees (Wetmore 1967). By the mid-16th century, when Europeans had managed to establish a foothold in Madagascar, the new French Governor, Sieur Etienne de Flacourt, wrote in 1661 that the Great Elephant Bird was still found in the south of the island, "seeking the most deserted places" to avoid human hunters (Tyson 2000). Villagers of Antandroy told of an Ostrich-like bird that was difficult to catch, according to Flacourt (Tyson 2000).

The exact date this giant bird became extinct is not known with certainty. Alan Feduccia (1996), an eminent paleo-ornithologist, asserts that elephant birds of many species were still widespread in the 10th century but gradually disappeared as a result of human activity. He cites an account by a French merchant sailor in 1848, who visited Madagascar and saw the shell of the Great Elephant Bird; he was told that it belonged to the chief and that the bird that produced such eggs "is still more rarely seen" (Feduccia 1996). Some authorities estimate that it died out in the mid-17th century, although there is no proof that any European ever saw one of these birds (Tyson 2000). It has been suggested that Europeans were responsible for the bird™s extinction by hunting and destroying its habitat (Quammen 1996). But Thomas Brooks (2000) of the Center for Applied Biodiversity Science, Conservation International, asserted in a list of extinct birds in *Threatened Birds of the World* (BI 2000) that all the elephant birds had disappeared by 1500. In a bizarre footnote to this species' epitaph, an *Aepyornis* egg washed up on Australia's western coast in 1995. No conclusive explanation for this strange event has been put forth, although it is likely that it became unearthed from long interment by rains, and washed out to sea. Much less is known of the other species of elephant birds, which existed in a variety of sizes down to a chicken-sized species.

Lemur-like primates once lived on many continents, but nowhere had they evolved into such a great variety of species. When the Malagasy people arrived some 1,500 years ago, lemurs occupied every habitat, even marshland. A species as tall as a man must have startled the Malagasy immigrants, giving rise to legends that these animals had superhuman powers. The first French naturalists were told by the Malagasy that these primates were thought to be the ghosts of sacred ancestors of man, inspiring the genus name Lemur, the word for ghost in Latin. The Malagasy considered some lemurs sacred and punished anyone who harmed them, but most species were feared as evil demons and were killed on sight.

From their arrival on Madagascar, the Malagasy hunted the larger species of lemurs, almost all of which are now extinct. Archaeological excavations show that they formed a staple in the immigrants' diets. Such diggings have

unearthed the skulls and bones of long•extinct lemurs in early Malagasy jars and kitchen middens; their heads had been split by ax-heads made from an extinct flightless bird (Jolly 1980).

In the centuries following colonization by the Malagasy immigrants, some 15 species of lemurs of eight genera became extinct (Mittermeier 1997). These extinct lemurs were, for the most part, far larger than surviving species and had evolved to fill many ecological niches. Three *Megaladapis* lemurs weighed between 90 and 170 pounds and moved slowly through the trees, feeding on foliage (Tattersall 1993). Another species, *Archaeolemur*, was about the size of a female baboon and lived on the ground (Tattersall 1993). Two *Palaeopropithecus* species weighed between 90 and 130 pounds and were sloth•like tree dwellers with flexible bodies (Tattersall 1993). These extinct lemurs had evolved many unusual means of movement and locomotion that have no parallels in living species of lemurs.

Largest of all, the massive 400•pound *Archaeoindris* was apparently a ground•dweller, moving on all fours; many of its anatomical characteristics are unlike any living primate (Tattersall 1993). One entire lemur family, Archaeolemuridae, was obliterated. In this family were many species of lemurs weighing between 35 and 55 pounds; they were powerfully built and short•legged (Tattersall 1993). The heaviest lemur surviving today, the Indri (*Indri indri*), weighs only about 15 pounds (Tattersall 1993). These lemurs had survived for millions of years, and their extinctions were indeed a major biological loss to the planet. According to primatologists, the surviving lemurs resemble the very earliest primates from the Eocene (Tattersall 1993). Like prosimians in Africa and Asia, but to a far greater degree, lemurs have a highly developed sense of smell. Some species have long, fox-like noses (Preston-Mafham 1991). Genetic analysis of their DNA has revealed that all lemurs are descended from a single ancestor that probably arrived from Africa about 60 million years ago (Garbutt 1999).

The Giant Aye-aye (*Daubentonia robusta*) lemur was somewhat larger and 2.5 to 5 times heavier than the surviving Aye-aye (see below), but in other respects was very similar (Garbutt 1999). It is known from subfossil remains found in southwestern Madagascar (Nowak 1999). The date of its disappearance is unknown but may be fairly recent.

Archaeologists have uncovered remains of a massive bird of prey, the Malagasy Crowned Eagle (*Stephanoaetus mahery*), which undoubtedly preyed on lemurs (Feduccia 1996). In fact, at one locality the diet of this eagle, based on the bones of eagles and lemurs found together, contained at least 80 percent primates, including specimens weighing up to 26.5 pounds (Feduccia 1996). Remains of another large eagle of the genus *Aquila* have been discovered, and it, too, preyed on large lemurs and became extinct after the arrival of the Malagasy. These extinct birds preyed on smaller lemurs as well, including some species still surviving (Feduccia 1996). A bird of prey flying overhead still elicits fear in lemurs, causing them to seek cover. Neither of the two remaining species of eagles on Madagascar preys on lemurs, but two hawk species have been seen preying on young lemurs (Garbutt 1999).

In addition to the Giant Elephant Bird, the large Snail-eating Coua (*Coua delalandei*), a member of the cuckoo family, became extinct. The last specimen of this large, slate-blue bird was taken on an islet off the east coast, Ile Sainte-Marie, in 1834 (Morris and Hawkins 1998); reports by observers who claimed to have seen the bird were recorded as late as 1930 (Fuller 1987). The causes of this bird's disappearance, and even its exact range, remain obscure (Langrand 1990). Many specimens of this bird were taken before its extinction and kept in museums in Leiden; London; New York; Paris; Philadelphia; Tananarive (Madagascar); and Cambridge (Massachusetts) (Fuller 1987). The long feathers of this bird were highly valued by the Malagasy, and hunting may have reduced its numbers to a critically low level (Fuller 1987). It is also possible that the many birds killed for zoological specimens may have pushed this already rare bird to extinction, since its distribution may have been limited to the tiny Ile Sainte-Marie. No reliable record exists of its presence on the main island of Madagascar, but there is hope that it might be found in lowland forest near the Bay of Antongil (Morris and Hawkins 1998). Ten closely related species of couas survive, all smaller than the Snail-eating Coua.

The Biological Wealth of an Impoverished Country

The Madagascar of today is still a remarkable place, although about 90 percent of the forests, including almost all lowland rainforests that were richest in wildlife, were destroyed (Mittermeier *et al.* 1999). Some 33 lemur species survive, along with all but one species of tenrec, various mongooses and their relatives, more chameleons than any other country, several hundred kinds of frogs and reptiles, and thousands of endemic invertebrates and plants. Madagascar has no native fish, but many introduced species. Its fauna and flora represent many extremely unusual and unique examples of evolution (Mittermeier *et al.* 1999). This island is considered one of the five most biologically important areas in the world; its primates are the world's highest priority for conservation (Mittermeier *et al.* 1999).

The Biological Wealth of an Impoverished Country: Forests and Plants

Madagascar has one of the richest floras in the world. Eighty percent of its plants are found nowhere else (McNeely *et al.* 1990, Preston-Mafham 1991). The diversity of plants that survived almost 2,000 years of forest destruction continues to astound biologists and conservationists. Tropical trees with fruit growing on their trunks (various species of the genus *Tambourissa*) are native, as is a cactus (*Rhipsalis*), related to American species, that lives in the rainforest. A tree, *Symphonia*, which has leathery leaves and red-and-white striped flowers that look like peppermint candies (Morell 1999), also survives. The Flame Tree (*Delonix regia*), which produces cascades of red flowers, is grown around the world for its beauty, but few realize that it originated in Madagascar (Preston-Mafham 1991). Miraculously, many endemic plants have survived the fires and tree cutting that have destroyed much of the island. One mountain chain has 150 endemic vascular plants, a very high number (Preston-Mafham 1991). They are among the 7,300 to 12,000 species of plants native to Madagascar (Preston-Mafham 1991). Its flowering plants make up 20 percent of all the plants in the African region (McNeely 1990). At least 191 botanical families, a very large number for a relatively small area, evolved from ancestor species (Preston-Mafham 1991).

Some 2,000 years ago, the eastern rainforest stretched in a band 100 miles wide from north to south, covering 27 million acres (Tyson 2000). Ninety percent of the plants were endemic, with a profusion of unusual ferns, some types growing on tree trunks; wild ginger, with delicate purple flowers; bamboos; and far more orchids than in an African rainforest (Preston-Mafham 1991). An early traveler described the woods as so dense that there was a fideep gloom: below the canopy at mid-day (Tyson 2000). Rainfall must have been greater and general climate more humid than at present as a result of these extensive rainforests. In the montane ridges, huge tree ferns, mosses and lichens cover the ground and hang from tree branches (Preston-Mafham 1991). Over the centuries, Malagasy burned many portions of the rainforest, especially in the south. Few tall trees remain in the rainforest today, although at one time there must have been many giants. During the 19th century, a palace was built for a woman ruler, centering on a 130-foot tree that had been carried by 5,000 laborers from the eastern rainforest (Tyson 2000). The palace was destroyed by an uprising in the 1850s. About this time, Malagasy dragged a tombstone through the forest, cutting 25,000 trees just to make a path (Tyson 2000). Early decrees banned cutting of virgin forest, with severe penalties, in the 19th century, but these were largely ignored (Tyson 2000).

About half of the island's forests had been cut by the late 19th century, and intensive cutting continued in the 20th century (Tyson 2000). The prime lowland forests throughout the island and three-fourths of the rainforest were cleared by the French for growing coffee and other crops in the first three decades of the century (Tyson 2000). The rainforest was heavily logged between 1950 and 1985, with 275,000 acres cleared and burned each year (Tyson 2000). The northeast Masoala Peninsula still retains sizeable areas of unlogged rainforest, but the southern region has been reduced to fragments of the original unbroken expanses. The remnants tend to be on sharp ridges where soil is poor and access difficult. For example, Ranomafana, a recently declared national park, straddles such an escarpment. Even so, many of its trees had been removed prior to its protection (Tyson 2000). What was once a closed-canopy, humid rainforest is now far dryer and cooler, with many openings among the trees, and some illegal logging continues (Tyson 2000). Still, botanists from the Missouri Botanical Garden, who were conducting a census of the trees in this park, counted 37 families of trees with 105 species in a 1-hectare plot (Tyson 2000). Outside the park's boundaries, rainforest is still being cleared and burned by the Malagasy, many of whom believe that their wealth lies in the amount of land they clear (Morell 1999).

The western dry, deciduous forest lies in the shadow of eastern mountains, which block moist ocean air currents (Preston-Mafham 1991). Trees do not attain heights of more than 80 feet, but many types of plants have adapted to this environment. Liana vines grow among the trees, and dead leaves carpet the forest floor. Large tamarind trees grow along rivers, and baobabs grow in plateaus (Preston-Mafham 1991). Beautiful orange bell flowers of the *Ipomoea carnea* plant burst into bloom during the short rainy season. As with the eastern rainforests, the once continuous stretches of deciduous forests have been largely destroyed, replaced by grasses able to survive in the eroded or bare soil.

Throughout the island, most deforested areas fail to regenerate into second-growth forests, even when left fallow, because Madagascar lacks vigorous colonizing trees that can quickly protect cleared ground and prevent further erosion (Preston-Mafham 2000). Cleared hillsides become covered in non-native grasses and exotic South American trees (*Psidium cattleyanum* and *Psidium guajava*) or plantations of eucalyptus, which inhibit the establishment of native seedlings (Preston-Mafham 1991; Sayer *et al.* 1992). Only if soils are rich and remnants of original forest are nearby will native forests regenerate. Unfortunately, the original forests and their native wildlife are lost permanently, and even regeneration cannot take place without a cessation of the slash-and-burn cycle, known as fitavyfl by the Malagasy (Preston-Mafham 1991). Moreover, foreign logging companies have obtained logging concessions on most of the unprotected remnants of native forest. Tree cutting consumes some 7.8 million cubic meters of wood per year, of which 7 million cubic meters is for fuel and charcoal (Sayer *et al.* 1992). Valuable timber trees have been logged to extinction in most of Madagascar. The two native species of ebony trees of the genus *Diospyros* have been heavily logged for centuries, and few large trees are left (Sayer *et al.* 1992). The understory plants, such as tree ferns, are also exploited, dug up to sell as potted plants (Sayer *et al.* 1992).

The net result of this logging and burning, especially in the barren central highlands, is the loss of "a priceless reservoir of plant and animal species, replaced by one of the most impoverished forms of vegetation on the planet" (Preston-Mafham 1991). Many species of trees and other plants are highly endangered. Madagascar is one of the world's 12 "hot spot" areas of tropical forests, having a high percentage of endemic species which are under great threat (McNeely *et al.* 1990). Since an estimated 94 percent of Madagascar's trees are endemic, and many occupy very restricted ranges, they are highly vulnerable to extinction. Further research will likely reveal even more threatened species. Some authorities believe that even this rich plant diversity must represent only a fraction of the "vast original flora," since 80 percent of the vegetation and forests is gone (Ayensu *et al.* 1984). The *1997 IUCN Red List of Threatened Plants* includes 19 species of plants that may have recently become extinct, and an additional 287 species that are threatened with extinction (Walter and Gillett 1998).

Resident since the days of the dinosaurs, trees of a family of primitive pines, Podocarpaceae, grow on the island. The family is represented by species in other parts of the world that were part of Gondwana, from South America west to Southeast Asia. Madagascar has a number of native Podocarps, of which four endemic species or varieties are listed by the *IUCN Red List* as either Vulnerable or Rare (Walter and Gillett 1998). At least 26 genera of plants are

native to Madagascar and South America, but not to Africa, and are believed to be remnants from Gondwana (Preston-Mafham 1991). Another one of these, Madagascar's national tree, the Traveller's Tree (*Ravenala madagascariensis*), is a palm-like species of the banana family (Musaceae). Its closest relative of the same genus grows in Brazil and Guiana, but not in Africa (Preston-Mafham 1991). This tree has leathery petals covering its pollen and nectar and is a key food source for both bats and lemurs. In return, it depends on lemurs for pollination. Lemurs feed on the nectar, getting their noses covered with pollen in the process. They are so fond of the nectar that they travel miles to find another Traveller's Tree, still carrying the nectar on their noses and, unknowingly, pollinate the next tree they feed on (Attenborough 1995).

A plant of the Winteraceae family that has been growing on the island for 30 million years was recently seen again after a period of 90 years (Hsu 1997). This tree, *Takhtajania perrieri*, has many primitive features, such as a lack of vessels to move water and minerals; like many of Madagascar's relict species, it once grew on much of continental Africa, but long ago disappeared there (Hsu 1997).

Madagascar has more palms (Palmae family) than all of Africa (Preston-Mafham 1991). Many are in danger, however. The *IUCN Red List of Threatened Plants* lists 148 native species in various categories (Walter and Gillett 1998). The Big-leaf Palm (*Marojeya darianii*) was chosen by the Species Survival Committee of the IUCN to be one of 12 critically endangered species highlighted at its 1988 General Assembly in Costa Rica. This species was only discovered in 1982 and is confined to a single swamp in the northeast (Prance 1990). An agricultural program to raise rice cleared half its habitat, and then failed. This huge-leafed palm has been over-harvested as a source of heart-of-palm, a commercially valuable product (Prance 1990). Huge palms are felled for their inner pith to supply this gourmet market. The majority of palms grow in the eastern rainforests in a great diversity of size. Two threatened palms, *Dypsis hildebrandtii* and *Dypsis louvelii*, are miniature delicate-fronded palms only 3 feet high (Preston-Mafham 1991). Others, like the threatened *Ravenea glauca*, are majestic giants with long, straight trunks rising 50 feet or more to a luxuriant crown. Palms do not often survive the fires set by the Malagasy to clear land, disappearing from one area after another (Preston-Mafham 1991).

On the entire continent of Africa, only one species of baobab tree is native, while seven species are found in Madagascar (Preston-Mafham 1991). These strange-looking trees have wide trunks that taper to a narrow crown, looking like upside-down trees. Some baobabs grow to immense size. One famous specimen measures 46 feet around the base of the trunk (Preston-Mafham 1991). Another species, *Alluaudia ascendens*, grows in the southern desert. Although it can reach a maximum height of 16 feet, it is usually far smaller (Preston-Mafham 1991). Each of the seven species has a slightly different shape and size, but all have gray bark that resembles unwrinkled elephant skin. Baobabs are extremely important to both wildlife and humans. The Malagasy cut holes in their massive trunks and hollow out the spongy pith where water accumulates. In the dry south, these trees become wells, and villagers set ladders against the trunks, climb to the hole cut from the trunk, and lower buckets into the pool of water. Natural holes in baobob trunks and branches provide important nesting holes for birds and lemurs. These trees are fire-resistant, and fortunately, they are worthless as timber because of their soft, pulpy cores. For this reason some stands of thousands of huge, very old baobabs remain in parts of the island. Because of the heavy livestock grazing, few young baobab seedlings can survive, however, and botanists believe that the spectacular vistas of these behemoths will gradually disappear (Preston-Mafham 1991).

One very strange group of Madagascan plants native to dry areas has nine species in the same genus, *Pachypodium*. These succulent plants lose their leaves at the onset of the dry season and have evolved into a variety of forms, all with gray, smooth bark. Eight of the nine species are threatened with extinction, according to the *IUCN Red List of Threatened Plants* (Walter and Gillett 1998). One of these, the endangered *Pachypodium decaryi*, is native to Antananarivo, the "tsingy" limestone crags of the northwest. Its smooth, silvery trunk resembles a large inverted turnip, fat at the base and tapering upward, topped by a messy mop of thin, straggly branches (Preston-Mafham 1991). It bears large, white flowers during the dry season. Its main population occurs in the Ankarana Special Reserve, which bans burning (Preston-Mafham 1991), but has recently been invaded by hordes of miners who are clearing vegetation to search for sapphires (Morell 1999). Other Pachypodiums have equally bizarre

shapes, such as the bulbous *Pachypodium rosulatum*, which resembles a huge gourd sprouting long, thin shafts from which its bright yellow flower bloom. The rare *Pachypodium densiflorum*, with the appearance of a domestic jade plant run amok, has a mass of short, gray branches sprouting from a squat gray base. All these plants are highly susceptible to fire. Ken Preston-Mafham, in *Madagascar: A Natural History*, describes the threat of "incessant brush fires which ravage the length and breadth of central Madagascar during the dry season. Within hours, hillsides which had been decorated with colorful rock gardens of rare succulents are converted into graveyards of charred embers." These brush fires have been intentionally set by Malagasy to improve grazing land for their cattle or clear land. Another threat to Pachypodia is collectors who tear specimens, especially bizarre forms, from mountain slopes (Preston-Mafham 1991). Few species are protected in reserves. Without strong conservation programs, these fascinating plants could easily disappear.

Other strange trees of the southern spiny desert include the Octopus Tree (*Didierea madagascariensis*), a member of an endemic family of 11 cactus-like species, Didiereaceae. This tree has no trunk, but a bouquet-like grouping of stems covered in long, needle-sharp spines that branch out in odd, twisted shapes. Although resembling cacti, this family has no close relatives anywhere in the world (Preston-Mafham 1991). Another member of the family, *Alluaudia procera*, has a thick trunk with very long spines that grow in curving rows upward, and small, rounded leaves along its branches. In spite of this, several lemur species are able to leap onto these plants without hurting themselves (Preston-Mafham 1991). Three species in this family, all of the *Alluaudia* genus, are Rare, according to the IUCN (Walter and Gillett 1998). One of these, *Alluaudia montagnacii*, has tall, solitary tapering stems ending in a tuft of flowers.

The discovery of the medicinal effects of the endemic Rosy Periwinkle (*Catharanthus roseus*) has saved thousands of human lives. Two potent alkaloid compounds found in this plant have proven effective in the treatment of Hodgkin™s' Disease, producing a 99 percent remission in patients with acute lymphocytic leukemia (Myers 1983). It also contains 75 different alkaloids, which could produce commercial substances (Preston-Mafham 1991). Fortunately, the Rosy Periwinkle is easy to propagate, grown in greenhouses around the world. Ongoing research is uncovering other Madagascan plants of medicinal value. Samples of plants are being tested in laboratories, and elderly Malagasy healers are being consulted. More than 50 species of wild coffee (*Coffea* spp.) grow in the island's eastern rainforests, providing an important genetic base for hybridizing with other strains because of their insect-resistance and low level of caffeine (Preston-Mafham 1991). These plants are symbolic of the great botanical wealth at risk.

The Biological Wealth of an Impoverished Country: Mammals

Home to some of the world's most fascinating, beautiful and curious mammals, Madagascar has approximately 117 native species, 90 percent of which exist nowhere else (Garbutt 1999). Excluding bats, all 88 native terrestrial mammals are endemic to Madagascar. Three-fourths of native mammals, or 66 species, are threatened with extinction; 49 of these are in higher categories of threat listed in the *2000 IUCN Red List of Threatened Species*. This represents 42 percent of all mammals found in Madagascar, by far the greatest percentage of threatened mammals of any country in the world (Hilton-Taylor 2000). As new species of mammals continue to be discovered, the numbers that are threatened continues to rise. A few have not been seen in the wild since their discovery. The majority is made of forest-dwellers, and a few inhabit marshy areas or woodland streams. The loss of forest, predation on them by Malagasy and domestic dogs, and introduction of exotic species of mammals that out-compete native species are combining to push many of the island's mammals toward extinction.

The Biological Wealth of an Impoverished Country: Mammals: Page 1
The publication of *Mammals of Madagascar*, by Nick Garbutt, in 1999 filled a void for a complete guide to all native mammals, illustrated with color photos of most species and major habitats. This supplemented *Madascar: A Natural History* in 1991, an important reference on mammals and their environment. Conservation work has focused mainly on lemurs, with many organizations involved, including Earthwatch Institute, which sponsors field research; Conservation International; Jersey Wildlife Preservation Trust (based in England); and CARE. Several of these groups sponsored biodiversity studies and helped establish national parks, benefiting thousands of species, including tenrecs and other native mammals. A growing number of Malagasy zoologists are taking part in studies and conservation work, and new programs have been initiated to help local people while conserving mammals and their environments. Certain mammals have received inadequate attention to date, notably bats, rodents and some viverrids, who will undoubtedly benefit from the swell of interest and enthusiasm for Madagascar fauna that has developed in recent years. Filmmakers have recently produced a number of excellent wildlife documentaries, photographing rare species and spreading knowledge and concern about endangered mammals (see Video section).

Among Madagascar's mammals are many primitive forms. The tenrecs' closest relatives are insectivores known as solenodons, native to Cuba, Hispaniola and other vestiges of Gondwana in the Caribbean. Tenrecs and solenodons may have had a common ancestor living on the supercontinent, progenitor of all mammals. The remains of similar species have been found in Africa and South America, indicating that they were once very widespread but died out on all but isolated refuges such as Madagascar and West Indian islands. Tenrecs belong to a family of insectivores, Tenrecidae, related to shrews, moles and hedgehogs, but quite distinct from them. Twenty-seven species of three types of tenrecs make up this family--spiny, furred and otter-shrews (Garbutt 1999). They range in size from the Common Tenrec (*Tenrec ecaudatus*), which resembles the European Hedgehog and weighs more than 5 pounds, to the shrew-like tenrecs, *Microgale* genus, weighing less than 2 ounces (Nowak 1999). Tenrecs have some very unusual physical characteristics placing them far from any close mammalian relative. They have variable body temperatures that change with the ambient temperature and, an even more reptilian or avian trait, a cloaca that combines urinal, rectal and generative canals into one (Garbutt 1999).

A striking tenrec is the Lowland Streaked Tenrec (*Hemicentetes semispinosus*). It and a similar species, the Highland Streaked Tenrec (*Hemicentetes nigriceps*), weigh about 5 to 7 ounces and measure some 6 inches in length. White stripes run down their backs like skunks, and barbed, porcupine-like spines are detachable (Eisenberg 1975). The Highland species has a stiff, white neck ruff rising several inches at the back of its head that can be stabbed into the nose of an unwary predator (Eisenberg 1975). Family groups forage together and communicate by vibrating quills that produce low-frequency sounds like dry grass being rubbed together; tenrecs can detect these sounds from distances of more than 4 meters (Garbutt 1999). They also make a number of sounds that are audible to humans.

The Aquatic Tenrec (*Limnogale mergulus*), listed as Endangered in the *2000 IUCN Red List of Threatened Species*, inhabits streams and lakes, living at altitudes between 600 and 2,000 meters (Nowak 1999). This 8-inch tenrec has clawed, webbed feet, and a long, thin tail for propelling it through the water to feed on small crustaceans and fish. Its habitat in the central highlands has been greatly affected by human disturbance and deforestation. The Aquatic Tenrec has at least one refuge, the new Ranomafana National Park, created for the bamboo lemurs (Preston-Mafham 1991). In 1990, Dr. David Stone managed to lure an Aquatic Tenrec into a live trap, the first one of its kind seen alive in 25 years (Preston-Mafham 1991). Later, four more were taken and studied in captivity for three weeks prior to being returned to the river Namorona in Ranomafana, one of the few clear, unsilted rivers left in Madagascar (Preston-Mafham 1991). This species requires such streams, and only the preservation of forests, such as that in

Ranomafana, will ensure its survival.

Another six species in this family, all shrew-tenrecs of the genus *Microgale*, are listed in the *2000 IUCN Red List of Threatened Species*. These tiny insectivores are found in all parts of Madagascar in areas of heavy vegetation, and have dark, soft fur. They range in size from 1.5 to 5 inches in length, and weigh as little as 1.8 ounces (Nowak 1999). Several of the threatened species are highly restricted in range and habitat, and one, *Microgale dryas*, listed as Critical, occurs only in Ambatovaky Special Reserve in the northeastern rainforest (Garbutt 1999).

The Biological Wealth of an Impoverished Country: Mammals: Page 2

Far better known to the world, the lemurs are the focus of many programs to conserve them, as well as research on their wild behavior and biology. New species continue to be discovered; most recently in 2000, three new species of tiny mouse lemurs. Three more have been rediscovered, an indication that other species may yet be discovered to add to the present total of 33 species (Garbutt 1999)**.** This is the only country with five families of primates, making up more than one-third of all primate families; it is home to 12 percent of all primate species and 21 percent of all primate genera (Mittermeier *et al.* 1999). Unlike Brazil, however, which is another center for endemic mammals, Madagascar is far smaller, the size of Kenya, covering 226,656 square miles, or 0.4 percent of Earth's surface (NYT 2000). The number of lemur species is not an indication of their variety since many subspecies differ so radically from one another that in the future, each may be accorded full species status. One species of sifaka, a long-legged kind of lemur, has one subspecies that is pitch black, and another that is pure white. At least 51 species and subspecies of lemurs are known to exist (Mittermeier *et al.* 1999).

The most gregarious of the lemurs are the Ring•tailed Lemurs (*Lemur catta*), who travel about in boisterous, friendly troops, living mainly on the ground. These lemurs have long, fox-like muzzles, large, soft golden-brown eyes, fluffy, gray fur, and black-and-white striped tails. Their body length is 15 to 17 inches, but their rope-like tails are half-again as long, from 21 to 24 inches (Nowak 1999). These 5-pound primates use their boldly patterned tails in a complex language of mutual visual and scent signals. They wave them about to show dominance, as a signal to follow other group members, or rub them on their wrist glands to wave at their rivals in territorial battles (Sleeper 1997). Moving about in troops of up to 25 individuals, they walk rapidly on the ground with the tail held high, waving it about. They wrap their tails around themselves for warmth on chilly nights. Extremely affectionate and playful, their core group is dominated by females (Jolly 1988).

In reserves where they are strictly protected, Ring-tailed Lemurs become very tame, napping on the ground in piles of leaves near tourists. Sometimes they sprawl out on their backs with arms spread wide apart. Females usually have a single young, but when twins are born, one may be "adopted" by a non-pregnant female, who may begin to produce milk in response to her surrogate role (Preston-Mafham 1991). Aunts also help in raising the young, and the daughter born the previous year babysits (Jolly 1988). Lemur babies are a source of great interest to the entire troop, females gathering around the mother and her young, grooming one another and the babies, forming a "grooming pod" (Preston-Mafham 1991). Only half of the infants survive their first year, and only 30 percent reach adulthood (Garbutt 1999). "A Lemur's Tale," shown on PBS in 1996, is a touching film about the death of a young Ring-tailed Lemur. Some fall from high branches, are killed by small carnivores or hawks, die of undiagnosed illness or starve in years of drought in their arid habitat. Ring-tailed Lemurs communicate with one another in a variety of sounds, from soft mewing contact calls to a territorial "bark-howl." Sometimes chasing and cuffing other members of their group, they are mainly peaceful, spending many hours a day in mutual grooming and in "snoozing-huddles," in which several animals form a complicated embrace from which tails and feet stick out in all directions (Preston-Mafham 1991).

In recent years, Ring•tailed Lemurs have been classified "high priority" for conservation by the IUCN and the Species Survival Commission (SSC) Primate Specialist Group because their habitat of dry woodlands in southern Madagascar

is disappearing at an alarming rate due to fires, overgrazing by livestock and tree cutting; they are also hunted with dogs in some areas, and captured as pets (Mittermeier *et al.* 1992, Garbutt 1999). Their distribution has become increasingly patchy as forests are cut (Garbutt 1999). The *2000 IUCN Red List of Threatened Species* lists the Ring-tailed Lemur as Vulnerable, or declining toward endangered status.

One of the strangest mammals in the world is the Aye•aye (*Daubentonia madagascariensis*), so unique that it is assigned to its own family, Daubentoniidae. When first discovered, scientists classified it as a squirrel because of its long, bushy tail and short•legged body. In 1863, however, after anatomical studies, the Aye•aye was revealed to be a lemur, in spite of incisor teeth that never stop growing, long, clawed fingers and other unlemur•like characteristics. Aye-ayes have a perpetually startled expression: huge, round protruding eyes dominate the face, the pupils completely surrounded by deep golden irises. Dark rings surround their eyes, heightening the eerie appearance. The rest of the face and body are gray to black, with long grizzled guard hairs. Spending the day in their twig and leaf nests, Aye-ayes emerge at night to forage for insects and fruit (Garbutt 1999). The Aye-aye's enormous ears are sensitive to the movements of insects under tree bark. At Duke University Primate Center, which has the world's largest number of captive lemurs, Aye•ayes have been filmed using their middle finger, which is twice the length of the other fingers, and skeletally thin, to tap on wood, listening for the movement of insects under the bark. When presented with a block of wood containing insect larvae in holes, the Aye•aye taps the wood and, cocking its head, can tell, even in the case of a hidden hole, the location of the insects, which it then extracts almost surgically, with its middle finger. This primate fills the ecological role of a woodpecker. Aye•ayes eat fruit as well, biting holes into the hard shells of coconuts and scraping the meat out with their middle fingers (Petter 1965). They have also been seen eating nuts of a native tree, nectar from the Traveller's Tree, fungus and lychee nuts (Garbutt 1999).

Aye-ayes have been heavily persecuted by the Malagasy, who consider them to be the embodiment of evil. In general, they are killed whenever seen. Dr. Ian Tattersall once found a dead Aye•aye with a wire pulled tight around its neck (McNulty 1975). In 1990, apparently to dispel the bad luck caused by its having entered a village, local people set an Aye•aye tail on a pole next to the road (Simons 1993). At one time, Aye-ayes were considered among the most endangered animals in the world, facing imminent extinction. To prevent their extinction, a few were captured and released on Nosy Mangabe, a small islet off the northeast coast. Fortunately, Aye•ayes survived on the main island, perhaps because coconut plantations provided food when their forests were cut. Feeding at night, they remained undetected until recently. The Malagasy continue to persecute them.

Since the early 1980s, field surveys have revealed that Aye-ayes have a larger distribution than was originally thought. In 1991, they were seen for the first time in western Madagascar in the northern mountains (Simons 1993). With confirmed sightings in many eastern and northern forests and a few western localities, Aye-ayes inhabit a variety of forest types (Garbutt 1999). They can survive in secondary forest, coming out of their stick nests only at night. And while once thought solitary, groups of three to four individuals have been seen traveling together and feeding at foraging sites (Garbutt 1999). In spite of the greater distribution, the Aye-aye is an endangered species and almost certainly is declining (Garbutt 1999). Aye-ayes require large tracts of forest to maintain viable populations and to protect them from the persecution that often results in their deaths (Garbutt 1999). Although very rare in captivity, several captive births have occurred in recent years at the Duke University Primate Center and Jersey Wildlife Preservation Society zoo in England.

One lemur has recently been rediscovered in the wild and, in the process, an entirely new species was found. The Greater Bamboo Lemur (*Hapalemur simus*) seemed to have disappeared in the wild some time in the mid-19th century. Not until 1964 was this 5-pound, grizzled, gray-olive lemur seen again in a village market, where it was purchased by a French scientist. Unfortunately, it escaped. A pair captured in 1972 in a southeastern rainforest lived in the zoo in Madagascar's capital city, Antananarivo, until both male and female and their two offspring died (Quammen 1996).

Patricia Wright, an American primatologist, decided to search for this species in 1986 in its supposed range. Fossil evidence indicates that 1,000 years ago, the Greater Bamboo Lemur was widely distributed throughout most of

Madagascar's forests, and European naturalists saw it fairly regularly in the 19th century. When she saw a russet-colored lemur clinging to a trunk, making loud "tonking" calls, Wright assumed that she had rediscovered the Greater Bamboo Lemur. Although a different color, she concluded that these animals probably represented a color variation (Quammen 1996). A German primatologist, Bernhard Meier, made independent studies in this patch of rainforest at the same time, also discovering the reddish-gold lemur. Both scientists had great difficulty making observations because of its extreme shyness (Quammen 1996). Finally one was caught, and in 1987, after chromosomal and anatomical studies were done in France, this lemur was found to be an entirely new species (Jolly 1988). It was named the Golden Bamboo Lemur (*Hapalemur aureus*) in a joint zoological paper by Meier, Wright and three other biologists (Preston-Mafham 1991). After months of unsuccessful attempts, Wright took the first photographs of the Golden Bamboo Lemur in the wild. Its beautiful golden-red face mask and belly contrast with darker brown fur on the rest of its body. (See color photographs in Garbutt 1999, Jolly 1988 and Preston-Mafham 1991). This lemur has been found at another location further north, and it is not known whether these populations are isolated from one another. Its population is apparently very low, as only about 1,000 animals have been estimated in the original location of discovery, and its habitat continues to be cleared (Garbutt 1999). The *2000 IUCN Red List of Threatened Species* has classified the Golden Bamboo Lemur as Critical, the most endangered category. Its limited range places it in great jeopardy, and it has been hunted with slingshots; its long-term survival is not secure (Garbutt 1999).

The Greater Bamboo Lemur, the animal first sought, was later found in the same forest, resembling original descriptions and clearly a separate species from the Golden Bamboo Lemur; a third species of bamboo lemur, the Gray Bamboo Lemur (*Hapalemur griseus*), weighs only 2 pounds. It has smoky gray fur and golden eyes, and lives alongside the latter two species in this same forest. This lemur lives in other parts of Madagascar as well (Preston-Mafham 1991).

Each of these three bamboo lemurs eats different parts or species of bamboo plants. One eats the leaves, another the pith, and the third confines itself to new shoots, leaf bases and pith from narrow stems (Quammen 1996). Amazingly, chemical analyses of the plants eaten by the Golden Bamboo Lemur found them to have high concentrations of cyanide, a chemical usually toxic to mammals. Golden Bamboo Lemurs weigh only about 2.2 pounds, and Wright and her co-workers found that, based on toxicity tests of other mammals, they eat 12 times the amount of cyanide that should kill them (Quammen 1996). This is another example of the biological mysteries of Madagascan wildlife.

The Ranomafana forest, with its rare and endemic lemurs and other unusual fauna and flora, would likely have been cut by the Malagasy for more farmland, but Wright spent five years in a successful effort to protect it in the newly•created Ranomafana National Park (Bohlen 1993, Mittermeier *et al.* 1992). This new park covers 108,000 acres of old-growth eastern lowland rainforest. Giant rosewood and other ancient trees tower above a lush understory. It is an extremely important--perhaps the most important--forest for lemurs. Fourteen species of lemurs and 18 other endemic species of mammals live in the park (Jolly 1988). Local people cooperated fully in setting the park™s boundaries, aware of the importance of saving forests. They had experienced a major catastrophe when a cyclone caused landslides, burying entire families in their homes, all precipitated by deforestation (Jolly 1988). In spite of these remarkable achievements, some tree cutting still occurs in Ranomafana National Park (Garbutt 1999).

Wright has continued to study lemurs, now specializing in the exquisite Diademed Sifaka (*Propithecus diadema*) (Brody 1998). Sifakas are the most acrobatic lemurs, leaping from tree to tree, but they have a unique means of locomotion to cross open spaces between trees. Standing on their long hind legs in an upright posture, they hop sideways, with their arms raised high above their heads. Sifakas can move very quickly in this amazing, dance-like gait, covering distances of more than 100 yards. They are also able to leap vertically to tree branches from a standing position, even carrying babies on their backs. One of their spectacular leaps, some 30 feet up, is the equivalent of a person jumping to the top of a telephone pole. The Golden-crowned or Tattersall's Sifaka (*Propithecus tattersalli*) is a beautiful, nearly all•white species with rich yellow-orange on the crown and tinges of this color on its back, legs and chest. Orange eyes contrast with a furless black face. The smallest of the sifakas, it is confined to a tiny area of only about 15 square miles of forest fragments in northeast Madagascar. The Golden-crowned Sifaka's small population of

fewer than 8,000 animals, fragmented into isolated populations, is threatened by forest cutting, brush fires, loss of habitat to agriculture and hunting (Garbutt 1999). Distributed in discontinuous patches of forest, these sifakas may become inbred if corridors are not acquired to link populations. A core part of their forest had been scheduled for cutting for charcoal when scientists named these sifakas. The PBS Nature program, fiMadagascar. Island of Ghosts,fl was the first to film these delicate lemurs (see Video section, Regional - Africa and Indian Ocean Islands). They move about in small groups and feed on a variety of unripe fruits, seeds, shoots, leaves, bark and flowers (Garbutt 1999). No reserve has been set aside for this highly endangered sifaka, although a three-parcel national park covering 20,000 hectares (49,420 acres) has been proposed to protect this species from extinction (Garbutt 1999). The IUCN classifies this species as Critical (Hilton-Taylor 2000).

Although many Malagasy have become far more aware of the need to protect lemurs, some do not understand their rarity or the importance of conserving them. Many rural people still hunt them for food or kill them because of superstitious beliefs. In some areas, the Malagasy try to sell lemurs to foreign scientists. Visiting zoologists studying lemurs have been approached by Malagasy holding captive, and usually injured or dying lemurs, in hopes of a reward. On one occasion, an endangered species of sifaka was brought to primatologist Dr. Alison Jolly, dragged half•choked by a vine around its neck, with one arm dangling loose below the elbow, a jagged bone protruding; blood oozed down its white fur, and it gasped for air through a muzzle smashed by a flung stone (Jolly 1980). Jolly expressed horror at its condition and refused to pay them any reward. She then amazed them by telling them it was a unique sifaka, found only in that small part of Madagascar. They were incredulous . . . not in Antananarivo? . . . Not in France? . . . Not in America? (Jolly 1980). For the majority of people, lemurs are familiar animals, easy to capture and valuable as food. Malagasy schools, established by the French colonial government, taught them only about European animals, encouraging people to assume that their lemurs were unimportant. Fortunately, many Malagasy are becoming concerned about protecting lemurs, and conservation education is taught in an increasing number of schools.

Some lemurs have bred in captivity in zoos and breeding centers, but most, like the endangered Indri (*Indri indri*), have never survived in captivity long enough to breed. In their rainforests, they perch high up, clinging to tree trunks to feed, and suddenly leaping vertically to a neighboring tree, pushing off with their extremely muscular, long legs. Panda-like fur of contrasting black and white--black faces and bodies and white arms and legs--gives them a dramatic appearance. Nearly tailless and heavy--but graceful--their eerie songs, sung at dawn and sometimes during the day, form a loud chorus of high-pitched voices that carries for long distances. Indris were once very common in the eastern rainforest, but much of their habitat has been burned away, making them extremely sensitive to the danger of fires. When a 1992 fire threatened a group in a reserve, they raised such a loud cry that the guards were alerted. They rushed to the scene and put out the fire (Rajaonson 1993).

Although originally found in the far north and central highlands, the Indri is now limited to a narrow strip encompassing only half the rainforests on the island (Garbutt 1999). Indris do not reach sexual maturity until between 7 and 9 years of age, and females are thought to give birth only every second or third year (Garbutt 1999). With such a low reproductive rate, they have been very vulnerable to habitat loss and hunting, especially by immigrants (Garbutt 1999). Moving about in small family groups, they are conspicuous to hunters. The Indri is one of the few lemurs whose killing is considered taboo by the Malagasy, but the old taboos are breaking down, resulting in capture and killing. In some cases, religious leaders encourage such killing. A lemur scientist met a Catholic priest who killed several Indris, roasted them and served them to his congregation, as recorded by Faith McNulty in 1975, and this killing has not ceased. In *Mammals of Madagascar* (Garbutt 1999), two terrified Indris were photographed clinging to poles in a hut, awaiting slaughter for food.

In contrast to the Indri, mouse lemurs (*Microcebus* spp) are so small that it is hard to think of them as primates. The tiniest is the newly discovered Pygmy Mouse Lemur (*Microcebus myoxinus*), with an average weight of only 30 grams, or 1.05 ounces, smaller than any other primate (Garbutt 1999). This tiny mammal is 2.73 inches long, with a tail just under 6 inches in length (Garbutt 1999). The other species are slightly larger, with body lengths ranging up to about 5 inches, and tails of equal or greater length (Garbutt 1999). These nocturnal lemurs have huge dark eyes and are agile and active, resembling African bushbabies. They feed on insects, spiders, and even small frogs and lizards, as

well as fruit, flowers and nectar (Nowak 1999). Females form groups and sleep in a nest together with up to nine individuals, while males usually nest alone or in pairs; occasionally males are found in a group of females (Nowak 1999).

A key to protecting lemurs and their forest homes is educating the people of Madagascar about them. The Jersey Wildlife Preservation Trust has put up posters with pictures of lemurs and their protected status around the island. Habitat protection is obviously key to conserving lemurs, and another recent development is the protection of the largest remaining area of rainforest in Madagascar. The Masoala Peninsula in the northeast is the sole home of the Red Ruffed Lemur (*Varecia variegata rubra*), a 9-pound, reddish subspecies of the Ruffed Lemur, but bearing little resemblance to the latter black-and-white species. With $3 million from USAID (United States Agency for International Development) and three years of planning, the new Masoala National Park, covering 210,000 hectares (518,910 acres or 840 square miles), was announced in June 1996 (Terry 1996). This immense park was formally signed into law on October 18, 1997 (Kremen 1998). Thai and Indonesian timber companies had hoped to log these virgin rainforests, but this new law will prevent clearcutting and slash-and-burn agriculture that would have destroyed the forest within less than 50 years. A coalition of organizations helped establish this park, including the Wildlife Conservation Society, CARE and the Peregrine Fund (Garbutt 1999). It will prevent the extinction of the endangered Red Ruffed Lemur, as well as that of the newly rediscovered Madagascar Serpent Eagle (*Eutriorchis astur*) (see below).

In 1997, five Ruffed Lemurs born and raised in the Duke University Primate Center in North Carolina were released in the Betampona Reserve in the northeast to bolster a small, isolated population of this species (Welch 1997). This reintroduction represented a goal in the captive-breeding program at Duke University, which has long planned such a return of these highly endangered primates to the wild. John Cleese, actor and a member of the 1970s British comedy team, Monty Python's Flying Circus, took an interest in the reintroduction program as an enthusiastic lemur admirer. After contributing to the Ruffed Lemur reintroduction program, he wanted to see how they were faring in the wild, and trekked to their remote release site. A delightful film based on this experience, "Lemurs with John Cleese," was shown on PBS in 1999. These Ruffed Lemurs have been released in an area of dense rainforest and rugged hillsides, a long hike from the nearest road. The biologists and assistants who take part in this reintroduction program show their dedication by living for long periods under extremely primitive conditions. Cleese managed to inject humor into this otherwise arduous situation.

At least six species of lemurs, and perhaps more, serve the ecologically important role of pollinating flowers. Many of Madagascar's plants produce unusually large flowers with strong odors and copious nectars attracting lemurs to feed on them. Should any of these lemurs become extinct, the plants that they pollinate will likely follow. Lemurs also play an important role in dispersing seeds. Research by the German Primate Centre at Hamburg University has found that Brown Lemurs are crucial to the regeneration of the western dry forests. About 10 percent of the island's tree species rely largely or entirely on this species to disperse seeds, which pass through their digestive systems.

The surviving lemurs are in extreme danger of following their relatives into extinction. Conservation organizations accord them extremely high priority among endangered primates, and they are the focus of many programs to preserve them. Twenty-nine of the 33 species are listed in the *2000 IUCN Red List of Threatened Species*, all but seven in higher categories of threat. This is an increase of nine species in the four years since the previous edition of the *IUCN Red List* was published (Baillie and Groombridge 1996). Three species and several more subspecies are in the Critical category of species on the verge of extinction, while seven are Endangered, an increase of four species since 1996. All lemurs are listed on Appendix I of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), the category prohibiting commercial trade, and as Endangered on the U.S. Endangered Species Act.

Although lemurs are protected by Madagascan law, hunting is a major cause of mortality. High fines and even jail sentences may be imposed for killing a lemur, but the severity of the penalties might make officials reluctant to enforce the laws (Peterson 1989). Blowguns, snares, traps, sharpened sticks, slings, stones, guns or even clubs are used to kill them (Peterson 1989). To kill small species of nocturnal lemurs, trees are sometimes cut down, and

hunters seize them from their nest holes (Peterson 1989). In the late 1980s, a "sport" hunter bragged of killing 12 highly endangered Verreaux's Sifakas in one afternoon (Peterson 1989). In spite of education programs launched in the 1990s urging the Malagasy to protect lemurs, and the rise in tourists who come to see them, which provides revenues, few have benefited from tourism. Hunting remains a major threat (Garbutt 1999). The rise in human population has resulted in an increased demand for food, particularly protein, far more than the ailing agricultural system can supply (Garbutt 1999). The larger lemur species are especially affected. Because laws against killing lemurs are not enforced, much more education is needed about their potential value in attracting tourism and research funds that provide new jobs. Already tourism has raised income levels among some Malagasy, but hunger is still widespread (Tyson 2000).

In the late 1980s, a World Bank official studying the extreme and worsening poverty on the island said that there might come a time when the people of the capital city would scale the walls of the city zoo and eat the lemurs: "On the downward spiral, animals are at the bottom" (Peterson 1989). Such a tragedy is not inconceivable considering that hunger and poverty have deepened in the decade since. Conservation programs must involve communities while providing an incentive to conserve lemurs. Otherwise, it may be impossible to persuade the Malagasy not to slaughter them.

Although the status of lemurs is deteriorating along with their forests, much is being done to prevent their extinction. The past two decades have been of critical importance to lemur conservation. These extraordinary animals are receiving worldwide attention, and habitat protection for some species has been achieved. Not too long ago, their extinctions seemed inevitable and imminent. Conservation education programs, including showing slides of lemurs and other wildlife to rural children, have been launched. Wright helped to finance the building of new schools and the renovation of existing schools near Ranomafana National Park (Tyson 2000). A number of international organizations are integrating lemur and biodiversity studies with the economic development of entire communities (Garbutt 1999).

For a growing number of Malagasy, learning how special their lemurs are has made lemurs a source of pride and an important national treasure. In the future, Malagasy children may learn from an early age about lemurs and want to protect them. A few decades ago, few films had been made of these fascinating primates, while today many films show their habitats, biology and conservation work on their behalf. One is fiSpirits of the Forest,fl a charming film about many species of lemurs. Others are listed in the Video Section • Mammals. Films of lemurs and the island's environment would provide new insights about these animals if shown to the Malagasy people. Lemurs have also been prominently featured in *Madagascar: A Natural History*, by Ken Preston-Mafham, a beautiful and informative book, and the first guide book, *Mammals of Madagascar*, which provides color photos of nearly every species and subspecies, as well as information on habitats, conservation and status (Garbutt 1999).

In some areas of Madagascar, notably on Nosy Be island, lemurs are fully protected by taboo respected by the Malagasy. Here, beautiful Black Lemurs are fed by the villagers and tourists. This island is being developed intensively for tourism, and the strict nature reserve may be made into a national park (Tyson 2000). This will have mixed results, with new income flowing to the local people from park fees--one of the few countries where this occurs--yet with habitat lost and wildlife disturbed as a result of new hotels and a crush of visitors (Tyson 2000).

The gentle, curious gazes and charming behavior of lemurs have left an indelible impression on many people, and their extinction would be tragic, not just for biological reasons, but also because of their unique and delightful qualities.

The Biological Wealth of an Impoverished Country: Mammals: Page 3
Bats, which perform vital ecological roles in controlling insect populations and pollinating plants, tend to be ignored

and often persecuted. Madagascar is no exception. Fifteen species of the 29 species of bats are endemic, living nowhere else (Garbutt 1999). The remaining 14 species live in mainland Africa as well. Fourteen species, or almost half the native bats, are listed by the *2000 IUCN Red List of Threatened Species*. The Yellow Bat (*Scotophilus borbonicus*), the most endangered, is listed as Critical (Hilton-Taylor 2000). This bat has been seen in both eastern and western regions but is extremely rare. A Vulnerable species, the Sucker-footed Bat (*Myzopoda aurita*), is the sole member of its family, Myzopodidae, and an extremely unusual bat. It is able to walk up tree leaves using sucker disks at the bend of its wings and on its feet to adhere to the slippery leaves (Jolly 1988). Only 2 inches long, with a forearm length of 1.9 inches, this tiny bat occurred in East Africa during the Pleistocene, but at present, it is found only in several locations in the eastern rainforest region of Madagascar (Garbutt 1999). It roosts in the Traveller™s Tree. It possesses a complex echolocation system and emits very long calls used to hunt insects (Garbutt 1999).

The largest bat, the endemic Madagascar Flying Fox (*Pteropus rufus*), has a 4-foot wing-span. An extremely colorful bat, its crown and nape are yellowish, and its upper chest and shoulders are rufous to golden brown (Garbutt 1999). It feeds on fruit juices by squeezing pieces of fruit pulp in its mouth, swallowing the juice and very soft fruit pulp, especially of figs, papayas, lychees and guavas (Garbutt 1999). Colonies of these bats roost in tall trees in primary forests or plantations (Garbutt 1999). One large roost at the Berenty reserve has decreased, apparently because of daytime disturbance by tourists who come to see them hanging upside down in the tamarind trees (Preston-Mafham 1991). Elsewhere on Madagascar, the species has declined precipitously from hunting for its meat; only on inaccessible offshore islands do these bats survive without persecution (Preston-Mafham 1991). Of Asian origin, this species is related to fruit bats in the Mascarene Islands. Through captive studies, flying foxes have been found to be extremely devoted to one another (see discussion of Rodrigues Flying Fox in Chapter One).

The Biological Wealth of an Impoverished Country: Mammals: Page 4

The Viverrid family is represented in Madagascar by mongooses, civets, and related carnivores that have evolved into eight species of three endemic subfamilies (Preston-Mafham 1991). Their ancestor is thought to have originated in Africa, and may have colonized the island at an early period. The largest carnivore on the island is the Fossa, or Fosa (*Cryptoprocta ferox*). A zoological oddity, it resembles the Jaguarundi, a neotropical cat, but most authorities place it either in the Viverrid family with civets (Preston-Mafham 1991) or the Herpestidae family with mongoose (Nowak 1999). The only member of its genus, it walks flat on its feet, rather than on its toes like cats (Nowak 1999). Sleek and slender, with golden reddish-brown fur, it has a small head with a blunt, dog-like muzzle, and an extremely long tail. Males weigh up to 22 pounds, with a body length of 2.6 feet and a tail of equal length, while the smaller females measure 2.3 feet and weigh about 15 pounds (Garbutt 1999). It has scent glands which discharge a strong odor when the animal is irritated (Nowak 1999). Widespread but rare in forests throughout the island, this nocturnal predator kills small lemurs, rodents and tenrecs, as well as birds, reptiles, amphibians, invertebrates and, reputedly, domestic chickens (Garbutt 1999). The Fossa often excavates animals from their burrows and can pursue fleeing prey by climbing up trees (Nowak 1999).

The first research study of the Fossa is being conducted by zoologist Luke Dollar, funded by the Earthwatch Institute. Helped by volunteers, he is radio-tracking several Fossa to determine their movements, habits and territory size. As the largest predator on the island, the Fossa plays an extremely important role in the evolution, behavior and population dynamics of lemurs and other prey animals. During the research project, several Fossa have shown extreme confidence by raiding the tents of the researchers when unoccupied, ransacking them and even chewing metal objects, leather boots, rucksacks, soap and bottles of malaria tablets (Garbutt 1999). For centuries, Fossas have been persecuted by the Malagasy, believing them to be ferocious and evil.

The Fossa gives birth to a litter of two to four young, which mature very slowly and may not be fully independent until they are about 4 years old (Garbutt 1999). This slow rate of reproduction has made the Fossa vulnerable to

extinction. Along with losses from killing by the Malagasy, its forest home has been steadily whittled away by slash-and-burn agriculture. The Fossa is listed as Endangered in the *2000 IUCN Red List of Threatened Species*, a higher category of threat than it received in the 1996 version of this list.

Gerald Durrell, renowned author and conservationist, traveled in the western forests to capture Aye-ayes for captive breeding. He encountered a Fossa venturing out during the day--an unusual behavior: "A flash of russet red caught my eye in the bushes some six feet in front of the vehicle and, suddenly, from out of the undergrowth, silent as a cloud shadow, came a Fossa which walked languidly to the middle of the road and sat down" (Durrell 1993). Remaining there, the Fossa proceeded to groom himself, apparently unaware of Durrell's presence. Then, with a sigh and a wide yawn, the Fossa crossed the road and disappeared into the forest, "his immense sickle of a tail swinging from side to side like a bellrope behind him. To have spent ten minutes with such a rare and beautiful creature was a privilege" (Durrell 1993).

The Falanouc (*Eupleres goudotii*), sole member of its genus and a viverrid, is the size of a domestic cat. It has dense, woolly fur and an extremely pointed and narrow muzzle. Native to humid eastern lowland forests and marsh areas and portions of the northwest, Falanoucs are active at twilight and during the night. Feeding mainly on earthworms and other invertebrates, they use their long snouts and tiny, conical teeth to catch prey in leaf litter (Garbutt 1999). The species is rare or extremely rare over most of its range and is classified as Endangered by the IUCN (Hilton-Taylor 2000). Like the Fossa, it has declined as a result of deforestation, drainage of marshes, hunting by the Malagasy, attacks by feral domestic dogs, and possibly competition with the introduced Small Indian Civet (*Viverricula indica*).

The Malagasy Civet or Fanaloka has the scientific name *Fossa fossana*, which has been confused with the Fossa. Like the Fossa and Falanouc, it is the only member of its genus. Looking more like spotted civets from mainland Africa and Asia, this reddish 3-pound carnivore has rows of black spots on its back, merging into stripes toward its bushy, grayish tail. Its distribution is far more restricted than the Fossa's or the Falanouc's, being confined to eastern rainforests which have been reduced to less than 10 percent of their original size. Sheltering in tree holes or crevices, the Malagasy Civet lives in pairs and feeds on crustaceans, worms, small eels and frogs (Nowak 1999). A pair has a single young, and a captive civet lived 11 years. Hunting and trapping have also threatened the Malagasy Civet, which is listed as Vulnerable by the IUCN (Hilton-Taylor 2000).

Five other viverrids, all mongooses, are native to Madagascar, and all are threatened with extinction from a loss of forest habitat and persecution. A few have very restricted distributions. They tend to be secretive unless in a secure forest reserve, and little attention has been paid to their conservation, biology or habitat requirements. Several are uniform brown or russet, while two have bold black dorsal stripes ending in white, bushy tails. One, the Brown-tailed Mongoose (*Salanoia concolor*), is native to the northeast rainforests, but almost nothing is known of this small carnivore (Garbutt 1999). All of the eight native civets, mongooses and related animals are listed as Vulnerable or Endangered by the *2000 IUCN Red List of Threatened Species*.

The Biological Wealth of an Impoverished Country: Mammals: Page 5

Among Madagascar's 11 species of murid rodents are several extremely bizarre forms. The largest is the Giant Jumping Rat (*Hypogeomys antimena*), the size of a rabbit and weighing 2 pounds, 10 ounces (Preston-Mafham 1991). Restricted to a small area in western dry, deciduous forests north of Morondava, in west-central Madagascar, its entire range is thought to encompass only 39 square miles (Preston-Mafham 1991). Once far more widely distributed, remains have been found in southwest and central Madagascar (Garbutt 1999). These huge rodents search for food, such as fallen fruit, on the forest floor and feed by sitting on their hindquarters and holding food in their forepaws like a rabbit (Garbutt 1999). Giant Jumping Rats build deep burrows and, unlike the vast majority of rodents, a mated pair maintains long bonds with one another and with their young (Garbutt 1999). Male young leave after one year, and

females stay with both parents for two to three years (Garbutt 1999). Only one or two young are born in a litter, and predation by Fossa and the Madagascar Ground Boa (*Acrantophis madagascariensis*) is high (Garbutt 1999). With no reserve and a habitat that continues to decline, this huge-eared rodent is in danger of extinction. A reserve is planned for this species, which is listed as Endangered by the *2000 IUCN Red List of Threatened Species*. fiMadagascar. Island of Ghostsfl filmed the Giant Jumping Rat in the wild, one of the only videos of this fast-disappearing species (see Video section).

Eight of Madagascar's native rodents, or 73 percent, are listed by the IUCN in various categories of threat. Two are considered Critical: the Madagascar Mouse (*Macrotarsomys ingens*) and the Madagascar Rat (*Eliurus penicillatus*). The mouse is known only from a single area in northwestern Madagascar, in dry deciduous forests where the type specimen was found, and it is thought to be almost totally arboreal and nocturnal (Garbutt 1999). The Madagascar Rat has not been seen since the type specimen was collected in central-eastern montane rainforest.

The Biological Wealth of an Impoverished Country: Birds

The Biological Wealth of an Impoverished Country: Birds: Page 1

Until recently, the amazing lemurs and other mammals of Madagascar eclipsed its remarkable bird life. Apart from the extinct elephant birds, 120 species of the 204 native birds are unique to the island (Morris and Hawkins 1998). Like tropical birds of other parts of the world, most are dazzlingly beautiful in brilliant hues. Unlike most tropical birds, however, they represent fascinating examples of evolution, including families of birds that exist nowhere else, having evolved from a single ancestor into many forms, some very bizarre. Most ornithologists recognize five bird families as unique to Madagascar, each with extremely distinctive characteristics. Four of these have some or all species that are threatened. The fifth, a family consisting of a single bird, the Cuckoo-Roller (*Leptosomus discolor*), is secure for the moment (Morris and Hawkins 1998). A few thousand years ago, there may have been far more native bird species that disappeared without a trace as their habitats were destroyed.

Native birds are not thriving, as people and livestock destroy their varied habitats, to which they had adapted over thousands of years. A total of 41 species, all but three of which are endemic, have been listed in the *2000 IUCN Red List of Threatened Species*, based on the research of BirdLife International published in 2000 in *Threatened Birds of the World*. The latter book illustrates each threatened Madagascan bird and describes status, population numbers, distribution and other pertinent information. The three non-endemic birds also breed in the neighboring Comoros or Seychelles (BI 2000). Thus, 20 percent of all native birds and 34 percent of endemic birds are threatened, five species listed as Critical, six as Endangered, 16 as Vulnerable, and 14 as Near-Threatened (BI 2000). Moreover, many native birds that were once widespread have become restricted to isolated forest reserves and parks, not yet endangered but far less numerous than in previous times. While the percentage of threatened birds is less than that of endemic mammals, it is significant, especially considering that 27 species are either Critical, Endangered or Vulnerable in the *2000 IUCN Red List of Threatened Species.* Madagascar has more threatened birds that all of the continental United States (excluding Puerto Rico and Hawaii). Its threatened birds total 41 threatened species, five greater than the United States™ 36 (BI 2000). Only 4 percent of the 810 breeding birds native to continental US and Canada combined (Sibley 2000) are threatened. If birds in the United States faced the same degree of threat as Madagascar's birds, at

least 162 species would be threatened with extinction.

Fortunately for the future of these unique birds, organizations such as BirdLife International; the Peregrine Fund; Conservation International; the Jersey Wildlife Preservation Trust; and an ad hoc group, The Working Group on Birds in the Madagascar Region, are researching and working to conserve Madagascar's native birds. Malagasy ornithologists and members of the public are participating in surveys, studies and conservation programs. An inventory of the status and taxonomy of all of Madagascar's birds is in progress (Morris and Hawkins 1998).

In spite of Madagascar™s many unusual birds, interesting to specialists and amateur birdwatchers alike, no bird guide or text illustrating and describing the island's avifauna existed until 1990, when Olivier Langrand's *Guide to the Birds of Madagascar* was published, providing information on natural history, status, habitats and distribution, as well as color paintings of all native birds. This material supplemented the lengthy descriptions in *Threatened Birds of Africa and Related Islands*, a 1985 publication of the International Council for Bird Preservation, now called BirdLife International (Collar and Stuart 1985). *Madagascar: A Natural History*, by Ken Preston-Mafham (1991), included extensive information on many native birds and their habitats. *Birds of Madagascar, A Photographic Guide* (Morris and Hawkins 1998), published in 1998, updates the latter publications with vivid color photographs illustrating almost all native birds, including many species discovered or rediscovered during the 1990s, such as the two new species, the Cryptic Warbler (*Cryptosylvicola randrianasoloi*) and the Red-shouldered Vanga (*Calicalicus rufocarpalis*), and the rediscovery of several birds thought extinct: the Madagascar Serpent Eagle, Madagascar Red Owl (*Tyto soumagnei*) and Red-tailed or Fanovana Newtonia (*Newtonia fanovanae*). The 1990s also saw the making of many films about the island's wildlife, including its birds (see Video section).

The Biological Wealth of an Impoverished Country: Birds: Page 2

Birds native to aquatic habitats have declined even more dramatically than many forest birds. The largest lake on Madagascar, Lake Alaotra in the northeast, was once a paradise of waterbirds, turtles, frogs and other wildlife. Traditionally, portions of the lake were used by the Malagasy for rice cultivation, without serious damage to the environment or resident wildlife. But as their populations and food requirements grew, people began to destroy more and more of the natural marsh and reed beds that lined the lake, and cleared the surrounding forest for firewood and agriculture. This destroyed the lake's water quality. With no trees to hold back the soil and conserve water, this once-beautiful lake became heavily silted by runoff (Durrell 1993). Added to this, non-native tilapia fish were introduced into the lake as a food source for the local people. The fish eat vegetation needed by dragonflies and other fauna that form the basis of the lake's food chain (Preston-Mafham 1991). This ecological collapse has greatly reduced rice production on the lake, although reeds are still being cleared for rice growing, fragmenting wildlife habitat (Garbutt 1999).

The effects on native aquatic birds have been catastrophic. Lake Alaotra is the only known habitat of the endemic Alaotra Grebe (*Tachybaptus rufolavatus*), which is presumed extinct (BI 2000, Morris and Hawkins 1998). No sightings have been made since 1985, when only two birds were seen. It declined from loss of its habitat, hunting and hybridizing with the Little Grebe (*Podiceps ruficollis*), a recent arrival from Africa (Morris and Hawkins 1998). Many fruitless searches for the species have been carried out in the lake and surrounding area since then (BI 2000, Morris and Hawkins 1998). This small, black-capped grebe was very sedentary and may have been nearly flightless because of its extremely short wings.

Another waterbird restricted to Lake Alaotra, the Madagascar Pochard (*Aythya innotata*), is also probably extinct, having been eliminated by the same threats as the Alaotra Grebe (BI 2000). This duck declined steeply from 1930 on, and the last known bird, a male, was captured in August 1991, having been caught in fishing gear. This bird later died, and intensive searches in 1989 and 1990, and again in 1993 and 1994, failed to discover more Madagascar Pochards

(BI 2000, Collar *et al.* 1994). A handsome bird, the pochard was chestnut-colored, with dark gray bill and yellow eyes (see photograph in Morris and Hawkins 1998). A shy species, its breeding and behavior were studied, but apparently nothing was done during its precipitous decline to prevent its extinction. Classified as Critical, hope remains that a few birds exist in wetland habitats around Lake Alaotra (Morris and Hawkins 1998).

The Jersey Wildlife Preservation Trust has begun education campaigns in the vicinity of Lake Alaotra to teach local people about the presence of the highly endangered Alaotra Reed Lemur or Bandru (*Hapalemur griseus alaotrensis*), a subspecies of the Grey Bamboo Lemur, and the importance of protecting the reed and papyrus beds. This lemur has been classified as Critical by the IUCN. The only lemur to live in an aquatic environment, the Alaotra Reed Lemur is larger than other subspecies of the Grey Gentle Lemur and lives in close, family groups (Garbutt 1999). To move about in the reed beds, they climb up a reed stem until it bends, and then walk along it to reach the next stem; their major food is the endemic papyrus, along with grasses and ferns (Garbutt 1999). Lake Alaotra's reed beds are its sole habitat, and although previously widespread in this and another lake to the north, only two isolated populations of lemurs, one of which numbers fewer than 60 animals and is on the verge of extinction, remain in marsh fragments (Garbutt 1999). This lemur has the most restricted range of any lemur species or subspecies (Garbutt 1999). The film, fiMadagascar. A World Apart,fl includes a moving segment on these lemurs feeding among the papyrus when a Malagasy canoe enters the marsh and sets a fire, causing the terrified lemurs to flee. (See Video section). Local village leaders have requested that the government set aside a protected zone in the marshes. There is hope that this lake will be brought back as a functioning ecosystem in the future and that a strict sanctuary will be set aside for this endangered lemur and the highly endangered waterbirds.

While sizeable areas of forest have been protected, few aquatic environments on Madagascar have been preserved, and native waterbird species are declining precipitously. The Madagascar Little Grebe (*Tachybaptus pelzelnii*) was once common and widespread in many parts of the island; with the pollution and destruction of marshes throughout the island for rice farms, this bird has declined greatly. The introduced tilapia was threatening this species by consuming its food supply. This grebe also hybridizes with the introduced Little Grebe (Collar *et al.* 1994). The Little Grebe, an African species which has colonized the island, prefers the habitat created by the tilapia, and is now abundant (Langrand 1990). The Madagascar Little Grebe has also drowned in fish nets, and has lost the vegetation it needed for nesting (BI 2000). It is expected to follow the Alaotra Grebe and Madagascar Pochard into extinction.

Another endemic waterbird, the Sakalava Rail (*Amaurornis olivieri*), native to western wetlands, is also extinct or nearly so. A small, sooty-black bird with yellow beak and pinkish-red legs and feet, it was native to streams and marshes in the western parts of the island. For more than 30 years, this species was not seen at all. In 1995, one was glimpsed at Lake Bemamba, and another in 1999 at the same lake (BI 2000). This species is classified as Critical (BI 2000), and Lake Bemamba and other lakes and wetlands on the west coast may be given protection by the Malagasy government, which has ratified the Ramsar Convention on wetlands preservation (BI 2000).

As a result of extensive habitat destruction and hunting, the Madagascar or Bernier's Teal (*Anas bernieri*) has likewise declined to endangered status in the few sites from which it is known on the west coast. Once widespread on the island, it is now restricted to a few marshes and shallow lakes. Small populations remain on Bemamba Lake and a few other sites (Morris and Hawkins 1998), and a flock of 67 was seen in another area (BI 2000). In 1970, 60 of these birds were seen on a lake, and as soon as this became known, European sportsmen went to the lake and killed more than 25 percent of the population (Curry-Lindahl 1972). In the 1970s, Bernier's Teal inhabited Lake Masama, but heavy hunting by both Europeans and natives with dogs has nearly eliminated them (Todd 1979). In 1993, four birds were captured for captive breeding (Collar *et al.* 1994). The Jersey Wildlife Preservation Trust is working to preserve this beleaguered species and the marshes of the west. The Madagascar Teal has been seen in three protected areas, and a conservation program at one lake has been initiated (BI 2000).

The critically endangered Madagascar Fish Eagle (*Haliaeetus vociferoides*) numbers about 250 pairs in the 600-kilometer stretch of western coastline to which it has become confined (BI 2000). This large eagle resembles the African Fish Eagle, from which it probably evolved, but instead of a snowy white head and upper body, it is streaked

with brown and has shaggy, buff crown feathers. About 35 inches long, with a 6.5-foot-wingspan, it is by far the largest bird on Madagascar. Persecuted by local people, these eagles have been shot and their nests destroyed. On one occasion in the 1990s, ornithologists saw some immigrants cut the tree where an active nest of a Madagascar Fish Eagle was located, and proceed to kill and eat the chicks! The only remaining habitat for this species is the western coast, where mangrove swamps are rapidly being destroyed (Langrand 1990, Preston-Mafham 1991). The Peregrine Fund is sponsoring research on this species, and 10 nests have been located in an area on the west coast in the Three Lakes Complex (BI 2000). The Fund has removed and raised chicks that would have been killed by siblings and released them to augment the population. The fish it feeds on are being depleted, however, by a gill-net fishery that has recently been established. A new Malagasy law allows local communities to control their own resources, and the people in this region are being encouraged to formalize conservation regulations prohibiting gill netting and tree cutting.

The Biological Wealth of an Impoverished Country: Birds: Page 3

Birds native to aquatic habitats have declined even more dramatically than many forest birds. The largest lake on Madagascar, Lake Alaotra in the northeast, was once a paradise of waterbirds, turtles, frogs and other wildlife. Traditionally, portions of the lake were used by the Malagasy for rice cultivation, without serious damage to the environment or resident wildlife. But as their populations and food requirements grew, people began to destroy more and more of the natural marsh and reed beds that lined the lake, and cleared the surrounding forest for firewood and agriculture. This destroyed the lake's water quality. With no trees to hold back the soil and conserve water, this once-beautiful lake became heavily silted by runoff (Durrell 1993). Added to this, non-native tilapia fish were introduced into the lake as a food source for the local people. The fish it feeds on are being depleted, however, by a gill-net fishery that has recently been established. A new Malagasy law allows local communities to control their own resources, and the people in this region are being encouraged to formalize conservation regulations prohibiting gill netting and tree

cutting.

The Biological Wealth of an Impoverished Country: Birds: Page 4
As more and more bird-watchers come to Madagascar, the government may place a higher priority on bird conservation. A special fund to which bird-watchers could contribute might be established to purchase and maintain refuges and to conduct conservation education and other projects for local people, especially in aquatic habitats. The preservation of threatened Madagascan birds has reached a critical point. The most endangered habitats, the last of the western forests, aquatic environments, and many parts of the eastern lowland rainforests, continue to decline. The fragmentation of forests that forces animals into islands of isolation needs to be studied and remedied by establishing habitat corridors between them. One Malagasy ornithologist, Aristide Andrianarimisa, is researching the effects of forest fragmentation on birds.

Pete Morris and Frank Hawkins, authors of *Birds of Madagascar. A Photographic Guide*, state that their purpose in writing their book was to inspire people to visit Madagascar and take an interest in its avifauna and the plight of so many threatened birds, as well as to promote greater interest in wildlife and conservation among the Malagasy people. Ecotourists bring revenue to the island and, thereby, help to preserve natural areas and wildlife (Morris and Hawkins 1998). The discovery of a new species of songbird, the Cryptic Warbler, by bird-watchers in Ranomafana National Park, is an exciting byproduct of ecotourism and an indication that the study of Madagascar's birds has just begun. It also proves that amateurs play an important role in bird observation. *Birds of Madagascar* establishes a good precedent by identifying, on a species-by-species basis, the avian habitats and those birds lacking reserves within their ranges. The authors request that people coming to see the wildlife of the island let the government know why they have come in order to convince decision makers that biodiversity conservation represents a worthy investment (Morris and Hawkins 1998).

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians
The distribution and diversity of Madagascar's reptiles and amphibians have not been carefully researched until the present. Chris Raxworthy, a British herpetologist, is in the process of carrying out the first methodical survey of the estimated 500 non-marine species, all of which are endemic (Holmes 1997). To date, at least 300 reptile and about 200 frog species have been identified (Tyson 2000). This would make it one of the top five countries in the world for diversity of reptiles and amphibians. The British Isles, by contrast, with about half the land area of Madagascar, have only six species of reptiles (Preston•Mafham 1991). Even the ranges of newly described lizards and frogs will not be delineated precisely for some time. Some areas remain unexplored by herpetologists, and Raxworthy finds new species of lizards and frogs on each expedition into the tangled swamps and forest fragments. On one day when accompanied by a journalist, he and fellow researchers, including Malagasy biologists, found a bright green day gecko, a strikingly beautiful yellow-and-black snake, tiny frogs resembling lichens, a leaf-tailed gecko and 4-inch chameleons with upper legs the colors of Rainbow Trout, and lower legs like toothpicks (Holmes 1997). In a reserve on Nosy Be island, he and some Earthwatch Institute volunteers rediscovered a 10-inch green lizard that had been lost to science since the 1890s, when last collected (Tyson 2000). Raxworthy is doing inventories in reserves as part of an island-wide biodiversity program, and hopes that in some impenetrable area, giant tortoises long considered extinct will be rediscovered (Holmes 1997).

Page 1 (Threatened)
Page 2 (Tortoises and Turtles)
Page 3 (Lizards)

Page 4 (Snakes)
Page 5 (Amphibians)

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 1
Of these native reptiles and amphibians, at least 19 are known to be threatened with extinction. A preliminary list includes 17 species of reptiles (four tortoises, a freshwater turtle, four sea turtles, a gecko, four chameleons and three boa snakes) and two amphibians, both frogs. All are in higher categories of threat: Endangered or Vulnerable by the *2000 IUCN Red List of Threatened Species* (Hilton-Taylor 2000). All but the sea turtles are endemic to Madagascar.

The arid regions at the northern and southern ends of Madagascar are home to two intricately patterned tortoises, both in danger of extinction. In the north is a species considered by many to be the world's most endangered tortoise: the 18-inch Madagascar or Plowshare Tortoise (*Geochelone yniphora*), whose tan, domed shell is marked with narrow black lines in delicate hexagonal patterns. The Plowshare name came about because of a protuberance on the tortoise™s lower shell that turns up, a kind of knob that remotely resembles a plowshare. This knob is used by males in sparring contests. From the 17th century onward, thousands of these tortoises, which were once abundant and widespread, were shipped every year to the nearby Comoro Islands to use as meat for settlers, driving the species to the edge of extinction before the trade finally ended in the 19th century (Juvic *et al.* 1981). Their populations never recovered, due to the continued take by villagers for pets and the massive destruction of their habitat. Known to the Malagasy as the "Angonoka," this tortoise was headed for extinction until 1985 when the Jersey Wildlife Preservation Trust was requested by the IUCN to work with the Malagasy government in formulating a rescue plan, Project Angonoka (Reid 1995). Research on the tortoise™s wild status and behavior began immediately, and a captive-breeding program was established at a government forestry station (Reid 1995).

By 1986, eight adult tortoises had been gathered from the wild and placed in an enclosure which had ample vegetation and conditions natural enough that two male Angonokas immediately began their fights of strength (Reid 1995). Gerald Durrell, founder of the Jersey Wildlife Preservation Trust, in his book, *The Aye-aye and I* (1993), described lone males showing no interest in breeding, even if surrounded by females. But when another male is present, they face each other prepared for combat: "The two males, rotund as Tweedledum and Tweedledee dressed for battle, approach each other at what, for a tortoise, is a smart trot. The shells clash together, and then the plowshare comes into use. Each male struggles to get this projection beneath his opponent and overturn him to win a victory in this bloodless duel" (Durrell 1993). Finally, when one is able to overturn his opponent, he lumbers over to mate with the female while the vanquished male "wanders dispiritedly away" (Durrell 1993).

Project Angonoka has shown success both in captive breeding these tortoises, which may number only between 300 and 1,000 in the wild, and in working with local people to conserve remaining wild populations (Durbin *et al.* 1996). In fact, by 1995, a total of 140 captive-bred juveniles, ranging in age from 10 months to 6 years, had been produced at the breeding center. The breeding program was described in an illustrated article entitled "Observations on Hatchling and Juvenile Captive-bred Angonoka in Madagascar," published in the Jersey Wildlife Preservation Trust's annual journal, *The Dodo,* issued early in 1996. Within months, the captive-breeding program was devastated by the theft of 76 animals--two adult females and 74 hatchlings. On May 6, 1996, someone cut through the flimsy chain-link fence and the wire of the enclosure and took half the animals that were the fruit of a decade's work. Not until a female is 20 years old does she begin breeding, so the loss of two breeding females and their hatchlings dealt the program a devastating setback (McNeil 1996a). The burglary may have been an inside job, since the dog on the premises did not bark to alert the personnel who were sleeping close by (Tyson 2000). It is unlikely that these adult females will breed in captivity, as there are almost no adult male Plowshare Tortoises in breeding programs, and without more than one, no breeding occurs.

Animal smugglers care little about the effect of their actions on the survival of endangered species. Reptile collectors will pay thousands of dollars for rare specimens, and this break-in had been planned. A Dutch rare animal dealer had advertised Plowshare hatchlings for sale the month before, at $3,000 apiece, saying they would be "available soon" (McNeil 1996a). Ten of the hatchlings were traced to Prague, where wildlife law enforcement is weak, and others were suspected to be in the Netherlands, where they would be sold to collectors in the United States, Spain, Germany and Japan (McNeil 1996a). The loss of these tortoises cost the breeding program years of work. Don Reid, the Conservation Field Officer in charge of the Plowshare Tortoise captive-breeding program, had experimented for years to achieve a proper diet for the tortoises, arranged male combats, and conducted lengthy experiments to learn proper conditions for the eggs to hatch (Reid 1995). These tortoises became so tame that they would stretch their necks out to be scratched (McNeil 1996a). Although discouraged by the theft, he continued the breeding program; 40 new tortoise hatchlings were produced in late 1996, bringing the total to 130 juveniles. In 1998, several of the smuggled tortoises were seized from a Malaysian animal dealer in Mexico City who had been the subject of a long-term U.S. Fish and Wildlife Service undercover investigation. The same year, three more Plowshare Tortoises were seized in Belgium as they were being imported (TRAFFIC 1999a). The species is listed by the *2000 IUCN Red List of Threatened Species* as Vulnerable, and is protected by the Malagasy government, which bans trade.

Officials from the Jersey Wildlife Preservation Trust and other conservationists have sponsored education programs aimed at informing local people about the tortoises and their rarity. This has resulted in their cooperation in helping to guard wild tortoises from poachers and control brush fires (Durbin *et al.* 1996). This region in northwestern Madagascar has lost most of its forest cover; Arab residents cut trees and burn them to clear the land for agriculture, and feral pigs kill the young wild tortoises (Durbin *et al.* 1996). So much clearance of natural vegetation has taken place that the climate has become increasingly more arid, causing ponds to dry up. Tree cutters are now turning to the mangroves, causing siltation of the inlets, which affects prawn harvests (Durbin *et al.* 1996) and destroys a key aquatic environment on the island.

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 2

The Plowshare Tortoises have been reduced to a few forest sites, and in spite of the urgent need for a reserve, none has been set aside. The area is getting conservation help with the formation of a new organization by conservation biologists, the Association to Safeguard the Environment. Its purpose is to involve local people in environmental projects, such as planting cashew trees, learning fire suppression methods, and trapping bush pigs; they are also giving conservation lessons to children and conducting literacy classes (Durbin *et al.* 1996).

The Radiated Tortoise (*Geochelone radiata*) inhabits the drylands of the extreme south, where the strange Didierea plants and other desert vegetation grow in open shrubland. Many people consider this tortoise to be the most beautiful in the world. Delicate yellow sunburst patterns adorn the top of its 16-inch-long black shell, and the underside is marked with diamond patterns. These tortoises also declined after tens of thousands were killed to supply local villagers with meat, or exported to the Comoro Islands from the 17th century on for meat markets abroad. In 1922 alone, 22,000 of these tortoises were exported (Jolly 1980). The legal trade did not cease until 1930. The tortoise populations have not rebounded, and illegal capture for collectors and zoos may be the explanation. The slow reproduction of this species means that it cannot quickly make up for losses in its population. An extremely long-lived species, it has evolved with low natural mortality and has few young. As an example of its longevity, a Radiated Tortoise of unknown age presented to the Queen of Tonga by Captain Cook in the 1770s, lived until 1966, making it almost 190 years old at its death (Jackson 1993).

The lovely patterns on this tortoise's shell, which vary from individual to individual, have placed it in great demand around the world, encouraging poverty-stricken Malagasy to risk jail to earn the money that these tortoises bring.

Thousands of Radiated Tortoises have been collected for the international market, sold in Europe, North America and elsewhere for $2,000 or more per animal. In spite of having a range that is far larger than that of the Plowshare Tortoise, the Radiated Tortoise is declining rapidly toward extinction. The species is listed by the *2000 IUCN Red List of Threatened Species* as Vulnerable. Export and collection of Radiated Tortoises are prohibited by the Malagasy government, with severe penalties for violations including prison sentences. The United States lists both the Radiated and Plowshare Tortoises on the Endangered Species Act, which prohibits commercial importation. International commercial trade is banned by their listing on Appendix I of CITES. Still, the smuggling continues, fed by the many wealthy collectors who have no conscience about the effect their purchase has on wild populations, and the zoos that knowingly purchase smuggled animals. Malagasy authorities have failed to put an end to the poaching, especially of the Radiated Tortoise and other southern species.

Donovan Webster, a journalist, researched the rampant smuggling of Radiated Tortoises and other wildlife from the island for *The New York Times Magazine*, which published his lengthy article on February 16, 1997. The magazine cover featured the article and read: "I was caught in Madagascar. Peddled for 30 cents. Smuggled to Orlando. Sold for $10,000. I'm a rare, coveted tortoise--coldblooded contraband." Webster found that Madagascar was a "pirate's paradise," with little or no local enforcement of conservation laws. Its long and unpatrolled coastline is used by smugglers, who load tortoises onto small boats at night, with little fear of arrest (Webster 1997). Although some enforcement of capture bans takes place in the range of the Radiated Tortoise, local people have learned to avoid arrest.

The contrast between the attitudes of local people toward the Plowshare Tortoise in the north, where education programs have been carried out by the Jersey Wildlife Preservation Trust, and the south, where no strong program exists to protect the Radiated Tortoise and other wildlife, could not be more dramatic. In the south, poaching Radiated Tortoises and other reptiles is considered an accepted form of revenue by the extremely poor people of the region. At local bars and restaurants, Webster was approached by people who offered to produce a rare snake within 24 hours. Snakes are a favorite animal for smugglers because they can be secreted in small bags and placed in luggage or, if they are small enough, in pockets. He refused a boa, which was offered at $300 and could be sold for $2,000 in the United States (Webster 1997).

Webster exposed a large-scale and fairly open trade in Radiated Tortoises in local markets within the range of these tortoises. He visited a woman who was reputed to have many of these tortoises for sale. She showed him 24 Radiated Tortoises which she kept ready for sale to anyone who would pay the right price; they were crowded into a make-shift pen in her living room, stacked two and three deep in filthy conditions (Webster 1997). They grunted and made hissing sounds when disturbed, scratching and scrabbling against one another and the pen sides; their shells were covered with dust, and most appeared to be sickly (Webster 1997). The woman tossed the tortoises back into the pile after handling them. She claimed that she sold them to local people for $1.35, and to outsiders for $4 or more, depending on how many tortoises she had at the time (Webster 1997). She also admitted supplying a smuggler who arrived once a week in a canoe at a remote beach with any Radiated Tortoises she had in stock (Webster 1997).

These tortoises are absurdly easy to collect in the wild, living in open shrubland and moving so slowly that they can be picked up as easily as rocks. Webster witnessed the capture of one mature tortoise which Benjamin, one of the collectors, located in the shadow of a boulder. When he approached, the tortoise hissed and tried to crawl beneath bushes, but it was easily grabbed, and he flipped it on its back; soon he caught two other adult tortoises who had a baby the size of a small stone wedged beneath them in an apparent attempt to protect it (Webster 1997). Collectors wrap string around the tortoises™ shells to form handles for carrying them. When they met at the end of the day, they had taken 54 mature tortoises and many young ones, making it a "banner day" (Webster 1997). The occasional presence of enforcement officers and World Wildlife Fund (WWF) representatives did not seem to present any anxiety of threat of arrest to the collectors (Webster 1997).

Each Radiated Tortoise is worth at least $2,000 once smuggled out of Madagascar, and those with unusually exquisite patterns bring as much as $10,000 (Webster 1997). Benjamin later admitted that he was aware that the tortoises were

becoming rarer and that their range had shrunk in recent years; he also knew that many were very old, probably older than his own 53 years. It was obvious that the tortoises would soon be gone, but he believed this was his only potential income source; he was uncertain about how he would make a living when there were no more Radiated Tortoises (Webster 1997).

Some of the smuggled Radiated Tortoises leaving Madagascar have been seized by importing countries. In May 1992, for example, a Dutch citizen arriving from Madagascar was stopped by Customs at Roissy Airport in the Netherlands in possession of 46 Radiated Tortoises as well as 14 bamboo lemurs of several species and seven endangered Madagascar Boas (*Acrantophis madagascariensis*); the animals were confiscated and returned to Madagascar (TRAFFIC 1992). In 1998, a Radiated Tortoise was among many rare tortoises seized in Belgium as they were being imported, and U.S. authorities, under fiOperation Chameleon,fl an undercover investigation of trafficking in illegal Madagascar reptiles, seized Radiated Tortoises from an American reptile dealer in Miami. In May 1999, French Customs officers seized 450 tortoises smuggled by three Malagasy citizens living in Paris (TRAFFIC 1999b). Among them were 120 Radiated Tortoises; the suspects were not arrested (TRAFFIC 1999b).

Most ecotourism on the island has been developed for viewing lemurs, chameleons and birds, but the Radiated Tortoise and its extraordinary habitat of endemic plants have the potential of attracting many tourists. Also living in this tortoise's habitat are spectacular sifakas, many unusual birds, and other reptiles. In Beza-Mahafaly Reserve, scientists are studying the ecology and longevity of these tortoises, as well as searching for a permanent form of marking that would make them unattractive to collectors. The Radiated Tortoise could be conserved while helping local people like Benjamin. Grants from international organizations could finance jobs held by local people, such as ex-poachers, to protect the tortoises and serve as wardens. Former collectors could help educate schoolchildren and local people about protecting Radiated Tortoises and other wildlife. Organizations, such as Earthwatch Institute, might sponsor research to study the status of these tortoises. The presence of scientists would pose a deterrent to poachers.

Two other endemic tortoises, the Spider Tortoise (*Pyxis archnoides*) and the highly endangered Flat•shelled Tortoise (*Pyxis planicauda*), are much smaller, about 5 or 6 inches long (Preston•Mafham 1991). The latter tortoise is restricted to a forest of only 40 square miles, and a captive•breeding program is attempting to prevent its extinction. Both these tortoises lay only a single, large egg (Preston•Mafham 1991). These tortoises are also in demand by reptile collectors. In August 1996, six men were indicted after being arrested with four Spider Tortoises in their luggage at the Orlando International Airport in Florida. They were part of a smuggling ring supplying rare reptiles to collectors. In 1999, 330 Spider Tortoises were seized along with Radiated Tortoises in the case cited above (TRAFFIC 1999b).

The Madagascar Big-headed Turtle (*Erymnochelys madagascariensis*), is an endangered freshwater species listed in the *2000 IUCN Red List of Threatened Species* and on Appendix II of CITES. This turtle is related to South American river turtles, another link that may date back to the time before Madagascar drifted away from Gondwana. The Jersey Wildlife Preservation Trust began a breeding program for these turtles in 1999 with the objective of releasing young turtles back into the wild after educating local people.

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 3

Madagascar is home to two•thirds of the world's chameleons--at least 62 species--more than any other country (Tyson 2000). Among the island's endemic chameleons are the world's smallest and largest species. The smallest, *Brookesia minima*, is only 1.3 inches long, while the largest, *Furcifer oustaleti*, measures 27 inches in length (Preston•Mafham 1991). Their conical eyes, moving independently, can look forward and backward at the same time, swiveling almost 180 degrees in either direction (Preston-Mafham 1991). This adaptation, processing totally divergent information spontaneously, would confuse most vertebrates, but chameleons, even very young ones, are adept at using these dual periscopes to locate insects and other prey. They hold onto the thinnest branch with their prehensile tails, and with

long, thin legs bent at the knees, they walk in an odd back-and-forth swaying motion that resembles leaves moving in the wind. Their chunky bodies and spindly legs give them an awkward appearance, but they are superbly adapted to catching their prey by unfurling a long, sticky tongue--curled upside their mouth--with lightning speed, nailing an unaware insect with astonishing accuracy.

Their camouflage coloration, which varies greatly from bright greens, mottled browns, reds and blues, helps protect them from avian and mammal predators. Contrary to general opinion, chameleons do not change colors as they move about in the trees or on the ground to match their background. When they suddenly change colors, it is as a territorial or sexual display meant for other chameleons (Preston-Mafham 1991). Some species have horns and other protuberances, giving them the appearance of miniature dinosaurs. A few species show sexual dimorphism, or a physical difference between the sexes. The contrast can be so striking that some were considered separate species when first identified (Burger and Price 1996). In one species, for example, the female is black and yellow, and the male a mottled brown and white (Burger and Price 1996).

Chameleons are heavily exploited by collectors who capture them for sale in pet stores around the world, threatening them. Collectors will pay $1,000 or more per animal for rare species. This trade, which involves thousands of individuals, has caused declines in many species. The Malagasy government has banned trade in most species, but enforcement is not strong. One chameleon, *Chamaeleo brevicornis*, of which 795 were exported in the first six months of 1990, is restricted to only a few areas of primary forest (Behra 1993). An ongoing study will evaluate whether to allow trade in the commoner species. Chameleons captured and shipped abroad for the pet trade suffer very high mortality as a result of inhumane transport conditions and inadequate care in pet stores and people's homes. They require special conditions of temperature and humidity, and many have specialized diets. In short, they are not suited to being house pets. In the care of specialists, they can be kept alive, but most captive breeding has been unsuccessful. Some of the rarer species, such as the beautiful blue-green Parson's Chameleon (*Chamaeleo parsonii*), which can reach lengths of more than 20 inches, have not been bred to the second generation**,** and mortality is high. All chameleons are on Appendix II of CITES, which requires export permits, but none has been listed on Appendix I of CITES, which would ban commercial trade.

Although some chameleons have adapted to disturbed habitats, such as weedy fields and shrub landscape, the majority favor natural habitats. The small *Brookesia* chameleons, of which one species is listed by IUCN as Vulnerable (Hilton-Taylor 2000), require undisturbed, primary old-growth forest. Three other chameleons, all *Furcifer* genus, are listed as Vulnerable by IUCN. All are in decline, approaching endangered status.

Although many Malagasy regard chameleons as ugly porters of bad luck (Burger and Price 1996), for tourists, they are the second most popular animals, after lemurs. Some Malagasy, aware of the fascination with which chameleons are held by tourists, capture them and offer them for viewing or sale.

Another lizard being captured for the pet trade is the extraordinary 4-inch-long Leaf•tailed Gecko, *Uroplatus fimbriatus*, a true master of camouflage. Resting during the day with its head tight against a tree trunk, an elaborate lacy fringe along the underside of the body allows it to melt into the tree, while its skin is patterned to resemble tree bark. Even its golden eyes are streaked with tiny dark lines that imitate bark. With broad, flattened front feet splayed out against the bark and hind legs held vertically under a spatula•like tail, it becomes virtually invisible (Preston•Mafham 1991). If discovered, however, it has a defense. Opening its mouth wide to reveal a crimson•red tongue, it raises its tail vertically and emits an ear-splitting screech, no doubt intended to be a fearsome display (Preston•Mafham 1991, Tyson 1994). Malagasy boys have discovered the haunts of the Leaf-tailed Geckos, and capture hundreds--thousands by their accounting--for sale to foreign middlemen who pay them less than $1. They are sold in the United States for $250 a pair (Tyson 1994, Tyson 2000). On Nosy Be island off the northern coast, schoolboys claim to have captured 40,000 over the past six years (Tyson 2000). A threatened gecko, Standing's Day Gecko (*Phelsuma standingi*), is native to the spiny forests of the south and is one of the most coveted by collectors (Tyson 2000). It is hunted out of many areas because Malagasy have captured hundreds, receiving $1.20 per gecko, while reporting only a few to authorities (Tyson 2000). It is on CITES Appendix II, and sells in the United States for

$80 to $200 apiece (Tyson 2000). Most species of geckos bring the village collectors only about 3 U.S. cents, while the exporter receives $9 to $13 and U.S. retailers get $75 or more (Burger and Price 1996). In most cases, these pet reptiles live a very short time, and represent a mere toy to the consumer.

The export trade in live lizards involves an enormous number of animals. One gecko, *Phelsuma serraticauda*, was known only from a few museum specimens until 1,360 specimens were chronicled as exported during the first six months of 1990 for the pet trade (Behra 1993). During this same period, 22,837 lizards--geckos, *Phelsuma* genus, and chameleons, *Chamaeleo* genus--were exported from Madagascar (Behra 1993). Between 1986 and 1991, almost 145,000 lizards of 17 species were exported; of these at least 38,325 were chameleons of 21 species (Burger and Price 1996). Many of these are species that are endemic to restricted areas, or threatened in the wild. The U.S. Fish and Wildlife Service™s fiOperation Chameleonfl succeeded in arresting 19 people in 1998, among whom was a major Malaysian smuggler and an American, Tommy Crutchfield, who was arrested at Miami International Airport with suitcases full of rare snakes, tortoises and lizards. In another case, a Canadian and a Dutchman were arrested at Chiang Kai-shek International Airport in Taiwan with numerous chameleons and geckos, including some threatened Standing's Day Geckos.

Several gecko species have extremely limited ranges. A newly described leaf gecko, *Uroplatus malama*, is known from a single specimen taken in a remnant of lowland rainforest in southeastern Madagascar (Burger and Price 1996). Only two specimens of a closely related species, *Uroplatus malahelo*, exist, native to a small patch of forest in the south (Burger and Price 1996). When discovered, its habitat was being logged, and the species may already be extinct (Burger and Price 1996). An extremely rare lizard, *Zonosaurus boettgeri*, known from two specimens that were taken in the 1890s and subsequently disappeared, has been rediscovered on the island of Nosy Be by herpetologist Chris Raxworthy and volunteers from Earthwatch Institute (Tyson 2000). The two individual lizards were killed as specimens upon rediscovery (Tyson 2000).

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 4

Among Madagascar's 80 types of snakes--all non-poisonous--are three boas, whose closest relatives are found in South America (Burger and Price 1996). They are thought to be among the island's most ancient inhabitants, resident since the early breakup of Gondwana (Preston•Mafham 1991). All are considered Vulnerable by the IUCN (Hilton-Taylor 2000): Dumeril's Boa (*Acrantophis dumerili*), Madagascar Boa (*Acrantophis madagascariensis)*, and the Madagascar Tree Boa (*Sanzinia madagascariensis*). The first two are Madagascar's largest snakes, reaching almost 6 feet in length; Dumeril's Boa is restricted to the south and southwest, while the Madagascar Boa is found in the north and northeast (Preston•Mafham 1991). Both species require humid habitats along streams and watercourses. Placid and slow•moving, they are often killed or captured by local people. The Madagascar Tree Boa is smaller and more common, shaded in delicate grayish-green with a purplish•blue tinge. Little is known of any of these species' life histories and diets (Preston•Mafham 1994). A very rare and possibly extinct snake, *Pararhadinea albignaci*, is known only from a single specimen picked up, dead, off the road in eastern Madagascar in 1970. This species has never been seen alive in its forest home (Preston-Mafham 1991).

One of the most extraordinary snakes in the world, *Langaha nasuta*, mimics a dry, pencil-thin twig to camouflage itself among the leaves. The female's nose is extended into a leaf•shaped structure adorned with scales and small tooth•like projections, while the nose of the male is elongated, tapering into a sharp point to resemble a thorn (photo in Preston•Mafham 1991 and Lamar 1997).

A smuggling operation involving hundreds of Madagascar reptiles was exposed in August 1996, when six men were charged with conspiracy to smuggle rare Madagascar reptiles into the United States and Canada. According to the U.S. Justice Department, two men were arrested at Orlando International Airport in Florida with 61 Madagascan tree

snakes in their suitcases that were to be sold at a large reptile breeders show in Orlando (Reuters 1996). Four Germans, one Canadian and one South African were indicted. Simon Harris, the South African, had $100,000 worth of rare reptiles in his luggage; he cooperated to implicate the other suspects, who are still being sought (Reuters 1996). These smugglers shipped snakes and tortoises, concealed in suitcases, from Europe to Canada and the United States and received payment by international wire transfers. Most of the snakes and tortoises were listed on CITES. In 1998, 26 Madagascan Tree Boas were seized in Belgium, and an American reptile dealer was caught by the U.S. Fish and Wildlife Service with the latter species and Dumeril's Ground Boas in his luggage at Miami International Airport (TRAFFIC 1999a).

The sea turtles inhabiting Madagascar's coastal waters are heavily exploited in spite of their listing on Appendix I of CITES. A survey in 1971 estimated that 13,000 were killed along the west coast alone (Burger and Price 1996). Little is known of their present populations.

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 5

Some 176 species of amphibians, all frogs, have been named and described (Mittermeier *et al.* 1999). Raxworthy estimates that there are another 124, many of which have already been found but not yet described scientifically (Tyson 2000). Salamanders and toads are absent from Madagascar. All but two frogs are endemic, one of which was introduced from Asia by French colonialists as a gourmet food source (Burger and Price 1996). The majority are native to rainforest environments, the most endangered type of habitat on the island. In one such area, a montane rainforest in the Andasibe region, 90 species are native--the highest diversity of frogs in the world (Burger and Price 1996). Since 1990, 13 new species of a single, colorful genus, *Boophis*, have been described, and others await naming by scientists (Burger and Price 1996). A candidate for the world's smallest frog--and perhaps the world's smallest vertebrate--is a minute frog, *Stumpffia pygmaea*, which measures less than 3 millimeters in length (0.117 inches) (Burger and Price 1996). This frog lays its eggs in foam nests hidden among leaves on the forest floor, and the tadpoles grow into froglets without ever feeding (Burger and Price 1996).

The most spectacular Malagasy frog may be the bright red Tomato Frog (*Dyscophus antongili*), which secretes poisonous white mucous when threatened. Some authorities consider the species to be endangered (Bauer 1995), while the *2000 IUCN Red List of Threatened Species* lists it as Vulnerable. To protect it from trade, it is listed on Appendix I of CITES. Fat and squat, this toad-like frog is large enough to cover the palm of a hand (Preston-Mafham 1991). Tomato Frogs have a very restricted range in the region of Tamatave on the east coast; some live in plantations, where pools of water gather, and even in garden ponds (Preston-Mafham 1991). Collectors, pet dealers and zoos have offered thousands of dollars for these frogs, and illegal shipments containing 40 or more Tomato Frogs have been confiscated.

One study entitled "The Export of Reptiles and Amphibians from Madagascar," by Olivier Behra (1993), chronicled the extent of exploitation of frogs. In 1988, 230 frogs of the genus *Mantella*, endemic to Madagascar, were exported. The demand increased, causing exports to rise astronomically to 11,058 in 1989; in the first six months of 1990 alone, almost 11,000 were exported, mainly to Denmark and other European countries, the United States and Japan (Behra 1993). These brightly colored little frogs are sold as pets and to decorate terrariums. The most popular Madagascar frog in this trade is the tiny Golden Mantella (*Mantella aurantiaca*), of which 3,237 were exported in the first six months of 1990 (Behra 1993). This frog is restricted to eastern Madagascar, and is apparently rare and declining (IUCN 1994). It lives in pandanus swamps in rainforests, which are rapidly disappearing, and no part of its habitat has been set aside in a reserve (IUCN 1994). Unlike most frogs, the Golden Mantella is slow-reproducing (IUCN 1994). In the 1990s, 3,000 to 6,000 were exported annually from Madagascar, and in 1994, two proposals sought to list this species on CITES, one on Appendix I and the other on Appendix II. The latter proposal succeeded, which is unfortunate, since it allows the trade to continue. The *2000 IUCN Red List of Threatened Species* lists the Golden

Mantella as Vulnerable (see photos of gold and red phases of this species in Lamar 1997).

In 1998, two people were arrested in Taiwan trying to smuggle frogs of two *Mantella* species (*Mantella madagascariensis* and *Mantella aurantiaca*), along with some Madagascar lizards. Another seizure of 50 Mantella frogs occurred at Zaventem Airport in Belgium in 1998 as they were being smuggled from Madagascar (TRAFFIC 1999a). Such seizures involved shipments without the proper export permits. Appendix I listing under CITES would provide greater protection.

The Biological Wealth of an Impoverished Country: Invertebrates

Like the rest of its fauna, Madagascar's invertebrates are extraordinary. One insect from the age of the dinosaurs, the Giraffe-necked Weevil (*Trachelophorus giraffa*), has an elongated neck which rises vertically, then makes a right-angle turn and extends horizontally, and ends in a tiny head with furry antennae. Amazingly, this insect has counterparts in New Zealand known as giraffe weevils (Molloy 1994). This may be explained by the fact that New Zealand was also part of Gondwana prior to its breakup (Molloy 1994). Other ancient species include the 100 species of hissing cockroaches. Some are far larger than any other cockroach species in the world; their heavy bodies resemble long-extinct trilobites. The largest species measure up to four inches long, and thousands are exported for the novelty pet trade and for zoos. When touched, they hiss loudly, and males aggressively charge one another with their armored, knobbed shields (Preston-Mafham 1991).

One of the richest land-snail faunas in the world is native, with more than 380 species named so far, 361 of which are endemic and differ greatly from land snails in Africa (Preston-Mafham 1991). Many are threatened, however, by introduced African Giant Snails (*Achatina fulica*) and several other non-native snails introduced to control the African Giant Snail, but threatening native species instead. One native snail, *Tropidophora deburghiae*, is considered endangered by some authorities. Brilliantly colored slugs, or shell-less snails up to 6 inches long, striped in black-and-red or yellow-and-brown, live on the damp rainforest floor (Preston-Mafham 1991). Many have limited distributions and can be easily eliminated by habitat destruction (Preston-Mafham 1991).

An extremely ancient family of spiders, Archaeidae, first described from a specimen frozen in amber several million years old, has seven species on Madagascar, one in South Africa, three in Australia, five in New Zealand and one at the tip of South America; these species appear to be vestiges from the ancient supercontinent (Preston-Mafham 1991). The Archaeidae spiders have strange, grotesquely shaped bodies, visible only through a microscope since they are only 0.14 inches long; they live among leaf litter on the ground (Preston-Mafham 1991). Some Madagascar spiders are extremely bizarre, with shapes that resemble bat-winged leaves, bright red thorns, or mottled brown lumps on logs (Preston-Mafham 1991).

Millipedes on Madagascar reach 6 inches and exude droplets of poison when attacked; Brown Lemurs have found ways of avoiding this toxin and feed on them (Preston-Mafham 1991). Shield-bugs, or stink-bugs, of the family Pentatomidae, have 220 species on Madagascar, many of which are brightly colored in reds, oranges and blacks; 120 species of water bugs, of which 80 percent are endemic, and a variety of assassin bugs add to the rich insect fauna (Preston-Mafham 1991). About 20,000 beetle species, including 500 species of endemic jewel-beetles, are native to Madagascar. Jewel-beetles, with their colorful, metallic bodies, appear during the rainy season in southern and western forests (Preston-Mafham 1991). Many species of scarab beetles, among which are dung beetles, are also native to Madagascar; one endemic genus, *Helictopleurus*, roll the dung balls into their nests and lay their eggs in them (Preston-Mafham 1991).

Madagascar's butterflies, totaling 300 species, are not as diverse as in some parts of the world, such as the Tambopata Natural Reserve in Peru, which has 1,300 species. This may be because they colonized the island fairly recently.

Another possibility is that many species have faded into extinction, leaving no trace, when the plant species upon which they depended were driven to extinction by habitat destruction. Since 80 percent of the island's forests have been cut, hundreds or thousands of species may have disappeared without a trace millennia ago. One Madagascar butterfly, a pale cream-and-black Swallowtail, *Papilio mangoura*, is hotly pursued by collectors because of its rarity (Preston-Mafham 1991). Several butterflies of the Nymphalidae family, or Fritillaries, are threatened, as are two species of the family Acraeidae.

In the 19th century, Charles Darwin learned of a spectacular, white Madagascar orchid (*Angraecum sesquipedale*) that had an extremely long, nectar-bearing tube dangling down from the flower. He reasoned that it could be pollinated only by an insect that could reach its nectar. He guessed that it might be "some huge moth, with a wonderfully long proboscis." Entomologists verified his belief with the 1903 discovery of the hawkmoth, *Xanthopan morgani praedicta*. This moth has a 9-inch tongue that it keeps wound in a spiral in its mouth, unfurling it to reach the nectar of this particular orchid. In a similar arrangement, another orchid (*Angraecum arachnites*), exudes a strange odor that attracts only one pollinator, the rainforest hawkmoth, *Panogena lingens* (Preston-Mafham 1991). The nectar at the base of this orchid's long, twisted tube can be reached only by this single species of moth--and not even every individual, but only one race of this moth which has a long, tapered proboscis (Preston-Mafham 1991). These species co-evolved, and should the moths become extinct, the orchids would have no pollinators and would follow them into extinction. Another unusual moth, the huge Comet Moth (*Argema mittrei*), is one of the largest moths in the world (Preston-Mafham 1991).

Preserving Madagascar's Natural Wonders

This fourth largest island in the world is, in many respects, a minicontinent. This evolutionary treasure-house is of great importance from a worldwide perspective. Madagascar's diversity of life forms is so great that as many as 200,000 species, most of them undescribed, may be native, of which an estimated 150,000 are endemic species (Daley 1997). The habitat loss is proceeding so rapidly, however, that the underfunded biological assessment studies will be unable to appraise this biological wealth before it disappears before their very eyes. Logging and burning have reduced the forested area from 120,000 to 20,000 square miles; this destruction still consumes vast areas each year (Daley 1997). It is estimated that all the remaining accessible forests will disappear within the next 35 years (Sayer *et al.* 1992). With the impending loss of these treasures, many conservationists and scientists consider Madagascar the world's most threatened natural area (Sayer *et al.* 1992).

Less than 5 percent of Madagascar is protected in reserves and parks. Even if these lands remain intact, they represent too small a percentage of forest to preserve the island's genetic heritage. Other than Masoala National Park, which encompasses most of an entire peninsula, some 840 square miles, most reserves are relatively small--islands of forest surrounded by denuded land. Should all surrounding forest be leveled, these isolated fragments would not be sufficient to prevent genetic impoverishment, inbreeding, and eventual extinction of the very species the reserves were meant to protect. Recent research in the Amazon has shown that forest fragmentation results in extinctions, in direct relation to the size of the reserve (Peters and Lovejoy 1990). The larger the reserve, the fewer extinctions. For this reason, Masoala National Park is receiving special attention from scientists. Stanford University's Center for Conservation Biology is analyzing a Geographic Information System (Kremen 1998). So far, this research has revealed that forests on the eastern border of the park are the most threatened, with a likelihood that they will be completely burned away within 25 years (Kremen 1998). The borders of the park were delineated according to the results of biological surveys, a method that is so new that it has not even been used in the United States. Claire Kremen of the Wildlife Conservation Society, with additional support from the National Geographic Society, worked with a Malagasy entomologist and two American ornithologists to conduct detailed biological species diversity studies in this rugged terrain (Kremen 1998). Five new species of butterflies and many other insects were discovered. Each had its own micro-habitat, endemic to that area. Habitats included in the national park are lowland rainforest; cloud

forest and montane heath; coastal and seasonally flooded forest; mangrove; marsh; estuary; bay; lagoon; and coral reef. Lemurs and a vast array of wildlife and plants will benefit from this new park.

Masoala National Park will not displace villages but will conduct education programs and involve them in the conservation of local wildlife. The Missouri Botanical Garden is also involved in the management of Masoala National Park, helping to inventory its rare plants and working with local people for non-destructive agricultural and fisheries industries. Work is also proceeding to stop the cutting of forests for firewood on Masoala and to provide public education on land use (Sayer *et al.* 1992). Some 300 or so villages exist within or nearby Masoala National Park, and the cooperation of the local people is crucial to the success of this park. The final plan for the park involved a compromise in which some cutting of four relatively fast-growing trees, including rosewood, would be allowed. Local communities, which will profit from the products, will be allowed to harvest palm seeds and butterflies. This will prevent the slash-and-burn destruction that was eating rapidly away at this forest (Kremen 1998). This park's endemic plants and animals, including the Red Ruffed Lemur, which exists only in the park, rely for their survival on the protection of this last sizeable rainforest. It will represent an experiment in conservation management that will have serious consequences should it fail. It is, however, one of the first times that ecological rules are being worked out with large numbers of local people to help protect such a large area. Elsewhere in Madagascar, similar projects are in the works.

Many of Madagascar's rarest species are not protected in any reserves, however, and may soon be lost. Reserves and parks, the last refuge for many species, are regularly pillaged for trees, and wildlife is killed or captured. A herpetologist surveying in Bemaraha Reserve, in the western part of the island, discovered a pile of illegally cut trees that had been marked with red paint as part of a botanist's study by the trail in 1996 (Holmes 1997). This is not an isolated occurrence. The native wildlife and plants are among the most endangered in the world. More than 124 vertebrate species are listed in the *2000 IUCN Red List of Threatened Species* (Hilton-Taylor 2000), as well as 306 species of plants (Walter and Gillett 1998). While this crisis is occurring, new species of lemurs, reptiles, invertebrates and plants are being discovered, making the preservation of the environment all the more urgent. Obviously, the amazing biological diversity of Madagascar has not been fully assessed and may be far greater than previously thought.

Several species thought long-extinct are rumored to survive, adding even more mystery to the picture. Many Malagasy have told scientists of having seen an animal that might be a pygmy hippopotamus. Shown a picture of an African Common Hippopotamus, they have said that it was similar, but had floppy ears, uncloven hooves, dark skin, except for pinkish areas around the eyes and mouth, and was the size of a calf or small cow (Tyson 2000). As recently as 1976, a man told biologists of having seen and heard one grunting; many unsolicited, independent accounts from Malagasy have agreed on these details (Tyson 2000). They call the animal "kilopilopitsofy," and many are afraid of being chased by it (Tyson 2000). The Common Hippopotamus of Africa also grunts and kills more people than any other animal on the continent.

A long-lost primate, ground-dwelling and the size of a 7-year-old child, has also been reported by several Malagasy (Tyson 2000). This may be the same animal that was described to primatologist Alison Jolly (1980). A Malagasy told her that he had been given a young lemur of a type he had never seen before. This lemur had very dark fur, walked on its hind legs, one foot after the other, rather than hopping like a sifaka, and had a flat face different from the pointed muzzles of living lemurs. After only two months, this lemur died, and its skeleton was buried in an unknown place (Jolly 1980). An old man recently told a similar story of having seen such an animal in 1952. Called the "kidoky" by others who have seen it, it has a dark coat with white spots above and below a flat, round face. When alarmed, it flees by leaping forward in short hops like a baboon. Its call was described as a long, single whoop, and other villagers who had seen the animal said it was solitary (Tyson 2000). Scientists have said that if it exists, it might be an *Archaeolemur* or *Hadropithecus* (Tyson 2000). The fact that their descriptions seem so similar to species known to have existed makes them all the more intriguing.

Alarm calls about the impending demise of Madagascar's natural world have been sounded for decades (Jolly 1980,

1988; McNulty 1975; Preston•Mafham 1991; Tyson 2000). Visitors to the island are united in their descriptions of a ravaged, eroded and deforested land. Jacques•Yves Cousteau and his team visited the island for a television special aired in 1995. As they sailed toward Madagascar, they were stunned to see huge, wide, red stains of eroded soil in the water, emanating from the island's rivers, and wisps of smoke from burning forests. These red rivers are bleeding the island's life blood, its topsoil. They are so pronounced that they are among the few natural phenomena on Earth visible from orbiting space craft. Cousteau's helicopter flights over the central plateau revealed a landscape among the most devastated on the planet. A research team sponsored by Earthwatch Institute described the island from the air, "Two features of the landscape stood out even from 10 kilometers up: barrenness and smoke" (Tyson 1994).

Although erosion remains a major problem, some progress has been made to stop it (Morell 1999). Erosion costs Madagascar between $100 million and $290 million per year, caused mainly by the continued slash-and-burn agriculture (Tyson 2000). It has been extremely difficult to convince many Malagasy that the last of the forests will disappear within a generation if they do not seek alternative means of growing crops. To that end, Cornell University's International Institute for Food, Agriculture and Development, run by Norman Uphoff, has been helping farmers in the vicinity of Ranomafana National Park (Tyson 2000). These desperately poor farmers have no electricity or plumbing and struggle to feed large families on soil that is leaching its nutrients. Norman Uphoff discovered that the native Wild Ginger plant had high concentrations of phosphate, and he encouraged its use as fertilizer (Tyson 2000). By supplying seedlings and information, the Cornell program also has helped establish fish farms. Their agronomists have advised farmers to mix crops and to plant certain species in order to keep the soil rich and retard erosion; they have supplied seedlings (Tyson 2000). This agricultural advice has been helpful, but because some rural people have so many children, many are unable to produce enough crops to feed their families (Tyson 2000). Other projects involve encouraging rice cultivation with more suitable seed varieties, improved irrigation systems and application of fertilizer (Garbutt 1999). Using native bees in honey-making is also being taught to the Malagasy, who often fell old-growth trees to obtain honey (Garbutt 1999). The Kew Botanical Gardens in London and Britain's Royal Palm Society are researching the marketing of seeds from some native palm trees (Terry 1996).

International aid organizations could help preserve forests by donating fertilizer so the Malagasy would not need to practice slash-and-burn when forest soil ceases to produce crops. The urgent task of supplying the Malagasy people with methods of producing food and fuel in environmentally non-destructive ways has just begun. Villagers would be more likely to preserve trees now cut for firewood if they were provided with solar cookers or given propane tanks for fuel. Bio-gas, or methane, produced by animal dung and sewage, could be used to provide fuel and fertilizer. Such projects have been launched by international agencies in some countries of Central Asia.

Madagascar's human population is growing at a rate of 3.1 percent per year and reached 12,596,000 in 1992 (55 persons per square mile) (Anon. 1994). By 1995, it had grown to 13.9 million (61 persons per square mile) (McNeil 1996b). Another increase to 14,462,509 people (64 persons per square mile) was registered in the 1999 *World Almanac*. The *2001 New York Times Almanac* noted a population of 15,506,472, based on a July 2000 estimate. Thus, 3 million people were added to the population in just eight years. Along with the original Asians, more recent immigrants from Africa, India, Pakistan, China, Europe, and Arab countries add to the diversity. They have long since passed the carrying capacity of the land, and rice must be imported to feed the people. As one of the world's 12 poorest countries, Madagascar's external debt is approximately $4.25 billion. Average annual income is only $780 (NYT 2000). The unemployment rate is about 33 percent, and 51 percent of children are malnourished, according to a study by USAID (Tyson 2000). The literacy rate is 46 percent, and only 42 percent of children attend schools; 70 percent of children ages 6 to 9 have had no formal education (Tyson 2000). Jacques Cousteau's team filmed hordes of desperately poor people as they combed dumps for scraps of metal and food. Some people even live in these dumps in holes they have dug in the soil. Such scenes are symptoms of extreme overpopulation and rampant poverty that can also be seen in parts of Brazil and Asia.

One of the reasons that illiteracy is so high in Madagascar is that millions of people must spend their days searching for food, water and firewood, requiring the help of their children, who are then unable to attend school. In general, foreign corporations have looted the island's resources, leaving no economic base that would help the people as a

whole. One U.S. company, the Esso Corporation, is owed $25 million by the Madagascan government and demanded payment in spite of the country's cash reserves of less than $2 million (McNeil 1996b). Because of the country's debt levels, the World Bank and the International Monetary Fund are now in charge of its finances (McNeil 1996b), a potentially dangerous situation for both the people and the environment. On the positive side, a "Debt for Nature" swap was carried out in Madagascar, in which a portion of the foreign debt was exchanged for the establishment of nature reserves and parks.

To date, efforts to slow the population growth rate are still in their early stages. A program that addresses population growth, based not on threats or punishment, but on persuasion, was launched by Population Communications International (PCI) of New York City in 1996. As the organization has done in other countries, it trains local people to create communication programs for radio and television with a message that limiting family size is advantageous. The majority of the population on the island lives in cities and has access to these media. The programs, described as "soap operas" by PCI, create melodramas with characters the audience can identify with, who act out dramas. The characters in these dramas come to realize that different behavior, such as having fewer children, will result in positive changes in their lives (Ryerson 1994). In many cases, this involves elevating the status of women, and convincing men that women must be allowed to make decisions about their own reproduction (Ryerson 1994). PCI is cooperating with organizations that are actively trying to conserve the wildlife of Madagascar, such as Conservation International and the African Wildlife Foundation. Ranomafana National Park began a family planning center in 1994 to help the people of the region, many of whom have as many as 14 children, of which 62 percent are underweight and 17 percent malnourished, according to a study by the University of North Carolina (Tyson 2000).

Madagascar is a magnet for scientists from around the world and has been the recipient of millions of dollars in foreign aid and grants from international conservation agencies. Conservationists are initiating many highly inventive and effective programs to interest the Malagasy in conservation and employ them in biodiversity work. Environmental education is a key to the future of Madagascar, and programs are being carried out at Beza-Mahafaly Reserve. This protected portion of endangered spiny desert and shrubland was established when the local Mahafaly people agreed to donate the land, and funds were raised by Alison Richard, a Yale primatologist, for a training program for Malagasy scientists (Tyson 2000). Patricia Wright has set up a similar program in which Malagasy students complete master's theses based on wildlife research in Ranomafana National Park, and some students travel to the United States to receive advanced training in biodiversity and environmental protection (Tyson 2000). They will help guide the country in new directions in the future. It also opens new worlds to these students, who, in turn, will make young people aware of the natural treasures in their country. Schools that Patricia Wright has helped establish in the area of the park teach environmental education to young people. Others are also helping introduce this subject to children. Josephine Andrews, a Scottish scientist studying Black Lemurs in Nosy Be since 1988, teaches children about the lemurs with the help of a Malagasy named Julien, who guides people around the forest preserve (Tyson 2000). "If the kids are really into it, then the adults will switch on as well," she said (Tyson 1994). Forests are the key to the future survival of the island and its people, and an education program aimed at rural people, teaching the value of trees in preventing floods, landslides and in maintaining the flow of rivers and streams, could save countless trees.

Scientists--both Malagasy and foreign--working on the island, could share their findings by talking with local people about the uniqueness of Madagascar's natural world. Ornithologists with the Peregrine Fund, who rediscovered the Red Owl and taught local schoolchildren about the species donated money from bird-watchers to the school, provided such an example. Scientists typically conduct research and depart without having taught local people about their findings. Villagers near Ranomafana National Park were so interested in learning about research results that they asked Wright for copies of reports. She began a bimonthly newsletter, in the Malagasy language, describing the natural history of the park (Tyson 2000).

Films and books about Madagascar's wildlife and plants tend to be distributed only in foreign countries, and never translated into Malagasy. Translations of books and subtitled films could be shown to schoolchildren to introduce them to Madagascar's tremendously interesting and beautiful natural world. It is ironic that Westerners may be more familiar with lemurs and chameleons that most Malagasy. Some projects for the future might include donation of solar

collectors and windmills to supply power to rural people. This could elevate their standard of living and cut back on firewood collection for fuel. Donation of projection and video equipment to regional schools provided with electricity would help them appreciate their natural heritage through viewing nature films of Madagascan wildlife. Satellite dishes would facilitate communication with people around the world through the Internet.

The government of Madagascar developed a 20-year National Conservation Strategy and Environmental Action Plan as long ago as 1984. In 1986, a survey of protected areas began with the aim of implementing management plans for priority protected areas and recommending new protected areas, as well as training Malagasy people to work in reserve management and conservation biology. The government has been working to create a sense of pride and ownership in the nation's biodiversity through this program (Morell 1999). The President of Madagascar has stated that the environment is important, a key to whether foreign scientists and tourists will be able to come to the country and aid in its conservation in the future (Tyson 2000). The World Bank and various organizations funded this Environmental Action Plan with $168 million for its first five years (Tyson 2000). This has resulted in many biological studies, education of a growing number of Malagasy for conservation work and a Biodiversity Planning Centre (Sayer *et al.* 1992). The Geographical Information System database is a cornerstone of the government program, concentrating data from all fields to help establish conservation priorities (Tyson 2000). Conservation International has an office in the capital and is contributing to biological inventory data, as it has in other countries, as well as conducting research on particular species and data management. It coordinates its work with local organizations and trains Malagasy scientists (Sayer *et al.* 1992).

Ecotourism is another budding industry, and Madagascar is one of the few countries in the world to share park fees with local people. As a result of an initiative put forth by a Malagasy non-governmental organization, the National Association for the Management of Protected Areas, one-half of all fees are given to local people (Tyson 2000). Ninety-three villages in the Ranomafana National Park area received about $10,000 in a recent year from park fees; a committee designated by the villages decides how to spend the money. In 1995 they bought seeds and built campgrounds, a crafts training center and small dams (Tyson 2000). Many local people are employed as park workers, and the aim of the program is to turn over management of this park and its biodiversity work to the Malagasy people. There needs to be a national park system with strict rules for management and protection, according to Patricia Wright, who deplored the illegal tree cutting by the previous park director at Ranomafana (Tyson 2000). She also has proposed that a national biodiversity institute be built, which would offer centralized training in biology and technology, as well as five new long-term biodiversity research stations similar to those in La Selva National Park in Costa Rica and the Smithsonian Institution's Panama tropical research laboratory (Tyson 2000).

Jobs, which are desperately needed by the Malagasy, are increasing as a result of the rise in the number of tourists. Selling crafts to tourists, running hotels and restaurants, and serving as guides are among these. Villagers who used to demand that parks be declassified so that they could legally gather wood, now request that more national parks be established, an apparent result of the new income that comes from fees and tourism (Morell 1999). International tourists have provided a major new source of revenue in Madagascar's economy and are helping the Malagasy see their wildlife in a new way, as so fascinating and biologically important that visitors come from every continent to view it. *Madagascar. The Bradt Travel Guide*, by Hilary Bradt (1999), published in various editions since 1988, is a useful aid for tourists, providing information about accommodations, natural history, protected areas, and the Malagasy and their history. Nature reserves and parks provide jobs by attracting scientists who employ local people, another incentive for the Malagasy to urge that more protected areas be set aside.

Compensation for lost access to forests has not been paid in the past, and new arrangements reached with villagers to allow some extraction of resources from the forests may heal some of these wounds and placate those who still wish to cut trees. Medicinal plants obtained from Madagascar may be another source of revenue in the future. The Rosy Periwinkle may be only one of many native plants highly valuable in treating disease. Research on the potential of other plants may uncover other such treasures. In the past, revenues from plants used for medicine have not been returned in part to the country of origin, but recently a new trend has begun. In one case, a pharmaceutical company agreed to pay people in a South American country a portion of the revenues gained from any native plant providing a

marketable drug.

Another potential source of revenue is the placement of videocameras connected to the Internet, which present websites with general information as well as live camera views of wildlife. South African parks have a number of these videocameras placed at water holes, animal dens and other key areas that capture live views of animals transmitted to the Internet for a small viewing fee. This has proven very successful, funding many of the South African National Parks system™s expenses. A similar system could be established in Madagascar with solar-powered videocameras, which have already been in use in Alaska, trained on tree canopies, rainforest flowers or lemurs, along with websites that provide basic information on Madagascar's environment, biodiversity and the Malagasy people. For millions of people who cannot visit Madagascar, such a website might be fascinating as a learning tool for teachers and the public, as well as an exciting view of these unique animals and their environments. If managed in such a way that profits were shared between poor Malagasy to alleviate their poverty, and conservation organizations to preserve biodiversity, such a system has great potential.

A satellite connection with classrooms in the United States or other countries would be another opportunity for interactive communication and learning. In December 2000, for example, students in an American classroom talked with students in a school in Guyana about endangered Giant Otters and their conservation through a visual satellite hookup. Students and others might set up an interactive link with biologists and conservationists working in Madagascar, asking questions and offering help. Students have provided many excellent ideas for conservation, and classes have raised money to save rainforests and threatened wildlife habitat and to help stop poaching of endangered species in countries half a world away from their own. Malagasy young people might be inspired and enthusiastic through talking with others of their own age about conservation and biodiversity. Video cameras and still cameras might be donated to Malagasy students and young people to record nature and compete for prizes with their results.

Madagascar™s Lessons

Madagascar's story is one of ecological catastrophe and the gradual extermination of its life forms. One's first response might be that its experience is as far from the rest of the world as it is geographically remote. However, it is from the extremes that one acquires basic knowledge. The effects of immigrants, whether human, animal, plant or disease, can devastate natural ecosystems wherever they occur. Islands are especially vulnerable to the effects of invasive species, including humans, because their flora and fauna have limited habitats and tend to be endemic, with small populations.

Exotic or non-indigenous species threaten 350 species of birds, or 30 percent of all threatened birds listed by BirdLife International in *Threatened Birds of the World* (BI 2000). Likewise, 361 plant species and 69 species of mammals listed by the *2000 IUCN Red List of Threatened Species* are threatened as a result of non-indigenous species (Hilton-Taylor 2000). The effects of invasive species, including humans, have been the major cause of extinction of virtually all bird species, almost all of which have occurred on islands. In the case of Madagascar, the Malagasy and other immigrant peoples and their livestock, and their subsequent hunting and habitat destruction, presented the vulnerable native species with threats against which they had no defense. Islands throughout the world continue to suffer losses in biodiversity, as do areas with large numbers of endemic species in mainland areas. Species with restricted ranges are the most likely to go extinct or become endangered. Such species dominate the list of birds in *Threatened Birds of the World* (BI 2000). In this age of international commerce, where plant diseases and other viruses are brought into countries in shiploads of lumber or ballast water, and exotic animals and plants continue to colonize and be released in delicate ecosystems with endemic species, whether on islands or mainlands, it has become extremely difficult to defend native species from such invasions. Nevertheless, through preserving native plants and animals and legislating against such introductions, while removing non-native species, ecosystems and their diversity can be protected. Preserving natural ecosystems is vitally important, not just for wildlife preservation, but for humans

as well, so that precious water supplies, topsoils and biological diversity, which stabilize all ecosystems, are protected. These lessons have not yet been put into practice in Madagascar or in many other parts of the world, including developed countries. Ecological and faunal changes may be so gradual that they go unnoticed until ecosystems have been destroyed.

Madagascar Testing Quotes

About 500 A.D., immigrant people from Asia, most probably Indonesia or Malaysia, arrived on Madagascar's shores in hand-hewn canoes, bringing domestic animals with them. They began clearing forests and burning them for farmland, and turned lakes and wetlands into rice paddies. Cleared land produced crops for only a few years until the thin soil became sterile. Farmers then moved on to other parts of the forest, in this slash-and-burn agriculture. At some point, African herdsmen colonized the island, bringing zebu cattle, which crowded out wildlife (Tyson 2000). Gradually, abuse of the land eroded the soil in the central highlands to bare earth, pocketed and gouged by deep gullies and cavernous holes. This region had harbored a great variety of lemurs, along with a wealth of birds, reptiles and unique plants. Throughout the island, wildlife declined as habitats disappeared, isolating animals in smaller and smaller patches of forest and wetlands. The large lemurs, tortoises and elephant birds were avidly hunted.

Within 600 years of the arrival of the Malagasy, extinctions claimed many native animals. Several elephant bird species, the larger lemurs and many native plants vanished. Two kinds of pygmy hippos inhabited the island. The Madagascar Hippopotamuses (*Hippopotamus lemerlei*), an amphibious species, and *Hippopotamus madagascariensis*, a forest species, were both about 6.5 feet long and 2.5 feet tall, smaller than the Common Hippopotamus of Africa, which is about 10 feet long (Tyson 2000). From genetic and anatomical analysis, both seem to have evolved from the latter species (Tyson 2000). The hippos had been widely distributed and very common prior to the arrival of the Malagasy (Dewar 1984). Their bones have been found with marks indicating that they had been butchered (Tyson 2000). Both died out long before Europeans arrived. The native crocodile, whose large bones have been found, is believed by some scientists to represent large specimens of Nile Crocodiles, the species native today (Tyson 2000). It is thus possible that the crocodile survived. A large mongoose-like viverrid, *Cryptoprocta spelea*, and a very unusual aardvark-like animal, *Plesiorycteropus madagascariensis*, died out at an early date (Dewar 1984).

Prior to the arrival of humans, elephant birds had been abundant in most parts of the island, as attested by the prevalence of their bones. There were two genera, and from six to 12 species of these birds (Tyson 2000). It is likely that the flightless birds fell prey to the primitive weapons of the Malagasy and were crowded out of their habitats by livestock (Tyson 2000). The last to die out was the Great Elephant Bird (*Aepyornis maximus*), which may have survived until recent times by retreating to remote swamps. Dr. Alexander Wetmore of the Smithsonian Institution examined bones of a Great Elephant Bird unearthed in archeological excavations in the 1960s. He was amazed by their size: "The incredible femur, or thighbone, of this ponderous bird is by far the largest I have ever seen" (Wetmore 1967). Estimated to weigh at least 1,000 pounds, more than three times the weight of an Ostrich, it produced eggs larger than any dinosaur's, with a capacity of 2 gallons (equivalent to seven Ostrich eggs), 180 chicken eggs or 12,000 hummingbird eggs (Bradbury 1919, Fuller 1987). When one was X•rayed, the bones of an embryo three•fourths developed were revealed (Wetmore 1967). Something had interrupted the embryo's growth and frozen it within the eggshell for hundreds and perhaps thousands of years (Wetmore 1967).

Despite its fearsome size, the Great Elephant Bird lacked a hooked beak for tearing prey and was plainly not a predator (Wetmore 1967). Its large, clawed feet may have helped it defend itself against the small native predators but were not enough to protect it from Malagasy arrows. Its short legs prevented it from running as fast as its relative, the Ostrich, but it may have been quite agile when chased. This vegetarian bird browsed and cropped plants, able to reach with its long neck to the lower branches of trees (Wetmore 1967). By the mid-16th century, when Europeans had managed to establish a foothold in Madagascar, the new French Governor, Sieur Etienne de Flacourt, wrote in 1661

that the Great Elephant Bird was still found in the south of the island, "seeking the most deserted places" to avoid human hunters (Tyson 2000). Villagers of Antandroy told of an Ostrich-like bird that was difficult to catch, according to Flacourt (Tyson 2000).

The exact date this giant bird became extinct is not known with certainty. Alan Feduccia (1996), an eminent paleo-ornithologist, asserts that elephant birds of many species were still widespread in the 10th century but gradually disappeared as a result of human activity. He cites an account by a French merchant sailor in 1848, who visited Madagascar and saw the shell of the Great Elephant Bird; he was told that it belonged to the chief and that the bird that produced such eggs "is still more rarely seen" (Feduccia 1996). Some authorities estimate that it died out in the mid-17th century, although there is no proof that any European ever saw one of these birds (Tyson 2000). It has been suggested that Europeans were responsible for the bird™s extinction by hunting and destroying its habitat (Quammen 1996). But Thomas Brooks (2000) of the Center for Applied Biodiversity Science, Conservation International, asserted in a list of extinct birds in *Threatened Birds of the World* (BI 2000) that all the elephant birds had disappeared by 1500. In a bizarre footnote to this species' epitaph, an *Aepyornis* egg washed up on Australia's western coast in 1995. No conclusive explanation for this strange event has been put forth, although it is likely that it became unearthed from long interment by rains, and washed out to sea. Much less is known of the other species of elephant birds, which existed in a variety of sizes down to a chicken-sized species.

Lemur-like primates once lived on many continents, but nowhere had they evolved into such a great variety of species. When the Malagasy people arrived some 1,500 years ago, lemurs occupied every habitat, even marshland. A species as tall as a man must have startled the Malagasy immigrants, giving rise to legends that these animals had superhuman powers. The first French naturalists were told by the Malagasy that these primates were thought to be the ghosts of sacred ancestors of man, inspiring the genus name Lemur, the word for ghost in Latin. The Malagasy considered some lemurs sacred and punished anyone who harmed them, but most species were feared as evil demons and were killed on sight.

From their arrival on Madagascar, the Malagasy hunted the larger species of lemurs, almost all of which are now extinct. Archaeological excavations show that they formed a staple in the immigrants' diets. Such diggings have unearthed the skulls and bones of long•extinct lemurs in early Malagasy jars and kitchen middens; their heads had been split by ax-heads made from an extinct flightless bird (Jolly 1980).

In the centuries following colonization by the Malagasy immigrants, some 15 species of lemurs of eight genera became extinct (Mittermeier 1997). These extinct lemurs were, for the most part, far larger than surviving species and had evolved to fill many ecological niches. Three *Megaladapis* lemurs weighed between 90 and 170 pounds and moved slowly through the trees, feeding on foliage (Tattersall 1993). Another species, *Archaeolemur*, was about the size of a female baboon and lived on the ground (Tattersall 1993). Two *Palaeopropithecus* species weighed between 90 and 130 pounds and were sloth•like tree dwellers with flexible bodies (Tattersall 1993). These extinct lemurs had evolved many unusual means of movement and locomotion that have no parallels in living species of lemurs.

Largest of all, the massive 400•pound *Archaeoindris* was apparently a ground•dweller, moving on all fours; many of its anatomical characteristics are unlike any living primate (Tattersall 1993). One entire lemur family, Archaeolemuridae, was obliterated. In this family were many species of lemurs weighing between 35 and 55 pounds; they were powerfully built and short•legged (Tattersall 1993). The heaviest lemur surviving today, the Indri (*Indri indri*), weighs only about 15 pounds (Tattersall 1993). These lemurs had survived for millions of years, and their extinctions were indeed a major biological loss to the planet. According to primatologists, the surviving lemurs resemble the very earliest primates from the Eocene (Tattersall 1993). Like prosimians in Africa and Asia, but to a far greater degree, lemurs have a highly developed sense of smell. Some species have long, fox-like noses (Preston-Mafham 1991). Genetic analysis of their DNA has revealed that all lemurs are descended from a single ancestor that probably arrived from Africa about 60 million years ago (Garbutt 1999).

The Giant Aye-aye (*Daubentonia robusta*) lemur was somewhat larger and 2.5 to 5 times heavier than the surviving

Aye-aye (see below), but in other respects was very similar (Garbutt 1999). It is known from subfossil remains found in southwestern Madagascar (Nowak 1999). The date of its disappearance is unknown but may be fairly recent.

Archaeologists have uncovered remains of a massive bird of prey, the Malagasy Crowned Eagle (*Stephanoaetus mahery*), which undoubtedly preyed on lemurs (Feduccia 1996). In fact, at one locality the diet of this eagle, based on the bones of eagles and lemurs found together, contained at least 80 percent primates, including specimens weighing up to 26.5 pounds (Feduccia 1996). Remains of another large eagle of the genus *Aquila* have been discovered, and it, too, preyed on large lemurs and became extinct after the arrival of the Malagasy. These extinct birds preyed on smaller lemurs as well, including some species still surviving (Feduccia 1996). A bird of prey flying overhead still elicits fear in lemurs, causing them to seek cover. Neither of the two remaining species of eagles on Madagascar preys on lemurs, but two hawk species have been seen preying on young lemurs (Garbutt 1999).

In addition to the Giant Elephant Bird, the large Snail-eating Coua (*Coua delalandei*), a member of the cuckoo family, became extinct. The last specimen of this large, slate-blue bird was taken on an islet off the east coast, Ile Sainte-Marie, in 1834 (Morris and Hawkins 1998); reports by observers who claimed to have seen the bird were recorded as late as 1930 (Fuller 1987). The causes of this bird's disappearance, and even its exact range, remain obscure (Langrand 1990). Many specimens of this bird were taken before its extinction and kept in museums in Leiden; London; New York; Paris; Philadelphia; Tananarive (Madagascar); and Cambridge (Massachusetts) (Fuller 1987). The long feathers of this bird were highly valued by the Malagasy, and hunting may have reduced its numbers to a critically low level (Fuller 1987). It is also possible that the many birds killed for zoological specimens may have pushed this already rare bird to extinction, since its distribution may have been limited to the tiny Ile Sainte-Marie. No reliable record exists of its presence on the main island of Madagascar, but there is hope that it might be found in lowland forest near the Bay of Antongil (Morris and Hawkins 1998). Ten closely related species of couas survive, all smaller than the Snail-eating Coua.

Madagascar and other Islands

http://www.endangeredspecieshandbook.org/madagascar_human.php

Madagascar

Imagine an island more than 1,000 miles long in a blue tropical ocean. Forests cover vast areas, interspersed with swamps where crocodiles 8 meters long lie in wait to prey on pygmy hippopotamuses. Thousands of giant tortoises with shells 4 feet across lumber about. In the forests and in dryer parts of the island live some of the strangest primates to have ever existed on Earth. Some 45 species of these lemurs live throughout the island and range in size from the world's smallest primate, weighing about 1 ounce, to a lemur the size of a Gorilla (Tattersall 1993).

Huge white birds plod along forest trails and through savannah grasses. Many kinds of these birds inhabit the island. The largest resembles an Ostrich, but is far more massive in build, weighing 1,000 pounds (Feduccia 1996). It stands 10 feet tall and lays 20-pound eggs, 13 inches long (Feduccia 1996, Greenway 1967). More than 100 other kinds of tropical birds that exist nowhere else fly in forests and deserts and wade in still marshes.

Primitive hedgehog-like mammals, called tenrecs, scurry in forest underbrush. One type of tenrec lives in cold mountain streams, swimming with webbed feet and flattened tail, while another has spines like a porcupine and stripes down its back like a skunk. It communicates with its young by vibrating its spines.

Hundreds of kinds of amphibians and reptiles inhabit forests, aquatic environments, savannahs and drylands. Frogs of every imaginable color and pattern leap in green shadows. Chameleons, some brilliantly colored, and others shades of mottled brown, creep invisibly about. The largest, 2 feet long, can capture mice and birds, while the smallest, measuring only 1.5 inches, feeds on insects (Amos 1980). Tortoises with shells adorned in delicate yellow sunburst patterns inhabit shrub and deserts.

Plants exist in unparalleled variety, a botanical paradise. Relicts of species long-extinct on mainland areas--tall tree ferns, palms, red-flowered flame trees, massive deciduous and rainforest trees, giant tamarinds and aloes, desert oddities, and baobabs of many sizes--grow in even the driest parts of the island. Orchids in a rainbow of colors bloom among the deep green rainforests. Waterfalls abound, cascading down tall cliffs into rivers and lakes. Along the west coast, a dry deciduous forest stretches the length of the island**.** The central highlands are a mosaic of woodland and savannah, while the eastern regions are covered in dense, humid rainforest. In the extreme south, a desert environment prevails, harboring *Didierea*, strange cactus-resembling plants that form long, spiny, twisted shafts rising 30 feet into the air. An impenetrable wilderness of limestone spikes and sharp rocks dominates the far north. Rare birds and lemurs find refuge in this craggy landscape and feed in oases watered by meandering streams.

Flightlessness, fearlessness, gigantism, dwarfism, and survival of ancient species all occurred in this evolutionary laboratory. That such a large land mass went uninhabited by humans for so long is truly remarkable. Nowhere else on the planet has such a large land area remained isolated for such a prolonged period, allowing a flowering of diverse life forms to flourish and adapt to the island's many habitats and terrains in this mild, tropical climate. Such is the history of the island from Madagascar in 400 A.D., a century before the arrival of the Malagasy people of Asia. Had humans reached Madagascar earlier, it might not have evolved its diverse, yet vulnerable, fauna and flora.

How such an extraordinary diversity of animals and plants inhabits Madagascar is tied to its geological history. Some 160 million years ago, when Africa, Australia, New Zealand and South America were united in the super-continent Gondwana, Madagascar was attached to eastern Africa and what is now peninsular India. Dinosaurs, giant turtles, crocodiles, primitive mammals, reptilian birds and lizards roamed on this massive land mass. Gondwana gradually broke apart as a result of movements of tectonic plates covering the Earth's crust. For many millions of years, India and Madagascar formed a mini-continent. Then, about 88 million years ago, they split along Madagascar's east coast, and peninsular India moved northward toward Asia (Garbutt 1999, Tyson 2000). Paleontologists have only recently discovered that Madagascar was home to dinosaurs and other primitive animals quite unlike those found in other parts of the world. The oldest known species of dinosaur, dating back 227 million years, may be the ancestor of all dinosaurs (Flynn 2000). One dinosaur had teeth that were clove-shaped (Stenzelt and Thiessen 2000). Seven species of crocodiles inhabited Madagascar from the Cretaceous period onward, including a pug-nosed vegetarian species (Flynn 2000). About 65 million years ago, the last dinosaurs died out, concurrent with their extinction throughout the world. Some native plants and animals survived from the time when Madagascar was part of Gondwana. Giant tortoises, crocodiles, boas, tenrec ancestors and possibly an early form of elephant birds may have lived on the super-continent, although most ornithologists are certain that the ancestor of the elephant bird flew to the island and became flightless (Feduccia 1996). Plants of many kinds, virtually unchanged from their ancient forms, grow on the island.

Immigrant animals arrived during the millennia from many sources. Because Madagascar separated from India and Gondwana long before the evolution of the prosimians that were the ancestors of the lemurs, these primates must have come from mainland Africa, where their close relatives, bush babies and galagos, survive today. Some scientists believe they might have traveled over a land connection that existed between Africa and Madagascar at some point (Tyson 2000). Others dispute that there ever was such a land bridge and maintain that they arrived by sea, perhaps sheltering on large mats of floating vegetation or clinging to uprooted tree trunks that swept down mainland rivers to the sea and washed up on Madagascar's shores. Few modern mammals of Africa, whether baboons, monkeys, gazelles, antelope or other hoofed mammals, reached Madagascar. The hippopotamuses must have originated in Africa, but how they came to the island is another mystery.

Over many millennia, a blossoming of evolution occurred in this mild, tropical climate of Gondwandan and immigrant species, radiating into entire new families and creating a flora and fauna of great diversity unlike any in the world. Birds, bats and insects flew or were blown to the island by wind currents and storms from Africa and Asia. No large carnivores arrived, however. The largest mammal predators are relatives of mongooses, primitive viverrids. Grazing and browsing roles were filled by hippopotamuses, land tortoises, lemurs and elephant birds.

Human Settlers Invade Paradise

About 500 A.D., immigrant people from Asia, most probably Indonesia or Malaysia, arrived on Madagascar's shores in hand-hewn canoes, bringing domestic animals with them. They began clearing forests and burning them for farmland, and turned lakes and wetlands into rice paddies. Cleared land produced crops for only a few years until the thin soil became sterile. Farmers then moved on to other parts of the forest, in this slash-and-burn agriculture. At some point, African herdsmen colonized the island, bringing zebu cattle, which crowded out wildlife (Tyson 2000). Gradually, abuse of the land eroded the soil in the central highlands to bare earth, pocketed and gouged by deep gullies and cavernous holes. This region had harbored a great variety of lemurs, along with a wealth of birds, reptiles and unique plants. Throughout the island, wildlife declined as habitats disappeared, isolating animals in smaller and smaller patches of forest and wetlands. The large lemurs, tortoises and elephant birds were avidly hunted.

Within 600 years of the arrival of the Malagasy, extinctions claimed many native animals. Several elephant bird species, the larger lemurs and many native plants vanished. Two kinds of pygmy hippos inhabited the island. The Madagascar Hippopotamuses (*Hippopotamus lemerlei*), an amphibious species, and *Hippopotamus madagascariensis*, a forest species, were both about 6.5 feet long and 2.5 feet tall, smaller than the Common Hippopotamus of Africa, which is about 10 feet long (Tyson 2000). From genetic and anatomical analysis, both seem to have evolved from the latter species (Tyson 2000). The hippos had been widely distributed and very common prior to the arrival of the Malagasy (Dewar 1984). Their bones have been found with marks indicating that they had been butchered (Tyson 2000). Both died out long before Europeans arrived. The native crocodile, whose large bones have been found, is believed by some scientists to represent large specimens of Nile Crocodiles, the species native today (Tyson 2000). It is thus possible that the crocodile survived. A large mongoose-like viverrid, *Cryptoprocta spelea*, and a very unusual aardvark-like animal, *Plesiorycteropus madagascariensis*, died out at an early date (Dewar 1984).

Prior to the arrival of humans, elephant birds had been abundant in most parts of the island, as attested by the prevalence of their bones. There were two genera, and from six to 12 species of these birds (Tyson 2000). It is likely that the flightless birds fell prey to the primitive weapons of the Malagasy and were crowded out of their habitats by livestock (Tyson 2000). The last to die out was the Great Elephant Bird (*Aepyornis maximus*), which may have survived until recent times by retreating to remote swamps. Dr. Alexander Wetmore of the Smithsonian Institution examined bones of a Great Elephant Bird unearthed in archeological excavations in the 1960s. He was amazed by their size: "The incredible femur, or thighbone, of this ponderous bird is by far the largest I have ever seen" (Wetmore 1967). Estimated to weigh at least 1,000 pounds, more than three times the weight of an Ostrich, it produced eggs larger than any dinosaur's, with a capacity of 2 gallons (equivalent to seven Ostrich eggs), 180 chicken eggs or 12,000 hummingbird eggs (Bradbury 1919, Fuller 1987). When one was X•rayed, the bones of an embryo three•fourths developed were revealed (Wetmore 1967). Something had interrupted the embryo's growth and frozen it within the eggshell for hundreds and perhaps thousands of years (Wetmore 1967).

Despite its fearsome size, the Great Elephant Bird lacked a hooked beak for tearing prey and was plainly not a predator (Wetmore 1967). Its large, clawed feet may have helped it defend itself against the small native predators but were not enough to protect it from Malagasy arrows. Its short legs prevented it from running as fast as its relative, the

Ostrich, but it may have been quite agile when chased. This vegetarian bird browsed and cropped plants, able to reach with its long neck to the lower branches of trees (Wetmore 1967). By the mid-16th century, when Europeans had managed to establish a foothold in Madagascar, the new French Governor, Sieur Etienne de Flacourt, wrote in 1661 that the Great Elephant Bird was still found in the south of the island, "seeking the most deserted places" to avoid human hunters (Tyson 2000). Villagers of Antandroy told of an Ostrich-like bird that was difficult to catch, according to Flacourt (Tyson 2000).

The exact date this giant bird became extinct is not known with certainty. Alan Feduccia (1996), an eminent paleo-ornithologist, asserts that elephant birds of many species were still widespread in the 10th century but gradually disappeared as a result of human activity. He cites an account by a French merchant sailor in 1848, who visited Madagascar and saw the shell of the Great Elephant Bird; he was told that it belonged to the chief and that the bird that produced such eggs "is still more rarely seen" (Feduccia 1996). Some authorities estimate that it died out in the mid-17th century, although there is no proof that any European ever saw one of these birds (Tyson 2000). It has been suggested that Europeans were responsible for the bird™s extinction by hunting and destroying its habitat (Quammen 1996). But Thomas Brooks (2000) of the Center for Applied Biodiversity Science, Conservation International, asserted in a list of extinct birds in *Threatened Birds of the World* (BI 2000) that all the elephant birds had disappeared by 1500. In a bizarre footnote to this species' epitaph, an *Aepyornis* egg washed up on Australia's western coast in 1995. No conclusive explanation for this strange event has been put forth, although it is likely that it became unearthed from long interment by rains, and washed out to sea. Much less is known of the other species of elephant birds, which existed in a variety of sizes down to a chicken-sized species.

Lemur-like primates once lived on many continents, but nowhere had they evolved into such a great variety of species. When the Malagasy people arrived some 1,500 years ago, lemurs occupied every habitat, even marshland. A species as tall as a man must have startled the Malagasy immigrants, giving rise to legends that these animals had superhuman powers. The first French naturalists were told by the Malagasy that these primates were thought to be the ghosts of sacred ancestors of man, inspiring the genus name Lemur, the word for ghost in Latin. The Malagasy considered some lemurs sacred and punished anyone who harmed them, but most species were feared as evil demons and were killed on sight.

From their arrival on Madagascar, the Malagasy hunted the larger species of lemurs, almost all of which are now extinct. Archaeological excavations show that they formed a staple in the immigrants' diets. Such diggings have unearthed the skulls and bones of long•extinct lemurs in early Malagasy jars and kitchen middens; their heads had been split by ax-heads made from an extinct flightless bird (Jolly 1980).

In the centuries following colonization by the Malagasy immigrants, some 15 species of lemurs of eight genera became extinct (Mittermeier 1997). These extinct lemurs were, for the most part, far larger than surviving species and had evolved to fill many ecological niches. Three *Megaladapis* lemurs weighed between 90 and 170 pounds and moved slowly through the trees, feeding on foliage (Tattersall 1993). Another species, *Archaeolemur*, was about the size of a female baboon and lived on the ground (Tattersall 1993). Two *Palaeopropithecus* species weighed between 90 and 130 pounds and were sloth•like tree dwellers with flexible bodies (Tattersall 1993). These extinct lemurs had evolved many unusual means of movement and locomotion that have no parallels in living species of lemurs.

Largest of all, the massive 400•pound *Archaeoindris* was apparently a ground•dweller, moving on all fours; many of its anatomical characteristics are unlike any living primate (Tattersall 1993). One entire lemur family, Archaeolemuridae, was obliterated. In this family were many species of lemurs weighing between 35 and 55 pounds; they were powerfully built and short•legged (Tattersall 1993). The heaviest lemur surviving today, the Indri (*Indri indri*), weighs only about 15 pounds (Tattersall 1993). These lemurs had survived for millions of years, and their extinctions were indeed a major biological loss to the planet. According to primatologists, the surviving lemurs resemble the very earliest primates from the Eocene (Tattersall 1993). Like prosimians in Africa and Asia, but to a far greater degree, lemurs have a highly developed sense of smell. Some species have long, fox-like noses (Preston-Mafham 1991). Genetic analysis of their DNA has revealed that all lemurs are descended from a single

ancestor that probably arrived from Africa about 60 million years ago (Garbutt 1999).

The Giant Aye-aye (*Daubentonia robusta*) lemur was somewhat larger and 2.5 to 5 times heavier than the surviving Aye-aye (see below), but in other respects was very similar (Garbutt 1999). It is known from subfossil remains found in southwestern Madagascar (Nowak 1999). The date of its disappearance is unknown but may be fairly recent.

Archaeologists have uncovered remains of a massive bird of prey, the Malagasy Crowned Eagle (*Stephanoaetus mahery*), which undoubtedly preyed on lemurs (Feduccia 1996). In fact, at one locality the diet of this eagle, based on the bones of eagles and lemurs found together, contained at least 80 percent primates, including specimens weighing up to 26.5 pounds (Feduccia 1996). Remains of another large eagle of the genus *Aquila* have been discovered, and it, too, preyed on large lemurs and became extinct after the arrival of the Malagasy. These extinct birds preyed on smaller lemurs as well, including some species still surviving (Feduccia 1996). A bird of prey flying overhead still elicits fear in lemurs, causing them to seek cover. Neither of the two remaining species of eagles on Madagascar preys on lemurs, but two hawk species have been seen preying on young lemurs (Garbutt 1999).

In addition to the Giant Elephant Bird, the large Snail-eating Coua (*Coua delalandei*), a member of the cuckoo family, became extinct. The last specimen of this large, slate-blue bird was taken on an islet off the east coast, Ile Sainte-Marie, in 1834 (Morris and Hawkins 1998); reports by observers who claimed to have seen the bird were recorded as late as 1930 (Fuller 1987). The causes of this bird's disappearance, and even its exact range, remain obscure (Langrand 1990). Many specimens of this bird were taken before its extinction and kept in museums in Leiden; London; New York; Paris; Philadelphia; Tananarive (Madagascar); and Cambridge (Massachusetts) (Fuller 1987). The long feathers of this bird were highly valued by the Malagasy, and hunting may have reduced its numbers to a critically low level (Fuller 1987). It is also possible that the many birds killed for zoological specimens may have pushed this already rare bird to extinction, since its distribution may have been limited to the tiny Ile Sainte-Marie. No reliable record exists of its presence on the main island of Madagascar, but there is hope that it might be found in lowland forest near the Bay of Antongil (Morris and Hawkins 1998). Ten closely related species of couas survive, all smaller than the Snail-eating Coua.

The Biological Wealth of an Impoverished Country

The Madagascar of today is still a remarkable place, although about 90 percent of the forests, including almost all lowland rainforests that were richest in wildlife, were destroyed (Mittermeier *et al.* 1999). Some 33 lemur species survive, along with all but one species of tenrec, various mongooses and their relatives, more chameleons than any other country, several hundred kinds of frogs and reptiles, and thousands of endemic invertebrates and plants. Madagascar has no native fish, but many introduced species. Its fauna and flora represent many extremely unusual and unique examples of evolution (Mittermeier *et al.* 1999). This island is considered one of the five most biologically important areas in the world; its primates are the world's highest priority for conservation (Mittermeier *et al.* 1999).

The Biological Wealth of an Impoverished Country: Forests and Plants

Madagascar has one of the richest floras in the world. Eighty percent of its plants are found nowhere else (McNeely *et al.* 1990, Preston-Mafham 1991). The diversity of plants that survived almost 2,000 years of forest destruction continues to astound biologists and conservationists. Tropical trees with fruit growing on their trunks (various species of the genus *Tambourissa*) are native, as is a cactus (*Rhipsalis*), related to American species, that lives in the rainforest. A tree, *Symphonia*, which has leathery leaves and red-and-white striped flowers that look like peppermint candies (Morell 1999), also survives. The Flame Tree (*Delonix regia*), which produces cascades of red flowers, is grown around the world for its beauty, but few realize that it originated in Madagascar (Preston-Mafham 1991). Miraculously, many endemic plants have survived the fires and tree cutting that have destroyed much of the island. One mountain chain has 150 endemic vascular plants, a very high number (Preston-Mafham 1991). They are among the 7,300 to 12,000 species of plants native to Madagascar (Preston-Mafham 1991). Its flowering plants make up 20 percent of all the plants in the African region (McNeely 1990). At least 191 botanical families, a very large number for a relatively small area, evolved from ancestor species (Preston-Mafham 1991).

Some 2,000 years ago, the eastern rainforest stretched in a band 100 miles wide from north to south, covering 27 million acres (Tyson 2000). Ninety percent of the plants were endemic, with a profusion of unusual ferns, some types growing on tree trunks; wild ginger, with delicate purple flowers; bamboos; and far more orchids than in an African rainforest (Preston-Mafham 1991). An early traveler described the woods as so dense that there was a fideep gloom: below the canopy at mid-day (Tyson 2000). Rainfall must have been greater and general climate more humid than at present as a result of these extensive rainforests. In the montane ridges, huge tree ferns, mosses and lichens cover the ground and hang from tree branches (Preston-Mafham 1991). Over the centuries, Malagasy burned many portions of the rainforest, especially in the south. Few tall trees remain in the rainforest today, although at one time there must have been many giants. During the 19th century, a palace was built for a woman ruler, centering on a 130-foot tree that had been carried by 5,000 laborers from the eastern rainforest (Tyson 2000). The palace was destroyed by an uprising in the 1850s. About this time, Malagasy dragged a tombstone through the forest, cutting 25,000 trees just to make a path (Tyson 2000). Early decrees banned cutting of virgin forest, with severe penalties, in the 19th century, but these were largely ignored (Tyson 2000).

About half of the island's forests had been cut by the late 19th century, and intensive cutting continued in the 20th century (Tyson 2000). The prime lowland forests throughout the island and three-fourths of the rainforest were cleared by the French for growing coffee and other crops in the first three decades of the century (Tyson 2000). The rainforest was heavily logged between 1950 and 1985, with 275,000 acres cleared and burned each year (Tyson 2000). The northeast Masoala Peninsula still retains sizeable areas of unlogged rainforest, but the southern region has been reduced to fragments of the original unbroken expanses. The remnants tend to be on sharp ridges where soil is poor and access difficult. For example, Ranomafana, a recently declared national park, straddles such an escarpment. Even so, many of its trees had been removed prior to its protection (Tyson 2000). What was once a closed-canopy, humid rainforest is now far dryer and cooler, with many openings among the trees, and some illegal logging continues (Tyson 2000). Still, botanists from the Missouri Botanical Garden, who were conducting a census of the trees in this park, counted 37 families of trees with 105 species in a 1-hectare plot (Tyson 2000). Outside the park's boundaries, rainforest is still being cleared and burned by the Malagasy, many of whom believe that their wealth lies in the amount of land they clear (Morell 1999).

The western dry, deciduous forest lies in the shadow of eastern mountains, which block moist ocean air currents (Preston-Mafham 1991). Trees do not attain heights of more than 80 feet, but many types of plants have adapted to this environment. Liana vines grow among the trees, and dead leaves carpet the forest floor. Large tamarind trees grow along rivers, and baobabs grow in plateaus (Preston-Mafham 1991). Beautiful orange bell flowers of the *Ipomoea carnea* plant burst into bloom during the short rainy season. As with the eastern rainforests, the once continuous stretches of deciduous forests have been largely destroyed, replaced by grasses able to survive in the eroded or bare soil.

Throughout the island, most deforested areas fail to regenerate into second-growth forests, even when left fallow,

because Madagascar lacks vigorous colonizing trees that can quickly protect cleared ground and prevent further erosion (Preston-Mafham 2000). Cleared hillsides become covered in non-native grasses and exotic South American trees (*Psidium cattleyanum* and *Psidium guajava*) or plantations of eucalyptus, which inhibit the establishment of native seedlings (Preston-Mafham 1991; Sayer *et al.* 1992). Only if soils are rich and remnants of original forest are nearby will native forests regenerate. Unfortunately, the original forests and their native wildlife are lost permanently, and even regeneration cannot take place without a cessation of the slash-and-burn cycle, known as fitavyfl by the Malagasy (Preston-Mafham 1991). Moreover, foreign logging companies have obtained logging concessions on most of the unprotected remnants of native forest. Tree cutting consumes some 7.8 million cubic meters of wood per year, of which 7 million cubic meters is for fuel and charcoal (Sayer *et al.* 1992). Valuable timber trees have been logged to extinction in most of Madagascar. The two native species of ebony trees of the genus *Diospyros* have been heavily logged for centuries, and few large trees are left (Sayer *et al.* 1992). The understory plants, such as tree ferns, are also exploited, dug up to sell as potted plants (Sayer *et al.* 1992).

The net result of this logging and burning, especially in the barren central highlands, is the loss of "a priceless reservoir of plant and animal species, replaced by one of the most impoverished forms of vegetation on the planet" (Preston-Mafham 1991). Many species of trees and other plants are highly endangered. Madagascar is one of the world's 12 "hot spot" areas of tropical forests, having a high percentage of endemic species which are under great threat (McNeely *et al.* 1990). Since an estimated 94 percent of Madagascar's trees are endemic, and many occupy very restricted ranges, they are highly vulnerable to extinction. Further research will likely reveal even more threatened species. Some authorities believe that even this rich plant diversity must represent only a fraction of the "vast original flora," since 80 percent of the vegetation and forests is gone (Ayensu *et al.* 1984). The *1997 IUCN Red List of Threatened Plants* includes 19 species of plants that may have recently become extinct, and an additional 287 species that are threatened with extinction (Walter and Gillett 1998).

Resident since the days of the dinosaurs, trees of a family of primitive pines, Podocarpaceae, grow on the island. The family is represented by species in other parts of the world that were part of Gondwana, from South America west to Southeast Asia. Madagascar has a number of native Podocarps, of which four endemic species or varieties are listed by the *IUCN Red List* as either Vulnerable or Rare (Walter and Gillett 1998). At least 26 genera of plants are native to Madagascar and South America, but not to Africa, and are believed to be remnants from Gondwana (Preston-Mafham 1991). Another one of these, Madagascar's national tree, the Traveller's Tree (*Ravenala madagascariensis*), is a palm-like species of the banana family (Musaceae). Its closest relative of the same genus grows in Brazil and Guiana, but not in Africa (Preston-Mafham 1991). This tree has leathery petals covering its pollen and nectar and is a key food source for both bats and lemurs. In return, it depends on lemurs for pollination. Lemurs feed on the nectar, getting their noses covered with pollen in the process. They are so fond of the nectar that they travel miles to find another Traveller's Tree, still carrying the nectar on their noses and, unknowingly, pollinate the next tree they feed on (Attenborough 1995).

A plant of the Winteraceae family that has been growing on the island for 30 million years was recently seen again after a period of 90 years (Hsu 1997). This tree, *Takhtajania perrieri*, has many primitive features, such as a lack of vessels to move water and minerals; like many of Madagascar's relict species, it once grew on much of continental Africa, but long ago disappeared there (Hsu 1997).

Madagascar has more palms (Palmae family) than all of Africa (Preston-Mafham 1991). Many are in danger, however. The *IUCN Red List of Threatened Plants* lists 148 native species in various categories (Walter and Gillett 1998). The Big-leaf Palm (*Marojeya darianii*) was chosen by the Species Survival Committee of the IUCN to be one of 12 critically endangered species highlighted at its 1988 General Assembly in Costa Rica. This species was only discovered in 1982 and is confined to a single swamp in the northeast (Prance 1990). An agricultural program to raise rice cleared half its habitat, and then failed. This huge-leafed palm has been over-harvested as a source of heart-of-palm, a commercially valuable product (Prance 1990). Huge palms are felled for their inner pith to supply this gourmet market. The majority of palms grow in the eastern rainforests in a great diversity of size. Two threatened palms, *Dypsis hildebrandtii* and *Dypsis louvelii*, are miniature delicate-fronded palms only 3 feet high

(Preston-Mafham 1991). Others, like the threatened *Ravenea glauca*, are majestic giants with long, straight trunks rising 50 feet or more to a luxuriant crown. Palms do not often survive the fires set by the Malagasy to clear land, disappearing from one area after another (Preston-Mafham 1991).

On the entire continent of Africa, only one species of baobab tree is native, while seven species are found in Madagascar (Preston-Mafham 1991). These strange-looking trees have wide trunks that taper to a narrow crown, looking like upside-down trees. Some baobabs grow to immense size. One famous specimen measures 46 feet around the base of the trunk (Preston-Mafham 1991). Another species, *Alluaudia ascendens*, grows in the southern desert. Although it can reach a maximum height of 16 feet, it is usually far smaller (Preston-Mafham 1991). Each of the seven species has a slightly different shape and size, but all have gray bark that resembles unwrinkled elephant skin. Baobabs are extremely important to both wildlife and humans. The Malagasy cut holes in their massive trunks and hollow out the spongy pith where water accumulates. In the dry south, these trees become wells, and villagers set ladders against the trunks, climb to the hole cut from the trunk, and lower buckets into the pool of water. Natural holes in baobob trunks and branches provide important nesting holes for birds and lemurs. These trees are fire-resistant, and fortunately, they are worthless as timber because of their soft, pulpy cores. For this reason some stands of thousands of huge, very old baobabs remain in parts of the island. Because of the heavy livestock grazing, few young baobab seedlings can survive, however, and botanists believe that the spectacular vistas of these behemoths will gradually disappear (Preston-Mafham 1991).

One very strange group of Madagascan plants native to dry areas has nine species in the same genus, *Pachypodium*. These succulent plants lose their leaves at the onset of the dry season and have evolved into a variety of forms, all with gray, smooth bark. Eight of the nine species are threatened with extinction, according to the *IUCN Red List of Threatened Plants* (Walter and Gillett 1998). One of these, the endangered *Pachypodium decaryi*, is native to Antananarivo, the "tsingy" limestone crags of the northwest. Its smooth, silvery trunk resembles a large inverted turnip, fat at the base and tapering upward, topped by a messy mop of thin, straggly branches (Preston-Mafham 1991). It bears large, white flowers during the dry season. Its main population occurs in the Ankarana Special Reserve, which bans burning (Preston-Mafham 1991), but has recently been invaded by hordes of miners who are clearing vegetation to search for sapphires (Morell 1999). Other Pachypodiums have equally bizarre shapes, such as the bulbous *Pachypodium rosulatum*, which resembles a huge gourd sprouting long, thin shafts from which its bright yellow flower bloom. The rare *Pachypodium densiflorum*, with the appearance of a domestic jade plant run amok, has a mass of short, gray branches sprouting from a squat gray base. All these plants are highly susceptible to fire. Ken Preston-Mafham, in *Madagascar: A Natural History*, describes the threat of "incessant brush fires which ravage the length and breadth of central Madagascar during the dry season. Within hours, hillsides which had been decorated with colorful rock gardens of rare succulents are converted into graveyards of charred embers." These brush fires have been intentionally set by Malagasy to improve grazing land for their cattle or clear land. Another threat to Pachypodia is collectors who tear specimens, especially bizarre forms, from mountain slopes (Preston-Mafham 1991). Few species are protected in reserves. Without strong conservation programs, these fascinating plants could easily disappear.

Other strange trees of the southern spiny desert include the Octopus Tree (*Didierea madagascariensis*), a member of an endemic family of 11 cactus-like species, Didiereaceae. This tree has no trunk, but a bouquet-like grouping of stems covered in long, needle-sharp spines that branch out in odd, twisted shapes. Although resembling cacti, this family has no close relatives anywhere in the world (Preston-Mafham 1991). Another member of the family, *Alluaudia procera*, has a thick trunk with very long spines that grow in curving rows upward, and small, rounded leaves along its branches. In spite of this, several lemur species are able to leap onto these plants without hurting themselves (Preston-Mafham 1991). Three species in this family, all of the *Alluaudia* genus, are Rare, according to the IUCN (Walter and Gillett 1998). One of these, *Alluaudia montagnacii*, has tall, solitary tapering stems ending in a tuft of flowers.

The discovery of the medicinal effects of the endemic Rosy Periwinkle (*Catharanthus roseus*) has saved thousands of human lives. Two potent alkaloid compounds found in this plant have proven effective in the treatment of

Hodgkin™s' Disease, producing a 99 percent remission in patients with acute lymphocytic leukemia (Myers 1983). It also contains 75 different alkaloids, which could produce commercial substances (Preston-Mafham 1991). Fortunately, the Rosy Periwinkle is easy to propagate, grown in greenhouses around the world. Ongoing research is uncovering other Madagascan plants of medicinal value. Samples of plants are being tested in laboratories, and elderly Malagasy healers are being consulted. More than 50 species of wild coffee (*Coffea* spp.) grow in the island's eastern rainforests, providing an important genetic base for hybridizing with other strains because of their insect-resistance and low level of caffeine (Preston-Mafham 1991). These plants are symbolic of the great botanical wealth at risk.

The Biological Wealth of an Impoverished Country: Mammals

Home to some of the world's most fascinating, beautiful and curious mammals, Madagascar has approximately 117 native species, 90 percent of which exist nowhere else (Garbutt 1999). Excluding bats, all 88 native terrestrial mammals are endemic to Madagascar. Three-fourths of native mammals, or 66 species, are threatened with extinction; 49 of these are in higher categories of threat listed in the *2000 IUCN Red List of Threatened Species*. This represents 42 percent of all mammals found in Madagascar, by far the greatest percentage of threatened mammals of any country in the world (Hilton-Taylor 2000). As new species of mammals continue to be discovered, the numbers that are threatened continues to rise. A few have not been seen in the wild since their discovery. The majority is made of forest-dwellers, and a few inhabit marshy areas or woodland streams. The loss of forest, predation on them by Malagasy and domestic dogs, and introduction of exotic species of mammals that out-compete native species are combining to push many of the island's mammals toward extinction.

The Biological Wealth of an Impoverished Country: Mammals: Page 1

The publication of *Mammals of Madagascar*, by Nick Garbutt, in 1999 filled a void for a complete guide to all native mammals, illustrated with color photos of most species and major habitats. This supplemented *Madascar: A Natural History* in 1991, an important reference on mammals and their environment. Conservation work has focused mainly on lemurs, with many organizations involved, including Earthwatch Institute, which sponsors field research; Conservation International; Jersey Wildlife Preservation Trust (based in England); and CARE. Several of these groups sponsored biodiversity studies and helped establish national parks, benefiting thousands of species, including tenrecs and other native mammals. A growing number of Malagasy zoologists are taking part in studies and conservation work, and new programs have been initiated to help local people while conserving mammals and their environments. Certain mammals have received inadequate attention to date, notably bats, rodents and some viverrids, who will undoubtedly benefit from the swell of interest and enthusiasm for Madagascar fauna that has developed in recent years. Filmmakers have recently produced a number of excellent wildlife documentaries, photographing rare species and spreading knowledge and concern about endangered mammals (see Video section).

Among Madagascar's mammals are many primitive forms. The tenrecs' closest relatives are insectivores known as solenodons, native to Cuba, Hispaniola and other vestiges of Gondwana in the Caribbean. Tenrecs and solenodons may have had a common ancestor living on the supercontinent, progenitor of all mammals. The remains of similar

species have been found in Africa and South America, indicating that they were once very widespread but died out on all but isolated refuges such as Madagascar and West Indian islands. Tenrecs belong to a family of insectivores, Tenrecidae, related to shrews, moles and hedgehogs, but quite distinct from them. Twenty-seven species of three types of tenrecs make up this family--spiny, furred and otter-shrews (Garbutt 1999). They range in size from the Common Tenrec (*Tenrec ecaudatus*), which resembles the European Hedgehog and weighs more than 5 pounds, to the shrew-like tenrecs, *Microgale* genus, weighing less than 2 ounces (Nowak 1999). Tenrecs have some very unusual physical characteristics placing them far from any close mammalian relative. They have variable body temperatures that change with the ambient temperature and, an even more reptilian or avian trait, a cloaca that combines urinal, rectal and generative canals into one (Garbutt 1999).

A striking tenrec is the Lowland Streaked Tenrec (*Hemicentetes semispinosus*). It and a similar species, the Highland Streaked Tenrec (*Hemicentetes nigriceps*), weigh about 5 to 7 ounces and measure some 6 inches in length. White stripes run down their backs like skunks, and barbed, porcupine-like spines are detachable (Eisenberg 1975). The Highland species has a stiff, white neck ruff rising several inches at the back of its head that can be stabbed into the nose of an unwary predator (Eisenberg 1975). Family groups forage together and communicate by vibrating quills that produce low-frequency sounds like dry grass being rubbed together; tenrecs can detect these sounds from distances of more than 4 meters (Garbutt 1999). They also make a number of sounds that are audible to humans.

The Aquatic Tenrec (*Limnogale mergulus*), listed as Endangered in the *2000 IUCN Red List of Threatened Species*, inhabits streams and lakes, living at altitudes between 600 and 2,000 meters (Nowak 1999). This 8-inch tenrec has clawed, webbed feet, and a long, thin tail for propelling it through the water to feed on small crustaceans and fish. Its habitat in the central highlands has been greatly affected by human disturbance and deforestation. The Aquatic Tenrec has at least one refuge, the new Ranomafana National Park, created for the bamboo lemurs (Preston-Mafham 1991). In 1990, Dr. David Stone managed to lure an Aquatic Tenrec into a live trap, the first one of its kind seen alive in 25 years (Preston-Mafham 1991). Later, four more were taken and studied in captivity for three weeks prior to being returned to the river Namorona in Ranomafana, one of the few clear, unsilted rivers left in Madagascar (Preston-Mafham 1991). This species requires such streams, and only the preservation of forests, such as that in Ranomafana, will ensure its survival.

Another six species in this family, all shrew-tenrecs of the genus *Microgale*, are listed in the *2000 IUCN Red List of Threatened Species*. These tiny insectivores are found in all parts of Madagascar in areas of heavy vegetation, and have dark, soft fur. They range in size from 1.5 to 5 inches in length, and weigh as little as 1.8 ounces (Nowak 1999). Several of the threatened species are highly restricted in range and habitat, and one, *Microgale dryas*, listed as Critical, occurs only in Ambatovaky Special Reserve in the northeastern rainforest (Garbutt 1999).

The Biological Wealth of an Impoverished Country: Mammals: Page 2

Far better known to the world, the lemurs are the focus of many programs to conserve them, as well as research on their wild behavior and biology. New species continue to be discovered; most recently in 2000, three new species of tiny mouse lemurs. Three more have been rediscovered, an indication that other species may yet be discovered to add to the present total of 33 species (Garbutt 1999)**.** This is the only country with five families of primates, making up more than one-third of all primate families; it is home to 12 percent of all primate species and 21 percent of all primate genera (Mittermeier *et al.* 1999). Unlike Brazil, however, which is another center for endemic mammals, Madagascar is far smaller, the size of Kenya, covering 226,656 square miles, or 0.4 percent of Earth's surface (NYT 2000). The number of lemur species is not an indication of their variety since many subspecies differ so radically from one another that in the future, each may be accorded full species status. One species of sifaka, a long-legged kind of lemur, has one subspecies that is pitch black, and another that is pure white. At least 51 species and subspecies of lemurs are known to exist (Mittermeier *et al.* 1999).

The most gregarious of the lemurs are the Ring•tailed Lemurs (*Lemur catta*), who travel about in boisterous, friendly troops, living mainly on the ground. These lemurs have long, fox-like muzzles, large, soft golden-brown eyes, fluffy, gray fur, and black-and-white striped tails. Their body length is 15 to 17 inches, but their rope-like tails are half-again as long, from 21 to 24 inches (Nowak 1999). These 5-pound primates use their boldly patterned tails in a complex language of mutual visual and scent signals. They wave them about to show dominance, as a signal to follow other group members, or rub them on their wrist glands to wave at their rivals in territorial battles (Sleeper 1997). Moving about in troops of up to 25 individuals, they walk rapidly on the ground with the tail held high, waving it about. They wrap their tails around themselves for warmth on chilly nights. Extremely affectionate and playful, their core group is dominated by females (Jolly 1988).

In reserves where they are strictly protected, Ring-tailed Lemurs become very tame, napping on the ground in piles of leaves near tourists. Sometimes they sprawl out on their backs with arms spread wide apart. Females usually have a single young, but when twins are born, one may be "adopted" by a non-pregnant female, who may begin to produce milk in response to her surrogate role (Preston-Mafham 1991). Aunts also help in raising the young, and the daughter born the previous year babysits (Jolly 1988). Lemur babies are a source of great interest to the entire troop, females gathering around the mother and her young, grooming one another and the babies, forming a "grooming pod" (Preston-Mafham 1991). Only half of the infants survive their first year, and only 30 percent reach adulthood (Garbutt 1999). "A Lemur's Tale," shown on PBS in 1996, is a touching film about the death of a young Ring-tailed Lemur. Some fall from high branches, are killed by small carnivores or hawks, die of undiagnosed illness or starve in years of drought in their arid habitat. Ring-tailed Lemurs communicate with one another in a variety of sounds, from soft mewing contact calls to a territorial "bark-howl." Sometimes chasing and cuffing other members of their group, they are mainly peaceful, spending many hours a day in mutual grooming and in "snoozing-huddles," in which several animals form a complicated embrace from which tails and feet stick out in all directions (Preston-Mafham 1991).

In recent years, Ring•tailed Lemurs have been classified "high priority" for conservation by the IUCN and the Species Survival Commission (SSC) Primate Specialist Group because their habitat of dry woodlands in southern Madagascar is disappearing at an alarming rate due to fires, overgrazing by livestock and tree cutting; they are also hunted with dogs in some areas, and captured as pets (Mittermeier *et al.* 1992, Garbutt 1999). Their distribution has become increasingly patchy as forests are cut (Garbutt 1999). The *2000 IUCN Red List of Threatened Species* lists the Ring-tailed Lemur as Vulnerable, or declining toward endangered status.

One of the strangest mammals in the world is the Aye•aye (*Daubentonia madagascariensis*), so unique that it is assigned to its own family, Daubentoniidae. When first discovered, scientists classified it as a squirrel because of its long, bushy tail and short•legged body. In 1863, however, after anatomical studies, the Aye•aye was revealed to be a lemur, in spite of incisor teeth that never stop growing, long, clawed fingers and other unlemur•like characteristics. Aye-ayes have a perpetually startled expression: huge, round protruding eyes dominate the face, the pupils completely surrounded by deep golden irises. Dark rings surround their eyes, heightening the eerie appearance. The rest of the face and body are gray to black, with long grizzled guard hairs. Spending the day in their twig and leaf nests, Aye-ayes emerge at night to forage for insects and fruit (Garbutt 1999). The Aye-aye's enormous ears are sensitive to the movements of insects under tree bark. At Duke University Primate Center, which has the world's largest number of captive lemurs, Aye•ayes have been filmed using their middle finger, which is twice the length of the other fingers, and skeletally thin, to tap on wood, listening for the movement of insects under the bark. When presented with a block of wood containing insect larvae in holes, the Aye•aye taps the wood and, cocking its head, can tell, even in the case of a hidden hole, the location of the insects, which it then extracts almost surgically, with its middle finger. This primate fills the ecological role of a woodpecker. Aye•ayes eat fruit as well, biting holes into the hard shells of coconuts and scraping the meat out with their middle fingers (Petter 1965). They have also been seen eating nuts of a native tree, nectar from the Traveller's Tree, fungus and lychee nuts (Garbutt 1999).

Aye-ayes have been heavily persecuted by the Malagasy, who consider them to be the embodiment of evil. In general, they are killed whenever seen. Dr. Ian Tattersall once found a dead Aye•aye with a wire pulled tight around its neck

(McNulty 1975). In 1990, apparently to dispel the bad luck caused by its having entered a village, local people set an Aye•aye tail on a pole next to the road (Simons 1993). At one time, Aye-ayes were considered among the most endangered animals in the world, facing imminent extinction. To prevent their extinction, a few were captured and released on Nosy Mangabe, a small islet off the northeast coast. Fortunately, Aye•ayes survived on the main island, perhaps because coconut plantations provided food when their forests were cut. Feeding at night, they remained undetected until recently. The Malagasy continue to persecute them.

Since the early 1980s, field surveys have revealed that Aye-ayes have a larger distribution than was originally thought. In 1991, they were seen for the first time in western Madagascar in the northern mountains (Simons 1993). With confirmed sightings in many eastern and northern forests and a few western localities, Aye-ayes inhabit a variety of forest types (Garbutt 1999). They can survive in secondary forest, coming out of their stick nests only at night. And while once thought solitary, groups of three to four individuals have been seen traveling together and feeding at foraging sites (Garbutt 1999). In spite of the greater distribution, the Aye-aye is an endangered species and almost certainly is declining (Garbutt 1999). Aye-ayes require large tracts of forest to maintain viable populations and to protect them from the persecution that often results in their deaths (Garbutt 1999). Although very rare in captivity, several captive births have occurred in recent years at the Duke University Primate Center and Jersey Wildlife Preservation Society zoo in England.

One lemur has recently been rediscovered in the wild and, in the process, an entirely new species was found. The Greater Bamboo Lemur (*Hapalemur simus*) seemed to have disappeared in the wild some time in the mid-19th century. Not until 1964 was this 5-pound, grizzled, gray-olive lemur seen again in a village market, where it was purchased by a French scientist. Unfortunately, it escaped. A pair captured in 1972 in a southeastern rainforest lived in the zoo in Madagascar's capital city, Antananarivo, until both male and female and their two offspring died (Quammen 1996).

Patricia Wright, an American primatologist, decided to search for this species in 1986 in its supposed range. Fossil evidence indicates that 1,000 years ago, the Greater Bamboo Lemur was widely distributed throughout most of Madagascar's forests, and European naturalists saw it fairly regularly in the 19th century. When she saw a russet-colored lemur clinging to a trunk, making loud "tonking" calls, Wright assumed that she had rediscovered the Greater Bamboo Lemur. Although a different color, she concluded that these animals probably represented a color variation (Quammen 1996). A German primatologist, Bernhard Meier, made independent studies in this patch of rainforest at the same time, also discovering the reddish-gold lemur. Both scientists had great difficulty making observations because of its extreme shyness (Quammen 1996). Finally one was caught, and in 1987, after chromosomal and anatomical studies were done in France, this lemur was found to be an entirely new species (Jolly 1988). It was named the Golden Bamboo Lemur (*Hapalemur aureus*) in a joint zoological paper by Meier, Wright and three other biologists (Preston-Mafham 1991). After months of unsuccessful attempts, Wright took the first photographs of the Golden Bamboo Lemur in the wild. Its beautiful golden-red face mask and belly contrast with darker brown fur on the rest of its body. (See color photographs in Garbutt 1999, Jolly 1988 and Preston-Mafham 1991). This lemur has been found at another location further north, and it is not known whether these populations are isolated from one another. Its population is apparently very low, as only about 1,000 animals have been estimated in the original location of discovery, and its habitat continues to be cleared (Garbutt 1999). The *2000 IUCN Red List of Threatened Species* has classified the Golden Bamboo Lemur as Critical, the most endangered category. Its limited range places it in great jeopardy, and it has been hunted with slingshots; its long-term survival is not secure (Garbutt 1999).

The Greater Bamboo Lemur, the animal first sought, was later found in the same forest, resembling original descriptions and clearly a separate species from the Golden Bamboo Lemur; a third species of bamboo lemur, the Gray Bamboo Lemur (*Hapalemur griseus*), weighs only 2 pounds. It has smoky gray fur and golden eyes, and lives alongside the latter two species in this same forest. This lemur lives in other parts of Madagascar as well (Preston-Mafham 1991).

Each of these three bamboo lemurs eats different parts or species of bamboo plants. One eats the leaves, another the pith, and the third confines itself to new shoots, leaf bases and pith from narrow stems (Quammen 1996). Amazingly, chemical analyses of the plants eaten by the Golden Bamboo Lemur found them to have high concentrations of cyanide, a chemical usually toxic to mammals. Golden Bamboo Lemurs weigh only about 2.2 pounds, and Wright and her co-workers found that, based on toxicity tests of other mammals, they eat 12 times the amount of cyanide that should kill them (Quammen 1996). This is another example of the biological mysteries of Madagascan wildlife.

The Ranomafana forest, with its rare and endemic lemurs and other unusual fauna and flora, would likely have been cut by the Malagasy for more farmland, but Wright spent five years in a successful effort to protect it in the newly•created Ranomafana National Park (Bohlen 1993, Mittermeier *et al.* 1992). This new park covers 108,000 acres of old-growth eastern lowland rainforest. Giant rosewood and other ancient trees tower above a lush understory. It is an extremely important--perhaps the most important--forest for lemurs. Fourteen species of lemurs and 18 other endemic species of mammals live in the park (Jolly 1988). Local people cooperated fully in setting the park™s boundaries, aware of the importance of saving forests. They had experienced a major catastrophe when a cyclone caused landslides, burying entire families in their homes, all precipitated by deforestation (Jolly 1988). In spite of these remarkable achievements, some tree cutting still occurs in Ranomafana National Park (Garbutt 1999).

Wright has continued to study lemurs, now specializing in the exquisite Diademed Sifaka (*Propithecus diadema*) (Brody 1998). Sifakas are the most acrobatic lemurs, leaping from tree to tree, but they have a unique means of locomotion to cross open spaces between trees. Standing on their long hind legs in an upright posture, they hop sideways, with their arms raised high above their heads. Sifakas can move very quickly in this amazing, dance-like gait, covering distances of more than 100 yards. They are also able to leap vertically to tree branches from a standing position, even carrying babies on their backs. One of their spectacular leaps, some 30 feet up, is the equivalent of a person jumping to the top of a telephone pole. The Golden-crowned or Tattersall's Sifaka (*Propithecus tattersalli*) is a beautiful, nearly all•white species with rich yellow-orange on the crown and tinges of this color on its back, legs and chest. Orange eyes contrast with a furless black face. The smallest of the sifakas, it is confined to a tiny area of only about 15 square miles of forest fragments in northeast Madagascar. The Golden-crowned Sifaka's small population of fewer than 8,000 animals, fragmented into isolated populations, is threatened by forest cutting, brush fires, loss of habitat to agriculture and hunting (Garbutt 1999). Distributed in discontinuous patches of forest, these sifakas may become inbred if corridors are not acquired to link populations. A core part of their forest had been scheduled for cutting for charcoal when scientists named these sifakas. The PBS Nature program, fiMadagascar. Island of Ghosts,fl was the first to film these delicate lemurs (see Video section, Regional - Africa and Indian Ocean Islands). They move about in small groups and feed on a variety of unripe fruits, seeds, shoots, leaves, bark and flowers (Garbutt 1999). No reserve has been set aside for this highly endangered sifaka, although a three-parcel national park covering 20,000 hectares (49,420 acres) has been proposed to protect this species from extinction (Garbutt 1999). The IUCN classifies this species as Critical (Hilton-Taylor 2000).

Although many Malagasy have become far more aware of the need to protect lemurs, some do not understand their rarity or the importance of conserving them. Many rural people still hunt them for food or kill them because of superstitious beliefs. In some areas, the Malagasy try to sell lemurs to foreign scientists. Visiting zoologists studying lemurs have been approached by Malagasy holding captive, and usually injured or dying lemurs, in hopes of a reward. On one occasion, an endangered species of sifaka was brought to primatologist Dr. Alison Jolly, dragged half•choked by a vine around its neck, with one arm dangling loose below the elbow, a jagged bone protruding; blood oozed down its white fur, and it gasped for air through a muzzle smashed by a flung stone (Jolly 1980). Jolly expressed horror at its condition and refused to pay them any reward. She then amazed them by telling them it was a unique sifaka, found only in that small part of Madagascar. They were incredulous . . . not in Antananarivo? . . . Not in France? . . . Not in America? (Jolly 1980). For the majority of people, lemurs are familiar animals, easy to capture and valuable as food. Malagasy schools, established by the French colonial government, taught them only about European animals, encouraging people to assume that their lemurs were unimportant. Fortunately, many Malagasy are becoming concerned about protecting lemurs, and conservation education is taught in an increasing number of schools.

Some lemurs have bred in captivity in zoos and breeding centers, but most, like the endangered Indri (*Indri indri*), have never survived in captivity long enough to breed. In their rainforests, they perch high up, clinging to tree trunks to feed, and suddenly leaping vertically to a neighboring tree, pushing off with their extremely muscular, long legs. Panda-like fur of contrasting black and white--black faces and bodies and white arms and legs--gives them a dramatic appearance. Nearly tailless and heavy--but graceful--their eerie songs, sung at dawn and sometimes during the day, form a loud chorus of high-pitched voices that carries for long distances. Indris were once very common in the eastern rainforest, but much of their habitat has been burned away, making them extremely sensitive to the danger of fires. When a 1992 fire threatened a group in a reserve, they raised such a loud cry that the guards were alerted. They rushed to the scene and put out the fire (Rajaonson 1993).

Although originally found in the far north and central highlands, the Indri is now limited to a narrow strip encompassing only half the rainforests on the island (Garbutt 1999). Indris do not reach sexual maturity until between 7 and 9 years of age, and females are thought to give birth only every second or third year (Garbutt 1999). With such a low reproductive rate, they have been very vulnerable to habitat loss and hunting, especially by immigrants (Garbutt 1999). Moving about in small family groups, they are conspicuous to hunters. The Indri is one of the few lemurs whose killing is considered taboo by the Malagasy, but the old taboos are breaking down, resulting in capture and killing. In some cases, religious leaders encourage such killing. A lemur scientist met a Catholic priest who killed several Indris, roasted them and served them to his congregation, as recorded by Faith McNulty in 1975, and this killing has not ceased. In *Mammals of Madagascar* (Garbutt 1999), two terrified Indris were photographed clinging to poles in a hut, awaiting slaughter for food.

In contrast to the Indri, mouse lemurs (*Microcebus* spp) are so small that it is hard to think of them as primates. The tiniest is the newly discovered Pygmy Mouse Lemur (*Microcebus myoxinus*), with an average weight of only 30 grams, or 1.05 ounces, smaller than any other primate (Garbutt 1999). This tiny mammal is 2.73 inches long, with a tail just under 6 inches in length (Garbutt 1999). The other species are slightly larger, with body lengths ranging up to about 5 inches, and tails of equal or greater length (Garbutt 1999). These nocturnal lemurs have huge dark eyes and are agile and active, resembling African bushbabies. They feed on insects, spiders, and even small frogs and lizards, as well as fruit, flowers and nectar (Nowak 1999). Females form groups and sleep in a nest together with up to nine individuals, while males usually nest alone or in pairs; occasionally males are found in a group of females (Nowak 1999).

A key to protecting lemurs and their forest homes is educating the people of Madagascar about them. The Jersey Wildlife Preservation Trust has put up posters with pictures of lemurs and their protected status around the island. Habitat protection is obviously key to conserving lemurs, and another recent development is the protection of the largest remaining area of rainforest in Madagascar. The Masoala Peninsula in the northeast is the sole home of the Red Ruffed Lemur (*Varecia variegata rubra*), a 9-pound, reddish subspecies of the Ruffed Lemur, but bearing little resemblance to the latter black-and-white species. With $3 million from USAID (United States Agency for International Development) and three years of planning, the new Masoala National Park, covering 210,000 hectares (518,910 acres or 840 square miles), was announced in June 1996 (Terry 1996). This immense park was formally signed into law on October 18, 1997 (Kremen 1998). Thai and Indonesian timber companies had hoped to log these virgin rainforests, but this new law will prevent clearcutting and slash-and-burn agriculture that would have destroyed the forest within less than 50 years. A coalition of organizations helped establish this park, including the Wildlife Conservation Society, CARE and the Peregrine Fund (Garbutt 1999). It will prevent the extinction of the endangered Red Ruffed Lemur, as well as that of the newly rediscovered Madagascar Serpent Eagle (*Eutriorchis astur*) (see below).

In 1997, five Ruffed Lemurs born and raised in the Duke University Primate Center in North Carolina were released in the Betampona Reserve in the northeast to bolster a small, isolated population of this species (Welch 1997). This reintroduction represented a goal in the captive-breeding program at Duke University, which has long planned such a return of these highly endangered primates to the wild. John Cleese, actor and a member of the 1970s British comedy team, Monty Python's Flying Circus, took an interest in the reintroduction program as an enthusiastic lemur admirer.

After contributing to the Ruffed Lemur reintroduction program, he wanted to see how they were faring in the wild, and trekked to their remote release site. A delightful film based on this experience, "Lemurs with John Cleese," was shown on PBS in 1999. These Ruffed Lemurs have been released in an area of dense rainforest and rugged hillsides, a long hike from the nearest road. The biologists and assistants who take part in this reintroduction program show their dedication by living for long periods under extremely primitive conditions. Cleese managed to inject humor into this otherwise arduous situation.

At least six species of lemurs, and perhaps more, serve the ecologically important role of pollinating flowers. Many of Madagascar's plants produce unusually large flowers with strong odors and copious nectars attracting lemurs to feed on them. Should any of these lemurs become extinct, the plants that they pollinate will likely follow. Lemurs also play an important role in dispersing seeds. Research by the German Primate Centre at Hamburg University has found that Brown Lemurs are crucial to the regeneration of the western dry forests. About 10 percent of the island's tree species rely largely or entirely on this species to disperse seeds, which pass through their digestive systems.

The surviving lemurs are in extreme danger of following their relatives into extinction. Conservation organizations accord them extremely high priority among endangered primates, and they are the focus of many programs to preserve them. Twenty-nine of the 33 species are listed in the *2000 IUCN Red List of Threatened Species*, all but seven in higher categories of threat. This is an increase of nine species in the four years since the previous edition of the *IUCN Red List* was published (Baillie and Groombridge 1996). Three species and several more subspecies are in the Critical category of species on the verge of extinction, while seven are Endangered, an increase of four species since 1996. All lemurs are listed on Appendix I of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), the category prohibiting commercial trade, and as Endangered on the U.S. Endangered Species Act.

Although lemurs are protected by Madagascan law, hunting is a major cause of mortality. High fines and even jail sentences may be imposed for killing a lemur, but the severity of the penalties might make officials reluctant to enforce the laws (Peterson 1989). Blowguns, snares, traps, sharpened sticks, slings, stones, guns or even clubs are used to kill them (Peterson 1989). To kill small species of nocturnal lemurs, trees are sometimes cut down, and hunters seize them from their nest holes (Peterson 1989). In the late 1980s, a "sport" hunter bragged of killing 12 highly endangered Verreaux's Sifakas in one afternoon (Peterson 1989). In spite of education programs launched in the 1990s urging the Malagasy to protect lemurs, and the rise in tourists who come to see them, which provides revenues, few have benefited from tourism. Hunting remains a major threat (Garbutt 1999). The rise in human population has resulted in an increased demand for food, particularly protein, far more than the ailing agricultural system can supply (Garbutt 1999). The larger lemur species are especially affected. Because laws against killing lemurs are not enforced, much more education is needed about their potential value in attracting tourism and research funds that provide new jobs. Already tourism has raised income levels among some Malagasy, but hunger is still widespread (Tyson 2000).

In the late 1980s, a World Bank official studying the extreme and worsening poverty on the island said that there might come a time when the people of the capital city would scale the walls of the city zoo and eat the lemurs: "On the downward spiral, animals are at the bottom" (Peterson 1989). Such a tragedy is not inconceivable considering that hunger and poverty have deepened in the decade since. Conservation programs must involve communities while providing an incentive to conserve lemurs. Otherwise, it may be impossible to persuade the Malagasy not to slaughter them.

Although the status of lemurs is deteriorating along with their forests, much is being done to prevent their extinction. The past two decades have been of critical importance to lemur conservation. These extraordinary animals are receiving worldwide attention, and habitat protection for some species has been achieved. Not too long ago, their extinctions seemed inevitable and imminent. Conservation education programs, including showing slides of lemurs and other wildlife to rural children, have been launched. Wright helped to finance the building of new schools and the renovation of existing schools near Ranomafana National Park (Tyson 2000). A number of international organizations are integrating lemur and biodiversity studies with the economic development of entire communities (Garbutt 1999).

For a growing number of Malagasy, learning how special their lemurs are has made lemurs a source of pride and an important national treasure. In the future, Malagasy children may learn from an early age about lemurs and want to protect them. A few decades ago, few films had been made of these fascinating primates, while today many films show their habitats, biology and conservation work on their behalf. One is fiSpirits of the Forest,fl a charming film about many species of lemurs. Others are listed in the Video Section • Mammals. Films of lemurs and the island's environment would provide new insights about these animals if shown to the Malagasy people. Lemurs have also been prominently featured in *Madagascar: A Natural History*, by Ken Preston-Mafham, a beautiful and informative book, and the first guide book, *Mammals of Madagascar*, which provides color photos of nearly every species and subspecies, as well as information on habitats, conservation and status (Garbutt 1999).

In some areas of Madagascar, notably on Nosy Be island, lemurs are fully protected by taboo respected by the Malagasy. Here, beautiful Black Lemurs are fed by the villagers and tourists. This island is being developed intensively for tourism, and the strict nature reserve may be made into a national park (Tyson 2000). This will have mixed results, with new income flowing to the local people from park fees--one of the few countries where this occurs--yet with habitat lost and wildlife disturbed as a result of new hotels and a crush of visitors (Tyson 2000).

The gentle, curious gazes and charming behavior of lemurs have left an indelible impression on many people, and their extinction would be tragic, not just for biological reasons, but also because of their unique and delightful qualities.

The Biological Wealth of an Impoverished Country: Mammals: Page 3

Bats, which perform vital ecological roles in controlling insect populations and pollinating plants, tend to be ignored and often persecuted. Madagascar is no exception. Fifteen species of the 29 species of bats are endemic, living nowhere else (Garbutt 1999). The remaining 14 species live in mainland Africa as well. Fourteen species, or almost half the native bats, are listed by the *2000 IUCN Red List of Threatened Species*. The Yellow Bat (*Scotophilus borbonicus*), the most endangered, is listed as Critical (Hilton-Taylor 2000). This bat has been seen in both eastern and western regions but is extremely rare. A Vulnerable species, the Sucker-footed Bat (*Myzopoda aurita*), is the sole member of its family, Myzopodidae, and an extremely unusual bat. It is able to walk up tree leaves using sucker disks at the bend of its wings and on its feet to adhere to the slippery leaves (Jolly 1988). Only 2 inches long, with a forearm length of 1.9 inches, this tiny bat occurred in East Africa during the Pleistocene, but at present, it is found only in several locations in the eastern rainforest region of Madagascar (Garbutt 1999). It roosts in the Traveller™s Tree. It possesses a complex echolocation system and emits very long calls used to hunt insects (Garbutt 1999).

The largest bat, the endemic Madagascar Flying Fox (*Pteropus rufus*), has a 4-foot wing-span. An extremely colorful bat, its crown and nape are yellowish, and its upper chest and shoulders are rufous to golden brown (Garbutt 1999). It feeds on fruit juices by squeezing pieces of fruit pulp in its mouth, swallowing the juice and very soft fruit pulp, especially of figs, papayas, lychees and guavas (Garbutt 1999). Colonies of these bats roost in tall trees in primary forests or plantations (Garbutt 1999). One large roost at the Berenty reserve has decreased, apparently because of daytime disturbance by tourists who come to see them hanging upside down in the tamarind trees (Preston-Mafham 1991). Elsewhere on Madagascar, the species has declined precipitously from hunting for its meat; only on inaccessible offshore islands do these bats survive without persecution (Preston-Mafham 1991). Of Asian origin, this species is related to fruit bats in the Mascarene Islands. Through captive studies, flying foxes have been found to be extremely devoted to one another (see discussion of Rodrigues Flying Fox in Chapter One).

The Biological Wealth of an Impoverished Country: Mammals: Page 4
The Viverrid family is represented in Madagascar by mongooses, civets, and related carnivores that have evolved into eight species of three endemic subfamilies (Preston-Mafham 1991). Their ancestor is thought to have originated in Africa, and may have colonized the island at an early period. The largest carnivore on the island is the Fossa, or Fosa (*Cryptoprocta ferox*). A zoological oddity, it resembles the Jaguarundi, a neotropical cat, but most authorities place it either in the Viverrid family with civets (Preston-Mafham 1991) or the Herpestidae family with mongoose (Nowak 1999). The only member of its genus, it walks flat on its feet, rather than on its toes like cats (Nowak 1999). Sleek and slender, with golden reddish-brown fur, it has a small head with a blunt, dog-like muzzle, and an extremely long tail. Males weigh up to 22 pounds, with a body length of 2.6 feet and a tail of equal length, while the smaller females measure 2.3 feet and weigh about 15 pounds (Garbutt 1999). It has scent glands which discharge a strong odor when the animal is irritated (Nowak 1999). Widespread but rare in forests throughout the island, this nocturnal predator kills small lemurs, rodents and tenrecs, as well as birds, reptiles, amphibians, invertebrates and, reputedly, domestic chickens (Garbutt 1999). The Fossa often excavates animals from their burrows and can pursue fleeing prey by climbing up trees (Nowak 1999).

The first research study of the Fossa is being conducted by zoologist Luke Dollar, funded by the Earthwatch Institute. Helped by volunteers, he is radio-tracking several Fossa to determine their movements, habits and territory size. As the largest predator on the island, the Fossa plays an extremely important role in the evolution, behavior and population dynamics of lemurs and other prey animals. During the research project, several Fossa have shown extreme confidence by raiding the tents of the researchers when unoccupied, ransacking them and even chewing metal objects, leather boots, rucksacks, soap and bottles of malaria tablets (Garbutt 1999). For centuries, Fossas have been persecuted by the Malagasy, believing them to be ferocious and evil.

The Fossa gives birth to a litter of two to four young, which mature very slowly and may not be fully independent until they are about 4 years old (Garbutt 1999). This slow rate of reproduction has made the Fossa vulnerable to extinction. Along with losses from killing by the Malagasy, its forest home has been steadily whittled away by slash-and-burn agriculture. The Fossa is listed as Endangered in the *2000 IUCN Red List of Threatened Species*, a higher category of threat than it received in the 1996 version of this list.

Gerald Durrell, renowned author and conservationist, traveled in the western forests to capture Aye-ayes for captive breeding. He encountered a Fossa venturing out during the day--an unusual behavior: "A flash of russet red caught my eye in the bushes some six feet in front of the vehicle and, suddenly, from out of the undergrowth, silent as a cloud shadow, came a Fossa which walked languidly to the middle of the road and sat down" (Durrell 1993). Remaining there, the Fossa proceeded to groom himself, apparently unaware of Durrell's presence. Then, with a sigh and a wide yawn, the Fossa crossed the road and disappeared into the forest, "his immense sickle of a tail swinging from side to side like a bellrope behind him. To have spent ten minutes with such a rare and beautiful creature was a privilege" (Durrell 1993).

The Falanouc (*Eupleres goudotii*), sole member of its genus and a viverrid, is the size of a domestic cat. It has dense, woolly fur and an extremely pointed and narrow muzzle. Native to humid eastern lowland forests and marsh areas and portions of the northwest, Falanoucs are active at twilight and during the night. Feeding mainly on earthworms and other invertebrates, they use their long snouts and tiny, conical teeth to catch prey in leaf litter (Garbutt 1999). The species is rare or extremely rare over most of its range and is classified as Endangered by the IUCN (Hilton-Taylor 2000). Like the Fossa, it has declined as a result of deforestation, drainage of marshes, hunting by the Malagasy, attacks by feral domestic dogs, and possibly competition with the introduced Small Indian Civet (*Viverricula indica*).

The Malagasy Civet or Fanaloka has the scientific name *Fossa fossana*, which has been confused with the Fossa. Like the Fossa and Falanouc, it is the only member of its genus. Looking more like spotted civets from mainland Africa and Asia, this reddish 3-pound carnivore has rows of black spots on its back, merging into stripes toward its bushy, grayish tail. Its distribution is far more restricted than the Fossa's or the Falanouc's, being confined to eastern rainforests which have been reduced to less than 10 percent of their original size. Sheltering in tree holes or crevices, the Malagasy Civet lives in pairs and feeds on crustaceans, worms, small eels and frogs (Nowak 1999). A pair has a single young, and a captive civet lived 11 years. Hunting and trapping have also threatened the Malagasy Civet, which is listed as Vulnerable by the IUCN (Hilton-Taylor 2000).

Five other viverrids, all mongooses, are native to Madagascar, and all are threatened with extinction from a loss of forest habitat and persecution. A few have very restricted distributions. They tend to be secretive unless in a secure forest reserve, and little attention has been paid to their conservation, biology or habitat requirements. Several are uniform brown or russet, while two have bold black dorsal stripes ending in white, bushy tails. One, the Brown-tailed Mongoose (*Salanoia concolor*), is native to the northeast rainforests, but almost nothing is known of this small carnivore (Garbutt 1999). All of the eight native civets, mongooses and related animals are listed as Vulnerable or Endangered by the *2000 IUCN Red List of Threatened Species*.

The Biological Wealth of an Impoverished Country: Mammals: Page 5

Among Madagascar's 11 species of murid rodents are several extremely bizarre forms. The largest is the Giant Jumping Rat (*Hypogeomys antimena*), the size of a rabbit and weighing 2 pounds, 10 ounces (Preston-Mafham 1991). Restricted to a small area in western dry, deciduous forests north of Morondava, in west-central Madagascar, its entire range is thought to encompass only 39 square miles (Preston-Mafham 1991). Once far more widely distributed, remains have been found in southwest and central Madagascar (Garbutt 1999). These huge rodents search for food, such as fallen fruit, on the forest floor and feed by sitting on their hindquarters and holding food in their forepaws like a rabbit (Garbutt 1999). Giant Jumping Rats build deep burrows and, unlike the vast majority of rodents, a mated pair maintains long bonds with one another and with their young (Garbutt 1999). Male young leave after one year, and females stay with both parents for two to three years (Garbutt 1999). Only one or two young are born in a litter, and predation by Fossa and the Madagascar Ground Boa (*Acrantophis madagascariensis*) is high (Garbutt 1999). With no reserve and a habitat that continues to decline, this huge-eared rodent is in danger of extinction. A reserve is planned for this species, which is listed as Endangered by the *2000 IUCN Red List of Threatened Species*. fiMadagascar. Island of Ghostsfl filmed the Giant Jumping Rat in the wild, one of the only videos of this fast-disappearing species (see Video section).

Eight of Madagascar's native rodents, or 73 percent, are listed by the IUCN in various categories of threat. Two are considered Critical: the Madagascar Mouse (*Macrotarsomys ingens*) and the Madagascar Rat (*Eliurus penicillatus*). The mouse is known only from a single area in northwestern Madagascar, in dry deciduous forests where the type specimen was found, and it is thought to be almost totally arboreal and nocturnal (Garbutt 1999). The Madagascar Rat has not been seen since the type specimen was collected in central-eastern montane rainforest.

The Biological Wealth of an Impoverished Country: Birds: Page 1

Until recently, the amazing lemurs and other mammals of Madagascar eclipsed its remarkable bird life. Apart from the extinct elephant birds, 120 species of the 204 native birds are unique to the island (Morris and Hawkins 1998). Like tropical birds of other parts of the world, most are dazzlingly beautiful in brilliant hues. Unlike most tropical birds, however, they represent fascinating examples of evolution, including families of birds that exist nowhere else, having evolved from a single ancestor into many forms, some very bizarre. Most ornithologists recognize five bird families as unique to Madagascar, each with extremely distinctive characteristics. Four of these have some or all species that are threatened. The fifth, a family consisting of a single bird, the Cuckoo-Roller (*Leptosomus discolor*), is secure for the moment (Morris and Hawkins 1998). A few thousand years ago, there may have been far more native bird species that disappeared without a trace as their habitats were destroyed.

Native birds are not thriving, as people and livestock destroy their varied habitats, to which they had adapted over thousands of years. A total of 41 species, all but three of which are endemic, have been listed in the *2000 IUCN Red List of Threatened Species*, based on the research of BirdLife International published in 2000 in *Threatened Birds of the World*. The latter book illustrates each threatened Madagascan bird and describes status, population numbers, distribution and other pertinent information. The three non-endemic birds also breed in the neighboring Comoros or Seychelles (BI 2000). Thus, 20 percent of all native birds and 34 percent of endemic birds are threatened, five species listed as Critical, six as Endangered, 16 as Vulnerable, and 14 as Near-Threatened (BI 2000). Moreover, many native birds that were once widespread have become restricted to isolated forest reserves and parks, not yet endangered but far less numerous than in previous times. While the percentage of threatened birds is less than that of endemic mammals, it is significant, especially considering that 27 species are either Critical, Endangered or Vulnerable in the *2000 IUCN Red List of Threatened Species.* Madagascar has more threatened birds that all of the continental United States (excluding Puerto Rico and Hawaii). Its threatened birds total 41 threatened species, five greater than the United States™ 36 (BI 2000). Only 4 percent of the 810 breeding birds native to continental US and Canada combined (Sibley 2000) are threatened. If birds in the United States faced the same degree of threat as Madagascar's birds, at least 162 species would be threatened with extinction.

Fortunately for the future of these unique birds, organizations such as BirdLife International; the Peregrine Fund; Conservation International; the Jersey Wildlife Preservation Trust; and an ad hoc group, The Working Group on Birds in the Madagascar Region, are researching and working to conserve Madagascar's native birds. Malagasy ornithologists and members of the public are participating in surveys, studies and conservation programs. An inventory of the status and taxonomy of all of Madagascar's birds is in progress (Morris and Hawkins 1998).

In spite of Madagascar™s many unusual birds, interesting to specialists and amateur birdwatchers alike, no bird guide or text illustrating and describing the island's avifauna existed until 1990, when Olivier Langrand's *Guide to the Birds of Madagascar* was published, providing information on natural history, status, habitats and distribution, as well as color paintings of all native birds. This material supplemented the lengthy descriptions in *Threatened Birds of Africa and Related Islands*, a 1985 publication of the International Council for Bird Preservation, now called BirdLife International (Collar and Stuart 1985). *Madagascar: A Natural History*, by Ken Preston-Mafham (1991), included extensive information on many native birds and their habitats. *Birds of Madagascar, A Photographic Guide* (Morris and Hawkins 1998), published in 1998, updates the latter publications with vivid color photographs illustrating almost all native birds, including many species discovered or rediscovered during the 1990s, such as the two new species, the Cryptic Warbler (*Cryptosylvicola randrianasoloi*) and the Red-shouldered Vanga (*Calicalicus rufocarpalis*), and the rediscovery of several birds thought extinct: the Madagascar Serpent Eagle, Madagascar Red Owl (*Tyto soumagnei*) and Red-tailed or Fanovana Newtonia (*Newtonia fanovanae*). The 1990s also saw the making of many films about the island's wildlife, including its birds (see Video section).

The Biological Wealth of an Impoverished Country: Birds: Page 2
Birds native to aquatic habitats have declined even more dramatically than many forest birds. The largest lake on Madagascar, Lake Alaotra in the northeast, was once a paradise of waterbirds, turtles, frogs and other wildlife. Traditionally, portions of the lake were used by the Malagasy for rice cultivation, without serious damage to the environment or resident wildlife. But as their populations and food requirements grew, people began to destroy more and more of the natural marsh and reed beds that lined the lake, and cleared the surrounding forest for firewood and agriculture. This destroyed the lake's water quality. With no trees to hold back the soil and conserve water, this once-beautiful lake became heavily silted by runoff (Durrell 1993). Added to this, non-native tilapia fish were introduced into the lake as a food source for the local people. The fish eat vegetation needed by dragonflies and other fauna that form the basis of the lake's food chain (Preston-Mafham 1991). This ecological collapse has greatly reduced rice production on the lake, although reeds are still being cleared for rice growing, fragmenting wildlife habitat (Garbutt 1999).

The effects on native aquatic birds have been catastrophic. Lake Alaotra is the only known habitat of the endemic Alaotra Grebe (*Tachybaptus rufolavatus*), which is presumed extinct (BI 2000, Morris and Hawkins 1998). No sightings have been made since 1985, when only two birds were seen. It declined from loss of its habitat, hunting and hybridizing with the Little Grebe (*Podiceps ruficollis*), a recent arrival from Africa (Morris and Hawkins 1998). Many fruitless searches for the species have been carried out in the lake and surrounding area since then (BI 2000, Morris and Hawkins 1998). This small, black-capped grebe was very sedentary and may have been nearly flightless because of its extremely short wings.

Another waterbird restricted to Lake Alaotra, the Madagascar Pochard (*Aythya innotata*), is also probably extinct, having been eliminated by the same threats as the Alaotra Grebe (BI 2000). This duck declined steeply from 1930 on, and the last known bird, a male, was captured in August 1991, having been caught in fishing gear. This bird later died, and intensive searches in 1989 and 1990, and again in 1993 and 1994, failed to discover more Madagascar Pochards (BI 2000, Collar *et al.* 1994). A handsome bird, the pochard was chestnut-colored, with dark gray bill and yellow eyes (see photograph in Morris and Hawkins 1998). A shy species, its breeding and behavior were studied, but apparently nothing was done during its precipitous decline to prevent its extinction. Classified as Critical, hope remains that a few birds exist in wetland habitats around Lake Alaotra (Morris and Hawkins 1998).

The Jersey Wildlife Preservation Trust has begun education campaigns in the vicinity of Lake Alaotra to teach local people about the presence of the highly endangered Alaotra Reed Lemur or Bandru (*Hapalemur griseus alaotrensis*), a subspecies of the Grey Bamboo Lemur, and the importance of protecting the reed and papyrus beds. This lemur has been classified as Critical by the IUCN. The only lemur to live in an aquatic environment, the Alaotra Reed Lemur is larger than other subspecies of the Grey Gentle Lemur and lives in close, family groups (Garbutt 1999). To move about in the reed beds, they climb up a reed stem until it bends, and then walk along it to reach the next stem; their major food is the endemic papyrus, along with grasses and ferns (Garbutt 1999). Lake Alaotra's reed beds are its sole habitat, and although previously widespread in this and another lake to the north, only two isolated populations of lemurs, one of which numbers fewer than 60 animals and is on the verge of extinction, remain in marsh fragments (Garbutt 1999). This lemur has the most restricted range of any lemur species or subspecies (Garbutt 1999). The film, fiMadagascar. A World Apart,fl includes a moving segment on these lemurs feeding among the papyrus when a Malagasy canoe enters the marsh and sets a fire, causing the terrified lemurs to flee. (See Video section). Local village leaders have requested that the government set aside a protected zone in the marshes. There is hope that this lake will be brought back as a functioning ecosystem in the future and that a strict sanctuary will be set aside for this endangered lemur and the highly endangered waterbirds.

While sizeable areas of forest have been protected, few aquatic environments on Madagascar have been preserved, and native waterbird species are declining precipitously. The Madagascar Little Grebe (*Tachybaptus pelzelnii*) was once common and widespread in many parts of the island; with the pollution and destruction of marshes throughout the island for rice farms, this bird has declined greatly. The introduced tilapia was threatening this species by consuming its food supply. This grebe also hybridizes with the introduced Little Grebe (Collar *et al.* 1994). The Little Grebe, an African species which has colonized the island, prefers the habitat created by the tilapia, and is now abundant (Langrand 1990). The Madagascar Little Grebe has also drowned in fish nets, and has lost the vegetation it needed for nesting (BI 2000). It is expected to follow the Alaotra Grebe and Madagascar Pochard into extinction.

Another endemic waterbird, the Sakalava Rail (*Amaurornis olivieri*), native to western wetlands, is also extinct or nearly so. A small, sooty-black bird with yellow beak and pinkish-red legs and feet, it was native to streams and marshes in the western parts of the island. For more than 30 years, this species was not seen at all. In 1995, one was glimpsed at Lake Bemamba, and another in 1999 at the same lake (BI 2000). This species is classified as Critical (BI 2000), and Lake Bemamba and other lakes and wetlands on the west coast may be given protection by the Malagasy government, which has ratified the Ramsar Convention on wetlands preservation (BI 2000).

As a result of extensive habitat destruction and hunting, the Madagascar or Bernier's Teal (*Anas bernieri*) has likewise declined to endangered status in the few sites from which it is known on the west coast. Once widespread on the island, it is now restricted to a few marshes and shallow lakes. Small populations remain on Bemamba Lake and a few other sites (Morris and Hawkins 1998), and a flock of 67 was seen in another area (BI 2000). In 1970, 60 of these birds were seen on a lake, and as soon as this became known, European sportsmen went to the lake and killed more than 25 percent of the population (Curry-Lindahl 1972). In the 1970s, Bernier's Teal inhabited Lake Masama, but heavy hunting by both Europeans and natives with dogs has nearly eliminated them (Todd 1979). In 1993, four birds were captured for captive breeding (Collar *et al.* 1994). The Jersey Wildlife Preservation Trust is working to preserve this beleaguered species and the marshes of the west. The Madagascar Teal has been seen in three protected areas, and a conservation program at one lake has been initiated (BI 2000).

The critically endangered Madagascar Fish Eagle (*Haliaeetus vociferoides*) numbers about 250 pairs in the 600-kilometer stretch of western coastline to which it has become confined (BI 2000). This large eagle resembles the African Fish Eagle, from which it probably evolved, but instead of a snowy white head and upper body, it is streaked with brown and has shaggy, buff crown feathers. About 35 inches long, with a 6.5-foot-wingspan, it is by far the largest bird on Madagascar. Persecuted by local people, these eagles have been shot and their nests destroyed. On one occasion in the 1990s, ornithologists saw some immigrants cut the tree where an active nest of a Madagascar Fish Eagle was located, and proceed to kill and eat the chicks! The only remaining habitat for this species is the western coast, where mangrove swamps are rapidly being destroyed (Langrand 1990, Preston-Mafham 1991). The Peregrine Fund is sponsoring research on this species, and 10 nests have been located in an area on the west coast in the Three Lakes Complex (BI 2000). The Fund has removed and raised chicks that would have been killed by siblings and released them to augment the population. The fish it feeds on are being depleted, however, by a gill-net fishery that has recently been established. A new Malagasy law allows local communities to control their own resources, and the people in this region are being encouraged to formalize conservation regulations prohibiting gill netting and tree cutting.

The Biological Wealth of an Impoverished Country: Birds: Page 3

Birds native to aquatic habitats have declined even more dramatically than many forest birds. The largest lake on Madagascar, Lake Alaotra in the northeast, was once a paradise of waterbirds, turtles, frogs and other wildlife. Traditionally, portions of the lake were used by the Malagasy for rice cultivation, without serious damage to the environment or resident wildlife. But as their populations and food requirements grew, people began to destroy more

and more of the natural marsh and reed beds that lined the lake, and cleared the surrounding forest for firewood and agriculture. This destroyed the lake's water quality. With no trees to hold back the soil and conserve water, this once-beautiful lake became heavily silted by runoff (Durrell 1993). Added to this, non-native tilapia fish were introduced into the lake as a food source for the local people. The fish eat vegetation needed by dragonflies and other fauna that form the basis of the lake's food chain (Preston-Mafham 1991). This ecological collapse has greatly reduced rice production on the lake, although reeds are still being cleared for rice growing, fragmenting wildlife habitat (Garbutt 1999).

The effects on native aquatic birds have been catastrophic. Lake Alaotra is the only known habitat of the endemic Alaotra Grebe (*Tachybaptus rufolavatus*), which is presumed extinct (BI 2000, Morris and Hawkins 1998). No sightings have been made since 1985, when only two birds were seen. It declined from loss of its habitat, hunting and hybridizing with the Little Grebe (*Podiceps ruficollis*), a recent arrival from Africa (Morris and Hawkins 1998). Many fruitless searches for the species have been carried out in the lake and surrounding area since then (BI 2000, Morris and Hawkins 1998). This small, black-capped grebe was very sedentary and may have been nearly flightless because of its extremely short wings.

Another waterbird restricted to Lake Alaotra, the Madagascar Pochard (*Aythya innotata*), is also probably extinct, having been eliminated by the same threats as the Alaotra Grebe (BI 2000). This duck declined steeply from 1930 on, and the last known bird, a male, was captured in August 1991, having been caught in fishing gear. This bird later died, and intensive searches in 1989 and 1990, and again in 1993 and 1994, failed to discover more Madagascar Pochards (BI 2000, Collar *et al.* 1994). A handsome bird, the pochard was chestnut-colored, with dark gray bill and yellow eyes (see photograph in Morris and Hawkins 1998). A shy species, its breeding and behavior were studied, but apparently nothing was done during its precipitous decline to prevent its extinction. Classified as Critical, hope remains that a few birds exist in wetland habitats around Lake Alaotra (Morris and Hawkins 1998).

The Jersey Wildlife Preservation Trust has begun education campaigns in the vicinity of Lake Alaotra to teach local people about the presence of the highly endangered Alaotra Reed Lemur or Bandru (*Hapalemur griseus alaotrensis*), a subspecies of the Grey Bamboo Lemur, and the importance of protecting the reed and papyrus beds. This lemur has been classified as Critical by the IUCN. The only lemur to live in an aquatic environment, the Alaotra Reed Lemur is larger than other subspecies of the Grey Gentle Lemur and lives in close, family groups (Garbutt 1999). To move about in the reed beds, they climb up a reed stem until it bends, and then walk along it to reach the next stem; their major food is the endemic papyrus, along with grasses and ferns (Garbutt 1999). Lake Alaotra's reed beds are its sole habitat, and although previously widespread in this and another lake to the north, only two isolated populations of lemurs, one of which numbers fewer than 60 animals and is on the verge of extinction, remain in marsh fragments (Garbutt 1999). This lemur has the most restricted range of any lemur species or subspecies (Garbutt 1999). The film, fiMadagascar. A World Apart,fl includes a moving segment on these lemurs feeding among the papyrus when a Malagasy canoe enters the marsh and sets a fire, causing the terrified lemurs to flee. (See Video section). Local village leaders have requested that the government set aside a protected zone in the marshes. There is hope that this lake will be brought back as a functioning ecosystem in the future and that a strict sanctuary will be set aside for this endangered lemur and the highly endangered waterbirds.

While sizeable areas of forest have been protected, few aquatic environments on Madagascar have been preserved, and native waterbird species are declining precipitously. The Madagascar Little Grebe (*Tachybaptus pelzelnii*) was once common and widespread in many parts of the island; with the pollution and destruction of marshes throughout the island for rice farms, this bird has declined greatly. The introduced tilapia was threatening this species by consuming its food supply. This grebe also hybridizes with the introduced Little Grebe (Collar *et al.* 1994). The Little Grebe, an African species which has colonized the island, prefers the habitat created by the tilapia, and is now abundant (Langrand 1990). The Madagascar Little Grebe has also drowned in fish nets, and has lost the vegetation it needed for nesting (BI 2000). It is expected to follow the Alaotra Grebe and Madagascar Pochard into extinction.

Another endemic waterbird, the Sakalava Rail (*Amaurornis olivieri*), native to western wetlands, is also extinct or

nearly so. A small, sooty-black bird with yellow beak and pinkish-red legs and feet, it was native to streams and marshes in the western parts of the island. For more than 30 years, this species was not seen at all. In 1995, one was glimpsed at Lake Bemamba, and another in 1999 at the same lake (BI 2000). This species is classified as Critical (BI 2000), and Lake Bemamba and other lakes and wetlands on the west coast may be given protection by the Malagasy government, which has ratified the Ramsar Convention on wetlands preservation (BI 2000).

As a result of extensive habitat destruction and hunting, the Madagascar or Bernier's Teal (*Anas bernieri*) has likewise declined to endangered status in the few sites from which it is known on the west coast. Once widespread on the island, it is now restricted to a few marshes and shallow lakes. Small populations remain on Bemamba Lake and a few other sites (Morris and Hawkins 1998), and a flock of 67 was seen in another area (BI 2000). In 1970, 60 of these birds were seen on a lake, and as soon as this became known, European sportsmen went to the lake and killed more than 25 percent of the population (Curry-Lindahl 1972). In the 1970s, Bernier's Teal inhabited Lake Masama, but heavy hunting by both Europeans and natives with dogs has nearly eliminated them (Todd 1979). In 1993, four birds were captured for captive breeding (Collar *et al.* 1994). The Jersey Wildlife Preservation Trust is working to preserve this beleaguered species and the marshes of the west. The Madagascar Teal has been seen in three protected areas, and a conservation program at one lake has been initiated (BI 2000).

The critically endangered Madagascar Fish Eagle (*Haliaeetus vociferoides*) numbers about 250 pairs in the 600-kilometer stretch of western coastline to which it has become confined (BI 2000). This large eagle resembles the African Fish Eagle, from which it probably evolved, but instead of a snowy white head and upper body, it is streaked with brown and has shaggy, buff crown feathers. About 35 inches long, with a 6.5-foot-wingspan, it is by far the largest bird on Madagascar. Persecuted by local people, these eagles have been shot and their nests destroyed. On one occasion in the 1990s, ornithologists saw some immigrants cut the tree where an active nest of a Madagascar Fish Eagle was located, and proceed to kill and eat the chicks! The only remaining habitat for this species is the western coast, where mangrove swamps are rapidly being destroyed (Langrand 1990, Preston-Mafham 1991). The Peregrine Fund is sponsoring research on this species, and 10 nests have been located in an area on the west coast in the Three Lakes Complex (BI 2000). The Fund has removed and raised chicks that would have been killed by siblings and released them to augment the population. The fish it feeds on are being depleted, however, by a gill-net fishery that has recently been established. A new Malagasy law allows local communities to control their own resources, and the people in this region are being encouraged to formalize conservation regulations prohibiting gill netting and tree cutting.

The Biological Wealth of an Impoverished Country: Birds: Page 4

As more and more bird-watchers come to Madagascar, the government may place a higher priority on bird conservation. A special fund to which bird-watchers could contribute might be established to purchase and maintain refuges and to conduct conservation education and other projects for local people, especially in aquatic habitats. The preservation of threatened Madagascan birds has reached a critical point. The most endangered habitats, the last of the western forests, aquatic environments, and many parts of the eastern lowland rainforests, continue to decline. The fragmentation of forests that forces animals into islands of isolation needs to be studied and remedied by establishing habitat corridors between them. One Malagasy ornithologist, Aristide Andrianarimisa, is researching the effects of forest fragmentation on birds.

Pete Morris and Frank Hawkins, authors of *Birds of Madagascar. A Photographic Guide*, state that their purpose in writing their book was to inspire people to visit Madagascar and take an interest in its avifauna and the plight of so many threatened birds, as well as to promote greater interest in wildlife and conservation among the Malagasy people. Ecotourists bring revenue to the island and, thereby, help to preserve natural areas and wildlife (Morris and Hawkins 1998). The discovery of a new species of songbird, the Cryptic Warbler, by bird-watchers in Ranomafana National

Park, is an exciting byproduct of ecotourism and an indication that the study of Madagascar's birds has just begun. It also proves that amateurs play an important role in bird observation. *Birds of Madagascar* establishes a good precedent by identifying, on a species-by-species basis, the avian habitats and those birds lacking reserves within their ranges. The authors request that people coming to see the wildlife of the island let the government know why they have come in order to convince decision makers that biodiversity conservation represents a worthy investment (Morris and Hawkins 1998).

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians

The distribution and diversity of Madagascar's reptiles and amphibians have not been carefully researched until the present. Chris Raxworthy, a British herpetologist, is in the process of carrying out the first methodical survey of the estimated 500 non-marine species, all of which are endemic (Holmes 1997). To date, at least 300 reptile and about 200 frog species have been identified (Tyson 2000). This would make it one of the top five countries in the world for diversity of reptiles and amphibians. The British Isles, by contrast, with about half the land area of Madagascar, have only six species of reptiles (Preston•Mafham 1991). Even the ranges of newly described lizards and frogs will not be delineated precisely for some time. Some areas remain unexplored by herpetologists, and Raxworthy finds new species of lizards and frogs on each expedition into the tangled swamps and forest fragments. On one day when accompanied by a journalist, he and fellow researchers, including Malagasy biologists, found a bright green day gecko, a strikingly beautiful yellow-and-black snake, tiny frogs resembling lichens, a leaf-tailed gecko and 4-inch chameleons with upper legs the colors of Rainbow Trout, and lower legs like toothpicks (Holmes 1997). In a reserve on Nosy Be island, he and some Earthwatch Institute volunteers rediscovered a 10-inch green lizard that had been lost to science since the 1890s, when last collected (Tyson 2000). Raxworthy is doing inventories in reserves as part of an island-wide biodiversity program, and hopes that in some impenetrable area, giant tortoises long considered extinct will be rediscovered (Holmes 1997).

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 1

Of these native reptiles and amphibians, at least 19 are known to be threatened with extinction. A preliminary list includes 17 species of reptiles (four tortoises, a freshwater turtle, four sea turtles, a gecko, four chameleons and three boa snakes) and two amphibians, both frogs. All are in higher categories of threat: Endangered or Vulnerable by the *2000 IUCN Red List of Threatened Species* (Hilton-Taylor 2000). All but the sea turtles are endemic to Madagascar.

The arid regions at the northern and southern ends of Madagascar are home to two intricately patterned tortoises, both in danger of extinction. In the north is a species considered by many to be the world's most endangered tortoise: the 18-inch Madagascar or Plowshare Tortoise (*Geochelone yniphora*), whose tan, domed shell is marked with narrow black lines in delicate hexagonal patterns. The Plowshare name came about because of a protuberance on the tortoise™s lower shell that turns up, a kind of knob that remotely resembles a plowshare. This knob is used by males in sparring contests. From the 17th century onward, thousands of these tortoises, which were once abundant and widespread, were shipped every year to the nearby Comoro Islands to use as meat for settlers, driving the species to the edge of extinction before the trade finally ended in the 19th century (Juvic *et al.* 1981). Their populations never

recovered, due to the continued take by villagers for pets and the massive destruction of their habitat. Known to the Malagasy as the "Angonoka," this tortoise was headed for extinction until 1985 when the Jersey Wildlife Preservation Trust was requested by the IUCN to work with the Malagasy government in formulating a rescue plan, Project Angonoka (Reid 1995). Research on the tortoise™s wild status and behavior began immediately, and a captive-breeding program was established at a government forestry station (Reid 1995).

By 1986, eight adult tortoises had been gathered from the wild and placed in an enclosure which had ample vegetation and conditions natural enough that two male Angonokas immediately began their fights of strength (Reid 1995). Gerald Durrell, founder of the Jersey Wildlife Preservation Trust, in his book, *The Aye-aye and I* (1993), described lone males showing no interest in breeding, even if surrounded by females. But when another male is present, they face each other prepared for combat: "The two males, rotund as Tweedledum and Tweedledee dressed for battle, approach each other at what, for a tortoise, is a smart trot. The shells clash together, and then the plowshare comes into use. Each male struggles to get this projection beneath his opponent and overturn him to win a victory in this bloodless duel" (Durrell 1993). Finally, when one is able to overturn his opponent, he lumbers over to mate with the female while the vanquished male "wanders dispiritedly away" (Durrell 1993).

Project Angonoka has shown success both in captive breeding these tortoises, which may number only between 300 and 1,000 in the wild, and in working with local people to conserve remaining wild populations (Durbin *et al.* 1996). In fact, by 1995, a total of 140 captive-bred juveniles, ranging in age from 10 months to 6 years, had been produced at the breeding center. The breeding program was described in an illustrated article entitled "Observations on Hatchling and Juvenile Captive-bred Angonoka in Madagascar," published in the Jersey Wildlife Preservation Trust's annual journal, *The Dodo,* issued early in 1996. Within months, the captive-breeding program was devastated by the theft of 76 animals--two adult females and 74 hatchlings. On May 6, 1996, someone cut through the flimsy chain-link fence and the wire of the enclosure and took half the animals that were the fruit of a decade's work. Not until a female is 20 years old does she begin breeding, so the loss of two breeding females and their hatchlings dealt the program a devastating setback (McNeil 1996a). The burglary may have been an inside job, since the dog on the premises did not bark to alert the personnel who were sleeping close by (Tyson 2000). It is unlikely that these adult females will breed in captivity, as there are almost no adult male Plowshare Tortoises in breeding programs, and without more than one, no breeding occurs.

Animal smugglers care little about the effect of their actions on the survival of endangered species. Reptile collectors will pay thousands of dollars for rare specimens, and this break-in had been planned. A Dutch rare animal dealer had advertised Plowshare hatchlings for sale the month before, at $3,000 apiece, saying they would be "available soon" (McNeil 1996a). Ten of the hatchlings were traced to Prague, where wildlife law enforcement is weak, and others were suspected to be in the Netherlands, where they would be sold to collectors in the United States, Spain, Germany and Japan (McNeil 1996a). The loss of these tortoises cost the breeding program years of work. Don Reid, the Conservation Field Officer in charge of the Plowshare Tortoise captive-breeding program, had experimented for years to achieve a proper diet for the tortoises, arranged male combats, and conducted lengthy experiments to learn proper conditions for the eggs to hatch (Reid 1995). These tortoises became so tame that they would stretch their necks out to be scratched (McNeil 1996a). Although discouraged by the theft, he continued the breeding program; 40 new tortoise hatchlings were produced in late 1996, bringing the total to 130 juveniles. In 1998, several of the smuggled tortoises were seized from a Malaysian animal dealer in Mexico City who had been the subject of a long-term U.S. Fish and Wildlife Service undercover investigation. The same year, three more Plowshare Tortoises were seized in Belgium as they were being imported (TRAFFIC 1999a). The species is listed by the *2000 IUCN Red List of Threatened Species* as Vulnerable, and is protected by the Malagasy government, which bans trade.

Officials from the Jersey Wildlife Preservation Trust and other conservationists have sponsored education programs aimed at informing local people about the tortoises and their rarity. This has resulted in their cooperation in helping to guard wild tortoises from poachers and control brush fires (Durbin *et al.* 1996). This region in northwestern Madagascar has lost most of its forest cover; Arab residents cut trees and burn them to clear the land for agriculture,

and feral pigs kill the young wild tortoises (Durbin *et al.* 1996). So much clearance of natural vegetation has taken place that the climate has become increasingly more arid, causing ponds to dry up. Tree cutters are now turning to the mangroves, causing siltation of the inlets, which affects prawn harvests (Durbin *et al.* 1996) and destroys a key aquatic environment on the island.

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 2

The Plowshare Tortoises have been reduced to a few forest sites, and in spite of the urgent need for a reserve, none has been set aside. The area is getting conservation help with the formation of a new organization by conservation biologists, the Association to Safeguard the Environment. Its purpose is to involve local people in environmental projects, such as planting cashew trees, learning fire suppression methods, and trapping bush pigs; they are also giving conservation lessons to children and conducting literacy classes (Durbin *et al.* 1996).

The Radiated Tortoise (*Geochelone radiata*) inhabits the drylands of the extreme south, where the strange Didierea plants and other desert vegetation grow in open shrubland. Many people consider this tortoise to be the most beautiful in the world. Delicate yellow sunburst patterns adorn the top of its 16-inch-long black shell, and the underside is marked with diamond patterns. These tortoises also declined after tens of thousands were killed to supply local villagers with meat, or exported to the Comoro Islands from the 17th century on for meat markets abroad. In 1922 alone, 22,000 of these tortoises were exported (Jolly 1980). The legal trade did not cease until 1930. The tortoise populations have not rebounded, and illegal capture for collectors and zoos may be the explanation. The slow reproduction of this species means that it cannot quickly make up for losses in its population. An extremely long-lived species, it has evolved with low natural mortality and has few young. As an example of its longevity, a Radiated Tortoise of unknown age presented to the Queen of Tonga by Captain Cook in the 1770s, lived until 1966, making it almost 190 years old at its death (Jackson 1993).

The lovely patterns on this tortoise's shell, which vary from individual to individual, have placed it in great demand around the world, encouraging poverty-stricken Malagasy to risk jail to earn the money that these tortoises bring. Thousands of Radiated Tortoises have been collected for the international market, sold in Europe, North America and elsewhere for $2,000 or more per animal. In spite of having a range that is far larger than that of the Plowshare Tortoise, the Radiated Tortoise is declining rapidly toward extinction. The species is listed by the *2000 IUCN Red List of Threatened Species* as Vulnerable. Export and collection of Radiated Tortoises are prohibited by the Malagasy government, with severe penalties for violations including prison sentences. The United States lists both the Radiated and Plowshare Tortoises on the Endangered Species Act, which prohibits commercial importation. International commercial trade is banned by their listing on Appendix I of CITES. Still, the smuggling continues, fed by the many wealthy collectors who have no conscience about the effect their purchase has on wild populations, and the zoos that knowingly purchase smuggled animals. Malagasy authorities have failed to put an end to the poaching, especially of the Radiated Tortoise and other southern species.

Donovan Webster, a journalist, researched the rampant smuggling of Radiated Tortoises and other wildlife from the island for *The New York Times Magazine*, which published his lengthy article on February 16, 1997. The magazine cover featured the article and read: "I was caught in Madagascar. Peddled for 30 cents. Smuggled to Orlando. Sold for $10,000. I'm a rare, coveted tortoise--coldblooded contraband." Webster found that Madagascar was a "pirate's paradise," with little or no local enforcement of conservation laws. Its long and unpatrolled coastline is used by smugglers, who load tortoises onto small boats at night, with little fear of arrest (Webster 1997). Although some enforcement of capture bans takes place in the range of the Radiated Tortoise, local people have learned to avoid arrest.

The contrast between the attitudes of local people toward the Plowshare Tortoise in the north, where education

programs have been carried out by the Jersey Wildlife Preservation Trust, and the south, where no strong program exists to protect the Radiated Tortoise and other wildlife, could not be more dramatic. In the south, poaching Radiated Tortoises and other reptiles is considered an accepted form of revenue by the extremely poor people of the region. At local bars and restaurants, Webster was approached by people who offered to produce a rare snake within 24 hours. Snakes are a favorite animal for smugglers because they can be secreted in small bags and placed in luggage or, if they are small enough, in pockets. He refused a boa, which was offered at $300 and could be sold for $2,000 in the United States (Webster 1997).

Webster exposed a large-scale and fairly open trade in Radiated Tortoises in local markets within the range of these tortoises. He visited a woman who was reputed to have many of these tortoises for sale. She showed him 24 Radiated Tortoises which she kept ready for sale to anyone who would pay the right price; they were crowded into a make-shift pen in her living room, stacked two and three deep in filthy conditions (Webster 1997). They grunted and made hissing sounds when disturbed, scratching and scrabbling against one another and the pen sides; their shells were covered with dust, and most appeared to be sickly (Webster 1997). The woman tossed the tortoises back into the pile after handling them. She claimed that she sold them to local people for $1.35, and to outsiders for $4 or more, depending on how many tortoises she had at the time (Webster 1997). She also admitted supplying a smuggler who arrived once a week in a canoe at a remote beach with any Radiated Tortoises she had in stock (Webster 1997).

These tortoises are absurdly easy to collect in the wild, living in open shrubland and moving so slowly that they can be picked up as easily as rocks. Webster witnessed the capture of one mature tortoise which Benjamin, one of the collectors, located in the shadow of a boulder. When he approached, the tortoise hissed and tried to crawl beneath bushes, but it was easily grabbed, and he flipped it on its back; soon he caught two other adult tortoises who had a baby the size of a small stone wedged beneath them in an apparent attempt to protect it (Webster 1997). Collectors wrap string around the tortoises™ shells to form handles for carrying them. When they met at the end of the day, they had taken 54 mature tortoises and many young ones, making it a "banner day" (Webster 1997). The occasional presence of enforcement officers and World Wildlife Fund (WWF) representatives did not seem to present any anxiety of threat of arrest to the collectors (Webster 1997).

Each Radiated Tortoise is worth at least $2,000 once smuggled out of Madagascar, and those with unusually exquisite patterns bring as much as $10,000 (Webster 1997). Benjamin later admitted that he was aware that the tortoises were becoming rarer and that their range had shrunk in recent years; he also knew that many were very old, probably older than his own 53 years. It was obvious that the tortoises would soon be gone, but he believed this was his only potential income source; he was uncertain about how he would make a living when there were no more Radiated Tortoises (Webster 1997).

Some of the smuggled Radiated Tortoises leaving Madagascar have been seized by importing countries. In May 1992, for example, a Dutch citizen arriving from Madagascar was stopped by Customs at Roissy Airport in the Netherlands in possession of 46 Radiated Tortoises as well as 14 bamboo lemurs of several species and seven endangered Madagascar Boas (*Acrantophis madagascariensis*); the animals were confiscated and returned to Madagascar (TRAFFIC 1992). In 1998, a Radiated Tortoise was among many rare tortoises seized in Belgium as they were being imported, and U.S. authorities, under fiOperation Chameleon,fl an undercover investigation of trafficking in illegal Madagascar reptiles, seized Radiated Tortoises from an American reptile dealer in Miami. In May 1999, French Customs officers seized 450 tortoises smuggled by three Malagasy citizens living in Paris (TRAFFIC 1999b). Among them were 120 Radiated Tortoises; the suspects were not arrested (TRAFFIC 1999b).

Most ecotourism on the island has been developed for viewing lemurs, chameleons and birds, but the Radiated Tortoise and its extraordinary habitat of endemic plants have the potential of attracting many tourists. Also living in this tortoise's habitat are spectacular sifakas, many unusual birds, and other reptiles. In Beza-Mahafaly Reserve, scientists are studying the ecology and longevity of these tortoises, as well as searching for a permanent form of marking that would make them unattractive to collectors. The Radiated Tortoise could be conserved while helping local people like Benjamin. Grants from international organizations could finance jobs held by local people, such as

ex-poachers, to protect the tortoises and serve as wardens. Former collectors could help educate schoolchildren and local people about protecting Radiated Tortoises and other wildlife. Organizations, such as Earthwatch Institute, might sponsor research to study the status of these tortoises. The presence of scientists would pose a deterrent to poachers.

Two other endemic tortoises, the Spider Tortoise (*Pyxis archnoides*) and the highly endangered Flat•shelled Tortoise (*Pyxis planicauda*), are much smaller, about 5 or 6 inches long (Preston•Mafham 1991). The latter tortoise is restricted to a forest of only 40 square miles, and a captive•breeding program is attempting to prevent its extinction. Both these tortoises lay only a single, large egg (Preston•Mafham 1991). These tortoises are also in demand by reptile collectors. In August 1996, six men were indicted after being arrested with four Spider Tortoises in their luggage at the Orlando International Airport in Florida. They were part of a smuggling ring supplying rare reptiles to collectors. In 1999, 330 Spider Tortoises were seized along with Radiated Tortoises in the case cited above (TRAFFIC 1999b).

The Madagascar Big-headed Turtle (*Erymnochelys madagascariensis*), is an endangered freshwater species listed in the *2000 IUCN Red List of Threatened Species* and on Appendix II of CITES. This turtle is related to South American river turtles, another link that may date back to the time before Madagascar drifted away from Gondwana. The Jersey Wildlife Preservation Trust began a breeding program for these turtles in 1999 with the objective of releasing young turtles back into the wild after educating local people.

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 3

Madagascar is home to two•thirds of the world's chameleons--at least 62 species--more than any other country (Tyson 2000). Among the island's endemic chameleons are the world's smallest and largest species. The smallest, *Brookesia minima*, is only 1.3 inches long, while the largest, *Furcifer oustaleti*, measures 27 inches in length (Preston•Mafham 1991). Their conical eyes, moving independently, can look forward and backward at the same time, swiveling almost 180 degrees in either direction (Preston-Mafham 1991). This adaptation, processing totally divergent information spontaneously, would confuse most vertebrates, but chameleons, even very young ones, are adept at using these dual periscopes to locate insects and other prey. They hold onto the thinnest branch with their prehensile tails, and with long, thin legs bent at the knees, they walk in an odd back-and-forth swaying motion that resembles leaves moving in the wind. Their chunky bodies and spindly legs give them an awkward appearance, but they are superbly adapted to catching their prey by unfurling a long, sticky tongue--curled upside their mouth--with lightning speed, nailing an unaware insect with astonishing accuracy.

Their camouflage coloration, which varies greatly from bright greens, mottled browns, reds and blues, helps protect them from avian and mammal predators. Contrary to general opinion, chameleons do not change colors as they move about in the trees or on the ground to match their background. When they suddenly change colors, it is as a territorial or sexual display meant for other chameleons (Preston-Mafham 1991). Some species have horns and other protuberances, giving them the appearance of miniature dinosaurs. A few species show sexual dimorphism, or a physical difference between the sexes. The contrast can be so striking that some were considered separate species when first identified (Burger and Price 1996). In one species, for example, the female is black and yellow, and the male a mottled brown and white (Burger and Price 1996).

Chameleons are heavily exploited by collectors who capture them for sale in pet stores around the world, threatening them. Collectors will pay $1,000 or more per animal for rare species. This trade, which involves thousands of individuals, has caused declines in many species. The Malagasy government has banned trade in most species, but enforcement is not strong. One chameleon, *Chamaeleo brevicornis*, of which 795 were exported in the first six months of 1990, is restricted to only a few areas of primary forest (Behra 1993). An ongoing study will evaluate whether to allow trade in the commoner species. Chameleons captured and shipped abroad for the pet trade suffer very high mortality as a result of inhumane transport conditions and inadequate care in pet stores and people's homes. They

require special conditions of temperature and humidity, and many have specialized diets. In short, they are not suited to being house pets. In the care of specialists, they can be kept alive, but most captive breeding has been unsuccessful. Some of the rarer species, such as the beautiful blue-green Parson's Chameleon (*Chamaeleo parsonii*), which can reach lengths of more than 20 inches, have not been bred to the second generation**,** and mortality is high. All chameleons are on Appendix II of CITES, which requires export permits, but none has been listed on Appendix I of CITES, which would ban commercial trade.

Although some chameleons have adapted to disturbed habitats, such as weedy fields and shrub landscape, the majority favor natural habitats. The small *Brookesia* chameleons, of which one species is listed by IUCN as Vulnerable (Hilton-Taylor 2000), require undisturbed, primary old-growth forest. Three other chameleons, all *Furcifer* genus, are listed as Vulnerable by IUCN. All are in decline, approaching endangered status.

Although many Malagasy regard chameleons as ugly porters of bad luck (Burger and Price 1996), for tourists, they are the second most popular animals, after lemurs. Some Malagasy, aware of the fascination with which chameleons are held by tourists, capture them and offer them for viewing or sale.

Another lizard being captured for the pet trade is the extraordinary 4-inch-long Leaf•tailed Gecko, *Uroplatus fimbriatus*, a true master of camouflage. Resting during the day with its head tight against a tree trunk, an elaborate lacy fringe along the underside of the body allows it to melt into the tree, while its skin is patterned to resemble tree bark. Even its golden eyes are streaked with tiny dark lines that imitate bark. With broad, flattened front feet splayed out against the bark and hind legs held vertically under a spatula•like tail, it becomes virtually invisible (Preston•Mafham 1991). If discovered, however, it has a defense. Opening its mouth wide to reveal a crimson•red tongue, it raises its tail vertically and emits an ear-splitting screech, no doubt intended to be a fearsome display (Preston•Mafham 1991, Tyson 1994). Malagasy boys have discovered the haunts of the Leaf-tailed Geckos, and capture hundreds--thousands by their accounting--for sale to foreign middlemen who pay them less than $1. They are sold in the United States for $250 a pair (Tyson 1994, Tyson 2000). On Nosy Be island off the northern coast, schoolboys claim to have captured 40,000 over the past six years (Tyson 2000). A threatened gecko, Standing's Day Gecko (*Phelsuma standingi*), is native to the spiny forests of the south and is one of the most coveted by collectors (Tyson 2000). It is hunted out of many areas because Malagasy have captured hundreds, receiving $1.20 per gecko, while reporting only a few to authorities (Tyson 2000). It is on CITES Appendix II, and sells in the United States for $80 to $200 apiece (Tyson 2000). Most species of geckos bring the village collectors only about 3 U.S. cents, while the exporter receives $9 to $13 and U.S. retailers get $75 or more (Burger and Price 1996). In most cases, these pet reptiles live a very short time, and represent a mere toy to the consumer.

The export trade in live lizards involves an enormous number of animals. One gecko, *Phelsuma serraticauda*, was known only from a few museum specimens until 1,360 specimens were chronicled as exported during the first six months of 1990 for the pet trade (Behra 1993). During this same period, 22,837 lizards--geckos, *Phelsuma* genus, and chameleons, *Chamaeleo* genus--were exported from Madagascar (Behra 1993). Between 1986 and 1991, almost 145,000 lizards of 17 species were exported; of these at least 38,325 were chameleons of 21 species (Burger and Price 1996). Many of these are species that are endemic to restricted areas, or threatened in the wild. The U.S. Fish and Wildlife Service™s fiOperation Chameleonfl succeeded in arresting 19 people in 1998, among whom was a major Malaysian smuggler and an American, Tommy Crutchfield, who was arrested at Miami International Airport with suitcases full of rare snakes, tortoises and lizards. In another case, a Canadian and a Dutchman were arrested at Chiang Kai-shek International Airport in Taiwan with numerous chameleons and geckos, including some threatened Standing's Day Geckos.

Several gecko species have extremely limited ranges. A newly described leaf gecko, *Uroplatus malama*, is known from a single specimen taken in a remnant of lowland rainforest in southeastern Madagascar (Burger and Price 1996). Only two specimens of a closely related species, *Uroplatus malahelo*, exist, native to a small patch of forest in the south (Burger and Price 1996). When discovered, its habitat was being logged, and the species may already be extinct (Burger and Price 1996). An extremely rare lizard, *Zonosaurus boettgeri*, known from two specimens that were taken

in the 1890s and subsequently disappeared, has been rediscovered on the island of Nosy Be by herpetologist Chris Raxworthy and volunteers from Earthwatch Institute (Tyson 2000). The two individual lizards were killed as specimens upon rediscovery (Tyson 2000).

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 4
Among Madagascar's 80 types of snakes--all non-poisonous--are three boas, whose closest relatives are found in South America (Burger and Price 1996). They are thought to be among the island's most ancient inhabitants, resident since the early breakup of Gondwana (Preston•Mafham 1991). All are considered Vulnerable by the IUCN (Hilton-Taylor 2000): Dumeril's Boa (*Acrantophis dumerili*), Madagascar Boa (*Acrantophis madagascariensis)*, and the Madagascar Tree Boa (*Sanzinia madagascariensis*). The first two are Madagascar's largest snakes, reaching almost 6 feet in length; Dumeril's Boa is restricted to the south and southwest, while the Madagascar Boa is found in the north and northeast (Preston•Mafham 1991). Both species require humid habitats along streams and watercourses. Placid and slow•moving, they are often killed or captured by local people. The Madagascar Tree Boa is smaller and more common, shaded in delicate grayish-green with a purplish•blue tinge. Little is known of any of these species' life histories and diets (Preston•Mafham 1994). A very rare and possibly extinct snake, *Pararhadinea albignaci*, is known only from a single specimen picked up, dead, off the road in eastern Madagascar in 1970. This species has never been seen alive in its forest home (Preston-Mafham 1991).

One of the most extraordinary snakes in the world, *Langaha nasuta*, mimics a dry, pencil-thin twig to camouflage itself among the leaves. The female's nose is extended into a leaf•shaped structure adorned with scales and small tooth•like projections, while the nose of the male is elongated, tapering into a sharp point to resemble a thorn (photo in Preston•Mafham 1991 and Lamar 1997).

A smuggling operation involving hundreds of Madagascar reptiles was exposed in August 1996, when six men were charged with conspiracy to smuggle rare Madagascar reptiles into the United States and Canada. According to the U.S. Justice Department, two men were arrested at Orlando International Airport in Florida with 61 Madagascan tree snakes in their suitcases that were to be sold at a large reptile breeders show in Orlando (Reuters 1996). Four Germans, one Canadian and one South African were indicted. Simon Harris, the South African, had $100,000 worth of rare reptiles in his luggage; he cooperated to implicate the other suspects, who are still being sought (Reuters 1996). These smugglers shipped snakes and tortoises, concealed in suitcases, from Europe to Canada and the United States and received payment by international wire transfers. Most of the snakes and tortoises were listed on CITES. In 1998, 26 Madagascan Tree Boas were seized in Belgium, and an American reptile dealer was caught by the U.S. Fish and Wildlife Service with the latter species and Dumeril's Ground Boas in his luggage at Miami International Airport (TRAFFIC 1999a).

The sea turtles inhabiting Madagascar's coastal waters are heavily exploited in spite of their listing on Appendix I of CITES. A survey in 1971 estimated that 13,000 were killed along the west coast alone (Burger and Price 1996). Little is known of their present populations.

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 5
Some 176 species of amphibians, all frogs, have been named and described (Mittermeier *et al.* 1999). Raxworthy estimates that there are another 124, many of which have already been found but not yet described scientifically (Tyson 2000). Salamanders and toads are absent from Madagascar. All but two frogs are endemic, one of which was introduced from Asia by French colonialists as a gourmet food source (Burger and Price 1996). The majority are

native to rainforest environments, the most endangered type of habitat on the island. In one such area, a montane rainforest in the Andasibe region, 90 species are native--the highest diversity of frogs in the world (Burger and Price 1996). Since 1990, 13 new species of a single, colorful genus, *Boophis*, have been described, and others await naming by scientists (Burger and Price 1996). A candidate for the world's smallest frog--and perhaps the world's smallest vertebrate--is a minute frog, *Stumpffia pygmaea*, which measures less than 3 millimeters in length (0.117 inches) (Burger and Price 1996). This frog lays its eggs in foam nests hidden among leaves on the forest floor, and the tadpoles grow into froglets without ever feeding (Burger and Price 1996).

The most spectacular Malagasy frog may be the bright red Tomato Frog (*Dyscophus antongili*), which secretes poisonous white mucous when threatened. Some authorities consider the species to be endangered (Bauer 1995), while the *2000 IUCN Red List of Threatened Species* lists it as Vulnerable. To protect it from trade, it is listed on Appendix I of CITES. Fat and squat, this toad-like frog is large enough to cover the palm of a hand (Preston-Mafham 1991). Tomato Frogs have a very restricted range in the region of Tamatave on the east coast; some live in plantations, where pools of water gather, and even in garden ponds (Preston-Mafham 1991). Collectors, pet dealers and zoos have offered thousands of dollars for these frogs, and illegal shipments containing 40 or more Tomato Frogs have been confiscated.

One study entitled "The Export of Reptiles and Amphibians from Madagascar," by Olivier Behra (1993), chronicled the extent of exploitation of frogs. In 1988, 230 frogs of the genus *Mantella*, endemic to Madagascar, were exported. The demand increased, causing exports to rise astronomically to 11,058 in 1989; in the first six months of 1990 alone, almost 11,000 were exported, mainly to Denmark and other European countries, the United States and Japan (Behra 1993). These brightly colored little frogs are sold as pets and to decorate terrariums. The most popular Madagascar frog in this trade is the tiny Golden Mantella (*Mantella aurantiaca*), of which 3,237 were exported in the first six months of 1990 (Behra 1993). This frog is restricted to eastern Madagascar, and is apparently rare and declining (IUCN 1994). It lives in pandanus swamps in rainforests, which are rapidly disappearing, and no part of its habitat has been set aside in a reserve (IUCN 1994). Unlike most frogs, the Golden Mantella is slow-reproducing (IUCN 1994). In the 1990s, 3,000 to 6,000 were exported annually from Madagascar, and in 1994, two proposals sought to list this species on CITES, one on Appendix I and the other on Appendix II. The latter proposal succeeded, which is unfortunate, since it allows the trade to continue. The *2000 IUCN Red List of Threatened Species* lists the Golden Mantella as Vulnerable (see photos of gold and red phases of this species in Lamar 1997).

In 1998, two people were arrested in Taiwan trying to smuggle frogs of two *Mantella* species (*Mantella madagascariensis* and *Mantella aurantiaca*), along with some Madagascar lizards. Another seizure of 50 Mantella frogs occurred at Zaventem Airport in Belgium in 1998 as they were being smuggled from Madagascar (TRAFFIC 1999a). Such seizures involved shipments without the proper export permits. Appendix I listing under CITES would provide greater protection.

The Biological Wealth of an Impoverished Country: Invertebrates

Like the rest of its fauna, Madagascar's invertebrates are extraordinary. One insect from the age of the dinosaurs, the Giraffe-necked Weevil (*Trachelophorus giraffa*), has an elongated neck which rises vertically, then makes a right-angle turn and extends horizontally, and ends in a tiny head with furry antennae. Amazingly, this insect has counterparts in New Zealand known as giraffe weevils (Molloy 1994). This may be explained by the fact that New Zealand was also part of Gondwana prior to its breakup (Molloy 1994). Other ancient species include the 100 species of hissing cockroaches. Some are far larger than any other cockroach species in the world; their heavy bodies resemble long-extinct trilobites. The largest species measure up to four inches long, and thousands are exported for the novelty pet trade and for zoos. When touched, they hiss loudly, and males aggressively charge one another with their armored, knobbed shields (Preston-Mafham 1991).

One of the richest land-snail faunas in the world is native, with more than 380 species named so far, 361 of which are endemic and differ greatly from land snails in Africa (Preston-Mafham 1991). Many are threatened, however, by introduced African Giant Snails (*Achatina fulica*) and several other non-native snails introduced to control the African Giant Snail, but threatening native species instead. One native snail, *Tropidophora deburghiae*, is considered endangered by some authorities. Brilliantly colored slugs, or shell-less snails up to 6 inches long, striped in black-and-red or yellow-and-brown, live on the damp rainforest floor (Preston-Mafham 1991). Many have limited distributions and can be easily eliminated by habitat destruction (Preston-Mafham 1991).

An extremely ancient family of spiders, Archaeidae, first described from a specimen frozen in amber several million years old, has seven species on Madagascar, one in South Africa, three in Australia, five in New Zealand and one at the tip of South America; these species appear to be vestiges from the ancient supercontinent (Preston-Mafham 1991). The Archaeidae spiders have strange, grotesquely shaped bodies, visible only through a microscope since they are only 0.14 inches long; they live among leaf litter on the ground (Preston-Mafham 1991). Some Madagascar spiders are extremely bizarre, with shapes that resemble bat-winged leaves, bright red thorns, or mottled brown lumps on logs (Preston-Mafham 1991).

Millipedes on Madagascar reach 6 inches and exude droplets of poison when attacked; Brown Lemurs have found ways of avoiding this toxin and feed on them (Preston-Mafham 1991). Shield-bugs, or stink-bugs, of the family Pentatomidae, have 220 species on Madagascar, many of which are brightly colored in reds, oranges and blacks; 120 species of water bugs, of which 80 percent are endemic, and a variety of assassin bugs add to the rich insect fauna (Preston-Mafham 1991). About 20,000 beetle species, including 500 species of endemic jewel-beetles, are native to Madagascar. Jewel-beetles, with their colorful, metallic bodies, appear during the rainy season in southern and western forests (Preston-Mafham 1991). Many species of scarab beetles, among which are dung beetles, are also native to Madagascar; one endemic genus, *Helictopleurus*, roll the dung balls into their nests and lay their eggs in them (Preston-Mafham 1991).

Madagascar's butterflies, totaling 300 species, are not as diverse as in some parts of the world, such as the Tambopata Natural Reserve in Peru, which has 1,300 species. This may be because they colonized the island fairly recently. Another possibility is that many species have faded into extinction, leaving no trace, when the plant species upon which they depended were driven to extinction by habitat destruction. Since 80 percent of the island's forests have been cut, hundreds or thousands of species may have disappeared without a trace millennia ago. One Madagascar butterfly, a pale cream-and-black Swallowtail, *Papilio mangoura*, is hotly pursued by collectors because of its rarity (Preston-Mafham 1991). Several butterflies of the Nymphalidae family, or Fritillaries, are threatened, as are two species of the family Acraeidae.

In the 19th century, Charles Darwin learned of a spectacular, white Madagascar orchid (*Angraecum sesquipedale*) that had an extremely long, nectar-bearing tube dangling down from the flower. He reasoned that it could be pollinated only by an insect that could reach its nectar. He guessed that it might be "some huge moth, with a wonderfully long proboscis." Entomologists verified his belief with the 1903 discovery of the hawkmoth, *Xanthopan morgani praedicta*. This moth has a 9-inch tongue that it keeps wound in a spiral in its mouth, unfurling it to reach the nectar of this particular orchid. In a similar arrangement, another orchid (*Angraecum arachnites*), exudes a strange odor that attracts only one pollinator, the rainforest hawkmoth, *Panogena lingens* (Preston-Mafham 1991). The nectar at the base of this orchid's long, twisted tube can be reached only by this single species of moth--and not even every individual, but only one race of this moth which has a long, tapered proboscis (Preston-Mafham 1991). These species co-evolved, and should the moths become extinct, the orchids would have no pollinators and would follow them into extinction. Another unusual moth, the huge Comet Moth (*Argema mittrei*), is one of the largest moths in the world (Preston-Mafham 1991).

Preserving Madagascar's Natural Wonders

This fourth largest island in the world is, in many respects, a minicontinent. This evolutionary treasure-house is of great importance from a worldwide perspective. Madagascar's diversity of life forms is so great that as many as 200,000 species, most of them undescribed, may be native, of which an estimated 150,000 are endemic species (Daley 1997). The habitat loss is proceeding so rapidly, however, that the underfunded biological assessment studies will be unable to appraise this biological wealth before it disappears before their very eyes. Logging and burning have reduced the forested area from 120,000 to 20,000 square miles; this destruction still consumes vast areas each year (Daley 1997). It is estimated that all the remaining accessible forests will disappear within the next 35 years (Sayer *et al.* 1992). With the impending loss of these treasures, many conservationists and scientists consider Madagascar the world's most threatened natural area (Sayer *et al.* 1992).

Less than 5 percent of Madagascar is protected in reserves and parks. Even if these lands remain intact, they represent too small a percentage of forest to preserve the island's genetic heritage. Other than Masoala National Park, which encompasses most of an entire peninsula, some 840 square miles, most reserves are relatively small--islands of forest surrounded by denuded land. Should all surrounding forest be leveled, these isolated fragments would not be sufficient to prevent genetic impoverishment, inbreeding, and eventual extinction of the very species the reserves were meant to protect. Recent research in the Amazon has shown that forest fragmentation results in extinctions, in direct relation to the size of the reserve (Peters and Lovejoy 1990). The larger the reserve, the fewer extinctions. For this reason, Masoala National Park is receiving special attention from scientists. Stanford University's Center for Conservation Biology is analyzing a Geographic Information System (Kremen 1998). So far, this research has revealed that forests on the eastern border of the park are the most threatened, with a likelihood that they will be completely burned away within 25 years (Kremen 1998). The borders of the park were delineated according to the results of biological surveys, a method that is so new that it has not even been used in the United States. Claire Kremen of the Wildlife Conservation Society, with additional support from the National Geographic Society, worked with a Malagasy entomologist and two American ornithologists to conduct detailed biological species diversity studies in this rugged terrain (Kremen 1998). Five new species of butterflies and many other insects were discovered. Each had its own micro-habitat, endemic to that area. Habitats included in the national park are lowland rainforest; cloud forest and montane heath; coastal and seasonally flooded forest; mangrove; marsh; estuary; bay; lagoon; and coral reef. Lemurs and a vast array of wildlife and plants will benefit from this new park.

Masoala National Park will not displace villages but will conduct education programs and involve them in the conservation of local wildlife. The Missouri Botanical Garden is also involved in the management of Masoala National Park, helping to inventory its rare plants and working with local people for non-destructive agricultural and fisheries industries. Work is also proceeding to stop the cutting of forests for firewood on Masoala and to provide public education on land use (Sayer *et al.* 1992). Some 300 or so villages exist within or nearby Masoala National Park, and the cooperation of the local people is crucial to the success of this park. The final plan for the park involved a compromise in which some cutting of four relatively fast-growing trees, including rosewood, would be allowed. Local communities, which will profit from the products, will be allowed to harvest palm seeds and butterflies. This will prevent the slash-and-burn destruction that was eating rapidly away at this forest (Kremen 1998). This park's endemic plants and animals, including the Red Ruffed Lemur, which exists only in the park, rely for their survival on the protection of this last sizeable rainforest. It will represent an experiment in conservation management that will have serious consequences should it fail. It is, however, one of the first times that ecological rules are being worked out with large numbers of local people to help protect such a large area. Elsewhere in Madagascar, similar projects are in the works.

Many of Madagascar's rarest species are not protected in any reserves, however, and may soon be lost. Reserves and

parks, the last refuge for many species, are regularly pillaged for trees, and wildlife is killed or captured. A herpetologist surveying in Bemaraha Reserve, in the western part of the island, discovered a pile of illegally cut trees that had been marked with red paint as part of a botanist's study by the trail in 1996 (Holmes 1997). This is not an isolated occurrence. The native wildlife and plants are among the most endangered in the world. More than 124 vertebrate species are listed in the *2000 IUCN Red List of Threatened Species* (Hilton-Taylor 2000), as well as 306 species of plants (Walter and Gillett 1998). While this crisis is occurring, new species of lemurs, reptiles, invertebrates and plants are being discovered, making the preservation of the environment all the more urgent. Obviously, the amazing biological diversity of Madagascar has not been fully assessed and may be far greater than previously thought.

Several species thought long-extinct are rumored to survive, adding even more mystery to the picture. Many Malagasy have told scientists of having seen an animal that might be a pygmy hippopotamus. Shown a picture of an African Common Hippopotamus, they have said that it was similar, but had floppy ears, uncloven hooves, dark skin, except for pinkish areas around the eyes and mouth, and was the size of a calf or small cow (Tyson 2000). As recently as 1976, a man told biologists of having seen and heard one grunting; many unsolicited, independent accounts from Malagasy have agreed on these details (Tyson 2000). They call the animal "kilopilopitsofy," and many are afraid of being chased by it (Tyson 2000). The Common Hippopotamus of Africa also grunts and kills more people than any other animal on the continent.

A long-lost primate, ground-dwelling and the size of a 7-year-old child, has also been reported by several Malagasy (Tyson 2000). This may be the same animal that was described to primatologist Alison Jolly (1980). A Malagasy told her that he had been given a young lemur of a type he had never seen before. This lemur had very dark fur, walked on its hind legs, one foot after the other, rather than hopping like a sifaka, and had a flat face different from the pointed muzzles of living lemurs. After only two months, this lemur died, and its skeleton was buried in an unknown place (Jolly 1980). An old man recently told a similar story of having seen such an animal in 1952. Called the "kidoky" by others who have seen it, it has a dark coat with white spots above and below a flat, round face. When alarmed, it flees by leaping forward in short hops like a baboon. Its call was described as a long, single whoop, and other villagers who had seen the animal said it was solitary (Tyson 2000). Scientists have said that if it exists, it might be an *Archaeolemur* or *Hadropithecus* (Tyson 2000). The fact that their descriptions seem so similar to species known to have existed makes them all the more intriguing.

Alarm calls about the impending demise of Madagascar's natural world have been sounded for decades (Jolly 1980, 1988; McNulty 1975; Preston•Mafham 1991; Tyson 2000). Visitors to the island are united in their descriptions of a ravaged, eroded and deforested land. Jacques•Yves Cousteau and his team visited the island for a television special aired in 1995. As they sailed toward Madagascar, they were stunned to see huge, wide, red stains of eroded soil in the water, emanating from the island's rivers, and wisps of smoke from burning forests. These red rivers are bleeding the island's life blood, its topsoil. They are so pronounced that they are among the few natural phenomena on Earth visible from orbiting space craft. Cousteau's helicopter flights over the central plateau revealed a landscape among the most devastated on the planet. A research team sponsored by Earthwatch Institute described the island from the air, "Two features of the landscape stood out even from 10 kilometers up: barrenness and smoke" (Tyson 1994).

Although erosion remains a major problem, some progress has been made to stop it (Morell 1999). Erosion costs Madagascar between $100 million and $290 million per year, caused mainly by the continued slash-and-burn agriculture (Tyson 2000). It has been extremely difficult to convince many Malagasy that the last of the forests will disappear within a generation if they do not seek alternative means of growing crops. To that end, Cornell University's International Institute for Food, Agriculture and Development, run by Norman Uphoff, has been helping farmers in the vicinity of Ranomafana National Park (Tyson 2000). These desperately poor farmers have no electricity or plumbing and struggle to feed large families on soil that is leaching its nutrients. Norman Uphoff discovered that the native Wild Ginger plant had high concentrations of phosphate, and he encouraged its use as fertilizer (Tyson 2000). By supplying seedlings and information, the Cornell program also has helped establish fish farms. Their agronomists have advised farmers to mix crops and to plant certain species in order to keep the soil rich and retard erosion; they

have supplied seedlings (Tyson 2000). This agricultural advice has been helpful, but because some rural people have so many children, many are unable to produce enough crops to feed their families (Tyson 2000). Other projects involve encouraging rice cultivation with more suitable seed varieties, improved irrigation systems and application of fertilizer (Garbutt 1999). Using native bees in honey-making is also being taught to the Malagasy, who often fell old-growth trees to obtain honey (Garbutt 1999). The Kew Botanical Gardens in London and Britain's Royal Palm Society are researching the marketing of seeds from some native palm trees (Terry 1996).

International aid organizations could help preserve forests by donating fertilizer so the Malagasy would not need to practice slash-and-burn when forest soil ceases to produce crops. The urgent task of supplying the Malagasy people with methods of producing food and fuel in environmentally non-destructive ways has just begun. Villagers would be more likely to preserve trees now cut for firewood if they were provided with solar cookers or given propane tanks for fuel. Bio-gas, or methane, produced by animal dung and sewage, could be used to provide fuel and fertilizer. Such projects have been launched by international agencies in some countries of Central Asia.

Madagascar's human population is growing at a rate of 3.1 percent per year and reached 12,596,000 in 1992 (55 persons per square mile) (Anon. 1994). By 1995, it had grown to 13.9 million (61 persons per square mile) (McNeil 1996b). Another increase to 14,462,509 people (64 persons per square mile) was registered in the 1999 *World Almanac*. The *2001 New York Times Almanac* noted a population of 15,506,472, based on a July 2000 estimate. Thus, 3 million people were added to the population in just eight years. Along with the original Asians, more recent immigrants from Africa, India, Pakistan, China, Europe, and Arab countries add to the diversity. They have long since passed the carrying capacity of the land, and rice must be imported to feed the people. As one of the world's 12 poorest countries, Madagascar's external debt is approximately $4.25 billion. Average annual income is only $780 (NYT 2000). The unemployment rate is about 33 percent, and 51 percent of children are malnourished, according to a study by USAID (Tyson 2000). The literacy rate is 46 percent, and only 42 percent of children attend schools; 70 percent of children ages 6 to 9 have had no formal education (Tyson 2000). Jacques Cousteau's team filmed hordes of desperately poor people as they combed dumps for scraps of metal and food. Some people even live in these dumps in holes they have dug in the soil. Such scenes are symptoms of extreme overpopulation and rampant poverty that can also be seen in parts of Brazil and Asia.

One of the reasons that illiteracy is so high in Madagascar is that millions of people must spend their days searching for food, water and firewood, requiring the help of their children, who are then unable to attend school. In general, foreign corporations have looted the island's resources, leaving no economic base that would help the people as a whole. One U.S. company, the Esso Corporation, is owed $25 million by the Madagascan government and demanded payment in spite of the country's cash reserves of less than $2 million (McNeil 1996b). Because of the country's debt levels, the World Bank and the International Monetary Fund are now in charge of its finances (McNeil 1996b), a potentially dangerous situation for both the people and the environment. On the positive side, a "Debt for Nature" swap was carried out in Madagascar, in which a portion of the foreign debt was exchanged for the establishment of nature reserves and parks.

To date, efforts to slow the population growth rate are still in their early stages. A program that addresses population growth, based not on threats or punishment, but on persuasion, was launched by Population Communications International (PCI) of New York City in 1996. As the organization has done in other countries, it trains local people to create communication programs for radio and television with a message that limiting family size is advantageous. The majority of the population on the island lives in cities and has access to these media. The programs, described as "soap operas" by PCI, create melodramas with characters the audience can identify with, who act out dramas. The characters in these dramas come to realize that different behavior, such as having fewer children, will result in positive changes in their lives (Ryerson 1994). In many cases, this involves elevating the status of women, and convincing men that women must be allowed to make decisions about their own reproduction (Ryerson 1994). PCI is cooperating with organizations that are actively trying to conserve the wildlife of Madagascar, such as Conservation International and the African Wildlife Foundation. Ranomafana National Park began a family planning center in 1994 to help the people of the region, many of whom have as many as 14 children, of which 62 percent are underweight and 17 percent

malnourished, according to a study by the University of North Carolina (Tyson 2000).

Madagascar is a magnet for scientists from around the world and has been the recipient of millions of dollars in foreign aid and grants from international conservation agencies. Conservationists are initiating many highly inventive and effective programs to interest the Malagasy in conservation and employ them in biodiversity work. Environmental education is a key to the future of Madagascar, and programs are being carried out at Beza-Mahafaly Reserve. This protected portion of endangered spiny desert and shrubland was established when the local Mahafaly people agreed to donate the land, and funds were raised by Alison Richard, a Yale primatologist, for a training program for Malagasy scientists (Tyson 2000). Patricia Wright has set up a similar program in which Malagasy students complete master's theses based on wildlife research in Ranomafana National Park, and some students travel to the United States to receive advanced training in biodiversity and environmental protection (Tyson 2000). They will help guide the country in new directions in the future. It also opens new worlds to these students, who, in turn, will make young people aware of the natural treasures in their country. Schools that Patricia Wright has helped establish in the area of the park teach environmental education to young people. Others are also helping introduce this subject to children. Josephine Andrews, a Scottish scientist studying Black Lemurs in Nosy Be since 1988, teaches children about the lemurs with the help of a Malagasy named Julien, who guides people around the forest preserve (Tyson 2000). "If the kids are really into it, then the adults will switch on as well," she said (Tyson 1994). Forests are the key to the future survival of the island and its people, and an education program aimed at rural people, teaching the value of trees in preventing floods, landslides and in maintaining the flow of rivers and streams, could save countless trees.

Scientists--both Malagasy and foreign--working on the island, could share their findings by talking with local people about the uniqueness of Madagascar's natural world. Ornithologists with the Peregrine Fund, who rediscovered the Red Owl and taught local schoolchildren about the species donated money from bird-watchers to the school, provided such an example. Scientists typically conduct research and depart without having taught local people about their findings. Villagers near Ranomafana National Park were so interested in learning about research results that they asked Wright for copies of reports. She began a bimonthly newsletter, in the Malagasy language, describing the natural history of the park (Tyson 2000).

Films and books about Madagascar's wildlife and plants tend to be distributed only in foreign countries, and never translated into Malagasy. Translations of books and subtitled films could be shown to schoolchildren to introduce them to Madagascar's tremendously interesting and beautiful natural world. It is ironic that Westerners may be more familiar with lemurs and chameleons that most Malagasy. Some projects for the future might include donation of solar collectors and windmills to supply power to rural people. This could elevate their standard of living and cut back on firewood collection for fuel. Donation of projection and video equipment to regional schools provided with electricity would help them appreciate their natural heritage through viewing nature films of Madagascan wildlife. Satellite dishes would facilitate communication with people around the world through the Internet.

The government of Madagascar developed a 20-year National Conservation Strategy and Environmental Action Plan as long ago as 1984. In 1986, a survey of protected areas began with the aim of implementing management plans for priority protected areas and recommending new protected areas, as well as training Malagasy people to work in reserve management and conservation biology. The government has been working to create a sense of pride and ownership in the nation's biodiversity through this program (Morell 1999). The President of Madagascar has stated that the environment is important, a key to whether foreign scientists and tourists will be able to come to the country and aid in its conservation in the future (Tyson 2000). The World Bank and various organizations funded this Environmental Action Plan with $168 million for its first five years (Tyson 2000). This has resulted in many biological studies, education of a growing number of Malagasy for conservation work and a Biodiversity Planning Centre (Sayer *et al.* 1992). The Geographical Information System database is a cornerstone of the government program, concentrating data from all fields to help establish conservation priorities (Tyson 2000). Conservation International has an office in the capital and is contributing to biological inventory data, as it has in other countries, as well as conducting research on particular species and data management. It coordinates its work with local organizations and trains Malagasy scientists (Sayer *et al.* 1992).

Ecotourism is another budding industry, and Madagascar is one of the few countries in the world to share park fees with local people. As a result of an initiative put forth by a Malagasy non-governmental organization, the National Association for the Management of Protected Areas, one-half of all fees are given to local people (Tyson 2000). Ninety-three villages in the Ranomafana National Park area received about $10,000 in a recent year from park fees; a committee designated by the villages decides how to spend the money. In 1995 they bought seeds and built campgrounds, a crafts training center and small dams (Tyson 2000). Many local people are employed as park workers, and the aim of the program is to turn over management of this park and its biodiversity work to the Malagasy people. There needs to be a national park system with strict rules for management and protection, according to Patricia Wright, who deplored the illegal tree cutting by the previous park director at Ranomafana (Tyson 2000). She also has proposed that a national biodiversity institute be built, which would offer centralized training in biology and technology, as well as five new long-term biodiversity research stations similar to those in La Selva National Park in Costa Rica and the Smithsonian Institution's Panama tropical research laboratory (Tyson 2000).

Jobs, which are desperately needed by the Malagasy, are increasing as a result of the rise in the number of tourists. Selling crafts to tourists, running hotels and restaurants, and serving as guides are among these. Villagers who used to demand that parks be declassified so that they could legally gather wood, now request that more national parks be established, an apparent result of the new income that comes from fees and tourism (Morell 1999). International tourists have provided a major new source of revenue in Madagascar's economy and are helping the Malagasy see their wildlife in a new way, as so fascinating and biologically important that visitors come from every continent to view it. *Madagascar. The Bradt Travel Guide*, by Hilary Bradt (1999), published in various editions since 1988, is a useful aid for tourists, providing information about accommodations, natural history, protected areas, and the Malagasy and their history. Nature reserves and parks provide jobs by attracting scientists who employ local people, another incentive for the Malagasy to urge that more protected areas be set aside.

Compensation for lost access to forests has not been paid in the past, and new arrangements reached with villagers to allow some extraction of resources from the forests may heal some of these wounds and placate those who still wish to cut trees. Medicinal plants obtained from Madagascar may be another source of revenue in the future. The Rosy Periwinkle may be only one of many native plants highly valuable in treating disease. Research on the potential of other plants may uncover other such treasures. In the past, revenues from plants used for medicine have not been returned in part to the country of origin, but recently a new trend has begun. In one case, a pharmaceutical company agreed to pay people in a South American country a portion of the revenues gained from any native plant providing a marketable drug.

Another potential source of revenue is the placement of videocameras connected to the Internet, which present websites with general information as well as live camera views of wildlife. South African parks have a number of these videocameras placed at water holes, animal dens and other key areas that capture live views of animals transmitted to the Internet for a small viewing fee. This has proven very successful, funding many of the South African National Parks system™s expenses. A similar system could be established in Madagascar with solar-powered videocameras, which have already been in use in Alaska, trained on tree canopies, rainforest flowers or lemurs, along with websites that provide basic information on Madagascar's environment, biodiversity and the Malagasy people. For millions of people who cannot visit Madagascar, such a website might be fascinating as a learning tool for teachers and the public, as well as an exciting view of these unique animals and their environments. If managed in such a way that profits were shared between poor Malagasy to alleviate their poverty, and conservation organizations to preserve biodiversity, such a system has great potential.

A satellite connection with classrooms in the United States or other countries would be another opportunity for interactive communication and learning. In December 2000, for example, students in an American classroom talked with students in a school in Guyana about endangered Giant Otters and their conservation through a visual satellite hookup. Students and others might set up an interactive link with biologists and conservationists working in Madagascar, asking questions and offering help. Students have provided many excellent ideas for conservation, and

classes have raised money to save rainforests and threatened wildlife habitat and to help stop poaching of endangered species in countries half a world away from their own. Malagasy young people might be inspired and enthusiastic through talking with others of their own age about conservation and biodiversity. Video cameras and still cameras might be donated to Malagasy students and young people to record nature and compete for prizes with their results.

Madagascar™s Lessons

Madagascar's story is one of ecological catastrophe and the gradual extermination of its life forms. One's first response might be that its experience is as far from the rest of the world as it is geographically remote. However, it is from the extremes that one acquires basic knowledge. The effects of immigrants, whether human, animal, plant or disease, can devastate natural ecosystems wherever they occur. Islands are especially vulnerable to the effects of invasive species, including humans, because their flora and fauna have limited habitats and tend to be endemic, with small populations.

Exotic or non-indigenous species threaten 350 species of birds, or 30 percent of all threatened birds listed by BirdLife International in *Threatened Birds of the World* (BI 2000). Likewise, 361 plant species and 69 species of mammals listed by the *2000 IUCN Red List of Threatened Species* are threatened as a result of non-indigenous species (Hilton-Taylor 2000). The effects of invasive species, including humans, have been the major cause of extinction of virtually all bird species, almost all of which have occurred on islands. In the case of Madagascar, the Malagasy and other immigrant peoples and their livestock, and their subsequent hunting and habitat destruction, presented the vulnerable native species with threats against which they had no defense. Islands throughout the world continue to suffer losses in biodiversity, as do areas with large numbers of endemic species in mainland areas. Species with restricted ranges are the most likely to go extinct or become endangered. Such species dominate the list of birds in *Threatened Birds of the World* (BI 2000). In this age of international commerce, where plant diseases and other viruses are brought into countries in shiploads of lumber or ballast water, and exotic animals and plants continue to colonize and be released in delicate ecosystems with endemic species, whether on islands or mainlands, it has become extremely difficult to defend native species from such invasions. Nevertheless, through preserving native plants and animals and legislating against such introductions, while removing non-native species, ecosystems and their diversity can be protected. Preserving natural ecosystems is vitally important, not just for wildlife preservation, but for humans as well, so that precious water supplies, topsoils and biological diversity, which stabilize all ecosystems, are protected. These lessons have not yet been put into practice in Madagascar or in many other parts of the world, including developed countries. Ecological and faunal changes may be so gradual that they go unnoticed until ecosystems have been destroyed.

Madagascar Testing Quotes

About 500 A.D., immigrant people from Asia, most probably Indonesia or Malaysia, arrived on Madagascar's shores in hand-hewn canoes, bringing domestic animals with them. They began clearing forests and burning them for farmland, and turned lakes and wetlands into rice paddies. Cleared land produced crops for only a few years until the thin soil became sterile. Farmers then moved on to other parts of the forest, in this slash-and-burn agriculture. At some point, African herdsmen colonized the island, bringing zebu cattle, which crowded out wildlife (Tyson 2000). Gradually, abuse of the land eroded the soil in the central highlands to bare earth, pocketed and gouged by deep gullies and cavernous holes. This region had harbored a great variety of lemurs, along with a wealth of birds, reptiles and unique plants. Throughout the island, wildlife declined as habitats disappeared, isolating animals in smaller and smaller patches of forest and wetlands. The large lemurs, tortoises and elephant birds were avidly hunted.

Within 600 years of the arrival of the Malagasy, extinctions claimed many native animals. Several elephant bird species, the larger lemurs and many native plants vanished. Two kinds of pygmy hippos inhabited the island. The Madagascar Hippopotamuses (*Hippopotamus lemerlei*), an amphibious species, and *Hippopotamus madagascariensis*, a forest species, were both about 6.5 feet long and 2.5 feet tall, smaller than the Common Hippopotamus of Africa, which is about 10 feet long (Tyson 2000). From genetic and anatomical analysis, both seem to have evolved from the latter species (Tyson 2000). The hippos had been widely distributed and very common prior to the arrival of the Malagasy (Dewar 1984). Their bones have been found with marks indicating that they had been butchered (Tyson 2000). Both died out long before Europeans arrived. The native crocodile, whose large bones have been found, is believed by some scientists to represent large specimens of Nile Crocodiles, the species native today (Tyson 2000). It is thus possible that the crocodile survived. A large mongoose-like viverrid, *Cryptoprocta spelea*, and a very unusual aardvark-like animal, *Plesiorycteropus madagascariensis*, died out at an early date (Dewar 1984).

Prior to the arrival of humans, elephant birds had been abundant in most parts of the island, as attested by the prevalence of their bones. There were two genera, and from six to 12 species of these birds (Tyson 2000). It is likely that the flightless birds fell prey to the primitive weapons of the Malagasy and were crowded out of their habitats by livestock (Tyson 2000). The last to die out was the Great Elephant Bird (*Aepyornis maximus*), which may have survived until recent times by retreating to remote swamps. Dr. Alexander Wetmore of the Smithsonian Institution examined bones of a Great Elephant Bird unearthed in archeological excavations in the 1960s. He was amazed by their size: "The incredible femur, or thighbone, of this ponderous bird is by far the largest I have ever seen" (Wetmore 1967). Estimated to weigh at least 1,000 pounds, more than three times the weight of an Ostrich, it produced eggs larger than any dinosaur's, with a capacity of 2 gallons (equivalent to seven Ostrich eggs), 180 chicken eggs or 12,000 hummingbird eggs (Bradbury 1919, Fuller 1987). When one was X•rayed, the bones of an embryo three•fourths developed were revealed (Wetmore 1967). Something had interrupted the embryo's growth and frozen it within the eggshell for hundreds and perhaps thousands of years (Wetmore 1967).

Despite its fearsome size, the Great Elephant Bird lacked a hooked beak for tearing prey and was plainly not a predator (Wetmore 1967). Its large, clawed feet may have helped it defend itself against the small native predators but were not enough to protect it from Malagasy arrows. Its short legs prevented it from running as fast as its relative, the Ostrich, but it may have been quite agile when chased. This vegetarian bird browsed and cropped plants, able to reach with its long neck to the lower branches of trees (Wetmore 1967). By the mid-16th century, when Europeans had managed to establish a foothold in Madagascar, the new French Governor, Sieur Etienne de Flacourt, wrote in 1661 that the Great Elephant Bird was still found in the south of the island, "seeking the most deserted places" to avoid human hunters (Tyson 2000). Villagers of Antandroy told of an Ostrich-like bird that was difficult to catch, according to Flacourt (Tyson 2000).

The exact date this giant bird became extinct is not known with certainty. Alan Feduccia (1996), an eminent paleo-ornithologist, asserts that elephant birds of many species were still widespread in the 10th century but gradually disappeared as a result of human activity. He cites an account by a French merchant sailor in 1848, who visited Madagascar and saw the shell of the Great Elephant Bird; he was told that it belonged to the chief and that the bird that produced such eggs "is still more rarely seen" (Feduccia 1996). Some authorities estimate that it died out in the mid-17th century, although there is no proof that any European ever saw one of these birds (Tyson 2000). It has been suggested that Europeans were responsible for the bird™s extinction by hunting and destroying its habitat (Quammen 1996). But Thomas Brooks (2000) of the Center for Applied Biodiversity Science, Conservation International, asserted in a list of extinct birds in *Threatened Birds of the World* (BI 2000) that all the elephant birds had disappeared by 1500. In a bizarre footnote to this species' epitaph, an *Aepyornis* egg washed up on Australia's western coast in 1995. No conclusive explanation for this strange event has been put forth, although it is likely that it became unearthed from long interment by rains, and washed out to sea. Much less is known of the other species of elephant birds, which existed in a variety of sizes down to a chicken-sized species.

Lemur-like primates once lived on many continents, but nowhere had they evolved into such a great variety of species. When the Malagasy people arrived some 1,500 years ago, lemurs occupied every habitat, even marshland. A

species as tall as a man must have startled the Malagasy immigrants, giving rise to legends that these animals had superhuman powers. The first French naturalists were told by the Malagasy that these primates were thought to be the ghosts of sacred ancestors of man, inspiring the genus name Lemur, the word for ghost in Latin. The Malagasy considered some lemurs sacred and punished anyone who harmed them, but most species were feared as evil demons and were killed on sight.

From their arrival on Madagascar, the Malagasy hunted the larger species of lemurs, almost all of which are now extinct. Archaeological excavations show that they formed a staple in the immigrants' diets. Such diggings have unearthed the skulls and bones of long•extinct lemurs in early Malagasy jars and kitchen middens; their heads had been split by ax-heads made from an extinct flightless bird (Jolly 1980).

In the centuries following colonization by the Malagasy immigrants, some 15 species of lemurs of eight genera became extinct (Mittermeier 1997). These extinct lemurs were, for the most part, far larger than surviving species and had evolved to fill many ecological niches. Three *Megaladapis* lemurs weighed between 90 and 170 pounds and moved slowly through the trees, feeding on foliage (Tattersall 1993). Another species, *Archaeolemur*, was about the size of a female baboon and lived on the ground (Tattersall 1993). Two *Palaeopropithecus* species weighed between 90 and 130 pounds and were sloth•like tree dwellers with flexible bodies (Tattersall 1993). These extinct lemurs had evolved many unusual means of movement and locomotion that have no parallels in living species of lemurs.

Largest of all, the massive 400•pound *Archaeoindris* was apparently a ground•dweller, moving on all fours; many of its anatomical characteristics are unlike any living primate (Tattersall 1993). One entire lemur family, Archaeolemuridae, was obliterated. In this family were many species of lemurs weighing between 35 and 55 pounds; they were powerfully built and short•legged (Tattersall 1993). The heaviest lemur surviving today, the Indri (*Indri indri*), weighs only about 15 pounds (Tattersall 1993). These lemurs had survived for millions of years, and their extinctions were indeed a major biological loss to the planet. According to primatologists, the surviving lemurs resemble the very earliest primates from the Eocene (Tattersall 1993). Like prosimians in Africa and Asia, but to a far greater degree, lemurs have a highly developed sense of smell. Some species have long, fox-like noses (Preston-Mafham 1991). Genetic analysis of their DNA has revealed that all lemurs are descended from a single ancestor that probably arrived from Africa about 60 million years ago (Garbutt 1999).

The Giant Aye-aye (*Daubentonia robusta*) lemur was somewhat larger and 2.5 to 5 times heavier than the surviving Aye-aye (see below), but in other respects was very similar (Garbutt 1999). It is known from subfossil remains found in southwestern Madagascar (Nowak 1999). The date of its disappearance is unknown but may be fairly recent.

Archaeologists have uncovered remains of a massive bird of prey, the Malagasy Crowned Eagle (*Stephanoaetus mahery*), which undoubtedly preyed on lemurs (Feduccia 1996). In fact, at one locality the diet of this eagle, based on the bones of eagles and lemurs found together, contained at least 80 percent primates, including specimens weighing up to 26.5 pounds (Feduccia 1996). Remains of another large eagle of the genus *Aquila* have been discovered, and it, too, preyed on large lemurs and became extinct after the arrival of the Malagasy. These extinct birds preyed on smaller lemurs as well, including some species still surviving (Feduccia 1996). A bird of prey flying overhead still elicits fear in lemurs, causing them to seek cover. Neither of the two remaining species of eagles on Madagascar preys on lemurs, but two hawk species have been seen preying on young lemurs (Garbutt 1999).

In addition to the Giant Elephant Bird, the large Snail-eating Coua (*Coua delalandei*), a member of the cuckoo family, became extinct. The last specimen of this large, slate-blue bird was taken on an islet off the east coast, Ile Sainte-Marie, in 1834 (Morris and Hawkins 1998); reports by observers who claimed to have seen the bird were recorded as late as 1930 (Fuller 1987). The causes of this bird's disappearance, and even its exact range, remain obscure (Langrand 1990). Many specimens of this bird were taken before its extinction and kept in museums in Leiden; London; New York; Paris; Philadelphia; Tananarive (Madagascar); and Cambridge (Massachusetts) (Fuller 1987). The long feathers of this bird were highly valued by the Malagasy, and hunting may have reduced its numbers to a critically low level (Fuller 1987). It is also possible that the many birds killed for zoological specimens may have

pushed this already rare bird to extinction, since its distribution may have been limited to the tiny Ile Sainte-Marie. No reliable record exists of its presence on the main island of Madagascar, but there is hope that it might be found in lowland forest near the Bay of Antongil (Morris and Hawkins 1998). Ten closely related species of couas survive, all smaller than the Snail-eating Coua.

Madagascar Testing Quotes 2
Testing "quotes again" to see whether they are "going" to have 'slashes' added to them or not.

Madagascar and other Islands

Madagascar

Imagine an island more than 1,000 miles long in a blue tropical ocean. Forests cover vast areas, interspersed with swamps where crocodiles 8 meters long lie in wait to prey on pygmy hippopotamuses. Thousands of giant tortoises with shells 4 feet across lumber about. In the forests and in dryer parts of the island live some of the strangest primates to have ever existed on Earth. Some 45 species of these lemurs live throughout the island and range in size from the world's smallest primate, weighing about 1 ounce, to a lemur the size of a Gorilla (Tattersall 1993).

Huge white birds plod along forest trails and through savannah grasses. Many kinds of these birds inhabit the island. The largest resembles an Ostrich, but is far more massive in build, weighing 1,000 pounds (Feduccia 1996). It stands 10 feet tall and lays 20-pound eggs, 13 inches long (Feduccia 1996, Greenway 1967). More than 100 other kinds of tropical birds that exist nowhere else fly in forests and deserts and wade in still marshes.

Primitive hedgehog-like mammals, called tenrecs, scurry in forest underbrush. One type of tenrec lives in cold mountain streams, swimming with webbed feet and flattened tail, while another has spines like a porcupine and stripes down its back like a skunk. It communicates with its young by vibrating its spines.

Hundreds of kinds of amphibians and reptiles inhabit forests, aquatic environments, savannahs and drylands. Frogs of every imaginable color and pattern leap in green shadows. Chameleons, some brilliantly colored, and others shades of mottled brown, creep invisibly about. The largest, 2 feet long, can capture mice and birds, while the smallest, measuring only 1.5 inches, feeds on insects (Amos 1980). Tortoises with shells adorned in delicate yellow sunburst patterns inhabit shrub and deserts.

Plants exist in unparalleled variety, a botanical paradise. Relicts of species long-extinct on mainland areas--tall tree ferns, palms, red-flowered flame trees, massive deciduous and rainforest trees, giant tamarinds and aloes, desert oddities, and baobabs of many sizes--grow in even the driest parts of the island. Orchids in a rainbow of colors bloom among the deep green rainforests. Waterfalls abound, cascading down tall cliffs into rivers and lakes. Along the west coast, a dry deciduous forest stretches the length of the island**.** The central highlands are a mosaic of woodland and savannah, while the eastern regions are covered in dense, humid rainforest. In the extreme south, a desert environment prevails, harboring *Didierea*, strange cactus-resembling plants that form long, spiny, twisted shafts rising 30 feet into the air. An impenetrable wilderness of limestone spikes and sharp rocks dominates the far north. Rare birds and lemurs find refuge in this craggy landscape and feed in oases watered by meandering streams.

Flightlessness, fearlessness, gigantism, dwarfism, and survival of ancient species all occurred in this evolutionary laboratory. That such a large land mass went uninhabited by humans for so long is truly remarkable. Nowhere else on the planet has such a large land area remained isolated for such a prolonged period, allowing a flowering of diverse

life forms to flourish and adapt to the island's many habitats and terrains in this mild, tropical climate. Such is the history of the island from Madagascar in 400 A.D., a century before the arrival of the Malagasy people of Asia. Had humans reached Madagascar earlier, it might not have evolved its diverse, yet vulnerable, fauna and flora.

How such an extraordinary diversity of animals and plants inhabits Madagascar is tied to its geological history. Some 160 million years ago, when Africa, Australia, New Zealand and South America were united in the super-continent Gondwana, Madagascar was attached to eastern Africa and what is now peninsular India. Dinosaurs, giant turtles, crocodiles, primitive mammals, reptilian birds and lizards roamed on this massive land mass. Gondwana gradually broke apart as a result of movements of tectonic plates covering the Earth's crust. For many millions of years, India and Madagascar formed a mini-continent. Then, about 88 million years ago, they split along Madagascar's east coast, and peninsular India moved northward toward Asia (Garbutt 1999, Tyson 2000). Paleontologists have only recently discovered that Madagascar was home to dinosaurs and other primitive animals quite unlike those found in other parts of the world. The oldest known species of dinosaur, dating back 227 million years, may be the ancestor of all dinosaurs (Flynn 2000). One dinosaur had teeth that were clove-shaped (Stenzelt and Thiessen 2000). Seven species of crocodiles inhabited Madagascar from the Cretaceous period onward, including a pug-nosed vegetarian species (Flynn 2000). About 65 million years ago, the last dinosaurs died out, concurrent with their extinction throughout the world. Some native plants and animals survived from the time when Madagascar was part of Gondwana. Giant tortoises, crocodiles, boas, tenrec ancestors and possibly an early form of elephant birds may have lived on the super-continent, although most ornithologists are certain that the ancestor of the elephant bird flew to the island and became flightless (Feduccia 1996). Plants of many kinds, virtually unchanged from their ancient forms, grow on the island.

Immigrant animals arrived during the millennia from many sources. Because Madagascar separated from India and Gondwana long before the evolution of the prosimians that were the ancestors of the lemurs, these primates must have come from mainland Africa, where their close relatives, bush babies and galagos, survive today. Some scientists believe they might have traveled over a land connection that existed between Africa and Madagascar at some point (Tyson 2000). Others dispute that there ever was such a land bridge and maintain that they arrived by sea, perhaps sheltering on large mats of floating vegetation or clinging to uprooted tree trunks that swept down mainland rivers to the sea and washed up on Madagascar's shores. Few modern mammals of Africa, whether baboons, monkeys, gazelles, antelope or other hoofed mammals, reached Madagascar. The hippopotamuses must have originated in Africa, but how they came to the island is another mystery.

Over many millennia, a blossoming of evolution occurred in this mild, tropical climate of Gondwandan and immigrant species, radiating into entire new families and creating a flora and fauna of great diversity unlike any in the world. Birds, bats and insects flew or were blown to the island by wind currents and storms from Africa and Asia. No large carnivores arrived, however. The largest mammal predators are relatives of mongooses, primitive viverrids. Grazing and browsing roles were filled by hippopotamuses, land tortoises, lemurs and elephant birds.

Human Settlers Invade Paradise

About 500 A.D., immigrant people from Asia, most probably Indonesia or Malaysia, arrived on Madagascar's shores in hand-hewn canoes, bringing domestic animals with them. They began clearing forests and burning them for farmland, and turned lakes and wetlands into rice paddies. Cleared land produced crops for only a few years until the thin soil became sterile. Farmers then moved on to other parts of the forest, in this slash-and-burn agriculture. At some point, African herdsmen colonized the island, bringing zebu cattle, which crowded out wildlife (Tyson 2000). Gradually, abuse of the land eroded the soil in the central highlands to bare earth, pocketed and gouged by deep gullies and cavernous holes. This region had harbored a great variety of lemurs, along with a wealth of birds, reptiles

and unique plants. Throughout the island, wildlife declined as habitats disappeared, isolating animals in smaller and smaller patches of forest and wetlands. The large lemurs, tortoises and elephant birds were avidly hunted.

Within 600 years of the arrival of the Malagasy, extinctions claimed many native animals. Several elephant bird species, the larger lemurs and many native plants vanished. Two kinds of pygmy hippos inhabited the island. The Madagascar Hippopotamuses (*Hippopotamus lemerlei*), an amphibious species, and *Hippopotamus madagascariensis*, a forest species, were both about 6.5 feet long and 2.5 feet tall, smaller than the Common Hippopotamus of Africa, which is about 10 feet long (Tyson 2000). From genetic and anatomical analysis, both seem to have evolved from the latter species (Tyson 2000). The hippos had been widely distributed and very common prior to the arrival of the Malagasy (Dewar 1984). Their bones have been found with marks indicating that they had been butchered (Tyson 2000). Both died out long before Europeans arrived. The native crocodile, whose large bones have been found, is believed by some scientists to represent large specimens of Nile Crocodiles, the species native today (Tyson 2000). It is thus possible that the crocodile survived. A large mongoose-like viverrid, *Cryptoprocta spelea*, and a very unusual aardvark-like animal, *Plesiorycteropus madagascariensis*, died out at an early date (Dewar 1984).

Prior to the arrival of humans, elephant birds had been abundant in most parts of the island, as attested by the prevalence of their bones. There were two genera, and from six to 12 species of these birds (Tyson 2000). It is likely that the flightless birds fell prey to the primitive weapons of the Malagasy and were crowded out of their habitats by livestock (Tyson 2000). The last to die out was the Great Elephant Bird (*Aepyornis maximus*), which may have survived until recent times by retreating to remote swamps. Dr. Alexander Wetmore of the Smithsonian Institution examined bones of a Great Elephant Bird unearthed in archeological excavations in the 1960s. He was amazed by their size: "The incredible femur, or thighbone, of this ponderous bird is by far the largest I have ever seen" (Wetmore 1967). Estimated to weigh at least 1,000 pounds, more than three times the weight of an Ostrich, it produced eggs larger than any dinosaur's, with a capacity of 2 gallons (equivalent to seven Ostrich eggs), 180 chicken eggs or 12,000 hummingbird eggs (Bradbury 1919, Fuller 1987). When one was X•rayed, the bones of an embryo three•fourths developed were revealed (Wetmore 1967). Something had interrupted the embryo's growth and frozen it within the eggshell for hundreds and perhaps thousands of years (Wetmore 1967).

Despite its fearsome size, the Great Elephant Bird lacked a hooked beak for tearing prey and was plainly not a predator (Wetmore 1967). Its large, clawed feet may have helped it defend itself against the small native predators but were not enough to protect it from Malagasy arrows. Its short legs prevented it from running as fast as its relative, the Ostrich, but it may have been quite agile when chased. This vegetarian bird browsed and cropped plants, able to reach with its long neck to the lower branches of trees (Wetmore 1967). By the mid-16th century, when Europeans had managed to establish a foothold in Madagascar, the new French Governor, Sieur Etienne de Flacourt, wrote in 1661 that the Great Elephant Bird was still found in the south of the island, "seeking the most deserted places" to avoid human hunters (Tyson 2000). Villagers of Antandroy told of an Ostrich-like bird that was difficult to catch, according to Flacourt (Tyson 2000).

The exact date this giant bird became extinct is not known with certainty. Alan Feduccia (1996), an eminent paleo-ornithologist, asserts that elephant birds of many species were still widespread in the 10th century but gradually disappeared as a result of human activity. He cites an account by a French merchant sailor in 1848, who visited Madagascar and saw the shell of the Great Elephant Bird; he was told that it belonged to the chief and that the bird that produced such eggs "is still more rarely seen" (Feduccia 1996). Some authorities estimate that it died out in the mid-17th century, although there is no proof that any European ever saw one of these birds (Tyson 2000). It has been suggested that Europeans were responsible for the bird™s extinction by hunting and destroying its habitat (Quammen 1996). But Thomas Brooks (2000) of the Center for Applied Biodiversity Science, Conservation International, asserted in a list of extinct birds in *Threatened Birds of the World* (BI 2000) that all the elephant birds had disappeared by 1500. In a bizarre footnote to this species' epitaph, an *Aepyornis* egg washed up on Australia's western coast in 1995. No conclusive explanation for this strange event has been put forth, although it is likely that it became unearthed from long interment by rains, and washed out to sea. Much less is known of the other species of elephant birds, which existed in a variety of sizes down to a chicken-sized species.

Lemur-like primates once lived on many continents, but nowhere had they evolved into such a great variety of species. When the Malagasy people arrived some 1,500 years ago, lemurs occupied every habitat, even marshland. A species as tall as a man must have startled the Malagasy immigrants, giving rise to legends that these animals had superhuman powers. The first French naturalists were told by the Malagasy that these primates were thought to be the ghosts of sacred ancestors of man, inspiring the genus name Lemur, the word for ghost in Latin. The Malagasy considered some lemurs sacred and punished anyone who harmed them, but most species were feared as evil demons and were killed on sight.

From their arrival on Madagascar, the Malagasy hunted the larger species of lemurs, almost all of which are now extinct. Archaeological excavations show that they formed a staple in the immigrants' diets. Such diggings have unearthed the skulls and bones of long•extinct lemurs in early Malagasy jars and kitchen middens; their heads had been split by ax-heads made from an extinct flightless bird (Jolly 1980).

In the centuries following colonization by the Malagasy immigrants, some 15 species of lemurs of eight genera became extinct (Mittermeier 1997). These extinct lemurs were, for the most part, far larger than surviving species and had evolved to fill many ecological niches. Three *Megaladapis* lemurs weighed between 90 and 170 pounds and moved slowly through the trees, feeding on foliage (Tattersall 1993). Another species, *Archaeolemur*, was about the size of a female baboon and lived on the ground (Tattersall 1993). Two *Palaeopropithecus* species weighed between 90 and 130 pounds and were sloth•like tree dwellers with flexible bodies (Tattersall 1993). These extinct lemurs had evolved many unusual means of movement and locomotion that have no parallels in living species of lemurs.

Largest of all, the massive 400•pound *Archaeoindris* was apparently a ground•dweller, moving on all fours; many of its anatomical characteristics are unlike any living primate (Tattersall 1993). One entire lemur family, Archaeolemuridae, was obliterated. In this family were many species of lemurs weighing between 35 and 55 pounds; they were powerfully built and short•legged (Tattersall 1993). The heaviest lemur surviving today, the Indri (*Indri indri*), weighs only about 15 pounds (Tattersall 1993). These lemurs had survived for millions of years, and their extinctions were indeed a major biological loss to the planet. According to primatologists, the surviving lemurs resemble the very earliest primates from the Eocene (Tattersall 1993). Like prosimians in Africa and Asia, but to a far greater degree, lemurs have a highly developed sense of smell. Some species have long, fox-like noses (Preston-Mafham 1991). Genetic analysis of their DNA has revealed that all lemurs are descended from a single ancestor that probably arrived from Africa about 60 million years ago (Garbutt 1999).

The Giant Aye-aye (*Daubentonia robusta*) lemur was somewhat larger and 2.5 to 5 times heavier than the surviving Aye-aye (see below), but in other respects was very similar (Garbutt 1999). It is known from subfossil remains found in southwestern Madagascar (Nowak 1999). The date of its disappearance is unknown but may be fairly recent.

Archaeologists have uncovered remains of a massive bird of prey, the Malagasy Crowned Eagle (*Stephanoaetus mahery*), which undoubtedly preyed on lemurs (Feduccia 1996). In fact, at one locality the diet of this eagle, based on the bones of eagles and lemurs found together, contained at least 80 percent primates, including specimens weighing up to 26.5 pounds (Feduccia 1996). Remains of another large eagle of the genus *Aquila* have been discovered, and it, too, preyed on large lemurs and became extinct after the arrival of the Malagasy. These extinct birds preyed on smaller lemurs as well, including some species still surviving (Feduccia 1996). A bird of prey flying overhead still elicits fear in lemurs, causing them to seek cover. Neither of the two remaining species of eagles on Madagascar preys on lemurs, but two hawk species have been seen preying on young lemurs (Garbutt 1999).

In addition to the Giant Elephant Bird, the large Snail-eating Coua (*Coua delalandei*), a member of the cuckoo family, became extinct. The last specimen of this large, slate-blue bird was taken on an islet off the east coast, Ile Sainte-Marie, in 1834 (Morris and Hawkins 1998); reports by observers who claimed to have seen the bird were recorded as late as 1930 (Fuller 1987). The causes of this bird's disappearance, and even its exact range, remain obscure (Langrand 1990). Many specimens of this bird were taken before its extinction and kept in museums in

Leiden; London; New York; Paris; Philadelphia; Tananarive (Madagascar); and Cambridge (Massachusetts) (Fuller 1987). The long feathers of this bird were highly valued by the Malagasy, and hunting may have reduced its numbers to a critically low level (Fuller 1987). It is also possible that the many birds killed for zoological specimens may have pushed this already rare bird to extinction, since its distribution may have been limited to the tiny Ile Sainte-Marie. No reliable record exists of its presence on the main island of Madagascar, but there is hope that it might be found in lowland forest near the Bay of Antongil (Morris and Hawkins 1998). Ten closely related species of couas survive, all smaller than the Snail-eating Coua.

The Biological Wealth of an Impoverished Country

The Madagascar of today is still a remarkable place, although about 90 percent of the forests, including almost all lowland rainforests that were richest in wildlife, were destroyed (Mittermeier *et al.* 1999). Some 33 lemur species survive, along with all but one species of tenrec, various mongooses and their relatives, more chameleons than any other country, several hundred kinds of frogs and reptiles, and thousands of endemic invertebrates and plants. Madagascar has no native fish, but many introduced species. Its fauna and flora represent many extremely unusual and unique examples of evolution (Mittermeier *et al.* 1999). This island is considered one of the five most biologically important areas in the world; its primates are the world's highest priority for conservation (Mittermeier *et al.* 1999).

The Biological Wealth of an Impoverished Country: Forests and Plants

Madagascar has one of the richest floras in the world. Eighty percent of its plants are found nowhere else (McNeely *et al.* 1990, Preston-Mafham 1991). The diversity of plants that survived almost 2,000 years of forest destruction continues to astound biologists and conservationists. Tropical trees with fruit growing on their trunks (various species of the genus *Tambourissa*) are native, as is a cactus (*Rhipsalis*), related to American species, that lives in the rainforest. A tree, *Symphonia*, which has leathery leaves and red-and-white striped flowers that look like peppermint candies (Morell 1999), also survives. The Flame Tree (*Delonix regia*), which produces cascades of red flowers, is grown around the world for its beauty, but few realize that it originated in Madagascar (Preston-Mafham 1991). Miraculously, many endemic plants have survived the fires and tree cutting that have destroyed much of the island. One mountain chain has 150 endemic vascular plants, a very high number (Preston-Mafham 1991). They are among the 7,300 to 12,000 species of plants native to Madagascar (Preston-Mafham 1991). Its flowering plants make up 20 percent of all the plants in the African region (McNeely 1990). At least 191 botanical families, a very large number for a relatively small area, evolved from ancestor species (Preston-Mafham 1991).

Some 2,000 years ago, the eastern rainforest stretched in a band 100 miles wide from north to south, covering 27 million acres (Tyson 2000). Ninety percent of the plants were endemic, with a profusion of unusual ferns, some types growing on tree trunks; wild ginger, with delicate purple flowers; bamboos; and far more orchids than in an African rainforest (Preston-Mafham 1991). An early traveler described the woods as so dense that there was a fideep gloom: below the canopy at mid-day (Tyson 2000). Rainfall must have been greater and general climate more humid than at present as a result of these extensive rainforests. In the montane ridges, huge tree ferns, mosses and lichens cover the ground and hang from tree branches (Preston-Mafham 1991). Over the centuries, Malagasy burned many portions of

the rainforest, especially in the south. Few tall trees remain in the rainforest today, although at one time there must have been many giants. During the 19th century, a palace was built for a woman ruler, centering on a 130-foot tree that had been carried by 5,000 laborers from the eastern rainforest (Tyson 2000). The palace was destroyed by an uprising in the 1850s. About this time, Malagasy dragged a tombstone through the forest, cutting 25,000 trees just to make a path (Tyson 2000). Early decrees banned cutting of virgin forest, with severe penalties, in the 19th century, but these were largely ignored (Tyson 2000).

About half of the island's forests had been cut by the late 19th century, and intensive cutting continued in the 20th century (Tyson 2000). The prime lowland forests throughout the island and three-fourths of the rainforest were cleared by the French for growing coffee and other crops in the first three decades of the century (Tyson 2000). The rainforest was heavily logged between 1950 and 1985, with 275,000 acres cleared and burned each year (Tyson 2000). The northeast Masoala Peninsula still retains sizeable areas of unlogged rainforest, but the southern region has been reduced to fragments of the original unbroken expanses. The remnants tend to be on sharp ridges where soil is poor and access difficult. For example, Ranomafana, a recently declared national park, straddles such an escarpment. Even so, many of its trees had been removed prior to its protection (Tyson 2000). What was once a closed-canopy, humid rainforest is now far dryer and cooler, with many openings among the trees, and some illegal logging continues (Tyson 2000). Still, botanists from the Missouri Botanical Garden, who were conducting a census of the trees in this park, counted 37 families of trees with 105 species in a 1-hectare plot (Tyson 2000). Outside the park's boundaries, rainforest is still being cleared and burned by the Malagasy, many of whom believe that their wealth lies in the amount of land they clear (Morell 1999).

The western dry, deciduous forest lies in the shadow of eastern mountains, which block moist ocean air currents (Preston-Mafham 1991). Trees do not attain heights of more than 80 feet, but many types of plants have adapted to this environment. Liana vines grow among the trees, and dead leaves carpet the forest floor. Large tamarind trees grow along rivers, and baobabs grow in plateaus (Preston-Mafham 1991). Beautiful orange bell flowers of the *Ipomoea carnea* plant burst into bloom during the short rainy season. As with the eastern rainforests, the once continuous stretches of deciduous forests have been largely destroyed, replaced by grasses able to survive in the eroded or bare soil.

Throughout the island, most deforested areas fail to regenerate into second-growth forests, even when left fallow, because Madagascar lacks vigorous colonizing trees that can quickly protect cleared ground and prevent further erosion (Preston-Mafham 2000). Cleared hillsides become covered in non-native grasses and exotic South American trees (*Psidium cattleyanum* and *Psidium guajava*) or plantations of eucalyptus, which inhibit the establishment of native seedlings (Preston-Mafham 1991; Sayer *et al.* 1992). Only if soils are rich and remnants of original forest are nearby will native forests regenerate. Unfortunately, the original forests and their native wildlife are lost permanently, and even regeneration cannot take place without a cessation of the slash-and-burn cycle, known as fitavyfl by the Malagasy (Preston-Mafham 1991). Moreover, foreign logging companies have obtained logging concessions on most of the unprotected remnants of native forest. Tree cutting consumes some 7.8 million cubic meters of wood per year, of which 7 million cubic meters is for fuel and charcoal (Sayer *et al.* 1992). Valuable timber trees have been logged to extinction in most of Madagascar. The two native species of ebony trees of the genus *Diospyros* have been heavily logged for centuries, and few large trees are left (Sayer *et al.* 1992). The understory plants, such as tree ferns, are also exploited, dug up to sell as potted plants (Sayer *et al.* 1992).

The net result of this logging and burning, especially in the barren central highlands, is the loss of "a priceless reservoir of plant and animal species, replaced by one of the most impoverished forms of vegetation on the planet" (Preston-Mafham 1991). Many species of trees and other plants are highly endangered. Madagascar is one of the world's 12 "hot spot" areas of tropical forests, having a high percentage of endemic species which are under great threat (McNeely *et al.* 1990). Since an estimated 94 percent of Madagascar's trees are endemic, and many occupy very restricted ranges, they are highly vulnerable to extinction. Further research will likely reveal even more threatened species. Some authorities believe that even this rich plant diversity must represent only a fraction of the "vast original flora," since 80 percent of the vegetation and forests is gone (Ayensu *et al.* 1984). The *1997 IUCN Red*

List of Threatened Plants includes 19 species of plants that may have recently become extinct, and an additional 287 species that are threatened with extinction (Walter and Gillett 1998).

Resident since the days of the dinosaurs, trees of a family of primitive pines, Podocarpaceae, grow on the island. The family is represented by species in other parts of the world that were part of Gondwana, from South America west to Southeast Asia. Madagascar has a number of native Podocarps, of which four endemic species or varieties are listed by the *IUCN Red List* as either Vulnerable or Rare (Walter and Gillett 1998). At least 26 genera of plants are native to Madagascar and South America, but not to Africa, and are believed to be remnants from Gondwana (Preston-Mafham 1991). Another one of these, Madagascar's national tree, the Traveller's Tree (*Ravenala madagascariensis*), is a palm-like species of the banana family (Musaceae). Its closest relative of the same genus grows in Brazil and Guiana, but not in Africa (Preston-Mafham 1991). This tree has leathery petals covering its pollen and nectar and is a key food source for both bats and lemurs. In return, it depends on lemurs for pollination. Lemurs feed on the nectar, getting their noses covered with pollen in the process. They are so fond of the nectar that they travel miles to find another Traveller's Tree, still carrying the nectar on their noses and, unknowingly, pollinate the next tree they feed on (Attenborough 1995).

A plant of the Winteraceae family that has been growing on the island for 30 million years was recently seen again after a period of 90 years (Hsu 1997). This tree, *Takhtajania perrieri*, has many primitive features, such as a lack of vessels to move water and minerals; like many of Madagascar's relict species, it once grew on much of continental Africa, but long ago disappeared there (Hsu 1997).

Madagascar has more palms (Palmae family) than all of Africa (Preston-Mafham 1991). Many are in danger, however. The *IUCN Red List of Threatened Plants* lists 148 native species in various categories (Walter and Gillett 1998). The Big-leaf Palm (*Marojeya darianii*) was chosen by the Species Survival Committee of the IUCN to be one of 12 critically endangered species highlighted at its 1988 General Assembly in Costa Rica. This species was only discovered in 1982 and is confined to a single swamp in the northeast (Prance 1990). An agricultural program to raise rice cleared half its habitat, and then failed. This huge-leafed palm has been over-harvested as a source of heart-of-palm, a commercially valuable product (Prance 1990). Huge palms are felled for their inner pith to supply this gourmet market. The majority of palms grow in the eastern rainforests in a great diversity of size. Two threatened palms, *Dypsis hildebrandtii* and *Dypsis louvelii*, are miniature delicate-fronded palms only 3 feet high (Preston-Mafham 1991). Others, like the threatened *Ravenea glauca*, are majestic giants with long, straight trunks rising 50 feet or more to a luxuriant crown. Palms do not often survive the fires set by the Malagasy to clear land, disappearing from one area after another (Preston-Mafham 1991).

On the entire continent of Africa, only one species of baobab tree is native, while seven species are found in Madagascar (Preston-Mafham 1991). These strange-looking trees have wide trunks that taper to a narrow crown, looking like upside-down trees. Some baobabs grow to immense size. One famous specimen measures 46 feet around the base of the trunk (Preston-Mafham 1991). Another species, *Alluaudia ascendens*, grows in the southern desert. Although it can reach a maximum height of 16 feet, it is usually far smaller (Preston-Mafham 1991). Each of the seven species has a slightly different shape and size, but all have gray bark that resembles unwrinkled elephant skin. Baobabs are extremely important to both wildlife and humans. The Malagasy cut holes in their massive trunks and hollow out the spongy pith where water accumulates. In the dry south, these trees become wells, and villagers set ladders against the trunks, climb to the hole cut from the trunk, and lower buckets into the pool of water. Natural holes in baobob trunks and branches provide important nesting holes for birds and lemurs. These trees are fire-resistant, and fortunately, they are worthless as timber because of their soft, pulpy cores. For this reason some stands of thousands of huge, very old baobabs remain in parts of the island. Because of the heavy livestock grazing, few young baobab seedlings can survive, however, and botanists believe that the spectacular vistas of these behemoths will gradually disappear (Preston-Mafham 1991).

One very strange group of Madagascan plants native to dry areas has nine species in the same genus, *Pachypodium*. These succulent plants lose their leaves at the onset of the dry season and have evolved into a variety

of forms, all with gray, smooth bark. Eight of the nine species are threatened with extinction, according to the *IUCN Red List of Threatened Plants* (Walter and Gillett 1998). One of these, the endangered *Pachypodium decaryi*, is native to Antananarivo, the "tsingy" limestone crags of the northwest. Its smooth, silvery trunk resembles a large inverted turnip, fat at the base and tapering upward, topped by a messy mop of thin, straggly branches (Preston-Mafham 1991). It bears large, white flowers during the dry season. Its main population occurs in the Ankarana Special Reserve, which bans burning (Preston-Mafham 1991), but has recently been invaded by hordes of miners who are clearing vegetation to search for sapphires (Morell 1999). Other Pachypodiums have equally bizarre shapes, such as the bulbous *Pachypodium rosulatum*, which resembles a huge gourd sprouting long, thin shafts from which its bright yellow flower bloom. The rare *Pachypodium densiflorum*, with the appearance of a domestic jade plant run amok, has a mass of short, gray branches sprouting from a squat gray base. All these plants are highly susceptible to fire. Ken Preston-Mafham, in *Madagascar: A Natural History*, describes the threat of "incessant brush fires which ravage the length and breadth of central Madagascar during the dry season. Within hours, hillsides which had been decorated with colorful rock gardens of rare succulents are converted into graveyards of charred embers." These brush fires have been intentionally set by Malagasy to improve grazing land for their cattle or clear land. Another threat to Pachypodia is collectors who tear specimens, especially bizarre forms, from mountain slopes (Preston-Mafham 1991). Few species are protected in reserves. Without strong conservation programs, these fascinating plants could easily disappear.

Other strange trees of the southern spiny desert include the Octopus Tree (*Didierea madagascariensis*), a member of an endemic family of 11 cactus-like species, Didiereaceae. This tree has no trunk, but a bouquet-like grouping of stems covered in long, needle-sharp spines that branch out in odd, twisted shapes. Although resembling cacti, this family has no close relatives anywhere in the world (Preston-Mafham 1991). Another member of the family, *Alluaudia procera*, has a thick trunk with very long spines that grow in curving rows upward, and small, rounded leaves along its branches. In spite of this, several lemur species are able to leap onto these plants without hurting themselves (Preston-Mafham 1991). Three species in this family, all of the *Alluaudia* genus, are Rare, according to the IUCN (Walter and Gillett 1998). One of these, *Alluaudia montagnacii*, has tall, solitary tapering stems ending in a tuft of flowers.

The discovery of the medicinal effects of the endemic Rosy Periwinkle (*Catharanthus roseus*) has saved thousands of human lives. Two potent alkaloid compounds found in this plant have proven effective in the treatment of Hodgkin™s' Disease, producing a 99 percent remission in patients with acute lymphocytic leukemia (Myers 1983). It also contains 75 different alkaloids, which could produce commercial substances (Preston-Mafham 1991). Fortunately, the Rosy Periwinkle is easy to propagate, grown in greenhouses around the world. Ongoing research is uncovering other Madagascan plants of medicinal value. Samples of plants are being tested in laboratories, and elderly Malagasy healers are being consulted. More than 50 species of wild coffee (*Coffea* spp.) grow in the island's eastern rainforests, providing an important genetic base for hybridizing with other strains because of their insect-resistance and low level of caffeine (Preston-Mafham 1991). These plants are symbolic of the great botanical wealth at risk.

The Biological Wealth of an Impoverished Country: Mammals

Home to some of the world's most fascinating, beautiful and curious mammals, Madagascar has approximately 117 native species, 90 percent of which exist nowhere else (Garbutt 1999). Excluding bats, all 88 native terrestrial mammals are endemic to Madagascar. Three-fourths of native mammals, or 66 species, are threatened with extinction; 49 of these are in higher categories of threat listed in the *2000 IUCN Red List of Threatened Species*. This represents 42 percent of all mammals found in Madagascar, by far the greatest percentage of threatened mammals of any country in the world (Hilton-Taylor 2000). As new species of mammals continue to be discovered, the numbers that are threatened continues to rise. A few have not been seen in the wild since their discovery. The majority is made of

forest-dwellers, and a few inhabit marshy areas or woodland streams. The loss of forest, predation on them by Malagasy and domestic dogs, and introduction of exotic species of mammals that out-compete native species are combining to push many of the island's mammals toward extinction.

The Biological Wealth of an Impoverished Country: Mammals: Page 1

The publication of *Mammals of Madagascar*, by Nick Garbutt, in 1999 filled a void for a complete guide to all native mammals, illustrated with color photos of most species and major habitats. This supplemented *Madascar: A Natural History* in 1991, an important reference on mammals and their environment. Conservation work has focused mainly on lemurs, with many organizations involved, including Earthwatch Institute, which sponsors field research; Conservation International; Jersey Wildlife Preservation Trust (based in England); and CARE. Several of these groups sponsored biodiversity studies and helped establish national parks, benefiting thousands of species, including tenrecs and other native mammals. A growing number of Malagasy zoologists are taking part in studies and conservation work, and new programs have been initiated to help local people while conserving mammals and their environments. Certain mammals have received inadequate attention to date, notably bats, rodents and some viverrids, who will undoubtedly benefit from the swell of interest and enthusiasm for Madagascar fauna that has developed in recent years. Filmmakers have recently produced a number of excellent wildlife documentaries, photographing rare species and spreading knowledge and concern about endangered mammals (see Video section).

Among Madagascar's mammals are many primitive forms. The tenrecs' closest relatives are insectivores known as solenodons, native to Cuba, Hispaniola and other vestiges of Gondwana in the Caribbean. Tenrecs and solenodons may have had a common ancestor living on the supercontinent, progenitor of all mammals. The remains of similar species have been found in Africa and South America, indicating that they were once very widespread but died out on all but isolated refuges such as Madagascar and West Indian islands. Tenrecs belong to a family of insectivores, Tenrecidae, related to shrews, moles and hedgehogs, but quite distinct from them. Twenty-seven species of three types of tenrecs make up this family--spiny, furred and otter-shrews (Garbutt 1999). They range in size from the Common Tenrec (*Tenrec ecaudatus*), which resembles the European Hedgehog and weighs more than 5 pounds, to the shrew-like tenrecs, *Microgale* genus, weighing less than 2 ounces (Nowak 1999). Tenrecs have some very unusual physical characteristics placing them far from any close mammalian relative. They have variable body temperatures that change with the ambient temperature and, an even more reptilian or avian trait, a cloaca that combines urinal, rectal and generative canals into one (Garbutt 1999).

A striking tenrec is the Lowland Streaked Tenrec (*Hemicentetes semispinosus*). It and a similar species, the Highland Streaked Tenrec (*Hemicentetes nigriceps*), weigh about 5 to 7 ounces and measure some 6 inches in length. White stripes run down their backs like skunks, and barbed, porcupine-like spines are detachable (Eisenberg 1975). The Highland species has a stiff, white neck ruff rising several inches at the back of its head that can be stabbed into the nose of an unwary predator (Eisenberg 1975). Family groups forage together and communicate by vibrating quills that produce low-frequency sounds like dry grass being rubbed together; tenrecs can detect these sounds from distances of more than 4 meters (Garbutt 1999). They also make a number of sounds that are audible to humans.

The Aquatic Tenrec (*Limnogale mergulus*), listed as Endangered in the *2000 IUCN Red List of Threatened Species*, inhabits streams and lakes, living at altitudes between 600 and 2,000 meters (Nowak 1999). This 8-inch tenrec has

clawed, webbed feet, and a long, thin tail for propelling it through the water to feed on small crustaceans and fish. Its habitat in the central highlands has been greatly affected by human disturbance and deforestation. The Aquatic Tenrec has at least one refuge, the new Ranomafana National Park, created for the bamboo lemurs (Preston-Mafham 1991). In 1990, Dr. David Stone managed to lure an Aquatic Tenrec into a live trap, the first one of its kind seen alive in 25 years (Preston-Mafham 1991). Later, four more were taken and studied in captivity for three weeks prior to being returned to the river Namorona in Ranomafana, one of the few clear, unsilted rivers left in Madagascar (Preston-Mafham 1991). This species requires such streams, and only the preservation of forests, such as that in Ranomafana, will ensure its survival.

Another six species in this family, all shrew-tenrecs of the genus *Microgale*, are listed in the *2000 IUCN Red List of Threatened Species*. These tiny insectivores are found in all parts of Madagascar in areas of heavy vegetation, and have dark, soft fur. They range in size from 1.5 to 5 inches in length, and weigh as little as 1.8 ounces (Nowak 1999). Several of the threatened species are highly restricted in range and habitat, and one, *Microgale dryas*, listed as Critical, occurs only in Ambatovaky Special Reserve in the northeastern rainforest (Garbutt 1999).

The Biological Wealth of an Impoverished Country: Mammals: Page 2

Far better known to the world, the lemurs are the focus of many programs to conserve them, as well as research on their wild behavior and biology. New species continue to be discovered; most recently in 2000, three new species of tiny mouse lemurs. Three more have been rediscovered, an indication that other species may yet be discovered to add to the present total of 33 species (Garbutt 1999)**.** This is the only country with five families of primates, making up more than one-third of all primate families; it is home to 12 percent of all primate species and 21 percent of all primate genera (Mittermeier *et al.* 1999). Unlike Brazil, however, which is another center for endemic mammals, Madagascar is far smaller, the size of Kenya, covering 226,656 square miles, or 0.4 percent of Earth's surface (NYT 2000). The number of lemur species is not an indication of their variety since many subspecies differ so radically from one another that in the future, each may be accorded full species status. One species of sifaka, a long-legged kind of lemur, has one subspecies that is pitch black, and another that is pure white. At least 51 species and subspecies of lemurs are known to exist (Mittermeier *et al.* 1999).

The most gregarious of the lemurs are the Ring•tailed Lemurs (*Lemur catta*), who travel about in boisterous, friendly troops, living mainly on the ground. These lemurs have long, fox-like muzzles, large, soft golden-brown eyes, fluffy, gray fur, and black-and-white striped tails. Their body length is 15 to 17 inches, but their rope-like tails are half-again as long, from 21 to 24 inches (Nowak 1999). These 5-pound primates use their boldly patterned tails in a complex language of mutual visual and scent signals. They wave them about to show dominance, as a signal to follow other group members, or rub them on their wrist glands to wave at their rivals in territorial battles (Sleeper 1997). Moving about in troops of up to 25 individuals, they walk rapidly on the ground with the tail held high, waving it about. They wrap their tails around themselves for warmth on chilly nights. Extremely affectionate and playful, their core group is dominated by females (Jolly 1988).

In reserves where they are strictly protected, Ring-tailed Lemurs become very tame, napping on the ground in piles of leaves near tourists. Sometimes they sprawl out on their backs with arms spread wide apart. Females usually have a single young, but when twins are born, one may be "adopted" by a non-pregnant female, who may begin to produce milk in response to her surrogate role (Preston-Mafham 1991). Aunts also help in raising the young, and the daughter born the previous year babysits (Jolly 1988). Lemur babies are a source of great interest to the entire troop, females gathering around the mother and her young, grooming one another and the babies, forming a "grooming pod" (Preston-Mafham 1991). Only half of the infants survive their first year, and only 30 percent reach adulthood (Garbutt 1999). "A Lemur's Tale," shown on PBS in 1996, is a touching film about the death of a young Ring-tailed Lemur. Some fall from high branches, are killed by small carnivores or hawks, die of undiagnosed illness or starve in years of

drought in their arid habitat. Ring-tailed Lemurs communicate with one another in a variety of sounds, from soft mewing contact calls to a territorial "bark-howl." Sometimes chasing and cuffing other members of their group, they are mainly peaceful, spending many hours a day in mutual grooming and in "snoozing-huddles," in which several animals form a complicated embrace from which tails and feet stick out in all directions (Preston-Mafham 1991).

In recent years, Ring•tailed Lemurs have been classified "high priority" for conservation by the IUCN and the Species Survival Commission (SSC) Primate Specialist Group because their habitat of dry woodlands in southern Madagascar is disappearing at an alarming rate due to fires, overgrazing by livestock and tree cutting; they are also hunted with dogs in some areas, and captured as pets (Mittermeier *et al.* 1992, Garbutt 1999). Their distribution has become increasingly patchy as forests are cut (Garbutt 1999). The *2000 IUCN Red List of Threatened Species* lists the Ring-tailed Lemur as Vulnerable, or declining toward endangered status.

One of the strangest mammals in the world is the Aye•aye (*Daubentonia madagascariensis*), so unique that it is assigned to its own family, Daubentoniidae. When first discovered, scientists classified it as a squirrel because of its long, bushy tail and short•legged body. In 1863, however, after anatomical studies, the Aye•aye was revealed to be a lemur, in spite of incisor teeth that never stop growing, long, clawed fingers and other unlemur•like characteristics. Aye-ayes have a perpetually startled expression: huge, round protruding eyes dominate the face, the pupils completely surrounded by deep golden irises. Dark rings surround their eyes, heightening the eerie appearance. The rest of the face and body are gray to black, with long grizzled guard hairs. Spending the day in their twig and leaf nests, Aye-ayes emerge at night to forage for insects and fruit (Garbutt 1999). The Aye-aye's enormous ears are sensitive to the movements of insects under tree bark. At Duke University Primate Center, which has the world's largest number of captive lemurs, Aye•ayes have been filmed using their middle finger, which is twice the length of the other fingers, and skeletally thin, to tap on wood, listening for the movement of insects under the bark. When presented with a block of wood containing insect larvae in holes, the Aye•aye taps the wood and, cocking its head, can tell, even in the case of a hidden hole, the location of the insects, which it then extracts almost surgically, with its middle finger. This primate fills the ecological role of a woodpecker. Aye•ayes eat fruit as well, biting holes into the hard shells of coconuts and scraping the meat out with their middle fingers (Petter 1965). They have also been seen eating nuts of a native tree, nectar from the Traveller's Tree, fungus and lychee nuts (Garbutt 1999).

Aye-ayes have been heavily persecuted by the Malagasy, who consider them to be the embodiment of evil. In general, they are killed whenever seen. Dr. Ian Tattersall once found a dead Aye•aye with a wire pulled tight around its neck (McNulty 1975). In 1990, apparently to dispel the bad luck caused by its having entered a village, local people set an Aye•aye tail on a pole next to the road (Simons 1993). At one time, Aye-ayes were considered among the most endangered animals in the world, facing imminent extinction. To prevent their extinction, a few were captured and released on Nosy Mangabe, a small islet off the northeast coast. Fortunately, Aye•ayes survived on the main island, perhaps because coconut plantations provided food when their forests were cut. Feeding at night, they remained undetected until recently. The Malagasy continue to persecute them.

Since the early 1980s, field surveys have revealed that Aye-ayes have a larger distribution than was originally thought. In 1991, they were seen for the first time in western Madagascar in the northern mountains (Simons 1993). With confirmed sightings in many eastern and northern forests and a few western localities, Aye-ayes inhabit a variety of forest types (Garbutt 1999). They can survive in secondary forest, coming out of their stick nests only at night. And while once thought solitary, groups of three to four individuals have been seen traveling together and feeding at foraging sites (Garbutt 1999). In spite of the greater distribution, the Aye-aye is an endangered species and almost certainly is declining (Garbutt 1999). Aye-ayes require large tracts of forest to maintain viable populations and to protect them from the persecution that often results in their deaths (Garbutt 1999). Although very rare in captivity, several captive births have occurred in recent years at the Duke University Primate Center and Jersey Wildlife Preservation Society zoo in England.

One lemur has recently been rediscovered in the wild and, in the process, an entirely new species was found. The Greater Bamboo Lemur (*Hapalemur simus*) seemed to have disappeared in the wild some time in the mid-19th

century. Not until 1964 was this 5-pound, grizzled, gray-olive lemur seen again in a village market, where it was purchased by a French scientist. Unfortunately, it escaped. A pair captured in 1972 in a southeastern rainforest lived in the zoo in Madagascar's capital city, Antananarivo, until both male and female and their two offspring died (Quammen 1996).

Patricia Wright, an American primatologist, decided to search for this species in 1986 in its supposed range. Fossil evidence indicates that 1,000 years ago, the Greater Bamboo Lemur was widely distributed throughout most of Madagascar's forests, and European naturalists saw it fairly regularly in the 19th century. When she saw a russet-colored lemur clinging to a trunk, making loud "tonking" calls, Wright assumed that she had rediscovered the Greater Bamboo Lemur. Although a different color, she concluded that these animals probably represented a color variation (Quammen 1996). A German primatologist, Bernhard Meier, made independent studies in this patch of rainforest at the same time, also discovering the reddish-gold lemur. Both scientists had great difficulty making observations because of its extreme shyness (Quammen 1996). Finally one was caught, and in 1987, after chromosomal and anatomical studies were done in France, this lemur was found to be an entirely new species (Jolly 1988). It was named the Golden Bamboo Lemur (*Hapalemur aureus*) in a joint zoological paper by Meier, Wright and three other biologists (Preston-Mafham 1991). After months of unsuccessful attempts, Wright took the first photographs of the Golden Bamboo Lemur in the wild. Its beautiful golden-red face mask and belly contrast with darker brown fur on the rest of its body. (See color photographs in Garbutt 1999, Jolly 1988 and Preston-Mafham 1991). This lemur has been found at another location further north, and it is not known whether these populations are isolated from one another. Its population is apparently very low, as only about 1,000 animals have been estimated in the original location of discovery, and its habitat continues to be cleared (Garbutt 1999). The *2000 IUCN Red List of Threatened Species* has classified the Golden Bamboo Lemur as Critical, the most endangered category. Its limited range places it in great jeopardy, and it has been hunted with slingshots; its long-term survival is not secure (Garbutt 1999).

The Greater Bamboo Lemur, the animal first sought, was later found in the same forest, resembling original descriptions and clearly a separate species from the Golden Bamboo Lemur; a third species of bamboo lemur, the Gray Bamboo Lemur (*Hapalemur griseus*), weighs only 2 pounds. It has smoky gray fur and golden eyes, and lives alongside the latter two species in this same forest. This lemur lives in other parts of Madagascar as well (Preston-Mafham 1991).

Each of these three bamboo lemurs eats different parts or species of bamboo plants. One eats the leaves, another the pith, and the third confines itself to new shoots, leaf bases and pith from narrow stems (Quammen 1996). Amazingly, chemical analyses of the plants eaten by the Golden Bamboo Lemur found them to have high concentrations of cyanide, a chemical usually toxic to mammals. Golden Bamboo Lemurs weigh only about 2.2 pounds, and Wright and her co-workers found that, based on toxicity tests of other mammals, they eat 12 times the amount of cyanide that should kill them (Quammen 1996). This is another example of the biological mysteries of Madagascan wildlife.

The Ranomafana forest, with its rare and endemic lemurs and other unusual fauna and flora, would likely have been cut by the Malagasy for more farmland, but Wright spent five years in a successful effort to protect it in the newly•created Ranomafana National Park (Bohlen 1993, Mittermeier *et al.* 1992). This new park covers 108,000 acres of old-growth eastern lowland rainforest. Giant rosewood and other ancient trees tower above a lush understory. It is an extremely important--perhaps the most important--forest for lemurs. Fourteen species of lemurs and 18 other endemic species of mammals live in the park (Jolly 1988). Local people cooperated fully in setting the park™s boundaries, aware of the importance of saving forests. They had experienced a major catastrophe when a cyclone caused landslides, burying entire families in their homes, all precipitated by deforestation (Jolly 1988). In spite of these remarkable achievements, some tree cutting still occurs in Ranomafana National Park (Garbutt 1999).

Wright has continued to study lemurs, now specializing in the exquisite Diademed Sifaka (*Propithecus diadema*) (Brody 1998). Sifakas are the most acrobatic lemurs, leaping from tree to tree, but they have a unique means of locomotion to cross open spaces between trees. Standing on their long hind legs in an upright posture, they hop

sideways, with their arms raised high above their heads. Sifakas can move very quickly in this amazing, dance-like gait, covering distances of more than 100 yards. They are also able to leap vertically to tree branches from a standing position, even carrying babies on their backs. One of their spectacular leaps, some 30 feet up, is the equivalent of a person jumping to the top of a telephone pole. The Golden-crowned or Tattersall's Sifaka (*Propithecus tattersalli*) is a beautiful, nearly all•white species with rich yellow-orange on the crown and tinges of this color on its back, legs and chest. Orange eyes contrast with a furless black face. The smallest of the sifakas, it is confined to a tiny area of only about 15 square miles of forest fragments in northeast Madagascar. The Golden-crowned Sifaka's small population of fewer than 8,000 animals, fragmented into isolated populations, is threatened by forest cutting, brush fires, loss of habitat to agriculture and hunting (Garbutt 1999). Distributed in discontinuous patches of forest, these sifakas may become inbred if corridors are not acquired to link populations. A core part of their forest had been scheduled for cutting for charcoal when scientists named these sifakas. The PBS Nature program, fiMadagascar. Island of Ghosts,fl was the first to film these delicate lemurs (see Video section, Regional - Africa and Indian Ocean Islands). They move about in small groups and feed on a variety of unripe fruits, seeds, shoots, leaves, bark and flowers (Garbutt 1999). No reserve has been set aside for this highly endangered sifaka, although a three-parcel national park covering 20,000 hectares (49,420 acres) has been proposed to protect this species from extinction (Garbutt 1999). The IUCN classifies this species as Critical (Hilton-Taylor 2000).

Although many Malagasy have become far more aware of the need to protect lemurs, some do not understand their rarity or the importance of conserving them. Many rural people still hunt them for food or kill them because of superstitious beliefs. In some areas, the Malagasy try to sell lemurs to foreign scientists. Visiting zoologists studying lemurs have been approached by Malagasy holding captive, and usually injured or dying lemurs, in hopes of a reward. On one occasion, an endangered species of sifaka was brought to primatologist Dr. Alison Jolly, dragged half•choked by a vine around its neck, with one arm dangling loose below the elbow, a jagged bone protruding; blood oozed down its white fur, and it gasped for air through a muzzle smashed by a flung stone (Jolly 1980). Jolly expressed horror at its condition and refused to pay them any reward. She then amazed them by telling them it was a unique sifaka, found only in that small part of Madagascar. They were incredulous . . . not in Antananarivo? . . . Not in France? . . . Not in America? (Jolly 1980). For the majority of people, lemurs are familiar animals, easy to capture and valuable as food. Malagasy schools, established by the French colonial government, taught them only about European animals, encouraging people to assume that their lemurs were unimportant. Fortunately, many Malagasy are becoming concerned about protecting lemurs, and conservation education is taught in an increasing number of schools.

Some lemurs have bred in captivity in zoos and breeding centers, but most, like the endangered Indri (*Indri indri*), have never survived in captivity long enough to breed. In their rainforests, they perch high up, clinging to tree trunks to feed, and suddenly leaping vertically to a neighboring tree, pushing off with their extremely muscular, long legs. Panda-like fur of contrasting black and white--black faces and bodies and white arms and legs--gives them a dramatic appearance. Nearly tailless and heavy--but graceful--their eerie songs, sung at dawn and sometimes during the day, form a loud chorus of high-pitched voices that carries for long distances. Indris were once very common in the eastern rainforest, but much of their habitat has been burned away, making them extremely sensitive to the danger of fires. When a 1992 fire threatened a group in a reserve, they raised such a loud cry that the guards were alerted. They rushed to the scene and put out the fire (Rajaonson 1993).

Although originally found in the far north and central highlands, the Indri is now limited to a narrow strip encompassing only half the rainforests on the island (Garbutt 1999). Indris do not reach sexual maturity until between 7 and 9 years of age, and females are thought to give birth only every second or third year (Garbutt 1999). With such a low reproductive rate, they have been very vulnerable to habitat loss and hunting, especially by immigrants (Garbutt 1999). Moving about in small family groups, they are conspicuous to hunters. The Indri is one of the few lemurs whose killing is considered taboo by the Malagasy, but the old taboos are breaking down, resulting in capture and killing. In some cases, religious leaders encourage such killing. A lemur scientist met a Catholic priest who killed several Indris, roasted them and served them to his congregation, as recorded by Faith McNulty in 1975, and this killing has not ceased. In *Mammals of Madagascar* (Garbutt 1999), two terrified Indris were photographed clinging to poles in a hut, awaiting slaughter for food.

In contrast to the Indri, mouse lemurs (*Microcebus* spp) are so small that it is hard to think of them as primates. The tiniest is the newly discovered Pygmy Mouse Lemur (*Microcebus myoxinus*), with an average weight of only 30 grams, or 1.05 ounces, smaller than any other primate (Garbutt 1999). This tiny mammal is 2.73 inches long, with a tail just under 6 inches in length (Garbutt 1999). The other species are slightly larger, with body lengths ranging up to about 5 inches, and tails of equal or greater length (Garbutt 1999). These nocturnal lemurs have huge dark eyes and are agile and active, resembling African bushbabies. They feed on insects, spiders, and even small frogs and lizards, as well as fruit, flowers and nectar (Nowak 1999). Females form groups and sleep in a nest together with up to nine individuals, while males usually nest alone or in pairs; occasionally males are found in a group of females (Nowak 1999).

A key to protecting lemurs and their forest homes is educating the people of Madagascar about them. The Jersey Wildlife Preservation Trust has put up posters with pictures of lemurs and their protected status around the island. Habitat protection is obviously key to conserving lemurs, and another recent development is the protection of the largest remaining area of rainforest in Madagascar. The Masoala Peninsula in the northeast is the sole home of the Red Ruffed Lemur (*Varecia variegata rubra*), a 9-pound, reddish subspecies of the Ruffed Lemur, but bearing little resemblance to the latter black-and-white species. With $3 million from USAID (United States Agency for International Development) and three years of planning, the new Masoala National Park, covering 210,000 hectares (518,910 acres or 840 square miles), was announced in June 1996 (Terry 1996). This immense park was formally signed into law on October 18, 1997 (Kremen 1998). Thai and Indonesian timber companies had hoped to log these virgin rainforests, but this new law will prevent clearcutting and slash-and-burn agriculture that would have destroyed the forest within less than 50 years. A coalition of organizations helped establish this park, including the Wildlife Conservation Society, CARE and the Peregrine Fund (Garbutt 1999). It will prevent the extinction of the endangered Red Ruffed Lemur, as well as that of the newly rediscovered Madagascar Serpent Eagle (*Eutriorchis astur*) (see below).

In 1997, five Ruffed Lemurs born and raised in the Duke University Primate Center in North Carolina were released in the Betampona Reserve in the northeast to bolster a small, isolated population of this species (Welch 1997). This reintroduction represented a goal in the captive-breeding program at Duke University, which has long planned such a return of these highly endangered primates to the wild. John Cleese, actor and a member of the 1970s British comedy team, Monty Python's Flying Circus, took an interest in the reintroduction program as an enthusiastic lemur admirer. After contributing to the Ruffed Lemur reintroduction program, he wanted to see how they were faring in the wild, and trekked to their remote release site. A delightful film based on this experience, "Lemurs with John Cleese," was shown on PBS in 1999. These Ruffed Lemurs have been released in an area of dense rainforest and rugged hillsides, a long hike from the nearest road. The biologists and assistants who take part in this reintroduction program show their dedication by living for long periods under extremely primitive conditions. Cleese managed to inject humor into this otherwise arduous situation.

At least six species of lemurs, and perhaps more, serve the ecologically important role of pollinating flowers. Many of Madagascar's plants produce unusually large flowers with strong odors and copious nectars attracting lemurs to feed on them. Should any of these lemurs become extinct, the plants that they pollinate will likely follow. Lemurs also play an important role in dispersing seeds. Research by the German Primate Centre at Hamburg University has found that Brown Lemurs are crucial to the regeneration of the western dry forests. About 10 percent of the island's tree species rely largely or entirely on this species to disperse seeds, which pass through their digestive systems.

The surviving lemurs are in extreme danger of following their relatives into extinction. Conservation organizations accord them extremely high priority among endangered primates, and they are the focus of many programs to preserve them. Twenty-nine of the 33 species are listed in the *2000 IUCN Red List of Threatened Species*, all but seven in higher categories of threat. This is an increase of nine species in the four years since the previous edition of the *IUCN Red List* was published (Baillie and Groombridge 1996). Three species and several more subspecies are in the Critical category of species on the verge of extinction, while seven are Endangered, an increase of four species since 1996. All

lemurs are listed on Appendix I of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), the category prohibiting commercial trade, and as Endangered on the U.S. Endangered Species Act.

Although lemurs are protected by Madagascan law, hunting is a major cause of mortality. High fines and even jail sentences may be imposed for killing a lemur, but the severity of the penalties might make officials reluctant to enforce the laws (Peterson 1989). Blowguns, snares, traps, sharpened sticks, slings, stones, guns or even clubs are used to kill them (Peterson 1989). To kill small species of nocturnal lemurs, trees are sometimes cut down, and hunters seize them from their nest holes (Peterson 1989). In the late 1980s, a "sport" hunter bragged of killing 12 highly endangered Verreaux's Sifakas in one afternoon (Peterson 1989). In spite of education programs launched in the 1990s urging the Malagasy to protect lemurs, and the rise in tourists who come to see them, which provides revenues, few have benefited from tourism. Hunting remains a major threat (Garbutt 1999). The rise in human population has resulted in an increased demand for food, particularly protein, far more than the ailing agricultural system can supply (Garbutt 1999). The larger lemur species are especially affected. Because laws against killing lemurs are not enforced, much more education is needed about their potential value in attracting tourism and research funds that provide new jobs. Already tourism has raised income levels among some Malagasy, but hunger is still widespread (Tyson 2000).

In the late 1980s, a World Bank official studying the extreme and worsening poverty on the island said that there might come a time when the people of the capital city would scale the walls of the city zoo and eat the lemurs: "On the downward spiral, animals are at the bottom" (Peterson 1989). Such a tragedy is not inconceivable considering that hunger and poverty have deepened in the decade since. Conservation programs must involve communities while providing an incentive to conserve lemurs. Otherwise, it may be impossible to persuade the Malagasy not to slaughter them.

Although the status of lemurs is deteriorating along with their forests, much is being done to prevent their extinction. The past two decades have been of critical importance to lemur conservation. These extraordinary animals are receiving worldwide attention, and habitat protection for some species has been achieved. Not too long ago, their extinctions seemed inevitable and imminent. Conservation education programs, including showing slides of lemurs and other wildlife to rural children, have been launched. Wright helped to finance the building of new schools and the renovation of existing schools near Ranomafana National Park (Tyson 2000). A number of international organizations are integrating lemur and biodiversity studies with the economic development of entire communities (Garbutt 1999).

For a growing number of Malagasy, learning how special their lemurs are has made lemurs a source of pride and an important national treasure. In the future, Malagasy children may learn from an early age about lemurs and want to protect them. A few decades ago, few films had been made of these fascinating primates, while today many films show their habitats, biology and conservation work on their behalf. One is fiSpirits of the Forest,fl a charming film about many species of lemurs. Others are listed in the Video Section • Mammals. Films of lemurs and the island's environment would provide new insights about these animals if shown to the Malagasy people. Lemurs have also been prominently featured in *Madagascar: A Natural History*, by Ken Preston-Mafham, a beautiful and informative book, and the first guide book, *Mammals of Madagascar*, which provides color photos of nearly every species and subspecies, as well as information on habitats, conservation and status (Garbutt 1999).

In some areas of Madagascar, notably on Nosy Be island, lemurs are fully protected by taboo respected by the Malagasy. Here, beautiful Black Lemurs are fed by the villagers and tourists. This island is being developed intensively for tourism, and the strict nature reserve may be made into a national park (Tyson 2000). This will have mixed results, with new income flowing to the local people from park fees--one of the few countries where this occurs--yet with habitat lost and wildlife disturbed as a result of new hotels and a crush of visitors (Tyson 2000).

The gentle, curious gazes and charming behavior of lemurs have left an indelible impression on many people, and their extinction would be tragic, not just for biological reasons, but also because of their unique and delightful qualities.

The Biological Wealth of an Impoverished Country: Mammals: Page 3
Bats, which perform vital ecological roles in controlling insect populations and pollinating plants, tend to be ignored and often persecuted. Madagascar is no exception. Fifteen species of the 29 species of bats are endemic, living nowhere else (Garbutt 1999). The remaining 14 species live in mainland Africa as well. Fourteen species, or almost half the native bats, are listed by the *2000 IUCN Red List of Threatened Species*. The Yellow Bat (*Scotophilus borbonicus*), the most endangered, is listed as Critical (Hilton-Taylor 2000). This bat has been seen in both eastern and western regions but is extremely rare. A Vulnerable species, the Sucker-footed Bat (*Myzopoda aurita*), is the sole member of its family, Myzopodidae, and an extremely unusual bat. It is able to walk up tree leaves using sucker disks at the bend of its wings and on its feet to adhere to the slippery leaves (Jolly 1988). Only 2 inches long, with a forearm length of 1.9 inches, this tiny bat occurred in East Africa during the Pleistocene, but at present, it is found only in several locations in the eastern rainforest region of Madagascar (Garbutt 1999). It roosts in the Traveller™s Tree. It possesses a complex echolocation system and emits very long calls used to hunt insects (Garbutt 1999).

The largest bat, the endemic Madagascar Flying Fox (*Pteropus rufus*), has a 4-foot wing-span. An extremely colorful bat, its crown and nape are yellowish, and its upper chest and shoulders are rufous to golden brown (Garbutt 1999). It feeds on fruit juices by squeezing pieces of fruit pulp in its mouth, swallowing the juice and very soft fruit pulp, especially of figs, papayas, lychees and guavas (Garbutt 1999). Colonies of these bats roost in tall trees in primary forests or plantations (Garbutt 1999). One large roost at the Berenty reserve has decreased, apparently because of daytime disturbance by tourists who come to see them hanging upside down in the tamarind trees (Preston-Mafham 1991). Elsewhere on Madagascar, the species has declined precipitously from hunting for its meat; only on inaccessible offshore islands do these bats survive without persecution (Preston-Mafham 1991). Of Asian origin, this species is related to fruit bats in the Mascarene Islands. Through captive studies, flying foxes have been found to be extremely devoted to one another (see discussion of Rodrigues Flying Fox in Chapter One).

The Biological Wealth of an Impoverished Country: Mammals: Page 4
The Viverrid family is represented in Madagascar by mongooses, civets, and related carnivores that have evolved into eight species of three endemic subfamilies (Preston-Mafham 1991). Their ancestor is thought to have originated in Africa, and may have colonized the island at an early period. The largest carnivore on the island is the Fossa, or Fosa (*Cryptoprocta ferox*). A zoological oddity, it resembles the Jaguarundi, a neotropical cat, but most authorities place it either in the Viverrid family with civets (Preston-Mafham 1991) or the Herpestidae family with mongoose (Nowak 1999). The only member of its genus, it walks flat on its feet, rather than on its toes like cats (Nowak 1999). Sleek and slender, with golden reddish-brown fur, it has a small head with a blunt, dog-like muzzle, and an extremely long tail. Males weigh up to 22 pounds, with a body length of 2.6 feet and a tail of equal length, while the smaller females measure 2.3 feet and weigh about 15 pounds (Garbutt 1999). It has scent glands which discharge a strong odor when the animal is irritated (Nowak 1999). Widespread but rare in forests throughout the island, this nocturnal predator kills small lemurs, rodents and tenrecs, as well as birds, reptiles, amphibians, invertebrates and, reputedly, domestic chickens (Garbutt 1999). The Fossa often excavates animals from their burrows and can pursue fleeing prey by climbing up trees (Nowak 1999).

The first research study of the Fossa is being conducted by zoologist Luke Dollar, funded by the Earthwatch Institute. Helped by volunteers, he is radio-tracking several Fossa to determine their movements, habits and territory size. As the largest predator on the island, the Fossa plays an extremely important role in the evolution, behavior and population dynamics of lemurs and other prey animals. During the research project, several Fossa have shown

extreme confidence by raiding the tents of the researchers when unoccupied, ransacking them and even chewing metal objects, leather boots, rucksacks, soap and bottles of malaria tablets (Garbutt 1999). For centuries, Fossas have been persecuted by the Malagasy, believing them to be ferocious and evil.

The Fossa gives birth to a litter of two to four young, which mature very slowly and may not be fully independent until they are about 4 years old (Garbutt 1999). This slow rate of reproduction has made the Fossa vulnerable to extinction. Along with losses from killing by the Malagasy, its forest home has been steadily whittled away by slash-and-burn agriculture. The Fossa is listed as Endangered in the *2000 IUCN Red List of Threatened Species*, a higher category of threat than it received in the 1996 version of this list.

Gerald Durrell, renowned author and conservationist, traveled in the western forests to capture Aye-ayes for captive breeding. He encountered a Fossa venturing out during the day--an unusual behavior: "A flash of russet red caught my eye in the bushes some six feet in front of the vehicle and, suddenly, from out of the undergrowth, silent as a cloud shadow, came a Fossa which walked languidly to the middle of the road and sat down" (Durrell 1993). Remaining there, the Fossa proceeded to groom himself, apparently unaware of Durrell's presence. Then, with a sigh and a wide yawn, the Fossa crossed the road and disappeared into the forest, "his immense sickle of a tail swinging from side to side like a bellrope behind him. To have spent ten minutes with such a rare and beautiful creature was a privilege" (Durrell 1993).

The Falanouc (*Eupleres goudotii*), sole member of its genus and a viverrid, is the size of a domestic cat. It has dense, woolly fur and an extremely pointed and narrow muzzle. Native to humid eastern lowland forests and marsh areas and portions of the northwest, Falanoucs are active at twilight and during the night. Feeding mainly on earthworms and other invertebrates, they use their long snouts and tiny, conical teeth to catch prey in leaf litter (Garbutt 1999). The species is rare or extremely rare over most of its range and is classified as Endangered by the IUCN (Hilton-Taylor 2000). Like the Fossa, it has declined as a result of deforestation, drainage of marshes, hunting by the Malagasy, attacks by feral domestic dogs, and possibly competition with the introduced Small Indian Civet (*Viverricula indica*).

The Malagasy Civet or Fanaloka has the scientific name *Fossa fossana*, which has been confused with the Fossa. Like the Fossa and Falanouc, it is the only member of its genus. Looking more like spotted civets from mainland Africa and Asia, this reddish 3-pound carnivore has rows of black spots on its back, merging into stripes toward its bushy, grayish tail. Its distribution is far more restricted than the Fossa's or the Falanouc's, being confined to eastern rainforests which have been reduced to less than 10 percent of their original size. Sheltering in tree holes or crevices, the Malagasy Civet lives in pairs and feeds on crustaceans, worms, small eels and frogs (Nowak 1999). A pair has a single young, and a captive civet lived 11 years. Hunting and trapping have also threatened the Malagasy Civet, which is listed as Vulnerable by the IUCN (Hilton-Taylor 2000).

Five other viverrids, all mongooses, are native to Madagascar, and all are threatened with extinction from a loss of forest habitat and persecution. A few have very restricted distributions. They tend to be secretive unless in a secure forest reserve, and little attention has been paid to their conservation, biology or habitat requirements. Several are uniform brown or russet, while two have bold black dorsal stripes ending in white, bushy tails. One, the Brown-tailed Mongoose (*Salanoia concolor*), is native to the northeast rainforests, but almost nothing is known of this small carnivore (Garbutt 1999). All of the eight native civets, mongooses and related animals are listed as Vulnerable or Endangered by the *2000 IUCN Red List of Threatened Species*.

The Biological Wealth of an Impoverished Country: Mammals: Page 5
Among Madagascar's 11 species of murid rodents are several extremely bizarre forms. The largest is the Giant Jumping Rat (*Hypogeomys antimena*), the size of a rabbit and weighing 2 pounds, 10 ounces (Preston-Mafham 1991).

Restricted to a small area in western dry, deciduous forests north of Morondava, in west-central Madagascar, its entire range is thought to encompass only 39 square miles (Preston-Mafham 1991). Once far more widely distributed, remains have been found in southwest and central Madagascar (Garbutt 1999). These huge rodents search for food, such as fallen fruit, on the forest floor and feed by sitting on their hindquarters and holding food in their forepaws like a rabbit (Garbutt 1999). Giant Jumping Rats build deep burrows and, unlike the vast majority of rodents, a mated pair maintains long bonds with one another and with their young (Garbutt 1999). Male young leave after one year, and females stay with both parents for two to three years (Garbutt 1999). Only one or two young are born in a litter, and predation by Fossa and the Madagascar Ground Boa (*Acrantophis madagascariensis*) is high (Garbutt 1999). With no reserve and a habitat that continues to decline, this huge-eared rodent is in danger of extinction. A reserve is planned for this species, which is listed as Endangered by the *2000 IUCN Red List of Threatened Species*. fiMadagascar. Island of Ghostsfl filmed the Giant Jumping Rat in the wild, one of the only videos of this fast-disappearing species (see Video section).

Eight of Madagascar's native rodents, or 73 percent, are listed by the IUCN in various categories of threat. Two are considered Critical: the Madagascar Mouse (*Macrotarsomys ingens*) and the Madagascar Rat (*Eliurus penicillatus*). The mouse is known only from a single area in northwestern Madagascar, in dry deciduous forests where the type specimen was found, and it is thought to be almost totally arboreal and nocturnal (Garbutt 1999). The Madagascar Rat has not been seen since the type specimen was collected in central-eastern montane rainforest.

The Biological Wealth of an Impoverished Country: Birds

The Biological Wealth of an Impoverished Country: Birds: Page 1

Until recently, the amazing lemurs and other mammals of Madagascar eclipsed its remarkable bird life. Apart from the extinct elephant birds, 120 species of the 204 native birds are unique to the island (Morris and Hawkins 1998). Like tropical birds of other parts of the world, most are dazzlingly beautiful in brilliant hues. Unlike most tropical birds, however, they represent fascinating examples of evolution, including families of birds that exist nowhere else, having evolved from a single ancestor into many forms, some very bizarre. Most ornithologists recognize five bird families as unique to Madagascar, each with extremely distinctive characteristics. Four of these have some or all species that are threatened. The fifth, a family consisting of a single bird, the Cuckoo-Roller (*Leptosomus discolor*), is secure for the moment (Morris and Hawkins 1998). A few thousand years ago, there may have been far more native bird species that disappeared without a trace as their habitats were destroyed.

Native birds are not thriving, as people and livestock destroy their varied habitats, to which they had adapted over thousands of years. A total of 41 species, all but three of which are endemic, have been listed in the *2000 IUCN Red List of Threatened Species*, based on the research of BirdLife International published in 2000 in *Threatened Birds of the World*. The latter book illustrates each threatened Madagascan bird and describes status, population numbers, distribution and other pertinent information. The three non-endemic birds also breed in the neighboring Comoros or Seychelles (BI 2000). Thus, 20 percent of all native birds and 34 percent of endemic birds are threatened, five species listed as Critical, six as Endangered, 16 as Vulnerable, and 14 as Near-Threatened (BI 2000). Moreover, many native birds that were once widespread have become restricted to isolated forest reserves and parks, not yet endangered but

far less numerous than in previous times. While the percentage of threatened birds is less than that of endemic mammals, it is significant, especially considering that 27 species are either Critical, Endangered or Vulnerable in the *2000 IUCN Red List of Threatened Species*. Madagascar has more threatened birds that all of the continental United States (excluding Puerto Rico and Hawaii). Its threatened birds total 41 threatened species, five greater than the United States™ 36 (BI 2000). Only 4 percent of the 810 breeding birds native to continental US and Canada combined (Sibley 2000) are threatened. If birds in the United States faced the same degree of threat as Madagascar's birds, at least 162 species would be threatened with extinction.

Fortunately for the future of these unique birds, organizations such as BirdLife International; the Peregrine Fund; Conservation International; the Jersey Wildlife Preservation Trust; and an ad hoc group, The Working Group on Birds in the Madagascar Region, are researching and working to conserve Madagascar's native birds. Malagasy ornithologists and members of the public are participating in surveys, studies and conservation programs. An inventory of the status and taxonomy of all of Madagascar's birds is in progress (Morris and Hawkins 1998).

In spite of Madagascar™s many unusual birds, interesting to specialists and amateur birdwatchers alike, no bird guide or text illustrating and describing the island's avifauna existed until 1990, when Olivier Langrand's *Guide to the Birds of Madagascar* was published, providing information on natural history, status, habitats and distribution, as well as color paintings of all native birds. This material supplemented the lengthy descriptions in *Threatened Birds of Africa and Related Islands*, a 1985 publication of the International Council for Bird Preservation, now called BirdLife International (Collar and Stuart 1985). *Madagascar: A Natural History*, by Ken Preston-Mafham (1991), included extensive information on many native birds and their habitats. *Birds of Madagascar, A Photographic Guide* (Morris and Hawkins 1998), published in 1998, updates the latter publications with vivid color photographs illustrating almost all native birds, including many species discovered or rediscovered during the 1990s, such as the two new species, the Cryptic Warbler (*Cryptosylvicola randrianasoloi*) and the Red-shouldered Vanga (*Calicalicus rufocarpalis*), and the rediscovery of several birds thought extinct: the Madagascar Serpent Eagle, Madagascar Red Owl (*Tyto soumagnei*) and Red-tailed or Fanovana Newtonia (*Newtonia fanovanae*). The 1990s also saw the making of many films about the island's wildlife, including its birds (see Video section).

The Biological Wealth of an Impoverished Country: Birds: Page 2

Birds native to aquatic habitats have declined even more dramatically than many forest birds. The largest lake on Madagascar, Lake Alaotra in the northeast, was once a paradise of waterbirds, turtles, frogs and other wildlife. Traditionally, portions of the lake were used by the Malagasy for rice cultivation, without serious damage to the environment or resident wildlife. But as their populations and food requirements grew, people began to destroy more and more of the natural marsh and reed beds that lined the lake, and cleared the surrounding forest for firewood and agriculture. This destroyed the lake's water quality. With no trees to hold back the soil and conserve water, this once-beautiful lake became heavily silted by runoff (Durrell 1993). Added to this, non-native tilapia fish were introduced into the lake as a food source for the local people. The fish eat vegetation needed by dragonflies and other fauna that form the basis of the lake's food chain (Preston-Mafham 1991). This ecological collapse has greatly reduced rice production on the lake, although reeds are still being cleared for rice growing, fragmenting wildlife habitat (Garbutt 1999).

The effects on native aquatic birds have been catastrophic. Lake Alaotra is the only known habitat of the endemic Alaotra Grebe (*Tachybaptus rufolavatus*), which is presumed extinct (BI 2000, Morris and Hawkins 1998). No sightings have been made since 1985, when only two birds were seen. It declined from loss of its habitat, hunting and hybridizing with the Little Grebe (*Podiceps ruficollis*), a recent arrival from Africa (Morris and Hawkins 1998). Many fruitless searches for the species have been carried out in the lake and surrounding area since then (BI 2000, Morris and Hawkins 1998). This small, black-capped grebe was very sedentary and may have been nearly flightless because

of its extremely short wings.

Another waterbird restricted to Lake Alaotra, the Madagascar Pochard (*Aythya innotata*), is also probably extinct, having been eliminated by the same threats as the Alaotra Grebe (BI 2000). This duck declined steeply from 1930 on, and the last known bird, a male, was captured in August 1991, having been caught in fishing gear. This bird later died, and intensive searches in 1989 and 1990, and again in 1993 and 1994, failed to discover more Madagascar Pochards (BI 2000, Collar *et al.* 1994). A handsome bird, the pochard was chestnut-colored, with dark gray bill and yellow eyes (see photograph in Morris and Hawkins 1998). A shy species, its breeding and behavior were studied, but apparently nothing was done during its precipitous decline to prevent its extinction. Classified as Critical, hope remains that a few birds exist in wetland habitats around Lake Alaotra (Morris and Hawkins 1998).

The Jersey Wildlife Preservation Trust has begun education campaigns in the vicinity of Lake Alaotra to teach local people about the presence of the highly endangered Alaotra Reed Lemur or Bandru (*Hapalemur griseus alaotrensis*), a subspecies of the Grey Bamboo Lemur, and the importance of protecting the reed and papyrus beds. This lemur has been classified as Critical by the IUCN. The only lemur to live in an aquatic environment, the Alaotra Reed Lemur is larger than other subspecies of the Grey Gentle Lemur and lives in close, family groups (Garbutt 1999). To move about in the reed beds, they climb up a reed stem until it bends, and then walk along it to reach the next stem; their major food is the endemic papyrus, along with grasses and ferns (Garbutt 1999). Lake Alaotra's reed beds are its sole habitat, and although previously widespread in this and another lake to the north, only two isolated populations of lemurs, one of which numbers fewer than 60 animals and is on the verge of extinction, remain in marsh fragments (Garbutt 1999). This lemur has the most restricted range of any lemur species or subspecies (Garbutt 1999). The film, fiMadagascar. A World Apart,fl includes a moving segment on these lemurs feeding among the papyrus when a Malagasy canoe enters the marsh and sets a fire, causing the terrified lemurs to flee. (See Video section). Local village leaders have requested that the government set aside a protected zone in the marshes. There is hope that this lake will be brought back as a functioning ecosystem in the future and that a strict sanctuary will be set aside for this endangered lemur and the highly endangered waterbirds.

While sizeable areas of forest have been protected, few aquatic environments on Madagascar have been preserved, and native waterbird species are declining precipitously. The Madagascar Little Grebe (*Tachybaptus pelzelnii*) was once common and widespread in many parts of the island; with the pollution and destruction of marshes throughout the island for rice farms, this bird has declined greatly. The introduced tilapia was threatening this species by consuming its food supply. This grebe also hybridizes with the introduced Little Grebe (Collar *et al.* 1994). The Little Grebe, an African species which has colonized the island, prefers the habitat created by the tilapia, and is now abundant (Langrand 1990). The Madagascar Little Grebe has also drowned in fish nets, and has lost the vegetation it needed for nesting (BI 2000). It is expected to follow the Alaotra Grebe and Madagascar Pochard into extinction.

Another endemic waterbird, the Sakalava Rail (*Amaurornis olivieri*), native to western wetlands, is also extinct or nearly so. A small, sooty-black bird with yellow beak and pinkish-red legs and feet, it was native to streams and marshes in the western parts of the island. For more than 30 years, this species was not seen at all. In 1995, one was glimpsed at Lake Bemamba, and another in 1999 at the same lake (BI 2000). This species is classified as Critical (BI 2000), and Lake Bemamba and other lakes and wetlands on the west coast may be given protection by the Malagasy government, which has ratified the Ramsar Convention on wetlands preservation (BI 2000).

As a result of extensive habitat destruction and hunting, the Madagascar or Bernier's Teal (*Anas bernieri*) has likewise declined to endangered status in the few sites from which it is known on the west coast. Once widespread on the island, it is now restricted to a few marshes and shallow lakes. Small populations remain on Bemamba Lake and a few other sites (Morris and Hawkins 1998), and a flock of 67 was seen in another area (BI 2000). In 1970, 60 of these birds were seen on a lake, and as soon as this became known, European sportsmen went to the lake and killed more than 25 percent of the population (Curry-Lindahl 1972). In the 1970s, Bernier's Teal inhabited Lake Masama, but heavy hunting by both Europeans and natives with dogs has nearly eliminated them (Todd 1979). In 1993, four birds were captured for captive breeding (Collar *et al.* 1994). The Jersey Wildlife Preservation Trust is working to preserve

this beleaguered species and the marshes of the west. The Madagascar Teal has been seen in three protected areas, and a conservation program at one lake has been initiated (BI 2000).

The critically endangered Madagascar Fish Eagle (*Haliaeetus vociferoides*) numbers about 250 pairs in the 600-kilometer stretch of western coastline to which it has become confined (BI 2000). This large eagle resembles the African Fish Eagle, from which it probably evolved, but instead of a snowy white head and upper body, it is streaked with brown and has shaggy, buff crown feathers. About 35 inches long, with a 6.5-foot-wingspan, it is by far the largest bird on Madagascar. Persecuted by local people, these eagles have been shot and their nests destroyed. On one occasion in the 1990s, ornithologists saw some immigrants cut the tree where an active nest of a Madagascar Fish Eagle was located, and proceed to kill and eat the chicks! The only remaining habitat for this species is the western coast, where mangrove swamps are rapidly being destroyed (Langrand 1990, Preston-Mafham 1991). The Peregrine Fund is sponsoring research on this species, and 10 nests have been located in an area on the west coast in the Three Lakes Complex (BI 2000). The Fund has removed and raised chicks that would have been killed by siblings and released them to augment the population. The fish it feeds on are being depleted, however, by a gill-net fishery that has recently been established. A new Malagasy law allows local communities to control their own resources, and the people in this region are being encouraged to formalize conservation regulations prohibiting gill netting and tree cutting.

The Biological Wealth of an Impoverished Country: Birds: Page 3

Birds native to aquatic habitats have declined even more dramatically than many forest birds. The largest lake on Madagascar, Lake Alaotra in the northeast, was once a paradise of waterbirds, turtles, frogs and other wildlife. Traditionally, portions of the lake were used by the Malagasy for rice cultivation, without serious damage to the environment or resident wildlife. The fish it feeds on are being depleted, however, by a gill-net fishery that has recently been established. A new Malagasy law allows local communities to control their own resources, and the people in this region are being encouraged to formalize conservation regulations prohibiting gill netting and tree cutting.

The Biological Wealth of an Impoverished Country: Birds: Page 4

As more and more bird-watchers come to Madagascar, the government may place a higher priority on bird conservation. A special fund to which bird-watchers could contribute might be established to purchase and maintain refuges and to conduct conservation education and other projects for local people, especially in aquatic habitats. The preservation of threatened Madagascan birds has reached a critical point. The most endangered habitats, the last of the western forests, aquatic environments, and many parts of the eastern lowland rainforests, continue to decline. The fragmentation of forests that forces animals into islands of isolation needs to be studied and remedied by establishing habitat corridors between them. One Malagasy ornithologist, Aristide Andrianarimisa, is researching the effects of forest fragmentation on birds.

Pete Morris and Frank Hawkins, authors of *Birds of Madagascar. A Photographic Guide*, state that their purpose in writing their book was to inspire people to visit Madagascar and take an interest in its avifauna and the plight of so many threatened birds, as well as to promote greater interest in wildlife and conservation among the Malagasy people. Ecotourists bring revenue to the island and, thereby, help to preserve natural areas and wildlife (Morris and Hawkins 1998). The discovery of a new species of songbird, the Cryptic Warbler, by bird-watchers in Ranomafana National Park, is an exciting byproduct of ecotourism and an indication that the study of Madagascar's birds has just begun. It also proves that amateurs play an important role in bird observation. *Birds of Madagascar* establishes a good precedent by identifying, on a species-by-species basis, the avian habitats and those birds lacking reserves within their ranges. The authors request that people coming to see the wildlife of the island let the government know why they have come in order to convince decision makers that biodiversity conservation represents a worthy investment (Morris and Hawkins 1998).

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians

The distribution and diversity of Madagascar's reptiles and amphibians have not been carefully researched until the present. Chris Raxworthy, a British herpetologist, is in the process of carrying out the first methodical survey of the estimated 500 non-marine species, all of which are endemic (Holmes 1997). To date, at least 300 reptile and about 200 frog species have been identified (Tyson 2000). This would make it one of the top five countries in the world for diversity of reptiles and amphibians. The British Isles, by contrast, with about half the land area of Madagascar, have only six species of reptiles (Preston•Mafham 1991). Even the ranges of newly described lizards and frogs will not be delineated precisely for some time. Some areas remain unexplored by herpetologists, and Raxworthy finds new species of lizards and frogs on each expedition into the tangled swamps and forest fragments. On one day when accompanied by a journalist, he and fellow researchers, including Malagasy biologists, found a bright green day gecko, a strikingly beautiful yellow-and-black snake, tiny frogs resembling lichens, a leaf-tailed gecko and 4-inch chameleons with upper legs the colors of Rainbow Trout, and lower legs like toothpicks (Holmes 1997). In a reserve on Nosy Be island, he and some Earthwatch Institute volunteers rediscovered a 10-inch green lizard that had been lost to science since the 1890s, when last collected (Tyson 2000). Raxworthy is doing inventories in reserves as part of an

island-wide biodiversity program, and hopes that in some impenetrable area, giant tortoises long considered extinct will be rediscovered (Holmes 1997).

Page 1 (Threatened)
Page 2 (Tortoises and Turtles)
Page 3 (Lizards)
Page 4 (Snakes)
Page 5 (Amphibians)

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 1
Of these native reptiles and amphibians, at least 19 are known to be threatened with extinction. A preliminary list includes 17 species of reptiles (four tortoises, a freshwater turtle, four sea turtles, a gecko, four chameleons and three boa snakes) and two amphibians, both frogs. All are in higher categories of threat: Endangered or Vulnerable by the *2000 IUCN Red List of Threatened Species* (Hilton-Taylor 2000). All but the sea turtles are endemic to Madagascar.

The arid regions at the northern and southern ends of Madagascar are home to two intricately patterned tortoises, both in danger of extinction. In the north is a species considered by many to be the world's most endangered tortoise: the 18-inch Madagascar or Plowshare Tortoise (*Geochelone yniphora*), whose tan, domed shell is marked with narrow black lines in delicate hexagonal patterns. The Plowshare name came about because of a protuberance on the tortoise™s lower shell that turns up, a kind of knob that remotely resembles a plowshare. This knob is used by males in sparring contests. From the 17th century onward, thousands of these tortoises, which were once abundant and widespread, were shipped every year to the nearby Comoro Islands to use as meat for settlers, driving the species to the edge of extinction before the trade finally ended in the 19th century (Juvic *et al.* 1981). Their populations never recovered, due to the continued take by villagers for pets and the massive destruction of their habitat. Known to the Malagasy as the "Angonoka," this tortoise was headed for extinction until 1985 when the Jersey Wildlife Preservation Trust was requested by the IUCN to work with the Malagasy government in formulating a rescue plan, Project Angonoka (Reid 1995). Research on the tortoise™s wild status and behavior began immediately, and a captive-breeding program was established at a government forestry station (Reid 1995).

By 1986, eight adult tortoises had been gathered from the wild and placed in an enclosure which had ample vegetation and conditions natural enough that two male Angonokas immediately began their fights of strength (Reid 1995). Gerald Durrell, founder of the Jersey Wildlife Preservation Trust, in his book, *The Aye-aye and I* (1993), described lone males showing no interest in breeding, even if surrounded by females. But when another male is present, they face each other prepared for combat: "The two males, rotund as Tweedledum and Tweedledee dressed for battle, approach each other at what, for a tortoise, is a smart trot. The shells clash together, and then the plowshare comes into use. Each male struggles to get this projection beneath his opponent and overturn him to win a victory in this bloodless duel" (Durrell 1993). Finally, when one is able to overturn his opponent, he lumbers over to mate with the female while the vanquished male "wanders dispiritedly away" (Durrell 1993).

Project Angonoka has shown success both in captive breeding these tortoises, which may number only between 300 and 1,000 in the wild, and in working with local people to conserve remaining wild populations (Durbin *et al.* 1996). In fact, by 1995, a total of 140 captive-bred juveniles, ranging in age from 10 months to 6 years, had been produced at the breeding center. The breeding program was described in an illustrated article entitled "Observations on Hatchling and Juvenile Captive-bred Angonoka in Madagascar," published in the Jersey Wildlife Preservation Trust's annual journal, *The Dodo,* issued early in 1996. Within months, the captive-breeding program was devastated by the theft of 76 animals--two adult females and 74 hatchlings. On May 6, 1996, someone cut through the flimsy chain-link fence and the wire of the enclosure and took half the animals that were the fruit of a decade's work. Not until a female is 20

years old does she begin breeding, so the loss of two breeding females and their hatchlings dealt the program a devastating setback (McNeil 1996a). The burglary may have been an inside job, since the dog on the premises did not bark to alert the personnel who were sleeping close by (Tyson 2000). It is unlikely that these adult females will breed in captivity, as there are almost no adult male Plowshare Tortoises in breeding programs, and without more than one, no breeding occurs.

Animal smugglers care little about the effect of their actions on the survival of endangered species. Reptile collectors will pay thousands of dollars for rare specimens, and this break-in had been planned. A Dutch rare animal dealer had advertised Plowshare hatchlings for sale the month before, at $3,000 apiece, saying they would be "available soon" (McNeil 1996a). Ten of the hatchlings were traced to Prague, where wildlife law enforcement is weak, and others were suspected to be in the Netherlands, where they would be sold to collectors in the United States, Spain, Germany and Japan (McNeil 1996a). The loss of these tortoises cost the breeding program years of work. Don Reid, the Conservation Field Officer in charge of the Plowshare Tortoise captive-breeding program, had experimented for years to achieve a proper diet for the tortoises, arranged male combats, and conducted lengthy experiments to learn proper conditions for the eggs to hatch (Reid 1995). These tortoises became so tame that they would stretch their necks out to be scratched (McNeil 1996a). Although discouraged by the theft, he continued the breeding program; 40 new tortoise hatchlings were produced in late 1996, bringing the total to 130 juveniles. In 1998, several of the smuggled tortoises were seized from a Malaysian animal dealer in Mexico City who had been the subject of a long-term U.S. Fish and Wildlife Service undercover investigation. The same year, three more Plowshare Tortoises were seized in Belgium as they were being imported (TRAFFIC 1999a). The species is listed by the *2000 IUCN Red List of Threatened Species* as Vulnerable, and is protected by the Malagasy government, which bans trade.

Officials from the Jersey Wildlife Preservation Trust and other conservationists have sponsored education programs aimed at informing local people about the tortoises and their rarity. This has resulted in their cooperation in helping to guard wild tortoises from poachers and control brush fires (Durbin *et al.* 1996). This region in northwestern Madagascar has lost most of its forest cover; Arab residents cut trees and burn them to clear the land for agriculture, and feral pigs kill the young wild tortoises (Durbin *et al.* 1996). So much clearance of natural vegetation has taken place that the climate has become increasingly more arid, causing ponds to dry up. Tree cutters are now turning to the mangroves, causing siltation of the inlets, which affects prawn harvests (Durbin *et al.* 1996) and destroys a key aquatic environment on the island.

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 2

The Plowshare Tortoises have been reduced to a few forest sites, and in spite of the urgent need for a reserve, none has been set aside. The area is getting conservation help with the formation of a new organization by conservation biologists, the Association to Safeguard the Environment. Its purpose is to involve local people in environmental projects, such as planting cashew trees, learning fire suppression methods, and trapping bush pigs; they are also giving conservation lessons to children and conducting literacy classes (Durbin *et al.* 1996).

The Radiated Tortoise (*Geochelone radiata*) inhabits the drylands of the extreme south, where the strange Didierea plants and other desert vegetation grow in open shrubland. Many people consider this tortoise to be the most beautiful in the world. Delicate yellow sunburst patterns adorn the top of its 16-inch-long black shell, and the underside is marked with diamond patterns. These tortoises also declined after tens of thousands were killed to supply local villagers with meat, or exported to the Comoro Islands from the 17th century on for meat markets abroad. In 1922 alone, 22,000 of these tortoises were exported (Jolly 1980). The legal trade did not cease until 1930. The tortoise populations have not rebounded, and illegal capture for collectors and zoos may be the explanation. The slow reproduction of this species means that it cannot quickly make up for losses in its population. An extremely long-lived

species, it has evolved with low natural mortality and has few young. As an example of its longevity, a Radiated Tortoise of unknown age presented to the Queen of Tonga by Captain Cook in the 1770s, lived until 1966, making it almost 190 years old at its death (Jackson 1993).

The lovely patterns on this tortoise's shell, which vary from individual to individual, have placed it in great demand around the world, encouraging poverty-stricken Malagasy to risk jail to earn the money that these tortoises bring. Thousands of Radiated Tortoises have been collected for the international market, sold in Europe, North America and elsewhere for $2,000 or more per animal. In spite of having a range that is far larger than that of the Plowshare Tortoise, the Radiated Tortoise is declining rapidly toward extinction. The species is listed by the *2000 IUCN Red List of Threatened Species* as Vulnerable. Export and collection of Radiated Tortoises are prohibited by the Malagasy government, with severe penalties for violations including prison sentences. The United States lists both the Radiated and Plowshare Tortoises on the Endangered Species Act, which prohibits commercial importation. International commercial trade is banned by their listing on Appendix I of CITES. Still, the smuggling continues, fed by the many wealthy collectors who have no conscience about the effect their purchase has on wild populations, and the zoos that knowingly purchase smuggled animals. Malagasy authorities have failed to put an end to the poaching, especially of the Radiated Tortoise and other southern species.

Donovan Webster, a journalist, researched the rampant smuggling of Radiated Tortoises and other wildlife from the island for *The New York Times Magazine*, which published his lengthy article on February 16, 1997. The magazine cover featured the article and read: "I was caught in Madagascar. Peddled for 30 cents. Smuggled to Orlando. Sold for $10,000. I'm a rare, coveted tortoise--coldblooded contraband." Webster found that Madagascar was a "pirate's paradise," with little or no local enforcement of conservation laws. Its long and unpatrolled coastline is used by smugglers, who load tortoises onto small boats at night, with little fear of arrest (Webster 1997). Although some enforcement of capture bans takes place in the range of the Radiated Tortoise, local people have learned to avoid arrest.

The contrast between the attitudes of local people toward the Plowshare Tortoise in the north, where education programs have been carried out by the Jersey Wildlife Preservation Trust, and the south, where no strong program exists to protect the Radiated Tortoise and other wildlife, could not be more dramatic. In the south, poaching Radiated Tortoises and other reptiles is considered an accepted form of revenue by the extremely poor people of the region. At local bars and restaurants, Webster was approached by people who offered to produce a rare snake within 24 hours. Snakes are a favorite animal for smugglers because they can be secreted in small bags and placed in luggage or, if they are small enough, in pockets. He refused a boa, which was offered at $300 and could be sold for $2,000 in the United States (Webster 1997).

Webster exposed a large-scale and fairly open trade in Radiated Tortoises in local markets within the range of these tortoises. He visited a woman who was reputed to have many of these tortoises for sale. She showed him 24 Radiated Tortoises which she kept ready for sale to anyone who would pay the right price; they were crowded into a make-shift pen in her living room, stacked two and three deep in filthy conditions (Webster 1997). They grunted and made hissing sounds when disturbed, scratching and scrabbling against one another and the pen sides; their shells were covered with dust, and most appeared to be sickly (Webster 1997). The woman tossed the tortoises back into the pile after handling them. She claimed that she sold them to local people for $1.35, and to outsiders for $4 or more, depending on how many tortoises she had at the time (Webster 1997). She also admitted supplying a smuggler who arrived once a week in a canoe at a remote beach with any Radiated Tortoises she had in stock (Webster 1997).

These tortoises are absurdly easy to collect in the wild, living in open shrubland and moving so slowly that they can be picked up as easily as rocks. Webster witnessed the capture of one mature tortoise which Benjamin, one of the collectors, located in the shadow of a boulder. When he approached, the tortoise hissed and tried to crawl beneath bushes, but it was easily grabbed, and he flipped it on its back; soon he caught two other adult tortoises who had a baby the size of a small stone wedged beneath them in an apparent attempt to protect it (Webster 1997). Collectors wrap string around the tortoises™ shells to form handles for carrying them. When they met at the end of the day, they

had taken 54 mature tortoises and many young ones, making it a "banner day" (Webster 1997). The occasional presence of enforcement officers and World Wildlife Fund (WWF) representatives did not seem to present any anxiety of threat of arrest to the collectors (Webster 1997).

Each Radiated Tortoise is worth at least $2,000 once smuggled out of Madagascar, and those with unusually exquisite patterns bring as much as $10,000 (Webster 1997). Benjamin later admitted that he was aware that the tortoises were becoming rarer and that their range had shrunk in recent years; he also knew that many were very old, probably older than his own 53 years. It was obvious that the tortoises would soon be gone, but he believed this was his only potential income source; he was uncertain about how he would make a living when there were no more Radiated Tortoises (Webster 1997).

Some of the smuggled Radiated Tortoises leaving Madagascar have been seized by importing countries. In May 1992, for example, a Dutch citizen arriving from Madagascar was stopped by Customs at Roissy Airport in the Netherlands in possession of 46 Radiated Tortoises as well as 14 bamboo lemurs of several species and seven endangered Madagascar Boas (*Acrantophis madagascariensis*); the animals were confiscated and returned to Madagascar (TRAFFIC 1992). In 1998, a Radiated Tortoise was among many rare tortoises seized in Belgium as they were being imported, and U.S. authorities, under fiOperation Chameleon,fl an undercover investigation of trafficking in illegal Madagascar reptiles, seized Radiated Tortoises from an American reptile dealer in Miami. In May 1999, French Customs officers seized 450 tortoises smuggled by three Malagasy citizens living in Paris (TRAFFIC 1999b). Among them were 120 Radiated Tortoises; the suspects were not arrested (TRAFFIC 1999b).

Most ecotourism on the island has been developed for viewing lemurs, chameleons and birds, but the Radiated Tortoise and its extraordinary habitat of endemic plants have the potential of attracting many tourists. Also living in this tortoise's habitat are spectacular sifakas, many unusual birds, and other reptiles. In Beza-Mahafaly Reserve, scientists are studying the ecology and longevity of these tortoises, as well as searching for a permanent form of marking that would make them unattractive to collectors. The Radiated Tortoise could be conserved while helping local people like Benjamin. Grants from international organizations could finance jobs held by local people, such as ex-poachers, to protect the tortoises and serve as wardens. Former collectors could help educate schoolchildren and local people about protecting Radiated Tortoises and other wildlife. Organizations, such as Earthwatch Institute, might sponsor research to study the status of these tortoises. The presence of scientists would pose a deterrent to poachers.

Two other endemic tortoises, the Spider Tortoise (*Pyxis archnoides*) and the highly endangered Flat•shelled Tortoise (*Pyxis planicauda*), are much smaller, about 5 or 6 inches long (Preston•Mafham 1991). The latter tortoise is restricted to a forest of only 40 square miles, and a captive•breeding program is attempting to prevent its extinction. Both these tortoises lay only a single, large egg (Preston•Mafham 1991). These tortoises are also in demand by reptile collectors. In August 1996, six men were indicted after being arrested with four Spider Tortoises in their luggage at the Orlando International Airport in Florida. They were part of a smuggling ring supplying rare reptiles to collectors. In 1999, 330 Spider Tortoises were seized along with Radiated Tortoises in the case cited above (TRAFFIC 1999b).

The Madagascar Big-headed Turtle (*Erymnochelys madagascariensis*), is an endangered freshwater species listed in the *2000 IUCN Red List of Threatened Species* and on Appendix II of CITES. This turtle is related to South American river turtles, another link that may date back to the time before Madagascar drifted away from Gondwana. The Jersey Wildlife Preservation Trust began a breeding program for these turtles in 1999 with the objective of releasing young turtles back into the wild after educating local people.

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 3
Madagascar is home to two•thirds of the world's chameleons--at least 62 species--more than any other country (Tyson

2000). Among the island's endemic chameleons are the world's smallest and largest species. The smallest, *Brookesia minima*, is only 1.3 inches long, while the largest, *Furcifer oustaleti*, measures 27 inches in length (Preston•Mafham 1991). Their conical eyes, moving independently, can look forward and backward at the same time, swiveling almost 180 degrees in either direction (Preston-Mafham 1991). This adaptation, processing totally divergent information spontaneously, would confuse most vertebrates, but chameleons, even very young ones, are adept at using these dual periscopes to locate insects and other prey. They hold onto the thinnest branch with their prehensile tails, and with long, thin legs bent at the knees, they walk in an odd back-and-forth swaying motion that resembles leaves moving in the wind. Their chunky bodies and spindly legs give them an awkward appearance, but they are superbly adapted to catching their prey by unfurling a long, sticky tongue--curled upside their mouth--with lightning speed, nailing an unaware insect with astonishing accuracy.

Their camouflage coloration, which varies greatly from bright greens, mottled browns, reds and blues, helps protect them from avian and mammal predators. Contrary to general opinion, chameleons do not change colors as they move about in the trees or on the ground to match their background. When they suddenly change colors, it is as a territorial or sexual display meant for other chameleons (Preston-Mafham 1991). Some species have horns and other protuberances, giving them the appearance of miniature dinosaurs. A few species show sexual dimorphism, or a physical difference between the sexes. The contrast can be so striking that some were considered separate species when first identified (Burger and Price 1996). In one species, for example, the female is black and yellow, and the male a mottled brown and white (Burger and Price 1996).

Chameleons are heavily exploited by collectors who capture them for sale in pet stores around the world, threatening them. Collectors will pay $1,000 or more per animal for rare species. This trade, which involves thousands of individuals, has caused declines in many species. The Malagasy government has banned trade in most species, but enforcement is not strong. One chameleon, *Chamaeleo brevicornis*, of which 795 were exported in the first six months of 1990, is restricted to only a few areas of primary forest (Behra 1993). An ongoing study will evaluate whether to allow trade in the commoner species. Chameleons captured and shipped abroad for the pet trade suffer very high mortality as a result of inhumane transport conditions and inadequate care in pet stores and people's homes. They require special conditions of temperature and humidity, and many have specialized diets. In short, they are not suited to being house pets. In the care of specialists, they can be kept alive, but most captive breeding has been unsuccessful. Some of the rarer species, such as the beautiful blue-green Parson's Chameleon (*Chamaeleo parsonii*), which can reach lengths of more than 20 inches, have not been bred to the second generation**,** and mortality is high. All chameleons are on Appendix II of CITES, which requires export permits, but none has been listed on Appendix I of CITES, which would ban commercial trade.

Although some chameleons have adapted to disturbed habitats, such as weedy fields and shrub landscape, the majority favor natural habitats. The small *Brookesia* chameleons, of which one species is listed by IUCN as Vulnerable (Hilton-Taylor 2000), require undisturbed, primary old-growth forest. Three other chameleons, all *Furcifer* genus, are listed as Vulnerable by IUCN. All are in decline, approaching endangered status.

Although many Malagasy regard chameleons as ugly porters of bad luck (Burger and Price 1996), for tourists, they are the second most popular animals, after lemurs. Some Malagasy, aware of the fascination with which chameleons are held by tourists, capture them and offer them for viewing or sale.

Another lizard being captured for the pet trade is the extraordinary 4-inch-long Leaf•tailed Gecko, *Uroplatus fimbriatus*, a true master of camouflage. Resting during the day with its head tight against a tree trunk, an elaborate lacy fringe along the underside of the body allows it to melt into the tree, while its skin is patterned to resemble tree bark. Even its golden eyes are streaked with tiny dark lines that imitate bark. With broad, flattened front feet splayed out against the bark and hind legs held vertically under a spatula•like tail, it becomes virtually invisible (Preston•Mafham 1991). If discovered, however, it has a defense. Opening its mouth wide to reveal a crimson•red tongue, it raises its tail vertically and emits an ear-splitting screech, no doubt intended to be a fearsome display (Preston•Mafham 1991, Tyson 1994). Malagasy boys have discovered the haunts of the Leaf-tailed Geckos, and

capture hundreds--thousands by their accounting--for sale to foreign middlemen who pay them less than $1. They are sold in the United States for $250 a pair (Tyson 1994, Tyson 2000). On Nosy Be island off the northern coast, schoolboys claim to have captured 40,000 over the past six years (Tyson 2000). A threatened gecko, Standing's Day Gecko (*Phelsuma standingi*), is native to the spiny forests of the south and is one of the most coveted by collectors (Tyson 2000). It is hunted out of many areas because Malagasy have captured hundreds, receiving $1.20 per gecko, while reporting only a few to authorities (Tyson 2000). It is on CITES Appendix II, and sells in the United States for $80 to $200 apiece (Tyson 2000). Most species of geckos bring the village collectors only about 3 U.S. cents, while the exporter receives $9 to $13 and U.S. retailers get $75 or more (Burger and Price 1996). In most cases, these pet reptiles live a very short time, and represent a mere toy to the consumer.

The export trade in live lizards involves an enormous number of animals. One gecko, *Phelsuma serraticauda*, was known only from a few museum specimens until 1,360 specimens were chronicled as exported during the first six months of 1990 for the pet trade (Behra 1993). During this same period, 22,837 lizards--geckos, *Phelsuma* genus, and chameleons, *Chamaeleo* genus--were exported from Madagascar (Behra 1993). Between 1986 and 1991, almost 145,000 lizards of 17 species were exported; of these at least 38,325 were chameleons of 21 species (Burger and Price 1996). Many of these are species that are endemic to restricted areas, or threatened in the wild. The U.S. Fish and Wildlife Service™s fiOperation Chameleonfl succeeded in arresting 19 people in 1998, among whom was a major Malaysian smuggler and an American, Tommy Crutchfield, who was arrested at Miami International Airport with suitcases full of rare snakes, tortoises and lizards. In another case, a Canadian and a Dutchman were arrested at Chiang Kai-shek International Airport in Taiwan with numerous chameleons and geckos, including some threatened Standing's Day Geckos.

Several gecko species have extremely limited ranges. A newly described leaf gecko, *Uroplatus malama*, is known from a single specimen taken in a remnant of lowland rainforest in southeastern Madagascar (Burger and Price 1996). Only two specimens of a closely related species, *Uroplatus malahelo*, exist, native to a small patch of forest in the south (Burger and Price 1996). When discovered, its habitat was being logged, and the species may already be extinct (Burger and Price 1996). An extremely rare lizard, *Zonosaurus boettgeri*, known from two specimens that were taken in the 1890s and subsequently disappeared, has been rediscovered on the island of Nosy Be by herpetologist Chris Raxworthy and volunteers from Earthwatch Institute (Tyson 2000). The two individual lizards were killed as specimens upon rediscovery (Tyson 2000).

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 4

Among Madagascar's 80 types of snakes--all non-poisonous--are three boas, whose closest relatives are found in South America (Burger and Price 1996). They are thought to be among the island's most ancient inhabitants, resident since the early breakup of Gondwana (Preston•Mafham 1991). All are considered Vulnerable by the IUCN (Hilton-Taylor 2000): Dumeril's Boa (*Acrantophis dumerili*), Madagascar Boa (*Acrantophis madagascariensis)*, and the Madagascar Tree Boa (*Sanzinia madagascariensis*). The first two are Madagascar's largest snakes, reaching almost 6 feet in length; Dumeril's Boa is restricted to the south and southwest, while the Madagascar Boa is found in the north and northeast (Preston•Mafham 1991). Both species require humid habitats along streams and watercourses. Placid and slow•moving, they are often killed or captured by local people. The Madagascar Tree Boa is smaller and more common, shaded in delicate grayish-green with a purplish•blue tinge. Little is known of any of these species' life histories and diets (Preston•Mafham 1994). A very rare and possibly extinct snake, *Pararhadinea albignaci*, is known only from a single specimen picked up, dead, off the road in eastern Madagascar in 1970. This species has never been seen alive in its forest home (Preston-Mafham 1991).

One of the most extraordinary snakes in the world, *Langaha nasuta*, mimics a dry, pencil-thin twig to camouflage itself among the leaves. The female's nose is extended into a leaf•shaped structure adorned with scales and small

tooth•like projections, while the nose of the male is elongated, tapering into a sharp point to resemble a thorn (photo in Preston•Mafham 1991 and Lamar 1997).

A smuggling operation involving hundreds of Madagascar reptiles was exposed in August 1996, when six men were charged with conspiracy to smuggle rare Madagascar reptiles into the United States and Canada. According to the U.S. Justice Department, two men were arrested at Orlando International Airport in Florida with 61 Madagascan tree snakes in their suitcases that were to be sold at a large reptile breeders show in Orlando (Reuters 1996). Four Germans, one Canadian and one South African were indicted. Simon Harris, the South African, had $100,000 worth of rare reptiles in his luggage; he cooperated to implicate the other suspects, who are still being sought (Reuters 1996). These smugglers shipped snakes and tortoises, concealed in suitcases, from Europe to Canada and the United States and received payment by international wire transfers. Most of the snakes and tortoises were listed on CITES. In 1998, 26 Madagascan Tree Boas were seized in Belgium, and an American reptile dealer was caught by the U.S. Fish and Wildlife Service with the latter species and Dumeril's Ground Boas in his luggage at Miami International Airport (TRAFFIC 1999a).

The sea turtles inhabiting Madagascar's coastal waters are heavily exploited in spite of their listing on Appendix I of CITES. A survey in 1971 estimated that 13,000 were killed along the west coast alone (Burger and Price 1996). Little is known of their present populations.

The Biological Wealth of an Impoverished Country: Reptiles and Amphibians: Page 5

Some 176 species of amphibians, all frogs, have been named and described (Mittermeier *et al.* 1999). Raxworthy estimates that there are another 124, many of which have already been found but not yet described scientifically (Tyson 2000). Salamanders and toads are absent from Madagascar. All but two frogs are endemic, one of which was introduced from Asia by French colonialists as a gourmet food source (Burger and Price 1996). The majority are native to rainforest environments, the most endangered type of habitat on the island. In one such area, a montane rainforest in the Andasibe region, 90 species are native--the highest diversity of frogs in the world (Burger and Price 1996). Since 1990, 13 new species of a single, colorful genus, *Boophis*, have been described, and others await naming by scientists (Burger and Price 1996). A candidate for the world's smallest frog--and perhaps the world's smallest vertebrate--is a minute frog, *Stumpffia pygmaea*, which measures less than 3 millimeters in length (0.117 inches) (Burger and Price 1996). This frog lays its eggs in foam nests hidden among leaves on the forest floor, and the tadpoles grow into froglets without ever feeding (Burger and Price 1996).

The most spectacular Malagasy frog may be the bright red Tomato Frog (*Dyscophus antongili*), which secretes poisonous white mucous when threatened. Some authorities consider the species to be endangered (Bauer 1995), while the *2000 IUCN Red List of Threatened Species* lists it as Vulnerable. To protect it from trade, it is listed on Appendix I of CITES. Fat and squat, this toad-like frog is large enough to cover the palm of a hand (Preston-Mafham 1991). Tomato Frogs have a very restricted range in the region of Tamatave on the east coast; some live in plantations, where pools of water gather, and even in garden ponds (Preston-Mafham 1991). Collectors, pet dealers and zoos have offered thousands of dollars for these frogs, and illegal shipments containing 40 or more Tomato Frogs have been confiscated.

One study entitled "The Export of Reptiles and Amphibians from Madagascar," by Olivier Behra (1993), chronicled the extent of exploitation of frogs. In 1988, 230 frogs of the genus *Mantella*, endemic to Madagascar, were exported. The demand increased, causing exports to rise astronomically to 11,058 in 1989; in the first six months of 1990 alone, almost 11,000 were exported, mainly to Denmark and other European countries, the United States and Japan (Behra 1993). These brightly colored little frogs are sold as pets and to decorate terrariums. The most popular Madagascar frog in this trade is the tiny Golden Mantella (*Mantella aurantiaca*), of which 3,237 were exported in the first six

months of 1990 (Behra 1993). This frog is restricted to eastern Madagascar, and is apparently rare and declining (IUCN 1994). It lives in pandanus swamps in rainforests, which are rapidly disappearing, and no part of its habitat has been set aside in a reserve (IUCN 1994). Unlike most frogs, the Golden Mantella is slow-reproducing (IUCN 1994). In the 1990s, 3,000 to 6,000 were exported annually from Madagascar, and in 1994, two proposals sought to list this species on CITES, one on Appendix I and the other on Appendix II. The latter proposal succeeded, which is unfortunate, since it allows the trade to continue. The *2000 IUCN Red List of Threatened Species* lists the Golden Mantella as Vulnerable (see photos of gold and red phases of this species in Lamar 1997).

In 1998, two people were arrested in Taiwan trying to smuggle frogs of two *Mantella* species (*Mantella madagascariensis* and *Mantella aurantiaca*), along with some Madagascar lizards. Another seizure of 50 Mantella frogs occurred at Zaventem Airport in Belgium in 1998 as they were being smuggled from Madagascar (TRAFFIC 1999a). Such seizures involved shipments without the proper export permits. Appendix I listing under CITES would provide greater protection.

The Biological Wealth of an Impoverished Country: Invertebrates

Like the rest of its fauna, Madagascar's invertebrates are extraordinary. One insect from the age of the dinosaurs, the Giraffe-necked Weevil (*Trachelophorus giraffa*), has an elongated neck which rises vertically, then makes a right-angle turn and extends horizontally, and ends in a tiny head with furry antennae. Amazingly, this insect has counterparts in New Zealand known as giraffe weevils (Molloy 1994). This may be explained by the fact that New Zealand was also part of Gondwana prior to its breakup (Molloy 1994). Other ancient species include the 100 species of hissing cockroaches. Some are far larger than any other cockroach species in the world; their heavy bodies resemble long-extinct trilobites. The largest species measure up to four inches long, and thousands are exported for the novelty pet trade and for zoos. When touched, they hiss loudly, and males aggressively charge one another with their armored, knobbed shields (Preston-Mafham 1991).

One of the richest land-snail faunas in the world is native, with more than 380 species named so far, 361 of which are endemic and differ greatly from land snails in Africa (Preston-Mafham 1991). Many are threatened, however, by introduced African Giant Snails (*Achatina fulica*) and several other non-native snails introduced to control the African Giant Snail, but threatening native species instead. One native snail, *Tropidophora deburghiae*, is considered endangered by some authorities. Brilliantly colored slugs, or shell-less snails up to 6 inches long, striped in black-and-red or yellow-and-brown, live on the damp rainforest floor (Preston-Mafham 1991). Many have limited distributions and can be easily eliminated by habitat destruction (Preston-Mafham 1991).

An extremely ancient family of spiders, Archaeidae, first described from a specimen frozen in amber several million years old, has seven species on Madagascar, one in South Africa, three in Australia, five in New Zealand and one at the tip of South America; these species appear to be vestiges from the ancient supercontinent (Preston-Mafham 1991). The Archaeidae spiders have strange, grotesquely shaped bodies, visible only through a microscope since they are only 0.14 inches long; they live among leaf litter on the ground (Preston-Mafham 1991). Some Madagascar spiders are extremely bizarre, with shapes that resemble bat-winged leaves, bright red thorns, or mottled brown lumps on logs (Preston-Mafham 1991).

Millipedes on Madagascar reach 6 inches and exude droplets of poison when attacked; Brown Lemurs have found ways of avoiding this toxin and feed on them (Preston-Mafham 1991). Shield-bugs, or stink-bugs, of the family Pentatomidae, have 220 species on Madagascar, many of which are brightly colored in reds, oranges and blacks; 120 species of water bugs, of which 80 percent are endemic, and a variety of assassin bugs add to the rich insect fauna (Preston-Mafham 1991). About 20,000 beetle species, including 500 species of endemic jewel-beetles, are native to Madagascar. Jewel-beetles, with their colorful, metallic bodies, appear during the rainy season in southern and

western forests (Preston-Mafham 1991). Many species of scarab beetles, among which are dung beetles, are also native to Madagascar; one endemic genus, *Helictopleurus*, roll the dung balls into their nests and lay their eggs in them (Preston-Mafham 1991).

Madagascar's butterflies, totaling 300 species, are not as diverse as in some parts of the world, such as the Tambopata Natural Reserve in Peru, which has 1,300 species. This may be because they colonized the island fairly recently. Another possibility is that many species have faded into extinction, leaving no trace, when the plant species upon which they depended were driven to extinction by habitat destruction. Since 80 percent of the island's forests have been cut, hundreds or thousands of species may have disappeared without a trace millennia ago. One Madagascar butterfly, a pale cream-and-black Swallowtail, *Papilio mangoura*, is hotly pursued by collectors because of its rarity (Preston-Mafham 1991). Several butterflies of the Nymphalidae family, or Fritillaries, are threatened, as are two species of the family Acraeidae.

In the 19th century, Charles Darwin learned of a spectacular, white Madagascar orchid (*Angraecum sesquipedale*) that had an extremely long, nectar-bearing tube dangling down from the flower. He reasoned that it could be pollinated only by an insect that could reach its nectar. He guessed that it might be "some huge moth, with a wonderfully long proboscis." Entomologists verified his belief with the 1903 discovery of the hawkmoth, *Xanthopan morgani praedicta*. This moth has a 9-inch tongue that it keeps wound in a spiral in its mouth, unfurling it to reach the nectar of this particular orchid. In a similar arrangement, another orchid (*Angraecum arachnites*), exudes a strange odor that attracts only one pollinator, the rainforest hawkmoth, *Panogena lingens* (Preston-Mafham 1991). The nectar at the base of this orchid's long, twisted tube can be reached only by this single species of moth--and not even every individual, but only one race of this moth which has a long, tapered proboscis (Preston-Mafham 1991). These species co-evolved, and should the moths become extinct, the orchids would have no pollinators and would follow them into extinction. Another unusual moth, the huge Comet Moth (*Argema mittrei*), is one of the largest moths in the world (Preston-Mafham 1991).

Preserving Madagascar's Natural Wonders

This fourth largest island in the world is, in many respects, a minicontinent. This evolutionary treasure-house is of great importance from a worldwide perspective. Madagascar's diversity of life forms is so great that as many as 200,000 species, most of them undescribed, may be native, of which an estimated 150,000 are endemic species (Daley 1997). The habitat loss is proceeding so rapidly, however, that the underfunded biological assessment studies will be unable to appraise this biological wealth before it disappears before their very eyes. Logging and burning have reduced the forested area from 120,000 to 20,000 square miles; this destruction still consumes vast areas each year (Daley 1997). It is estimated that all the remaining accessible forests will disappear within the next 35 years (Sayer *et al.* 1992). With the impending loss of these treasures, many conservationists and scientists consider Madagascar the world's most threatened natural area (Sayer *et al.* 1992).

Less than 5 percent of Madagascar is protected in reserves and parks. Even if these lands remain intact, they represent too small a percentage of forest to preserve the island's genetic heritage. Other than Masoala National Park, which encompasses most of an entire peninsula, some 840 square miles, most reserves are relatively small--islands of forest surrounded by denuded land. Should all surrounding forest be leveled, these isolated fragments would not be sufficient to prevent genetic impoverishment, inbreeding, and eventual extinction of the very species the reserves were meant to protect. Recent research in the Amazon has shown that forest fragmentation results in extinctions, in direct relation to the size of the reserve (Peters and Lovejoy 1990). The larger the reserve, the fewer extinctions. For this reason, Masoala National Park is receiving special attention from scientists. Stanford University's Center for Conservation Biology is analyzing a Geographic Information System (Kremen 1998). So far, this research has revealed that forests on the eastern border of the park are the most threatened, with a likelihood that they will be

completely burned away within 25 years (Kremen 1998). The borders of the park were delineated according to the results of biological surveys, a method that is so new that it has not even been used in the United States. Claire Kremen of the Wildlife Conservation Society, with additional support from the National Geographic Society, worked with a Malagasy entomologist and two American ornithologists to conduct detailed biological species diversity studies in this rugged terrain (Kremen 1998). Five new species of butterflies and many other insects were discovered. Each had its own micro-habitat, endemic to that area. Habitats included in the national park are lowland rainforest; cloud forest and montane heath; coastal and seasonally flooded forest; mangrove; marsh; estuary; bay; lagoon; and coral reef. Lemurs and a vast array of wildlife and plants will benefit from this new park.

Masoala National Park will not displace villages but will conduct education programs and involve them in the conservation of local wildlife. The Missouri Botanical Garden is also involved in the management of Masoala National Park, helping to inventory its rare plants and working with local people for non-destructive agricultural and fisheries industries. Work is also proceeding to stop the cutting of forests for firewood on Masoala and to provide public education on land use (Sayer *et al.* 1992). Some 300 or so villages exist within or nearby Masoala National Park, and the cooperation of the local people is crucial to the success of this park. The final plan for the park involved a compromise in which some cutting of four relatively fast-growing trees, including rosewood, would be allowed. Local communities, which will profit from the products, will be allowed to harvest palm seeds and butterflies. This will prevent the slash-and-burn destruction that was eating rapidly away at this forest (Kremen 1998). This park's endemic plants and animals, including the Red Ruffed Lemur, which exists only in the park, rely for their survival on the protection of this last sizeable rainforest. It will represent an experiment in conservation management that will have serious consequences should it fail. It is, however, one of the first times that ecological rules are being worked out with large numbers of local people to help protect such a large area. Elsewhere in Madagascar, similar projects are in the works.

Many of Madagascar's rarest species are not protected in any reserves, however, and may soon be lost. Reserves and parks, the last refuge for many species, are regularly pillaged for trees, and wildlife is killed or captured. A herpetologist surveying in Bemaraha Reserve, in the western part of the island, discovered a pile of illegally cut trees that had been marked with red paint as part of a botanist's study by the trail in 1996 (Holmes 1997). This is not an isolated occurrence. The native wildlife and plants are among the most endangered in the world. More than 124 vertebrate species are listed in the *2000 IUCN Red List of Threatened Species* (Hilton-Taylor 2000), as well as 306 species of plants (Walter and Gillett 1998). While this crisis is occurring, new species of lemurs, reptiles, invertebrates and plants are being discovered, making the preservation of the environment all the more urgent. Obviously, the amazing biological diversity of Madagascar has not been fully assessed and may be far greater than previously thought.

Several species thought long-extinct are rumored to survive, adding even more mystery to the picture. Many Malagasy have told scientists of having seen an animal that might be a pygmy hippopotamus. Shown a picture of an African Common Hippopotamus, they have said that it was similar, but had floppy ears, uncloven hooves, dark skin, except for pinkish areas around the eyes and mouth, and was the size of a calf or small cow (Tyson 2000). As recently as 1976, a man told biologists of having seen and heard one grunting; many unsolicited, independent accounts from Malagasy have agreed on these details (Tyson 2000). They call the animal "kilopilopitsofy," and many are afraid of being chased by it (Tyson 2000). The Common Hippopotamus of Africa also grunts and kills more people than any other animal on the continent.

A long-lost primate, ground-dwelling and the size of a 7-year-old child, has also been reported by several Malagasy (Tyson 2000). This may be the same animal that was described to primatologist Alison Jolly (1980). A Malagasy told her that he had been given a young lemur of a type he had never seen before. This lemur had very dark fur, walked on its hind legs, one foot after the other, rather than hopping like a sifaka, and had a flat face different from the pointed muzzles of living lemurs. After only two months, this lemur died, and its skeleton was buried in an unknown place (Jolly 1980). An old man recently told a similar story of having seen such an animal in 1952. Called the "kidoky" by others who have seen it, it has a dark coat with white spots above and below a flat, round face. When alarmed, it flees

by leaping forward in short hops like a baboon. Its call was described as a long, single whoop, and other villagers who had seen the animal said it was solitary (Tyson 2000). Scientists have said that if it exists, it might be an *Archaeolemur* or *Hadropithecus* (Tyson 2000). The fact that their descriptions seem so similar to species known to have existed makes them all the more intriguing.

Alarm calls about the impending demise of Madagascar's natural world have been sounded for decades (Jolly 1980, 1988; McNulty 1975; Preston•Mafham 1991; Tyson 2000). Visitors to the island are united in their descriptions of a ravaged, eroded and deforested land. Jacques•Yves Cousteau and his team visited the island for a television special aired in 1995. As they sailed toward Madagascar, they were stunned to see huge, wide, red stains of eroded soil in the water, emanating from the island's rivers, and wisps of smoke from burning forests. These red rivers are bleeding the island's life blood, its topsoil. They are so pronounced that they are among the few natural phenomena on Earth visible from orbiting space craft. Cousteau's helicopter flights over the central plateau revealed a landscape among the most devastated on the planet. A research team sponsored by Earthwatch Institute described the island from the air, "Two features of the landscape stood out even from 10 kilometers up: barrenness and smoke" (Tyson 1994).

Although erosion remains a major problem, some progress has been made to stop it (Morell 1999). Erosion costs Madagascar between $100 million and $290 million per year, caused mainly by the continued slash-and-burn agriculture (Tyson 2000). It has been extremely difficult to convince many Malagasy that the last of the forests will disappear within a generation if they do not seek alternative means of growing crops. To that end, Cornell University's International Institute for Food, Agriculture and Development, run by Norman Uphoff, has been helping farmers in the vicinity of Ranomafana National Park (Tyson 2000). These desperately poor farmers have no electricity or plumbing and struggle to feed large families on soil that is leaching its nutrients. Norman Uphoff discovered that the native Wild Ginger plant had high concentrations of phosphate, and he encouraged its use as fertilizer (Tyson 2000). By supplying seedlings and information, the Cornell program also has helped establish fish farms. Their agronomists have advised farmers to mix crops and to plant certain species in order to keep the soil rich and retard erosion; they have supplied seedlings (Tyson 2000). This agricultural advice has been helpful, but because some rural people have so many children, many are unable to produce enough crops to feed their families (Tyson 2000). Other projects involve encouraging rice cultivation with more suitable seed varieties, improved irrigation systems and application of fertilizer (Garbutt 1999). Using native bees in honey-making is also being taught to the Malagasy, who often fell old-growth trees to obtain honey (Garbutt 1999). The Kew Botanical Gardens in London and Britain's Royal Palm Society are researching the marketing of seeds from some native palm trees (Terry 1996).

International aid organizations could help preserve forests by donating fertilizer so the Malagasy would not need to practice slash-and-burn when forest soil ceases to produce crops. The urgent task of supplying the Malagasy people with methods of producing food and fuel in environmentally non-destructive ways has just begun. Villagers would be more likely to preserve trees now cut for firewood if they were provided with solar cookers or given propane tanks for fuel. Bio-gas, or methane, produced by animal dung and sewage, could be used to provide fuel and fertilizer. Such projects have been launched by international agencies in some countries of Central Asia.

Madagascar's human population is growing at a rate of 3.1 percent per year and reached 12,596,000 in 1992 (55 persons per square mile) (Anon. 1994). By 1995, it had grown to 13.9 million (61 persons per square mile) (McNeil 1996b). Another increase to 14,462,509 people (64 persons per square mile) was registered in the 1999 *World Almanac*. The *2001 New York Times Almanac* noted a population of 15,506,472, based on a July 2000 estimate. Thus, 3 million people were added to the population in just eight years. Along with the original Asians, more recent immigrants from Africa, India, Pakistan, China, Europe, and Arab countries add to the diversity. They have long since passed the carrying capacity of the land, and rice must be imported to feed the people. As one of the world's 12 poorest countries, Madagascar's external debt is approximately $4.25 billion. Average annual income is only $780 (NYT 2000). The unemployment rate is about 33 percent, and 51 percent of children are malnourished, according to a study by USAID (Tyson 2000). The literacy rate is 46 percent, and only 42 percent of children attend schools; 70 percent of children ages 6 to 9 have had no formal education (Tyson 2000). Jacques Cousteau's team filmed hordes of desperately poor people as they combed dumps for scraps of metal and food. Some people even live in these dumps in

holes they have dug in the soil. Such scenes are symptoms of extreme overpopulation and rampant poverty that can also be seen in parts of Brazil and Asia.

One of the reasons that illiteracy is so high in Madagascar is that millions of people must spend their days searching for food, water and firewood, requiring the help of their children, who are then unable to attend school. In general, foreign corporations have looted the island's resources, leaving no economic base that would help the people as a whole. One U.S. company, the Esso Corporation, is owed $25 million by the Madagascan government and demanded payment in spite of the country's cash reserves of less than $2 million (McNeil 1996b). Because of the country's debt levels, the World Bank and the International Monetary Fund are now in charge of its finances (McNeil 1996b), a potentially dangerous situation for both the people and the environment. On the positive side, a "Debt for Nature" swap was carried out in Madagascar, in which a portion of the foreign debt was exchanged for the establishment of nature reserves and parks.

To date, efforts to slow the population growth rate are still in their early stages. A program that addresses population growth, based not on threats or punishment, but on persuasion, was launched by Population Communications International (PCI) of New York City in 1996. As the organization has done in other countries, it trains local people to create communication programs for radio and television with a message that limiting family size is advantageous. The majority of the population on the island lives in cities and has access to these media. The programs, described as "soap operas" by PCI, create melodramas with characters the audience can identify with, who act out dramas. The characters in these dramas come to realize that different behavior, such as having fewer children, will result in positive changes in their lives (Ryerson 1994). In many cases, this involves elevating the status of women, and convincing men that women must be allowed to make decisions about their own reproduction (Ryerson 1994). PCI is cooperating with organizations that are actively trying to conserve the wildlife of Madagascar, such as Conservation International and the African Wildlife Foundation. Ranomafana National Park began a family planning center in 1994 to help the people of the region, many of whom have as many as 14 children, of which 62 percent are underweight and 17 percent malnourished, according to a study by the University of North Carolina (Tyson 2000).

Madagascar is a magnet for scientists from around the world and has been the recipient of millions of dollars in foreign aid and grants from international conservation agencies. Conservationists are initiating many highly inventive and effective programs to interest the Malagasy in conservation and employ them in biodiversity work. Environmental education is a key to the future of Madagascar, and programs are being carried out at Beza-Mahafaly Reserve. This protected portion of endangered spiny desert and shrubland was established when the local Mahafaly people agreed to donate the land, and funds were raised by Alison Richard, a Yale primatologist, for a training program for Malagasy scientists (Tyson 2000). Patricia Wright has set up a similar program in which Malagasy students complete master's theses based on wildlife research in Ranomafana National Park, and some students travel to the United States to receive advanced training in biodiversity and environmental protection (Tyson 2000). They will help guide the country in new directions in the future. It also opens new worlds to these students, who, in turn, will make young people aware of the natural treasures in their country. Schools that Patricia Wright has helped establish in the area of the park teach environmental education to young people. Others are also helping introduce this subject to children. Josephine Andrews, a Scottish scientist studying Black Lemurs in Nosy Be since 1988, teaches children about the lemurs with the help of a Malagasy named Julien, who guides people around the forest preserve (Tyson 2000). "If the kids are really into it, then the adults will switch on as well," she said (Tyson 1994). Forests are the key to the future survival of the island and its people, and an education program aimed at rural people, teaching the value of trees in preventing floods, landslides and in maintaining the flow of rivers and streams, could save countless trees.

Scientists--both Malagasy and foreign--working on the island, could share their findings by talking with local people about the uniqueness of Madagascar's natural world. Ornithologists with the Peregrine Fund, who rediscovered the Red Owl and taught local schoolchildren about the species donated money from bird-watchers to the school, provided such an example. Scientists typically conduct research and depart without having taught local people about their findings. Villagers near Ranomafana National Park were so interested in learning about research results that they asked Wright for copies of reports. She began a bimonthly newsletter, in the Malagasy language, describing the

natural history of the park (Tyson 2000).

Films and books about Madagascar's wildlife and plants tend to be distributed only in foreign countries, and never translated into Malagasy. Translations of books and subtitled films could be shown to schoolchildren to introduce them to Madagascar's tremendously interesting and beautiful natural world. It is ironic that Westerners may be more familiar with lemurs and chameleons that most Malagasy. Some projects for the future might include donation of solar collectors and windmills to supply power to rural people. This could elevate their standard of living and cut back on firewood collection for fuel. Donation of projection and video equipment to regional schools provided with electricity would help them appreciate their natural heritage through viewing nature films of Madagascan wildlife. Satellite dishes would facilitate communication with people around the world through the Internet.

The government of Madagascar developed a 20-year National Conservation Strategy and Environmental Action Plan as long ago as 1984. In 1986, a survey of protected areas began with the aim of implementing management plans for priority protected areas and recommending new protected areas, as well as training Malagasy people to work in reserve management and conservation biology. The government has been working to create a sense of pride and ownership in the nation's biodiversity through this program (Morell 1999). The President of Madagascar has stated that the environment is important, a key to whether foreign scientists and tourists will be able to come to the country and aid in its conservation in the future (Tyson 2000). The World Bank and various organizations funded this Environmental Action Plan with $168 million for its first five years (Tyson 2000). This has resulted in many biological studies, education of a growing number of Malagasy for conservation work and a Biodiversity Planning Centre (Sayer *et al.* 1992). The Geographical Information System database is a cornerstone of the government program, concentrating data from all fields to help establish conservation priorities (Tyson 2000). Conservation International has an office in the capital and is contributing to biological inventory data, as it has in other countries, as well as conducting research on particular species and data management. It coordinates its work with local organizations and trains Malagasy scientists (Sayer *et al.* 1992).

Ecotourism is another budding industry, and Madagascar is one of the few countries in the world to share park fees with local people. As a result of an initiative put forth by a Malagasy non-governmental organization, the National Association for the Management of Protected Areas, one-half of all fees are given to local people (Tyson 2000). Ninety-three villages in the Ranomafana National Park area received about $10,000 in a recent year from park fees; a committee designated by the villages decides how to spend the money. In 1995 they bought seeds and built campgrounds, a crafts training center and small dams (Tyson 2000). Many local people are employed as park workers, and the aim of the program is to turn over management of this park and its biodiversity work to the Malagasy people. There needs to be a national park system with strict rules for management and protection, according to Patricia Wright, who deplored the illegal tree cutting by the previous park director at Ranomafana (Tyson 2000). She also has proposed that a national biodiversity institute be built, which would offer centralized training in biology and technology, as well as five new long-term biodiversity research stations similar to those in La Selva National Park in Costa Rica and the Smithsonian Institution's Panama tropical research laboratory (Tyson 2000).

Jobs, which are desperately needed by the Malagasy, are increasing as a result of the rise in the number of tourists. Selling crafts to tourists, running hotels and restaurants, and serving as guides are among these. Villagers who used to demand that parks be declassified so that they could legally gather wood, now request that more national parks be established, an apparent result of the new income that comes from fees and tourism (Morell 1999). International tourists have provided a major new source of revenue in Madagascar's economy and are helping the Malagasy see their wildlife in a new way, as so fascinating and biologically important that visitors come from every continent to view it. *Madagascar. The Bradt Travel Guide*, by Hilary Bradt (1999), published in various editions since 1988, is a useful aid for tourists, providing information about accommodations, natural history, protected areas, and the Malagasy and their history. Nature reserves and parks provide jobs by attracting scientists who employ local people, another incentive for the Malagasy to urge that more protected areas be set aside.

Compensation for lost access to forests has not been paid in the past, and new arrangements reached with villagers to

allow some extraction of resources from the forests may heal some of these wounds and placate those who still wish to cut trees. Medicinal plants obtained from Madagascar may be another source of revenue in the future. The Rosy Periwinkle may be only one of many native plants highly valuable in treating disease. Research on the potential of other plants may uncover other such treasures. In the past, revenues from plants used for medicine have not been returned in part to the country of origin, but recently a new trend has begun. In one case, a pharmaceutical company agreed to pay people in a South American country a portion of the revenues gained from any native plant providing a marketable drug.

Another potential source of revenue is the placement of videocameras connected to the Internet, which present websites with general information as well as live camera views of wildlife. South African parks have a number of these videocameras placed at water holes, animal dens and other key areas that capture live views of animals transmitted to the Internet for a small viewing fee. This has proven very successful, funding many of the South African National Parks system™s expenses. A similar system could be established in Madagascar with solar-powered videocameras, which have already been in use in Alaska, trained on tree canopies, rainforest flowers or lemurs, along with websites that provide basic information on Madagascar's environment, biodiversity and the Malagasy people. For millions of people who cannot visit Madagascar, such a website might be fascinating as a learning tool for teachers and the public, as well as an exciting view of these unique animals and their environments. If managed in such a way that profits were shared between poor Malagasy to alleviate their poverty, and conservation organizations to preserve biodiversity, such a system has great potential.

A satellite connection with classrooms in the United States or other countries would be another opportunity for interactive communication and learning. In December 2000, for example, students in an American classroom talked with students in a school in Guyana about endangered Giant Otters and their conservation through a visual satellite hookup. Students and others might set up an interactive link with biologists and conservationists working in Madagascar, asking questions and offering help. Students have provided many excellent ideas for conservation, and classes have raised money to save rainforests and threatened wildlife habitat and to help stop poaching of endangered species in countries half a world away from their own. Malagasy young people might be inspired and enthusiastic through talking with others of their own age about conservation and biodiversity. Video cameras and still cameras might be donated to Malagasy students and young people to record nature and compete for prizes with their results.

Madagascar™s Lessons

Madagascar's story is one of ecological catastrophe and the gradual extermination of its life forms. One's first response might be that its experience is as far from the rest of the world as it is geographically remote. However, it is from the extremes that one acquires basic knowledge. The effects of immigrants, whether human, animal, plant or disease, can devastate natural ecosystems wherever they occur. Islands are especially vulnerable to the effects of invasive species, including humans, because their flora and fauna have limited habitats and tend to be endemic, with small populations.

Exotic or non-indigenous species threaten 350 species of birds, or 30 percent of all threatened birds listed by BirdLife International in *Threatened Birds of the World* (BI 2000). Likewise, 361 plant species and 69 species of mammals listed by the *2000 IUCN Red List of Threatened Species* are threatened as a result of non-indigenous species (Hilton-Taylor 2000). The effects of invasive species, including humans, have been the major cause of extinction of virtually all bird species, almost all of which have occurred on islands. In the case of Madagascar, the Malagasy and other immigrant peoples and their livestock, and their subsequent hunting and habitat destruction, presented the vulnerable native species with threats against which they had no defense. Islands throughout the world continue to suffer losses in biodiversity, as do areas with large numbers of endemic species in mainland areas. Species with restricted ranges are the most likely to go extinct or become endangered. Such species dominate the list of birds in

Threatened Birds of the World (BI 2000). In this age of international commerce, where plant diseases and other viruses are brought into countries in shiploads of lumber or ballast water, and exotic animals and plants continue to colonize and be released in delicate ecosystems with endemic species, whether on islands or mainlands, it has become extremely difficult to defend native species from such invasions. Nevertheless, through preserving native plants and animals and legislating against such introductions, while removing non-native species, ecosystems and their diversity can be protected. Preserving natural ecosystems is vitally important, not just for wildlife preservation, but for humans as well, so that precious water supplies, topsoils and biological diversity, which stabilize all ecosystems, are protected. These lessons have not yet been put into practice in Madagascar or in many other parts of the world, including developed countries. Ecological and faunal changes may be so gradual that they go unnoticed until ecosystems have been destroyed.

Madagascar Testing Quotes

About 500 A.D., immigrant people from Asia, most probably Indonesia or Malaysia, arrived on Madagascar's shores in hand-hewn canoes, bringing domestic animals with them. They began clearing forests and burning them for farmland, and turned lakes and wetlands into rice paddies. Cleared land produced crops for only a few years until the thin soil became sterile. Farmers then moved on to other parts of the forest, in this slash-and-burn agriculture. At some point, African herdsmen colonized the island, bringing zebu cattle, which crowded out wildlife (Tyson 2000). Gradually, abuse of the land eroded the soil in the central highlands to bare earth, pocketed and gouged by deep gullies and cavernous holes. This region had harbored a great variety of lemurs, along with a wealth of birds, reptiles and unique plants. Throughout the island, wildlife declined as habitats disappeared, isolating animals in smaller and smaller patches of forest and wetlands. The large lemurs, tortoises and elephant birds were avidly hunted.

Within 600 years of the arrival of the Malagasy, extinctions claimed many native animals. Several elephant bird species, the larger lemurs and many native plants vanished. Two kinds of pygmy hippos inhabited the island. The Madagascar Hippopotamuses (*Hippopotamus lemerlei*), an amphibious species, and *Hippopotamus madagascariensis*, a forest species, were both about 6.5 feet long and 2.5 feet tall, smaller than the Common Hippopotamus of Africa, which is about 10 feet long (Tyson 2000). From genetic and anatomical analysis, both seem to have evolved from the latter species (Tyson 2000). The hippos had been widely distributed and very common prior to the arrival of the Malagasy (Dewar 1984). Their bones have been found with marks indicating that they had been butchered (Tyson 2000). Both died out long before Europeans arrived. The native crocodile, whose large bones have been found, is believed by some scientists to represent large specimens of Nile Crocodiles, the species native today (Tyson 2000). It is thus possible that the crocodile survived. A large mongoose-like viverrid, *Cryptoprocta spelea*, and a very unusual aardvark-like animal, *Plesiorycteropus madagascariensis*, died out at an early date (Dewar 1984).

Prior to the arrival of humans, elephant birds had been abundant in most parts of the island, as attested by the prevalence of their bones. There were two genera, and from six to 12 species of these birds (Tyson 2000). It is likely that the flightless birds fell prey to the primitive weapons of the Malagasy and were crowded out of their habitats by livestock (Tyson 2000). The last to die out was the Great Elephant Bird (*Aepyornis maximus*), which may have survived until recent times by retreating to remote swamps. Dr. Alexander Wetmore of the Smithsonian Institution examined bones of a Great Elephant Bird unearthed in archeological excavations in the 1960s. He was amazed by their size: "The incredible femur, or thighbone, of this ponderous bird is by far the largest I have ever seen" (Wetmore 1967). Estimated to weigh at least 1,000 pounds, more than three times the weight of an Ostrich, it produced eggs larger than any dinosaur's, with a capacity of 2 gallons (equivalent to seven Ostrich eggs), 180 chicken eggs or 12,000 hummingbird eggs (Bradbury 1919, Fuller 1987). When one was X•rayed, the bones of an embryo three•fourths developed were revealed (Wetmore 1967). Something had interrupted the embryo's growth and frozen it within the eggshell for hundreds and perhaps thousands of years (Wetmore 1967).

Despite its fearsome size, the Great Elephant Bird lacked a hooked beak for tearing prey and was plainly not a predator (Wetmore 1967). Its large, clawed feet may have helped it defend itself against the small native predators but were not enough to protect it from Malagasy arrows. Its short legs prevented it from running as fast as its relative, the Ostrich, but it may have been quite agile when chased. This vegetarian bird browsed and cropped plants, able to reach with its long neck to the lower branches of trees (Wetmore 1967). By the mid-16th century, when Europeans had managed to establish a foothold in Madagascar, the new French Governor, Sieur Etienne de Flacourt, wrote in 1661 that the Great Elephant Bird was still found in the south of the island, "seeking the most deserted places" to avoid human hunters (Tyson 2000). Villagers of Antandroy told of an Ostrich-like bird that was difficult to catch, according to Flacourt (Tyson 2000).

The exact date this giant bird became extinct is not known with certainty. Alan Feduccia (1996), an eminent paleo-ornithologist, asserts that elephant birds of many species were still widespread in the 10th century but gradually disappeared as a result of human activity. He cites an account by a French merchant sailor in 1848, who visited Madagascar and saw the shell of the Great Elephant Bird; he was told that it belonged to the chief and that the bird that produced such eggs "is still more rarely seen" (Feduccia 1996). Some authorities estimate that it died out in the mid-17th century, although there is no proof that any European ever saw one of these birds (Tyson 2000). It has been suggested that Europeans were responsible for the bird™s extinction by hunting and destroying its habitat (Quammen 1996). But Thomas Brooks (2000) of the Center for Applied Biodiversity Science, Conservation International, asserted in a list of extinct birds in *Threatened Birds of the World* (BI 2000) that all the elephant birds had disappeared by 1500. In a bizarre footnote to this species' epitaph, an *Aepyornis* egg washed up on Australia's western coast in 1995. No conclusive explanation for this strange event has been put forth, although it is likely that it became unearthed from long interment by rains, and washed out to sea. Much less is known of the other species of elephant birds, which existed in a variety of sizes down to a chicken-sized species.

Lemur-like primates once lived on many continents, but nowhere had they evolved into such a great variety of species. When the Malagasy people arrived some 1,500 years ago, lemurs occupied every habitat, even marshland. A species as tall as a man must have startled the Malagasy immigrants, giving rise to legends that these animals had superhuman powers. The first French naturalists were told by the Malagasy that these primates were thought to be the ghosts of sacred ancestors of man, inspiring the genus name Lemur, the word for ghost in Latin. The Malagasy considered some lemurs sacred and punished anyone who harmed them, but most species were feared as evil demons and were killed on sight.

From their arrival on Madagascar, the Malagasy hunted the larger species of lemurs, almost all of which are now extinct. Archaeological excavations show that they formed a staple in the immigrants' diets. Such diggings have unearthed the skulls and bones of long•extinct lemurs in early Malagasy jars and kitchen middens; their heads had been split by ax-heads made from an extinct flightless bird (Jolly 1980).

In the centuries following colonization by the Malagasy immigrants, some 15 species of lemurs of eight genera became extinct (Mittermeier 1997). These extinct lemurs were, for the most part, far larger than surviving species and had evolved to fill many ecological niches. Three *Megaladapis* lemurs weighed between 90 and 170 pounds and moved slowly through the trees, feeding on foliage (Tattersall 1993). Another species, *Archaeolemur*, was about the size of a female baboon and lived on the ground (Tattersall 1993). Two *Palaeopropithecus* species weighed between 90 and 130 pounds and were sloth•like tree dwellers with flexible bodies (Tattersall 1993). These extinct lemurs had evolved many unusual means of movement and locomotion that have no parallels in living species of lemurs.

Largest of all, the massive 400•pound *Archaeoindris* was apparently a ground•dweller, moving on all fours; many of its anatomical characteristics are unlike any living primate (Tattersall 1993). One entire lemur family, Archaeolemuridae, was obliterated. In this family were many species of lemurs weighing between 35 and 55 pounds; they were powerfully built and short•legged (Tattersall 1993). The heaviest lemur surviving today, the Indri (*Indri indri*), weighs only about 15 pounds (Tattersall 1993). These lemurs had survived for millions of years, and their extinctions were indeed a major biological loss to the planet. According to primatologists, the surviving lemurs

resemble the very earliest primates from the Eocene (Tattersall 1993). Like prosimians in Africa and Asia, but to a far greater degree, lemurs have a highly developed sense of smell. Some species have long, fox-like noses (Preston-Mafham 1991). Genetic analysis of their DNA has revealed that all lemurs are descended from a single ancestor that probably arrived from Africa about 60 million years ago (Garbutt 1999).

The Giant Aye-aye (*Daubentonia robusta*) lemur was somewhat larger and 2.5 to 5 times heavier than the surviving Aye-aye (see below), but in other respects was very similar (Garbutt 1999). It is known from subfossil remains found in southwestern Madagascar (Nowak 1999). The date of its disappearance is unknown but may be fairly recent.

Archaeologists have uncovered remains of a massive bird of prey, the Malagasy Crowned Eagle (*Stephanoaetus mahery*), which undoubtedly preyed on lemurs (Feduccia 1996). In fact, at one locality the diet of this eagle, based on the bones of eagles and lemurs found together, contained at least 80 percent primates, including specimens weighing up to 26.5 pounds (Feduccia 1996). Remains of another large eagle of the genus *Aquila* have been discovered, and it, too, preyed on large lemurs and became extinct after the arrival of the Malagasy. These extinct birds preyed on smaller lemurs as well, including some species still surviving (Feduccia 1996). A bird of prey flying overhead still elicits fear in lemurs, causing them to seek cover. Neither of the two remaining species of eagles on Madagascar preys on lemurs, but two hawk species have been seen preying on young lemurs (Garbutt 1999).

In addition to the Giant Elephant Bird, the large Snail-eating Coua (*Coua delalandei*), a member of the cuckoo family, became extinct. The last specimen of this large, slate-blue bird was taken on an islet off the east coast, Ile Sainte-Marie, in 1834 (Morris and Hawkins 1998); reports by observers who claimed to have seen the bird were recorded as late as 1930 (Fuller 1987). The causes of this bird's disappearance, and even its exact range, remain obscure (Langrand 1990). Many specimens of this bird were taken before its extinction and kept in museums in Leiden; London; New York; Paris; Philadelphia; Tananarive (Madagascar); and Cambridge (Massachusetts) (Fuller 1987). The long feathers of this bird were highly valued by the Malagasy, and hunting may have reduced its numbers to a critically low level (Fuller 1987). It is also possible that the many birds killed for zoological specimens may have pushed this already rare bird to extinction, since its distribution may have been limited to the tiny Ile Sainte-Marie. No reliable record exists of its presence on the main island of Madagascar, but there is hope that it might be found in lowland forest near the Bay of Antongil (Morris and Hawkins 1998). Ten closely related species of couas survive, all smaller than the Snail-eating Coua.

Endangered Species Handbook

Persecution and Hunting:

Persecution and Hunting

Roman Slaughters

The tradition of killing animals for pleasure has a long history in Asia and Europe. So popular was hunting in ancient Rome that mosaics and paintings often depicted this pastime as a heroic activity. Slaughtering animals was considered a form of entertainment, and people scoured the countryside for bears, Lions, stags and boars to pursue with spears and dogs (Attenborough 1987). As the Roman Empire grew to encompass the entire Mediterranean basin, its citizens traveled throughout the region to hunt and bring back animals to be killed in primitive contests in the coliseums of Rome and other cities. The coliseum games continued for more than 400 years in more than 70 amphitheaters, the largest seating up to 50,000 people on stone benches arranged around a central arena (Attenborough 1987).

Roman emperors curried favor with the public by upstaging their predecessors in killing more animals and producing more spectacular displays of slaughter (Morris 1990). Emperor Titus inaugurated the Roman Coliseum by declaring 100 days of celebration, during which enormous numbers of animals were speared by gladiators. On the opening day, 5,000 animals were slaughtered, and over the next two days, 3,000 more were killed (Morris 1990). The caged animals were kept underground in dungeons where they were not fed, and on the day of the festival, they were hauled in their cages onto lifts that brought them into the center of the arena. As the crowd roared with excitement, drums were beaten, trumpets blown, and the terrified animals were set loose (Attenborough 1987). Sometimes the animals were goaded to attack one another, and at other times, men armed with spears and tridents pursued them around barriers made from shrubs in imitation of hunts in the wild (Attenborough 1987). One arena hunt resulted in the killing of 300 Ostriches and 200 Alpine Chamois (Morris 1990).

Lions, Tigers, bears, bulls, Leopards, Giraffes and deer died after being tormented, stabbed and gored (Morris 1990). Big cats that had been starved were released into the ring where a human slave or prisoner of war was lashed to a post; the animals clawed at the person before they themselves were speared and stabbed by gladiators (Attenborough 1987). In some of the larger slaughters, 500 Lions, more than 400 Leopards, or 100 bears would be killed in a single day (Morris 1990). Hippos, even rhinoceroses and crocodiles, were brought into these arenas, and sometimes gladiators employed bizarre methods of killing such as decapitating fleeing ostriches with crescent-shaped arrows (Morris 1990).

The Roman audiences cheered these brutal slaughters enthusiastically as a rule, but when 20 elephants were pitted against heavily armed warriors, the screaming of these gentle animals as they were wounded caused the crowd to boo the emperor for his cruelty (Morris 1990). This did not stop their use in the games however. These slaughters virtually eliminated large mammals from the Mediterranean area. North African Elephants (*Loxodonta africana*) were exterminated, having been hunted and captured to die in these arenas (Leakey and Lewin 1995). Elephants were also used by the Romans for transport and even conscripted for battle by Hannibal, a Carthaginian general who used them in a deadly march across the Alps, in which all the elephants died of exposure. Romans were probably the key element in the disappearances of the Asian Elephant (*Elephas maximus*) from West Asia as well (Leakey and Lewin 1995).

Prior to the expansion of the Roman Empire, Atlas Bears (*Ursus arctos crowtheri*) lived in the mountains and forests of North Africa, the only bears on the African continent. Named for their last refuge in the Atlas Mountains of Morocco, they were a race of the Brown Bear which is native to Eurasia and North America. North Africa was the species' most southerly distribution. When Romans entered North Africa, they cut the forest habitat of this bear and slaughtered thousands for sport. Others were collected for coliseum combat, where they were attacked by smaller animals, or gladiators wielding axes, spears and other weapons. Over the centuries, the Atlas Mountain forests were leveled for building materials, and colonial landowners used the cleared land for grazing livestock (Day 1981). The

Atlas Bear became restricted to Mount Atlas, where an 18th century French naturalist discovered a fresh skin, upon which the first scientific description was based (Day 1981). Even as late as 1830, the bears were common enough to be captured and sent to French zoos. In 1840, an English scientist concluded that this bear, smaller than the American Black Bear (*Ursus americanus*), was a distinct subspecies. It was stocky, with a short face, blackish-brown, shaggy fur on its back, and orange-rufous fur on its belly (Day 1981). This differentiates it so much from the Brown Bear that modern taxonomists might consider the two distinct species. Although Atlas Bears became increasingly rare, they received no protection from hunting, and the last of these bears were shot around 1870 (Day 1981).

Herodotus and Aristotle, philosophers of ancient Greece, wrote that Lions once lived in that country (Attenborough 1987). Two thousand years ago, the range of these big cats extended eastward in a continuous band to India and Pakistan and throughout the African continent. The Lion disappeared at an early time from Italy and Greece after being hunted and captured by the thousands for gladiator spectacles. When European Lions had been killed off, Romans turned to North Africa. The Barbary or Atlas Lion (*Panthera leo leo*), once distributed through much of the region north of the Sahara, fell victim to hunting and Roman Coliseum games. Known for its enormous mane, which covered virtually half its body, the male Barbary Lion was one of the largest of all races of Lions (Day 1981). It was also the nominate, or first subspecies named. This massive animal weighed as much as 500 pounds and measured up to 10 feet long from the tip of his nose to the tip of his tail (Day 1981). After centuries of hunting, persecution and habitat loss, these Lions withdrew to remote forests, where the last of them were systematically hunted down. Arabian tribesmen in Tunisia and Algeria chased them for sport, and later, French colonial governments paid bounties for their skins; by the 19th century, hunters had exterminated the last of the lions in Algeria (Day 1981). Government lists recorded the bounty fees paid, with fewer each year; only one skin was submitted for payment in Algeria in 1884 (Day 1981). Their final refuge, like the Atlas Bear's, was the wilderness forest of Morocco's Atlas Mountains, where hunters killed the last one around 1922 (Day 1981). Although officially extinct, some of these Lions may still survive in captivity. Certain circus and zoo Lions resembling the original Barbary Lion have been identified, and an effort is being made to gather a breeding colony of these animals. Whether they are, in fact, direct blood lines from the original North African Lions remains to be seen.

By the 13th century, Lions had been eliminated in the eastern Mediterranean; they disappeared from Iraq, Iran and Pakistan by the 1800s (McClung 1976). The last Lion in the Saudi Arabian peninsula was killed in 1923. For most ancient cultures of the Middle East and West Asia, killing one of these great cats, especially a large male, was considered a heroic deed worthy of being recorded in paintings and mosaics. Many such art works remain from Assyrian and other West Asian cultures. By the mid-19th century, Asiatic Lions (*Panthera leo persica*) had become confined to India, but were still widespread in that country (McClung 1976). During the last half of the 19th century, however, Indian Lions came under siege by British Colonial officers, who traditionally proudly took a Lion pelt back to England; a single hunter boasted of shooting 300 Indian Lions in 1860 (IUCN 1978). Under such pressure, Lions disappeared from all of India, save the Gir Forest in the southwest, by 1884 (IUCN 1978). In 1900, protection was finally accorded the last of these Lions, when their populations had been reduced to fewer than 100 animals (McClung 1976). Today, the Gir Forest Lions number a few hundred animals, all that remain of these proud cats on the Eurasian continent. Confined to a habitat that was rapidly being whittled away by villagers cutting firewood, and overgrazed by livestock, the Gir Lions are now protected in the Sasan Gir National Park of western India where, in recent years their population has increased.

Hunting by Romans and later peoples, combined with capture for the colosseum games, devastated the wildlife of North Africa and the entire Mediterranean region. Large predators, as well as deer and other ungulates, disappeared altogether or become endangered. Few conservation programs exist to protect remaining populations from hunting and persecution.

Predator Prejudice

The Roman tradition of persecuting predators spread throughout Europe and intensified in proceeding centuries, reaching superstitious depths in the Middle Ages. Beliefs that fiwerewolvesfl existed resulted in the persecution of wolves in Europe and Russia that continues today. Fairy tales are still recounted to children, in which wolves and bears are depicted as voracious killers. These stories, especially those by the Grimm brothers, frighten small children with tales of wolves, that pursued and ate small children and adults alike. "Little Red Riding Hood" and other stories instilled horror and hatred of predators. In Russia, the destruction of wolves was considered a great benefit to people, as well, with folklore embodied in tales such as "Peter and the Wolf." Persecution of wolves in that country continues to this day. With the spread of domestic livestock throughout Europe, official programs were instituted to destroy wolves (McIntyre 1995). Wolves were not the only animals killed in these programs. Lynx and Brown Bear were also eliminated from all but the most remote areas of Western Europe.

When Europeans settled in America, they brought these prejudices with them, treating native predators as vermin. Most colonies passed laws similar to Massachusetts' 1630 law requiring that "every English man that killeth a wolf . . . shall have allowed him one penny" (McIntyre 1995), and South Carolina's 1695 "Act for Destroying Beasts of Prey," which mandated that all Native American braves be required to bring in one skin of a wolf, panther, or bear, or two Bobcat skins each year. If he failed to do so, he would be "severely whipped," but if more than one skin was provided, he would receive a reward (Nowak 1972). In the East, these programs systematically killed off Gray Wolves, bears and Cougars. Large predators were effectively eliminated in the eastern states by the early 1800s, except for the Black Bear, which became greatly reduced in range and numbers.

The US government ran predator control programs throughout the country. Traps and poisons were the major tools used. Poison was liberally spread over most of the West. Thallium sulfate, strychnine, Compound 1080, and cyanide were distributed in great quantities, killing not only wolves, bears, and Coyotes, but foxes, weasels, ferrets, eagles and other birds. Any animals that ate the poisoned bait died, as well as those feeding on their carcasses. All these poisons caused a painful death, and most killed slowly. Poisoned animals could take hours to die from Compound 1080, and sometimes days after ingesting thallium sulfate. Strychnine, an extremely painful poison, can make water supplies lethal, killing humans, dogs and livestock. The wild predators that consumed Strychnine would vomit while dying from convulsions. Their bodies spread more poison, which remained toxic for a year or more.

Trapping was equally indiscriminate in its victims. Irrational prejudices against predators resulted in the total extermination, even in remote wilderness areas, of America's wolves and almost all its bears through bounty systems, federal subsidies and government control programs. Trappers and poisoners combed the countryside, randomly placing poison and traps.

Prejudice against predators affects a wide spectrum of animals, from foxes and bears to bats and birds of prey. Although the number of species that have become threatened as a result of control programs and random killing is less than those threatened by habitat destruction, the ecological consequences have affected a host of species within their habitats. These animals have co-evolved with their prey, the wolf making the deer fleet; wild cats making gazelles, zebras and hundreds of other ungulates agile. Although there is dispute as to the effect that predators have on the populations of their prey, overpopulations of deer and other ungulates have occurred in many parts of the world where predators have been eliminated. When ungulates overpopulate, they tend to overgraze their habitats, eliminating many types of vegetation, as well as birds and other wildlife dependent on that vegetation for feeding and habitat. Thus, thousands of species may be adversely affected when predators are destroyed.

Many species of snakes, as well as small carnivores such as foxes, eat large numbers of rodents, performing

important roles in preventing population explosions of these prey animals. Bats, as the most important predator of insects, control insect populations, as documented by many scientific studies. These mammals, although more abundant in number and diversity than carnivores, have declined radically in recent years, as evidenced by the enormous number now listed in the *2000 IUCN Red List of Threatened Species*. From a humane point of view, predator control has brought out the worst in human character, suppressing reason and compassion to allow fear and hate to dominate. As science has learned more about the importance of predators, and they are being protected and reintroduced in a growing number of areas in the world, prejudices remain, as do centuries-old ways of raising livestock that involve killing predators. These latter problems need to be addressed with the same vigor that has elevated predators to their rightful place at the top of their food chains in the eyes of conservationists and scientists.

Wolves, Wild Dogs and Foxes

Wolves have suffered more inhumane treatment and loss of range and populations than any other predator. The history of their survival and disappearance in various parts of the world is a reflection of the overwhelming importance of people's attitudes toward animals. When emotions, especially fear and negative superstition, rule people's minds, wolves can be destroyed on the basis of ignorance about their real threats to people and livestock. On the other hand, when people are aware of biological facts about the wolf and its ecological role, behavior, value to ecosystems, and the truth about its history of not attacking people, prejudices tend to dissipate. Native Americans had a natural affinity and respect for wolves, calling them "brother." The wolf's very survival as a species depends on its being treated with tolerance and respect. Gradually, this is happening in many parts of the world. Education and a change in government attitudes in many countries are needed to conserve this species, along with better ways of raising livestock.

Wolves, Wild Dogs and Foxes: Page 1

Prior to European settlement of North America, two wolf species lived throughout the forests of the East: the widespread Gray Wolf (*Canis lupus*), the same species that is native to Eurasia, and the Red Wolf (*Canis rufus*), a uniquely American species of the Southeast. Some biologists estimate that there were 2 million wolves on the continent at this time. European settlers entered the American wilderness and set about killing off these animals. The book, *War Against the Wolf. America's Campaign to Exterminate the Wolf*, by Rick McIntyre (1995), chronicles the history of this extermination program, based on historical and modern documents. Colonists dug pit traps and filled them with vertical stakes, which impaled wolves falling onto them. When hunters found an animal in the pit, they would leap in and ham-string the cowering wolf. John James Audubon described a farmer who captured wolves in a pit trap, severed the tendons in their hind legs, then tossed the crippled animals into a pack of dogs which tore them

apart (McIntyre 1995). The new colonists and their professional hunters set toothed traps that held the animal's leg while the teeth broke through its skin, wounding and breaking bones. Some who captured wolves cut off the lower jaw and turned the animal free to starve (Laycock 1990). Others set them afire, or started forest fires to rid the woods of wolves (Laycock 1990). Strychnine and thallium were placed in meat baits. Wolf pups were ripped apart by dogs, stomped to death, or burned alive in their dens. One predator hunter threw baited fish hooks, attached to lines, into wolf dens, waited until the pups swallowed the hooks, which embedded in their stomachs, then dragged them out of the den and killed them (McIntyre 1995).

Europeans were convinced that wolves hunted humans, even entering towns to kill children as they slept. In truth, wolves are neither ferocious nor killers of people. No case of a non-rabid North American wolf killing a human has ever been documented (McIntyre 1995, Nowak 1999). Very passive when trapped, they do not even attack the trapper as other predators might. Native Americans took wolf pups out of dens for pets without ever being attacked by the parents.

Red Wolves, named for their reddish-brown coats, had other color phases as well. Prior to their near-extinction, they exhibited a range of colors from black to gray and brown. The genes for these color phases were eliminated along with the wolves themselves in predator-control programs. Originally, this wolf inhabited the United States as far west as Oklahoma and eastern Texas, north to Indiana, as well as the southeast. The Red Wolf is the only surviving wolf that evolved in North America. This species and its ancestor, *Canis edwardii*, had been resident in forests as far north as Pennsylvania since the middle Quaternary epoch (Nowak 1979). Dr. Ronald Nowak, an expert on wild canids, maintains that the Red Wolf is a far more ancient species than the Gray Wolf. The latter species is thought to have evolved more recently in Eurasia, during the early Pleistocene, and migrated into North America across the Bering land bridge that linked the continents (Nowak 1979).

Weighing only 20 to 40 kilograms (44 to 88 pounds), and 660 to 790 millimeters (26 to 31 inches) tall at the shoulder, the Red Wolf is larger than the Coyote (*Canis latrans*), but smaller than the Gray Wolf. Mating for life, it breeds in February or March, producing two to six pups in March or April. The pair dens in hollow logs or along banks of canals or ditches. These wolves did not usually form packs, but were most often seen in pairs or small family groups. They were systematically trapped, shot and poisoned out of their range. From the 17th century onward, in state after state, these wolves were exterminated to the last animal, pushing this species toward extinction. Federal predator-control programs took some 50,000 Red Wolves from 1937 onward, until they were virtually extinct in the wild (Laycock 1990). It was not until 1962 that this wolf's highly endangered status received any attention from biologists and wildlife officials. Still, no action was taken to stop state trapping and predator-control programs for another 11 years.

By the 1970s, the Red Wolf had been completely exterminated, except a small population that survived in one county in southwestern Louisiana and in adjoining areas of eastern Texas (Carley 1975). Coyotes had moved into the range of the Red Wolf and interbred with some of the last members of the species. This hybridization spelled the demise of wild Red Wolves. It has been suggested that this interbreeding occurred only because Red Wolves had become so rare that they were unable to find mates of their own species. A live-trapping program to capture the last, pure-blooded specimens, as the only way of saving the species, began in 1973 in Texas, funded by the US Endangered Species Act (ESA). Fewer than 100 animals remained. After capture, X-rays were taken of these animals' skulls to determine which were pure-bred and which were hybrids, based on their skull shape and dimensions.

A number of these hybrids, as well as the pure-blooded Red Wolves, were in poor health from mange, heartworm and other parasites when captured (Carley 1975). Their last attempt to survive in the wild had obviously been a difficult one. Their remaining habitat in Texas and Louisiana had become a mosaic of agricultural and residential development, leaving little natural forest. Moreover, they were under constant threat from trappers and hunters. After five years of live-trapping, only 40 pure-blooded Red Wolves were identified, and they were sent for captive breeding at the Point Defiance Zoo in Tacoma, Washington. No further Red Wolves were found, and in 1979, Howard McCarley and Curtis Carley of the Red Wolf Recovery Team, authorized under the US Endangered Species Act, announced in a status

report, "Recent findings indicate that the only extant subspecies (*Canis rufus gregoryi*), once occurring from eastern Texas to eastern Mississippi, for all practical purposes is extinct in the wild" (McCarley and Carley 1979). The other subspecies of the Red Wolf, the Florida Red Wolf (*Canis rufus floridanus*), had become extinct by 1917 (Day 1981). So many wolves of the Florida race, which once ranged into Georgia and southern Tennessee, were black, that this wolf was originally named the Black Wolf. This genetic strain is now lost.

Of the 40 captive Red Wolves, 14 were selected to form the nucleus of a Fish and Wildlife Service-sponsored captive-breeding colony (Nowak 1999). In 1977, offspring were successfully produced, and by 1989, there were 83 descendants, and the last surviving wild-caught Red Wolf died (Nowak 1991). In 1993, the captive colony consisted of more than 187 animals in 31 breeding facilities. By 1995, there were 289 living descendants from the original wild Red Wolves, the majority in Point Defiance Zoo in Tacoma, Washington (Nowak 1999). In the mid-1980s, reintroduction programs began with the release of several of the captive-bred wolves to the wild. This was the first time the American government had ever sought to introduce and protect wild populations of wolves, instead of eliminating them. Since the Coyote is now present throughout the Red Wolf's original range, attempts were made to find reintroduction areas without Coyotes to prevent hybridization and competition. In 1987, four pairs of Red Wolves were reintroduced into the 120,000-acre Alligator River National Wildlife Refuge, an island in North Carolina without resident Coyotes. A pair released on Bulls Island in Cape Romain National Wildlife Refuge in South Carolina produced two pups in 1988. These pups were captured and released in the Alligator River Refuge in 1989. Another pair, introduced to Horn Island off the Mississippi Coast, produced seven pups in May 1989. By the close of 1993, 46 to 60 animals survived in these newly wild populations by Fish and Wildlife Service counts.

In 1991, a pair of Red Wolves and their two pups were set free in Great Smoky Mountains National Park in Tennessee. Jan DeBlieu, a writer on endangered species, witnessed the release of the wolf family (McIntyre 1995). This area has resident Coyotes, which arrived in the mid-1980s, and the interaction between the two species will be closely watched. Several Coyotes and the adult Red Wolves have radio transmitters and were tracked by a number of biologists after their release. DeBlieu was present when, soon after their release, the male and pups traveled 2 miles away from the female, who lay quietly in a field. Suddenly the researchers heard the prolonged, low howl of the male wolf and high-pitched yaps of the pups, a song "not heard in the Smokies for one hundred years" (McIntyre 1995). They were calling the female, who ran toward them. This national park receives 8.6 million visitors a year--more than any other park in the system. The visitors tend to stay near roads, however, and most of the park is roadless wilderness. Prey is abundant, and both the adults and pups began catching rodents and rabbits, hunting at dawn to avoid tourists during the day (McIntyre 1995). By late summer 1994, there were seven Red Wolves in Great Smoky Mountains National Park. Two more family groups were released the following year, but the available prey in Great Smoky Mountains National Park is limited in the mountainous terrain (Rancourt 1997). As many as 26 wolves lived in the park in 1997 (Rancourt 1997). A few pairs have produced young.

For the most part, these reintroduced wolves have survived with few conflicts with local people, mainly due to the extensive education programs and hearings held by the Fish and Wildlife Service in each area prior to releases. Some private landowners in North Carolina became apprehensive about the potential threat to children and livestock. The Fish and Wildlife Service has paid claimants for losses even when no proof was submitted that it was, in fact, a wolf at fault. One livestock owner admitted that the Red Wolves had become "good neighbors." Yet even these limited reintroductions have provoked resentment in some local communities which harbor ancient prejudices about wolves. The North Carolina state legislature passed a law early in 1995 that defied the US Endangered Species Act, allowing people to kill wolves that attacked livestock. The Fish and Wildlife Service accommodated these concerns by changing its policy in April 1995 to allow killing of Red Wolves thought, but not proven, to be attacking livestock in North Carolina and Tennessee. One of the first wolves killed, male number 464, was shot in 1995 in North Carolina by a landowner who caught him digging under his dog's pen. This wolf had been released the previous year near Alligator River National Wildlife Refuge, but prey was scarce, so Fish and Wildlife Service personnel recaptured him and freed him on the mainland. Number 464 had not been guilty of preying on livestock.

Further incidents between residents and Red Wolves occurred in 1997 and 1998, with wolf pups that were attempting

to disperse into new territory being trapped. One young wolf that had been taken in a leghold trap in North Carolina was rescued by the Fish and Wildlife Service and returned to a penned enclosure in 1998. The local county representative stated that wolves were unwanted intruders and would be dealt with by residents. This does not bode well for reestablishment of these wolves.

If the Red Wolf survives this irrational prejudice, it may reoccupy many of its original haunts. The threat of hybridization with the Coyote will remain, however, and without corridors of habitat to link reintroduced populations, these wolves risk becoming inbred. With education of the public, one day the Red Wolf may be restored as a natural predator, benefiting its prey and ecosystem.

Wolves, Wild Dogs and Foxes: Page 2

Unlike the Red Wolf, Gray Wolves traveled in large packs in the Great Plains of the West. Many of the wolves painted by George Catlin, the great 19th-century artist of Native Americans and wildlife of the Plains, were beige or pure white, as are many of the wolves of the grasslands of northern Canada. Early hunters killed wolves for their pelts by trapping, poisoning and shooting. Many were used for target practice in the open country. When livestock ranchers took over huge tracts of land in the West, the Gray Wolf became a target for total extermination. Cowboys often roped wolves and dragged them to their deaths across rough ground (McIntyre 1995). Federal trappers used even more brutal killing methods (McIntyre 1995).

James Josiah Webb, who wrote a memoir of events in the Santa Fe, New Mexico, area from 1844 to 1861, recounted that two men conducted a wolf-killing operation by spreading strychnine bait placed in chunks of bison meat around the prairie. The number of wolves that once inhabited the region was so dense that they found 64 dead wolves within 1.5 miles of their camp in a single day after a poisoning; they bragged that they earned $4,000, an enormous sum in those days, by selling wolf pelts (McIntyre 1995).

As wolves were exterminated in one state or territory after another, a few of these intelligent animals managed to escape traps, guns and poison, earning the label of "outlaws." These wolves ranged alone or in small packs, and in the last days of the western wolf, some trappers spent months or years in determined pursuit of them. The ability of these wolves to elude their persecutors were truly amazing. One of the most famous such cases was described by Ernest Thompson Seton, an English artist and writer, in *Wild Animals I Have Known* (1899). Based on fact and documented by photographs, it concerned Lobo, an enormous wolf, called "The King" by Mexican residents who lived near a huge cattle ranch in northern New Mexico. For many years in the 1890s, Lobo led a pack of five wolves. He had a distinctive, deep howl that ranchmen recognized among the howls of the other wolves. He was by far the largest wolf in the pack and exceeded the size of other wolves in the region. Whereas most wolf paws measured 4 3/4 inches, Lobo's were 5 1/2 inches long. His mate, whom the Mexicans called Blanca, was a large, magnificent white wolf.

These wolves, like many others of the West during this period, had been deprived of their natural prey, White-tailed and Mule Deer and Elk, which had been hunted out by settlers and replaced with livestock. The wolves turned to livestock as the only large prey available and, in doing so, became the target of ranchers' wrath. Western ranchers, like many livestock owners in Europe, believed that they should be able to release cattle to roam free without herding them into shelter at night. This situation had existed in Western Europe after large predators were eliminated from all but the most remote areas. In their new ranches, allocated to them by the government, ranchers sought to recreate the European model. This required the destruction of large predators.

Lobo and his pack refused to eat dead animals that they encountered, apparently to avoid poison, and survived on calves and sheep that they killed themselves. When Lobo and his pack killed a cow, ranchers immediately put poison in the carcass. But when the wolves returned the next day to eat, they somehow knew which parts of the carcass were

poisoned, and pulled out the poisoned chunks, throwing them aside, eating only the unpoisoned portions. Lobo also avoided the traps set for him and hid from hunters on horseback who pursued him. Trappers came from great distances to claim the high bounty on Lobo, but all failed to kill him. Ernest Thompson Seton decided to try to kill Lobo himself for the $1,000 bounty. He scattered poisoned baits, covering the human scent with other odors, and the following day, found that one after another of the baits was gone. Assuming that he would come upon the body of Lobo, he was surprised to find his five baits in a pile. Lobo had picked them up, one after another without eating them, and left them as a message to Seton. Seton obtained special steel jaw leghold wolf traps and set them in concealed places in Lobo's territory. When he came out to check the traps, he found Lobo's tracks leading from trap to trap. The canny wolf had discovered each of the traps during the night, scratching earth away to reveal the chain and trap, continuing from trap to trap until he encountered one in the center of the trail. Lobo then retraced his steps, placing each paw exactly in its old track until he found no more traps, using his paw to flip stones and earth clods to spring every trap.

Seton finally succeeded in trapping Blanca by setting hidden traps among parts of a cow carcass and covering the area with Coyote scent. Lobo avoided the traps, but Blanca made a fatal error and blundered into one. When Seton and the others found her dragging the heavy trap, she turned to fight, howling across the canyon. Lobo howled back, while Seton and the others brutally killed her. Throwing lassos over her neck and holding the ends of the ropes, they galloped horses in opposite directions until her body was torn apart. When he wrote of the event years later, Seton (1899) called the killing a tragedy. They heard the howls of Lobo for days afterward. Seton described it as having "an unmistakable note of sorrow in it, now. It was no longer the loud, defiant howl, but a long, plaintive wail." When they found Lobo's tracks at the spot where Blanca had been killed, Seton reflected, "Now, indeed I truly know that Blanca was his mate."

Soon afterward, Lobo came near the ranch house. His tracks showed that he had galloped about in a reckless manner before he blundered into a trap set in a pasture. He was able to pull out of it, but Seton then set 130 steel jaw leghold wolf traps in groups of four on every trail leading into Lobo's home canyon, and dragged Blanca's body around the area to leave her scent. He even removed one of her paws, with which he made a line of tracks on the soil covering each trap. Within days, Lobo was caught with all four legs in a trap set, having followed Blanca's scent and forgetting all caution. When Seton approached the trapped wolf, Lobo managed to stand, in spite of severe injuries, and howled his deep call, but no members of his pack responded. Seton and others wrapped ropes around his neck, put a stick in his mouth and lashed his jaws closed. His feet were tied, and when he was placed on Seton's horse, he refused to look at any of his captors. At the ranch, Seton placed a collar around his neck, secured him to the pasture with a strong chain, and Lobo lay calmly, gazing across the prairie.

When Seton came out the next morning, Lobo was dead. On measuring his body, Seton found that Lobo weighed 150 pounds and was 3 feet tall at the shoulder. He was one of the largest wolves ever trapped in the Southwest. The largest Gray Wolves are native to northern Canada and Alaska and weigh up to 176 pounds, but most wolves of the Southwest were far smaller and lighter (Nowak 1991). Scientists who measured the skulls of the pair estimated that Lobo was 4 to 5 years old when he was killed, and Blanca was 7 (McIntyre 1995). Photos of Lobo and Blanca caught in traps are reproduced in Rick McIntyre's 1995 book, *War Against the Wolf*. Lobo and Blanca were exceptional specimens, and their slaughter represented an irreplaceable genetic loss. The treatment they received will remain a blot on human "kind." Lobo was killed on January 31, 1894, near Currumpaw, and his pelt is kept at the Ernest Thompson Seton Memorial Library and Museum at the Philmont Scout Ranch near Cimarron, New Mexico (McIntyre 1995). This experience changed Seton's attitude, and he expressed strong feelings of guilt in his description of his treatment of these wolves.

Government programs did not reflect Seton's newfound sympathy for wolves. In fact, predator-control programs intensified in the early years of the 20th century. Ranchers convinced the federal government to launch an all-out attack on predators, primarily wolves. The Forest Service and the Bureau of Biological Survey used poisons and traps to kill adult animals and many cruel methods to kill the pups in dens in their efforts to try to exterminate the wolf. In 1907 alone, the Forest Service killed more than 1,800 Gray Wolves and 23,000 Coyotes, among other animals

(Laycock 1990). After the US Congress authorized the first substantial appropriation for hiring government hunters in 1915, federal wolf-control programs achieved an unprecedented level. Hundreds of agents combed the most remote wildernesses, spreading poison even where no cattle or livestock grazed. A point system was established; the highest number of points, 15, was accorded for killing a Mountain Lion or a Gray Wolf (Laycock 1990). Hired hunters earning high point totals made the Honor Roll, while others might be fired; they were expected to kill virtually every predator in their assigned area (Laycock 1990).

Within a few decades, many thousands of Gray Wolves had been killed. They were eliminated from more than 95 percent of their range in the lower 48 states by the 1930s (Robbins 1997). A few wolves, using their intelligence and survival senses, managed, like Lobo and his pack, to survive somewhat longer, but they were killed in the end. The Custer Wolf, a large female also known as "Old Three-Toes" because she had lost a toe in a steel jaw leghold trap set by a government trapper, became as infamous as Lobo and Blanca. After her mate and pups were killed, the Custer Wolf survived until caught in a trap that became snagged on rocks (McIntyre 1995).

Vernon Bailey, a biologist with the US Biological Survey, the government agency that later became the Fish and Wildlife Service, conducted wildlife and plant studies as well as predator-control programs. He noted early in the century that the Biological Survey had conducted "the most systematic and successful war on these pests ever undertaken" (McIntyre 1995). The loss of virtually all wolves in the vast area encompassing the lower 48 states may be the most devastating predator-control campaign in history.

If not for the fact that the predator-control programs of the territorial and provincial governments of Alaska and Canada did not succeed in totally exterminating the wolf, the species might be extinct on the continent. Although wolves were persecuted and trapped for their fur in the latter areas, they survived in the far north and in the eastern forests of Ontario and Quebec and have now reoccupied most of their original range in Canada.

The Gray Wolf is able to adapt to a wide variety of habitats and climates, whether searing deserts, shrublands, grasslands, forests of all types, frozen tundra or even marshlands. It had the largest range of any terrestrial mammal on Earth, other than humans (Nowak 1999). Wolves had lived for thousands of years on the continent, their environment and prey altering drastically through the Ice Ages, needing only the presence of large prey to survive. Wolf intelligence, in fact, exceeds that of the domestic dog, which has a brain 31 percent smaller (Busch 1995). In spite of the wolf™s survival abilities, the fragmentation of packs by predator-control agents prevented them from hunting normally and hastened their disappearance soon after control methods began. This need to live in a pack for hunting and companionship made the species vulnerable to extermination. When persecuted, Gray Wolves do not desert one another, and many cases have been documented of wolves sacrificing their lives in an effort to save a pack mate. This altruistic trait also contributed to their extermination. The traits that humans most admire about domestic dogs were inherited from the wolf--loyalty, intelligence, playfulness and affection. Wolf pups were first domesticated by hunter gatherers tens of thousands of years ago, and even after selective breeding by humans in the intervening centuries, they still retain many of the wolf's best qualities.

Wolf packs have a lead pair, known to biologists as the alpha male and female, who are the only members of the pack that produce cubs. They mate for life, and dominate other wolves in the pack. They are usually the fittest and largest. Other pack members challenge for leadership, which can result in a change in the alpha pair. The entire pack, which includes adult females and males and pups from the previous year's litter, cares for the pups, ensuring that the strongest pass on their genes to future generations. Young unmated females and males "baby-sit" the pups when the alpha pair and the rest of the pack are out hunting. When the pups are about six weeks old, their baby-sitters spend hours with them in wrestling matches, games of tag and other rambunctious activities. Within the pack, wolves are extremely friendly and devoted to one another, barking and yipping with delight on meeting, and before and after hunts. They howl at night, communicating with other wolf packs which howl back. Bonds between wolves, especially mated pairs, are very strong, as illustrated by the saga of Lobo and Blanca, and many other cases of wolves in apparent mourning for lost mates have been documented. For many days, one male Mexican wolf, howling plaintively, followed a government trapper who had killed the wolf™s mate and carried off her pelt.

Other species of canids show similar behavior. The African Wild Dog (*Lycaeon pictus*), a highly endangered wild canid, hunts on the African plains in even larger packs than Gray Wolves, numbering up to 26 animals, yet only one female in the pack has pups. The alpha female might have 16 pups, and if another female in the pack has a litter, the alpha female will steal the cubs and nurse them, even if the litter size reaches 20 or more. Fewer than 5,000 of these beautiful animals, sometimes called Painted Wolves because of their black-and-yellow spotted coats, remain in the wild, and they are in steep decline (Nowak 1991). In Zimbabwe, where there are only about 300 to 500 animals, they are still persecuted by farmers. Even in national parks, they often lose prey when chased off by Spotted Hyenas or Lions.

The ecology of the Gray Wolf has been studied since the 1940s, revealing it to be completely different from the prejudicial folklore of Europe. Adolph Murie, one of America's greatest biologists, conducted studies of wolves in Mount McKinley (now known as Denali) National Park, where they were neither persecuted nor hunted. In his study, *The Wolves of Mount McKinley* (Murie 1944), he revealed: "It appears that wolves prey mainly on the weak classes of sheep, that is, the old, the diseased, and the young in their first year. Such predation would seem to benefit the species over a long period of time and indicates a normal prey-predator adjustment in Mount McKinley National Park." By examining the carcasses of Caribou and other mammals killed by wolves in the park, Dr. Murie found that most were in poor physical condition. Wolf packs test their prey by isolating and then chasing individual animals to detect weaknesses, and the majority of their chases do not result in a kill.

In spite of more than 50 years of biological studies of wolves that have shown them to be a positive rather than a negative influence on their prey, there are still many who disagree. Predator-control programs have been authorized in Alaska, Canada and parts of Eurasia in misguided attempts to protect deer, Elk, Moose, American Bison and Caribou. A trophy hunting organization, Safari Club International, paid the British Columbia government to kill wolves in that province (Williams 1991). The real motivation for these eradication programs is often to promote artificial increases in populations of ungulates, such as Moose, Caribou and deer, for sport hunting.

Over the ages, prey species of wolves have evolved to survive their attacks by becoming faster and stronger. The largest and healthiest deer on the North American continent have been found in areas where wolves are resident predators. The number of wolves in a pack varies according to the size of the prey: packs of up to 15 are needed to bring down bison, while packs of seven or fewer hunt deer (Nowak 1999). Wolves hunting large prey run in shifts, with tired members of the pack replaced by rested wolves. They will sometimes need to run for many miles after Caribou, Moose, American Bison or deer before they succeed in singling out one they are able to bring down; an average of only one in 10 chases is successful. Native Americans have always been aware of the important relationship between the wolf and its prey. The Keewatin Inuits have an ancient saying: "The caribou feeds the wolf, but it is the wolf who keeps the caribou strong" (Busch 1995). The healthiest members of each prey species are able to fend off wolf packs, and only in unusual circumstances can wolves kill them. For the vast majority of prey species, wolves sense weakness in their prey, evidenced by body stance, uncoordinated movements, the smell of wounds or, most often, by their lack of endurance when being chased (McIntyre 1995).

When wolves are hunted out of an area with deer and other ungulates, the latter animals often increase in numbers to such great levels that they strip their habitat of vegetation. The overpopulation of White-tailed Deer in many parts of the northeastern United States, especially in suburban locations, has resulted from a lack of natural predators. Their absence has created a major imbalance in eastern forest ecosystems, where they have become so numerous that they consume young trees and new growth on mature trees.

Wolves, Wild Dogs and Foxes: Page 3
Although Gray Wolves were completely eliminated from the eastern states south of Canada and east of Minnesota by 1930 (McIntyre 1995), a few remnant populations survived in northern Minnesota and northern Montana. The first US Endangered Species Act in 1967 listed all wolves in the lower 48 states and Mexico as Endangered. In 1973, another Endangered Species Act was enacted, replacing the 1967 Act. Five years later, the category for the wolves of Minnesota was changed to Threatened. In subsequent years, wolves were reintroduced to the southwest, Wyoming, Montana and Idaho, listed as Threatened experimental populations. All other wolves south of Canada are still listed as Endangered. Wolves have wandered from Minnesota and south from Canada to neighboring Wisconsin and Michigan, with about 50 wolves living in each state (Nowak 1999). Prior to eradication programs beginning in the 19th century, between 9,000 and 16,000 wolves were estimated to have occupied these three states (Savage 1996). Bounty programs killed 150 wolves a year in Minnesota alone between 1949 and 1954, and this state did not withdraw its bounty until 1965; Wisconsin stopped bountying wolves in 1957, and Michigan in 1960 (Savage 1996).

The wolves of Minnesota have gradually increased in range in the past 30 years, but they remain thinly distributed in the northern portion of the state. State regulations allow them to be killed if found preying on domestic livestock, with little or no proof of depredation. Minnesota has a compensation program for livestock owners but does not attempt to relocate wolves, even though depredations have occurred on only 1 percent of farms in that state (Savage 1996). In Wisconsin, large areas have been closed to Coyote hunting during the deer season, which has greatly decreased wolf mortality there, since many wolves were shot--either mistakenly or intentionally--by hunters (Savage 1996). Unlike Minnesota, Wisconsin relocates wolves found preying on livestock and compensates owners of livestock killed by wolves; Michigan's Upper Peninsula, where wolves are found, has no livestock (Savage 1996).

Although many Minnesota residents consider wolves to be threats to livestock and resent the protection they receive from the US Endangered Species Act, for others, they are a thrilling symbol of wilderness and the America that existed several hundred years ago. Ellen Hawkins and her husband Gary live in a wilderness cabin surrounded by Superior National Forest land, prime wolf country in northern Minnesota. Because they are avid wildlife watchers, they put out food for birds, foxes, Fishers, Martens and weasels, and state officials bring the couple road-killed deer which they place in a clearing 200 yards below their house for wildlife to feed on. They saw wolves very rarely and felt lucky to hear their howls or find their tracks (Hawkins 1988). One December day, they spotted a wolf feeding on a deer carcass on their property and noticed that he was wearing a radio collar, placed by the Fish and Wildlife Service to track many of Minnesota's wolves.

Their excitement at seeing the wolf, who brought "magic to the place," dimmed when they realized he was injured. He limped, holding up his right front foot, and they saw him fall in the snow (Hawkins 1988). He kept his tail down, a sign of subservience and fear, and moved stiffly and awkwardly. He spent five days feeding on the deer, lying in the snow near it, and seemed weaker each day. On the sixth day, he disappeared from the clearing, and in the middle of the night, an amazing event occurred: "We were confronted by his face pressed against our window" (Hawkins 1988). As they stood gaping at him, they heard him thump his nose on the glass, still staring at them. The wolf then went to another window, and they found themselves again eye-to-eye with him. He had climbed a snowdrift onto their greenhouse roof and now sat leaning against the window, looking back over his shoulder at them. The Hawkinses found some chicken and tossed it onto the roof next to him, while offering him a pan of gravy. The wolf looked at the food, and then at them, but did not eat.

The temperature was 25 degrees below zero F., and they decided the wolf needed warmth. Gary got a blanket and put it around the wolf, who jumped at first, and then quieted down. His passive response made them think that he should be brought indoors. They got an old quilt, and Gary picked up the sick wolf, carrying him into their living room. The wolf was somewhat dazed, but hardly moved. They called their neighbor, who came 12 miles to see the frail and sickly wolf sitting near the stove in their living room. Uninterested in food, the wolf looked about and seemed to warm up, leaning against the stove until his fur singed. They saw that he had lost part of his front foot, and they heard him wheezing as he breathed. Within minutes, his condition deteriorated, and he began pawing at his mouth. His wheezing grew into a "terrible, deep gurgling" (Hawkins 1988). Gary moved close to the wolf and began to stroke its

head. The wolf stood up with effort, but then slumped down to lie beside the stove. Gary removed the collar so that the wolf could breathe more easily, and they saw that it had a number--6530--with the address of the Fish and Wildlife Service. The wolf suddenly staggered into the middle of the room, spasmed and struggled for breath. Gradually they saw his eyes become unfocussed, and the light faded out as he died (Hawkins 1988).

They later learned that Wolf 6530 left his pack when he was nearly 2 years old and wandered for eight months before he returned to his family. He stayed with them only two months before walking 40 miles to another hunting area. Finally, fatally ill, he came to the Hawkins' house, which was 45 miles from his pack. An autopsy revealed that he had died of a fungal pneumonia, the first such case of wolf mortality. The disease may have been brought on by stress and lack of nourishment (Hawkins 1988). Although his coat was thick, he was emaciated, weighing only 55 pounds. At his age he should have weighed at least 75 pounds. He had a tear on his lower lip, had lost three pads on his right foot, and one pad was mutilated on his left foot (Hawkins 1988). A biologist with the Fish and Wildlife Service was contacted about Wolf 6530 and, in his opinion, the wolf's foot wounds were probably the result of getting caught in a fox trap and dragging the trap about until its toes rotted off (Hawkins 1988). As long as he was dragging the trap, he was unable to hunt with the pack, and this may have explained why he was forced to wander in search of carrion.

Many Minnesota wolves and those dispersing to neighboring states and southern Canada have been trapped in leghold traps. In fact, Wolf 6530's brother had been killed by a trapper in Ontario, 115 miles to the northeast, at the age of 18 months (Hawkins 1988). Wolf 6530 had suffered for many months, and his life ended prematurely. Wolves can live 10 years or more in the wild. Only because he had turned to people during his last days did his story come to light. Ellen Hawkins reflected on the extraordinary event: "We'll never know what motivated him to come our way. I can only say that I'm grateful to Wolf 6530 for sharing his last, desperate moments of life. His act gave us a sense of connection with his world that we would never have had, and our commitment to live in harmony with that world has been strengthened. We will always carry with us the vivid image of the wolf at the window" (Hawkins 1988). The dying wolf may have sensed that the Hawkinses were friends of wildlife, having seen them put out food and watch him without taking any aggressive action toward him. Because he was a highly social animal who had been forced into solitude for most of his short life, he may have sought their company, sensing that he was close to death, preferring humans to an isolated and painful death without his pack mates. Whatever his motivation, his appeal to the Hawkinses' prior to dying was evidence of the complexity of this fascinating creature, and an indictment of the continued use of the inhumane steel jaw leghold trap.

Wolves, Wild Dogs and Foxes: Page 4

To counter the strong anti-wolf prejudice, a new organization called the International Wolf Center in Ely, Minnesota, has live wolves in an enclosure, museum exhibits and field classes. The 50,000 visitors it has received in the past few years brought $3 million to the local economy (Chadwick 1998). But wolves in Minnesota and elsewhere continue to be taken in traps set for other types of animals, causing injury or death. One study on wolves taken in various types of traps was published in the *Journal of Wildlife Management* (Ballenberghe 1984). It investigated injuries and mortality of 126 wolves trapped in northeastern Minnesota and Alaska. Traps used included steel jaw leghold traps of various types, some with teeth, others with smooth offset jaws; steel cable foot snares; and cable neck snares equipped with devices that prevented the loop from fully closing (Ballenberghe 1984). The results confirmed that steel jaw leghold traps caused the greatest number of injuries and mortalities: 41 percent of 109 adults, yearlings and pups caught in these traps incurred serious foot and leg injuries, defined as lacerations, damage to tissue, bone breakage, and joint dislocations (Ballenberghe 1984). Three wolves, including a pup, had broken leg bones; two others lost front feet after they were nearly amputated by the trap. One young male with broken radius and ulna bones in his foreleg was released in this study to stumble off; this wolf was caught by a trapper several months later (Ballenberghe 1984).

Other injuries resulted when trapped animals gnawed their own feet off and chewed on the traps, breaking teeth and

splitting lips. The steel jaw leghold traps caused tissue, muscle and tendon injuries, even when checked daily (Ballenberghe 1984). Since the observations carried out were not done by a veterinarian, or with aid of X-rays and other sophisticated tools to arrive at diagnoses, many unnoticed or undetectable damage to nerves, ligaments and other body parts almost certainly went undetected. Other effects of trapping noted in his study were heat and water stress; stress from risk of discovery and killing by people happening upon them; killing by other predators finding them trapped; and undiagnosed trauma (Ballenberghe 1984). In the same study, a wolf was killed by a cable neck snare when it passed over his chest and closed around his stomach. Long-term effects from broken teeth, severed tendons and poorly healed bones made survival unlikely. This was the case with Wolf 6530, described above, who suffered for many months with an injured paw after pulling free from a leghold trap, becoming weaker and weaker until he died.

Another method tested involved darting animals with tranquilizers from helicopters, which resulted in the euthanizing of a wolf after it became paralyzed when the dart penetrated its spinal column (Ballenberghe 1984). Of the animals darted, 85 percent sustained injuries and soft tissue damage. The Ballenberghe study also cited other research projects with even higher mortalities, and commented, "None of the wolf capture methods discussed here resulted in study animals that were free of injuries, but some methods clearly had more potential to inflict serious injuries than others."

The steel jaw leghold traps that Ballenberghe found to be the most injurious are the very traps that are still used by the Fish and Wildlife Service, Animal Damage Control (ADC)*, state game departments and others, killing wolves and many non-target animals. The US Department of Agriculture's Animal Damage Control program, which traps hundreds of thousands of Coyotes, Cougars and other predators for the benefit of livestock owners, has been responsible for the incidental trapping of endangered and threatened species, from Bald Eagles (*Haliaeetus leucocephalus*) to Gray Wolves.

---

*Animal Damage Control (ADC) has since been changed to fiWildlife Services.fl

---

Many wolves are trapped by wire snares. A loop of wire pulls tight and cuts through the skin when the animal steps into it or, in the case of a neck snare, it is placed a few feet off the ground and strangles and cuts through the flesh of an animal blundering into it. Most US states allow wire snares, and wolves are taken in them in Alaska. The Alaska Department of Fish and Game has sponsored various control programs or "studies" on wolves, using airplanes, steel jaw leghold traps and, most often, wire snares. The avowed purpose of recent state research, which involved trapping wolves in a large wildlife management area near Fairbanks, was to determine their population and effect on ungulate prey, such as Moose, Caribou and Elk. In fact, this and similar "studies" have been launched after hunters urged the state to eliminate wolves in order to leave more prey species. The rationale of the trapping program is based on the premise that killing wolves will result in increases in the population of these prey animals. A program in the 1970s involved the elimination of wolves from a 3,000-square-mile area, but according to Warren Ballard, a retired game biologist from Alaska, the Moose population did not rebound after wolves were exterminated (Egan 1992). Moreover, it creates an imbalance in the ecosystem. Killing of ungulates by human hunters does not cull the sick and old, but rather the fittest and largest.

In 1992, such a wolf "research" program, involving the setting of thousands of wire snares, was carried out south of Fairbanks. Gordon Haber, a conservationist and wolf biologist who has worked for decades on behalf of Alaska's wolves, brought television crews to film the snaring operation in December 1994. They were shocked by the scene that awaited them. Four wolves had been caught in wire snares, two of them pups. One was dead, and three were still alive, terrified and in great pain. A 6-month-old pup, with its paw caught in a neck snare, had chewed off its foreleg in a futile effort to escape. Another had been snared around the chest, causing deep wounds. The other two had been snared by the leg. All these snares had been set to catch the wolves by the neck and kill them, yet none did. Members of the pack milled about nearby, unwilling to leave their fellows. Two snared Caribou were lying dead nearby. A trapper was filmed as he attempted to shoot the wolves, repeatedly missing or wounding them because he used the wrong caliber ammunition in his gun. He shot one pup five times in the head and body at point-blank range with the

wrong gauge ammunition. The pup, wounded, remained standing. The trapper then reloaded with other ammunition, and this time shot all three wolves fatally.

The film of this massacre was shown on national news programs, causing outrage around the country. Alaska Governor Tony Knowles called off the hunt, ordered a review and stated, "That's no way to treat an animal." Six hundred and eighty-five snares set for this program were removed from state lands, but not before 12 more wolves had been killed. More than 1,000 snares had been set by the state for this "study," which lasted two years. On February 2, 1995, Governor Knowles made public the results of the Gray Wolf kill review. During the program, 134 wolves were snared, 37 of which were found alive and had to be shot. Also caught in the neck snares were Moose, Caribou, Grizzly Bears, Wolverines, Coyotes, Red Foxes, Arctic Hares, Common Ravens and Golden Eagles (AWI 1995). This gruesome haul of non-target animals is typical of the indiscriminate nature of snares.

Governor Knowles canceled the wolf kill indefinitely and ordered a review of Alaska's entire predator-control policy. This "research" program was permanently canceled in February 1995. A biologist with the Alaska Department of Fish and Game admitted in 1997, while appraising the program, that it had been ill-conceived, poorly run and politically motivated. He insisted, however, that wolves had suffered no pain from the snaring and even from chewing off their own paws. This failure to acknowledge proven neurological effects of such injuries is not unusual among state game department officials.

In 1996, the Alaska Department of Fish and Game began a new program to curtail the wolf population in the Fortymile region near Fairbanks. This time, the program consisted of sterilizing the alpha male and female of each of the 15 wolf packs in the area, with plans to relocate all "subordinate" wolves (Trost 1998). The plan to reduce all 15 packs to a single sterile pair was intended to increase the number of Caribou for hunters (Trost 1998). The Alaska Wildlife Alliance strongly opposed this project, and Gordon Haber expressed the opinion that it would reduce the wolves of the area to the brink of extinction (Trost 1998). This research program was described as "based on assumptions" by the National Academy of Sciences.

Alaska's trapping regulations are the laxest in the country, with no visitation requirement, meaning that trappers are not required, as in most states, to check traps daily for animals. Animals suffer in steel jaw leghold traps or snares for days. One case is known of a trapped Lynx--brought food by its mate--that lived for six weeks with its leg caught in a leghold trap.

No state regulations govern the manner in which trapped animals are killed, and trappers often stomp trapped animals to death to obtain pelts without damage--such as that caused by bullet holes--to the pelt. The Alaska Game Department takes advantage of the strong ties between wolf pack mates by requiring trappers of wolves to count the number of wolves in the packs of the animals they trap. Pack mates will usually remain by their trapped pack mate, even when it is dead in a trap.

Wolves, Wild Dogs and Foxes: Page 5

Aerial hunting of wolves was carried out for decades in Alaska by private parties and the Alaska Department of Fish and Game itself. Prior to 1972, wolves could be hunted from airplanes for sport, or by state predator-control agents. Federal legislation was enacted in that year to ban such hunting, with high penalties including confiscation of aircraft, large fines and even jail terms. In fact, Director of Wildlife Conservation David Kelleyhouse, known as "Machine Gun Kelleyhouse," suggested that the best way to control wolves was to machine-gun them. In 1991, a state law was passed in Alaska that allowed shooting of wolves if the aircraft landed 330 feet away from the animals. This legislation was virtually impossible to enforce. Many hunters flew over wolf packs, hazing them until the wolves were too exhausted to escape. Then they would land and kill the wolves. The law failed to protect wolves from this type of

harassment and killing. Among the misuses alleged were trappers checking their trap lines by flying from one set to another, and killing wolves and other predators they saw. Another common practice that was targeted was the "recreational" aerial hunting of wolves. Conservationists in Alaska began a petition campaign to change the law through voter ballot referendum for the November 1996 national election, having failed to persuade the legislature to enact a stricter law. This ballot was openly opposed by many members of the Alaska Department of Fish and Game, who were then chastised for this lobbying by the Governor. The ballot was voted into law by the Alaskan public. The new law states that no one who flies an aircraft to an area and lands, may shoot a Gray Wolf, fox, Lynx or Wolverine on the ground the same day. This closed the loophole left by the previous law.

Wolf hunting is carried out by snowmobilers in many parts of Alaska. Brenda Peterson, an eyewitness to one of these hunts, described it, and photos taken of the event documented the wolves being chased into a tight group and killed (McIntyre 1995). Six black wolves, an entire family, died "splayfooted against one another," having run for their lives at a gallop of 35 miles per hour as the snowmobilers herded them into a terrified, dense mass, and then shot them at point-blank range (McIntyre 1995).

The total kill of wolves by hunters and trappers in Alaska in recent years has declined from 1,600 taken in the winter 1993 to 1994 to 1,180 taken in 1995 to 1996, according to the Alaska Department of Fish and Game. With a total wolf population in the state in late 1995 estimated at about 7,000, the kill represents 17 percent of the total population. This is probably threatening some populations. One race of Alaskan wolves, the Alexander Archipelago Wolf (*Canis lupus ligoni*), an extremely rare subspecies, resides in the heavily logged Tongass National Forest. In spite of various threats, the US Department of the Interior has refused to list the wolf on the US Endangered Species Act (see Forests chapter).

Within the past few decades, wolves have again become resident in several western states. Beginning in the 1970s, a few Gray Wolves crossed the border from Canada into Montana's Glacier National Park where a population of about 100 wolves in 10 packs now lives (Stevens 1997).

In the 1990s, the Fish and Wildlife Service began a reintroduction program of wolves into Yellowstone National Park and portions of Idaho and Montana to the north. Historically, wolves were killed to the last individual in Yellowstone National Park by park service personnel under predator-control laws. Their return is a vindication of their importance in the ecosystem. From the start, the project was fraught with difficulties and controversy, with conservationists pitted against one another as to methods and regulations, and many cattle and sheep ranchers opposing the entire project, vowing to kill any wolves that strayed out of the park. Defenders of Wildlife began a fund to repay ranchers for lost livestock, which helped convince some ranchers to accept the project. Of the 14 Canadian wolves released in 1995 in Yellowstone National Park, almost all remained within the park. Two packs produced a total of nine pups, and 17 more wolves from Canada were set free in the park in 1996. The largest of the reintroduced wolves and his mate left the park, and he was gunned down by a drunken man for sport; he skinned this big male and threw the carcass into the brush. Later, the wolf's pregnant mate found the skinless carcass and dug a den beside it. The hunter who, in defiance, sported a shirt reading "Northern Rockies Wolf Reduction Project," spent six months in jail and a year of supervised probation after being found guilty of deliberately killing the wolf.

These Canadian wolves, taken from areas where they were hunted and trapped, experienced a trap- and gun-free environment in Yellowstone National Park. They have adapted well, preying mainly on Elk, which had become overpopulated. Only a few Bison have been taken. Within a few years, the wolves have had major effects on the park's ecosystem. Grizzly Bears have benefited by feeding off the remains of wolf kills, as have ravens, foxes, Bald Eagles and Golden Eagles. The park's aspen trees have also benefited. Researchers from Oregon State University determined

that until the late 1920s, young aspens were able to survive and mature within existing groves, but after the last wolves were killed off about 1926, the aspens began to die out because the overpopulated Elk browsed on these trees in the winter, stunting them. Another change that resulted from the absence of wolves was the disappearance of smaller birds, such as the Calliope Hummingbird (*Stellula calliope*) and Willow Flycatcher (*Empidonax traillii*), from brushy areas that were heavily browsed by the large populations of Elk and other ungulates. Wildlife Conservation Society (WCS) biologists have been researching the many effects of the return of wolves on the park's ecology (WCS 2000).

By 1996, three packs of wolves occupied the park, and a fourth pack of four wolves lived on the park's northwestern border. Their total population in Yellowstone has risen to about 185, exceeding the expectations of scientists (Murphy 2000). Although detractors remain, wolves have garnered a great deal of support. Scientists have come to Yellowstone National Park to study the wolves, some saying it is the best place in the world to see these animals in an open habitat, exhibiting natural behavior. Tourists, likewise, have flocked to see the Yellowstone wolves, bringing $43 million a year to the area, according to Defenders of Wildlife (Rembert and Motavalli 1998). Visitors have been thrilled to see these wolves streak across the grasslands, meet in affectionate, playful groups and raise their melodious voices in group howls. The wolves are expected to be a major tourist attraction in the future, perhaps rivaling the world-renowned geysers. Television films have been made of the wolves, chronicling their reintroduction and pack behavior, and *The Return of the Wolf to Yellowstone*, a book by Thomas McNamee (1997), recounts their reintroduction.

The wolves were released under a special designation of the US Endangered Species Act known as "non-essential, experimental populations," a category that permits authorities to kill them if they are found preying on livestock, or even if they cause adverse effects on wild ungulates such as deer and Elk. It is not legal to kill them for sport deliberately (FWS 1994). As a result, many wolves straying outside Yellowstone National Park have not fared well. One pack of 13 that roamed the plateaus north of the park declined to a single wolf in one year; all but three, who are now back in captivity, died or were shot (Murphy 2000). Several conservation organizations sued the Fish and Wildlife Service to appeal the non-essential designation, stating that there were already some wolves present that would be killed at will because of the designation. Livestock owners also sued the government, requesting that the program be stopped and the wolves be removed. These lawsuits were not heard in federal court until late 1997, after 66 wolves had been brought from Canada to Yellowstone and Idaho in 1995 and 1996.

In December 1997, the lawsuits from both sides of the wolf issue were finally heard in a US District Court, which came to the stunning decision that the Fish and Wildlife Service had violated the US Endangered Species Act by declaring the wolves an experimental population because wolves that might already be present would be denied full protection of the law. The judge ordered that the reintroduced wolves be removed from the park, but stayed his own decision pending appeal. Secretary of the Interior Bruce Babbitt expressed the Department's support for keeping the wolves in the wild. The Fish and Wildlife Service stated that should the decision be upheld on appeal, the wolves would have to be euthanized, as there was no area where they could be released (Chadwick 1998). The decision was appealed and overturned in January 2000, allowing the wolves to remain as part of Yellowstone's ecosystem for the indefinite future.

For the long-term success of the reintroduction of Gray Wolves into this region, the entire Yellowstone ecosystem, which extends well beyond the limits of the national park and other federal lands, should be protected. Already, much prime habitat that was once occupied by wildlife has been converted for agriculture, livestock and homes. Growth of housing and spread of the urban landscape in Jackson, Wyoming, are gobbling up thousands of acres each year. At least one cattle ranch has recently been purchased as a buffer for wolves and bison straying out of Yellowstone National Park. Efforts should be made to acquire more habitat so Yellowstone's wolves and those to the north could be linked through forest corridors to avoid inbreeding and provide space for expanding populations. The Greater Yellowstone Coalition has proposed a program called Y to Y, or Yellowstone to Yukon, that seeks an even more ambitious goal: to link reserves and parks between the two areas, providing a vast wildlife corridor. Much of the land in this linkage area is already federally owned. Grizzly Bears and wolves are among the many wildlife species that

require enormous amounts of habitat, and unless action is taken now, populations of these and other wide-ranging animals will become isolated and inbred.

Central Idaho has 12 million acres of national forest land and was chosen as a release site because of the enormous potential habitat. Opposition to the reintroduction in Idaho was strong, and the state legislature blocked the involvement of the state wildlife department (Robbins 1997). The Nez Perce tribe, which has a strong commitment to preserving the wolf, stepped into the void and became the first Indian tribe to manage an endangered species in an entire state (Robbins 1997). The project is headed by a tribal leader, Jaime Pinkham, a forest biologist who returned to his tribal roots and became manager of the Nez Perce Department of Natural Resources (Robbins 1997). Conservation groups, such as the Gray Wolf Education and Research Center in Idaho, are attempting to change the anti-wolf opinions of local ranchers with films, several penned wolves and other programs. Unfortunately, wolves have been released in Idaho and in Montana, where many have been shot, trapped or died from other causes. They lack the protection of a large national park where hunting and trapping are prohibited, and many ranchers graze cows and sheep in and near the national forests.

Most wolves prefer wild prey, but because of the large number of livestock in the region, the success of these releases may depend on whether the wolves can be conditioned to keep away from livestock. Several of the reintroduced wolves have killed calves in Idaho and Montana, resulting in anger from ranchers who have convinced the Governors and many state delegates to legislate against the program. Fears have even become irrational. Some ranch mothers sent letters to Idaho's Congressional delegation demanding that children be guarded from wolf attacks at school bus stops (Corbett 2000). The Republican delegation from Idaho passed a unanimous resolution at their convention, calling for the immediate removal of all reintroduced wolves (Corbett 2000). Signs urging that wolves be killed were placed in store windows in Idaho. Fish and Wildlife Service biologists killed 82 wolves during the first five years of the program, after complaints from livestock owners (Corbett 2000). Several wolves were shot under questionable circumstances. After a calf was killed, for example, the Service ordered three adult males of the pack killed from a helicopter; sharpshooters, unable to kill the adults, ended up shooting three pups (Murphy 2000). After ranchers reported that a pack had backed a group of his horses against a cliff, the alpha male was removed, leaving his mate alone and the pack without a leader (Murphy 2000).

Some environmentalists protested these killings and threatened to interfere before more wolves were shot (Corbett 2000). David Gaillard of the Predator Conservation Alliance questioned the wisdom or purpose of introducing wolves that needed to be controlled and trained (Murphy 2000). Experiments are underway using electric shock collars that shock a wolf when it comes close to a cow or calf wearing a collar that sets it off. This is a crude approach, which inflicts pain on the wolves and may not even succeed in its intent. Some humane organizations that have protested these collars have rightly stated that almost no efforts have been made to teach ranchers to protect their livestock with sheepherding dogs, pen them in at night and before calving and lambing, and use other means of preventing predation.

Wolves, Wild Dogs and Foxes: Page 7

Historically, the critically endangered Mexican Gray Wolves (*Canis lupus baileyi*) roamed montane woodlands and drylands in northwestern Mexico and extreme southern Arizona, New Mexico and Texas. After centuries of persecution, they disappeared altogether from the United States and verged on extinction in Mexico. In 1976, the subspecies was listed on the US Endangered Species Act, and in 1982, the Fish and Wildlife Service approved a recovery plan in which a professional trapper was hired to capture the last few wild wolves in Mexico. Only five of these wolves were found, and in this 11th-hour rescue, they were live-trapped in Chihuahua and Durango for captive breeding (Brown 1995). They have bred well in captivity and, in 1998, numbered 175 distributed in a number of American zoos (Bass 1998). Through genetic testing, new strains of pure Mexican Wolves have been identified in

Mexican Wolves already in captivity; this adds to the subspecies™ known diversity (Brown 1995). Smaller than northern wolves, males weigh 60 to 70 pounds and females 50 to 60 pounds.

The recovery plan's major goal was to reintroduce Mexican Gray Wolves into portions of their original range in a joint project by the Fish and Wildlife Service, the ADC program which had been responsible for their demise, the US Army, and the state wildlife departments of Arizona and New Mexico (Brown 1995). Surveys conducted in the region determined that most people favored the reintroductions (Brown 1995). Ted Turner, the founder of Cable News Network (CNN) and other cable stations, is New Mexico's largest landowner with more than 1 million acres. He offered one of his ranches, Ladder Ranch, which is near the Blue Range mountains release site, as a holding area and paid an employee to oversee construction of holding pens (Bass 1998). This was supported by his organization, the Turner Endangered Species Fund (Bass 1998).

Although the public as a whole supported the wolf reintroduction, many New Mexican ranchers expressed great antipathy. The national forest release sites allow hunting and trapping. Many volunteers and a grassroots organization, Preserve Arizona's Wolves (PAWS), have worked for decades to bring about this reintroduction and volunteered their time to help on Ted Turner's ranch preparing for the arrival of wolves from two zoos (Bass 1998). In December 1997, four wolves, two sisters and two brothers from separate zoos, arrived at Turner's ranch and were paired off male-and-female in separate pens, where they stayed for several months (Bass 1998). More arrived and spent time in acclimatization pens before release. The release program failed. Of 11 Mexican wolves released in the area, five died, one disappeared and is presumed dead, and five have been returned to captivity near Alpine, Arizona (Sink 1998). One pup born in the wild is missing and presumed dead, since its mother was shot in August 1998 (Sink 1998). A New Mexican rancher is said to have offered $35,000 to anyone who would kill all the wolves returned to the wild (Sink 1998).

Among the wolves that were shot was one of a newly formed--but strongly bonded--pair, Val and Minnie (Bodo 1999). Soon after release from the holding cage, Val was shot by a camper who claimed that the wolf charged at him; a necropsy revealed that the wolf had been killed standing still, broadside to the man (Bodo 1999). The female, Minnie, who had been born at the Rio Grande Zoo in Albuquerque, was pregnant with four pups when her mate was killed. She was returned to her holding pen and began to try frantically to dig and leap her way out of the pen (Bodo 1999). Her pups were born, but all died. At the end of 1998, she was shipped to the Living Desert Wildlife and Botanical Park in Palm Desert, California, where she paced or remained curled up in a spot of dirt, failing to interact with her surroundings or a male put in her pen (Bodo 1999). She was spayed and will remain in captivity for the rest of her life. As for the other deaths, no examples of livestock predation were found. About 140 of these wolves remain in captivity (Nowak 1999).

The reintroduction of Mexican Gray Wolves will be far more difficult than the Yellowstone National Park reintroduction, which involved transplant of wild Canadian wolves. These captive-born wolves have no knowledge of wild survival. They will need to learn how to hunt large prey as a pack, as well as how to survive the many threats humans pose to them. Their intelligence and instincts may be the deciding factors for their survival.

The legal status of the Gray Wolf in the lower 48 states seems destined to change in the near future. The Fish and Wildlife Service wants to change the status of the species from Endangered to Threatened in all but the southwest, where the Mexican subspecies is being reintroduced, and remove the Minnesota wolves altogether from the US Endangered Species Act (Revkin 2000). Minnesota wolves continue to be persecuted, and suffer from parasitic heartworms and deadly canine parovirus disease spread by domestic dogs (Nowak 1999). Delisting undoubtedly will unleash unrestricted hunting and trapping of these animals. Total legal control will revert to the state of Minnesota should this proposal be finalized.

The wolves in the West, from Yellowstone National Park to Idaho, Montana and Washington, would be listed as Threatened when removed from the experimental category. This category has much more flexibility concerning how much protection a species receives. Penalties are lower, and species may be hunted and trapped under the category.

Some ranchers in the West are prepared to eliminate wolves outside national parks. One rancher in Montana installed loud alarms that are triggered by the radio collars used to monitor most of the area's wolf packs (Revkin 2000).

The approximately 3,500 wolves south of Alaska, most of which are in Minnesota, occupy only about 5 percent of their original range, and as a result of prejudice and unfounded fear, these wolves are still being persecuted. Several states have enacted laws banning reintroduction of wolves, which would also apply to wolves crossing over the state's borders. Proposals to reintroduce wolves into Maine or New York have also been met with opposition by many (Higgins 2000). A major education program is needed to allay these fears and to train ranchers to protect their herds and flocks, compensating them for any losses. Although the detractors speak more loudly than the defenders of wolves, the latter probably far outnumber the former in the United States as a whole. It may fall to private conservation and humane organizations to turn the tide in favor of the wolves to return them to a greater percentage of their original range in the lower 48 states.

Wolves, Wild Dogs and Foxes: Page 8

Elsewhere, the history of the Gray Wolf is similar. As early as 300 B.C., Celtic people in the British Isles began breeding wolfhounds for chasing and killing wolves (McIntyre 1995). The King of Scots decreed in the second century B.C. that anyone killing a wolf would be rewarded with an ox (McIntyre 1995). In Anglo-Saxon England, January was designated Wolf Month, to be devoted to the slaughter of wolves; during the reign of King Edgar of England, beginning in 953, a tribute of 300 wolf skins per year was demanded. In 1281, King Edward I hired a man to devote himself entirely to killing wolves (McIntyre 1995). Over the next centuries, wolf extermination campaigns continued in the British Isles, and forests were leveled for livestock grazing and agriculture. The last wolf in Ireland was killed in 1821, and a wolf killed in Scotland in 1848 resulted in the extinction of the species throughout the British Isles (McIntyre 1995).

In France, Emperor Charlemagne founded an order of knights for killing wolves, called the Louveterie, about A.D. 800 (McIntyre 1995). Wolves were exterminated 1,000 years ago in all but remote forests of the French Pyrenees on the border with Spain. By the 20th century, only a handful of Gray Wolves survived in these forests, and apparently they were killed off in the 1950s. In the early 1990s, small numbers of Gray Wolves crossed over the Alps from Italy into southeastern France. In 1999, the French government decided to remove these 40 wolves, killing or caging them, after complaints by herdsmen that the wolves were killing sheep (Newman 1999). Environmentalists claimed the sheep were being killed by feral dogs (Newman 1999).

The last wolf in what is now Germany was killed in 1847 (McIntyre 1995). Within the past decade, a few wolves have entered eastern Germany from Poland, which has a population of about 1,000 wolves (McNamee 1997). Polish wolves have been heavily persecuted for centuries, and only in 1998 did the species receive official protection (Nowak and Myslajek 1999). They occur mainly in eastern mountains where they have come into conflict with livestock owners. An organization, Wolfnet, has been working with livestock owners to compensate them for losses and protect them against predation by wolves (Nowak and Myslajek 1999). Wolfnet travels around the country educating the public, government officials and students about the behavior, biology and intelligence of wolves, attempting to undo the mistaken beliefs that result in many killings of wolves (Nowak and Myslajek 1999).

Scandinavia has nearly wiped out its wolves, with only about 25 in Norway and Sweden and fewer than 100 in Finland (McNamee 1997). In 2001, the Norwegian government allowed the killing of some of the few remaining wolves because of complaints by livestock owners, despite protests from wildlife organizations in the country. An unknown--but small--number also survive in Greenland (McNamee 1997).

In Spain, wolves may total from 1,500 to 2,000, the largest population in Western Europe (McNamee 1997, Binder

2000). They are heavily persecuted there, however. At one time wolves were found throughout the Iberian peninsula, but they are now confined to the northern portions of Spain and Portugal (Bergman 1997). In Portugal, only about 150 survive. The wolves of Spain and Portugal are listed by the *2000 IUCN Red List of Threatened Species* as Conservation Dependent. At least half of rural people in areas where wolves remain in Iberia believe the animals should be exterminated altogether, while another 35 percent want them "controlled," allowing only a few to survive (Bergman 1997). Wolves may be sport hunted in Spain, resulting in the deaths of at least 300 animals a year; added to this mortality, the practice of denning, or killing pups in a den, is legal, and 25 percent of wolves are killed in this manner (Bergman 1997). Luis Mariano Barrientos, a biologist studying Spain's wolves, has documented that they kill relatively few sheep, which are usually protected by mastiff dogs and shepherds. He says that the wolves are killed because of prejudice and persecution, and laments, "It's a national disgrace. A barbarity" (Bergman 1997). A recent study recommended that a strict compensation program be set up. At present, indemnities are paid only if local administrations choose to do so, and many do not (Bergman 1997). This results in great resentment toward wolves. The wolves of Spain survive by stealth, hiding in fallow fields and moving about at night, and when they howl, they risk their lives (Bergman 1997). For long-term survival in Spain, they need a large sanctuary with natural prey species.

Small populations of Gray Wolves still remain in pockets of the Mediterranean region. About 500 wolves survive in Italy, listed as Vulnerable by the International Union for the Conservation of Nature (IUCN). Very little wilderness remains in the country, and wolves have been squeezed into agricultural and livestock grazing areas (McNamee 1997). Their survival until the 20th century is due to an attitude of tolerance, unlike the prejudice and hatred toward wolves so common in Europe. No national extermination campaign was ever launched, and herders corral their sheep at night and protect their flocks with guard dogs (McNamee 1997). Because of a lack of natural prey, such as deer, in the region, these wolves occasionally kill livestock. When this happens, herders put out poison or shoot the wolves. Italian wolves live in pairs or groups of three in most areas because there are no large ungulates to hunt in packs. This has made them quiet, nocturnal and shy. These wolves also prey on small mammals, such as rabbits and marmots (McNamee 1997). Only in a few national parks, such as the Abruzzi east of Rome where about 20 to 30 wolves hunt deer, do they exhibit natural behavior, forming packs and howling (McNamee 1997). Even there, however, sheep are allowed to graze within park boundaries, and sheep owners have been soliciting members of the public to "adopt" a sheep to contribute to the cooperative farm (Stanley 2000). By the 1970s, wolves numbered only a few hundred, but after the government accorded the species full protection in 1976, they began to increase in numbers and range (McNamee 1997). They now occupy the entire country, and if there are livestock losses, owners are compensated and are not allowed to kill the wolves (McNamee 1997). Professor Luigi Boitani, a wolf biologist at the University of Rome, commented at a wolf conference that most of the Italian public is in favor of wolves and more opposed to control programs than some wildlife managers, like himself (Binder 2000). The official protection given to these wolves is far stronger than that given to either the Gray or Red Wolf in the United States.

Southeastern Europe's wolf populations are fragmented, but increasing in some countries. The former Yugoslavia has about 930; Hungary, 50; Romania, which protects the species, 2,500; Bulgaria, fewer than 100; Slovakia, 350; and Greece, 300 to 500 (McNamee 1997). Romania is the only one of these countries where people have a tradition of honoring wolves; sheep in the country are protected by guard dogs, and wolves prey mainly on native ungulates. In some areas the wolves have taken to ranging through city trash piles for food (Binder 2000). Croatia allowed unlimited killing of wolves until 1995 when fines of up to $6,000 were imposed for killing wolves (Binder 2000). This had the counter-effect of encouraging wolf killing, resulting in the deaths of more than 40 wolves, and no one has paid a fine; about 100 wolves remain in the country (Binder 2000).

In the eastern Mediterranean, there are estimates of a few wolves remaining in Lebanon; about 30 in Egypt; 200 in Jordan; 150 to 300 in Israel; several thousand in Turkey; and about 1,000 in Iran (McNamee 1997). In Saudi Arabia, where wolves are killed to protect livestock, hunters often string up a wolf carcass on a pole for all to see (Binder 2000). Dr. Iyad A. Nader of the King Khalid Wildfire Research Center in Riyadh, estimated that up to 700 wolves remain in three protected areas of Saudi Arabia, but elsewhere in the country they have no legal protection (Binder 2000). Wolves are persecuted by livestock herders in all the latter countries.

Just after World War II, there were between 150,000 and 200,000 wolves in the Soviet Union, but beginning in 1947, an intensive government control program drastically reduced their numbers (Nowak 1999). The annual kill was 40,000 to 50,000 until 1962, when it dropped to 15,000; in the 1970s, some 50,000 wolves were estimated to survive in the entire country, including the Central Asian Republics (Nowak 1999). After an increase in wolf populations, a sizeable bounty was paid for killing them; and in 1980, 35,573 pelts were taken through aerial hunting, poisoning and other means (Nowak 1999). fiThe Russian Grey Wolffl (1993, Anderson Video, California) chronicled this bounty hunting and other persecution. In the past 70 years, more than 1.5 million animals have been killed; about 20,000 wolf pelts are marketed in Russia every year (Busch 1995). In the early 1990s, 17,000 men were employed by the Russian government to kill wolves. Since then, the national bounty has been rescinded, and only some state governments pay the equivalent of $25 for a female; the central government no longer encourages poisoning wolves (Binder 2000). In the Russian Far East, a bounty program to kill wolves has been in place for decades, but with the economic chaos following the fall of the Soviet Union, funds to pay the bounties dried up (Specter 1997). A 2001 Cable News Network (CNN) report profiled a government trapper who killed female wolves for the bounty, then raised the orphan cubs for release. The report suggested that persecution continued at high levels and that most Russians wanted the species exterminated.

The Wolf Almanac (Busch 1995) states that some 96 Russian wildlife reserves harbor wolves, and they are hunted actively in 41 of these. They are reported to be safest in certain large reserves, such as the Caucasian, Altai and Pechyora-Ilych reserves, unless they stray outside to prey on livestock (Busch 1995). Wrangel Island in the Arctic Ocean is to be made into a nature preserve with a wolf colony to cull the large herds of Musk Oxen and Caribou (Binder 2000).

Japan's wolves were killed off 100 years ago, and public opinion is negative about their reintroduction. Biologists want them reintroduced to control Japan's overpopulated Sika Deer, which are damaging forests (Binder 2000).

In Kazakhstan and Central Asia, wolves and Saiga antelope have coexisted for eons, but during this century, both have come under heavy hunting. A film, fiThe Saiga of Kazakhstanfl (see Video Section), describes the detrimental effect that wolf control programs have had on Saiga. Wolves are estimated to number between 90,000 and 100,000 in the country, but biologists claim that they kill large numbers of domestic camels, cows and sheep (Binder 2000). Killing wolves is considered a sport in Kyrgyzstan, south of Kazakhstan, where Golden Eagles are used as falconry birds to hunt foxes, badgers, Lynx and wolves (Kinzer 1999).

Mongolia has an estimated 10,000 wolves; China only about 400; and Afghanistan, 1,000 (McNamee 1997). In Tibet, wolves are heavily persecuted by livestock owners, and in the vast Chang Tang Reserve, it is the only species without legal protection. Wolf carcasses can be seen lying next to roads, the animals having been shot by hunters in vehicles, and biologist George Schaller (1998) saw three wolf bodies in a village dump with their jaws wired shut.

India has fewer than 1,000 wolves by some estimates (McNamee 1997), and between 800 and 2,000 in the opinion of Dr. Yadvendradev Jhala of the Wildlife Institute of India. The species is held in great fear by many Indian people, who regard wolves as man-eaters. A century ago, a bounty program resulted in the slaying of 2,600 wolves (Burns 1996). Indian Gray Wolves (*Canis lupus pallipes*) were finally accorded official protection in India in 1992. Rudyard Kipling's *The Jungle Book* tells the story of Mowgli, an Indian orphan raised by wolves. This story may have a basis in fact because many unwanted children are abandoned and placed in the woods, according to *The Wolf Almanac*, and Indian folklore recounts many cases of small children raised by wild wolves (Busch 1995). Such a child was discovered in 1972 at the age of four, apparently having been adopted by a pack of wolves. He was placed in Mother Theresa's refuge for orphans in Lucknow, where he died after seven years (Busch 1995). In spite of such true stories, the average Indian has little but fear and loathing for wolves.

Working to help India's wolves, Dr. Jhala and the Wildlife Institute of India are conducting surveys and appraising their status. For centuries, these wolves have lost habitat and prey species to the country's growing human population. When wolves turned to livestock, persecution followed. Dr. Jhala admits, "It is extremely difficult to conserve a

species when the majority of the human population is opposed to its survival" (*Earthwatch* 1996). Beginning in 1988, Dr. Jhala conducted the first-ever ecological study of Indian wolves for his doctorate at Virginia Polytechnic Institute, with funding from the National Geographic Society and the Smithsonian Institution (*Earthwatch*, 1996). Earthwatch contributed to this research in 1996 with its volunteer program of paying participants in Dr. Jhala's studies. These volunteers followed radio-tracked wolves in the 3,400-hectare (8,401-acre) Velavadar National Park of western India, one of the wolf's last strongholds, observed Blackbuck (*Antilope cervicapra*), Nilgai (*Boselaphus tragocamelus*) and other rare wildlife, and interviewed local farmers through interpreters about their opinions of this species.

Wolves, Wild Dogs and Foxes: Page 9

Official protection from hunting and trapping has been accorded very few wolf populations in the world, even where they are on the verge of extinction. In some areas, however, attitudes are changing, most dramatically in the United States, where documentary films and books on their behavior and importance in ecosystems, as well as recordings of their howls can now be seen in bookstores throughout the country. Superb photography illustrates some of these, most notably *White Wolf: Living with an Arctic Legend* (Brandenburg 1992), which provides glimpses into the lives of these fascinating canids in the Canadian north. Reintroductions of wolves into portions of their former range in the American West bode well for their future, unless the prejudices of many livestock ranchers hold sway. Canada may have the largest population of wolves in the world, estimated at between 30,000 and 60,000, with about 4,000 killed for fur each year (Nowak 1999). According to genetic studies, the wolves of southern Ontario and southern Quebec have apparently hybridized with Coyotes, as have wolves in neighboring Minnesota and Isle Royale, Michigan (Nowak 1999).

The ecotourism potential for wolf viewing in many parts of the world is considerable. In Ontario, Canada, visitors to Algonquin Provincial Park have come to hear packs howl since the 1960s. One of the first wolf conservationists, Canadian wolf biologist Dr. Douglas Pimlott, initiated these tours and educated thousands of people about the biology, importance to ecosystems and behavior of wolves. Their value in attracting tourists and contributing to healthy ecosystems far exceeds that of their pelts.

For some other species of wild dogs, attitude changes may not be enough to save them. The Dhole or Asiatic Wild Dog (*Cuon alpinus*), a small canid the size of a Coyote, is native to Asia, from southern Siberia and Central Asia east to India and Indonesia (Nowak 1999). This wild dog has rusty red fur on its upper parts, and white on its chest and belly. Hunting in large packs, Dholes pursue large prey, such as deer, wild pigs, antelope and wild sheep (Nowak 1999). Their social structure is not well known but appears similar to the Gray Wolf's, with a leader and lower-ranking members of the pack (Nowak 1999). Although Dholes seldom take livestock, they have been poisoned intensively and hunted throughout their range; they are also persecuted by hunters who regard them as competitors for game species (Nowak 1999). Dholes have disappeared from much of their habitat, and the *2000 IUCN Red List of Threatened Species* lists the species as Vulnerable, the category below Endangered, indicating a serious decline.

Similar in appearance, the Simien or Ethiopian Wolf (*Canis simensis*) is endemic to Ethiopia. Scientists were unsure in the past whether this animal was a dog, a wolf, a jackal or a fox. Most zoologists now describe it as a wolf. It may be related to the small race of Gray Wolf, *Canis lupus arabs*, that inhabits the Arabian Peninsula across the Red Sea (Nowak 1999). Simien Wolves have a head and body length of about 3 feet, are about 2 feet tall at the shoulder, and weigh from 11 to 19 kilograms (Nowak 1999).

The only wolf not preying on animals larger than itself, such as deer, but living in packs, Ethiopian Wolves feed mainly on small rodents (Gottelli and Sillero-Zubiri 1994). Once their range was far greater, encompassing most of Ethiopia's highlands, but with the development of agriculture and spread of livestock grazing, these wolves lost the majority of their habitat and came under totally unmerited persecution as a threat to domestic animals (Nowak 1999).

Today, they have become restricted to only about six locations in the Ethiopian highlands. Discovered in the Simien Mountains of the northwest, the subspecies, *Canis simensis simensis*, was estimated at only about 40 animals in the 1980s. These wolves are so shy that even in the Simien Mountains National Park they have become nocturnal and stay in burrows when humans are in the vicinity. A crew from Survival Anglia, a British nature film company, spent weeks in the early 1990s seeking to photograph the Simien Wolves in this park, finally having to settle for a long-distance view of a solitary wolf.

Wolves of the Bale Mountains, separated by hundreds of miles, are larger and redder than the Simien Mountains race, and this subspecies, *Canis simensis citernii*, is somewhat more numerous than the other race. Only about 440 Simien Wolves were thought to survive in the Bale Mountains in the early 1990s, with perhaps another 100 in the Simien Mountains (Gottelli and Sillero-Zubiri 1994). Today, estimates are even lower. The Bale Mountains population is estimated at 270 to 370 animals, and 70 to 150 survive in the Simien Mountains (Nowak 1999). This species is thus at the edge of extinction. It is listed as Critical in the *2000 IUCN Red List of Threatened Species*, protected by law in Ethiopia and listed as Endangered on the US Endangered Species Act.

The Wildlife Conservation Society (formerly the New York Zoological Society) has funded research projects on the Simien Wolf for many years, including the studies of two zoologists, Dada Gottelli and Claudio Sillero-Zubiri in Bale National Park. Simien Wolves use their long legs to dig into rodent tunnels, aided by their acute senses of hearing and smell. In Bale Mountains National Park, 14 rodent species are native and three dominant species are endemic to the region, providing a huge food base for the wolves. They specialize in preying on the endemic Ethiopian Mole Rat (*Tachyoryctes macrocephalus*). The mazes of tunnels that these rats excavate aerate the soil, creating rich topsoil which nourishes the lush grasses in this highland ecosystem. The wolves have been seen hunting cooperatively, chasing young antelope and hares (Nowak 1999).

Livestock grazing is allowed in Bale Mountains National Park, and Simien Wolves wander among the cattle, presenting no threat. The wolves in this park have not been persecuted, unlike those elsewhere in Ethiopia, and do not hide from people. Filmmakers shooting the 1990 BBC film, fiKing Solomon's Mountains,fl found the wolves in the open during the day, with adults hunting rodents, and pups playing wrestling games. Like other wolves, they are extremely affectionate with one another and yip in group choruses, sounding like Coyotes. Packs range in size from five to 13 animals, and they defend territories. As in Gray Wolf packs, only one female in the pack breeds, and because of limited habitat, nonbreeding females often stay with the pack, acting as "aunts" instead of leaving to begin their own packs (Gottelli and Sillero-Zubiri 1994).

Domestic dogs, brought into Bale Mountains National Park by the Oromo people to protect their flocks of sheep and cattle from hyenas, are a major threat to this species (Gottelli and Sillero-Zubiri 1994). Wolves have succumbed to diseases introduced by these dogs, which are not fed but set free to fend for themselves. Between 1992 and 1995, the Bale Mountains wolves were decimated by an outbreak of canine distemper acquired from these dogs, reducing the wolves from 240 to 140 (Anon. 1996). In the mid-1990s, more died of rabies. An even more ominous threat is their interbreeding with domestic dogs. The film fiKing Solomon's Mountainsfl showed a pack of wild Simien Wolves led by a large black dog that had become the lead female. Another film, fiLast Wolves of Ethiopia,fl shown on a National Geographic Explorer program in early 1998, recounted the story of a young female Simien Wolf who was ousted from her pack and, after a few years of wandering, paired with a hybrid wolf-dog. In general, male domestic dogs have bred with female wolves, diluting the genetic integrity of this highly endangered animal (Gottelli and Sillero-Zubiri 1994). Some populations of pure Simien Wolves are showing signs of inbreeding, due to their small genetic base. The combination of these threats has led scientists to predict imminent extinction for this beautiful wild dog.

To prevent their extinction, attempts are being made to convince the Oromo tribespeople to control their dogs, but scientists have concluded that captive-breeding may be the only way to save the species (Gottelli and Sillero-Zubiri 1994). There is no possibility of preventing these people from entering the park because of the tribe's centuries-old ties with this region and the potential of bad relations with them that could have serious repercussions on the conservation of park wildlife (Gottelli and Sillero-Zubiri 1994). As a means of controlling the domestic dogs, they could be

neutered, vaccinated against disease, and provided supplemental food to prevent their attacking native ungulates in the park. A vaccination program has recently been carried out in the Serengeti, where domestic dogs transmitted canine distemper that killed one-third of the Lions in the region.

The South American Maned Wolf (*Chrysocyon brachyurus*) has also declined, although not as drastically as the Ethiopian Wolf. This long-legged wolf, weighing only about 44 pounds, hunts in the tall grasses of pampas and llanos, and eats rodents and other small mammals, birds, reptiles, insects, fruit and other vegetation (Nowak 1999). With shaggy red fur and black legs, it has been called a Red Fox on stilts. It is the sole member of its genus and the only wolf in Latin America. The Falkland Island Wolf (*Dusicyon australis*), native to the Falkland Islands off Argentina, became extinct in 1876 after large numbers were killed by fur traders and poisoned by sheep ranchers (Allen 1942). The size of a large Coyote, it may have evolved from foxes. Maned Wolves have been falsely accused of killing livestock, and persecution has caused them to disappear from Uruguay and most of Argentina. They have become rare in Brazil and the rest of their range in south-central South America. The Maned Wolf is listed on the US Endangered Species Act as Endangered and on the *2000 IUCN Red List of Threatened Species* as Near-threatened.

Wolves, Wild Dogs and Foxes: Page 10

Small predators also underwent persecution in North America in the late 19th and early 20th centuries. Two tiny western foxes that were once considered to be the same species, the Swift Fox (*Vulpes velox*), native to shortgrass prairie, and the Kit Fox (*Vulpes macrotis*) of intermountain and desert grasslands further west, both declined as a result of predator-control programs. Both are shades of tawny, reddish-brown and tan, stand about 1 foot tall, measure 23 to 31 inches long, and weigh less than 5 pounds (Nowak 1999). Although not considered threats to cows or sheep, foxes traditionally have been killed because of their possible threat to poultry. In wilderness areas, they have been killed merely because of predator prejudice. These foxes subsist on small rodents and even insects, such as grasshoppers, and are, therefore, beneficial.

The Swift Fox was named for its speed when streaking across the prairie, clocked at about 25 miles per hour (Turbak 1993). The Canadian populations of the Northern Swift Fox (*Vulpes velox hebes*), native to southern Saskatchewan, Alberta and Manitoba, and the northern edge of the shortgrass prairie that once stretched to Texas, are listed as Endangered on the US Endangered Species Act but are extinct. They disappeared from the wild by the 1930s, after control programs were implemented, and Canadian wildlife authorities have reintroduced Swift Foxes of a related subspecies from Colorado, Wyoming and South Dakota (Nowak 1999). Some reproduction has taken place.

Swift and Kit Foxes began to decline in the 19th century, and Ernest Thompson Seton commented on the vulnerability of this species: "Harmless to man and mankind's interests; and yet he is going fast with all the other innocent and lovely wild things. Yes, faster than most, for he is the least cunning of our foxes--so guileless that he readily takes the poisoned baits used nowadays for killing coyotes" (Seton 1899). In fact, almost none of these foxes was seen in the wild from the early 1920s to the late 1950s, a period of heavy predator-control and poison campaigns (Chambers 1978). Both species have lost the majority of their habitats to agriculture. In North Dakota, the state lists the Swift Fox as an endangered species, with no breeding populations. The last known occurrence of the Swift Fox in this state was in the mid-1980s (Turbak 1993). Further south, this species is known to survive in southwestern Kansas, Nebraska, Montana, Wyoming and South Dakota (Chambers 1978). Some areas of unplowed prairie provide refuge. This fox has been able to colonize on roadsides next to fields and in the few remaining unpoisoned prairie dog towns. Some research has been carried out on the wild behavior and habitat needs of Swift Foxes in the Midwest, and there is room for cautious optimism that increased attention to this little fox will result in strong legislation to preserve it and prevent persecution and poisoning. Author Glenn Chambers was researching an article for *Audubon* magazine, "Little Fox on the Prairie" when he saw a fox family being killed by two farmers who poured gasoline in the den entrance and set fire to it. The male fox, provider of food for the vixen and pups, was found in a ditch a few yards away, his rib

cage ripped out by a high-velocity bullet (Chambers 1978). The vixen had escaped the burning den with two of the pups, but the farmers shot her as she watched over them (Chambers 1978).

Kit Foxes occupy deserts, dry grasslands, and montane areas with scattered trees from Utah north to Washington state and west to California. They prey mainly on kangaroo rats and other small rodents. A subspecies from southern California known as the San Joaquin Kit Fox (*Vulpes macrotis mutica*) is listed on the US Endangered Species Act as Endangered. Settlement and farming of the region reduced their habitat, and predator control has eliminated entire populations, causing them to dwindle to a few thousand animals. This delicate, little buffy-yellow fox is now restricted to a tiny remnant of its once immense habitat of mixed grasslands, deserts and shrub in California. Their original range stretched from San Joaquin and Stanislaus counties in the north to Kern County in the south. They probably numbered at least 12,000 prior to settlement (Turbak 1993). Tame and trusting, they became targets for hunters; even schoolboys with rifles have been seen shooting them as sport (Turbak 1993). One hunter was seen shooting a pair's tiny cubs one after another as they played at the den entrance, then killing the mother when she emerged to protect them (Turbak 1993).

Foxes have been considered threats to livestock and domestic poultry by European settlers. The Cape Fox (*Vulpes chama*) of dry country in southern Africa was the object of control programs by European settlers under the misapprehension that it preyed on domestic poultry. This resulted in declines in the numbers and range of this small, silvery-gray fox (Nowak 1999). The Hoary Fox (*Lycalopex vetulus*) of south-central Brazil, an endemic species of savannah grasslands, is persecuted by local people for presumed predation on domestic fowl (Nowak 1999). Although very shy, it courageously defends itself and its young when threatened (Nowak 1999). Little is known of its status, listed as Data Deficient by the IUCN. Argentine Gray Foxes (*Dusicyon griseus*), native to Patagonian grasslands, have been poisoned by livestock owners who distribute strychnine bait. Their populations have declined in many areas as a result, and thousands of non-target mammals and birds have died from these poisons. Such poisoning is illegal in Argentina, and efforts are being made by biologists and conservationists to stop this senseless killing.

Eight species of foxes are listed as Data Deficient by the *2000 IUCN Red List of Threatened Species*, and two species as Conservation Dependent. This is an indication of the lack of research on these ecologically important species, which perform the important role of consuming large numbers of rodents. Red Foxes (*Vulpes vulpes*), native to North America, Eurasia and northern Africa, have been persecuted as well, hunted as sport in England and parts of the United States, and killed by many farmers and livestock owners. One Midwestern town even rounded up these foxes once a year and beat them to death with sticks. After a *Life* magazine article describing this cruel persecution and the resulting public outcry, it ended. Fox hunting in England may end in the near future as the Parliament has voted to stop this cruel activity.

Bears

The immense Grizzly or Brown Bear, which once roamed the prairies and woodlands of western North America, inspired awe and fear in explorers and settlers alike. For thousands of years, Native Americans revered this bear. The Cree called it a four-legged human, and other tribes considered it a brother or cousin. They felt a kinship based on its intelligence and respected its great strength. They could not easily hunt it with bows and arrows, and when wounded, it showed great courage defending itself, able to cause severe injuries or death with its 5-inch claws.

The Grizzly reigned as the fearsome and unchallenged king of all wildlife on the continent, numbering at least 100,000 prior to the arrival of Europeans (Nowak 1999). These extremely adaptable bears lived in every western North American habitat except deserts. Arriving from Asia by way of the Bering Strait 12,000 years ago when sea levels were lower, Grizzlies gradually colonized western regions, the biggest of an array of large carnivores that inhabited the continent at that time, including dire wolves, hyenas and sabre-toothed cats. They survived the frigid and

harsh climate of the Pleistocene Ice Age. They thrived in prairies, especially those with scattered woodlands. In the 1500s, their range extended from the Arctic tundra south through the shortgrass prairie to the pine forests of northern Mexico, and west to the Pacific Ocean. In fact, the original range of the Grizzly Bear may have been larger than previously thought, reaching east to the Atlantic in Canada. A Grizzly skull has been found in a midden of the late 18th century, and pelts of these bears reportedly were taken in Labrador as late as 1927 (Nowak 1999).

Grizzly Bears of North America and Brown Bears of Eurasia were previously considered separate species, but today they are classified as a single one, *Ursus arctos*. The bears that live along the southern Alaskan coast and offshore islands, such as the Kodiak, are the world's largest carnivores (Nowak 1999). Weighing up to 780 kilograms (1,716 pounds), Kodiak Grizzlies have a shoulder height up to 1,500 millimeters (58.5 inches, or almost 5 feet), and a body length ranging up to 2,800 millimeters (109.2 inches, or 9 feet) (Nowak 1999). Standing height can be almost 12 feet. Adult males are larger than adult females. North American Grizzlies are far larger than bears of the same species native to southern Europe, which average only 70 kilograms (154 pounds) (Nowak 1999). Grizzlies of the northern portion of the lower 48 states are only somewhat smaller than the Alaskan bears, while those native to Arizona, New Mexico and Mexico, all now extinct, were smaller still, weighing less than 1,000 pounds.

Reproducing at a very slow rate, Brown Bear females have an average of two cubs only once every two to four years, and the cubs stay with their mother for this entire period (Nowak 1999). On occasion, only one cub is born, and sometimes up to four. If the mother is killed at any time before the cubs leave to be on their own, the cubs will also die because they are unable to fend for themselves, destroying two generations. The training period of these bears is extremely long, an indication of their slow maturation and the complexity of learning about food sources and other keys to survival. Another reason for this long apprenticeship is the potential of attacks by male Grizzly Bears. Until a young bear is 3 years old or older, it is not large enough to withstand an attack by an adult male, requiring the protection of its mother. Males continue to grow until they are 10 to 11 years old, and may provoke fights with younger bears to chase them from the territory, which prevents inbreeding. Females remain fertile until well into their 20s. Females in the Yellowstone region are known to live to be 25 years old, and Grizzly Bears may have the potential to live 50 years in captivity (Nowak 1999). They do not reach sexual maturity until they are at least 4 to 6 years old. These bears have a low natural death rate, and when combined with their slow reproduction, they are very vulnerable to extinction should they suffer high mortality.

A large habitat requirement is another aspect of their vulnerability. In the Arctic, a single Grizzly requires more than 100 square miles of tundra, and in the Yellowstone area, each bear occupies about 88 square kilometers (Nowak 1999). In regions where they are distributed sparsely, they can be eliminated easily, and even where they are more numerous, persecution and trophy hunting have caused local extinctions.

The strength, intelligence and size of the Grizzly, which have served it so well for thousands of years, were no match for European guns. Explorers, trappers and, later, settlers, slaughtered thousands of Grizzlies, killing them on sight. The first to disappear were the bears of the Great Plains, where the landscape was open and provided little cover. In some cases, these bears showed almost mythic strength upon being shot. Meriwether Lewis of the Lewis and Clark expedition of 1804 reported that one wounded bear ran at a fast clip for nearly a quarter of a mile before it fell dead after being shot through the heart (Peck 1990). Persecution of bears often includes the killing of their cubs. Early in the 20th century, President Theodore Roosevelt refused to kill bear cubs pointed out by his hunting guide, and when this was publicized in newspapers, he became a folk hero as a result. Toy manufacturers took advantage of the story by producing stuffed animal "Teddy Bears," which remain popular today. President Theodore Roosevelt left a legacy of destructive trophy hunting, however, including the killing of many adult bears.

Settlers moving into the West hunted these bears, and during the late 19th and early 20th centuries, government predator-control agents began campaigns to eliminate these bears. Much of the zeal with which the bears were slaughtered was based on a misconception: they were thought to be vicious man-eaters. In fact, they are mainly vegetarian and only occasionally kill animals for meat. The most common animals killed by Grizzly Bears are various types of rodents, such as ground squirrels and, in some areas, fish. Elk calves are killed as part of their diet in some

areas. The staple foods of the Grizzly diet are green shoots, sedges, clover and lilies early in the spring and, later in the summer, berries, roots, fruit, acorns and nuts, with occasional rodents (Peacock 1996). These bears do not consider humans to be natural prey, and attacks are rare. Prejudices dominated, however, and hunters who killed them were considered heroes and rewarded with bounty money. To protect their livestock, ranchers insisted that government hunters kill off every Grizzly Bear, and after several centuries of uncontrolled hunting, trapping and poisoning, the bears became extinct in their vast original realm south of Canada except for a few hundred animals protected in Yellowstone and Glacier National Parks.

All 26 subspecies of Grizzly Bears south of Canada and Alaska, except *Ursus arctos horribilis*, became extinct by the 1950s, and some disappeared during the 19th century. The latter subspecies, named from specimens obtained in northeastern Montana, barely survived. In fact, *Ursus horribilis* was the species' scientific name until recently, an indication of the prejudice against it. Now considered a subspecies, *Ursus arctos horribilis* is listed on the US Endangered Species Act as Threatened, and this subspecies is used to indicate all Brown Bears in the lower 48 states.

Grizzly populations still occupy only 1 percent of their original range in the lower 48 states and number fewer than 1,000 (Nowak 1999). This includes Yellowstone and Glacier National Parks, whose protection prevented their total extinction south of Canada, a few wilderness areas in Idaho, western Montana, and Washington. Human activities such as road building disturb them and cause them to desert otherwise prime habitat. They are no longer the fearless animals that Lewis and Clark encountered, but have become very shy outside of national parks after centuries of persecution. Although they may pose a potential threat to humans who enter their last retreats, people are a far greater threat to them.

Their rugged wilderness habitat in Montana is being developed rapidly, and Grizzly populations, which had risen somewhat after their listing on the US Endangered Species Act, are now in danger of disappearing again. Added to this, some ranchers in the region still persecute them. A prime habitat for Grizzly Bears, the 329,000-acre Swan Valley of northwestern Montana borders the Bob Marshall Wilderness area, a country of open grassland and forest with breathtaking mountain views. Until recently, this landscape remained almost unchanged from its original state. Ranching, road building and other activities, and an increasing human population in this region, however, are now ruining its wilderness character and threatening the Grizzlies (Pelletier and Servheen 1995). Through cooperation with local residents, the Fish and Wildlife Service is identifying important habitat areas and linkage corridors for the Grizzly Bears in this part of Montana to prevent conflict with humans. These zones would be a link between the small population of bears in the Mission Mountains to the west and those in the Bob Marshall Wilderness area (Pelletier and Servheen 1995). The land is a checkerboard of ownership by private individuals, state, federal and corporate entities; in an unusual project, all private and public lands will be included in a management plan, with input by local citizens (Pelletier and Servheen 1995). These bears remain under the continual threat of being shot by ranchers fearful for their livestock and apprehensive about possible land restrictions in areas where Grizzly Bears are resident. Sport hunting of this small population is also allowed.

Grizzly Bears are still depicted in the media as dangerous man-eaters, resulting in a prejudiced view by the American public. A number of television programs produced by the National Geographic Society, CBS, the Discovery Channel, Fox and others have perpetuated this image. With titles such as "Dangerous to Man!," "Bear Attacks" and "Man-eaters," these programs often demonize the bears and interview people who have been attacked while camping in the bears™ habitat. Very few such attacks have occurred, and almost none has been fatal. After centuries of being shot at and harassed by humans, Grizzly Bears tend to avoid people. When camping inside national parks where Grizzlies are resident, special precautions must be taken, and it should be kept in mind that the parks are *their* home, and humans are the intruders. The national parks, where hunting is banned, are their only refuge. Some documented cases of attacks have occurred when a mother bear felt her cubs were threatened by humans, especially if they approached the cubs. Mother Grizzlies may be the fiercest protectors of their young in the animal world, a trait that should be admired from a distance. Television programs that sensationalize the potential threat of animals do not note the hundreds of Grizzly Bears killed by humans every year in North America. They also fail to show the many bears that are merely wounded by hunters and suffer a long death, or the cubs that are orphaned and die of starvation.

The irrational fear and hatred aroused by misinformation often result in mortalities to these bears by armed tourists and residents in their range who misinterpret the bears' behavior. Many bears have had to be destroyed because tourists fed them, and they became fearless, capable of swiping food or destroying tents and property. Information on avoiding Grizzly Bear encounters is available from National Park Service rangers, other federally employed biologists, and many conservation and humane organizations. Only with tolerance, respect and an informed public concerned about preserving these bears can they survive.

Ecotourism in the threatened and unprotected portions of the Grizzlies™ range is in the early stages of development. Portions of the revenues from tours could be spent to acquire habitat and conduct local education programs. In Alaska, this has been highly successful, with tourists coming from around the world to see these bears fishing for salmon. Montana has some of the most spectacular scenery on the continent, sweeping vistas and vast open spaces that rival those of East Africa. They could be a magnet for tourists anxious to see Grizzly Bears and other native wildlife against a background of snow-capped peaks. Unfortunately, much of their prime valley habitats have been taken over by ranchers and private homes. The tourism in the area has been of a highly commercial and exploitative nature. For example, in some Montana towns, tourists see many stuffed Grizzlies in local businesses, and one can have one's photograph taken posed in a cutout painting of a Grizzly Bear appearing to attack.

If sizeable portions of Montana valley habitats were acquired for the Grizzly Bears, tourists could be taken on van tours, similar to those that now operate in East Africa. For the more athletic, groups of tourists could be taken on guided walks into the high country. Portions of the funds from the tours could be used to purchase privately owned land, to fund public education about these bears and their survival, and to compensate ranchers for livestock losses. The Nez Perce tribe is working with the Fish and Wildlife Service on a project to reintroduce the Grizzly Bear into the Selway Bitterroot wilderness of Idaho and Montana, another magnificent area for ecotourism (Robbins 1997).

Plans to reintroduce Grizzlies into the 1.9 million-acre San Juan National Forest in southwestern Colorado have sparked controversy and prejudice (Papich 2000). Decades after Grizzlies disappeared from the state, the Fish and Wildlife Service reintroduction project has been applauded by local conservation organizations, such as the Colorado Grizzly Project, and opposed by ranchers and even hiking groups who fear attacks (Papich 2000). Returning the Grizzly Bear to portions of its former range in the lower 48 states, even into immense wilderness areas, will be a slow process, possible only after extensive education and a change in the accepted practice of releasing livestock in national forests without sheepdogs, herders or other protections.

The Mexican Grizzly (*Ursus arctos nelsoni*) persisted in the remote mountains of northern Mexico until it was poisoned, shot and trapped to extinction in the late 1960s (Day 1981). This race was smaller than northern Grizzlies, weighing about 700 pounds. Quite numerous and widespread, the Mexican Grizzly had an enormous range in the pine forests of the northeast until efforts began to exterminate it. Only about 30 animals remained by 1960. Although some individuals tried to protect these last bears, others set out to destroy them, and a campaign of poisoning, trapping and hunting, sponsored by ranchers, resulted in the killing of the last animal in the early 1960s (Day 1981). In 1968, biologist Carl Koford conducted a three-month survey in the isolated mountain canyons of Chihuahua where they had last been seen, and he saw no sign of Grizzly Bears (Day 1981). Subsequently, they were declared extinct.

Hunters in many parts of the Grizzly Bear's range in Canada kill the species in such numbers that many biologists consider it to be threatened there. The Canadian Broadcasting Company's "Nature of Things" program produced a film, fiGrizzlies: Losing Ground,fl which painted a dim picture of this bear's future in Canada. They are killed by ranchers and hunted for trophies and for their gallbladders, which are used in Traditional Medicine. Many are killed by park rangers merely because they come too close to tourists. They are being driven from their wilderness homes by unrestricted logging and mining as well.

Brown Bears are already extinct in North Africa, Austria, Belgium, Denmark, Germany, Israel, Jordan, Lebanon, Liechtenstein, Luxembourg, the Netherlands, Portugal, Switzerland, Syria and the United Kingdom. They are

endangered in the few countries where they remain in Western Europe. In Scandinavia, there may be as many as 700 Brown Bears, with populations of less than 1,000 in Slovia, Romania and Bulgaria, and possibly 2,000 in the former Yugoslavia (Nowak 1999). Fewer than a dozen Brown Bears survive in France's Pyrenees Mountains where, despite protests from around the world, a major highway was built through the center of their habitat. Brown Bears are heavily persecuted throughout Eurasia for body parts, especially gallbladders. They are considered endangered in Central Asia's mountains where *Ursus arctos isabellinus* occurs, a CITES Appendix I race, and the Tibetan Brown Bear (*U.a. pruinosus*) is listed as Endangered on the US Endangered Species Act. Outside Russia, only about 4,500 to 7,600 of these bears remain in China, and isolated populations survive in Mongolia, northern Japan and Turkey (Nowak 1999).

The South American Spectacled Bear (*Tremarctos ornatus*) is classified as Vulnerable by the IUCN, with persecution by ranchers a major cause (Nowak 1999). These 300-pound black bears have large circles of white fur around the eyes and white circular markings on the neck and chest. They feed on fruit, bamboo hearts, corn, and other vegetation with about 4 percent of their diet composed of rodents and insects (Nowak 1999). Spectacled Bears are native to the Andes of western Venezuela, Colombia, Ecuador, Peru and western Bolivia. This high-altitude, shy bear is active mainly at dusk and at night and poses no threat to livestock, yet ranchers and landowners have persecuted and hunted it in Peru and other countries because of the mistaken belief that it kills livestock (Nowak 1999).

With the destruction of their high-altitude, humid forest and grasslands replaced in many areas by agriculture, some bears have raided corn fields to survive; many of these bears have been shot by farmers (Nowak 1999). This bear is declining throughout its range, and few areas remain where it can forage without being hunted, either by livestock ranchers, farmers, or for its body parts to sell to Asian markets for traditional medicine. Only a few national parks exist within its range, and populations have become fragmented and isolated from one another. A biological study of these bears in Bolivia by British zoologist Susanna Paisley is uncovering new information about their natural history and the threats posed by radio-tracking. A film about her study and the local people helping her, fiBears of the High Andes,fl was shown on a National Geographic Explorer television program in 1998, providing a unique glimpse into the lives of these rare bears.

Otters

The Eurasian or Common Otter (*Lutra lutra*) has been persecuted since the 13th century in Britain, and a dog, the Otter Hound, was bred to hunt it (Chanin 1985). This otter was officially designated as a pest by a 1566 English law, which authorized local constables to offer bounties for their destruction because of their supposed predation on fish (Chanin 1985). At that time, fish ponds on the estates of the wealthy were stocked to supply the tables of the affluent (Chanin 1985). They were also thought to be competitors with fishermen for game fish such as trout. For hundreds of years, high bounties were paid, contributing to their disappearance from many areas (Chanin 1985). Hunting otters with dogs was the only effective manner of pursuit, and in the 16th century, the Assembly of Norwich decreed that fishermen should conduct two or three otter hunts per year to avoid being fined (Chanin 1985). Estate game keepers continued over the centuries to persecute these playful animals in the British Isles, pushing them close to extinction.

In Europe, prejudices are gradually fading, but the Common Otter, despite its name, is no longer common. It has declined drastically in Britain and most of western Europe, and is rare throughout much of its range elsewhere in eastern Europe and Asia as a result of continued persecution, fur trapping, habitat loss and chemical contamination of its environment (Chanin 1985). This species is listed on Appendix I of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), the category designating species in danger of extinction, and in which commercial trade is not allowed between the Party nations. The *2000 IUCN Red List of Threatened Species* classifies the species as Vulnerable. An increasing number of people are becoming acquainted with this delightful

animal. Not until 1978 did the otter receive official protection from hunting and trapping in England and Wales, and in the intervening years, a strong "Save the Otter" campaign, begun by Friends of the Earth, has had positive results (Chanin 1985). Surveys completed during the 1970s found that otters had become extremely rare in England, and were in steep decline. In parts of southwestern England, otters are now increasing with legal protection, and they are being reintroduced into areas where they had been hunted or trapped out. In 1982, protection was added in Scotland, in spite of continued opposition from otter hunters and those who harbored old prejudices (Chanin 1985). In the Netherlands, reintroductions of otters are returning them to long vacant habitat.

Izaak Walton's views of the otter were not scientifically refuted until the 20th century. Best known as the author of the 17th century book, *The Compleat Angler*, a compendium of information about fishing in England, he quoted a fishermen of the times: ". . . my purpose is to bestow a day or two in helping to destroy some of those villainous vermon; for I hate them perfectly, because they love fish so well, or rather, because they destroy so much, indeed, so much, that in my judgment, all men that keep otter-dogs ought to have pensions from the King to encourage them to destroy the very breed of these base otters, they do so much mischief." Scientific studies of otter diets established that these animals did not pose threats to game fish populations. A 1942 study found that North American River Otters (*Lutra canadensis*) prefer slow-moving forage fish, such as suckers, mudminnows and sticklebacks, to fast-moving trout. Some game fish are taken, but subsequent studies established that such fish make up a small percentage of the otter's diet. A 1955 study by biologist Richard Ryder examined stomachs of River Otters (*Lutra canadensis*) trapped in Michigan and found forage fishes (primarily mudminnows) in 56 percent, crayfishes in 22 percent, amphibians in 17 percent, insects in 13 percent, and trout in 13 percent of all otters examined. Ryder concluded that otters are opportunistic feeders, catching prey items in proportion to their abundance and in inverse proportion to their swimming ability. Thus they benefit game fish by removing overpopulated fish species that compete with trout for food from streams and waterways. In a dramatic demonstration to illustrate its food preferences, a River Otter was placed in a large tank with both trout and crayfish. Ignoring the fast-moving trout, the otter went directly for the crayfish.

Other species of otters also have been found to prefer slow fish, especially bottom-dwellers not desired by either sport or commercial fishermen. Yet they are still being persecuted in many parts of the world. The Marine Otter (*Lutra felina*), a small otter native to the Pacific coast of western South America, has been so persecuted by fishermen for alleged damage to fisheries (Nowak 1999) that it is now listed as Endangered on the *2000 IUCN Red List of Threatened Species*. The Sea Otter (*Enhydris lutris*), protected from previous hunting for the fur trade, began to recover its numbers in the North Pacific, but has recently declined to Endangered status as well as a result of persecution by fishermen, oil spills and predation by Killer Whales.

One young California Sea Otter filmed by Jacques Cousteau became very tame, cavorting with the cameramen and allowing itself to be petted. A few days after the Cousteau crew left the area, this young otter washed up dead on the beach, having been shot. It was conjectured that this friendly otter had approached a boat with fishermen who shot it. Fishermen have overharvested abalone beds for these extremely valuable mollusks and blamed Sea Otters for depleting them, yet abalone form only a small part of their diet. Some Sea Otters eat no abalone at all, specializing in other foods. Moreover, they eat sea creatures that prey on the kelp, without which abalone and other wildlife would not flourish. This species is considered a positive element in the ecosystem.

River Otters in North America were persecuted by European colonists, many of whom shot them on sight. These animals, described by early explorers as highly visible, bold and playful, became shy, secretive and nocturnal after centuries of persecution and fur trapping in the United States and Canada. By the 1950s, they had disappeared altogether from vast areas in the country, from Pennsylvania south to northern Georgia and throughout the Midwest south of Michigan and Minnesota, west to Utah (Nilsson 1985). Beginning in the 1970s, reintroductions of otters live-trapped in Canada, Michigan and other areas where they are still relatively common, have taken place in West Virginia, Arizona, Tennessee, upstate New York, Missouri and several other Midwestern states. In some cases, the reintroductions have failed, but for the most part, the North American River Otter is on the way to reoccupying its original range.

Otters are not regarded benignly by fish hatchery managers and commercial catfish farmers in the South. State Fish Departments and the Fish and Wildlife Service operate hundreds of hatcheries throughout the country, raising trout and other fish. Many of these are non-native species, such as Brown Trout, a European species, or native species, such as Rainbow Trout, that are released far from their natural ranges for the benefit of sport fishermen. These hatchery programs are regarded negatively by many ecologists who have documented that the released fish often cause great damage to ecosystems, outcompeting native fish and introducing diseases. Yet state and federal agencies conduct control programs on otters who raid their ponds. Rather than screen the ponds from otters, who can hardly be blamed for finding hatchery fish easy to catch, these authorities have had laws changed in many states to allow shooting and trapping of otters that come onto hatchery property. Placing screening over fish ponds and hatcheries--and fencing them--will prevent otters, as well as fish-eating birds such as egrets, herons, Ospreys and Bald Eagles, from preying on the fish being raised. This should be carried out instead of lethal methods, which also sometimes kill protected waterbirds. Such control programs do not achieve success in any case because even if depredating River Otters are killed, other otters will be attracted to the ponds, replacing those killed.

Eleven species of otters are listed by the *2000 IUCN Red List of Threatened Species*, four as Endangered, three as Vulnerable, one as Near-threatened, and three as Data Deficient. This represents a high rate of threat, 85 percent, as the otter, or Lutrinae family, has only 13 species. Otters tend to be thinly distributed in their ranges, wide-ranging, slow-reproducing and long-lived--all qualities that make them vulnerable to population declines.

Seals and Sea Lions

The Caribbean or West Indian Monk Seal (*Monachus tropicalis*) was the first animal seen by Christopher Columbus in the New World in the late 15th century, and his crew slaughtered these seals on an islet off the coast of Hispaniola (Day 1981). The only seals native to the Caribbean, they were quite large--6.5 feet long (Nowak 1999). They were heavily exploited beginning in the 17th century for their oil, which was used as a fuel for lamps and, later, for their fur. Scattered populations of the Caribbean Monk Seal survived on islets and beaches far from human habitation until the 20th century (Nowak 1999). Even these last seals were persecuted by fishermen who regarded them as competitors. The last known population of these seals lived on the Triangle Keys, small sandy islets off the Yucatan Peninsula of Mexico, and in 1911, fishermen slaughtered every one of the remaining 200 Monk Seals (Day 1981). Although a few seals were seen after that time, including the sighting of a small colony on a bank midway between Jamaica and Honduras in 1952, an aerial survey of all possible habitats carried out in 1972, and a 1980 expedition, failed to find any sign that the Caribbean Monk Seal remained alive (Nowak 1999). The species was officially declared extinct a few years later, although a few recent reports have given hope that the species may have reappeared (Nowak 1999).

The Japanese Sea Lion (*Zalophus californianus japonicus*), a subspecies of the California Sea Lion, was native to Japan, North Korea, and South Korea, and shooting by fishermen played a major role in its extinction (IUCN 1978).

Commercial fishermen have been responsible for the near-extinction of the Mediterranean Monk Seal (*Monachus monachus*). Once common along the coasts of the Mediterranean Sea, and along the Atlantic coasts of northwestern Africa, this seal is on the verge of extinction, its status listed in the *2000 IUCN Red List of Threatened Species* as Critical. Although resort and industrial development contributed to its decline, shooting by fishermen has been the major cause (Nowak 1999). Many seals drown when they become entangled in fishing nets as well. In past centuries, these seals could be seen on beaches along the Mediterranean, where they would have their pups. After severe persecution, however, they began to hide in the remote caves along the coasts and on uninhabited islets (Attenborough 1987).

In 1981, Greek fishermen threatened to kill off all the remaining Monk Seals on Greek shores if they were not paid compensation for the fish the seals would eat. The Fauna and Flora Preservation Society (now Fauna and Flora International), a London-based organization, raised the money after public appeals in newspapers, which amounted to several thousand dollars.
Fishermen throughout the region became even more intent on eliminating these seals after commercial factory fishing ships began to deplete fish stocks in the Mediterranean.

In spite of legislation protecting the seals, fishermen continue to shoot these seals, which are suffering from lost food supply in most areas. The once pristine waters are now overloaded with sewage and contaminated by chemical and oil spills (Attenborough 1987). The total population of this seal was fewer than 350 in the late 1980s (Attenborough 1987). A 1996 survey found 288 animals, mainly along the African coast in the Atlantic (*BBC Wildlife* 1996). Unfortunately, the largest population in the African islands was decimated in 1998 by a die-off, apparently caused by toxic chemicals.

Mediterranean Monk Seals are extinct in Cyprus, Lebanon, the Canary Islands and Syria, and probably extinct in most other Mediterranean countries. Researchers are conducting radio tracking studies of young seals to discover breeding calves with the goal of reintroducing the seals in the Canary Islands where they have been extinct for over 400 years (*BBC Wildlife* 1996).

The attitude that seals and other fish-eating animals are depriving humans of food is prevalent in many parts of the world and has resulted in the killing of countless fish-eating mammals and birds. The Marine Mammal Protection Act (MMPA) of 1972, which prohibits killing marine mammals in US waters, allows killing of "depredating" seals and sea lions under permit. Such permits are given to kill seals destroying nets to steal fish and/or having a deleterious effect on commercial fish species through their predation. Some Alaskan fishermen, who net the largest fish catches in the world, still resent that the fish are taken by seals and other marine mammals in their waters, and illegal shooting of these protected mammals frequently occurs. Sea lions along the coasts of California, Oregon and Washington have been shot illegally by the hundreds since the MMPA went into effect, and many permits have been given for legal killing. These killings have had a negative effect on many populations of these sea mammals.

Wild Cats
While it may be difficult for most Americans to think of the regal Cheetah as vermin, in the southern African country of Namibia, cattle ranchers treat these endangered and beautiful cats as enemies, trapping and shooting, and even poisoning them. White South Africans have acquired huge landholdings to raise cattle at the expense of the environment in this arid land, fencing off large sections from native wildlife. The majority of Namibian ranchers lack compassion or respect for this graceful cat and, without any compunction, kill females, young kittens and any adult Cheetah on their properties, whether or not the animals pose a threat to their livestock. One rancher told American conservationist Laurie Marker, who is seeking to reverse this trend, that he personally had killed 160 Cheetahs on his property. Marker has taken on the daunting task of trying to convince ranchers of the importance of protecting these endangered cats.

Cheetahs are the world's fastest land animal, reaching 70 miles per hour in pursuit of gazelles, foals of large ungulates, such as zebra and, occasionally, smaller mammals, such as hares. For hundreds of thousands of years, they have adapted to changes in the environment of their once vast range, and are superbly designed as predators. In the North American Pleistocene, more than 10,000 years ago, a cheetah-like cat ranged over the continent, preying on the Pronghorn, the world's fastest hoofed animal. This cat became extinct, perhaps as a result of hunting by Pleistocene hunters.

Prior to the 20th century, Cheetahs remained common in savannah habitats south of the Sahara, and in 1900, their population may have totaled 100,000 animals. Since then, a steady decline in their populations and a shrinking of their range have placed them in endangered status. Cheetahs underwent a dramatic decline in the 1960s when spotted cat fur became fashionable. US imports were stopped when the species was listed on the US Endangered Species Act in the late 1960s, and commercial international trade became illegal when Cheetahs were included on Appendix I of CITES in the early 1970s. Killing them for the fur trade devastated their populations because they are distributed so sparsely over their range--even a kill of a few thousand in each country endangered them. Added to this, they have endured persecution by livestock herders and ranch owners, combined with loss of savannah habitat and their prey species. In areas where there are large populations of Lion and hyena, adult Cheetahs and their cubs are preyed upon by the latter predators, who also steal their kills (Hunter 1998). Trophy hunting also has taken a toll on these cats.

By the early 1970s, they numbered only 15,000, according to Peter Jackson, head of the Cat Specialist Group of the World Conservation Union (Newman 1997). Cheetah biologist Luke Hunter (1998) estimates their total population today at a maximum of 12,000 animals, with safe populations in only five or six of the 26 countries where they may be present. In parts of southern Africa, Cheetahs were numerous until a few decades ago when white ranchers fenced off thousands of square miles of grassland. Within these ranches, which cover much of the land area in Namibia and Botswana, landowners killed off predators as well as native ungulates. The once abundant wildebeests, zebras, oryx, gazelles and antelope that migrated in the hundreds of thousands in this region became reduced to scattered numbers.

Namibia, with its arid, open habitat, still has about 2,500 Cheetahs, perhaps the largest population in Africa, but at the present rate of killing by ranchers, they will be extinct there within a decade. In the 1980s, 1,000 Cheetahs were killed by ranchers, and the Namibian Cheetah population dropped about 50 percent between 1984 and 1994 (Schick 1994).

A 1997 PBS television special, fiIn the Wild,fl featured actress Holly Hunter traveling to southern Africa in search of Cheetahs. A visit to Namibia's Etosha National Park, where these cats were once fairly common, failed to find a single Cheetah, in spite of expert help from native Bushmen trackers. An outbreak of Anthrax, spread by domestic livestock, had recently occurred in the park. Some 20 Cheetahs had died, and the disease also killed elephants and other wildlife.

Marker co-founded the Cheetah Conservation Fund in 1990, and since it has been in operation, it has changed many ranchers from Cheetah-haters to Cheetah-protectors. Few knew of the Cheetah's worldwide plight, and many cooperated when informed. One successful strategy to protect livestock introduced by Marker has been the use of donkeys to guard cattle herds. These animals easily fend off Cheetahs with their powerful kicking hooves (Schick 1994). Baboons have also been trained to guard livestock because of their aggression toward Cheetahs (Schick 1994). Recommendations such as bringing cows closer to homesteads during calving season have also been made to ranchers (Schick 1994). Many ranchers did not realize that Cheetahs prey on livestock only when their own natural prey, primarily gazelles and Impalas, have become scarce because of killing or fencing by the ranchers (Schick 1994).

Within the past few years, many ranchers have been convinced to use box traps to capture Cheetahs unharmed instead of killing these cats. Marker ear-tags the animals and returns them to local protected areas (Schick 1994), or arranges to have them moved. In the early 1990s alone, 75 Cheetahs were removed from ranches where they were being persecuted and were introduced into other areas. One farmer caught a female with five cubs and wanted to keep the cubs as pets. Marker convinced him to give up the female and four of her cubs, but he insisted on keeping the largest one. Although keeping Cheetahs as pets is not good for their welfare or conservation, it is an improvement over their wholesale destruction. Leghold traps are used by some ranchers, and in 1996 Marker acquired two 3-week-old Cheetah cubs whose mother had been killed in one of these traps. They will have to remain in captivity because of their young age when orphaned.

An organization known as Africat has sponsored the capture and transport of 100 wild Namibian Cheetahs to South Africa. This organization reports that ranchers capturing Cheetahs in large box traps often sell them to breeders rather than reintroduction programs, a practice that it does not condone. Translocating adult Namibian Cheetahs to South African reserves where they had become extinct has been very successful. In one case in 1995, three males were

released in Madikwe Game Reserve where four other Namibian Cheetahs had been introduced in 1994, and all survived. A male, four females and five cubs were released in Pilanesburg National Park in 1995, and there were no fatalities (*Oryx* 1996). Most of South Africa's Cheetahs were eliminated by Boers in the 19th century, and the government is now returning them to their original range within national parks. Outside of national parks, they may be in as great danger as the Cheetahs further north.

Lions have continued to decrease in Africa south of the Sahara from a variety of factors, of which persecution by livestock raisers is a major one. Outside of national parks, these big cats have become rare or absent, and in 1996, the species was first listed by the IUCN as Vulnerable. The *2000 IUCN Red List of Threatened Species* also classified the African Lion as Vulnerable. They disappeared long ago from areas with scarce ungulate populations and large numbers of herdspeople who persecuted them, such as the arid regions of southern Africa and the sub-Saharan. In recent years, they have declined throughout the continent. Outside of parks, the Maasai and other tribes with livestock herds routinely kill Lions and other predators to protect their cattle (Hunter 1998). Lions are particularly vulnerable to persecution and hunting because, like wolves, they hunt in groups. When persecuted, they may not be able to survive hunting alone or in pairs.

Some parks are not large enough to maintain healthy Lion populations, and when they leave parks to wander in search of prey, they are often killed by ranchers or hunters. In the southern African country of Namibia, for example, the 300-mile-long, 25-mile-wide Skeleton Coast National Park skirts the Atlantic coast. Two filmmakers, Jen and Des Bartlett, chronicled the disappearance of Lions from the park. A small population of Lions inhabited the park in the early 1990s, and one pair was radio-collared by park rangers. Shortly thereafter, both Lions were shot dead by livestock herders when the Lions left the park. The Bartletts had known the female for five years, and she was pregnant with four cubs when shot. The killing of Lions to protect livestock is legal in Namibia, and with the death of the last specimen in the park, an elderly and emaciated animal shown in their National Geographic Society film, fiSurvivors of the Skeleton Coast,fl these great cats are now extinct in the area.

Wild cats have been hunted heavily and killed off throughout the Middle East. Leopards (*Panthera pardus*) still persist in small pockets, escaping detection with nocturnal hunting, and hiding in rock crevasses and trees during the day. As a general rule, wherever Leopards are seen in the Middle East, they are shot or poisoned as potential threats to the ubiquitous sheep and goats. In a few areas, such as remote portions of the Saudi Arabian Peninsula, Leopards are protected in national parks. These Leopards are very adaptable in their prey and can subsist on small animals, such as hares--unlike the Lion, which requires larger prey.

Eight subspecies of Leopards are listed on the *2000 IUCN Red List of Threatened Species*, all in Endangered or Critical categories. They range from North Africa across Asia to Java, Indonesia. Races such as the South Arabian Leopard (*Panthera pardus nimr*) of Saudi Arabia, United Arab Emirates and Yemen; North Persian (*P.p.saxicolor*) of Afghanistan, Iran and Turkmenistan; and the Anatolian Leopard (*P.p.tulliana*) of Turkey, have populations so small that they may become inbred and disappear within a few decades. The South Arabian Leopard is the focus of a conservation program organized by officials and conservationists from Saudi Arabia, Yemen, Oman and the United Arab Emirates. Only 100 to 200 of these cats survive, and they continue to be persecuted by livestock owners and hunters (*Oryx* 1996). The "Leopard Group of Arabia" was formed in 1995, and each country will prepare a plan for conservation of the Leopard, review its own wildlife legislation, conduct surveys, and make proposals for protected areas (*Oryx* 1996). This group is also working to increase populations of native prey, reduce livestock numbers in the Leopards™ habitat, and conduct public education programs (*Oryx* 1996).

Snow Leopards (*Panthera uncia*), native to the mountains of Asia, from Pakistan east to China, are endangered from hunting for pelts and as trophies, and by persecution from herdsmen who kill them as a threat to their livestock. Their total population may be as low as 4,500 or as high as 7,500 (Sunquist 1997). In their stark, rocky and high desert habitats, these cats prey upon wild sheep, goats, deer and marmots (Sunquist 1997). Their original range stretched for 4,000 miles and encompassed 1.2 million square miles in a wide arc, curving from east to west in the Himalayas through former Soviet Republics, Nepal, Pakistan, Afghanistan, Bhutan, Sikkim, and Mongolia to China, including a

total of twelve countries (Baillie and Groombridge 1996). They have disappeared from vast areas within this region, however, and continue to decline.

Until the 20th century, few herdspeople roamed these remote and forbidding regions, and Snow Leopards and their prey were left unmolested in most areas. In the past 50 years, however, human populations have risen dramatically. In western China, the government has used subsidies to encourage settlement of the western steppe, and large numbers of people have entered previously uninhabited areas with their livestock. In western Nepal, villages now dot the Himalayan slopes at 9,800 feet, and people scratch out a living from meager potato, barley and wheat crops (Sunquist 1997). Each household has only a few sheep and goats and cannot afford to lose even one to predators (Sunquist 1997).

Some 1 million Mongolian herders subsist in a barren landscape, dependent on their yaks, goats and sheep. These people, whose livestock compete with wildlife for the scarce grasses, also hunt native animals which the Snow Leopard needs to survive--Blue Sheep, ibex, deer and others. Even marmots are killed in very large numbers for their meat and skins (Sunquist 1997). When their natural prey disappears, and Snow Leopards begin to prey on livestock, herders poison, trap or shoot these cats in retaliation. In many areas, herders kill Snow Leopards as a potential threat, even when they have not lost livestock, in order to sell their valuable pelts.

Dr. George Schaller of the Wildlife Conservation Society has conducted studies on the diet of Snow Leopards and, in most areas, found less than 5 percent of livestock in their diet, based on feces analyses (Schaller 1998). As numbers of livestock in the Snow Leopard's range rise and herders penetrate further into the mountains and high pastures, livestock losses occur that sometimes result in extermination campaigns (Schaller 1998). Herding practices in these areas often encourage predation by Snow Leopards, with sheep and goats, and mares with their foals left unguarded (Schaller 1998). Depletion of their prey has increased in recent years, with government policies that encourage marmot hunting, pika poisoning and, until the late 1980s, Blue Sheep market hunting (Schaller 1998).

In Tibet, Dr. Schaller has arranged with local herdspeople to pay them for any losses they incur to Snow Leopard predation, and he has hired local Tibetans to assist in field studies of these cats, giving them a financial incentive to protect the cats. Likewise, in Pakistan, a new program organized by an American conservationist, Helen Freeman, founder of the Seattle-based International Snow Leopard Trust, has sponsored some 90 projects for the species, including many field studies. Its web page (www.snowleopard.org/islt) follows the movements of radio-tracked Snow Leopards. Gary Larson, the popular *Far Side* cartoonist, created a Snow Leopard design for the organization to use on its shirts (Sunquist 1997). Grade-schoolers all over the country have raised money by selling T-shirts for the International Snow Leopard Trust. In 1988, through the education programs and compensation for livestock losses conducted by this organization, a Pakistani livestock owner trapped a young Snow Leopard found preying on livestock, contacted the government and, before news crews, set it free. In the past, it would have been killed routinely.

The International Snow Leopard Trust and the Mongolian Association for Conservation of Nature and Environment are providing tea, noodles and clothing to livestock grazers in Snow Leopard territory in the Altay Mountains of Mongolia, with the understanding that they will protect wildlife (Schaller 1998). One village requested children's clothing, flour, candles, soap and tea, and these requests were filled (Sunquist 1997). The concept of involving local people in the conservation of wildlife is extremely important and, wherever practiced, has had beneficial long-term results for all concerned.

Bats

Bats live on every continent except Antarctica and serve extremely important ecological roles as pollinators, seed

dispersers and consumers of vast quantities of insects. Although some societies value these useful animals, many persecute all bats, based on irrational prejudice and fears of rabies. The Romanian legend of Dracula, in which a man turns into a blood-thirsty vampire bat at night and flies about seeking victims, has created a ridiculous and false impression. Real vampire bats are small, only about 3 inches in length and weighing about an ounce (Wilson 1997). The three species inhabit neotropical forests and are rare in natural habitat. Only when large numbers of livestock are grazed in an area do these mammals, who suck blood from large animals such as livestock, become common (Wilson 1997). They rarely cause the livestock harm. They are capable of transmitting disease to their host animal, but very rarely do so (Wilson 1997). Bat Conservation International has worked effectively to allay fears about vampire bats and helped many people to see them in the positive light of their value to ecosystems, economies (through pollination), seed dispersal and insect control and their interest as diverse, successful species. But Dr. Merlin Tuttle, founder and Executive Director of the organization, believes that persuading the public that bats are not to be feared is still an uphill battle, in spite of progress made in education programs (Raver 2001). Exaggerated headlines about bats and rabies tend to undo rational education programs. In fact, Dr. Tuttle says that over the past 20 years, the United States has had 1.5 human cases of bat rabies per year, hardly deserving the hysteria that so many people feel at the mere mention of bats (Raver 2001).

One positive change in recent years is the increase in people who rise to the defense of bats when newspaper stories appear about the threats of vampire bats and bat control in buildings (Garvin 1999, Gross 2000). Letters to the editor often make the point that bats are basically beneficial, and articles depicting them as fearsome enemies are misleading and cause persecution of wild bats. One article in *The New York Times* (Gross 2000) profiled a bat control professional who paid house calls when people complained of bats having entered their homes. He set glue traps, which bats blundered into and then broke their necks, and sent their bodies to a laboratory in the state capital for rabies testing (Gross 2000). Experts have found that only 1 to 4 percent of bats are rabid, and conservationists suggest that bats be set free rather than killed (Gross 2000). A more humane approach to the problem of bats in the attic was developed by Cal Kosky, a wildlife biologist with the Pennsylvania Game Commission. He tapes a piece of plastic or netting over the top of the entrance hole on the outside of the house (Raver 2001). Bats are able to fly out, but are blocked on return. A bat house is placed strategically close to the old hole to provide them with a new home (Raver 2001). Bat Conservation International has an educational video, "Building Homes for Bats," which explains how to construct bat houses to attract bats to backyards where they eat mosquitoes and other insect pests (Raver 2001).* Sensible advice can also be obtained from Dr. Tuttle's 1988 book, *America's Neighborhood Bats. Understanding and Learning to Live in Harmony with Them*.

Prejudice against bats has had serious consequences for many populations that roost in accessible places, such as open caves. The largest bat colony in the United States, located in Eagle Creek Cave in Arizona, had 30 to 50 million individuals until the 1960s, when vandals and human disturbance reduced them to only 30,000 (Wilson 1997). Several species of North American bats have become endangered as a result of deliberate killing by people, disturbance by spelunkers, and tourists entering the caves (Nowak 1999). The Gray Bat (*Myotis grisescens*) and the Indiana Bat (*Myotis sodalis*) of the eastern and Midwestern United States, for example, are both endangered as a result of these activities. Dr. Tuttle has found that the total number of Gray Bats in 22 major summer colonies declined from 1.2 million prior to 1968 to 293,600 in 1976, a loss of 75 percent (Nowak 1999). The Indiana Bat fell from 640,361 in 1960 to 459,876 in 1975; by 1993, 347,890 remained (Nowak 1999). Both species are listed as Endangered by both the *2000 IUCN Red List of Threatened Species* and the US Endangered Species Act. In Europe, the Pond Bat (*Myotis dasycneme*), a related species, has been reduced to only 3,000 in western Europe and fewer than 7,000 in its entire range (Nowak 1999). It is listed as Vulnerable by the IUCN. Many other European myotis bats also have declined to Endangered or Threatened status from habitat loss, disturbance of hibernating colonies in caves and mines, and blocking up of nursery sites in large buildings, such as cathedrals and castles (Nowak 1999). Rather than killing bats that roost in buildings, or blocking up entries, Bat Conservation International encourages the placement of bat houses nearby, which the bats tend to occupy instead. Similar efforts are needed in Europe. Even when allowed to roost in buildings, many bats are poisoned by chemicals used to treat wood in western Europe (Nowak 1999).

Bat caves are often vandalized when bats hibernate in the winter. Vandals enter caves and knock semi-conscious bats

to the ground, killing them by the thousands, or even millions. Even entering a hibernation cave can result in mortality because disturbances can arouse them and they use up so much stored energy that they do not survive the winter (Wilson 1997). Many bat caves now have gates that allow bats to fly through the open grating, but keep people out; they have helped protect important bat hibernation areas where bats from large areas congregate (Wilson 1997).

The importance of bats as pollinators is discussed at length in *The Natural History of Pollination*, by Michael Proctor, Peter Yeo and Andrew Lack (1996). Many types of flowers have evolved to be pollinated by bats, opening only at night. Their internal pollen-carrying structures are designed to drop pollen on the bat's face when it feeds on nectar (Proctor *et al*. 1996). A great variety of bats and plants coexist, perfectly adapted to one another. Dr. Tuttle's dramatic photos of many such flowers have been published in *National Geographic* magazine and in the useful book, *Bats in Question. The Smithsonian Answer Book* (Wilson 1997). He also has made films of bats for nature documentaries. Many bats are extremely attractive, and their sonar is so complex and sensitive that it is only partially understood by scientists. *Walker's Mammals of the World*, by Ronald Nowak (1999), is another important source of information on bat biology, taxonomy, behavior, conservation and related subjects.

After rodents, bats have the greatest number of species of any mammals, with the most diversity in tropical areas. The number of threatened species has increased dramatically over the past decade as a result of persecution, killing for food, pesticides and other toxic chemicals, and loss of their habitat (see Appendix for list of threatened species). The majority of species at risk suffers from a combination of these factors.

Birds of Prey

Birds of prey have been persecuted for hundreds of years in Europe and other parts of the world, usually as suspected predators of chickens or small livestock, such as goat kids or lambs. In most parts of the world, they still are given no official protection.

Hawks, eagles, owls, falcons and other birds of prey that breed in North America were excluded from the 1918 Migratory Bird Treaty Act (MBTA), signed with Great Britain on behalf of Canada. The Treaty covered almost all other species of native birds, banning hunting and killing as well as harassment and destruction of nests. This exposed birds of prey to continued indiscriminate shooting for sport, hunting from aircraft, poisoning and even capture in pole traps, which catch birds by the feet and hang them upside down in nooses.

Populations of birds of prey that breed in Canada and the northern United States migrate south during the fall, some to Latin America and others to southern states. Flying along thermal wind currents, they funnel into flyways as they pass through mountain chains. In the eastern United States, thousands of hawks, and a smaller number of eagles and falcons, pass over the Allegheny Mountains of Pennsylvania during October, November and December every year. Kittatinny Ridge, near the town of Kempton, came to be known as Hawk Mountain because of the huge numbers of birds of prey passing near it. For generations in the 19th and early 20th centuries, hunters gathered every fall on the rocky ridge to shoot these birds by the hundreds as they soared by. Dead hawks, falcons and eagles accumulated in huge piles, while wounded birds staggered around or lay helplessly immobile on the ground (Brett 1973).

This carnage was considered a form of sport, justified by old prejudices. Rosalie Edge, an ardent conservationist, spearheaded the movement to stop this hunt in the 1930s (Brett 1973). This courageous woman publicized the slaughter of birds of prey, and after a campaign in which she enlisted the help of influential conservationists, she succeeded in purchasing the mountain as a sanctuary (Brett 1973). Edge persuaded an ornithologist, Maurice Broun,

and his wife, to oversee the sanctuary and prevent hunting. They remained on Hawk Mountain for 32 years and served as guides for the more than 40,000 visitors who come every year to see the spectacle of hawks flying over and alongside the mountain ridge (Brett 1973). Rosalie Edge died in 1962, but the sanctuary continues as a non-profit organization staffed with ornithologists, educators, and volunteers, who chronicle by species and number the birds that fly past the ridge.

Hawk Mountain Sanctuary is one of the country's first examples of private ecotourism, and it has accomplished a great deal in teaching the public about birds of prey as useful animals in ecosystems, as well as providing exciting views of these birds as they soar past the ridge. In the morning, before the thermal winds warm up, hawks fly at low elevations, giving visitors a view of their tails and backs from above, an especially colorful sight in the case of the Red-tailed Hawk (*Buteo jamaicensis*), while in the afternoon, they fly higher, transported along by the thermals. Sometimes a visitor to Hawk Mountain can see a hawk or other bird of prey at close range, only 15 or 20 feet away, as they fly close to the ridge, the intricate patterns of their feathers in full view.

In spite of the preservation of Hawk Mountain and several other key hawk habitats, legal protection from hunting did not come in the United States until 10 years after the death of Rosalie Edge. During these years, thousands of hawks and other birds of prey were shot because of ignorance or as sport. Little was understood about their value in controlling rodents and rabbits. In 1960 alone, 12,000 Golden Eagles (*Aquila chrysaetos*) were killed in Texas in a massive campaign to eliminate them. A major victory for birds of prey was their addition to the Migratory Bird Treaty Act in 1972. The bans on hunting that have protected other native land birds were finally accorded these raptors. This was carried out through a memorandum enacted with Mexico, which had signed the Migratory Bird Treaty Act in 1936. It prohibits, except as allowed under specific conditions, the taking, possession, purchase, sale, or bartering of any migratory bird, including the feathers or other parts, nests, eggs or migratory bird products. "Taking" is defined as pursuing, hunting, shooting, shooting at, poisoning, wounding, killing, capturing, trapping, or collecting migratory birds. Individuals and organizations may be fined up to $5,000 and $10,000 respectively, and those convicted may face up to six months imprisonment for misdemeanor violations of the Act. Felony violations may result in fines of up to $25,000 for individuals and $500,000 for organizations and up to two years imprisonment for those convicted. This strong legislation has not stopped the killing of birds of prey altogether, but it has deterred the type of slaughters that were once common.

Although Bald Eagles were revered by native tribes, especially those in the Pacific Northwest, they became victims of prejudice by European colonists, who accused them of damaging fish stocks. A bounty in Alaska resulted in the killing of some 150,000 of these eagles between 1917 and 1953. This species is the national bird, the official symbol of the United States of America, yet historically it has been given little respect. Some even called them "gangster birds" because they were thought to be scavengers of fish caught by other birds. In truth, they are superb fishers with extraordinarily keen vision and are acrobatic in flight. Bounty programs and random shooting of Bald Eagles from colonial times onward caused these birds to disappear from much of their original range, which encompassed the entire continent of North America, including arid regions in the Southwest.

The Bald Eagle Protection Act was enacted in 1940 to protect it from extinction, and amended in 1962 to extend protection to Golden Eagles, primarily to protect immature Bald Eagles, which resemble them. A 1972 incident involving the slaughter of hundreds of Golden Eagles by western ranchers shooting from aircraft resulted in increasing fines under the law from $500 to $5,000 and/or one year imprisonment for subsequent offenses. The amendments also specifically included poisoning in the definition of taking, since both Bald and Golden Eagles had been poisoned by ranchers. These amendments also included the same high penalties for possession of eagle feathers, nests or eggs, and made federal grazing permits subject to cancellation for violations of the Act. In addition, they added a new facet to the enforcement of the Act: one-half of any fine can be paid to a person who provides information leading to a conviction. To augment this protection, the Airborne Hunting Act was enacted in 1972 to prevent the killing of wildlife from aircraft.

After 1973, the killing of a Bald Eagle constituted a violation of the US Endangered Species Act, the Bald and Golden

Eagle Protection Act, and the Migratory Bird Treaty Act, the combined penalties of which could amount to long jail sentences and very high fines. In spite of all these legal steps taken to protect eagles, killings continue. Many are deliberate and carried out in remote areas where there is little fear of prosecution, and others are done by hunters ignorant of the law or the identity of their targets. The protection of native birds, their identification, and laws applying to them should be taught in schools in North America, but such information is usually acquired by chance if at all. Each year, 300 to 400 eagles--Bald and Golden--are found dead. In some cases, hunters still believe folklore about birds of prey being destructive, and shoot them intentionally. A Bald Eagle shot in Maine in 1994 was killed by an 85-year-old man who deliberately killed the bird because he believed these birds were killing geese. He told game wardens that they should "do something about the eagles;" because of his age, he was only given a $2,500 fine, which was suspended. Bald Eagles feed mainly on fish and are not major predators of waterfowl.

Although the majority of eagles are killed when shot, many are found wounded, some in emaciated condition, unable to fly to obtain food and near death. One such Bald Eagle was found crippled in 1983 in Georgia, having been shot in the wing. He had been on the ground for a week, his wing bone exposed. In spite of attempts to save his wing, veterinarians had to amputate it because of infection, and the eagle was taken into a rehabilitation program. Named Osceola, he has played an important role in Wings of America, an education program at Dollywood in Tennessee. John Stokes, Osceola's caretaker, teaches children and adults about the effects of such shooting, stressing the impoverished life that Osceola leads, unable to fly and be free. Stokes decided to bring Osceola along on his hang-gliding trips to treat the bird to some of the sights the eagle had not seen in the many years since being shot. Harnessed into a specially made sling, the pair hang-glided, with Osceola positioned above Stokes, looking intently at the ground far below, turning his head frequently in apparent fascination. The film of Osceola hang-gliding was shown on nationwide television in 1996, and some 500,000 people attend lectures featuring this maimed eagle every year. The National Audubon Society series for young people, "Audubon's Animal Adventures," featured Osceola in the program entitled "Eagle Adventures," shown on the Disney channel.

In the past, it was impossible to prosecute offenders unless there were witnesses or other direct evidence to the killing. Today, a state-of-the-art forensic laboratory run by the US Fish and Wildlife Service in Washington state is able to necropsy dead eagles for cause of death. If shot, ammunition extracted from the birds is analyzed forensically, and cases are made with as much precision and scientific evidence as criminal investigations in which people are the victims.

Prejudices against birds of prey still persist among many who wrongly believe that they harm wildlife or present major threats to domestic animals. Biological studies have documented their ecological importance as major controls on rodent populations. Some birds of prey feed on snakes, insects or other potential pests. No species of raptor poses a significant threat to domestic animals.

The continent's densest population of birds of prey breeds in the craggy canyons and sagebrush shrubland of Idaho. This area has been set aside as the Birds of Prey National Conservation Area, lining 81 miles of the Snake River and covering 485,000 acres. Prior to its protection, this land was in the process of being converted to agriculture. The birds of prey had begun a steep decline from shooting and loss of habitat. Conservationists faced strong opposition to the plan, but overcame it, establishing this area in 1971, a year prior to the inclusion of birds of prey on the Migratory Bird Treat Act. It has since become a leading ecotourism destination for rafters and hikers, who are led on tours by naturalists from the Bureau of Land Management (BLM), which oversees the refuge. Fourteen species of raptors breed in the area or migrate through it, and the breeding population of hawks, eagles, owls and falcons has been estimated at 800 pairs. They provide exciting views of high-speed hunting of ground squirrels and birds, and their eerie shrieks resound through the canyons.

Waterfowl hunting is regulated by the Migratory Bird Treaty Act under regulations by the Fish and Wildlife Service. Unfortunately, the regulations have serious shortcomings that have resulted in many shootings of birds of prey. First, hunting can begin before dawn, when hunters are unable to identify birds by species. Each year, hundreds of birds of prey, including such endangered species as Peregrine Falcons, are shot accidentally. Second, the regulations do not

require that hunters be able to identify birds by species, including protected and endangered species. Since many ducks and geese are extremely difficult to identify, the failure of the Fish and Wildlife Service to require hunters to pass identification tests and begin hunting well after daybreak means that protected and endangered birds will continue to be shot.

In October, 1995, a Peregrine Falcon (*Falco peregrinus*) shot in Massachusetts was migrating south from Canada or Greenland during hunting season. It suffered neurological damage after being shot in the left wing while it was flying in a wildlife refuge area. The Assistant Director of the State Division of Fisheries and Wildlife, Tom French, stated that it appeared that the bird was not shot accidentally. This was the second shooting of a Peregrine Falcon in as many years. The reintroduction of captive-bred specimens of these birds into the eastern United States has been a success, with over 130 nesting pairs. Their long-term survival, however, will depend on adherence to laws prohibiting shooting or harming them.

For the future, the Migratory Bird Treaty Act would be far more effective if signed with Latin American and Caribbean nations to protect North American birds wintering in those countries. This would be especially important in view of the decline in many of the continent's birds of prey, which are persecuted and killed by pesticides and poisons in their wintering grounds.

The California Condor (*Gymnogyps californianus*), North America's largest bird of prey, once soared over most of the continent. Its bones have been found among Florida's Pleistocene fossils, and 20,000 years ago, it was very common and widespread, feeding on the carrion of mastodons, bison and other large mammals. This giant bird's superb aerodynamic flight makes the most sophisticated man-made aircraft look clumsy by comparison. Condors have a positive role to play in ecosystems, feeding on carcasses and thereby ridding the environment of these potentially infectious contaminants. Although they declined in range over the centuries, condors were still widespread from Baja California, Mexico, north to Washington state, where Lewis and Clark saw them along the Columbia River in the early 19th century. They were often observed scavenging seal and whale carcasses along the California coast, and they nested as far east as the Sierra Nevada Mountains.

Settlers looked on condors as large targets, with their 10-foot wing span, and perhaps thought they were predatory birds. Hundreds were shot. These birds feed exclusively on carrion and do not hunt live animals. When word spread in the last years of the 19th century that the condors were approaching extinction, egg and specimen collectors preyed on the remaining birds. Between 1881 and 1910, 288 birds were killed as museum specimens (ICBP 1981). By the turn of the century, only a few hundred birds remained, yet killing was still legal. The ornithological journal *The Condor* began publication at this time and recorded many instances of these killings. In one case, an individual named Frank S. Daggett reported shooting a California Condor in 1901, wounding it in the wing and then, when it fell to the ground, shooting it three more times, still not killing it. Finally he clubbed it and shot it yet again before the bird died (Daggett 1901).

The California Condor continued its decline until only 60 birds remained in 1939 (Greenway 1967). The last population survived in a wilderness area of southern California. In spite of legal protection and the establishment of the Sespe Condor Refuge, the birds suffered high mortality from shooting, ingestion of lead shot from deer killed by hunters, feeding on animals killed by predator poisons, collisions with power lines, and accidental capture in leghold traps. Biologists from the Fish and Wildlife Service and the National Audubon Society were assigned to study and protect this small population in the 1960s and 1970s, but they did not publicize its precipitous decline or insist on further protection from the threats that continued to kill these birds. As these birds headed toward imminent extinction, nothing was done to stop deer hunting in their refuge, nor to prevent the use of steel jaw leghold traps or predator poisons in their diminishing range.

One of the last nests was in a regal setting befitting this massive bird: a huge natural hole in a giant, old Sequoia tree. The eggs from this nest and others were taken by the Fish and Wildlife Service for captive hatching. In 1980, one of the last wild chicks hatched in a cave and was being weighed and tested by biologists when it suddenly died. It had

been handled for more than an hour, during which time it repeatedly hissed and jabbed at the researcher. Later it was revealed that shock caused its death. The incident was filmed and shown on national television, resulting in the cancellation of the recovery program by the state of California, followed by a long period of re-evaluation and controversy. By 1981, the state reached an agreement with the Fish and Wildlife Service to allow capture of the last nine California Condors, but the program was delayed by lawsuits and wrangling over details. By the time it was finally decided to capture all remaining condors in 1987, only six survived (BI 2000).

The sad decision to remove all wild California Condors turned out to be the correct path to preserve the species, since its wide-ranging behavior exposed it to countless perils that were beyond the control of its protectors. To the amazement of many, the captive-breeding program succeeded beyond all expectations. The eggs laid by the captive condors were artificially incubated, and chicks were fed by workers, with puppets resembling adult condors covering their hands. So many birds were captive-bred at special facilities run by the Los Angeles Zoo and other breeding centers that by 1992, a reintroduction program began with release of captive-bred birds into the wild in southern California. Some of the released birds died after striking electric power wires or were injured and had to be returned to captivity. Several landed in suburban locations, perching on the decks and roofs of private homes and even, in one case, entering someone's home. Most residents did not recognize the birds™ great rarity and protected status, and put out food, such as hot dogs, for them. Finally, wildlife authorities and television news stations learned about the situation, and many Californians became aware of these giant and extremely rare birds. To many ornithologists, the behavior of these young condors indicated that the birds were tame and considered humans a source of food. The puppets apparently had not fooled them into thinking they were being fed by parent birds.

By July 1994, California Condors numbered 89 birds, 85 of which were in captive-breeding facilities, and four released birds (Collar *et al*. 1994). Six young condors were released in the Grand Canyon area in late 1996, with Fish and Wildlife Service personnel staying close to provide food and to radio-track the birds. Within a short time, one of the condors was killed by an eagle, an unexpected setback. The total California Condor population grew to 120 birds by early 1997, and only a year later it had increased to 147 birds, of which there were 97 in captivity, 28 returned to the wild in California's Los Padres National Forest, and 22 released in Arizona (BI 2000). The released birds are provided with livestock carcasses until they are able to find food on their own. The success of this program has not yet been proven by breeding in the wild, as all released birds are too young. Only time will tell whether these birds survive and reach the goal of 150 birds in separate populations. They are being trained to avoid some of the sources of mortality that killed them in the past, such as power lines, but as long as lead shot is used in deer hunting in their range, this will remain a potential threat to them.

Elsewhere in the world, birds of prey receive little or no protection from persecution. In Italy, shooting of migrating birds of prey has long been a "sport" in which gunners position themselves in concrete bunkers on hillsides and kill hawks, falcons and eagles as they fly by. One woman decided to fight the hunters and worked successfully for an official ban on shooting these birds. In spite of this, illegal shooting takes place in Italy, and every year during the migration season, conservationists from many parts of Europe come to help her enforce the ban. The campaign to stop hunting of these birds was described in a film, fiAnna and the Honey-Buzzardsfl (see Video section). In Australia, persecution of eagles and hawks is rampant. After shooting these birds, especially Wedge-tailed Eagles, they are often nailed to fence posts with their wings spread. Few of the ranchers who kill thousands of these birds seem aware of the important role they play in controlling rabbits.

Snakes

The prejudice against snakes may be traced in some cultures to the Biblical story of Adam and Eve, in which the snake represents the evil temptor. For many, snakes inspire great fear and loathing, and they are often killed upon sight. In the American West, rattlesnake hunts are carried out in many towns as an annual event, with thousands of

snakes captured. After being prodded and manhandled, they are killed, often by being skinned alive. The New Mexican Ridge-nosed Rattlesnake (*Crotalus willardi obscurus*) is a threatened species on the US Endangered Species Act, persecuted and overcollected in its limited range. In Eastern states, especially in the South, snakes are also hunted for sport, burned alive with gasoline poured down their dens, and killed in bizarre religious ceremonies. One town in Georgia has an annual war on rattlesnakes, killing as many as possible. For some species, this has resulted in serious declines. The Eastern Timber Rattlesnake (*Crotalus horridus*), the largest snake native to the United States, inhabits forested areas with rock faces, crevices and caves in the Northeast. It has become threatened in many parts of its range. These snakes, which range in size from 35 to 74 inches in length, are vulnerable to persecution because they congregate in large numbers in rocky dens and overwinter with other types of snakes for warmth. They hide under rocks where hunters and collectors find them. Timber Rattlesnakes are long-lived, known to survive 30 years or more. Females give birth only every other year, do not mature until age 4 or 5, and have only 5 to 17 young (Behler and King 1979). With such slow reproduction, they are vulnerable to declines when hunted.

This species has legal protection from hunting in Pennsylvania and New York and is listed on their state endangered laws, yet hunting still kills hundreds each year. One rattlesnake hunter, profiled by CNN, bragged that he had captured 9,000 Timber Rattlesnakes in his lifetime and planned to continue openly flouting laws protecting the species. He claimed that he enjoyed catching and killing these snakes so much that he would never stop, and some herpetologists accuse this man of single-handedly causing declines. He has been arrested many times and jailed for trading in endangered species, but refuses to stop. These snakes do not pose a threat to people unless they are sought out in their retreats.

Biologists point out that snakes are extremely useful ecologically, feeding on squirrels, mice, rats and other rodents, but since laws in the United States and around the world either fail to protect snakes or are not enforced, snakes often are persecuted and killed senselessly.

Rodent Control

Prior to settlement of North America, prairie dogs of many species inhabited towns of burrows that covered some 98 million acres of shortgrass prairies, from southern Canada to Mexico. One prairie dog town in the Texas Panhandle stretched over 25,000 square miles and held an estimated 400 million animals (Dold 1998). Prior to the 19th century, they are thought to have numbered 5 billion animals (DeBlieu 1993). These towns have since been destroyed, the prairie dogs killed, and the habitat used for agriculture, pastureland and development. A keystone species, prairie dogs create habitat for hundreds of other animals who live in their complex burrow systems. These rodents have been driven to endangered status after centuries of persecution and poison campaigns that were based on the belief by cattle ranchers that prairie dogs ate too much grass, depriving cattle of fodder. The US government sponsored the destruction of prairie dog towns beginning in 1900. The poisoning program was bolstered by inaccurate information from the US Biological Survey, which stated in 1902 that prairie dogs decreased productivity of grasslands by 50 to 75 percent (Dold 1998). Poison bait was distributed in the towns, gasoline was poured into their burrows and set afire, and they were shot by the thousands. A highly toxic poison, 1080, was used from the 1960s on, devastating prairie dog towns and killing vast numbers of animals, from foxes to Golden Eagles, who fed on the poisoned prairie dogs. This reduced prairie dog habitat to about 1.5 million acres, a fraction of their original range.

Modern biological research has unveiled the truth about the effect of these rodents on grasslands. Rich Reading, Director of Conservation Biology at the Denver Zoological Foundation, stated flatly that the Biological Survey's figures claiming that prairie dogs reduced grass by up to 75 percent, were "vastly in error" (Dold 1998). Studies by Dan Uresk, a Forest Service biologist, have concluded that prairie dogs eat only a small percentage of grass--from 4 to 7 percent (Dold 1998). James Detling of Colorado State University in Fort Collins has found that prairie dogs are natural fertilizers, whose incessant grass clipping increases the protein content and digestibility of grass (Long 1998).

Other studies have examined the claims of cattle ranchers against prairie dogs and have demonstrated again and again that these rodents actually improve forage quality for livestock and, by cropping the shortgrass prairie, stimulate it to grow, increasing the amount of grasses around the towns (Wuerthner 1996). The American Bison prospered in herds of 50 million, much of the species range lying within prairie dog towns of the short-grass prairies. Their major predator, the highly endangered Black-footed Ferret (*Mustela nigripes*), has been eliminated in the wild as a result of poisoning and shooting campaigns. At least 130 grassland species are associated with prairie dog towns (Godbey and Biggins 1994), and up to 170 vertebrate species have been seen in these towns.

Another complaint of cattlemen, that cattle fall into prairie dog burrows and break their legs, has also been refuted. Don Sharps, a wildlife consultant, asked an audience of 200 ranchers if any of them knew of a case of a horse or cow that had broken its leg in a prairie dog town, and no one said yes (Dold 1998). Such prejudices are passed down from generation to generation and fuel the persecution programs against these ecologically important rodents.

Slow-acting poisons, such as zinc phosphide, are used by many animal damage control programs. This chemical takes up to 12 hours to kill prairie dogs, who suffer extremely painful deaths (Wuerthner 1996). Another technique is the placement of gas cartridges in prairie dog burrows. These are ignited and burn the prairie dogs alive (Wuerthner 1996). On federal lands, these programs are conducted by the Wildlife Services unit of the Department of Agriculture at public expense. In the 1980s, more than $6 million was spent to eradicate 460,000 acres of dog towns on the Pine Ridge Indian Reservation in South Dakota (Line 1997). This was the largest remaining prairie dog town in the United States (Dold 1998) and the site of the only population of Black-footed Ferrets known to exist in the 1970s. In 1993, Animal Damage Control (now called fiWildlife Servicesfl) used, sold or distributed 220,000 fumitoxin tablets, 60,000 gas cartridges, and 21,000 pounds of zinc phosphate baits in the northern plains states to eradicate prairie dogs (Wuerthner 1996).

Studies about prairie dogs have revealed them to be surprisingly intelligent. They communicate in yips and chirps, some of which are warnings to other members of the town. A study by Professor Con Slobodchikoff of Northern Arizona University has revealed that prairie dogs™ calls convey specific information, such as what size a predator is, what type of animal, its speed of travel and level of threat (Dold 1998). Slobodchikoff created experiments in which two people walked through a prairie dog town that had experienced hunting; one carried a simulated rifle, while the other did not. The prairie dogs gave different calls for each person, and when the "hunter" returned in a few weeks without his rifle, they still gave the call for a man carrying a rifle (Dold 1998). Such communication goes far beyond what most people consider rodents to be capable of and shows their ability to react to a variety of threats, including the most serious one, human beings. Unfortunately, their warnings could not protect them from poison, shooting, and even bulldozing of their burrows.

Knowledge about the true role that prairie dogs play in grassland ecosystems has yet to reach most ranchers and others who have a hatred for these rodents that seems to reach no bounds. Many compare notes on how many prairie dogs they have killed, usually by high-powered bullets that cause them to disintegrate on contact (Long 1998). One group in eastern Colorado with 30 members calls themselves the Varmint Militia and kills prairie dogs as a sport. They recently spent two full days shooting prairie dogs until activity in the prairie dog town slowed (Long 1998). One militiaman bragged of having shot 20,000 prairie dogs and wants to retire from his exterminating business to shoot them full time (Long 1998). These shooters recount with glee the story of a recent protest. Some animal rights protesters tried to stop one of these hunts and chained themselves together, refusing to move; the Varmint Militia called the Kit Carson County sheriff, who placed them in jail for the weekend (Long 1998).

Although private shooting may be difficult to stop, many biologists and conservationists have recommended that all government poisoning and shooting on public land be halted and that subsidies be offered to ranchers who do not kill prairie dogs on their property (DeBlieu 1993). Unfortunately, no action has been taken in this direction.

Sport hunting of these rodents is encouraged by state game departments, and many towns organize hunts as a form of recreation. These hunts, which often involve the killing of hundreds of prairie dogs in a single afternoon, are taking a

high toll of these declining animals in many areas (Wuerthner 1996). A South Dakota organization, Varmint Hunters Association, brags that its 45,000 members do society a favor by killing prairie dogs. The vice president, Marc Minkin, told a reporter, "I'd like to be able to step out my back door in the morning and take a couple of shots before my morning coffee" (Dold 1998). The organized prairie dog shoots draw "hunters" from around the country; one hunt held in Nucla, Colorado, obliterated an entire town (Dold 1998). This hunt, which involves taking pot shots at prairie dogs emerging from their burrows, which they must do to feed, is totally unsportsmanlike--a virtual slaughter.

Even in national parks, poisoning takes place as a result of pressure from neighboring ranchers. In spite of abundant habitat in Theodore Roosevelt National Park, Badlands National Park, Wind Cave National Park and various national monuments in the Great Plains, only 6,000 acres of prairie dog towns have been protected (Wuerthner 1996). In most cases, park authorities have been threatened with lawsuits unless they poison prairie dogs. In South Dakota, home of Badlands National Park, a prime potential area for reintroduction of the endangered Black-footed Ferret, the state has declared prairie dogs to be noxious pests and mandates their control (Long 1998). At Devils Tower National Monument in Wyoming, the park rangers use rifles and poison to thin the ranks of its prairie dog colony (Long 1998).

Increasingly, development in the form of housing complexes, malls, highways and industrial centers, has gobbled up millions of acres of land in the West, much of it inhabited by prairie dogs. Some developers merely bulldoze the towns, while others pay to have a company use a giant vacuum cleaner that sucks prairie dogs out of the ground amid deafening noise similar to that of a jet airplane taking off. The proud inventor of this machine bragged that it was non-lethal, and the rodents could then be killed humanely or otherwise disposed of to allow development programs to proceed. In fact, most of the prairie dogs taken in this manner are killed or injured in the process (Dold 1998). The trauma involved for the prairie dogs must be extreme. Many of the prairie dogs removed from their burrows have been offered for sale as pets, advertised in eastern newspapers. Although loveable and cute, these animals are not suitable house pets because they are wild rodents who require extensive dirt to burrow in. They cannot adjust to the unnatural environment of a home. Unfortunately, this new invention has been given favorable publicity in the media. The majority of prairie dogs that survive this operation end up as pet food, according to CNN (December 15, 1996).

A more humane program involves the moving of prairie dogs to safer environments. A Colorado organization, Prairie Ecosystem Conservation Alliance, hoses prairie dog burrows with water and a biodegradable dish soap that creates frothy suds below ground. The suds irritate the eyes of the prairie dogs, who come to the surface where members of the Alliance are waiting to scoop them up and place them in carriers. They then truck them to a safe area, preferably one with empty burrows, and release them (Dold 1998). An even better solution is to save the towns, since the latter method will not save all the other animals inhabiting the burrows. The city of Boulder, Colorado, became the first town in the state to officially designate land to protect prairie dogs. In 1987 it set aside a preserve for prairie dogs, which now covers almost 5,000 acres (Dold 1998). Fort Collins, further north, began with a reserve of 268 acres and now has 1,700 acres (Dold 1998).

A Native American Gros Ventre tribesman, Mike Fox, has come full circle, from sponsoring prairie dog shoots on the Fort Belknap Indian Reservation in Montana to understanding their positive effect on grasslands by watching Bison graze near the towns on the "best grass around" (Long 1998). There are 400 American Bison on the reservation, and Fox, who manages the reservation's wildlife program, has sharply curtailed prairie dog shooting and accepted 23 Black-footed Ferrets to be reintroduced into the 500,000 acres of prairie on the reservation (Long 1998). He tells Indian ranchers, who still kill prairie dogs, that these animals were here before, and the ferret is not a new animal, but an old one returning (Long 1998).

All but 2 percent of original prairie dog populations are now gone, having been poisoned out to make way for livestock or agriculture. The majority of remaining towns are still unprotected, and the poisoning continues. Grasslands with prairie dogs support far higher densities of mammals, birds and other wildlife than those without them.

Several prairie dog species have been driven to near extinction. The Utah Prairie Dog (*Cynomys parvidens*), native to

south-central Utah, became endangered from these programs and the loss of habitat to livestock and agriculture. Listed on the US Endangered Species Act, this species has a restricted range in southwest Utah, and after poisoning programs, its population fell from an estimated 95,000 animals in 1920 to only 3,300 in 1972 (Nowak 1999). Through protection accorded by the US Endangered Species Act, Utah Prairie Dogs began to rebound, and by 1984, the species was downgraded from Endangered to Threatened on the US Endangered Species Act. Populations of prairie dogs fluctuate widely, and counts of Utah Prairie Dogs in the early 1990s ranged from 6,400 in the fall to 24,000 after they had pups in the spring (Nowak 1999). The species has recovered somewhat overall, mainly as a result of the Fish and Wildlife Service program of transplanting prairie dogs from private to public lands (Turbak 1993). Initially, many of the released prairie dogs failed to survive, and not until they began releasing males in the spring, who industriously spent the summer excavating burrows to accommodate other prairie dogs released in the fall, did transplants succeed (Turbak 1993). Utah Prairie Dogs hibernate each winter in compartments in the complex maze of their underground tunnels.

Although some Utah Prairie Dogs have been placed on public land, 60 percent of them still live on private land, where special US Endangered Species Act regulations allow farmers and ranchers to shoot or trap an annual quota of prairie dogs; a high of 6,000 were killed one year, and in 1992, 1,543 were killed (Turbak 1993). Education campaigns and tax incentives to protect prairie dog towns would be far preferable to quota systems.

Mexican Prairie Dogs (*Cynomys mexicanus*) of southern Coahuila and northern San Luis Potos, Mexico, have declined as their habitat has been converted to agriculture and grazing land for livestock, and many colonies were exterminated by poisoning. The largest remaining town covers only 4,400 hectares (Nowak 1999). The species is listed as Endangered by the US Endangered Species Act as well as by the *2000 IUCN Red List of Threatened Species*.

A third species, the Black-tailed Prairie Dog (*Cynomys ludovicianus*) has declined by 98 to 99 percent (Wuerthner 1996) in a range which once extended from Montana and southern Saskatchewan to northern Mexico (Nowak 1999). The Biodiversity Legal Foundation in Colorado filed a petition in October 1994 to list it as a Category 2 species under the US Endangered Species Act, a category just below Threatened. Although the Fish and Wildlife Service's own biologists supported this listing, the petition was denied after political pressure from ranchers (Wuerthner 1996).

Thus, at least three of North America's five species of prairie dogs are in grave danger of extinction, and the remaining two have declined precipitously. Their ecosystems are threatened as well, as are many of the species that depend on them. Although they are extremely photogenic and likeable, prairie dogs are not ecotourist attractions at present. With protection and more publicity, such as nature films and education programs, they could become so, and this would enhance their conservation.

Conservationists have proposed some huge reserves for prairie dogs that would link remnant populations in parts of the West, where much of the land is now under the control of the Bureau of Land Management of the Department of the Interior. The latter department favors cattle ranchers more than prairie dogs, but with outside pressure and publicity, such a plan might become reality. The Fish and Wildlife Service has had difficulty locating prairie dog towns that are protected from poison programs in which to reintroduce captive-bred Black-footed Ferrets.

For their long-term survival, prairie dogs need extremely large territories. At present, fragmented populations, which are often reduced to a few hundred animals widely separated from the nearest prairie dog town, have lost viability from lack of genetic interchange, and some scientists fear that their natural behavior may be altered by this isolation. These loveable animals need more friends to speak out on their behalf and demand that they be protected from poisoning, "sport" hunting and other persecutions, and that sanctuaries be established.

Economically, they may be worth far more alive than dead. The potential for using prairie dogs as a focal point for ecotourism is great. Tourists would be delighted by their behavior and fascinated to see the rich wildlife that inhabits their towns.

Trophy and Sport Hunting
During the late 19th and early 20th centuries, wealthy European and American big game hunters traveled to Asia, Africa and South America to "bag" large animals that they proudly displayed as stuffed animals and heads mounted on the walls of their homes. Maharajahs of India and British hunters took what Vincenz Ziswiler (1967), in his interesting book, *Extinct and Vanishing Animals*, describes as "a morbid pleasure in killing." Lord Ripon, an Englishman who died in 1923, was credited with killing 500,000 game birds and mammals--about 67 creatures for every shooting day of his life (McClung 1976).

One maharajah turned away from hunting and became a famous conservationist. Brajendra Singh, the last Maharajah of Bharatpur, hosted hundreds of hunts on his estate at the Keolada Ghana marsh 100 miles south of Delhi. A shoot organized by an English lord resulted in the killing of 4,323 ducks by 39 hunters in one day. In 1970, Brajendra Singh converted the duck shoot marsh into India's best known bird sanctuary. Singh died in 1995, having presided over the preservation of this vast marsh and its rare resident birds.

Trophy and Sport Hunting: Page 1
The most prestigious trophy for maharajahs and colonial hunters was the Tiger (*Panthera tigris*), largest of all cats. One maharajah shot at least 1,000 Tigers in his lifetime, while another complained that his total bag of Tigers was only 1,150 (McClung 1976). The number of Tigers killed by these two maharajahs equaled the entire population of these cats in India by the late 1960s. Tiger hunts were a royal pastime and employed hundreds of native "beaters," who drove the frightened cat toward a hunter who was perched safely atop an elephant.

Tigers require large territories. Even in the best habitats, their natural density is low. They probably once numbered 50,000 in India alone, however, when forests covered much of the country. Tigers were hunted to extinction on the Indonesian islands of Java and Bali, where each was a separate subspecies, and they have been hunted to endangered status on Sumatra. In the western portion of their range, the Anatolian or Caspian Tiger (*Panthera tigris virgata*) once ranged from Turkey eastward through the Caspian Sea region of Central Asia. Hunting eliminated these Tigers in Central Asia centuries ago, and only a few isolated populations remained in Turkey by 1900. The last individuals in Turkey were shot in 1972. This subspecies was driven to extinction by trophy hunting and persecution by livestock owners. By the 1960s, Indian Tigers were endangered, yet trophy hunting and killing by livestock herders for the fur trade continued. Indian President Indira Ghandi established a conservation program called Project Tiger in the 1970s, which set aside many reserves and accorded strong legal protection. When the species was beginning to increase in numbers, a trade in their body parts for Traditional Chinese Medicine reversed this recovery.

Today, fewer than 5,000 Tigers remain in the wild. At the present rate of killing--one Tiger per day--the species will become extinct in the wild within 30 years or less. Hunting of these magnificent cats intensified in the 1980s and has accelerated everywhere. They are killed by poison, traps and guns wherever they survive. Villagers and professional

hunters sell Tiger pelts, bones and other body parts in a network of smugglers that reaches from rural India, Bangladesh and Indochina to China, Japan and Taiwan. Tiger pelts are openly sold as trophies in many Asian countries, including Pakistan, Cambodia and Vietnam. They are displayed on shop walls, often with head attached. Some Tiger cubs are even part of this trade, killed and stuffed to be sold as tiny curios.

This magnificent cat will not survive long without legions of rangers guarding the remaining animals. Anti-poaching funding is inadequate in almost all its range. Indian parks and sanctuaries, many of them set aside for the Tiger, are understaffed, and dedicated wildlife wardens are underpaid and poorly equipped to combat poachers (Currey 1996). Some Indian park wardens have been bribed by poachers and watch as they skin dead Tigers (Breeden and Wright 1996). Elsewhere in the Tiger's range in Thailand, Cambodia and Burma, for example, few parks and protected areas have been set aside, and wildlife conservation has low priority.

The market for the pelts and stuffed trophies of these last Tigers among wealthy status-seekers in Asia and elsewhere has increased in recent years. One Taiwanese businessman profiled in a *National Geographic* article (Zich 1993) proudly displayed three stuffed Tigers which he had placed in his bedroom; one of the Tigers was standing on a Lion pelt with the head attached. He protested, "I worked so hard to make money. Now I spend it" (Zich 1993).

In spite of what appear to be overwhelming odds, new projects are attempting to turn the tide. Anti-poaching work in Siberia has helped arrest the steep decline of this critically endangered race of the Tiger in a joint United States-Russian program (Galster 1996). An international fund begun by Exxon Corporation, whose logo is a Tiger, has sponsored anti-poaching work and research throughout its range as well as education programs to persuade Asians not to purchase Tiger products. The US Congress appropriated several million dollars for anti-poaching campaigns, and organizations, such as the Wildlife Conservation Society based in New York City, have worked in Cambodia, Indonesia and other countries to survey and aid in conservation of the species. Scientists have cooperated in studies of the Tiger and aided governments in conservation programs, as described in the recent book, *Riding the Tiger. Tiger Conservation in Human-dominated Landscapes* (Seidensticker *et al*. 1999).

The Asiatic Cheetah (*Acinonyx jubatus venaticus*) once occurred throughout the Middle East as far as India. In the 16th century, the Indian emperor Akbar the Great kept more than 1,000 Cheetahs for hunting. Only one litter was produced by his Cheetahs, and the species died out in India and all of its Asian range except Iran, where fewer then 200 animals remain (Hunter 1998). It is classified as Critical, the most endangered category by the *2000 IUCN Red List of Threatened Species*. The Northwest African Cheetah (*Acinonys jubatus hecki*) is listed as Endangered by the IUCN. In reality, it is nearly extinct, with possible survival only in Algeria, Morocco and Niger, having disappeared from Egypt, Libya and Western Sahara. In the Saharan region, nomadic tribes, such as the Tuareg and Toubou, hunt Cheetah in desert areas of Mali, Niger and Chad, using saluki dogs (Hunter 1998). On occasion, Cheetah prey on young camels in the area, their natural prey having been eliminated. The tribes have such a hatred for Cheetah that they pursue them if they see their tracks, with or without proof of predation (Hunter 1998). Being followed for days in the extreme heat, the Cheetahs sometimes die from heat and stress even before the men and dogs reach them (Hunter 1998).

Trophy and Sport Hunting: Page 2

In the stark deserts of the Saudi Arabian Peninsula and the Mideast, wildlife is not abundant. Animals struggle just to survive in the harsh environment. A wild desert equine became a casualty of unrestricted hunting after World War I. The Syrian Wild Ass (*Equus hemionus hemippus*) was hunted to extinction for sport and meat. These wild asses had been hunted out of most of their original range by the 19th century, but in 1850, they were still seen commonly in large herds in the region once known as Mesopotamia, between the Tigris and Euphrates Rivers. Perfectly adapted to the searing desert heat and sparse vegetation, they ran from natural predators at great speed, and their sand-brown

coloration camouflaged them. After thousands of years of adaptation and survival, these delicately hued wild asses found themselves shot at by 20th century soldiers and other hunters. World War I troops and later, civilians in all-terrain vehicles, chased them at high speeds, killing entire herds of these equines for "sport." With no natural cover and unable to outrun jeeps, entire herds were slaughtered. The last known Syrian Wild Ass was shot in 1927 as it came down for water at the Al Ghams oasis in northern Arabia (Day 1981). The surviving populations of this species, the Asian Wild Ass (*Equus hemionus*), are listed as Endangered by the US Endangered Species Act.

After World War II, Arab sheikhs began hunting Arabian Oryx (*Oryx leucoryx*), Arabian Gazelles (*Gazella arabica*) and Arabian Ostrich (*Struthio camelus syriacus*) in all-terrain vehicles and trucks, mowing them down with repeating rifles, shotguns and even machine guns. These macabre and senseless hunts even involved the use of planes and helicopters for spotting. Sometimes animals were pursued until they dropped dead from exhaustion. In 1955, some 482 cars took part in a hunt during the course of a "royal goodwill tour" in northern Saudi Arabia, and every living animal seen was gunned down (McClung 1976). The Arabian Ostrich formerly ranged from Syria to the Arabian Peninsula, and it became a casualty of these forays. The last wild Ostrich was killed and eaten by Arabs near the Trans-Arab oil pipeline north of Bahrain between 1940 and 1945 (Greenway 1967).

The Arabian Oryx nearly followed the Ostrich into extinction when the last three individuals left in the wild were killed off in 1972 in southern Oman (IUCN 1978). This statuesque white antelope, with long, curved horns that arch over its back, once inhabited a wide range in the Middle East, from Syria and Israel to the Arabian Peninsula (Nowak 1999). It was saved from extinction by actions of the Fauna Preservation Society, headquartered in England, and the IUCN, which had undertaken an expedition in 1962 to capture some of the last wild Arabian Oryx for captive breeding. In eastern Aden, four oryx had been taken into captivity, and this herd was augmented from private game farms and zoos by another eight animals, which were transported to the Phoenix Zoo in Arizona. They adjusted easily to the desert climate of the American Southwest and soon bred in captivity. This herd has grown, and several zoos now breed them. Some of these stately animals have been reintroduced successfully into preserves in Oman and other parts of their original range. They have been studied by field biologists who have found that they reverted to wild behavior, with females in separate herds, and males solitary or in bachelor herds defending territories (Nowak 1999). Eighteen breeding herds occupied 14,121 square kilometers in Oman in two 1988 studies (Nowak 1999). In 1990, more Arabian Oryx were reintroduced into Saudi Arabia. There are now about 500 of these oryx in the wild and an additional 300 in captivity on the Arabian peninsula; 2,000 are held in zoos (Nowak 1999). For many Arab conservationists, the return of the Arabian Oryx has been an important event because this species has been very important to the cultures of the Arabian Peninsula for thousands of years. The reintroduced oryx have been guarded zealously to prevent another tragic disappearance.

Gazelles of dryland and open country were at one time abundant throughout North Africa and the Middle East, able to survive in the hottest and dryest of deserts. People have long hunted them for food, and there is little cover where they can hide. In ancient times, stone corrals were constructed into which gazelles were driven for slaughter, and until the early 20th century, these were still in use (Nowak 1999). Some Arab hunters still use captive and trained falcons to harass gazelles in order to frighten and confuse them so they can then be chased down by dogs (Nowak 1999). Two of these small and dainty ungulates have been hunted to extinction, and others have become very rare throughout the region. The Antelope Specialist Group of the IUCN lists the Saudi Gazelle (*Gazella saudiya*) as extinct in the wild and the Queen of Sheba's Gazelle (*Gazella bilkis*) of Saudi Arabia as extinct, with no captive populations. Until the 1990s, the latter species had been classified as Endangered. But the *2000 IUCN Red List of Threatened Species* reports that this delicate animal, which was considered very common in 1951, has not been seen in decades. A survey in 1992 in its range in mountains near Ta'izz failed to find any of these gazelles.

The *2000 IUCN Red List of Threatened Species* categorizes many other gazelles of the region as Threatened and Endangered. The Arabian Gazelle (*Gazella gazella*), native to the Arabian Peninsula, Israel and Palestine, is classified as Conservation Dependent, a category indicating that without strict protection it would decline to Threatened status. Five subspecies of this gazelle are listed in various categories, the most endangered being the Palestine Mountain Gazelle (*Gazella gazella gazella*) (Conservation Dependent) and the Acacia Gazelle (*Gazella gazella acaciae*)

(Critical) of Israel, and the Muscat Gazelle (*Gazella gazella muscatensis*) (Critical) of Oman. Another threatened gazelle is the Arabian Sand Gazelle (*Gazella subgutturosa marica*) (Vulnerable). These little Mideastern gazelles have been heavily persecuted and hunted. Added to the hunting, which is not well controlled, the Arabian Peninsula and much of Israel and Palestine have been heavily overgrazed by livestock, and the scarce oases are used for agriculture and livestock, leaving little natural vegetation for wildlife.

Reintroduced gazelles in Israel's Golan Heights increased to about 4,000 in the late 1980s, and government officials decided to allow the hunting of 2,000 of them by Arabs, who shot to wound rather than kill so that the animals could be killed ritually through throat slitting. This hunt, filmed by Afikim Productions and Survival Anglia in 1990, was a gruesome sight of crippled and dazed gazelles, stumbling about after the shooting.

The most avidly pursued animal by Arab sheikhs is undoubtedly the Houbara Bustard (*Chlamydotis undulata*). The meat of this large, long-legged bird of scrubby desert and sandy grasslands is considered an aphrodisiac by Arabs, although in fact it is a mild diuretic (Weaver 1992). It has been hunted relentlessly on the Arabian Peninsula, causing many populations to disappear. Arab sheikhs have hunted these birds for centuries using a trained falcon that catches the bird as it flies to escape. The great oil wealth accumulated by sheikhs of Saudi Arabia, Qatar, Bahrain, Kuwait and the United Arab Emirates has allowed them to indulge in this "sport" in a manner befitting the bejeweled and pampered rulers of ancient kingdoms. With these bustards so rare on the Arabian Peninsula, they now hunt them in Pakistan. Traditionally, the sheikhs used camels as transport, but today they drive in fleets of 60 or 70 customized all-terrain vehicles, careening through the desert at speeds up to 80 miles per hour, flattening the landscape, vegetation and small animals under their wheels (Weaver 1992). Armed with high-powered guns to shoot any animal that comes into view, the sheikh occupies an elevated seat that swivels 180 degrees to enable him to spot the Houbara Bustards and their tracks in the sand (Weaver 1992). The ecological damage done by the armies of vehicles that flatten vegetation, scar the landscape, and slaughter every animal they see is so severe that it may result in the local extinctions of many rare and delicate species of the Pakistani desert (Hoyo *et al*. 1996).

Many Houbara Bustards winter in Pakistan, converging from breeding areas in Kazakhstan and other countries in the region. Their breeding range extends to North Africa east across Asia to China. In Pakistan and 23 other countries, including India, Iran and Russia, the Houbara Bustard is totally protected from hunting (Weaver 1992). Yet by means of lavish gifts and payments to high government officials and landowners, wealthy Arabs have received special dispensation to pursue and kill thousands of these birds, which are considered endangered and declining in many parts of their range, especially in North Africa, Bahrain, Jordan, Iran, Iraq and India (Hoyo *et al*. 1996, BI 2000).

These extraordinary birds present a spectacular show with their elaborate courtship, strutting and displaying beautiful white puffs of head and body feathers.* Some hunting, mainly illegal, also occurs in their breeding grounds, which greatly disrupts their courtship, nesting and care of chicks.

*"Red Desert," a film in the series fiRealms of the Russian Bearfl described in the Video section, shows these birds displaying and hunting lizards.

The hunts have been carried on for decades in Pakistan, and Houbara Bustards have declined steadily as a result. As early as 1983, scientists and conservationists at a symposium on bustards convened by the International Council for Bird Preservation (now BirdLife International) unanimously called for a five-year ban on hunting (Weaver 1992). Although Pakistan's President at that time supported the symposium, he ignored the appeal and, the following year, allowed 25 parties from the Saudi Arabian Peninsula to hunt; they killed more than 5,000 Houbara Bustards (AWI 1985). Since that time, hunts have continued in spite of changes in administration in Pakistan, and although Arab hunters realize that these birds are heading toward extinction, they have not decreased their kills or practiced conservation. Moreover, they are now hunting in new areas, close to breeding grounds (BI 2000).

One sheikh, the cousin of the ruler of Dubai, found no Houbaras in the tract where he had arranged to hunt. He then moved his camp into Kirthar National Park, where he illegally killed more than 200 Houbaras in 10 days, along with

protected gazelles and ibex (Weaver 1992). As recently as the 1960s, Houbara Bustards were so numerous in Pakistan that they could be counted "like butterflies in a field," but by the 1990s, they became scarce in many areas, and their populations have experienced sharp downward trends (Weaver 1992). No restrictions are placed on the take of Houbaras by the visiting sheikhs.

Some Pakistani conservationists have fought the illegal arrangements made between the Arabs and government officials, and the Society for Conservation and Protection of the Environment (SCOPE), took the issue to the Sind High Court, which ruled in their favor (Weaver 1992). However, because Pakistani government officials rarely follow such provincial court decisions, the hunt did not end. When asked why the government has done so little to protect its wildlife, a well-known Pakistani environmentalist, Wahajuddin Ahmed Kermani, the retired Inspector General of Forests, replied, "Because we lack the moral fibre and the moral courage" (Weaver 1992).

Protests from conservationists in Europe and elsewhere have had no real effect either. Paul Goriup, the bustard expert at BirdLife International in Cambridge, United Kingdom, believes that populations of Houbara Bustards in Sind and Punjab provinces of Pakistan have become "terribly diminished," and hunting of breeding populations has a disastrous effect (Weaver 1992). Goriup contends that the species must be protected by the United Nations' Bonn Convention on Migratory Species to bring the issue to an international level (Weaver 1992). The Houbara Bustard is listed on Appendix I of CITES, which bans all commercial trade between member nations. Yet each year, 500 or more eggs, chicks and adult Houbaras are smuggled from Pakistan, a CITES member, by sheikhs who use them to train their falcons and for captive-breeding programs of dubious effectiveness. Abrar Mirza, the wildlife conservator for the Province of Sind, confiscates many such shipments, but most provincial wildlife officials merely look the other way, especially after receiving diamond-studded, gold Rolex watches and other such gifts from the Arabs (Weaver 1992). The confiscation of so many Appendix I birds in the United States would result in severe penalties, including possible jail sentences, but the effectiveness of CITES depends on the legislation each member country enacts to enforce it and the zeal with which these laws are enforced.

Sheikhs from the United Arab Emirates (UAE) were not so well-received in Turkmenistan in 1995 when they applied to the Ministry of Foreign Affairs to hunt Houbara Bustards. This Ministry forwarded the request to the Ministry of Nature Use which, quite unexpectedly, turned it down because the birds would be breeding (Zatoka 1995). Certain that they would be able to overcome this opposition, the sheikhs arrived in Turkmenistan ready to hunt without official approval, bringing their falcons (Zakota 1995). To their amazement, they were issued an official complaint by the Director of the Department for Animal Conservation and fined $40,000 (Zakota 1995). The sheikhs then turned to Turkmenistan's President Niyaziv, confident that they would be able to overturn the decisions of the wildlife department; instead, he backed up the decision of the Ministry of Nature Use, stating that it had jurisdiction in this issue (Zakota 1995). This was an extremely important precedent and a fine example of a country according its wildlife the respect and protection it deserves. Turkmenistan has a record of combating poaching and conducting environmental research and conservation programs (Zakota 1995).

One sheikh has renounced hunting and fostered environmental programs. Sheikh Zayed of the United Arab Emirates, while hunting gazelles with a rifle, realized that this amounted to "an outright attack on animals" and a cause for their possible extinction (Morgan 1998). He then began a program of setting tracts of land aside for wildlife and setting up breeding herds of endangered oryx, gazelles and other desert ungulates on an island off the coast (Morgan 1998). Other UAE sheikhs have obtained special favors when hunting on the African continent. The government of Tanzania granted exclusive hunting rights in one of the country's most important wildlife areas to a high-ranking official from UAE (Alexander 1993). The agreement was reached in secret with the Deputy Minister of Defense of that country, and he apparently has been allowed to hunt endangered species, such as Cheetah, with automatic weapons (Alexander 1993). The influence of wealthy Arabs in bending wildlife laws has reached to many corners of the world. One of their prime targets is North America for its beautiful Gyrfalcons (*Falco rusticolus*), listed on CITES Appendix I, one of the most coveted of all birds of prey for falconry. Their attempts at bribery, often successful, to obtain these protected birds from Canada resulted in the listing of this species on CITES to prevent any further commercialization of these birds, which was causing declines in their wild populations.

Trophy and Sport Hunting: Page 3
The vast Sahara has been the scene of similar hunts. Scimitar-horned Oryx (*Oryx dammah*) originally had a wide range in arid grasslands from Morocco and Senegal east to Egypt and the Sudan. In historic times, herds of 100 animals were commonly seen, and during wet season migrations, they traveled in groups of 1,000 animals or more. Their white and brown coloration allowed them to blend into the desert, and they were admired for their extremely long, back-curving horns. Their populations and range gradually shrank with hunting, overgrazing and agricultural encroachment on natural grasslands; the species disappeared from Egypt and Senegal in the 1850s. In the 1970s there were still an estimated 6,000 of these spectacular animals in the southern Sahara (Nowak 1999). The Haddad tribe of northern Chad centered their way of life around hunting these oryx, driving them into nets and killing them for their meat (Simon 1995).

Although traditional hunting made inroads into Scimitar-horned Oryx populations, the use of four-wheel-drive vehicles and modern firearms by prospectors and military personnel within the past 30 years drove the species to near extinction (Simon 1995). Groups of wealthy Middle Eastern hunters arrived with all-terrain vehicles and automatic rifles, eliminating these animals from most of their range. Chad's Ouadi Rime-Ouadi Achim Faunal Reserve became one of their only refuges by the 1970s, but the outbreak of war between that government's forces and Libyan-backed rebels in 1978 brought about an unregulated slaughter of the last population of Scimitar-horned Oryx within the reserve, reducing them to only a few hundred animals (Simon 1995). In an attempt to reintroduce these majestic antelope to their original range, 41 were captured in western Chad in 1966 and placed in captivity (Simon 1995). Some 500 of these oryx are part of the American Zoo Association's Species Survival Plan, and another 700 are in other zoos; an unknown number are in ranched herds, especially in Texas (Nowak 1999). A small number of Scimitar-horned Oryx were released into a national park in Tunisia in 1991 (Simon 1995), and others may be released in Niger (Nowak 1999). The IUCN listed this species as Critical in 1996, Extinct in Algeria, Egypt, Libya, Mauritania, Senegal, and Western Sahara, and Probably Extinct in Burkina Faso, Chad, Mali, Niger, and Sudan. The *2000 IUCN Red List of Threatened Species* listed the Scimitar-horned Oryx as Extinct in the wild.

The Addax (*Addax nasomaculatus*), a desert antelope which once ranged from Western Sahara and Mauritania to Egypt and Sudan, is now nearly extinct in the wild as a result of heavy hunting combined with loss of its grassland and shrubland habitat to agriculture and competition with livestock. Perfectly adapted to life in the desert, Addax are able to spend their lives without drinking water, deriving moisture from plants on which they feed (Nowak 1999). Instead of the long, arched horns of the Scimitar-horned Oryx, the Addax has horns that grow outward, then bend inward and upward. A stocky antelope that is not able to run quickly enough to flee men on horses, it has been easy prey for hunters and feral dogs. In recent years, remnant populations literally have been run to death by tourists in four-wheel-drive vehicles who pursue them until the animals fall dead in the sand (Nowak 1999). A herd in northeastern Niger was reduced to 50 to 200 animals when, according to some reports, they were wiped out by hunting. Fewer than 200 remained in north-central Chad, and another 50 along the border of Mali and eastern Mauritania in 1994 (Nowak 1999). The *1996 IUCN Red List of Threatened Animals* listed the Addax as Endangered, Extinct in Algeria, Egypt, Libya, and probably Sudan. The *2000 IUCN Red List of Threatened Species* upgraded its status to Critical. A small reintroduced population survives in Tunisia, but the wild population is at risk of disappearing altogether. More than 400 animals are in captivity, including a herd in a large dryland safari park in Texas called Fossil Rim.

Other Saharan animals have been ruthlessly pursued. Pelzeln's Gazelle (*Gazella dorcas pelzelni*) have been pushed to Vulnerable status by hunting. They are listed on the US Endangered Species Act. The Slender-horned Gazelle (*Gazella leptoceros*), native to North Africa, is now endangered throughout its range, according to the *2000 IUCN Red List of Threatened Species*. The hunting of these desert animals by men in all-terrain vehicles, some armed with

machine guns, reached such heights in the 1970s that they nearly became extinct, and their status has not improved in the intervening years. The endangered Dama Gazelle (*Gazella dama*), also a heavily hunted species, is extinct in Algeria, Libya, Mauritania, Morocco and Western Sahara; it has been reintroduced into Senegal, and populations are now confined to Chad, Mali, Niger and Sudan (Baillie and Groombridge 1996). Cuvier's Gazelle (*Gazella cuvieri*), another North African species, is also extinct in the Western Sahara and survives in endangered populations in Algeria, Morocco and Tunisia, according to the IUCN. In some cases, antelope and gazelles have been pursued by hunters in helicopters who shoot at them with rockets, a method also used to kill African Elephants in Chad, where the last Greater Kudus (*Tragelaphus strepsiceros*) were destroyed in 1976 (Anon. 1977).

Trophy and Sport Hunting: Page 4

Poachers have caused the extinction in Somalia of the endangered Hunter's Hartebeest or Hirola (*Damaliscus hunteri*), which now survives only in a restricted portion of scrubby desert of south-eastern Kenya. Looking somewhat like an Impala, this delicate, dryland antelope can live for weeks on very little water. This species is considered an evolutionary relic, having lived on earth for 15 million years, and is a progenitor of other hartebeests and the Topi; fossil evidence indicates that the Hirola's range once extended to South Africa (McKinley 1996). Kenyan populations totaled 14,000 in 1976, living along the Tana River and in the arid Garissa region to the east (McKinley 1996). In the 1980s, poachers killed off the region's African Elephants, who had kept the land clear of thorn bushes for grazers, such as the Hirola (McKinley 1996). A rinderpest epidemic brought in by cattle herders wiped out half the region's antelope between 1983 and 1985.

In the early 1990s, Somali refugees and troops fleeing from civil war in Somalia crossed into Kenya and began slaughtering the Hirola (McKinley 1996). By 1993, only 2,000 Hirola survived, and with unregulated hunting, a 1995 census found a total of 306 animals scattered in small groups over 45,000 square miles (McKinley 1996). Rangers from the Kenya Wildlife Service decided to capture and move as many as possible of the remaining animals to Tsavo National Park, where they could be guarded against illegal hunting. One hundred animals were moved to the park in 1995, and a year later, about 57 survived. In 1996, more were chased by helicopter into nets, sedated, blindfolded, and then taken by truck to a small plane which airlifted them to Tsavo. The habitat in Tsavo is lusher and greener than their native desert shrub, and the Hirola may not thrive there. Only time will tell. The *2000 IUCN Red List of Threatened Species* lists the species as Critical.

Trophy and Sport Hunting: Page 5

In South Africa, the Quagga (*Equus quagga*), a zebra-like equine, became extinct from hunting. Some zoologists consider these animals to have been a race of Burchell's Zebra (*Equus burchelli*), but others classify them as a full species. They had black, vertical stripes on the head and neck, while their back and haunches were uniform grayish or faintly striped. Native to the Cape Colony grassy plains, their limited and open habitat made them vulnerable to the Boer settlers, who killed them by the thousands (Day 1981). Many were tamed and used to guard domestic livestock at night because they gave loud alarm calls upon seeing predators (Day 1981). Some were even shipped to London and used as harness animals. The Boers used their skins for sacks and other practical purposes. By the 1850s, it had nearly disappeared from the Orange River area from relentless hunting (Nowak 1999). The last wild Quagga was killed in 1878, and in 1883, the last captive Quagga died in the Amsterdam Zoo (Day 1981). Photographs (Nowak 1999) and specimen skins exist with DNA that has been compared with living zebras. There has been talk of restoring a Quagga-like animal through selective breeding with Plains Zebras.

Many other South African species were reduced to endangered status or eliminated from the country altogether by

Boer hunting and their policy of clearing the land for livestock and agriculture. Although many parks have been set aside, wildlife as a whole has been crowded out of its natural environments in South Africa. Elephants became restricted to an area in the northeast that later became Kruger National Park, and only recently have they been reintroduced into a few parks elsewhere. Zebras have become extremely rare, with several races critically endangered (see Grasslands, Shrublands and Deserts chapter).

The high-altitude Simien Mountains National Park (6,234 to 14,535 feet) has many endangered endemics. A Survival Anglia film, fiEdge of the Abyss,fl records many of these species, including the Walia Ibex (*Capra walie*), a mountain goat found only in Ethiopia. It has a population of about 300 in the park and stays above 10,000 feet, browsing in the giant heath. These goats were common until the 1930s when hunting decimated their numbers. They also have lost habitat to agriculture and livestock. By the 1960s, there were only 200 Walia Ibex in the park, and although they have recovered somewhat, they still are poached for their magnificent, massive curved horns, hides and meat. Poachers enter the park and place nooses on the narrow mountain trails they must use to travel from one part of the park to another.

Trophy and Sport Hunting: Page 6

Local villagers in Kankani, India, have turned the tables on hunters of the threatened Blackbuck. This town, located in the Rajasthan desert of western India, has a history of preserving nature, refusing to allow an 18th century maharajah to cut their trees by encircling them and vowing to be killed rather than let the maharajah's men cut the trees (Bearak 1998). When hunters in all-terrain vehicles awoke the villagers with gunshots in October 1998, the villagers chased them off and got the license plate number of the driver (Bearak 1998). Some bucks of these striking black-and-white antelope had already been killed. "These animals are considered sacred to us, and we consider their lives more important than even our own," said a village elder of the Bishnoi people (Bearak 1998). The license turned out to belong to a famous movie actor, Salman Khan, star of many high-action, violent films (Bearak 1998). The story was told in many newspapers, and public opinion turned against Khan, who came to symbolize the callous rich who take pleasure in poaching endangered species like the Bengal Tiger and Sarus Crane (Bearak 1998). The week before, he had hunted Chinkara (*Gazella bennetti*), a Conservation Dependent species, according to the IUCN. On October 12, 1998, the actor was arrested, but he was unlikely to go to jail, as a result of his fame and wealth. The village elder said: "Between us and the animals there is complete trust. Our teachings tell us that we must serve as protectors and nurturers of all living things" (Bearak 1998).

Trophy Hunting Clubs

The US-based Boone and Crockett Club keeps records of trophy animals for North American mammals, and Safari Club International (SCI) maintains international records and promotes trophy hunting of animals worldwide. US state wildlife departments tend to favor sport hunting, and many earn large license fees from the trophy hunting of Bighorn Sheep, Elk, Grizzly Bear, Gray Wolf and other mammals. Trophy hunters in North America vie with one another to receive the "Outstanding Hunting Achievement" trophies awarded each year, primarily for having killed one each of 29 big game animals, some of which are on the US Endangered Species Act list (Williams 1991). Trophy hunting organizations have "master measurers" who check the size of horn, antlers and other measurements of animals killed for record books. SCI gives awards to those who kill at least 13 of the world's 22 species of "available" wild sheep (Williams 1991).

Rifles that fire at distant targets with telescopic lenses, elaborate blinds, heat sensors, and other technological gadgetry have weighted the contest so much in favor of the hunter that animals have become mere targets, with virtually no

hope of escape. Hunters using these high-powered rifles revel in recounting their experiences in hunting publications, whose writing fees help pay for their trips. One hunter's 1997 account recorded his delight in seeing the look of total shock of an Alaskan Dall Sheep (*Ovis dalli*) as it died from a shot he fired without it even having been aware of his presence. The hunter had selected the largest male with the most massive horns, which curved into a complete circle. Such hunting can so terrify animals that they run off cliff edges or flee into places from which they cannot escape.

Bernard Grzimek's *Animal Life Encyclopedia* recounts a hunt in the Canadian Rockies of Mountain Goats (*Oreamnos americanus*), in which five animals were pursued by hunters. They fled in terror, becoming entrapped on the ledge of an overhanging cliff, unable to move in any direction (Grzimek 1968). The hunters returned to their camp where they could see the goats as they stood on the ledge. The next day, the goats were still standing on the spot, but during the following days, they gradually became weakened and fell, one after another, usually at night, to their deaths. The last of the animals fell after 10 days (Grzimek 1968).

One US trophy hunter, Donald G. Cox, has hunted in 68 countries, taken 208 different species, including 125 from Africa, and has killed 23 of the world's spiral-horned antelope (Williams 1991). Trophy hunters try to kill as large a number of species as possible and as many trophy-sized animals as they can shoot. Many trophy hunting organizations claim to have made major contributions to conservation, but documentation is often lacking. SCI has published brochures in which it claims that it purchased habitat for endangered species. As it turned out, on investigation these claims were unsubstantiated (Williams 1991). Endangered animals are often the prime targets of trophy hunters. Safari Club International makes regular applications to the Fish and Wildlife Service to import trophies of endangered species. A 1978 application was particularly stunning because it requested permits to import 1,120 animals of a wide range of species, including Orangutans, various species of monkeys and crocodiles, and 39 species of endangered deer, gazelles, wild sheep, antelope, rhinoceroses, and 12 species of endangered wild cats. After a public outcry, the Safari Club withdrew its application, but in 1982, it was successful in its long battle to allow importation of Leopard trophies.

Trophy hunting clubs have made financial contributions to officials in foreign countries to receive permission to hunt endangered species and have convinced wildlife officials in countries such as Pakistan, Zimbabwe and Botswana that trophy hunting fees pay for conservation and should form the basis of wildlife management programs. The profits from trophy hunting pale beside those of ecotourism, however (see Trophy Hunting vs. Ecotourism Revenues section below).

Illegalities

Trophy hunting organizations have lobbied the US Department of the Interior for decades to weaken law enforcement "overzealousness" and have, on occasion, been successful. The Law Enforcement Division of the US Fish and Wildlife Service has tended to be strict in prosecuting trophy hunters for violations. In one case that inflamed Safari Club International members, it subpoenaed pages of the SCI™s *Record Book*, which listed many endangered species, to determine the details of the killing of various protected animals. To shield its members from prosecution, SCI returned information to their members on trophy animals killed at a time when they could not have been imported legally, and deleted this information in the SCI database to avoid further investigations (Williams 1991).

In another case, however, SCI influence won favors from the Department of the Interior. A highly placed official with the Fish and Wildlife Service, Richard Mitchell of the Office of Scientific Authority, allegedly accepted money from SCI in exchange for facilitating permits to get endangered species trophies into the United States (Williams 1991). Correspondence between Mitchell and SCI members included advice on registering as an institution with CITES on behalf of the trophy museum that the organization maintains in Arizona. Mitchell suggested that he would arrange to register several institutions in China and Pakistan in order to trade endangered species "specimens" with them

(Williams 1991). Another official, Assistant Secretary of the Interior G. Ray Arnett, who later co-founded a lobbying organization for trophy hunters, helped a fellow hunter caught importing an endangered species in the early 1980s by ordering agents to return the trophies to the smuggler, Thornton Snider (Williams 1991). Rick Parsons, who founded the Permit Office within the Fish and Wildlife Service, which gave permits to trophy hunters and others wishing to import endangered species, later became the Washington Counsel to Safari Club International, using his government experience to facilitate the permit process for trophy hunters and also lobbying at CITES Conferences on behalf of trophy hunters.

Ted Williams, in a 1991 article in *Audubon* magazine, tells of an appraiser for the Safari Club, R. Bruce Duncan, who arranged for many members of the club to mislabel the trophy animals they killed in foreign countries in order to import them into the United States without prosecution under the US Endangered Species Act (Williams 1991). One Club member imported a Jaguar (*Panthera onca*) pelt from Venezuela, labeled as a "goat hide" under Duncan's advice, and valued at $60; Duncan had appraised it at $11,000 (Williams 1991). Another SCI trophy hunter, Andrew Samuels, was the winner of the 1990 "Weatherby Award" given by a firearms company to the hunter who kills the greatest number of average, as well as record-sized, game animals throughout the entire world and whose character and sportsmanship are "beyond reproach" (Williams 1991). An undercover Fish and Wildlife Service Law Enforcement investigation revealed that Samuels had confided having illegally killed a Bighorn Sheep and numerous endangered foreign animals and smuggled them into the United States by falsifying shipping documents (Williams 1991). These included Jaguars, endangered wild Markhor goats (*Capra falconeri*), rare African antelope, Jentinck Duikers (*Cephalophus jentinki*), Ocelot (*Leopardus pardalis*), and a wild Asian sheep, the Punjab Urial (*Ovis orientalis punjabiensis*) (Williams 1991). Samuels paid $100,000 in fines, spent 30 days in jail, and performed 800 hours of community service; he also forfeited his world hunting rights for three years (Williams 1991).

In another case, John Funderburg, the curator of the North Carolina Museum of Natural Sciences in Raleigh, acquired more than 1,800 animals as "specimens," many of them endangered, that had been killed by trophy-hunting acquaintances (Williams 1991). They were donated to the museum as tax-exempt, but had little scientific value because they lacked information about the location or date where they were killed, and many were merely heads mounted for hanging on walls. Scientific specimens consist of the skins of entire animals, or their skeletons. A number of the donated trophy animals mysteriously disappeared from the collection, apparently returned to the donors (Williams 1991). In exchange for financial "donations" to the museum, the trophy hunters received the title of "associate curator," with certificates that allowed them to misrepresent themselves to foreign wildlife officials in order to obtain permits to kill protected animals (Williams 1991). Funderburg urged the hunters to send him the trophy animals via private taxidermists to avoid the attention of authorities, but a five-year undercover investigation by Fish and Wildlife Service Law Enforcement revealed all the details of this scam (Williams 1991).

The highly respected Smithsonian Institution has not been invulnerable to such unprincipled arrangements. A wealthy real estate developer, Kenneth Behring, pledged $20 million to the Institution's National Museum of Natural History in 1999, the largest donation in the 151-year history of the museum (Golden 1999). Behring, a trophy hunter and past president of Safari Club International, donated the remains of four endangered Central Asian wild sheep, including the Kara-Tau Argali (*Ovis ammon nigrimontana*) of Kazakhstan, listed as Critical by the *2000 IUCN Red List of Threatened Species*, to the museum. This animal cannot be imported legally because it is listed on the US Endangered Species Act, but on behalf of Behring, the Smithsonian petitioned the Department of the Interior to waive the ban in order to have the trophy shipped into their collection (Golden 1999). This action set an unfortunate precedent for this august institution. Behring is also under investigation for illegally killing three bull elephants in Mozambique, in spite of a $20,000 "donation" he made to a local hospital in the province (Golden 1999). The head of Mozambique's wildlife department, Arlito Cuco, said that the hunt was illegal, "Because according to the law in Mozambique, you cannot hunt for sport" (Golden 1999).

Hunting magazines often glorify the pursuit of endangered species. An article in *Sports Afield* encouraged the hunting in Mexico of Jaguar, Ocelot, and "crested Guan," or Horned Guan (*Oreophasis derbianus*), a highly endangered pheasant-like bird (Anon. 1981). It noted parenthetically, "However, United States laws prohibit bringing in skins"

(Anon. 1981).

Effects of Trophy Hunting on Animals

Among the most coveted of the "Grand Slam," or the most prestigious trophy animals, is the Brown Bear. The Kodiak Bear (*Ursus arctos middendorffi*) of Alaska represents a major trophy for hunters who come from all around the world to kill large males. This bear exceeds other subspecies in size, weight and skull size. These bears have been isolated since the end of the last Ice Age, and the abundant food supply of salmon runs, berry bushes and other edible plants in their habitat has produced this giant bear (Chadwick 1990). Trophy hunters pay $20,000 or more to private hunting guides for the privilege of shooting these bears. A recent study has revealed a potentially disastrous effect on the species of this trophy hunting. According to *The Kingdom. Wildlife in North America*, by the respected author and National Geographic Society correspondent Douglas Chadwick, "Continued harvesting of the biggest animals by trophy hunters has caused a decline in the average size of Kodiak Bears over the years" (Chadwick 1990). Thus, this record-size animal is gradually becoming smaller and smaller as a result of trophy hunting.

The pressure of hunters on some populations of Alaskan bears is so intense that it has altered the behavior of males, preventing their normal feeding on salmon runs. On Admiralty Island in southeastern Alaska, part of the Tongass National Forest, tourists watch female Brown Bears fishing with their cubs, but rarely see males because they have become so wary of people after years of being hunted; even females without cubs can be hunted on Admiralty Island (Crittenden 1997). The rich salmon rivers on this island are among the world's most productive, and since clearcutting of timber has been banned, salmon thrive in the clear water. Salmon is an important portion of the diet of male bears, yielding a great deal of protein and helping to fatten them for the winter. By frightening the male bears from the salmon rivers, which they have fished for thousands of years, humans may be affecting the health, survivability and size of these bears. Each year more than 40 Brown Bears are killed on Admiralty, and hunters are lobbying to reopen hunting in areas such as Pack Creek that are now closed to protect the fishing spots (Hanson 1998). This island deserves to be declared a National Park, which would protect these bears from hunting.

Another effect of hunting male bears has recently been documented by Swedish and Norwegian biologists, who found that in areas where resident adult male Brown Bears had been killed to thin the population, bear cubs suffered very high mortality for several years until dominant males reoccupied the territory (O'Neil 1997). Male bears, who have traditionally been considered threats to cubs, may be a danger only to cubs they have not fathered. Thus, the killing of bears by sport and trophy hunters may also result in the deaths of hundreds of bear cubs.

Russian Brown Bears have been hunted heavily in recent years. When a prominent government official, Prime Minister Viktor S. Chernomyrdin, announced early in 1997 that he wanted to trophy hunt a Brown Bear, local guides bulldozed a path to the den of a sleeping female bear (Filipov 1997). Tractors plowed a campsite for a large tent with mobile kitchen and cafeteria, and the Prime Minister flew in by helicopter (Filipov 1997). Chernomyrdin, accompanied by 12 hunters, rode a skimobile to the site, roused the bear and killed her two cubs and the mother. This incident received much adverse publicity in Russia. When the Prime Minister was criticized for his lack of sportsmanship, he replied: "What's wrong with that? Hunting of bears is not banned; it's a normal thing . . . I'd like to watch those who are writing about this meet those bears eye to eye to see their reaction" (Filipov 1997).

In Greece and Turkey, where Brown Bears are avidly hunted in spite of their dwindling numbers, cubs orphaned when their mothers are killed are often sold to zoos or to gypsies who treat them abusively. This trade is illegal in both countries, and the World Society for the Protection of Animals (WSPA) has saved many of these gypsy bears, who are dragged through the streets with nose rings and made to perform tricks. WSPA has placed several hundred of these abused bears in large wooded compounds, unfettered for the first time in their lives. Some had to be euthanized because of severe infections that had caused them extreme pain and serious physical disabilities that they had endured

for many years without veterinary treatment. The majority suffered the effects of malnutrition.

The animals trophy hunters seek--the finest specimens--are the very ones that should be left in the wild to maintain the species. Killing the largest specimens of a species, subspecies or population is likely to diminish it in size and survivability. This would seem elementary, but trophy hunters, state game departments, many in the Fish and Wildlife Service, the World Wildlife Fund and other organizations in favor of trophy hunting do not discuss or acknowledge this fact. Claims are made on behalf of trophy hunters that only old and non-breeding adults are killed, but this contention has been proven wrong in case after case. Brown and Grizzly Bears continue to breed until an advanced age. Other trophy animals have also been shown to be at their prime when shot.

Lions are a prime target of trophy hunters, who select the largest male specimens, especially those with enormous manes. Two filmmakers, Derek and Beverly Joubert, in producing their dramatic series, fiLions of Darknessfl for the National Geographic Society, followed three exceptionally large males for a long period. These magnificent Lions spent most of their lives in a national park in Botswana, but made the fatal mistake of leaving the park and entering a wildlife management area where trophy hunting was allowed. All were shot within a short time at the prime of their lives by trophy hunters.

Trophy hunting took a tragic and highly controversial turn when the government of Tanzania sold trophy hunting rights for African Elephants at more than $4,000 per animal in the early 1990s. The *2000 IUCN Red List of Threatened Species* classifies this species as Endangered. The government claimed that the largest animals, which for trophy hunters were the most desirable, were not active breeding males, but past the breeding age and, therefore, "excess." Tanzania issued 50 permits a year for trophy-hunted elephants (Brody 1994). At least four very tame bull elephants that had been studied for decades in Amboseli National Park in southern Kenya by biologist Cynthia Moss, author of two classic books, *Echo of the Elephants* and *Elephant Memories*, wandered into Tanzania in 1994, where they were shot at point-blank range by trophy hunters (Moss 1995). The hunters had received CITES permits from the Tanzanian government to export the tusks as hunting trophies (Moss 1995). Northern Hunting Enterprises, which organized the Tanzanian elephant hunt, is run by Rick Trappe, a German Tanzanian; the hunters were two Germans and an American (Brody 1994). One of the bulls killed, called "R.B.G.," was 47 years old at the time of his death, based on aging of the jaw--not old in elephant years--and so habituated to vehicles that he could be easily approached to within a few feet (Moss 1995). Cynthia Moss said she was "devastated" by the loss of the animals, who had come to trust researchers, tourists and rangers. She stated: "The message they got from us was, 'It's OK, we're not going to hurt you, you can trust us.' Then one day they walk two kilometers into Tanzania, where they'd been going for most of their lives, and they're blown away . . . I feel as if was lying to them" (Brody 1994). A spokesperson for the African Wildlife Foundation said: "The ethics of shooting these virtually tame animals is appalling. You can't call this a hunt of any kind" (Brody 1994). Had R.B.G. not been shot, he would have lived another 18 years, according to Moss (Brody 1994).

These were among a relatively small number of large, old bull elephants left in East Africa, protected through the ivory slaughters of the 1980s by the presence of field researchers and tourists. The assertion that they were non-breeding males was refuted by Moss, who had documented that they were active breeders and, in fact, among the top breeding bulls in the Amboseli population (Brody 1994). This disputes the view that they were not contributing to the gene pool and were "excess," worthy only of being used as targets. After protests and adverse publicity on television programs that reached the United States and elsewhere, Tanzania announced a ban on trophy hunting of elephants near the Tanzania/Kenya border on December 13, 1994, and initiated an investigation into the granting of permits to shoot the Amboseli bull elephants.

In spite of the supposed ban, two other big bulls of the Amboseli, Sleepy and Beach Ball, both in their 50s, were killed in Tanzania by trophy hunters in 1996. Both had fathered calves that were born after their deaths. The largest bull in Cynthia Moss's study area is the gigantic Dionysus who, at 55 years old, weighs some 6,000 kilograms, with 100-pound tusks. He probably owes his life to Cynthia Moss and other researchers who have deterred poachers, but should he wander into Tanzania, he may be killed. The females in the family, headed by Echo, an old matriarch, prefer

Dionysus above all the males, and he has fathered many calves. In a BBC film about her work in Africa, fiEcho of the Elephants. The Next Generationfl (PBS--WNET 1996), Moss pledged that she would spend the rest of her life watching over these elephants.

Another effect of trophy hunting of elephants and many other animals is an imbalance that is created between the sexes. The largest elephant bulls of both the African and Asian species have been killed off, leaving far too few males for the number of adult females. In some parts of Africa where the ivory massacres were the most intense during the 1970s and 1980s, virtually no adult males remained prior to the 1989 CITES ban on ivory. In Asia, adult male Asian Elephants (*Elephas maximus*), also listed as an Endangered species by IUCN, have become extremely rare because they were killed by ivory poachers. Females do not have tusks, and most have been spared by ivory hunters. In parts of Asia, males without tusks, a recessive trait, have come to dominate some populations, since they are not valuable for their ivory. This is altering the traits of the species.

After the largest bull African Elephants were killed off, trophy and ivory hunters turned to the older females, who have large tusks. They are essential in maintaining and leading family groups, providing experience, protection and guidance (Moss 1995). These older females, or matriarchs, have accumulated survival lore over many decades, acquired from previous matriarchs and their long life experiences. They also know the location of scarce water holes in the dry season, where to find minerals in clay they need for their nutrition, what plants are poisonous and other bits of survival lore that can mean the difference between life and death of herd members. Yet these matriarchs also were killed in the 1980s, leaving young, traumatized teen-aged females, who wandered in disarray, without the knowledge or authority of the older females. Females as young as 10 years old found themselves matriarchs of bands of orphan calves, many just weaned. Without direction, they often blundered, placing the calves at risk.

Scientists studying elephants over the past 30 years have documented hundreds of cases of trauma and apparent mourning when family members were killed. The elephants that suffer the most are the young who see their mothers and relatives butchered in front of them. Researchers in the 1990s have noted that many of these young elephants fail to develop normally and are extremely shy, unable to find food and cope with predators as effectively as adults. Some young males, who were calves when they watched as their families were slaughtered by poachers or in culls in South Africa, were released in national parks where they later became unruly and destructive to property and to other animals. Only when older elephants were released to lead and discipline them did they calm down and assume the peaceful personality that characterizes the species.

Zimbabwe, Botswana and Namibia submitted proposals in 1997 to the CITES Conference that the African Elephant's population in their countries be down listed from CITES Appendix I to Appendix II to allow export of trophy-killed elephants. Zimbabwe requested commercial trade in trophies, and Namibia, non-commercial trade. This proposal was amended to read "for non-commercial purposes" and adopted by the CITES members at the 1997 Conference. This is a step in the wrong direction, as hunters will arrive in these countries from around the world to kill the largest, prime elephants as trophies. Shooting elephants in open country where they have no cover is hardly sport, yet the hunting companies tout their massacre as a feat of bravery. Killing them as they come to drink at the few water holes that remain in the dry season in southern Africa is also unsportsmanlike. Matupula Hunters of Texas calls such hunting "exciting and rewarding." Their brochure states, "With the country dry and surface water limited, the elephant bulls can be tracked going to and from water, or in amongst the woodlands and forest where they feed and lay up" (Scully 1997).

Trophy Hunting vs. Ecotourism Revenues

The irony of the slaughter of elephants and other large mammals for trophies is that the funds accrued from trophy hunting or ivory are miniscule in comparison to the value of these animals as ecotourist drawing cards. In Kenya, a

1989 analysis on the viewing value of elephants found that between $25 and $30 million per year was earned in tourist dollars from people attracted to the elephants alone (Brody 1994). A new project provides a local Maasai tribe with about $23,000 a year from tour operators who camp there primarily to show visitors the big bull elephants that are now so rare in East Africa (Brody 1994). During the long life of an African Elephant, it may produce tourist revenue worth $1 million, distributed to a wide range of recipients, from airlines to travel companies, and to local economies (Currey and Moore 1994). By contrast, a trophy-hunted elephant brings a one-time fee of $4,000 to $20,000. Estimates for African Lions are similar. A fully maned male Lion, according to Lee Durrell (1986) in *State of the Ark*, is worth $500,000 as a tourist attraction, whereas a Lion shot for sport or trophy is worth between $3,500 and $8,500, and its skin about $1,000.

Ecotourism has shown an astronomic rise within the past decade, with magazines, books and films aimed at the ecotourist and soaring revenues accruing to countries that protect their natural heritage. Most tourists prefer to come to a country where the animals are tame and where senseless killing is not carried out. Countries that allow hunting of the largest specimens of their wildlife, whether elephants or Leopards, are likely to suffer loss of tourist revenue because they have fewer larger animals and the hunted species often become either shy, hiding from tourists, or belligerent, charging them. A recent article in *Africa. Environment and Wildlife*, a magazine affiliated with World Wildlife Fund South Africa, gave advice to tourists coming to Okavango. Daryl and Sharna Balfour (1998) recommended that tourists avoid coming during hunting season, which runs from early April to mid-September, because game is "scarce in this areas, skittish and almost impossible to approach." They further noted that the sound of gunfire and the sight of carcass-laden vehicles can be disconcerting (Balfour and Balfour 1998). Wildlife can remain shy throughout the year, especially sensitive, gun-shy animals like elephants, and even beyond the suffering caused to the animals, this trophy hunting potentially deprives the country of far greater revenues that tourists could contribute. Several tourists have been killed recently by charging African Elephants in areas where the animals had been trophy hunted.

Tourists coming to South Africa have increased in number in recent years, producing revenues totaling $6 billion in 1995; a large percentage of this total derives from tourists coming to see scenery and wildlife. By contrast only $2 million in trophy hunting fees for rhinos, and a few million dollars more for other animals, were earned in that year, according to the Natal Parks Board (Hughes and Brooks 1996).

Botswana earns $100 million per year from tourism and only a tiny fraction from trophy hunting, yet the government actively promotes the latter activity and has failed to give national park status to its crowning jewel, the Okavango Delta. Portions of this superb wildlife area have been designated as game reserves which allow hunting, but most remains unprotected (Balfour and Balfour 1998). By contrast, Kenya has designated vast areas as national parks and has encouraged ecotourism for decades, with the result that the government earned $500 million in 1996, up from $452 million in 1995. A new organization, Okavango Peoples' Wildlife Trust, in Botswana, is pressing for a complete ban on trophy hunting in the immense Okavango Delta wetland (Jackman 1997). As a result of livestock fencing in the area, African Buffalo are declining 18 percent a year, and Lion, zebra, Sable Antelope and waterbucks are also becoming scarce (Jackman 1997). This organization has proposed that all hunting, except for subsistence or problem animals, be banned and that the Delta be promoted as an ecotourism center, with low-impact camps for luxury visitors (Jackman 1997). New fencing has blocked about one-fourth of the Okavango to wildlife, who migrate to this oasis from surrounding desert areas as a vital refuge for many months during the year. These fences also have blocked wildlife migrations between Namibia and Angola, a disastrous event for many thousands of animals (Jackman 1997). This region has enormous potential for ecotourism that would far outweigh the revenues from cattle ranching or trophy hunting.

In general, funds from trophy hunting end up in government coffers and in the pockets of a few tour operators; the people of a country receive little of the revenues. By contrast, ecotourism funds are spread throughout the local economies, with hotels, taxis, buses, restaurants, souvenir shops and others benefiting from the greater number of tourists than hunters. In fact, the number of trophy hunters is miniscule in comparison to the number of ecotourists. In most countries, hunters amount to a few hundred or thousand, versus hundreds of thousands--or even millions--of

tourists. In some countries, a portion of trophy fees and the meat from slaughtered animals are shared with local villagers, but if they were given the same share of tourist money, it could be very profitable. This trend of sharing tourist revenues or park fees with local people is making an enormous difference in the lives of people around the world.

Meat Hunting

Three Asian wild cattle are endangered from hunting, and one of these is on the verge of extinction. The Kouprey (*Bos sauveli*), discovered in 1937, is classified as Critical by the *2000 IUCN Red List of Threatened Species*. Native to open lowland forests of Southeast Asia in Cambodia, Laos, Thailand and Vietnam, it is the size of a steer. Adult males weigh up to 1,980 pounds and stand 6 feet tall at the shoulder (Nowak 1999). Originally, the Kouprey's habitat consisted of low, rolling hills interrupted by patches of forest; it grazed in herds of up to 20 animals, covering some 15 kilometers a day in the open areas and entering the forest for shelter from the sun and refuge from predators (Nowak 1999).

Page 1 (Asia)

Page 3 (Markets)

Meat Hunting: Page 1

Today, much of the Kouprey's habitat has become a battleground for bands of guerrillas who have planted land mines throughout the region and hunt and snare wildlife for food. After the Vietnam War and the Khmer Rouge occupation of Cambodia, Kouprey were only seen rarely (Stewart-Cox 1995). A 1986 survey found fragmented, small populations remaining in most of its range (Nowak 1999). A few Kouprey were seen in the 1980s trying to migrate through the steep escarpment separating Cambodia and northeast Thailand, but they apparently died in booby-traps set for people (McNeely and Sochaczewski 1988). The skull and horns of a female Kouprey were offered for sale in a shop in Poipet, Cambodia, in 1994 for $400, according to biologists surveying illegal trade in the country (Martin and Phipps 1996). The Kouprey has little chance of surviving without protection from hunting unless a large sanctuary is set aside for it. No strong conservation measures have been taken to date. No Koupreys are in zoos. It is possible that this species is already extinct.

The Banteng (*Bos javanicus*) is similar in size to the Kouprey, with upturned horns and an extremely stocky build. Brown to bluish-black, Bantengs have white legs and a white rump patch. Their range is larger than that of the Kouprey, extending from India to Myanmar (Burma), Thailand and Indochina, south through the Malay Peninsula to Java and Borneo. These animals are being crowded out of their forest and shrubland habitat by settlements and logging, and they are extremely vulnerable to hunting. They have become wary and shy, and large herds are now rare. Banteng have been domesticated in Indonesia and bred with domestic cattle, producing fertile offspring (Nowak 1999). Wild, genetically pure Bantengs are extinct in Bangladesh, Brunei, and probably India as well, according to the *1996 IUCN Red List of Threatened Animals*. The 2000 version of this list also classifies the species as Endangered.

The Gaur (*Bos gaurus*), largest of the three Asian wild cattle, is the most numerous, yet it is listed as Vulnerable by the *2000 IUCN Red List of Threatened Species*. Ranging from Nepal and India to the Malay Peninsula, these massive animals weigh up to 1,000 kilograms (2,200 pounds) (Nowak 1999). They have become extremely rare to absent in all

but protected national parks, and their populations have been estimated as extremely low, only about 1,000 animals (Nowak 1999). These animals are killed whenever possible for their meat throughout their range.

The Annamite Mountains extend along the border between Laos and Vietnam, rising to more than 6,000 feet in some areas, where stands of wet evergreen broadleaf forest harbor some of the strangest and rarest mammals on earth. Not until the 1990s were these remote forests explored by scientists, who examined skins and horns of rare animals killed by Hmong tribespeople. First to come to light in 1992 was the extraordinary Sao la or Vu Quang Ox (*Pseudoryx nghetinhensis*), a beautiful, gray, goat-like antelope. Its genus, *Pseudoryx*, meaning false oryx, indicates its superficial resemblance to oryx because of its long, straight, backward pointing horns. Weighing up to 200 pounds and 35 inches tall, this relatively large animal somehow had escaped the attention of scientists. (See photo in Nowak 1999.) Soon after discovery of several pairs of its horns, rewards were offered for live specimens. Two young calves were captured in Vietnam and placed in the Hanoi Zoo; within weeks, both were dead (Rabinowitz and Schaller 1994). Others were captured by villagers hoping to receive rewards, and some of the animals died (Nowak 1999).

The Hmong people know the Sao la well and hunt them whenever they can. They believe these antelope number at most a few hundred animals (Rabinowitz 1997). Many have been killed since their discovery, and hunters indicate that it has disappeared from some areas (Nowak 1999). Only a few hundred Sao las are thought to exist in Vietnam and Laos, where heavy hunting presents a major threat to them in spite of official protection by the Vietnamese and Laotian governments (Nowak 1999). Wildlife Conservation Society biologist Alan Rabinowitz (1997) estimates that they are restricted to an 800-square-mile portion of the rugged mountain forests along the border. In 1994, soon after this animal was given its scientific name, it was listed on Appendix I of CITES to prevent international commercial trade. The *2000 IUCN Red List of Threatened Species* lists it as Endangered. Vietnam set aside the Vu Quang Nature Reserve for these very rare animals and prohibited snaring in the reserve (Rabinowitz and Schaller 1994).

Other rare and newly discovered or rediscovered animals of the Annamite Mountains include two species of muntjac, or barking deer, one of which is the largest of all muntjac species; a long-snouted, yellowish wild hog rediscovered from a skull fragment; a striped rabbit, based on fur pelts found in a local village, which may be the same species or related to the endangered Sumatra Short-eared Rabbit (*Nesolagus netscheri*); and a very endangered palm civet (Rabinowitz 1997). The muntjacs and palm civet were discovered as captive animals, but nothing is known of the others, and searches for the wild hog have been unsuccessful (Rabinowitz 1997). Had these intriguing and unusual animals been discovered in a wilderness area in North America, they would be the subjects of field surveys and strict protection, as well as extensive media coverage. In Asia, where diversity is far greater and conservation a luxury few can afford, even such fascinating species may fade into extinction for lack of funding for conservation programs.

Throughout the region, much of the larger wildlife, from deer to large predators, has been hunted out, and guerrilla warfare has left the land marked with bomb craters and land mines. Alan Rabinowitz (1997), who has lived in Southeast Asia and witnessed overhunting in many countries, says, "The killing of wildlife in Laos was unlike anything I had seen elsewhere." Even within the Nakai Nam Theun Reserve, "walls of death" were constructed of thatch, bamboo and small trees, with openings rigged with snares; animals walking along the wall would be caught when trying to pass through an opening, snared by a leg or the neck, to "die a slow death" (Rabinowitz 1997).

Meat Hunting: Page 2

A wildlife slaughter of enormous proportions is taking place in Central and West African countries. Rural people who once killed animals only for personal consumption now hunt professionally, and markets in villages and cities now sell thousands of monkeys, antelope, wild cats, pangolins and even endangered apes (Pearce 1995, McRae 1997). Hunters use wire snares and leghold traps, high-powered rifles and dogs to track down animals. The tropical rainforests of west-central Africa, which once teemed with wildlife and echoed with their calls, are now falling silent.

For miles surrounding villages, wildlife has largely disappeared as local peoples throughout this vast region are killing every animal to sell its meat and body parts. Professional hunters have taken so much wildlife that little is left for local tribes. Logging corporations based in Europe have launched this commercialization of bushmeat by opening up previously impenetrable wilderness areas with logging roads and offering to buy animals that local people kill. Both the forests and the wildlife are being devastated.

Logging companies have taken advantage of these impoverished countries' national debts, buying rights to clearcut the majority of the remaining primary tropical rainforest in West and central-west Africa at bargain prices. The last primary forests in Cameroon, the Congo, the Democratic Republic of Congo and the Central African Republic are being cut and bulldozed, and their wildlife exterminated. Five-hundred-year-old trees with massive trunks 20 feet around, standing more than 100 feet tall, fall daily. The old-growth forests that provide homes for a myriad of wildlife will soon be gone at the present rate of cutting. In some areas, the logging is selective for certain species of trees, but this reduces forest diversity, and hundreds of trees are destroyed in the process of obtaining a few. When great trees fall, they bring down others, and logging roads and entry roads into forest tracts take thousands more trees.

In a shocking and moving report, *Slaughter of the Apes. How the Tropical Timber Industry is Devouring Africa's Great Apes* (Pearce 1995), the World Society for the Protection of Animals documents the tragic and gruesome slaughter of hundreds of Gorillas, Chimpanzees and other wild animals in Central African countries in this trade. The commercialization of wildlife and environmental devastation that have resulted are activities totally antithetical to the legislation and conservation ethics of the European countries--France, Germany, Italy, the Netherlands, Belgium and Denmark--that are sponsoring the logging (Pearce 1995). Several documentary films shown on the National Geographic Explorer program and CNN have shown the markets with thousands of small antelope, Chimpanzees, Gorillas, monkeys and other mammals lying dead on tables, offered for sale. fiAfrica Extremefl and fiNdoki Adventurefl are National Geographic films shown in March 2001 that document the discovery of poachers' camps with dead forest antelope, Leopard skins and other wildlife. One incident of snaring was filmed. A hunter filmed in the remote Ndoki Forest of the former Zaire found a Forest Pig struggling in a wire snare. The hunter began hitting the pig in the head to cause death, while the animal screamed and kicked. Only after hitting the animal about six times did death finally occur. Local hunters interviewed by the photographers said they regularly killed Bongos (*Boocercus euryceros*), rare and extremely beautiful rainforest antelope that are closely related to giraffes. These films traced the 1,500-mile voyage by Wildlife Conservation Society biologist Michael Fay through the last rainforests of the Democratic Republic of Congo and Gabon to publicize the fact that these magnificent wildernesses are being logged and their wildlife killed, and urgent action is needed to stop these activities.

Hundreds of Lowland Gorillas are being killed for the meat trade and sold for $40 per animal. Loggers place orders for Gorilla meat, which encourages the snaring and shooting of virtually every Gorilla that local people are able to procure for this grisly trade. WSPA found that in one district of the Cameroon, 800 Gorillas a year were being killed (Pearce 1995). Swiss photographer Karl Ammann has spent years fighting this trade (McRae 1997), and in the late 1990s, conservationists from around the world began efforts to save these beleaguered apes from slaughter.

In the forests of southeastern Cameroon, Ammann and Michael McRae, a journalist, found an infant Gorilla being kept in a dark mud-hut; the tiny animal was cowering in the corner, grinding its teeth and straining against its tether. The owner explained that the Gorilla™s parents had been shot two weeks earlier by a village hunter, the male having been wounded as he charged to defend the family, but escaping. The mother Gorilla died clutching her baby; she was then gutted and carried out of the bush, cooked and eaten (McRae 1997). Malnourished baby Gorillas are kept to be sold to passing trucks, but usually die within days. Ammann, after years of witnessing these tragedies, concluded, "Chimpanzees have the will to live if they're separated from their family, but Gorillas fall into a depressive state, and just give up on life" (McRae 1997). One baby Gorilla photographed by WSPA had been stuffed into a suitcase, where the Gorilla died of starvation after days of suffering (Pearce 1995). Another baby Gorilla was filmed lying dead in a battered cardboard box. CNN reporter Gary Streiker filmed an orphan baby Gorilla, tied on a string leash, being kicked and taunted. Huge cargo boats chug along the Congo River and other waterways of the Central African rainforest that serve as highways, carrying hundreds of orphan Chimpanzees and Gorillas to markets, stuffed in boxes

and bound with rope. fiDown the Dark River,fl a 1996 film by CNN, captured the squalid and cruel conditions that baby Chimpanzees endured on these boats. When sold as pets, baby Chimpanzees are often placed in outdoor dirt yards, lonely, solitary little gnome-like figures with sad eyes, hugging themselves or clinging to dirty cotton cloths. When they grow older and become strong and difficult to manage, they are usually killed and eaten (McRae 1997).

The total Lowland Gorilla population is not known with any certainty, and "guesstimates" of 100,000 put forth in 1985 are probably greatly exaggerated. Their true numbers are probably half that, and in steep decline (McRae 1997). Several bushmeat hunters were interviewed in fiThe Bush Meat Trade,fl a film shown on the National Geographic Explorer television series in 1995. When asked why they shoot these magnificent and protected animals, the hunters defended themselves by saying: "What's wrong with killing a Gorilla? They're fierce." One of the hunters told McRae that he was sure Gorillas were plentiful: "In Cameroon there are a million Gorillas. Three weeks ago, I saw sixty in one day. I shot three and then stopped . . . Why should I feel bad for a Gorilla? He is just a stupid animal" (McRae 1997). The West African country of Gabon also has markets where huge amounts of bushmeat are offered for sale, including Chimpanzee heads and Gorilla parts (Walters 1996).

Monkeys are killed on sight by the hundreds by hunters for sale in meat markets. Traders on the boat trip filmed in fiDown the Dark Riverfl were transporting some 30 or more dead monkeys, strung together with cord wrapped around their necks. These colorful and delicate rainforest primates are rapidly disappearing throughout their range. Monkeys from the forests surrounding the Congo River are bought by traders from hunters along the boat routes, or by logging truck drivers, and sold for $1 each in cities such as Kinshasa to be smoked for human consumption. Some traders traveling on riverboats specialize in bushmeat and barter with local people for monkeys, apes, turtles and other animals, some kept alive for the journey to preserve freshness of the meat, and others dead, stacked in piles.

WSPA has launched a campaign called EscAPE to encourage African governments to enforce existing hunting laws and police the trade in ape meat and body parts. WSPA personnel have rescued baby Chimpanzees and Gorillas from being sold as pets or abandoned, placing them in zoos or sanctuaries. A conference organized by WSPA invited loggers, conservationists, government representatives and organization representatives to discuss the bushmeat market and possible ways of ending it. The loggers boycotted the meeting, but others attended and, after two days, drafted a long list of resolutions, including enforcing existing laws, instilling conservation ethics, and restricting the logging trade (McRae 1997). In December 1995, Ammann and WSPA presented information on the trade to a committee of the European Parliament, distributing their report (Pearce 1995), and at a subsequent meeting of Afro-Caribbean-Pacific nations and the European Union, 140 delegates passed a resolution urging action (McRae 1997).

The bushmeat trade has become the foremost threat to wildlife in Central and West Africa's forests, an even greater threat than logging (McRae 1997). Urgent action to substitute other sources of income is needed. Ecotourism has been suggested, as well as employing hunters to conduct wildlife counts and become rangers. To date, no coherent program has been set into place, and hunters claim that they will continue to kill large numbers of animals until they find an adequate substitute.

Bonobos (*Pan paniscus*), or Pygmy Chimpanzees, number only about 13,000 in a restricted area of the former Zaire's dwindling rainforests. As the most endangered of the apes, exploitation could cause their extinction. WSPA documented illegal trade in these primates (Pearce 1995).

A study of the bushmeat trade in western Cameroon found serious declines in several other species of primates, caused by the meat trade. The rare Preuss's Guenon (*Cercopithecus preussi*) and the highly endangered Drill (*Mandrillus leucophaeus*), a large monkey listed on the US Endangered Species Act and Appendix I of CITES, are also being hunted for market sale. In one hunt alone, 30 Drills were killed (King 1994). Troops in the area have declined in number. One monkey, the Russet-eared Guenon (*Cercopithecus erythrotis camerunensis*) has been hunted to extinction there, and all primates from the Mount Manenguba region have declined dramatically (King 1994). In Sierra Leone, 300 tons of monkey meat are exported to Liberia each month, decimating wild populations of Red

Colobus (*Procolobus badius*) and Diana Monkeys (*Cercopithecus diana*). All these primates are listed by the *2000 IUCN Red List of Threatened Species* as Endangered. Scientists predict extinction in the region for the Red Colobus in 10 years, and the Black and White Colobus (*Colobus guereza*) in 20 years. Gabonese markets also offer various species of monkeys for sale. In one market, three small monkey heads were lined up on a gutter curb. Two of the faces were expressionless, and the third was open-mouthed, its eyes staring under furrowed brows, "as if frozen in a final, terrified gaze" (Walters 1996).

The Gabonese bushmeat trade, while not linked to commercial logging, has nevertheless grown in size and, in 1993, accounted for almost 11 percent of the country's gross domestic product (Walters 1996). A 1993 study found that, in a single city, more than 5,000 animals of 43 species of mammals, reptiles and birds were sold per year. Guenons; the magnificent and colorful Mandrill (*Mandrillus sphinx*), a Vulnerable species; Black Colobus; Chimpanzees; Gorillas; four species of duiker antelope; pangolins; Brush-tailed Porcupines; mongooses; genets; civets; and African Golden Cats are among the mammals killed for sale in Gabonese markets (Walters 1996). Birds being sold in these markets include crowned eagles, vultures, hornbills, guineafowl and plaintain eaters (a type of turaco). Pythons, Gabon Vipers, Nile Monitors, hinge-back tortoises and even threatened West African Dwarf Crocodiles (*Osteolaemus tetraspis*) were being marketed. Even animals protected under Gabonese law as endangered species are offered openly for sale. In addition to Gorillas and Chimpanzees, the Giant Pangolin (*Manis gigantea*), a race of the Potto (*Perodicticus potto*), and Demidoff's Dwarf Galago (*Galagoides demidoff*), nocturnal primates, all threatened species, could be obtained clandestinely (Walters 1996). In some areas of Gabon, high-ranking government--as well as local--officials supply hunters in villages with rifles and ammunition. Hunters then decimate wildlife and exchange the dead animals with traders for beer or soap. The traders then sell them for large amounts in city markets (Walters 1996). Hunting takes place throughout the forests, which still cover much of the country, and even in protected reserves where hunting is not allowed (Walters 1996).

An environmental organization, ECOFAC, has set up an ecotourism project to attract visitors to one of Gabon's wildlife havens, the Lope Reserve. Paths have been made through the forests, and 24 elevated observation posts have been built by members of the Scottish Primate Research Group, who have spent years habituating mangabeys and Chimpanzees to human contact (Walters 1996). The goal is to provide local communities with an alternate form of income from tourism and, perhaps, to spread the concept throughout the country and elsewhere in tropical forests where viewing wildlife is not as easy as in open savannah habitats.

The wild animal trade of Central and West Africa is obliterating populations of small forest antelope, such as various species of duiker. Twelve species of central and west African duiker are listed in the *2000 IUCN Red List of Threatened Species*. The meat trade and unregulated hunting, accompanied by destruction of forests, are the major threats. These animals are killed by capture in snares, where they may struggle for days. Two small, delicate antelope, both on CITES Appendix II, the Blue Duiker (*Cephalophus monticola*) and Bay Duiker (*Cephalophus dorsalis*), are trapped in wire snares or taken in pit traps in the Cameroon (King 1994). Dismembered duikers were seen in a market in Libreville, the capital of Gabon, in 1995 (Walters 1996).

Illegal snaring for antelope meat in national parks has been a major threat to Mountain Gorillas (*Gorilla (gorilla) beringei*), who number only about 650 animals. Many have lost their hands to snares, but some have now learned to recognize these traps and spring them. In 1995, however, a baby Mountain Gorilla strayed from the group and became snared, crying and struggling in terror for almost 24 hours while family members watched helplessly until Virunga National Park guards cut him free. Others have died in these snares.

Congo's national park, Odzala National Park, an area of 1,000 square miles, until recently had the region's only unexploited populations of African Elephants, African Buffalo and other mammals. Because of a lack of guards, poachers are now invading the park. The European Economic Community has agreed to fund the hiring and training of guards, with help from the Congolese army. This country is nearly bankrupt, like neighboring countries, making wildlife protection extremely difficult. Private hunting safaris enter the Congo rainforest and, for a fee, a foreign hunter can kill rare species of antelope and other wildlife.

Those who eat African monkeys and apes may be risking death. Several people who ate a dead Chimpanzee they found in the forest in Gabon died of the dreaded ebola virus, and the disease threat is not well-known to those who eat the meat of primates. Sooty Mangabeys harbor a virus related to HIV-2, an AIDS-like virus, and McRae (1997) saw a hunter carrying dead mangabeys, dripping blood into scratches on his leg.

In the Amazon, primates are avidly hunted for meat. Russell Mittermeier, head of the IUCN Primate Specialist Group, states that thousands of primates are killed by hunters, causing local extinctions of woolly monkeys (*Lagothrix* spp.) and spider monkeys (*Ateles* spp.) in Peru and Brazil. Forest tribes in Suriname kill very large numbers of primates for food, selling the meat in many local markets. The Wildlife Conservation Society (WCS) has been working with several native tribes in South America, evaluating the effect of their hunting on wildlife. They have found that in many cases, natives were overhunting many animals, causing local extinctions, even when only killing for subsistence. Peccaries of various species have been extremely vulnerable.

Meat Hunting: Page 3

Fruit bats of Asia and Pacific islands are killed in large numbers for food, sold by the tens of thousands to markets in Southeast Asia. Two species of the western Pacific, the Little Mariana Fruit Bat (*Pteropus tokudae*) of Guam and the Mariana Fruit Bat (*Pteropus mariannus mariannus*) of Guam, Rota, Tinian, Saipan and Agiguan have both been exploited so heavily that they are nearly extinct. Both bats are listed on the US Endangered Species Act as Endangered, yet the trade continues. On Sulawesi Island in Indonesia, thousands of bats are caught by young boys using kites to entangle them as they fly overhead. These bats are vital as pollinators of many species of commercially important fruit.

Bushmeat hunters in Indonesia and Malaysia are wiping out the populations of many animals. On the island of Borneo, a study conducted by the Wildlife Conservation Society found that hunting, legal and illegal, was the single greatest threat to wildlife (Bennett 1994). In Sarawak and Sabah, two northern states on Borneo, Elizabeth Bennett and her assistants conducted a three-year study of native hunting. These rural people, who previously had hunted only for subsistence, now hunt to sell the meat to town markets (Bennett 1994). Areas that had been inaccessible were opened up by logging roads, and hunters now swarm in the forests, killing any animal they see (Bennett 1994). Except in the most remote areas, all local people now possess shotguns. Squirrels, which have a great diversity of species on Borneo, nearly disappeared in some areas, along with leaf monkeys (Bennett 1994). Bearded Pigs, macaques, deer and porcupines are hunted, speared and trapped by some tribes (Bennett 1994). The only taboo involves the killing of Orangutans, who are protected by legend. Hunting pressures were so great that Bennett predicted extinctions for many animals, and the effects on the forest ecology were equally dire, as seed dispersers are killed off (Bennett 1994). WCS is working with local peoples to educate them about the effects of their hunting, with the cooperation of the Forest Department of Sarawak and the Wildlife Department of Sabah (Bennett 1994).

On the neighboring island of Sulawesi, formerly known as Celebes, WCS conducted a similar study in the Tangkoko-DuaSudara Nature Reserve. The study found that in the past 15 years, populations of the endemic Bear Cuscuses (*Ailurops ursinus*), bear-like marsupials who hang by their prehensile tails from branches, had declined by 95 percent from hunting (Kinnaird and O'Brien 1996). Crested Black Macaques or Celebes Apes (*Macaca nigra*), tailless, all-black monkeys found only on Sulawesi and listed as Endangered by the *2000 IUCN Red List of Threatened Species*, have declined by 90 percent, due in large part to meat hunting (Kinnaird and O'Brien 1996). An extraordinary turkey-like bird that incubates its eggs in large, leaf mounds, the endemic Maleo (*Macrocephalon maleo*), a Vulnerable species (BI 2000), has declined 75 percent from hunting (Kinnaird and O'Brien 1996). Other endemic species affected by this hunting are the Mountain Anoa (*Bubalus quarlesi*), a CITES Appendix I threatened dwarf buffalo found only on Sulawesi that is on the verge of local extinction, and the threatened, gargoyle-headed

Babirusa (*Babyrousa babyrousa*), a tusked wild pig, whose total wild population is about 5,000 (Kinnaird and O'Brien 1996). Highly organized networks hunt and trade the meat from these threatened species. Some dealers acquire animals on order for traders in North Sulawesi by driving up to 375 miles to buy Babirusa and other meat from forest hunters (Kinnaird and O'Brien 1996).

When native peoples cease hunting for subsistence only and begin hunting for markets, wildlife can be decimated quickly. Even subsistence hunting has been shown to be detrimental in some areas, but when wild animal meat becomes an economic commodity, overhunting usually results. Market hunting in the United States caused the extinction of the Passenger Pigeon (*Ectopistes migratorius*) and Labrador Duck (*Camptorhynchus labradorium*). The Eskimo Curlew (*Numenis borealis*), heavily hunted for meat in the 19th century, is probably extinct as well. The American Bison, Elk, White-tailed Deer and many waterfowl species also nearly disappeared. Following the 19th century slaughters that decimated these animals, laws banning the sale of wild meat from mammals and birds were enacted and remain in force today. In other parts of the world, only extinctions may bring about strong legislation banning market hunting of wildlife.

Persecution and Hunting

http://www.endangeredspecieshandbook.org/persecution_effects.php

Roman Slaughters

The tradition of killing animals for pleasure has a long history in Asia and Europe. So popular was hunting in ancient Rome that mosaics and paintings often depicted this pastime as a heroic activity. Slaughtering animals was considered a form of entertainment, and people scoured the countryside for bears, Lions, stags and boars to pursue with spears and dogs (Attenborough 1987). As the Roman Empire grew to encompass the entire Mediterranean basin, its citizens traveled throughout the region to hunt and bring back animals to be killed in primitive contests in the coliseums of Rome and other cities. The coliseum games continued for more than 400 years in more than 70 amphitheaters, the largest seating up to 50,000 people on stone benches arranged around a central arena (Attenborough 1987).

Roman emperors curried favor with the public by upstaging their predecessors in killing more animals and producing more spectacular displays of slaughter (Morris 1990). Emperor Titus inaugurated the Roman Coliseum by declaring 100 days of celebration, during which enormous numbers of animals were speared by gladiators. On the opening day, 5,000 animals were slaughtered, and over the next two days, 3,000 more were killed (Morris 1990). The caged animals were kept underground in dungeons where they were not fed, and on the day of the festival, they were hauled in their cages onto lifts that brought them into the center of the arena. As the crowd roared with excitement, drums were beaten, trumpets blown, and the terrified animals were set loose (Attenborough 1987). Sometimes the animals were goaded to attack one another, and at other times, men armed with spears and tridents pursued them around barriers made from shrubs in imitation of hunts in the wild (Attenborough 1987). One arena hunt resulted in the killing of 300 Ostriches and 200 Alpine Chamois (Morris 1990).

Lions, Tigers, bears, bulls, Leopards, Giraffes and deer died after being tormented, stabbed and gored (Morris 1990). Big cats that had been starved were released into the ring where a human slave or prisoner of war was lashed to a post; the animals clawed at the person before they themselves were speared and stabbed by gladiators (Attenborough 1987). In some of the larger slaughters, 500 Lions, more than 400 Leopards, or 100 bears would be killed in a single day (Morris 1990). Hippos, even rhinoceroses and crocodiles, were brought into these arenas, and sometimes gladiators employed bizarre methods of killing such as decapitating fleeing ostriches with crescent-shaped arrows (Morris 1990).

The Roman audiences cheered these brutal slaughters enthusiastically as a rule, but when 20 elephants were pitted against heavily armed warriors, the screaming of these gentle animals as they were wounded caused the crowd to boo the emperor for his cruelty (Morris 1990). This did not stop their use in the games however. These slaughters virtually eliminated large mammals from the Mediterranean area. North African Elephants (*Loxodonta africana*) were exterminated, having been hunted and captured to die in these arenas (Leakey and Lewin 1995). Elephants were also used by the Romans for transport and even conscripted for battle by Hannibal, a Carthaginian general who used them in a deadly march across the Alps, in which all the elephants died of exposure. Romans were probably the key element in the disappearances of the Asian Elephant (*Elephas maximus*) from West Asia as well (Leakey and Lewin 1995).

Prior to the expansion of the Roman Empire, Atlas Bears (*Ursus arctos crowtheri*) lived in the mountains and forests of North Africa, the only bears on the African continent. Named for their last refuge in the Atlas Mountains of Morocco, they were a race of the Brown Bear which is native to Eurasia and North America. North Africa was the species' most southerly distribution. When Romans entered North Africa, they cut the forest habitat of this bear and slaughtered thousands for sport. Others were collected for coliseum combat, where they were attacked by smaller animals, or gladiators wielding axes, spears and other weapons. Over the centuries, the Atlas Mountain forests were leveled for building materials, and colonial landowners used the cleared land for grazing livestock (Day 1981). The

Atlas Bear became restricted to Mount Atlas, where an 18th century French naturalist discovered a fresh skin, upon which the first scientific description was based (Day 1981). Even as late as 1830, the bears were common enough to be captured and sent to French zoos. In 1840, an English scientist concluded that this bear, smaller than the American Black Bear (*Ursus americanus*), was a distinct subspecies. It was stocky, with a short face, blackish-brown, shaggy fur on its back, and orange-rufous fur on its belly (Day 1981). This differentiates it so much from the Brown Bear that modern taxonomists might consider the two distinct species. Although Atlas Bears became increasingly rare, they received no protection from hunting, and the last of these bears were shot around 1870 (Day 1981).

Herodotus and Aristotle, philosophers of ancient Greece, wrote that Lions once lived in that country (Attenborough 1987). Two thousand years ago, the range of these big cats extended eastward in a continuous band to India and Pakistan and throughout the African continent. The Lion disappeared at an early time from Italy and Greece after being hunted and captured by the thousands for gladiator spectacles. When European Lions had been killed off, Romans turned to North Africa. The Barbary or Atlas Lion (*Panthera leo leo*), once distributed through much of the region north of the Sahara, fell victim to hunting and Roman Coliseum games. Known for its enormous mane, which covered virtually half its body, the male Barbary Lion was one of the largest of all races of Lions (Day 1981). It was also the nominate, or first subspecies named. This massive animal weighed as much as 500 pounds and measured up to 10 feet long from the tip of his nose to the tip of his tail (Day 1981). After centuries of hunting, persecution and habitat loss, these Lions withdrew to remote forests, where the last of them were systematically hunted down. Arabian tribesmen in Tunisia and Algeria chased them for sport, and later, French colonial governments paid bounties for their skins; by the 19th century, hunters had exterminated the last of the lions in Algeria (Day 1981). Government lists recorded the bounty fees paid, with fewer each year; only one skin was submitted for payment in Algeria in 1884 (Day 1981). Their final refuge, like the Atlas Bear's, was the wilderness forest of Morocco's Atlas Mountains, where hunters killed the last one around 1922 (Day 1981). Although officially extinct, some of these Lions may still survive in captivity. Certain circus and zoo Lions resembling the original Barbary Lion have been identified, and an effort is being made to gather a breeding colony of these animals. Whether they are, in fact, direct blood lines from the original North African Lions remains to be seen.

By the 13th century, Lions had been eliminated in the eastern Mediterranean; they disappeared from Iraq, Iran and Pakistan by the 1800s (McClung 1976). The last Lion in the Saudi Arabian peninsula was killed in 1923. For most ancient cultures of the Middle East and West Asia, killing one of these great cats, especially a large male, was considered a heroic deed worthy of being recorded in paintings and mosaics. Many such art works remain from Assyrian and other West Asian cultures. By the mid-19th century, Asiatic Lions (*Panthera leo persica*) had become confined to India, but were still widespread in that country (McClung 1976). During the last half of the 19th century, however, Indian Lions came under siege by British Colonial officers, who traditionally proudly took a Lion pelt back to England; a single hunter boasted of shooting 300 Indian Lions in 1860 (IUCN 1978). Under such pressure, Lions disappeared from all of India, save the Gir Forest in the southwest, by 1884 (IUCN 1978). In 1900, protection was finally accorded the last of these Lions, when their populations had been reduced to fewer than 100 animals (McClung 1976). Today, the Gir Forest Lions number a few hundred animals, all that remain of these proud cats on the Eurasian continent. Confined to a habitat that was rapidly being whittled away by villagers cutting firewood, and overgrazed by livestock, the Gir Lions are now protected in the Sasan Gir National Park of western India where, in recent years their population has increased.

Hunting by Romans and later peoples, combined with capture for the colosseum games, devastated the wildlife of North Africa and the entire Mediterranean region. Large predators, as well as deer and other ungulates, disappeared altogether or become endangered. Few conservation programs exist to protect remaining populations from hunting and persecution.

Predator Prejudice

The Roman tradition of persecuting predators spread throughout Europe and intensified in proceeding centuries, reaching superstitious depths in the Middle Ages. Beliefs that fiwerewolvesfl existed resulted in the persecution of wolves in Europe and Russia that continues today. Fairy tales are still recounted to children, in which wolves and bears are depicted as voracious killers. These stories, especially those by the Grimm brothers, frighten small children with tales of wolves, that pursued and ate small children and adults alike. "Little Red Riding Hood" and other stories instilled horror and hatred of predators. In Russia, the destruction of wolves was considered a great benefit to people, as well, with folklore embodied in tales such as "Peter and the Wolf." Persecution of wolves in that country continues to this day. With the spread of domestic livestock throughout Europe, official programs were instituted to destroy wolves (McIntyre 1995). Wolves were not the only animals killed in these programs. Lynx and Brown Bear were also eliminated from all but the most remote areas of Western Europe.

When Europeans settled in America, they brought these prejudices with them, treating native predators as vermin. Most colonies passed laws similar to Massachusetts' 1630 law requiring that "every English man that killeth a wolf . . . shall have allowed him one penny" (McIntyre 1995), and South Carolina's 1695 "Act for Destroying Beasts of Prey," which mandated that all Native American braves be required to bring in one skin of a wolf, panther, or bear, or two Bobcat skins each year. If he failed to do so, he would be "severely whipped," but if more than one skin was provided, he would receive a reward (Nowak 1972). In the East, these programs systematically killed off Gray Wolves, bears and Cougars. Large predators were effectively eliminated in the eastern states by the early 1800s, except for the Black Bear, which became greatly reduced in range and numbers.

The US government ran predator control programs throughout the country. Traps and poisons were the major tools used. Poison was liberally spread over most of the West. Thallium sulfate, strychnine, Compound 1080, and cyanide were distributed in great quantities, killing not only wolves, bears, and Coyotes, but foxes, weasels, ferrets, eagles and other birds. Any animals that ate the poisoned bait died, as well as those feeding on their carcasses. All these poisons caused a painful death, and most killed slowly. Poisoned animals could take hours to die from Compound 1080, and sometimes days after ingesting thallium sulfate. Strychnine, an extremely painful poison, can make water supplies lethal, killing humans, dogs and livestock. The wild predators that consumed Strychnine would vomit while dying from convulsions. Their bodies spread more poison, which remained toxic for a year or more.

Trapping was equally indiscriminate in its victims. Irrational prejudices against predators resulted in the total extermination, even in remote wilderness areas, of America's wolves and almost all its bears through bounty systems, federal subsidies and government control programs. Trappers and poisoners combed the countryside, randomly placing poison and traps.

Prejudice against predators affects a wide spectrum of animals, from foxes and bears to bats and birds of prey. Although the number of species that have become threatened as a result of control programs and random killing is less than those threatened by habitat destruction, the ecological consequences have affected a host of species within their habitats. These animals have co-evolved with their prey, the wolf making the deer fleet; wild cats making gazelles, zebras and hundreds of other ungulates agile. Although there is dispute as to the effect that predators have on the populations of their prey, overpopulations of deer and other ungulates have occurred in many parts of the world where predators have been eliminated. When ungulates overpopulate, they tend to overgraze their habitats, eliminating many types of vegetation, as well as birds and other wildlife dependent on that vegetation for feeding and habitat. Thus, thousands of species may be adversely affected when predators are destroyed.

Many species of snakes, as well as small carnivores such as foxes, eat large numbers of rodents, performing

important roles in preventing population explosions of these prey animals. Bats, as the most important predator of insects, control insect populations, as documented by many scientific studies. These mammals, although more abundant in number and diversity than carnivores, have declined radically in recent years, as evidenced by the enormous number now listed in the *2000 IUCN Red List of Threatened Species*. From a humane point of view, predator control has brought out the worst in human character, suppressing reason and compassion to allow fear and hate to dominate. As science has learned more about the importance of predators, and they are being protected and reintroduced in a growing number of areas in the world, prejudices remain, as do centuries-old ways of raising livestock that involve killing predators. These latter problems need to be addressed with the same vigor that has elevated predators to their rightful place at the top of their food chains in the eyes of conservationists and scientists.

Wolves, Wild Dogs and Foxes

Wolves have suffered more inhumane treatment and loss of range and populations than any other predator. The history of their survival and disappearance in various parts of the world is a reflection of the overwhelming importance of people's attitudes toward animals. When emotions, especially fear and negative superstition, rule people's minds, wolves can be destroyed on the basis of ignorance about their real threats to people and livestock. On the other hand, when people are aware of biological facts about the wolf and its ecological role, behavior, value to ecosystems, and the truth about its history of not attacking people, prejudices tend to dissipate. Native Americans had a natural affinity and respect for wolves, calling them "brother." The wolf's very survival as a species depends on its being treated with tolerance and respect. Gradually, this is happening in many parts of the world. Education and a change in government attitudes in many countries are needed to conserve this species, along with better ways of raising livestock.

Wolves, Wild Dogs and Foxes: Page 1

Prior to European settlement of North America, two wolf species lived throughout the forests of the East: the widespread Gray Wolf (*Canis lupus*), the same species that is native to Eurasia, and the Red Wolf (*Canis rufus*), a uniquely American species of the Southeast. Some biologists estimate that there were 2 million wolves on the continent at this time. European settlers entered the American wilderness and set about killing off these animals. The book, *War Against the Wolf. America's Campaign to Exterminate the Wolf*, by Rick McIntyre (1995), chronicles the history of this extermination program, based on historical and modern documents. Colonists dug pit traps and filled them with vertical stakes, which impaled wolves falling onto them. When hunters found an animal in the pit, they would leap in and ham-string the cowering wolf. John James Audubon described a farmer who captured wolves in a pit trap, severed the tendons in their hind legs, then tossed the crippled animals into a pack of dogs which tore them

apart (McIntyre 1995). The new colonists and their professional hunters set toothed traps that held the animal's leg while the teeth broke through its skin, wounding and breaking bones. Some who captured wolves cut off the lower jaw and turned the animal free to starve (Laycock 1990). Others set them afire, or started forest fires to rid the woods of wolves (Laycock 1990). Strychnine and thallium were placed in meat baits. Wolf pups were ripped apart by dogs, stomped to death, or burned alive in their dens. One predator hunter threw baited fish hooks, attached to lines, into wolf dens, waited until the pups swallowed the hooks, which embedded in their stomachs, then dragged them out of the den and killed them (McIntyre 1995).

Europeans were convinced that wolves hunted humans, even entering towns to kill children as they slept. In truth, wolves are neither ferocious nor killers of people. No case of a non-rabid North American wolf killing a human has ever been documented (McIntyre 1995, Nowak 1999). Very passive when trapped, they do not even attack the trapper as other predators might. Native Americans took wolf pups out of dens for pets without ever being attacked by the parents.

Red Wolves, named for their reddish-brown coats, had other color phases as well. Prior to their near-extinction, they exhibited a range of colors from black to gray and brown. The genes for these color phases were eliminated along with the wolves themselves in predator-control programs. Originally, this wolf inhabited the United States as far west as Oklahoma and eastern Texas, north to Indiana, as well as the southeast. The Red Wolf is the only surviving wolf that evolved in North America. This species and its ancestor, *Canis edwardii*, had been resident in forests as far north as Pennsylvania since the middle Quaternary epoch (Nowak 1979). Dr. Ronald Nowak, an expert on wild canids, maintains that the Red Wolf is a far more ancient species than the Gray Wolf. The latter species is thought to have evolved more recently in Eurasia, during the early Pleistocene, and migrated into North America across the Bering land bridge that linked the continents (Nowak 1979).

Weighing only 20 to 40 kilograms (44 to 88 pounds), and 660 to 790 millimeters (26 to 31 inches) tall at the shoulder, the Red Wolf is larger than the Coyote (*Canis latrans*), but smaller than the Gray Wolf. Mating for life, it breeds in February or March, producing two to six pups in March or April. The pair dens in hollow logs or along banks of canals or ditches. These wolves did not usually form packs, but were most often seen in pairs or small family groups. They were systematically trapped, shot and poisoned out of their range. From the 17th century onward, in state after state, these wolves were exterminated to the last animal, pushing this species toward extinction. Federal predator-control programs took some 50,000 Red Wolves from 1937 onward, until they were virtually extinct in the wild (Laycock 1990). It was not until 1962 that this wolf's highly endangered status received any attention from biologists and wildlife officials. Still, no action was taken to stop state trapping and predator-control programs for another 11 years.

By the 1970s, the Red Wolf had been completely exterminated, except a small population that survived in one county in southwestern Louisiana and in adjoining areas of eastern Texas (Carley 1975). Coyotes had moved into the range of the Red Wolf and interbred with some of the last members of the species. This hybridization spelled the demise of wild Red Wolves. It has been suggested that this interbreeding occurred only because Red Wolves had become so rare that they were unable to find mates of their own species. A live-trapping program to capture the last, pure-blooded specimens, as the only way of saving the species, began in 1973 in Texas, funded by the US Endangered Species Act (ESA). Fewer than 100 animals remained. After capture, X-rays were taken of these animals' skulls to determine which were pure-bred and which were hybrids, based on their skull shape and dimensions.

A number of these hybrids, as well as the pure-blooded Red Wolves, were in poor health from mange, heartworm and other parasites when captured (Carley 1975). Their last attempt to survive in the wild had obviously been a difficult one. Their remaining habitat in Texas and Louisiana had become a mosaic of agricultural and residential development, leaving little natural forest. Moreover, they were under constant threat from trappers and hunters. After five years of live-trapping, only 40 pure-blooded Red Wolves were identified, and they were sent for captive breeding at the Point Defiance Zoo in Tacoma, Washington. No further Red Wolves were found, and in 1979, Howard McCarley and Curtis Carley of the Red Wolf Recovery Team, authorized under the US Endangered Species Act, announced in a status

report, "Recent findings indicate that the only extant subspecies (*Canis rufus gregoryi*), once occurring from eastern Texas to eastern Mississippi, for all practical purposes is extinct in the wild" (McCarley and Carley 1979). The other subspecies of the Red Wolf, the Florida Red Wolf (*Canis rufus floridanus*), had become extinct by 1917 (Day 1981). So many wolves of the Florida race, which once ranged into Georgia and southern Tennessee, were black, that this wolf was originally named the Black Wolf. This genetic strain is now lost.

Of the 40 captive Red Wolves, 14 were selected to form the nucleus of a Fish and Wildlife Service-sponsored captive-breeding colony (Nowak 1999). In 1977, offspring were successfully produced, and by 1989, there were 83 descendants, and the last surviving wild-caught Red Wolf died (Nowak 1991). In 1993, the captive colony consisted of more than 187 animals in 31 breeding facilities. By 1995, there were 289 living descendants from the original wild Red Wolves, the majority in Point Defiance Zoo in Tacoma, Washington (Nowak 1999). In the mid-1980s, reintroduction programs began with the release of several of the captive-bred wolves to the wild. This was the first time the American government had ever sought to introduce and protect wild populations of wolves, instead of eliminating them. Since the Coyote is now present throughout the Red Wolf's original range, attempts were made to find reintroduction areas without Coyotes to prevent hybridization and competition. In 1987, four pairs of Red Wolves were reintroduced into the 120,000-acre Alligator River National Wildlife Refuge, an island in North Carolina without resident Coyotes. A pair released on Bulls Island in Cape Romain National Wildlife Refuge in South Carolina produced two pups in 1988. These pups were captured and released in the Alligator River Refuge in 1989. Another pair, introduced to Horn Island off the Mississippi Coast, produced seven pups in May 1989. By the close of 1993, 46 to 60 animals survived in these newly wild populations by Fish and Wildlife Service counts.

In 1991, a pair of Red Wolves and their two pups were set free in Great Smoky Mountains National Park in Tennessee. Jan DeBlieu, a writer on endangered species, witnessed the release of the wolf family (McIntyre 1995). This area has resident Coyotes, which arrived in the mid-1980s, and the interaction between the two species will be closely watched. Several Coyotes and the adult Red Wolves have radio transmitters and were tracked by a number of biologists after their release. DeBlieu was present when, soon after their release, the male and pups traveled 2 miles away from the female, who lay quietly in a field. Suddenly the researchers heard the prolonged, low howl of the male wolf and high-pitched yaps of the pups, a song "not heard in the Smokies for one hundred years" (McIntyre 1995). They were calling the female, who ran toward them. This national park receives 8.6 million visitors a year--more than any other park in the system. The visitors tend to stay near roads, however, and most of the park is roadless wilderness. Prey is abundant, and both the adults and pups began catching rodents and rabbits, hunting at dawn to avoid tourists during the day (McIntyre 1995). By late summer 1994, there were seven Red Wolves in Great Smoky Mountains National Park. Two more family groups were released the following year, but the available prey in Great Smoky Mountains National Park is limited in the mountainous terrain (Rancourt 1997). As many as 26 wolves lived in the park in 1997 (Rancourt 1997). A few pairs have produced young.

For the most part, these reintroduced wolves have survived with few conflicts with local people, mainly due to the extensive education programs and hearings held by the Fish and Wildlife Service in each area prior to releases. Some private landowners in North Carolina became apprehensive about the potential threat to children and livestock. The Fish and Wildlife Service has paid claimants for losses even when no proof was submitted that it was, in fact, a wolf at fault. One livestock owner admitted that the Red Wolves had become "good neighbors." Yet even these limited reintroductions have provoked resentment in some local communities which harbor ancient prejudices about wolves. The North Carolina state legislature passed a law early in 1995 that defied the US Endangered Species Act, allowing people to kill wolves that attacked livestock. The Fish and Wildlife Service accommodated these concerns by changing its policy in April 1995 to allow killing of Red Wolves thought, but not proven, to be attacking livestock in North Carolina and Tennessee. One of the first wolves killed, male number 464, was shot in 1995 in North Carolina by a landowner who caught him digging under his dog's pen. This wolf had been released the previous year near Alligator River National Wildlife Refuge, but prey was scarce, so Fish and Wildlife Service personnel recaptured him and freed him on the mainland. Number 464 had not been guilty of preying on livestock.

Further incidents between residents and Red Wolves occurred in 1997 and 1998, with wolf pups that were attempting

to disperse into new territory being trapped. One young wolf that had been taken in a leghold trap in North Carolina was rescued by the Fish and Wildlife Service and returned to a penned enclosure in 1998. The local county representative stated that wolves were unwanted intruders and would be dealt with by residents. This does not bode well for reestablishment of these wolves.

If the Red Wolf survives this irrational prejudice, it may reoccupy many of its original haunts. The threat of hybridization with the Coyote will remain, however, and without corridors of habitat to link reintroduced populations, these wolves risk becoming inbred. With education of the public, one day the Red Wolf may be restored as a natural predator, benefiting its prey and ecosystem.

Wolves, Wild Dogs and Foxes: Page 2

Unlike the Red Wolf, Gray Wolves traveled in large packs in the Great Plains of the West. Many of the wolves painted by George Catlin, the great 19th-century artist of Native Americans and wildlife of the Plains, were beige or pure white, as are many of the wolves of the grasslands of northern Canada. Early hunters killed wolves for their pelts by trapping, poisoning and shooting. Many were used for target practice in the open country. When livestock ranchers took over huge tracts of land in the West, the Gray Wolf became a target for total extermination. Cowboys often roped wolves and dragged them to their deaths across rough ground (McIntyre 1995). Federal trappers used even more brutal killing methods (McIntyre 1995).

James Josiah Webb, who wrote a memoir of events in the Santa Fe, New Mexico, area from 1844 to 1861, recounted that two men conducted a wolf-killing operation by spreading strychnine bait placed in chunks of bison meat around the prairie. The number of wolves that once inhabited the region was so dense that they found 64 dead wolves within 1.5 miles of their camp in a single day after a poisoning; they bragged that they earned $4,000, an enormous sum in those days, by selling wolf pelts (McIntyre 1995).

As wolves were exterminated in one state or territory after another, a few of these intelligent animals managed to escape traps, guns and poison, earning the label of "outlaws." These wolves ranged alone or in small packs, and in the last days of the western wolf, some trappers spent months or years in determined pursuit of them. The ability of these wolves to elude their persecutors were truly amazing. One of the most famous such cases was described by Ernest Thompson Seton, an English artist and writer, in *Wild Animals I Have Known* (1899). Based on fact and documented by photographs, it concerned Lobo, an enormous wolf, called "The King" by Mexican residents who lived near a huge cattle ranch in northern New Mexico. For many years in the 1890s, Lobo led a pack of five wolves. He had a distinctive, deep howl that ranchmen recognized among the howls of the other wolves. He was by far the largest wolf in the pack and exceeded the size of other wolves in the region. Whereas most wolf paws measured 4 3/4 inches, Lobo's were 5 1/2 inches long. His mate, whom the Mexicans called Blanca, was a large, magnificent white wolf.

These wolves, like many others of the West during this period, had been deprived of their natural prey, White-tailed and Mule Deer and Elk, which had been hunted out by settlers and replaced with livestock. The wolves turned to livestock as the only large prey available and, in doing so, became the target of ranchers' wrath. Western ranchers, like many livestock owners in Europe, believed that they should be able to release cattle to roam free without herding them into shelter at night. This situation had existed in Western Europe after large predators were eliminated from all but the most remote areas. In their new ranches, allocated to them by the government, ranchers sought to recreate the European model. This required the destruction of large predators.

Lobo and his pack refused to eat dead animals that they encountered, apparently to avoid poison, and survived on calves and sheep that they killed themselves. When Lobo and his pack killed a cow, ranchers immediately put poison in the carcass. But when the wolves returned the next day to eat, they somehow knew which parts of the carcass were

poisoned, and pulled out the poisoned chunks, throwing them aside, eating only the unpoisoned portions. Lobo also avoided the traps set for him and hid from hunters on horseback who pursued him. Trappers came from great distances to claim the high bounty on Lobo, but all failed to kill him. Ernest Thompson Seton decided to try to kill Lobo himself for the $1,000 bounty. He scattered poisoned baits, covering the human scent with other odors, and the following day, found that one after another of the baits was gone. Assuming that he would come upon the body of Lobo, he was surprised to find his five baits in a pile. Lobo had picked them up, one after another without eating them, and left them as a message to Seton. Seton obtained special steel jaw leghold wolf traps and set them in concealed places in Lobo's territory. When he came out to check the traps, he found Lobo's tracks leading from trap to trap. The canny wolf had discovered each of the traps during the night, scratching earth away to reveal the chain and trap, continuing from trap to trap until he encountered one in the center of the trail. Lobo then retraced his steps, placing each paw exactly in its old track until he found no more traps, using his paw to flip stones and earth clods to spring every trap.

Seton finally succeeded in trapping Blanca by setting hidden traps among parts of a cow carcass and covering the area with Coyote scent. Lobo avoided the traps, but Blanca made a fatal error and blundered into one. When Seton and the others found her dragging the heavy trap, she turned to fight, howling across the canyon. Lobo howled back, while Seton and the others brutally killed her. Throwing lassos over her neck and holding the ends of the ropes, they galloped horses in opposite directions until her body was torn apart. When he wrote of the event years later, Seton (1899) called the killing a tragedy. They heard the howls of Lobo for days afterward. Seton described it as having "an unmistakable note of sorrow in it, now. It was no longer the loud, defiant howl, but a long, plaintive wail." When they found Lobo's tracks at the spot where Blanca had been killed, Seton reflected, "Now, indeed I truly know that Blanca was his mate."

Soon afterward, Lobo came near the ranch house. His tracks showed that he had galloped about in a reckless manner before he blundered into a trap set in a pasture. He was able to pull out of it, but Seton then set 130 steel jaw leghold wolf traps in groups of four on every trail leading into Lobo's home canyon, and dragged Blanca's body around the area to leave her scent. He even removed one of her paws, with which he made a line of tracks on the soil covering each trap. Within days, Lobo was caught with all four legs in a trap set, having followed Blanca's scent and forgetting all caution. When Seton approached the trapped wolf, Lobo managed to stand, in spite of severe injuries, and howled his deep call, but no members of his pack responded. Seton and others wrapped ropes around his neck, put a stick in his mouth and lashed his jaws closed. His feet were tied, and when he was placed on Seton's horse, he refused to look at any of his captors. At the ranch, Seton placed a collar around his neck, secured him to the pasture with a strong chain, and Lobo lay calmly, gazing across the prairie.

When Seton came out the next morning, Lobo was dead. On measuring his body, Seton found that Lobo weighed 150 pounds and was 3 feet tall at the shoulder. He was one of the largest wolves ever trapped in the Southwest. The largest Gray Wolves are native to northern Canada and Alaska and weigh up to 176 pounds, but most wolves of the Southwest were far smaller and lighter (Nowak 1991). Scientists who measured the skulls of the pair estimated that Lobo was 4 to 5 years old when he was killed, and Blanca was 7 (McIntyre 1995). Photos of Lobo and Blanca caught in traps are reproduced in Rick McIntyre's 1995 book, *War Against the Wolf*. Lobo and Blanca were exceptional specimens, and their slaughter represented an irreplaceable genetic loss. The treatment they received will remain a blot on human "kind." Lobo was killed on January 31, 1894, near Currumpaw, and his pelt is kept at the Ernest Thompson Seton Memorial Library and Museum at the Philmont Scout Ranch near Cimarron, New Mexico (McIntyre 1995). This experience changed Seton's attitude, and he expressed strong feelings of guilt in his description of his treatment of these wolves.

Government programs did not reflect Seton's newfound sympathy for wolves. In fact, predator-control programs intensified in the early years of the 20th century. Ranchers convinced the federal government to launch an all-out attack on predators, primarily wolves. The Forest Service and the Bureau of Biological Survey used poisons and traps to kill adult animals and many cruel methods to kill the pups in dens in their efforts to try to exterminate the wolf. In 1907 alone, the Forest Service killed more than 1,800 Gray Wolves and 23,000 Coyotes, among other animals

(Laycock 1990). After the US Congress authorized the first substantial appropriation for hiring government hunters in 1915, federal wolf-control programs achieved an unprecedented level. Hundreds of agents combed the most remote wildernesses, spreading poison even where no cattle or livestock grazed. A point system was established; the highest number of points, 15, was accorded for killing a Mountain Lion or a Gray Wolf (Laycock 1990). Hired hunters earning high point totals made the Honor Roll, while others might be fired; they were expected to kill virtually every predator in their assigned area (Laycock 1990).

Within a few decades, many thousands of Gray Wolves had been killed. They were eliminated from more than 95 percent of their range in the lower 48 states by the 1930s (Robbins 1997). A few wolves, using their intelligence and survival senses, managed, like Lobo and his pack, to survive somewhat longer, but they were killed in the end. The Custer Wolf, a large female also known as "Old Three-Toes" because she had lost a toe in a steel jaw leghold trap set by a government trapper, became as infamous as Lobo and Blanca. After her mate and pups were killed, the Custer Wolf survived until caught in a trap that became snagged on rocks (McIntyre 1995).

Vernon Bailey, a biologist with the US Biological Survey, the government agency that later became the Fish and Wildlife Service, conducted wildlife and plant studies as well as predator-control programs. He noted early in the century that the Biological Survey had conducted "the most systematic and successful war on these pests ever undertaken" (McIntyre 1995). The loss of virtually all wolves in the vast area encompassing the lower 48 states may be the most devastating predator-control campaign in history.

If not for the fact that the predator-control programs of the territorial and provincial governments of Alaska and Canada did not succeed in totally exterminating the wolf, the species might be extinct on the continent. Although wolves were persecuted and trapped for their fur in the latter areas, they survived in the far north and in the eastern forests of Ontario and Quebec and have now reoccupied most of their original range in Canada.

The Gray Wolf is able to adapt to a wide variety of habitats and climates, whether searing deserts, shrublands, grasslands, forests of all types, frozen tundra or even marshlands. It had the largest range of any terrestrial mammal on Earth, other than humans (Nowak 1999). Wolves had lived for thousands of years on the continent, their environment and prey altering drastically through the Ice Ages, needing only the presence of large prey to survive. Wolf intelligence, in fact, exceeds that of the domestic dog, which has a brain 31 percent smaller (Busch 1995). In spite of the wolf™s survival abilities, the fragmentation of packs by predator-control agents prevented them from hunting normally and hastened their disappearance soon after control methods began. This need to live in a pack for hunting and companionship made the species vulnerable to extermination. When persecuted, Gray Wolves do not desert one another, and many cases have been documented of wolves sacrificing their lives in an effort to save a pack mate. This altruistic trait also contributed to their extermination. The traits that humans most admire about domestic dogs were inherited from the wolf--loyalty, intelligence, playfulness and affection. Wolf pups were first domesticated by hunter gatherers tens of thousands of years ago, and even after selective breeding by humans in the intervening centuries, they still retain many of the wolf's best qualities.

Wolf packs have a lead pair, known to biologists as the alpha male and female, who are the only members of the pack that produce cubs. They mate for life, and dominate other wolves in the pack. They are usually the fittest and largest. Other pack members challenge for leadership, which can result in a change in the alpha pair. The entire pack, which includes adult females and males and pups from the previous year's litter, cares for the pups, ensuring that the strongest pass on their genes to future generations. Young unmated females and males "baby-sit" the pups when the alpha pair and the rest of the pack are out hunting. When the pups are about six weeks old, their baby-sitters spend hours with them in wrestling matches, games of tag and other rambunctious activities. Within the pack, wolves are extremely friendly and devoted to one another, barking and yipping with delight on meeting, and before and after hunts. They howl at night, communicating with other wolf packs which howl back. Bonds between wolves, especially mated pairs, are very strong, as illustrated by the saga of Lobo and Blanca, and many other cases of wolves in apparent mourning for lost mates have been documented. For many days, one male Mexican wolf, howling plaintively, followed a government trapper who had killed the wolf™s mate and carried off her pelt.

Other species of canids show similar behavior. The African Wild Dog (*Lycaeon pictus*), a highly endangered wild canid, hunts on the African plains in even larger packs than Gray Wolves, numbering up to 26 animals, yet only one female in the pack has pups. The alpha female might have 16 pups, and if another female in the pack has a litter, the alpha female will steal the cubs and nurse them, even if the litter size reaches 20 or more. Fewer than 5,000 of these beautiful animals, sometimes called Painted Wolves because of their black-and-yellow spotted coats, remain in the wild, and they are in steep decline (Nowak 1991). In Zimbabwe, where there are only about 300 to 500 animals, they are still persecuted by farmers. Even in national parks, they often lose prey when chased off by Spotted Hyenas or Lions.

The ecology of the Gray Wolf has been studied since the 1940s, revealing it to be completely different from the prejudicial folklore of Europe. Adolph Murie, one of America's greatest biologists, conducted studies of wolves in Mount McKinley (now known as Denali) National Park, where they were neither persecuted nor hunted. In his study, *The Wolves of Mount McKinley* (Murie 1944), he revealed: "It appears that wolves prey mainly on the weak classes of sheep, that is, the old, the diseased, and the young in their first year. Such predation would seem to benefit the species over a long period of time and indicates a normal prey-predator adjustment in Mount McKinley National Park." By examining the carcasses of Caribou and other mammals killed by wolves in the park, Dr. Murie found that most were in poor physical condition. Wolf packs test their prey by isolating and then chasing individual animals to detect weaknesses, and the majority of their chases do not result in a kill.

In spite of more than 50 years of biological studies of wolves that have shown them to be a positive rather than a negative influence on their prey, there are still many who disagree. Predator-control programs have been authorized in Alaska, Canada and parts of Eurasia in misguided attempts to protect deer, Elk, Moose, American Bison and Caribou. A trophy hunting organization, Safari Club International, paid the British Columbia government to kill wolves in that province (Williams 1991). The real motivation for these eradication programs is often to promote artificial increases in populations of ungulates, such as Moose, Caribou and deer, for sport hunting.

Over the ages, prey species of wolves have evolved to survive their attacks by becoming faster and stronger. The largest and healthiest deer on the North American continent have been found in areas where wolves are resident predators. The number of wolves in a pack varies according to the size of the prey: packs of up to 15 are needed to bring down bison, while packs of seven or fewer hunt deer (Nowak 1999). Wolves hunting large prey run in shifts, with tired members of the pack replaced by rested wolves. They will sometimes need to run for many miles after Caribou, Moose, American Bison or deer before they succeed in singling out one they are able to bring down; an average of only one in 10 chases is successful. Native Americans have always been aware of the important relationship between the wolf and its prey. The Keewatin Inuits have an ancient saying: "The caribou feeds the wolf, but it is the wolf who keeps the caribou strong" (Busch 1995). The healthiest members of each prey species are able to fend off wolf packs, and only in unusual circumstances can wolves kill them. For the vast majority of prey species, wolves sense weakness in their prey, evidenced by body stance, uncoordinated movements, the smell of wounds or, most often, by their lack of endurance when being chased (McIntyre 1995).

When wolves are hunted out of an area with deer and other ungulates, the latter animals often increase in numbers to such great levels that they strip their habitat of vegetation. The overpopulation of White-tailed Deer in many parts of the northeastern United States, especially in suburban locations, has resulted from a lack of natural predators. Their absence has created a major imbalance in eastern forest ecosystems, where they have become so numerous that they consume young trees and new growth on mature trees.

Wolves, Wild Dogs and Foxes: Page 3
Although Gray Wolves were completely eliminated from the eastern states south of Canada and east of Minnesota by 1930 (McIntyre 1995), a few remnant populations survived in northern Minnesota and northern Montana. The first US Endangered Species Act in 1967 listed all wolves in the lower 48 states and Mexico as Endangered. In 1973, another Endangered Species Act was enacted, replacing the 1967 Act. Five years later, the category for the wolves of Minnesota was changed to Threatened. In subsequent years, wolves were reintroduced to the southwest, Wyoming, Montana and Idaho, listed as Threatened experimental populations. All other wolves south of Canada are still listed as Endangered. Wolves have wandered from Minnesota and south from Canada to neighboring Wisconsin and Michigan, with about 50 wolves living in each state (Nowak 1999). Prior to eradication programs beginning in the 19th century, between 9,000 and 16,000 wolves were estimated to have occupied these three states (Savage 1996). Bounty programs killed 150 wolves a year in Minnesota alone between 1949 and 1954, and this state did not withdraw its bounty until 1965; Wisconsin stopped bountying wolves in 1957, and Michigan in 1960 (Savage 1996).

The wolves of Minnesota have gradually increased in range in the past 30 years, but they remain thinly distributed in the northern portion of the state. State regulations allow them to be killed if found preying on domestic livestock, with little or no proof of depredation. Minnesota has a compensation program for livestock owners but does not attempt to relocate wolves, even though depredations have occurred on only 1 percent of farms in that state (Savage 1996). In Wisconsin, large areas have been closed to Coyote hunting during the deer season, which has greatly decreased wolf mortality there, since many wolves were shot--either mistakenly or intentionally--by hunters (Savage 1996). Unlike Minnesota, Wisconsin relocates wolves found preying on livestock and compensates owners of livestock killed by wolves; Michigan's Upper Peninsula, where wolves are found, has no livestock (Savage 1996).

Although many Minnesota residents consider wolves to be threats to livestock and resent the protection they receive from the US Endangered Species Act, for others, they are a thrilling symbol of wilderness and the America that existed several hundred years ago. Ellen Hawkins and her husband Gary live in a wilderness cabin surrounded by Superior National Forest land, prime wolf country in northern Minnesota. Because they are avid wildlife watchers, they put out food for birds, foxes, Fishers, Martens and weasels, and state officials bring the couple road-killed deer which they place in a clearing 200 yards below their house for wildlife to feed on. They saw wolves very rarely and felt lucky to hear their howls or find their tracks (Hawkins 1988). One December day, they spotted a wolf feeding on a deer carcass on their property and noticed that he was wearing a radio collar, placed by the Fish and Wildlife Service to track many of Minnesota's wolves.

Their excitement at seeing the wolf, who brought "magic to the place," dimmed when they realized he was injured. He limped, holding up his right front foot, and they saw him fall in the snow (Hawkins 1988). He kept his tail down, a sign of subservience and fear, and moved stiffly and awkwardly. He spent five days feeding on the deer, lying in the snow near it, and seemed weaker each day. On the sixth day, he disappeared from the clearing, and in the middle of the night, an amazing event occurred: "We were confronted by his face pressed against our window" (Hawkins 1988). As they stood gaping at him, they heard him thump his nose on the glass, still staring at them. The wolf then went to another window, and they found themselves again eye-to-eye with him. He had climbed a snowdrift onto their greenhouse roof and now sat leaning against the window, looking back over his shoulder at them. The Hawkinses found some chicken and tossed it onto the roof next to him, while offering him a pan of gravy. The wolf looked at the food, and then at them, but did not eat.

The temperature was 25 degrees below zero F., and they decided the wolf needed warmth. Gary got a blanket and put it around the wolf, who jumped at first, and then quieted down. His passive response made them think that he should be brought indoors. They got an old quilt, and Gary picked up the sick wolf, carrying him into their living room. The wolf was somewhat dazed, but hardly moved. They called their neighbor, who came 12 miles to see the frail and sickly wolf sitting near the stove in their living room. Uninterested in food, the wolf looked about and seemed to warm up, leaning against the stove until his fur singed. They saw that he had lost part of his front foot, and they heard him wheezing as he breathed. Within minutes, his condition deteriorated, and he began pawing at his mouth. His wheezing grew into a "terrible, deep gurgling" (Hawkins 1988). Gary moved close to the wolf and began to stroke its

head. The wolf stood up with effort, but then slumped down to lie beside the stove. Gary removed the collar so that the wolf could breathe more easily, and they saw that it had a number--6530--with the address of the Fish and Wildlife Service. The wolf suddenly staggered into the middle of the room, spasmed and struggled for breath. Gradually they saw his eyes become unfocussed, and the light faded out as he died (Hawkins 1988).

They later learned that Wolf 6530 left his pack when he was nearly 2 years old and wandered for eight months before he returned to his family. He stayed with them only two months before walking 40 miles to another hunting area. Finally, fatally ill, he came to the Hawkins' house, which was 45 miles from his pack. An autopsy revealed that he had died of a fungal pneumonia, the first such case of wolf mortality. The disease may have been brought on by stress and lack of nourishment (Hawkins 1988). Although his coat was thick, he was emaciated, weighing only 55 pounds. At his age he should have weighed at least 75 pounds. He had a tear on his lower lip, had lost three pads on his right foot, and one pad was mutilated on his left foot (Hawkins 1988). A biologist with the Fish and Wildlife Service was contacted about Wolf 6530 and, in his opinion, the wolf's foot wounds were probably the result of getting caught in a fox trap and dragging the trap about until its toes rotted off (Hawkins 1988). As long as he was dragging the trap, he was unable to hunt with the pack, and this may have explained why he was forced to wander in search of carrion.

Many Minnesota wolves and those dispersing to neighboring states and southern Canada have been trapped in leghold traps. In fact, Wolf 6530's brother had been killed by a trapper in Ontario, 115 miles to the northeast, at the age of 18 months (Hawkins 1988). Wolf 6530 had suffered for many months, and his life ended prematurely. Wolves can live 10 years or more in the wild. Only because he had turned to people during his last days did his story come to light. Ellen Hawkins reflected on the extraordinary event: "We'll never know what motivated him to come our way. I can only say that I'm grateful to Wolf 6530 for sharing his last, desperate moments of life. His act gave us a sense of connection with his world that we would never have had, and our commitment to live in harmony with that world has been strengthened. We will always carry with us the vivid image of the wolf at the window" (Hawkins 1988). The dying wolf may have sensed that the Hawkinses were friends of wildlife, having seen them put out food and watch him without taking any aggressive action toward him. Because he was a highly social animal who had been forced into solitude for most of his short life, he may have sought their company, sensing that he was close to death, preferring humans to an isolated and painful death without his pack mates. Whatever his motivation, his appeal to the Hawkinses' prior to dying was evidence of the complexity of this fascinating creature, and an indictment of the continued use of the inhumane steel jaw leghold trap.

Wolves, Wild Dogs and Foxes: Page 4

To counter the strong anti-wolf prejudice, a new organization called the International Wolf Center in Ely, Minnesota, has live wolves in an enclosure, museum exhibits and field classes. The 50,000 visitors it has received in the past few years brought $3 million to the local economy (Chadwick 1998). But wolves in Minnesota and elsewhere continue to be taken in traps set for other types of animals, causing injury or death. One study on wolves taken in various types of traps was published in the *Journal of Wildlife Management* (Ballenberghe 1984). It investigated injuries and mortality of 126 wolves trapped in northeastern Minnesota and Alaska. Traps used included steel jaw leghold traps of various types, some with teeth, others with smooth offset jaws; steel cable foot snares; and cable neck snares equipped with devices that prevented the loop from fully closing (Ballenberghe 1984). The results confirmed that steel jaw leghold traps caused the greatest number of injuries and mortalities: 41 percent of 109 adults, yearlings and pups caught in these traps incurred serious foot and leg injuries, defined as lacerations, damage to tissue, bone breakage, and joint dislocations (Ballenberghe 1984). Three wolves, including a pup, had broken leg bones; two others lost front feet after they were nearly amputated by the trap. One young male with broken radius and ulna bones in his foreleg was released in this study to stumble off; this wolf was caught by a trapper several months later (Ballenberghe 1984).

Other injuries resulted when trapped animals gnawed their own feet off and chewed on the traps, breaking teeth and

splitting lips. The steel jaw leghold traps caused tissue, muscle and tendon injuries, even when checked daily (Ballenberghe 1984). Since the observations carried out were not done by a veterinarian, or with aid of X-rays and other sophisticated tools to arrive at diagnoses, many unnoticed or undetectable damage to nerves, ligaments and other body parts almost certainly went undetected. Other effects of trapping noted in his study were heat and water stress; stress from risk of discovery and killing by people happening upon them; killing by other predators finding them trapped; and undiagnosed trauma (Ballenberghe 1984). In the same study, a wolf was killed by a cable neck snare when it passed over his chest and closed around his stomach. Long-term effects from broken teeth, severed tendons and poorly healed bones made survival unlikely. This was the case with Wolf 6530, described above, who suffered for many months with an injured paw after pulling free from a leghold trap, becoming weaker and weaker until he died.

Another method tested involved darting animals with tranquilizers from helicopters, which resulted in the euthanizing of a wolf after it became paralyzed when the dart penetrated its spinal column (Ballenberghe 1984). Of the animals darted, 85 percent sustained injuries and soft tissue damage. The Ballenberghe study also cited other research projects with even higher mortalities, and commented, "None of the wolf capture methods discussed here resulted in study animals that were free of injuries, but some methods clearly had more potential to inflict serious injuries than others."

The steel jaw leghold traps that Ballenberghe found to be the most injurious are the very traps that are still used by the Fish and Wildlife Service, Animal Damage Control (ADC)*, state game departments and others, killing wolves and many non-target animals. The US Department of Agriculture's Animal Damage Control program, which traps hundreds of thousands of Coyotes, Cougars and other predators for the benefit of livestock owners, has been responsible for the incidental trapping of endangered and threatened species, from Bald Eagles (*Haliaeetus leucocephalus*) to Gray Wolves.

*Animal Damage Control (ADC) has since been changed to fiWildlife Services.fl

---

Many wolves are trapped by wire snares. A loop of wire pulls tight and cuts through the skin when the animal steps into it or, in the case of a neck snare, it is placed a few feet off the ground and strangles and cuts through the flesh of an animal blundering into it. Most US states allow wire snares, and wolves are taken in them in Alaska. The Alaska Department of Fish and Game has sponsored various control programs or "studies" on wolves, using airplanes, steel jaw leghold traps and, most often, wire snares. The avowed purpose of recent state research, which involved trapping wolves in a large wildlife management area near Fairbanks, was to determine their population and effect on ungulate prey, such as Moose, Caribou and Elk. In fact, this and similar "studies" have been launched after hunters urged the state to eliminate wolves in order to leave more prey species. The rationale of the trapping program is based on the premise that killing wolves will result in increases in the population of these prey animals. A program in the 1970s involved the elimination of wolves from a 3,000-square-mile area, but according to Warren Ballard, a retired game biologist from Alaska, the Moose population did not rebound after wolves were exterminated (Egan 1992). Moreover, it creates an imbalance in the ecosystem. Killing of ungulates by human hunters does not cull the sick and old, but rather the fittest and largest.

In 1992, such a wolf "research" program, involving the setting of thousands of wire snares, was carried out south of Fairbanks. Gordon Haber, a conservationist and wolf biologist who has worked for decades on behalf of Alaska's wolves, brought television crews to film the snaring operation in December 1994. They were shocked by the scene that awaited them. Four wolves had been caught in wire snares, two of them pups. One was dead, and three were still alive, terrified and in great pain. A 6-month-old pup, with its paw caught in a neck snare, had chewed off its foreleg in a futile effort to escape. Another had been snared around the chest, causing deep wounds. The other two had been snared by the leg. All these snares had been set to catch the wolves by the neck and kill them, yet none did. Members of the pack milled about nearby, unwilling to leave their fellows. Two snared Caribou were lying dead nearby. A trapper was filmed as he attempted to shoot the wolves, repeatedly missing or wounding them because he used the wrong caliber ammunition in his gun. He shot one pup five times in the head and body at point-blank range with the

wrong gauge ammunition. The pup, wounded, remained standing. The trapper then reloaded with other ammunition, and this time shot all three wolves fatally.

The film of this massacre was shown on national news programs, causing outrage around the country. Alaska Governor Tony Knowles called off the hunt, ordered a review and stated, "That's no way to treat an animal." Six hundred and eighty-five snares set for this program were removed from state lands, but not before 12 more wolves had been killed. More than 1,000 snares had been set by the state for this "study," which lasted two years. On February 2, 1995, Governor Knowles made public the results of the Gray Wolf kill review. During the program, 134 wolves were snared, 37 of which were found alive and had to be shot. Also caught in the neck snares were Moose, Caribou, Grizzly Bears, Wolverines, Coyotes, Red Foxes, Arctic Hares, Common Ravens and Golden Eagles (AWI 1995). This gruesome haul of non-target animals is typical of the indiscriminate nature of snares.

Governor Knowles canceled the wolf kill indefinitely and ordered a review of Alaska's entire predator-control policy. This "research" program was permanently canceled in February 1995. A biologist with the Alaska Department of Fish and Game admitted in 1997, while appraising the program, that it had been ill-conceived, poorly run and politically motivated. He insisted, however, that wolves had suffered no pain from the snaring and even from chewing off their own paws. This failure to acknowledge proven neurological effects of such injuries is not unusual among state game department officials.

In 1996, the Alaska Department of Fish and Game began a new program to curtail the wolf population in the Fortymile region near Fairbanks. This time, the program consisted of sterilizing the alpha male and female of each of the 15 wolf packs in the area, with plans to relocate all "subordinate" wolves (Trost 1998). The plan to reduce all 15 packs to a single sterile pair was intended to increase the number of Caribou for hunters (Trost 1998). The Alaska Wildlife Alliance strongly opposed this project, and Gordon Haber expressed the opinion that it would reduce the wolves of the area to the brink of extinction (Trost 1998). This research program was described as "based on assumptions" by the National Academy of Sciences.

Alaska's trapping regulations are the laxest in the country, with no visitation requirement, meaning that trappers are not required, as in most states, to check traps daily for animals. Animals suffer in steel jaw leghold traps or snares for days. One case is known of a trapped Lynx--brought food by its mate--that lived for six weeks with its leg caught in a leghold trap.

No state regulations govern the manner in which trapped animals are killed, and trappers often stomp trapped animals to death to obtain pelts without damage--such as that caused by bullet holes--to the pelt. The Alaska Game Department takes advantage of the strong ties between wolf pack mates by requiring trappers of wolves to count the number of wolves in the packs of the animals they trap. Pack mates will usually remain by their trapped pack mate, even when it is dead in a trap.

Wolves, Wild Dogs and Foxes: Page 5

Aerial hunting of wolves was carried out for decades in Alaska by private parties and the Alaska Department of Fish and Game itself. Prior to 1972, wolves could be hunted from airplanes for sport, or by state predator-control agents. Federal legislation was enacted in that year to ban such hunting, with high penalties including confiscation of aircraft, large fines and even jail terms. In fact, Director of Wildlife Conservation David Kelleyhouse, known as "Machine Gun Kelleyhouse," suggested that the best way to control wolves was to machine-gun them. In 1991, a state law was passed in Alaska that allowed shooting of wolves if the aircraft landed 330 feet away from the animals. This legislation was virtually impossible to enforce. Many hunters flew over wolf packs, hazing them until the wolves were too exhausted to escape. Then they would land and kill the wolves. The law failed to protect wolves from this type of

harassment and killing. Among the misuses alleged were trappers checking their trap lines by flying from one set to another, and killing wolves and other predators they saw. Another common practice that was targeted was the "recreational" aerial hunting of wolves. Conservationists in Alaska began a petition campaign to change the law through voter ballot referendum for the November 1996 national election, having failed to persuade the legislature to enact a stricter law. This ballot was openly opposed by many members of the Alaska Department of Fish and Game, who were then chastised for this lobbying by the Governor. The ballot was voted into law by the Alaskan public. The new law states that no one who flies an aircraft to an area and lands, may shoot a Gray Wolf, fox, Lynx or Wolverine on the ground the same day. This closed the loophole left by the previous law.

Wolf hunting is carried out by snowmobilers in many parts of Alaska. Brenda Peterson, an eyewitness to one of these hunts, described it, and photos taken of the event documented the wolves being chased into a tight group and killed (McIntyre 1995). Six black wolves, an entire family, died "splayfooted against one another," having run for their lives at a gallop of 35 miles per hour as the snowmobilers herded them into a terrified, dense mass, and then shot them at point-blank range (McIntyre 1995).

The total kill of wolves by hunters and trappers in Alaska in recent years has declined from 1,600 taken in the winter 1993 to 1994 to 1,180 taken in 1995 to 1996, according to the Alaska Department of Fish and Game. With a total wolf population in the state in late 1995 estimated at about 7,000, the kill represents 17 percent of the total population. This is probably threatening some populations. One race of Alaskan wolves, the Alexander Archipelago Wolf (*Canis lupus ligoni*), an extremely rare subspecies, resides in the heavily logged Tongass National Forest. In spite of various threats, the US Department of the Interior has refused to list the wolf on the US Endangered Species Act (see Forests chapter).

Within the past few decades, wolves have again become resident in several western states. Beginning in the 1970s, a few Gray Wolves crossed the border from Canada into Montana's Glacier National Park where a population of about 100 wolves in 10 packs now lives (Stevens 1997).

Wolves, Wild Dogs and Foxes: Page 6

In the 1990s, the Fish and Wildlife Service began a reintroduction program of wolves into Yellowstone National Park and portions of Idaho and Montana to the north. Historically, wolves were killed to the last individual in Yellowstone National Park by park service personnel under predator-control laws. Their return is a vindication of their importance in the ecosystem. From the start, the project was fraught with difficulties and controversy, with conservationists pitted against one another as to methods and regulations, and many cattle and sheep ranchers opposing the entire project, vowing to kill any wolves that strayed out of the park. Defenders of Wildlife began a fund to repay ranchers for lost livestock, which helped convince some ranchers to accept the project. Of the 14 Canadian wolves released in 1995 in Yellowstone National Park, almost all remained within the park. Two packs produced a total of nine pups, and 17 more wolves from Canada were set free in the park in 1996. The largest of the reintroduced wolves and his mate left the park, and he was gunned down by a drunken man for sport; he skinned this big male and threw the carcass into the brush. Later, the wolf's pregnant mate found the skinless carcass and dug a den beside it. The hunter who, in defiance, sported a shirt reading "Northern Rockies Wolf Reduction Project," spent six months in jail and a year of supervised probation after being found guilty of deliberately killing the wolf.

These Canadian wolves, taken from areas where they were hunted and trapped, experienced a trap- and gun-free environment in Yellowstone National Park. They have adapted well, preying mainly on Elk, which had become overpopulated. Only a few Bison have been taken. Within a few years, the wolves have had major effects on the park's ecosystem. Grizzly Bears have benefited by feeding off the remains of wolf kills, as have ravens, foxes, Bald Eagles and Golden Eagles. The park's aspen trees have also benefited. Researchers from Oregon State University determined

that until the late 1920s, young aspens were able to survive and mature within existing groves, but after the last wolves were killed off about 1926, the aspens began to die out because the overpopulated Elk browsed on these trees in the winter, stunting them. Another change that resulted from the absence of wolves was the disappearance of smaller birds, such as the Calliope Hummingbird (*Stellula calliope*) and Willow Flycatcher (*Empidonax traillii*), from brushy areas that were heavily browsed by the large populations of Elk and other ungulates. Wildlife Conservation Society (WCS) biologists have been researching the many effects of the return of wolves on the park's ecology (WCS 2000).

By 1996, three packs of wolves occupied the park, and a fourth pack of four wolves lived on the park's northwestern border. Their total population in Yellowstone has risen to about 185, exceeding the expectations of scientists (Murphy 2000). Although detractors remain, wolves have garnered a great deal of support. Scientists have come to Yellowstone National Park to study the wolves, some saying it is the best place in the world to see these animals in an open habitat, exhibiting natural behavior. Tourists, likewise, have flocked to see the Yellowstone wolves, bringing $43 million a year to the area, according to Defenders of Wildlife (Rembert and Motavalli 1998). Visitors have been thrilled to see these wolves streak across the grasslands, meet in affectionate, playful groups and raise their melodious voices in group howls. The wolves are expected to be a major tourist attraction in the future, perhaps rivaling the world-renowned geysers. Television films have been made of the wolves, chronicling their reintroduction and pack behavior, and *The Return of the Wolf to Yellowstone*, a book by Thomas McNamee (1997), recounts their reintroduction.

The wolves were released under a special designation of the US Endangered Species Act known as "non-essential, experimental populations," a category that permits authorities to kill them if they are found preying on livestock, or even if they cause adverse effects on wild ungulates such as deer and Elk. It is not legal to kill them for sport deliberately (FWS 1994). As a result, many wolves straying outside Yellowstone National Park have not fared well. One pack of 13 that roamed the plateaus north of the park declined to a single wolf in one year; all but three, who are now back in captivity, died or were shot (Murphy 2000). Several conservation organizations sued the Fish and Wildlife Service to appeal the non-essential designation, stating that there were already some wolves present that would be killed at will because of the designation. Livestock owners also sued the government, requesting that the program be stopped and the wolves be removed. These lawsuits were not heard in federal court until late 1997, after 66 wolves had been brought from Canada to Yellowstone and Idaho in 1995 and 1996.

In December 1997, the lawsuits from both sides of the wolf issue were finally heard in a US District Court, which came to the stunning decision that the Fish and Wildlife Service had violated the US Endangered Species Act by declaring the wolves an experimental population because wolves that might already be present would be denied full protection of the law. The judge ordered that the reintroduced wolves be removed from the park, but stayed his own decision pending appeal. Secretary of the Interior Bruce Babbitt expressed the Department's support for keeping the wolves in the wild. The Fish and Wildlife Service stated that should the decision be upheld on appeal, the wolves would have to be euthanized, as there was no area where they could be released (Chadwick 1998). The decision was appealed and overturned in January 2000, allowing the wolves to remain as part of Yellowstone's ecosystem for the indefinite future.

For the long-term success of the reintroduction of Gray Wolves into this region, the entire Yellowstone ecosystem, which extends well beyond the limits of the national park and other federal lands, should be protected. Already, much prime habitat that was once occupied by wildlife has been converted for agriculture, livestock and homes. Growth of housing and spread of the urban landscape in Jackson, Wyoming, are gobbling up thousands of acres each year. At least one cattle ranch has recently been purchased as a buffer for wolves and bison straying out of Yellowstone National Park. Efforts should be made to acquire more habitat so Yellowstone's wolves and those to the north could be linked through forest corridors to avoid inbreeding and provide space for expanding populations. The Greater Yellowstone Coalition has proposed a program called Y to Y, or Yellowstone to Yukon, that seeks an even more ambitious goal: to link reserves and parks between the two areas, providing a vast wildlife corridor. Much of the land in this linkage area is already federally owned. Grizzly Bears and wolves are among the many wildlife species that

require enormous amounts of habitat, and unless action is taken now, populations of these and other wide-ranging animals will become isolated and inbred.

Central Idaho has 12 million acres of national forest land and was chosen as a release site because of the enormous potential habitat. Opposition to the reintroduction in Idaho was strong, and the state legislature blocked the involvement of the state wildlife department (Robbins 1997). The Nez Perce tribe, which has a strong commitment to preserving the wolf, stepped into the void and became the first Indian tribe to manage an endangered species in an entire state (Robbins 1997). The project is headed by a tribal leader, Jaime Pinkham, a forest biologist who returned to his tribal roots and became manager of the Nez Perce Department of Natural Resources (Robbins 1997). Conservation groups, such as the Gray Wolf Education and Research Center in Idaho, are attempting to change the anti-wolf opinions of local ranchers with films, several penned wolves and other programs. Unfortunately, wolves have been released in Idaho and in Montana, where many have been shot, trapped or died from other causes. They lack the protection of a large national park where hunting and trapping are prohibited, and many ranchers graze cows and sheep in and near the national forests.

Most wolves prefer wild prey, but because of the large number of livestock in the region, the success of these releases may depend on whether the wolves can be conditioned to keep away from livestock. Several of the reintroduced wolves have killed calves in Idaho and Montana, resulting in anger from ranchers who have convinced the Governors and many state delegates to legislate against the program. Fears have even become irrational. Some ranch mothers sent letters to Idaho's Congressional delegation demanding that children be guarded from wolf attacks at school bus stops (Corbett 2000). The Republican delegation from Idaho passed a unanimous resolution at their convention, calling for the immediate removal of all reintroduced wolves (Corbett 2000). Signs urging that wolves be killed were placed in store windows in Idaho. Fish and Wildlife Service biologists killed 82 wolves during the first five years of the program, after complaints from livestock owners (Corbett 2000). Several wolves were shot under questionable circumstances. After a calf was killed, for example, the Service ordered three adult males of the pack killed from a helicopter; sharpshooters, unable to kill the adults, ended up shooting three pups (Murphy 2000). After ranchers reported that a pack had backed a group of his horses against a cliff, the alpha male was removed, leaving his mate alone and the pack without a leader (Murphy 2000).

Some environmentalists protested these killings and threatened to interfere before more wolves were shot (Corbett 2000). David Gaillard of the Predator Conservation Alliance questioned the wisdom or purpose of introducing wolves that needed to be controlled and trained (Murphy 2000). Experiments are underway using electric shock collars that shock a wolf when it comes close to a cow or calf wearing a collar that sets it off. This is a crude approach, which inflicts pain on the wolves and may not even succeed in its intent. Some humane organizations that have protested these collars have rightly stated that almost no efforts have been made to teach ranchers to protect their livestock with sheepherding dogs, pen them in at night and before calving and lambing, and use other means of preventing predation.

Wolves, Wild Dogs and Foxes: Page 7

Historically, the critically endangered Mexican Gray Wolves (*Canis lupus baileyi*) roamed montane woodlands and drylands in northwestern Mexico and extreme southern Arizona, New Mexico and Texas. After centuries of persecution, they disappeared altogether from the United States and verged on extinction in Mexico. In 1976, the subspecies was listed on the US Endangered Species Act, and in 1982, the Fish and Wildlife Service approved a recovery plan in which a professional trapper was hired to capture the last few wild wolves in Mexico. Only five of these wolves were found, and in this 11th-hour rescue, they were live-trapped in Chihuahua and Durango for captive breeding (Brown 1995). They have bred well in captivity and, in 1998, numbered 175 distributed in a number of American zoos (Bass 1998). Through genetic testing, new strains of pure Mexican Wolves have been identified in

Mexican Wolves already in captivity; this adds to the subspecies™ known diversity (Brown 1995). Smaller than northern wolves, males weigh 60 to 70 pounds and females 50 to 60 pounds.

The recovery plan's major goal was to reintroduce Mexican Gray Wolves into portions of their original range in a joint project by the Fish and Wildlife Service, the ADC program which had been responsible for their demise, the US Army, and the state wildlife departments of Arizona and New Mexico (Brown 1995). Surveys conducted in the region determined that most people favored the reintroductions (Brown 1995). Ted Turner, the founder of Cable News Network (CNN) and other cable stations, is New Mexico's largest landowner with more than 1 million acres. He offered one of his ranches, Ladder Ranch, which is near the Blue Range mountains release site, as a holding area and paid an employee to oversee construction of holding pens (Bass 1998). This was supported by his organization, the Turner Endangered Species Fund (Bass 1998).

Although the public as a whole supported the wolf reintroduction, many New Mexican ranchers expressed great antipathy. The national forest release sites allow hunting and trapping. Many volunteers and a grassroots organization, Preserve Arizona's Wolves (PAWS), have worked for decades to bring about this reintroduction and volunteered their time to help on Ted Turner's ranch preparing for the arrival of wolves from two zoos (Bass 1998). In December 1997, four wolves, two sisters and two brothers from separate zoos, arrived at Turner's ranch and were paired off male-and-female in separate pens, where they stayed for several months (Bass 1998). More arrived and spent time in acclimatization pens before release. The release program failed. Of 11 Mexican wolves released in the area, five died, one disappeared and is presumed dead, and five have been returned to captivity near Alpine, Arizona (Sink 1998). One pup born in the wild is missing and presumed dead, since its mother was shot in August 1998 (Sink 1998). A New Mexican rancher is said to have offered $35,000 to anyone who would kill all the wolves returned to the wild (Sink 1998).

Among the wolves that were shot was one of a newly formed--but strongly bonded--pair, Val and Minnie (Bodo 1999). Soon after release from the holding cage, Val was shot by a camper who claimed that the wolf charged at him; a necropsy revealed that the wolf had been killed standing still, broadside to the man (Bodo 1999). The female, Minnie, who had been born at the Rio Grande Zoo in Albuquerque, was pregnant with four pups when her mate was killed. She was returned to her holding pen and began to try frantically to dig and leap her way out of the pen (Bodo 1999). Her pups were born, but all died. At the end of 1998, she was shipped to the Living Desert Wildlife and Botanical Park in Palm Desert, California, where she paced or remained curled up in a spot of dirt, failing to interact with her surroundings or a male put in her pen (Bodo 1999). She was spayed and will remain in captivity for the rest of her life. As for the other deaths, no examples of livestock predation were found. About 140 of these wolves remain in captivity (Nowak 1999).

The reintroduction of Mexican Gray Wolves will be far more difficult than the Yellowstone National Park reintroduction, which involved transplant of wild Canadian wolves. These captive-born wolves have no knowledge of wild survival. They will need to learn how to hunt large prey as a pack, as well as how to survive the many threats humans pose to them. Their intelligence and instincts may be the deciding factors for their survival.

The legal status of the Gray Wolf in the lower 48 states seems destined to change in the near future. The Fish and Wildlife Service wants to change the status of the species from Endangered to Threatened in all but the southwest, where the Mexican subspecies is being reintroduced, and remove the Minnesota wolves altogether from the US Endangered Species Act (Revkin 2000). Minnesota wolves continue to be persecuted, and suffer from parasitic heartworms and deadly canine parovirus disease spread by domestic dogs (Nowak 1999). Delisting undoubtedly will unleash unrestricted hunting and trapping of these animals. Total legal control will revert to the state of Minnesota should this proposal be finalized.

The wolves in the West, from Yellowstone National Park to Idaho, Montana and Washington, would be listed as Threatened when removed from the experimental category. This category has much more flexibility concerning how much protection a species receives. Penalties are lower, and species may be hunted and trapped under the category.

Some ranchers in the West are prepared to eliminate wolves outside national parks. One rancher in Montana installed loud alarms that are triggered by the radio collars used to monitor most of the area's wolf packs (Revkin 2000).

The approximately 3,500 wolves south of Alaska, most of which are in Minnesota, occupy only about 5 percent of their original range, and as a result of prejudice and unfounded fear, these wolves are still being persecuted. Several states have enacted laws banning reintroduction of wolves, which would also apply to wolves crossing over the state's borders. Proposals to reintroduce wolves into Maine or New York have also been met with opposition by many (Higgins 2000). A major education program is needed to allay these fears and to train ranchers to protect their herds and flocks, compensating them for any losses. Although the detractors speak more loudly than the defenders of wolves, the latter probably far outnumber the former in the United States as a whole. It may fall to private conservation and humane organizations to turn the tide in favor of the wolves to return them to a greater percentage of their original range in the lower 48 states.

Wolves, Wild Dogs and Foxes: Page 8

Elsewhere, the history of the Gray Wolf is similar. As early as 300 B.C., Celtic people in the British Isles began breeding wolfhounds for chasing and killing wolves (McIntyre 1995). The King of Scots decreed in the second century B.C. that anyone killing a wolf would be rewarded with an ox (McIntyre 1995). In Anglo-Saxon England, January was designated Wolf Month, to be devoted to the slaughter of wolves; during the reign of King Edgar of England, beginning in 953, a tribute of 300 wolf skins per year was demanded. In 1281, King Edward I hired a man to devote himself entirely to killing wolves (McIntyre 1995). Over the next centuries, wolf extermination campaigns continued in the British Isles, and forests were leveled for livestock grazing and agriculture. The last wolf in Ireland was killed in 1821, and a wolf killed in Scotland in 1848 resulted in the extinction of the species throughout the British Isles (McIntyre 1995).

In France, Emperor Charlemagne founded an order of knights for killing wolves, called the Louveterie, about A.D. 800 (McIntyre 1995). Wolves were exterminated 1,000 years ago in all but remote forests of the French Pyrenees on the border with Spain. By the 20th century, only a handful of Gray Wolves survived in these forests, and apparently they were killed off in the 1950s. In the early 1990s, small numbers of Gray Wolves crossed over the Alps from Italy into southeastern France. In 1999, the French government decided to remove these 40 wolves, killing or caging them, after complaints by herdsmen that the wolves were killing sheep (Newman 1999). Environmentalists claimed the sheep were being killed by feral dogs (Newman 1999).

The last wolf in what is now Germany was killed in 1847 (McIntyre 1995). Within the past decade, a few wolves have entered eastern Germany from Poland, which has a population of about 1,000 wolves (McNamee 1997). Polish wolves have been heavily persecuted for centuries, and only in 1998 did the species receive official protection (Nowak and Myslajek 1999). They occur mainly in eastern mountains where they have come into conflict with livestock owners. An organization, Wolfnet, has been working with livestock owners to compensate them for losses and protect them against predation by wolves (Nowak and Myslajek 1999). Wolfnet travels around the country educating the public, government officials and students about the behavior, biology and intelligence of wolves, attempting to undo the mistaken beliefs that result in many killings of wolves (Nowak and Myslajek 1999).

Scandinavia has nearly wiped out its wolves, with only about 25 in Norway and Sweden and fewer than 100 in Finland (McNamee 1997). In 2001, the Norwegian government allowed the killing of some of the few remaining wolves because of complaints by livestock owners, despite protests from wildlife organizations in the country. An unknown--but small--number also survive in Greenland (McNamee 1997).

In Spain, wolves may total from 1,500 to 2,000, the largest population in Western Europe (McNamee 1997, Binder

2000). They are heavily persecuted there, however. At one time wolves were found throughout the Iberian peninsula, but they are now confined to the northern portions of Spain and Portugal (Bergman 1997). In Portugal, only about 150 survive. The wolves of Spain and Portugal are listed by the *2000 IUCN Red List of Threatened Species* as Conservation Dependent. At least half of rural people in areas where wolves remain in Iberia believe the animals should be exterminated altogether, while another 35 percent want them "controlled," allowing only a few to survive (Bergman 1997). Wolves may be sport hunted in Spain, resulting in the deaths of at least 300 animals a year; added to this mortality, the practice of denning, or killing pups in a den, is legal, and 25 percent of wolves are killed in this manner (Bergman 1997). Luis Mariano Barrientos, a biologist studying Spain's wolves, has documented that they kill relatively few sheep, which are usually protected by mastiff dogs and shepherds. He says that the wolves are killed because of prejudice and persecution, and laments, "It's a national disgrace. A barbarity" (Bergman 1997). A recent study recommended that a strict compensation program be set up. At present, indemnities are paid only if local administrations choose to do so, and many do not (Bergman 1997). This results in great resentment toward wolves. The wolves of Spain survive by stealth, hiding in fallow fields and moving about at night, and when they howl, they risk their lives (Bergman 1997). For long-term survival in Spain, they need a large sanctuary with natural prey species.

Small populations of Gray Wolves still remain in pockets of the Mediterranean region. About 500 wolves survive in Italy, listed as Vulnerable by the International Union for the Conservation of Nature (IUCN). Very little wilderness remains in the country, and wolves have been squeezed into agricultural and livestock grazing areas (McNamee 1997). Their survival until the 20th century is due to an attitude of tolerance, unlike the prejudice and hatred toward wolves so common in Europe. No national extermination campaign was ever launched, and herders corral their sheep at night and protect their flocks with guard dogs (McNamee 1997). Because of a lack of natural prey, such as deer, in the region, these wolves occasionally kill livestock. When this happens, herders put out poison or shoot the wolves. Italian wolves live in pairs or groups of three in most areas because there are no large ungulates to hunt in packs. This has made them quiet, nocturnal and shy. These wolves also prey on small mammals, such as rabbits and marmots (McNamee 1997). Only in a few national parks, such as the Abruzzi east of Rome where about 20 to 30 wolves hunt deer, do they exhibit natural behavior, forming packs and howling (McNamee 1997). Even there, however, sheep are allowed to graze within park boundaries, and sheep owners have been soliciting members of the public to "adopt" a sheep to contribute to the cooperative farm (Stanley 2000). By the 1970s, wolves numbered only a few hundred, but after the government accorded the species full protection in 1976, they began to increase in numbers and range (McNamee 1997). They now occupy the entire country, and if there are livestock losses, owners are compensated and are not allowed to kill the wolves (McNamee 1997). Professor Luigi Boitani, a wolf biologist at the University of Rome, commented at a wolf conference that most of the Italian public is in favor of wolves and more opposed to control programs than some wildlife managers, like himself (Binder 2000). The official protection given to these wolves is far stronger than that given to either the Gray or Red Wolf in the United States.

Southeastern Europe's wolf populations are fragmented, but increasing in some countries. The former Yugoslavia has about 930; Hungary, 50; Romania, which protects the species, 2,500; Bulgaria, fewer than 100; Slovakia, 350; and Greece, 300 to 500 (McNamee 1997). Romania is the only one of these countries where people have a tradition of honoring wolves; sheep in the country are protected by guard dogs, and wolves prey mainly on native ungulates. In some areas the wolves have taken to ranging through city trash piles for food (Binder 2000). Croatia allowed unlimited killing of wolves until 1995 when fines of up to $6,000 were imposed for killing wolves (Binder 2000). This had the counter-effect of encouraging wolf killing, resulting in the deaths of more than 40 wolves, and no one has paid a fine; about 100 wolves remain in the country (Binder 2000).

In the eastern Mediterranean, there are estimates of a few wolves remaining in Lebanon; about 30 in Egypt; 200 in Jordan; 150 to 300 in Israel; several thousand in Turkey; and about 1,000 in Iran (McNamee 1997). In Saudi Arabia, where wolves are killed to protect livestock, hunters often string up a wolf carcass on a pole for all to see (Binder 2000). Dr. Iyad A. Nader of the King Khalid Wildfire Research Center in Riyadh, estimated that up to 700 wolves remain in three protected areas of Saudi Arabia, but elsewhere in the country they have no legal protection (Binder 2000). Wolves are persecuted by livestock herders in all the latter countries.

Just after World War II, there were between 150,000 and 200,000 wolves in the Soviet Union, but beginning in 1947, an intensive government control program drastically reduced their numbers (Nowak 1999). The annual kill was 40,000 to 50,000 until 1962, when it dropped to 15,000; in the 1970s, some 50,000 wolves were estimated to survive in the entire country, including the Central Asian Republics (Nowak 1999). After an increase in wolf populations, a sizeable bounty was paid for killing them; and in 1980, 35,573 pelts were taken through aerial hunting, poisoning and other means (Nowak 1999). fiThe Russian Grey Wolffl (1993, Anderson Video, California) chronicled this bounty hunting and other persecution. In the past 70 years, more than 1.5 million animals have been killed; about 20,000 wolf pelts are marketed in Russia every year (Busch 1995). In the early 1990s, 17,000 men were employed by the Russian government to kill wolves. Since then, the national bounty has been rescinded, and only some state governments pay the equivalent of $25 for a female; the central government no longer encourages poisoning wolves (Binder 2000). In the Russian Far East, a bounty program to kill wolves has been in place for decades, but with the economic chaos following the fall of the Soviet Union, funds to pay the bounties dried up (Specter 1997). A 2001 Cable News Network (CNN) report profiled a government trapper who killed female wolves for the bounty, then raised the orphan cubs for release. The report suggested that persecution continued at high levels and that most Russians wanted the species exterminated.

The Wolf Almanac (Busch 1995) states that some 96 Russian wildlife reserves harbor wolves, and they are hunted actively in 41 of these. They are reported to be safest in certain large reserves, such as the Caucasian, Altai and Pechyora-Ilych reserves, unless they stray outside to prey on livestock (Busch 1995). Wrangel Island in the Arctic Ocean is to be made into a nature preserve with a wolf colony to cull the large herds of Musk Oxen and Caribou (Binder 2000).

Japan's wolves were killed off 100 years ago, and public opinion is negative about their reintroduction. Biologists want them reintroduced to control Japan's overpopulated Sika Deer, which are damaging forests (Binder 2000).

In Kazakhstan and Central Asia, wolves and Saiga antelope have coexisted for eons, but during this century, both have come under heavy hunting. A film, fiThe Saiga of Kazakhstanfl (see Video Section), describes the detrimental effect that wolf control programs have had on Saiga. Wolves are estimated to number between 90,000 and 100,000 in the country, but biologists claim that they kill large numbers of domestic camels, cows and sheep (Binder 2000). Killing wolves is considered a sport in Kyrgyzstan, south of Kazakhstan, where Golden Eagles are used as falconry birds to hunt foxes, badgers, Lynx and wolves (Kinzer 1999).

Mongolia has an estimated 10,000 wolves; China only about 400; and Afghanistan, 1,000 (McNamee 1997). In Tibet, wolves are heavily persecuted by livestock owners, and in the vast Chang Tang Reserve, it is the only species without legal protection. Wolf carcasses can be seen lying next to roads, the animals having been shot by hunters in vehicles, and biologist George Schaller (1998) saw three wolf bodies in a village dump with their jaws wired shut.

India has fewer than 1,000 wolves by some estimates (McNamee 1997), and between 800 and 2,000 in the opinion of Dr. Yadvendradev Jhala of the Wildlife Institute of India. The species is held in great fear by many Indian people, who regard wolves as man-eaters. A century ago, a bounty program resulted in the slaying of 2,600 wolves (Burns 1996). Indian Gray Wolves (*Canis lupus pallipes*) were finally accorded official protection in India in 1992. Rudyard Kipling's *The Jungle Book* tells the story of Mowgli, an Indian orphan raised by wolves. This story may have a basis in fact because many unwanted children are abandoned and placed in the woods, according to *The Wolf Almanac*, and Indian folklore recounts many cases of small children raised by wild wolves (Busch 1995). Such a child was discovered in 1972 at the age of four, apparently having been adopted by a pack of wolves. He was placed in Mother Theresa's refuge for orphans in Lucknow, where he died after seven years (Busch 1995). In spite of such true stories, the average Indian has little but fear and loathing for wolves.

Working to help India's wolves, Dr. Jhala and the Wildlife Institute of India are conducting surveys and appraising their status. For centuries, these wolves have lost habitat and prey species to the country's growing human population. When wolves turned to livestock, persecution followed. Dr. Jhala admits, "It is extremely difficult to conserve a

species when the majority of the human population is opposed to its survival" (*Earthwatch* 1996). Beginning in 1988, Dr. Jhala conducted the first-ever ecological study of Indian wolves for his doctorate at Virginia Polytechnic Institute, with funding from the National Geographic Society and the Smithsonian Institution (*Earthwatch*, 1996). Earthwatch contributed to this research in 1996 with its volunteer program of paying participants in Dr. Jhala's studies. These volunteers followed radio-tracked wolves in the 3,400-hectare (8,401-acre) Velavadar National Park of western India, one of the wolf's last strongholds, observed Blackbuck (*Antilope cervicapra*), Nilgai (*Boselaphus tragocamelus*) and other rare wildlife, and interviewed local farmers through interpreters about their opinions of this species.

Wolves, Wild Dogs and Foxes: Page 9

Official protection from hunting and trapping has been accorded very few wolf populations in the world, even where they are on the verge of extinction. In some areas, however, attitudes are changing, most dramatically in the United States, where documentary films and books on their behavior and importance in ecosystems, as well as recordings of their howls can now be seen in bookstores throughout the country. Superb photography illustrates some of these, most notably *White Wolf: Living with an Arctic Legend* (Brandenburg 1992), which provides glimpses into the lives of these fascinating canids in the Canadian north. Reintroductions of wolves into portions of their former range in the American West bode well for their future, unless the prejudices of many livestock ranchers hold sway. Canada may have the largest population of wolves in the world, estimated at between 30,000 and 60,000, with about 4,000 killed for fur each year (Nowak 1999). According to genetic studies, the wolves of southern Ontario and southern Quebec have apparently hybridized with Coyotes, as have wolves in neighboring Minnesota and Isle Royale, Michigan (Nowak 1999).

The ecotourism potential for wolf viewing in many parts of the world is considerable. In Ontario, Canada, visitors to Algonquin Provincial Park have come to hear packs howl since the 1960s. One of the first wolf conservationists, Canadian wolf biologist Dr. Douglas Pimlott, initiated these tours and educated thousands of people about the biology, importance to ecosystems and behavior of wolves. Their value in attracting tourists and contributing to healthy ecosystems far exceeds that of their pelts.

For some other species of wild dogs, attitude changes may not be enough to save them. The Dhole or Asiatic Wild Dog (*Cuon alpinus*), a small canid the size of a Coyote, is native to Asia, from southern Siberia and Central Asia east to India and Indonesia (Nowak 1999). This wild dog has rusty red fur on its upper parts, and white on its chest and belly. Hunting in large packs, Dholes pursue large prey, such as deer, wild pigs, antelope and wild sheep (Nowak 1999). Their social structure is not well known but appears similar to the Gray Wolf's, with a leader and lower-ranking members of the pack (Nowak 1999). Although Dholes seldom take livestock, they have been poisoned intensively and hunted throughout their range; they are also persecuted by hunters who regard them as competitors for game species (Nowak 1999). Dholes have disappeared from much of their habitat, and the *2000 IUCN Red List of Threatened Species* lists the species as Vulnerable, the category below Endangered, indicating a serious decline.

Similar in appearance, the Simien or Ethiopian Wolf (*Canis simensis*) is endemic to Ethiopia. Scientists were unsure in the past whether this animal was a dog, a wolf, a jackal or a fox. Most zoologists now describe it as a wolf. It may be related to the small race of Gray Wolf, *Canis lupus arabs*, that inhabits the Arabian Peninsula across the Red Sea (Nowak 1999). Simien Wolves have a head and body length of about 3 feet, are about 2 feet tall at the shoulder, and weigh from 11 to 19 kilograms (Nowak 1999).

The only wolf not preying on animals larger than itself, such as deer, but living in packs, Ethiopian Wolves feed mainly on small rodents (Gottelli and Sillero-Zubiri 1994). Once their range was far greater, encompassing most of Ethiopia's highlands, but with the development of agriculture and spread of livestock grazing, these wolves lost the majority of their habitat and came under totally unmerited persecution as a threat to domestic animals (Nowak 1999).

Today, they have become restricted to only about six locations in the Ethiopian highlands. Discovered in the Simien Mountains of the northwest, the subspecies, *Canis simensis simensis*, was estimated at only about 40 animals in the 1980s. These wolves are so shy that even in the Simien Mountains National Park they have become nocturnal and stay in burrows when humans are in the vicinity. A crew from Survival Anglia, a British nature film company, spent weeks in the early 1990s seeking to photograph the Simien Wolves in this park, finally having to settle for a long-distance view of a solitary wolf.

Wolves of the Bale Mountains, separated by hundreds of miles, are larger and redder than the Simien Mountains race, and this subspecies, *Canis simensis citernii*, is somewhat more numerous than the other race. Only about 440 Simien Wolves were thought to survive in the Bale Mountains in the early 1990s, with perhaps another 100 in the Simien Mountains (Gottelli and Sillero-Zubiri 1994). Today, estimates are even lower. The Bale Mountains population is estimated at 270 to 370 animals, and 70 to 150 survive in the Simien Mountains (Nowak 1999). This species is thus at the edge of extinction. It is listed as Critical in the *2000 IUCN Red List of Threatened Species*, protected by law in Ethiopia and listed as Endangered on the US Endangered Species Act.

The Wildlife Conservation Society (formerly the New York Zoological Society) has funded research projects on the Simien Wolf for many years, including the studies of two zoologists, Dada Gottelli and Claudio Sillero-Zubiri in Bale National Park. Simien Wolves use their long legs to dig into rodent tunnels, aided by their acute senses of hearing and smell. In Bale Mountains National Park, 14 rodent species are native and three dominant species are endemic to the region, providing a huge food base for the wolves. They specialize in preying on the endemic Ethiopian Mole Rat (*Tachyoryctes macrocephalus*). The mazes of tunnels that these rats excavate aerate the soil, creating rich topsoil which nourishes the lush grasses in this highland ecosystem. The wolves have been seen hunting cooperatively, chasing young antelope and hares (Nowak 1999).

Livestock grazing is allowed in Bale Mountains National Park, and Simien Wolves wander among the cattle, presenting no threat. The wolves in this park have not been persecuted, unlike those elsewhere in Ethiopia, and do not hide from people. Filmmakers shooting the 1990 BBC film, fiKing Solomon's Mountains,fl found the wolves in the open during the day, with adults hunting rodents, and pups playing wrestling games. Like other wolves, they are extremely affectionate with one another and yip in group choruses, sounding like Coyotes. Packs range in size from five to 13 animals, and they defend territories. As in Gray Wolf packs, only one female in the pack breeds, and because of limited habitat, nonbreeding females often stay with the pack, acting as "aunts" instead of leaving to begin their own packs (Gottelli and Sillero-Zubiri 1994).

Domestic dogs, brought into Bale Mountains National Park by the Oromo people to protect their flocks of sheep and cattle from hyenas, are a major threat to this species (Gottelli and Sillero-Zubiri 1994). Wolves have succumbed to diseases introduced by these dogs, which are not fed but set free to fend for themselves. Between 1992 and 1995, the Bale Mountains wolves were decimated by an outbreak of canine distemper acquired from these dogs, reducing the wolves from 240 to 140 (Anon. 1996). In the mid-1990s, more died of rabies. An even more ominous threat is their interbreeding with domestic dogs. The film fiKing Solomon's Mountainsfl showed a pack of wild Simien Wolves led by a large black dog that had become the lead female. Another film, fiLast Wolves of Ethiopia,fl shown on a National Geographic Explorer program in early 1998, recounted the story of a young female Simien Wolf who was ousted from her pack and, after a few years of wandering, paired with a hybrid wolf-dog. In general, male domestic dogs have bred with female wolves, diluting the genetic integrity of this highly endangered animal (Gottelli and Sillero-Zubiri 1994). Some populations of pure Simien Wolves are showing signs of inbreeding, due to their small genetic base. The combination of these threats has led scientists to predict imminent extinction for this beautiful wild dog.

To prevent their extinction, attempts are being made to convince the Oromo tribespeople to control their dogs, but scientists have concluded that captive-breeding may be the only way to save the species (Gottelli and Sillero-Zubiri 1994). There is no possibility of preventing these people from entering the park because of the tribe's centuries-old ties with this region and the potential of bad relations with them that could have serious repercussions on the conservation of park wildlife (Gottelli and Sillero-Zubiri 1994). As a means of controlling the domestic dogs, they could be

neutered, vaccinated against disease, and provided supplemental food to prevent their attacking native ungulates in the park. A vaccination program has recently been carried out in the Serengeti, where domestic dogs transmitted canine distemper that killed one-third of the Lions in the region.

The South American Maned Wolf (*Chrysocyon brachyurus*) has also declined, although not as drastically as the Ethiopian Wolf. This long-legged wolf, weighing only about 44 pounds, hunts in the tall grasses of pampas and llanos, and eats rodents and other small mammals, birds, reptiles, insects, fruit and other vegetation (Nowak 1999). With shaggy red fur and black legs, it has been called a Red Fox on stilts. It is the sole member of its genus and the only wolf in Latin America. The Falkland Island Wolf (*Dusicyon australis*), native to the Falkland Islands off Argentina, became extinct in 1876 after large numbers were killed by fur traders and poisoned by sheep ranchers (Allen 1942). The size of a large Coyote, it may have evolved from foxes. Maned Wolves have been falsely accused of killing livestock, and persecution has caused them to disappear from Uruguay and most of Argentina. They have become rare in Brazil and the rest of their range in south-central South America. The Maned Wolf is listed on the US Endangered Species Act as Endangered and on the *2000 IUCN Red List of Threatened Species* as Near-threatened.

Wolves, Wild Dogs and Foxes: Page 10

Small predators also underwent persecution in North America in the late 19th and early 20th centuries. Two tiny western foxes that were once considered to be the same species, the Swift Fox (*Vulpes velox*), native to shortgrass prairie, and the Kit Fox (*Vulpes macrotis*) of intermountain and desert grasslands further west, both declined as a result of predator-control programs. Both are shades of tawny, reddish-brown and tan, stand about 1 foot tall, measure 23 to 31 inches long, and weigh less than 5 pounds (Nowak 1999). Although not considered threats to cows or sheep, foxes traditionally have been killed because of their possible threat to poultry. In wilderness areas, they have been killed merely because of predator prejudice. These foxes subsist on small rodents and even insects, such as grasshoppers, and are, therefore, beneficial.

The Swift Fox was named for its speed when streaking across the prairie, clocked at about 25 miles per hour (Turbak 1993). The Canadian populations of the Northern Swift Fox (*Vulpes velox hebes*), native to southern Saskatchewan, Alberta and Manitoba, and the northern edge of the shortgrass prairie that once stretched to Texas, are listed as Endangered on the US Endangered Species Act but are extinct. They disappeared from the wild by the 1930s, after control programs were implemented, and Canadian wildlife authorities have reintroduced Swift Foxes of a related subspecies from Colorado, Wyoming and South Dakota (Nowak 1999). Some reproduction has taken place.

Swift and Kit Foxes began to decline in the 19th century, and Ernest Thompson Seton commented on the vulnerability of this species: "Harmless to man and mankind's interests; and yet he is going fast with all the other innocent and lovely wild things. Yes, faster than most, for he is the least cunning of our foxes--so guileless that he readily takes the poisoned baits used nowadays for killing coyotes" (Seton 1899). In fact, almost none of these foxes was seen in the wild from the early 1920s to the late 1950s, a period of heavy predator-control and poison campaigns (Chambers 1978). Both species have lost the majority of their habitats to agriculture. In North Dakota, the state lists the Swift Fox as an endangered species, with no breeding populations. The last known occurrence of the Swift Fox in this state was in the mid-1980s (Turbak 1993). Further south, this species is known to survive in southwestern Kansas, Nebraska, Montana, Wyoming and South Dakota (Chambers 1978). Some areas of unplowed prairie provide refuge. This fox has been able to colonize on roadsides next to fields and in the few remaining unpoisoned prairie dog towns. Some research has been carried out on the wild behavior and habitat needs of Swift Foxes in the Midwest, and there is room for cautious optimism that increased attention to this little fox will result in strong legislation to preserve it and prevent persecution and poisoning. Author Glenn Chambers was researching an article for *Audubon* magazine, "Little Fox on the Prairie" when he saw a fox family being killed by two farmers who poured gasoline in the den entrance and set fire to it. The male fox, provider of food for the vixen and pups, was found in a ditch a few yards away, his rib

cage ripped out by a high-velocity bullet (Chambers 1978). The vixen had escaped the burning den with two of the pups, but the farmers shot her as she watched over them (Chambers 1978).

Kit Foxes occupy deserts, dry grasslands, and montane areas with scattered trees from Utah north to Washington state and west to California. They prey mainly on kangaroo rats and other small rodents. A subspecies from southern California known as the San Joaquin Kit Fox (*Vulpes macrotis mutica*) is listed on the US Endangered Species Act as Endangered. Settlement and farming of the region reduced their habitat, and predator control has eliminated entire populations, causing them to dwindle to a few thousand animals. This delicate, little buffy-yellow fox is now restricted to a tiny remnant of its once immense habitat of mixed grasslands, deserts and shrub in California. Their original range stretched from San Joaquin and Stanislaus counties in the north to Kern County in the south. They probably numbered at least 12,000 prior to settlement (Turbak 1993). Tame and trusting, they became targets for hunters; even schoolboys with rifles have been seen shooting them as sport (Turbak 1993). One hunter was seen shooting a pair's tiny cubs one after another as they played at the den entrance, then killing the mother when she emerged to protect them (Turbak 1993).

Foxes have been considered threats to livestock and domestic poultry by European settlers. The Cape Fox (*Vulpes chama*) of dry country in southern Africa was the object of control programs by European settlers under the misapprehension that it preyed on domestic poultry. This resulted in declines in the numbers and range of this small, silvery-gray fox (Nowak 1999). The Hoary Fox (*Lycalopex vetulus*) of south-central Brazil, an endemic species of savannah grasslands, is persecuted by local people for presumed predation on domestic fowl (Nowak 1999). Although very shy, it courageously defends itself and its young when threatened (Nowak 1999). Little is known of its status, listed as Data Deficient by the IUCN. Argentine Gray Foxes (*Dusicyon griseus*), native to Patagonian grasslands, have been poisoned by livestock owners who distribute strychnine bait. Their populations have declined in many areas as a result, and thousands of non-target mammals and birds have died from these poisons. Such poisoning is illegal in Argentina, and efforts are being made by biologists and conservationists to stop this senseless killing.

Eight species of foxes are listed as Data Deficient by the *2000 IUCN Red List of Threatened Species*, and two species as Conservation Dependent. This is an indication of the lack of research on these ecologically important species, which perform the important role of consuming large numbers of rodents. Red Foxes (*Vulpes vulpes*), native to North America, Eurasia and northern Africa, have been persecuted as well, hunted as sport in England and parts of the United States, and killed by many farmers and livestock owners. One Midwestern town even rounded up these foxes once a year and beat them to death with sticks. After a *Life* magazine article describing this cruel persecution and the resulting public outcry, it ended. Fox hunting in England may end in the near future as the Parliament has voted to stop this cruel activity.

Bears

The immense Grizzly or Brown Bear, which once roamed the prairies and woodlands of western North America, inspired awe and fear in explorers and settlers alike. For thousands of years, Native Americans revered this bear. The Cree called it a four-legged human, and other tribes considered it a brother or cousin. They felt a kinship based on its intelligence and respected its great strength. They could not easily hunt it with bows and arrows, and when wounded, it showed great courage defending itself, able to cause severe injuries or death with its 5-inch claws.

The Grizzly reigned as the fearsome and unchallenged king of all wildlife on the continent, numbering at least 100,000 prior to the arrival of Europeans (Nowak 1999). These extremely adaptable bears lived in every western North American habitat except deserts. Arriving from Asia by way of the Bering Strait 12,000 years ago when sea levels were lower, Grizzlies gradually colonized western regions, the biggest of an array of large carnivores that inhabited the continent at that time, including dire wolves, hyenas and sabre-toothed cats. They survived the frigid and

harsh climate of the Pleistocene Ice Age. They thrived in prairies, especially those with scattered woodlands. In the 1500s, their range extended from the Arctic tundra south through the shortgrass prairie to the pine forests of northern Mexico, and west to the Pacific Ocean. In fact, the original range of the Grizzly Bear may have been larger than previously thought, reaching east to the Atlantic in Canada. A Grizzly skull has been found in a midden of the late 18th century, and pelts of these bears reportedly were taken in Labrador as late as 1927 (Nowak 1999).

Grizzly Bears of North America and Brown Bears of Eurasia were previously considered separate species, but today they are classified as a single one, *Ursus arctos*. The bears that live along the southern Alaskan coast and offshore islands, such as the Kodiak, are the world's largest carnivores (Nowak 1999). Weighing up to 780 kilograms (1,716 pounds), Kodiak Grizzlies have a shoulder height up to 1,500 millimeters (58.5 inches, or almost 5 feet), and a body length ranging up to 2,800 millimeters (109.2 inches, or 9 feet) (Nowak 1999). Standing height can be almost 12 feet. Adult males are larger than adult females. North American Grizzlies are far larger than bears of the same species native to southern Europe, which average only 70 kilograms (154 pounds) (Nowak 1999). Grizzlies of the northern portion of the lower 48 states are only somewhat smaller than the Alaskan bears, while those native to Arizona, New Mexico and Mexico, all now extinct, were smaller still, weighing less than 1,000 pounds.

Reproducing at a very slow rate, Brown Bear females have an average of two cubs only once every two to four years, and the cubs stay with their mother for this entire period (Nowak 1999). On occasion, only one cub is born, and sometimes up to four. If the mother is killed at any time before the cubs leave to be on their own, the cubs will also die because they are unable to fend for themselves, destroying two generations. The training period of these bears is extremely long, an indication of their slow maturation and the complexity of learning about food sources and other keys to survival. Another reason for this long apprenticeship is the potential of attacks by male Grizzly Bears. Until a young bear is 3 years old or older, it is not large enough to withstand an attack by an adult male, requiring the protection of its mother. Males continue to grow until they are 10 to 11 years old, and may provoke fights with younger bears to chase them from the territory, which prevents inbreeding. Females remain fertile until well into their 20s. Females in the Yellowstone region are known to live to be 25 years old, and Grizzly Bears may have the potential to live 50 years in captivity (Nowak 1999). They do not reach sexual maturity until they are at least 4 to 6 years old. These bears have a low natural death rate, and when combined with their slow reproduction, they are very vulnerable to extinction should they suffer high mortality.

A large habitat requirement is another aspect of their vulnerability. In the Arctic, a single Grizzly requires more than 100 square miles of tundra, and in the Yellowstone area, each bear occupies about 88 square kilometers (Nowak 1999). In regions where they are distributed sparsely, they can be eliminated easily, and even where they are more numerous, persecution and trophy hunting have caused local extinctions.

The strength, intelligence and size of the Grizzly, which have served it so well for thousands of years, were no match for European guns. Explorers, trappers and, later, settlers, slaughtered thousands of Grizzlies, killing them on sight. The first to disappear were the bears of the Great Plains, where the landscape was open and provided little cover. In some cases, these bears showed almost mythic strength upon being shot. Meriwether Lewis of the Lewis and Clark expedition of 1804 reported that one wounded bear ran at a fast clip for nearly a quarter of a mile before it fell dead after being shot through the heart (Peck 1990). Persecution of bears often includes the killing of their cubs. Early in the 20th century, President Theodore Roosevelt refused to kill bear cubs pointed out by his hunting guide, and when this was publicized in newspapers, he became a folk hero as a result. Toy manufacturers took advantage of the story by producing stuffed animal "Teddy Bears," which remain popular today. President Theodore Roosevelt left a legacy of destructive trophy hunting, however, including the killing of many adult bears.

Settlers moving into the West hunted these bears, and during the late 19th and early 20th centuries, government predator-control agents began campaigns to eliminate these bears. Much of the zeal with which the bears were slaughtered was based on a misconception: they were thought to be vicious man-eaters. In fact, they are mainly vegetarian and only occasionally kill animals for meat. The most common animals killed by Grizzly Bears are various types of rodents, such as ground squirrels and, in some areas, fish. Elk calves are killed as part of their diet in some

areas. The staple foods of the Grizzly diet are green shoots, sedges, clover and lilies early in the spring and, later in the summer, berries, roots, fruit, acorns and nuts, with occasional rodents (Peacock 1996). These bears do not consider humans to be natural prey, and attacks are rare. Prejudices dominated, however, and hunters who killed them were considered heroes and rewarded with bounty money. To protect their livestock, ranchers insisted that government hunters kill off every Grizzly Bear, and after several centuries of uncontrolled hunting, trapping and poisoning, the bears became extinct in their vast original realm south of Canada except for a few hundred animals protected in Yellowstone and Glacier National Parks.

All 26 subspecies of Grizzly Bears south of Canada and Alaska, except *Ursus arctos horribilis*, became extinct by the 1950s, and some disappeared during the 19th century. The latter subspecies, named from specimens obtained in northeastern Montana, barely survived. In fact, *Ursus horribilis* was the species' scientific name until recently, an indication of the prejudice against it. Now considered a subspecies, *Ursus arctos horribilis* is listed on the US Endangered Species Act as Threatened, and this subspecies is used to indicate all Brown Bears in the lower 48 states.

Grizzly populations still occupy only 1 percent of their original range in the lower 48 states and number fewer than 1,000 (Nowak 1999). This includes Yellowstone and Glacier National Parks, whose protection prevented their total extinction south of Canada, a few wilderness areas in Idaho, western Montana, and Washington. Human activities such as road building disturb them and cause them to desert otherwise prime habitat. They are no longer the fearless animals that Lewis and Clark encountered, but have become very shy outside of national parks after centuries of persecution. Although they may pose a potential threat to humans who enter their last retreats, people are a far greater threat to them.

Their rugged wilderness habitat in Montana is being developed rapidly, and Grizzly populations, which had risen somewhat after their listing on the US Endangered Species Act, are now in danger of disappearing again. Added to this, some ranchers in the region still persecute them. A prime habitat for Grizzly Bears, the 329,000-acre Swan Valley of northwestern Montana borders the Bob Marshall Wilderness area, a country of open grassland and forest with breathtaking mountain views. Until recently, this landscape remained almost unchanged from its original state. Ranching, road building and other activities, and an increasing human population in this region, however, are now ruining its wilderness character and threatening the Grizzlies (Pelletier and Servheen 1995). Through cooperation with local residents, the Fish and Wildlife Service is identifying important habitat areas and linkage corridors for the Grizzly Bears in this part of Montana to prevent conflict with humans. These zones would be a link between the small population of bears in the Mission Mountains to the west and those in the Bob Marshall Wilderness area (Pelletier and Servheen 1995). The land is a checkerboard of ownership by private individuals, state, federal and corporate entities; in an unusual project, all private and public lands will be included in a management plan, with input by local citizens (Pelletier and Servheen 1995). These bears remain under the continual threat of being shot by ranchers fearful for their livestock and apprehensive about possible land restrictions in areas where Grizzly Bears are resident. Sport hunting of this small population is also allowed.

Grizzly Bears are still depicted in the media as dangerous man-eaters, resulting in a prejudiced view by the American public. A number of television programs produced by the National Geographic Society, CBS, the Discovery Channel, Fox and others have perpetuated this image. With titles such as "Dangerous to Man!," "Bear Attacks" and "Man-eaters," these programs often demonize the bears and interview people who have been attacked while camping in the bears™ habitat. Very few such attacks have occurred, and almost none has been fatal. After centuries of being shot at and harassed by humans, Grizzly Bears tend to avoid people. When camping inside national parks where Grizzlies are resident, special precautions must be taken, and it should be kept in mind that the parks are *their* home, and humans are the intruders. The national parks, where hunting is banned, are their only refuge. Some documented cases of attacks have occurred when a mother bear felt her cubs were threatened by humans, especially if they approached the cubs. Mother Grizzlies may be the fiercest protectors of their young in the animal world, a trait that should be admired from a distance. Television programs that sensationalize the potential threat of animals do not note the hundreds of Grizzly Bears killed by humans every year in North America. They also fail to show the many bears that are merely wounded by hunters and suffer a long death, or the cubs that are orphaned and die of starvation.

The irrational fear and hatred aroused by misinformation often result in mortalities to these bears by armed tourists and residents in their range who misinterpret the bears' behavior. Many bears have had to be destroyed because tourists fed them, and they became fearless, capable of swiping food or destroying tents and property. Information on avoiding Grizzly Bear encounters is available from National Park Service rangers, other federally employed biologists, and many conservation and humane organizations. Only with tolerance, respect and an informed public concerned about preserving these bears can they survive.

Ecotourism in the threatened and unprotected portions of the Grizzlies™ range is in the early stages of development. Portions of the revenues from tours could be spent to acquire habitat and conduct local education programs. In Alaska, this has been highly successful, with tourists coming from around the world to see these bears fishing for salmon. Montana has some of the most spectacular scenery on the continent, sweeping vistas and vast open spaces that rival those of East Africa. They could be a magnet for tourists anxious to see Grizzly Bears and other native wildlife against a background of snow-capped peaks. Unfortunately, much of their prime valley habitats have been taken over by ranchers and private homes. The tourism in the area has been of a highly commercial and exploitative nature. For example, in some Montana towns, tourists see many stuffed Grizzlies in local businesses, and one can have one's photograph taken posed in a cutout painting of a Grizzly Bear appearing to attack.

If sizeable portions of Montana valley habitats were acquired for the Grizzly Bears, tourists could be taken on van tours, similar to those that now operate in East Africa. For the more athletic, groups of tourists could be taken on guided walks into the high country. Portions of the funds from the tours could be used to purchase privately owned land, to fund public education about these bears and their survival, and to compensate ranchers for livestock losses. The Nez Perce tribe is working with the Fish and Wildlife Service on a project to reintroduce the Grizzly Bear into the Selway Bitterroot wilderness of Idaho and Montana, another magnificent area for ecotourism (Robbins 1997).

Plans to reintroduce Grizzlies into the 1.9 million-acre San Juan National Forest in southwestern Colorado have sparked controversy and prejudice (Papich 2000). Decades after Grizzlies disappeared from the state, the Fish and Wildlife Service reintroduction project has been applauded by local conservation organizations, such as the Colorado Grizzly Project, and opposed by ranchers and even hiking groups who fear attacks (Papich 2000). Returning the Grizzly Bear to portions of its former range in the lower 48 states, even into immense wilderness areas, will be a slow process, possible only after extensive education and a change in the accepted practice of releasing livestock in national forests without sheepdogs, herders or other protections.

The Mexican Grizzly (*Ursus arctos nelsoni*) persisted in the remote mountains of northern Mexico until it was poisoned, shot and trapped to extinction in the late 1960s (Day 1981). This race was smaller than northern Grizzlies, weighing about 700 pounds. Quite numerous and widespread, the Mexican Grizzly had an enormous range in the pine forests of the northeast until efforts began to exterminate it. Only about 30 animals remained by 1960. Although some individuals tried to protect these last bears, others set out to destroy them, and a campaign of poisoning, trapping and hunting, sponsored by ranchers, resulted in the killing of the last animal in the early 1960s (Day 1981). In 1968, biologist Carl Koford conducted a three-month survey in the isolated mountain canyons of Chihuahua where they had last been seen, and he saw no sign of Grizzly Bears (Day 1981). Subsequently, they were declared extinct.

Hunters in many parts of the Grizzly Bear's range in Canada kill the species in such numbers that many biologists consider it to be threatened there. The Canadian Broadcasting Company's "Nature of Things" program produced a film, fiGrizzlies: Losing Ground,fl which painted a dim picture of this bear's future in Canada. They are killed by ranchers and hunted for trophies and for their gallbladders, which are used in Traditional Medicine. Many are killed by park rangers merely because they come too close to tourists. They are being driven from their wilderness homes by unrestricted logging and mining as well.

Brown Bears are already extinct in North Africa, Austria, Belgium, Denmark, Germany, Israel, Jordan, Lebanon, Liechtenstein, Luxembourg, the Netherlands, Portugal, Switzerland, Syria and the United Kingdom. They are

endangered in the few countries where they remain in Western Europe. In Scandinavia, there may be as many as 700 Brown Bears, with populations of less than 1,000 in Slovia, Romania and Bulgaria, and possibly 2,000 in the former Yugoslavia (Nowak 1999). Fewer than a dozen Brown Bears survive in France's Pyrenees Mountains where, despite protests from around the world, a major highway was built through the center of their habitat. Brown Bears are heavily persecuted throughout Eurasia for body parts, especially gallbladders. They are considered endangered in Central Asia's mountains where *Ursus arctos isabellinus* occurs, a CITES Appendix I race, and the Tibetan Brown Bear (*U.a. pruinosus*) is listed as Endangered on the US Endangered Species Act. Outside Russia, only about 4,500 to 7,600 of these bears remain in China, and isolated populations survive in Mongolia, northern Japan and Turkey (Nowak 1999).

The South American Spectacled Bear (*Tremarctos ornatus*) is classified as Vulnerable by the IUCN, with persecution by ranchers a major cause (Nowak 1999). These 300-pound black bears have large circles of white fur around the eyes and white circular markings on the neck and chest. They feed on fruit, bamboo hearts, corn, and other vegetation with about 4 percent of their diet composed of rodents and insects (Nowak 1999). Spectacled Bears are native to the Andes of western Venezuela, Colombia, Ecuador, Peru and western Bolivia. This high-altitude, shy bear is active mainly at dusk and at night and poses no threat to livestock, yet ranchers and landowners have persecuted and hunted it in Peru and other countries because of the mistaken belief that it kills livestock (Nowak 1999).

With the destruction of their high-altitude, humid forest and grasslands replaced in many areas by agriculture, some bears have raided corn fields to survive; many of these bears have been shot by farmers (Nowak 1999). This bear is declining throughout its range, and few areas remain where it can forage without being hunted, either by livestock ranchers, farmers, or for its body parts to sell to Asian markets for traditional medicine. Only a few national parks exist within its range, and populations have become fragmented and isolated from one another. A biological study of these bears in Bolivia by British zoologist Susanna Paisley is uncovering new information about their natural history and the threats posed by radio-tracking. A film about her study and the local people helping her, fiBears of the High Andes,fl was shown on a National Geographic Explorer television program in 1998, providing a unique glimpse into the lives of these rare bears.

Otters

The Eurasian or Common Otter (*Lutra lutra*) has been persecuted since the 13th century in Britain, and a dog, the Otter Hound, was bred to hunt it (Chanin 1985). This otter was officially designated as a pest by a 1566 English law, which authorized local constables to offer bounties for their destruction because of their supposed predation on fish (Chanin 1985). At that time, fish ponds on the estates of the wealthy were stocked to supply the tables of the affluent (Chanin 1985). They were also thought to be competitors with fishermen for game fish such as trout. For hundreds of years, high bounties were paid, contributing to their disappearance from many areas (Chanin 1985). Hunting otters with dogs was the only effective manner of pursuit, and in the 16th century, the Assembly of Norwich decreed that fishermen should conduct two or three otter hunts per year to avoid being fined (Chanin 1985). Estate game keepers continued over the centuries to persecute these playful animals in the British Isles, pushing them close to extinction.

In Europe, prejudices are gradually fading, but the Common Otter, despite its name, is no longer common. It has declined drastically in Britain and most of western Europe, and is rare throughout much of its range elsewhere in eastern Europe and Asia as a result of continued persecution, fur trapping, habitat loss and chemical contamination of its environment (Chanin 1985). This species is listed on Appendix I of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), the category designating species in danger of extinction, and in which commercial trade is not allowed between the Party nations. The *2000 IUCN Red List of Threatened Species* classifies the species as Vulnerable. An increasing number of people are becoming acquainted with this delightful

animal. Not until 1978 did the otter receive official protection from hunting and trapping in England and Wales, and in the intervening years, a strong "Save the Otter" campaign, begun by Friends of the Earth, has had positive results (Chanin 1985). Surveys completed during the 1970s found that otters had become extremely rare in England, and were in steep decline. In parts of southwestern England, otters are now increasing with legal protection, and they are being reintroduced into areas where they had been hunted or trapped out. In 1982, protection was added in Scotland, in spite of continued opposition from otter hunters and those who harbored old prejudices (Chanin 1985). In the Netherlands, reintroductions of otters are returning them to long vacant habitat.

Izaak Walton's views of the otter were not scientifically refuted until the 20th century. Best known as the author of the 17th century book, *The Compleat Angler*, a compendium of information about fishing in England, he quoted a fishermen of the times: ". . . my purpose is to bestow a day or two in helping to destroy some of those villainous vermon; for I hate them perfectly, because they love fish so well, or rather, because they destroy so much, indeed, so much, that in my judgment, all men that keep otter-dogs ought to have pensions from the King to encourage them to destroy the very breed of these base otters, they do so much mischief." Scientific studies of otter diets established that these animals did not pose threats to game fish populations. A 1942 study found that North American River Otters (*Lutra canadensis*) prefer slow-moving forage fish, such as suckers, mudminnows and sticklebacks, to fast-moving trout. Some game fish are taken, but subsequent studies established that such fish make up a small percentage of the otter's diet. A 1955 study by biologist Richard Ryder examined stomachs of River Otters (*Lutra canadensis*) trapped in Michigan and found forage fishes (primarily mudminnows) in 56 percent, crayfishes in 22 percent, amphibians in 17 percent, insects in 13 percent, and trout in 13 percent of all otters examined. Ryder concluded that otters are opportunistic feeders, catching prey items in proportion to their abundance and in inverse proportion to their swimming ability. Thus they benefit game fish by removing overpopulated fish species that compete with trout for food from streams and waterways. In a dramatic demonstration to illustrate its food preferences, a River Otter was placed in a large tank with both trout and crayfish. Ignoring the fast-moving trout, the otter went directly for the crayfish.

Other species of otters also have been found to prefer slow fish, especially bottom-dwellers not desired by either sport or commercial fishermen. Yet they are still being persecuted in many parts of the world. The Marine Otter (*Lutra felina*), a small otter native to the Pacific coast of western South America, has been so persecuted by fishermen for alleged damage to fisheries (Nowak 1999) that it is now listed as Endangered on the *2000 IUCN Red List of Threatened Species*. The Sea Otter (*Enhydris lutris*), protected from previous hunting for the fur trade, began to recover its numbers in the North Pacific, but has recently declined to Endangered status as well as a result of persecution by fishermen, oil spills and predation by Killer Whales.

One young California Sea Otter filmed by Jacques Cousteau became very tame, cavorting with the cameramen and allowing itself to be petted. A few days after the Cousteau crew left the area, this young otter washed up dead on the beach, having been shot. It was conjectured that this friendly otter had approached a boat with fishermen who shot it. Fishermen have overharvested abalone beds for these extremely valuable mollusks and blamed Sea Otters for depleting them, yet abalone form only a small part of their diet. Some Sea Otters eat no abalone at all, specializing in other foods. Moreover, they eat sea creatures that prey on the kelp, without which abalone and other wildlife would not flourish. This species is considered a positive element in the ecosystem.

River Otters in North America were persecuted by European colonists, many of whom shot them on sight. These animals, described by early explorers as highly visible, bold and playful, became shy, secretive and nocturnal after centuries of persecution and fur trapping in the United States and Canada. By the 1950s, they had disappeared altogether from vast areas in the country, from Pennsylvania south to northern Georgia and throughout the Midwest south of Michigan and Minnesota, west to Utah (Nilsson 1985). Beginning in the 1970s, reintroductions of otters live-trapped in Canada, Michigan and other areas where they are still relatively common, have taken place in West Virginia, Arizona, Tennessee, upstate New York, Missouri and several other Midwestern states. In some cases, the reintroductions have failed, but for the most part, the North American River Otter is on the way to reoccupying its original range.

Otters are not regarded benignly by fish hatchery managers and commercial catfish farmers in the South. State Fish Departments and the Fish and Wildlife Service operate hundreds of hatcheries throughout the country, raising trout and other fish. Many of these are non-native species, such as Brown Trout, a European species, or native species, such as Rainbow Trout, that are released far from their natural ranges for the benefit of sport fishermen. These hatchery programs are regarded negatively by many ecologists who have documented that the released fish often cause great damage to ecosystems, outcompeting native fish and introducing diseases. Yet state and federal agencies conduct control programs on otters who raid their ponds. Rather than screen the ponds from otters, who can hardly be blamed for finding hatchery fish easy to catch, these authorities have had laws changed in many states to allow shooting and trapping of otters that come onto hatchery property. Placing screening over fish ponds and hatcheries--and fencing them--will prevent otters, as well as fish-eating birds such as egrets, herons, Ospreys and Bald Eagles, from preying on the fish being raised. This should be carried out instead of lethal methods, which also sometimes kill protected waterbirds. Such control programs do not achieve success in any case because even if depredating River Otters are killed, other otters will be attracted to the ponds, replacing those killed.

Eleven species of otters are listed by the *2000 IUCN Red List of Threatened Species*, four as Endangered, three as Vulnerable, one as Near-threatened, and three as Data Deficient. This represents a high rate of threat, 85 percent, as the otter, or Lutrinae family, has only 13 species. Otters tend to be thinly distributed in their ranges, wide-ranging, slow-reproducing and long-lived--all qualities that make them vulnerable to population declines.

Seals and Sea Lions

The Caribbean or West Indian Monk Seal (*Monachus tropicalis*) was the first animal seen by Christopher Columbus in the New World in the late 15th century, and his crew slaughtered these seals on an islet off the coast of Hispaniola (Day 1981). The only seals native to the Caribbean, they were quite large--6.5 feet long (Nowak 1999). They were heavily exploited beginning in the 17th century for their oil, which was used as a fuel for lamps and, later, for their fur. Scattered populations of the Caribbean Monk Seal survived on islets and beaches far from human habitation until the 20th century (Nowak 1999). Even these last seals were persecuted by fishermen who regarded them as competitors. The last known population of these seals lived on the Triangle Keys, small sandy islets off the Yucatan Peninsula of Mexico, and in 1911, fishermen slaughtered every one of the remaining 200 Monk Seals (Day 1981). Although a few seals were seen after that time, including the sighting of a small colony on a bank midway between Jamaica and Honduras in 1952, an aerial survey of all possible habitats carried out in 1972, and a 1980 expedition, failed to find any sign that the Caribbean Monk Seal remained alive (Nowak 1999). The species was officially declared extinct a few years later, although a few recent reports have given hope that the species may have reappeared (Nowak 1999).

The Japanese Sea Lion (*Zalophus californianus japonicus*), a subspecies of the California Sea Lion, was native to Japan, North Korea, and South Korea, and shooting by fishermen played a major role in its extinction (IUCN 1978).

Commercial fishermen have been responsible for the near-extinction of the Mediterranean Monk Seal (*Monachus monachus*). Once common along the coasts of the Mediterranean Sea, and along the Atlantic coasts of northwestern Africa, this seal is on the verge of extinction, its status listed in the *2000 IUCN Red List of Threatened Species* as Critical. Although resort and industrial development contributed to its decline, shooting by fishermen has been the major cause (Nowak 1999). Many seals drown when they become entangled in fishing nets as well. In past centuries, these seals could be seen on beaches along the Mediterranean, where they would have their pups. After severe persecution, however, they began to hide in the remote caves along the coasts and on uninhabited islets (Attenborough 1987).

In 1981, Greek fishermen threatened to kill off all the remaining Monk Seals on Greek shores if they were not paid compensation for the fish the seals would eat. The Fauna and Flora Preservation Society (now Fauna and Flora International), a London-based organization, raised the money after public appeals in newspapers, which amounted to several thousand dollars.
Fishermen throughout the region became even more intent on eliminating these seals after commercial factory fishing ships began to deplete fish stocks in the Mediterranean.

In spite of legislation protecting the seals, fishermen continue to shoot these seals, which are suffering from lost food supply in most areas. The once pristine waters are now overloaded with sewage and contaminated by chemical and oil spills (Attenborough 1987). The total population of this seal was fewer than 350 in the late 1980s (Attenborough 1987). A 1996 survey found 288 animals, mainly along the African coast in the Atlantic (*BBC Wildlife* 1996). Unfortunately, the largest population in the African islands was decimated in 1998 by a die-off, apparently caused by toxic chemicals.

Mediterranean Monk Seals are extinct in Cyprus, Lebanon, the Canary Islands and Syria, and probably extinct in most other Mediterranean countries. Researchers are conducting radio tracking studies of young seals to discover breeding calves with the goal of reintroducing the seals in the Canary Islands where they have been extinct for over 400 years (*BBC Wildlife* 1996).

The attitude that seals and other fish-eating animals are depriving humans of food is prevalent in many parts of the world and has resulted in the killing of countless fish-eating mammals and birds. The Marine Mammal Protection Act (MMPA) of 1972, which prohibits killing marine mammals in US waters, allows killing of "depredating" seals and sea lions under permit. Such permits are given to kill seals destroying nets to steal fish and/or having a deleterious effect on commercial fish species through their predation. Some Alaskan fishermen, who net the largest fish catches in the world, still resent that the fish are taken by seals and other marine mammals in their waters, and illegal shooting of these protected mammals frequently occurs. Sea lions along the coasts of California, Oregon and Washington have been shot illegally by the hundreds since the MMPA went into effect, and many permits have been given for legal killing. These killings have had a negative effect on many populations of these sea mammals.

Wild Cats
While it may be difficult for most Americans to think of the regal Cheetah as vermin, in the southern African country of Namibia, cattle ranchers treat these endangered and beautiful cats as enemies, trapping and shooting, and even poisoning them. White South Africans have acquired huge landholdings to raise cattle at the expense of the environment in this arid land, fencing off large sections from native wildlife. The majority of Namibian ranchers lack compassion or respect for this graceful cat and, without any compunction, kill females, young kittens and any adult Cheetah on their properties, whether or not the animals pose a threat to their livestock. One rancher told American conservationist Laurie Marker, who is seeking to reverse this trend, that he personally had killed 160 Cheetahs on his property. Marker has taken on the daunting task of trying to convince ranchers of the importance of protecting these endangered cats.

Cheetahs are the world's fastest land animal, reaching 70 miles per hour in pursuit of gazelles, foals of large ungulates, such as zebra and, occasionally, smaller mammals, such as hares. For hundreds of thousands of years, they have adapted to changes in the environment of their once vast range, and are superbly designed as predators. In the North American Pleistocene, more than 10,000 years ago, a cheetah-like cat ranged over the continent, preying on the Pronghorn, the world's fastest hoofed animal. This cat became extinct, perhaps as a result of hunting by Pleistocene hunters.

Prior to the 20th century, Cheetahs remained common in savannah habitats south of the Sahara, and in 1900, their population may have totaled 100,000 animals. Since then, a steady decline in their populations and a shrinking of their range have placed them in endangered status. Cheetahs underwent a dramatic decline in the 1960s when spotted cat fur became fashionable. US imports were stopped when the species was listed on the US Endangered Species Act in the late 1960s, and commercial international trade became illegal when Cheetahs were included on Appendix I of CITES in the early 1970s. Killing them for the fur trade devastated their populations because they are distributed so sparsely over their range--even a kill of a few thousand in each country endangered them. Added to this, they have endured persecution by livestock herders and ranch owners, combined with loss of savannah habitat and their prey species. In areas where there are large populations of Lion and hyena, adult Cheetahs and their cubs are preyed upon by the latter predators, who also steal their kills (Hunter 1998). Trophy hunting also has taken a toll on these cats.

By the early 1970s, they numbered only 15,000, according to Peter Jackson, head of the Cat Specialist Group of the World Conservation Union (Newman 1997). Cheetah biologist Luke Hunter (1998) estimates their total population today at a maximum of 12,000 animals, with safe populations in only five or six of the 26 countries where they may be present. In parts of southern Africa, Cheetahs were numerous until a few decades ago when white ranchers fenced off thousands of square miles of grassland. Within these ranches, which cover much of the land area in Namibia and Botswana, landowners killed off predators as well as native ungulates. The once abundant wildebeests, zebras, oryx, gazelles and antelope that migrated in the hundreds of thousands in this region became reduced to scattered numbers.

Namibia, with its arid, open habitat, still has about 2,500 Cheetahs, perhaps the largest population in Africa, but at the present rate of killing by ranchers, they will be extinct there within a decade. In the 1980s, 1,000 Cheetahs were killed by ranchers, and the Namibian Cheetah population dropped about 50 percent between 1984 and 1994 (Schick 1994).

A 1997 PBS television special, fiIn the Wild,fl featured actress Holly Hunter traveling to southern Africa in search of Cheetahs. A visit to Namibia's Etosha National Park, where these cats were once fairly common, failed to find a single Cheetah, in spite of expert help from native Bushmen trackers. An outbreak of Anthrax, spread by domestic livestock, had recently occurred in the park. Some 20 Cheetahs had died, and the disease also killed elephants and other wildlife.

Marker co-founded the Cheetah Conservation Fund in 1990, and since it has been in operation, it has changed many ranchers from Cheetah-haters to Cheetah-protectors. Few knew of the Cheetah's worldwide plight, and many cooperated when informed. One successful strategy to protect livestock introduced by Marker has been the use of donkeys to guard cattle herds. These animals easily fend off Cheetahs with their powerful kicking hooves (Schick 1994). Baboons have also been trained to guard livestock because of their aggression toward Cheetahs (Schick 1994). Recommendations such as bringing cows closer to homesteads during calving season have also been made to ranchers (Schick 1994). Many ranchers did not realize that Cheetahs prey on livestock only when their own natural prey, primarily gazelles and Impalas, have become scarce because of killing or fencing by the ranchers (Schick 1994).

Within the past few years, many ranchers have been convinced to use box traps to capture Cheetahs unharmed instead of killing these cats. Marker ear-tags the animals and returns them to local protected areas (Schick 1994), or arranges to have them moved. In the early 1990s alone, 75 Cheetahs were removed from ranches where they were being persecuted and were introduced into other areas. One farmer caught a female with five cubs and wanted to keep the cubs as pets. Marker convinced him to give up the female and four of her cubs, but he insisted on keeping the largest one. Although keeping Cheetahs as pets is not good for their welfare or conservation, it is an improvement over their wholesale destruction. Leghold traps are used by some ranchers, and in 1996 Marker acquired two 3-week-old Cheetah cubs whose mother had been killed in one of these traps. They will have to remain in captivity because of their young age when orphaned.

An organization known as Africat has sponsored the capture and transport of 100 wild Namibian Cheetahs to South Africa. This organization reports that ranchers capturing Cheetahs in large box traps often sell them to breeders rather than reintroduction programs, a practice that it does not condone. Translocating adult Namibian Cheetahs to South African reserves where they had become extinct has been very successful. In one case in 1995, three males were

released in Madikwe Game Reserve where four other Namibian Cheetahs had been introduced in 1994, and all survived. A male, four females and five cubs were released in Pilanesburg National Park in 1995, and there were no fatalities (*Oryx* 1996). Most of South Africa's Cheetahs were eliminated by Boers in the 19th century, and the government is now returning them to their original range within national parks. Outside of national parks, they may be in as great danger as the Cheetahs further north.

Lions have continued to decrease in Africa south of the Sahara from a variety of factors, of which persecution by livestock raisers is a major one. Outside of national parks, these big cats have become rare or absent, and in 1996, the species was first listed by the IUCN as Vulnerable. The *2000 IUCN Red List of Threatened Species* also classified the African Lion as Vulnerable. They disappeared long ago from areas with scarce ungulate populations and large numbers of herdspeople who persecuted them, such as the arid regions of southern Africa and the sub-Saharan. In recent years, they have declined throughout the continent. Outside of parks, the Maasai and other tribes with livestock herds routinely kill Lions and other predators to protect their cattle (Hunter 1998). Lions are particularly vulnerable to persecution and hunting because, like wolves, they hunt in groups. When persecuted, they may not be able to survive hunting alone or in pairs.

Some parks are not large enough to maintain healthy Lion populations, and when they leave parks to wander in search of prey, they are often killed by ranchers or hunters. In the southern African country of Namibia, for example, the 300-mile-long, 25-mile-wide Skeleton Coast National Park skirts the Atlantic coast. Two filmmakers, Jen and Des Bartlett, chronicled the disappearance of Lions from the park. A small population of Lions inhabited the park in the early 1990s, and one pair was radio-collared by park rangers. Shortly thereafter, both Lions were shot dead by livestock herders when the Lions left the park. The Bartletts had known the female for five years, and she was pregnant with four cubs when shot. The killing of Lions to protect livestock is legal in Namibia, and with the death of the last specimen in the park, an elderly and emaciated animal shown in their National Geographic Society film, fiSurvivors of the Skeleton Coast,fl these great cats are now extinct in the area.

Wild cats have been hunted heavily and killed off throughout the Middle East. Leopards (*Panthera pardus*) still persist in small pockets, escaping detection with nocturnal hunting, and hiding in rock crevasses and trees during the day. As a general rule, wherever Leopards are seen in the Middle East, they are shot or poisoned as potential threats to the ubiquitous sheep and goats. In a few areas, such as remote portions of the Saudi Arabian Peninsula, Leopards are protected in national parks. These Leopards are very adaptable in their prey and can subsist on small animals, such as hares--unlike the Lion, which requires larger prey.

Eight subspecies of Leopards are listed on the *2000 IUCN Red List of Threatened Species*, all in Endangered or Critical categories. They range from North Africa across Asia to Java, Indonesia. Races such as the South Arabian Leopard (*Panthera pardus nimr*) of Saudi Arabia, United Arab Emirates and Yemen; North Persian (*P.p.saxicolor*) of Afghanistan, Iran and Turkmenistan; and the Anatolian Leopard (*P.p.tulliana*) of Turkey, have populations so small that they may become inbred and disappear within a few decades. The South Arabian Leopard is the focus of a conservation program organized by officials and conservationists from Saudi Arabia, Yemen, Oman and the United Arab Emirates. Only 100 to 200 of these cats survive, and they continue to be persecuted by livestock owners and hunters (*Oryx* 1996). The "Leopard Group of Arabia" was formed in 1995, and each country will prepare a plan for conservation of the Leopard, review its own wildlife legislation, conduct surveys, and make proposals for protected areas (*Oryx* 1996). This group is also working to increase populations of native prey, reduce livestock numbers in the Leopards™ habitat, and conduct public education programs (*Oryx* 1996).

Snow Leopards (*Panthera uncia*), native to the mountains of Asia, from Pakistan east to China, are endangered from hunting for pelts and as trophies, and by persecution from herdsmen who kill them as a threat to their livestock. Their total population may be as low as 4,500 or as high as 7,500 (Sunquist 1997). In their stark, rocky and high desert habitats, these cats prey upon wild sheep, goats, deer and marmots (Sunquist 1997). Their original range stretched for 4,000 miles and encompassed 1.2 million square miles in a wide arc, curving from east to west in the Himalayas through former Soviet Republics, Nepal, Pakistan, Afghanistan, Bhutan, Sikkim, and Mongolia to China, including a

total of twelve countries (Baillie and Groombridge 1996). They have disappeared from vast areas within this region, however, and continue to decline.

Until the 20th century, few herdspeople roamed these remote and forbidding regions, and Snow Leopards and their prey were left unmolested in most areas. In the past 50 years, however, human populations have risen dramatically. In western China, the government has used subsidies to encourage settlement of the western steppe, and large numbers of people have entered previously uninhabited areas with their livestock. In western Nepal, villages now dot the Himalayan slopes at 9,800 feet, and people scratch out a living from meager potato, barley and wheat crops (Sunquist 1997). Each household has only a few sheep and goats and cannot afford to lose even one to predators (Sunquist 1997).

Some 1 million Mongolian herders subsist in a barren landscape, dependent on their yaks, goats and sheep. These people, whose livestock compete with wildlife for the scarce grasses, also hunt native animals which the Snow Leopard needs to survive--Blue Sheep, ibex, deer and others. Even marmots are killed in very large numbers for their meat and skins (Sunquist 1997). When their natural prey disappears, and Snow Leopards begin to prey on livestock, herders poison, trap or shoot these cats in retaliation. In many areas, herders kill Snow Leopards as a potential threat, even when they have not lost livestock, in order to sell their valuable pelts.

Dr. George Schaller of the Wildlife Conservation Society has conducted studies on the diet of Snow Leopards and, in most areas, found less than 5 percent of livestock in their diet, based on feces analyses (Schaller 1998). As numbers of livestock in the Snow Leopard's range rise and herders penetrate further into the mountains and high pastures, livestock losses occur that sometimes result in extermination campaigns (Schaller 1998). Herding practices in these areas often encourage predation by Snow Leopards, with sheep and goats, and mares with their foals left unguarded (Schaller 1998). Depletion of their prey has increased in recent years, with government policies that encourage marmot hunting, pika poisoning and, until the late 1980s, Blue Sheep market hunting (Schaller 1998).

In Tibet, Dr. Schaller has arranged with local herdspeople to pay them for any losses they incur to Snow Leopard predation, and he has hired local Tibetans to assist in field studies of these cats, giving them a financial incentive to protect the cats. Likewise, in Pakistan, a new program organized by an American conservationist, Helen Freeman, founder of the Seattle-based International Snow Leopard Trust, has sponsored some 90 projects for the species, including many field studies. Its web page (www.snowleopard.org/islt) follows the movements of radio-tracked Snow Leopards. Gary Larson, the popular *Far Side* cartoonist, created a Snow Leopard design for the organization to use on its shirts (Sunquist 1997). Grade-schoolers all over the country have raised money by selling T-shirts for the International Snow Leopard Trust. In 1988, through the education programs and compensation for livestock losses conducted by this organization, a Pakistani livestock owner trapped a young Snow Leopard found preying on livestock, contacted the government and, before news crews, set it free. In the past, it would have been killed routinely.

The International Snow Leopard Trust and the Mongolian Association for Conservation of Nature and Environment are providing tea, noodles and clothing to livestock grazers in Snow Leopard territory in the Altay Mountains of Mongolia, with the understanding that they will protect wildlife (Schaller 1998). One village requested children's clothing, flour, candles, soap and tea, and these requests were filled (Sunquist 1997). The concept of involving local people in the conservation of wildlife is extremely important and, wherever practiced, has had beneficial long-term results for all concerned.

Bats

Bats live on every continent except Antarctica and serve extremely important ecological roles as pollinators, seed

dispersers and consumers of vast quantities of insects. Although some societies value these useful animals, many persecute all bats, based on irrational prejudice and fears of rabies. The Romanian legend of Dracula, in which a man turns into a blood-thirsty vampire bat at night and flies about seeking victims, has created a ridiculous and false impression. Real vampire bats are small, only about 3 inches in length and weighing about an ounce (Wilson 1997). The three species inhabit neotropical forests and are rare in natural habitat. Only when large numbers of livestock are grazed in an area do these mammals, who suck blood from large animals such as livestock, become common (Wilson 1997). They rarely cause the livestock harm. They are capable of transmitting disease to their host animal, but very rarely do so (Wilson 1997). Bat Conservation International has worked effectively to allay fears about vampire bats and helped many people to see them in the positive light of their value to ecosystems, economies (through pollination), seed dispersal and insect control and their interest as diverse, successful species. But Dr. Merlin Tuttle, founder and Executive Director of the organization, believes that persuading the public that bats are not to be feared is still an uphill battle, in spite of progress made in education programs (Raver 2001). Exaggerated headlines about bats and rabies tend to undo rational education programs. In fact, Dr. Tuttle says that over the past 20 years, the United States has had 1.5 human cases of bat rabies per year, hardly deserving the hysteria that so many people feel at the mere mention of bats (Raver 2001).

One positive change in recent years is the increase in people who rise to the defense of bats when newspaper stories appear about the threats of vampire bats and bat control in buildings (Garvin 1999, Gross 2000). Letters to the editor often make the point that bats are basically beneficial, and articles depicting them as fearsome enemies are misleading and cause persecution of wild bats. One article in *The New York Times* (Gross 2000) profiled a bat control professional who paid house calls when people complained of bats having entered their homes. He set glue traps, which bats blundered into and then broke their necks, and sent their bodies to a laboratory in the state capital for rabies testing (Gross 2000). Experts have found that only 1 to 4 percent of bats are rabid, and conservationists suggest that bats be set free rather than killed (Gross 2000). A more humane approach to the problem of bats in the attic was developed by Cal Kosky, a wildlife biologist with the Pennsylvania Game Commission. He tapes a piece of plastic or netting over the top of the entrance hole on the outside of the house (Raver 2001). Bats are able to fly out, but are blocked on return. A bat house is placed strategically close to the old hole to provide them with a new home (Raver 2001). Bat Conservation International has an educational video, "Building Homes for Bats," which explains how to construct bat houses to attract bats to backyards where they eat mosquitoes and other insect pests (Raver 2001).* Sensible advice can also be obtained from Dr. Tuttle's 1988 book, *America's Neighborhood Bats. Understanding and Learning to Live in Harmony with Them*.

Prejudice against bats has had serious consequences for many populations that roost in accessible places, such as open caves. The largest bat colony in the United States, located in Eagle Creek Cave in Arizona, had 30 to 50 million individuals until the 1960s, when vandals and human disturbance reduced them to only 30,000 (Wilson 1997). Several species of North American bats have become endangered as a result of deliberate killing by people, disturbance by spelunkers, and tourists entering the caves (Nowak 1999). The Gray Bat (*Myotis grisescens*) and the Indiana Bat (*Myotis sodalis*) of the eastern and Midwestern United States, for example, are both endangered as a result of these activities. Dr. Tuttle has found that the total number of Gray Bats in 22 major summer colonies declined from 1.2 million prior to 1968 to 293,600 in 1976, a loss of 75 percent (Nowak 1999). The Indiana Bat fell from 640,361 in 1960 to 459,876 in 1975; by 1993, 347,890 remained (Nowak 1999). Both species are listed as Endangered by both the *2000 IUCN Red List of Threatened Species* and the US Endangered Species Act. In Europe, the Pond Bat (*Myotis dasycneme*), a related species, has been reduced to only 3,000 in western Europe and fewer than 7,000 in its entire range (Nowak 1999). It is listed as Vulnerable by the IUCN. Many other European myotis bats also have declined to Endangered or Threatened status from habitat loss, disturbance of hibernating colonies in caves and mines, and blocking up of nursery sites in large buildings, such as cathedrals and castles (Nowak 1999). Rather than killing bats that roost in buildings, or blocking up entries, Bat Conservation International encourages the placement of bat houses nearby, which the bats tend to occupy instead. Similar efforts are needed in Europe. Even when allowed to roost in buildings, many bats are poisoned by chemicals used to treat wood in western Europe (Nowak 1999).

Bat caves are often vandalized when bats hibernate in the winter. Vandals enter caves and knock semi-conscious bats

to the ground, killing them by the thousands, or even millions. Even entering a hibernation cave can result in mortality because disturbances can arouse them and they use up so much stored energy that they do not survive the winter (Wilson 1997). Many bat caves now have gates that allow bats to fly through the open grating, but keep people out; they have helped protect important bat hibernation areas where bats from large areas congregate (Wilson 1997).

The importance of bats as pollinators is discussed at length in *The Natural History of Pollination*, by Michael Proctor, Peter Yeo and Andrew Lack (1996). Many types of flowers have evolved to be pollinated by bats, opening only at night. Their internal pollen-carrying structures are designed to drop pollen on the bat's face when it feeds on nectar (Proctor *et al*. 1996). A great variety of bats and plants coexist, perfectly adapted to one another. Dr. Tuttle's dramatic photos of many such flowers have been published in *National Geographic* magazine and in the useful book, *Bats in Question. The Smithsonian Answer Book* (Wilson 1997). He also has made films of bats for nature documentaries. Many bats are extremely attractive, and their sonar is so complex and sensitive that it is only partially understood by scientists. *Walker's Mammals of the World*, by Ronald Nowak (1999), is another important source of information on bat biology, taxonomy, behavior, conservation and related subjects.

After rodents, bats have the greatest number of species of any mammals, with the most diversity in tropical areas. The number of threatened species has increased dramatically over the past decade as a result of persecution, killing for food, pesticides and other toxic chemicals, and loss of their habitat (see Appendix for list of threatened species). The majority of species at risk suffers from a combination of these factors.

Birds of Prey

Birds of prey have been persecuted for hundreds of years in Europe and other parts of the world, usually as suspected predators of chickens or small livestock, such as goat kids or lambs. In most parts of the world, they still are given no official protection.

Hawks, eagles, owls, falcons and other birds of prey that breed in North America were excluded from the 1918 Migratory Bird Treaty Act (MBTA), signed with Great Britain on behalf of Canada. The Treaty covered almost all other species of native birds, banning hunting and killing as well as harassment and destruction of nests. This exposed birds of prey to continued indiscriminate shooting for sport, hunting from aircraft, poisoning and even capture in pole traps, which catch birds by the feet and hang them upside down in nooses.

Populations of birds of prey that breed in Canada and the northern United States migrate south during the fall, some to Latin America and others to southern states. Flying along thermal wind currents, they funnel into flyways as they pass through mountain chains. In the eastern United States, thousands of hawks, and a smaller number of eagles and falcons, pass over the Allegheny Mountains of Pennsylvania during October, November and December every year. Kittatinny Ridge, near the town of Kempton, came to be known as Hawk Mountain because of the huge numbers of birds of prey passing near it. For generations in the 19th and early 20th centuries, hunters gathered every fall on the rocky ridge to shoot these birds by the hundreds as they soared by. Dead hawks, falcons and eagles accumulated in huge piles, while wounded birds staggered around or lay helplessly immobile on the ground (Brett 1973).

This carnage was considered a form of sport, justified by old prejudices. Rosalie Edge, an ardent conservationist, spearheaded the movement to stop this hunt in the 1930s (Brett 1973). This courageous woman publicized the slaughter of birds of prey, and after a campaign in which she enlisted the help of influential conservationists, she succeeded in purchasing the mountain as a sanctuary (Brett 1973). Edge persuaded an ornithologist, Maurice Broun,

and his wife, to oversee the sanctuary and prevent hunting. They remained on Hawk Mountain for 32 years and served as guides for the more than 40,000 visitors who come every year to see the spectacle of hawks flying over and alongside the mountain ridge (Brett 1973). Rosalie Edge died in 1962, but the sanctuary continues as a non-profit organization staffed with ornithologists, educators, and volunteers, who chronicle by species and number the birds that fly past the ridge.

Hawk Mountain Sanctuary is one of the country's first examples of private ecotourism, and it has accomplished a great deal in teaching the public about birds of prey as useful animals in ecosystems, as well as providing exciting views of these birds as they soar past the ridge. In the morning, before the thermal winds warm up, hawks fly at low elevations, giving visitors a view of their tails and backs from above, an especially colorful sight in the case of the Red-tailed Hawk (*Buteo jamaicensis*), while in the afternoon, they fly higher, transported along by the thermals. Sometimes a visitor to Hawk Mountain can see a hawk or other bird of prey at close range, only 15 or 20 feet away, as they fly close to the ridge, the intricate patterns of their feathers in full view.

In spite of the preservation of Hawk Mountain and several other key hawk habitats, legal protection from hunting did not come in the United States until 10 years after the death of Rosalie Edge. During these years, thousands of hawks and other birds of prey were shot because of ignorance or as sport. Little was understood about their value in controlling rodents and rabbits. In 1960 alone, 12,000 Golden Eagles (*Aquila chrysaetos*) were killed in Texas in a massive campaign to eliminate them. A major victory for birds of prey was their addition to the Migratory Bird Treaty Act in 1972. The bans on hunting that have protected other native land birds were finally accorded these raptors. This was carried out through a memorandum enacted with Mexico, which had signed the Migratory Bird Treaty Act in 1936. It prohibits, except as allowed under specific conditions, the taking, possession, purchase, sale, or bartering of any migratory bird, including the feathers or other parts, nests, eggs or migratory bird products. "Taking" is defined as pursuing, hunting, shooting, shooting at, poisoning, wounding, killing, capturing, trapping, or collecting migratory birds. Individuals and organizations may be fined up to $5,000 and $10,000 respectively, and those convicted may face up to six months imprisonment for misdemeanor violations of the Act. Felony violations may result in fines of up to $25,000 for individuals and $500,000 for organizations and up to two years imprisonment for those convicted. This strong legislation has not stopped the killing of birds of prey altogether, but it has deterred the type of slaughters that were once common.

Although Bald Eagles were revered by native tribes, especially those in the Pacific Northwest, they became victims of prejudice by European colonists, who accused them of damaging fish stocks. A bounty in Alaska resulted in the killing of some 150,000 of these eagles between 1917 and 1953. This species is the national bird, the official symbol of the United States of America, yet historically it has been given little respect. Some even called them "gangster birds" because they were thought to be scavengers of fish caught by other birds. In truth, they are superb fishers with extraordinarily keen vision and are acrobatic in flight. Bounty programs and random shooting of Bald Eagles from colonial times onward caused these birds to disappear from much of their original range, which encompassed the entire continent of North America, including arid regions in the Southwest.

The Bald Eagle Protection Act was enacted in 1940 to protect it from extinction, and amended in 1962 to extend protection to Golden Eagles, primarily to protect immature Bald Eagles, which resemble them. A 1972 incident involving the slaughter of hundreds of Golden Eagles by western ranchers shooting from aircraft resulted in increasing fines under the law from $500 to $5,000 and/or one year imprisonment for subsequent offenses. The amendments also specifically included poisoning in the definition of taking, since both Bald and Golden Eagles had been poisoned by ranchers. These amendments also included the same high penalties for possession of eagle feathers, nests or eggs, and made federal grazing permits subject to cancellation for violations of the Act. In addition, they added a new facet to the enforcement of the Act: one-half of any fine can be paid to a person who provides information leading to a conviction. To augment this protection, the Airborne Hunting Act was enacted in 1972 to prevent the killing of wildlife from aircraft.

After 1973, the killing of a Bald Eagle constituted a violation of the US Endangered Species Act, the Bald and Golden

Eagle Protection Act, and the Migratory Bird Treaty Act, the combined penalties of which could amount to long jail sentences and very high fines. In spite of all these legal steps taken to protect eagles, killings continue. Many are deliberate and carried out in remote areas where there is little fear of prosecution, and others are done by hunters ignorant of the law or the identity of their targets. The protection of native birds, their identification, and laws applying to them should be taught in schools in North America, but such information is usually acquired by chance if at all. Each year, 300 to 400 eagles--Bald and Golden--are found dead. In some cases, hunters still believe folklore about birds of prey being destructive, and shoot them intentionally. A Bald Eagle shot in Maine in 1994 was killed by an 85-year-old man who deliberately killed the bird because he believed these birds were killing geese. He told game wardens that they should "do something about the eagles;" because of his age, he was only given a $2,500 fine, which was suspended. Bald Eagles feed mainly on fish and are not major predators of waterfowl.

Although the majority of eagles are killed when shot, many are found wounded, some in emaciated condition, unable to fly to obtain food and near death. One such Bald Eagle was found crippled in 1983 in Georgia, having been shot in the wing. He had been on the ground for a week, his wing bone exposed. In spite of attempts to save his wing, veterinarians had to amputate it because of infection, and the eagle was taken into a rehabilitation program. Named Osceola, he has played an important role in Wings of America, an education program at Dollywood in Tennessee. John Stokes, Osceola's caretaker, teaches children and adults about the effects of such shooting, stressing the impoverished life that Osceola leads, unable to fly and be free. Stokes decided to bring Osceola along on his hang-gliding trips to treat the bird to some of the sights the eagle had not seen in the many years since being shot. Harnessed into a specially made sling, the pair hang-glided, with Osceola positioned above Stokes, looking intently at the ground far below, turning his head frequently in apparent fascination. The film of Osceola hang-gliding was shown on nationwide television in 1996, and some 500,000 people attend lectures featuring this maimed eagle every year. The National Audubon Society series for young people, "Audubon's Animal Adventures," featured Osceola in the program entitled "Eagle Adventures," shown on the Disney channel.

In the past, it was impossible to prosecute offenders unless there were witnesses or other direct evidence to the killing. Today, a state-of-the-art forensic laboratory run by the US Fish and Wildlife Service in Washington state is able to necropsy dead eagles for cause of death. If shot, ammunition extracted from the birds is analyzed forensically, and cases are made with as much precision and scientific evidence as criminal investigations in which people are the victims.

Prejudices against birds of prey still persist among many who wrongly believe that they harm wildlife or present major threats to domestic animals. Biological studies have documented their ecological importance as major controls on rodent populations. Some birds of prey feed on snakes, insects or other potential pests. No species of raptor poses a significant threat to domestic animals.

The continent's densest population of birds of prey breeds in the craggy canyons and sagebrush shrubland of Idaho. This area has been set aside as the Birds of Prey National Conservation Area, lining 81 miles of the Snake River and covering 485,000 acres. Prior to its protection, this land was in the process of being converted to agriculture. The birds of prey had begun a steep decline from shooting and loss of habitat. Conservationists faced strong opposition to the plan, but overcame it, establishing this area in 1971, a year prior to the inclusion of birds of prey on the Migratory Bird Treat Act. It has since become a leading ecotourism destination for rafters and hikers, who are led on tours by naturalists from the Bureau of Land Management (BLM), which oversees the refuge. Fourteen species of raptors breed in the area or migrate through it, and the breeding population of hawks, eagles, owls and falcons has been estimated at 800 pairs. They provide exciting views of high-speed hunting of ground squirrels and birds, and their eerie shrieks resound through the canyons.

Waterfowl hunting is regulated by the Migratory Bird Treaty Act under regulations by the Fish and Wildlife Service. Unfortunately, the regulations have serious shortcomings that have resulted in many shootings of birds of prey. First, hunting can begin before dawn, when hunters are unable to identify birds by species. Each year, hundreds of birds of prey, including such endangered species as Peregrine Falcons, are shot accidentally. Second, the regulations do not

require that hunters be able to identify birds by species, including protected and endangered species. Since many ducks and geese are extremely difficult to identify, the failure of the Fish and Wildlife Service to require hunters to pass identification tests and begin hunting well after daybreak means that protected and endangered birds will continue to be shot.

In October, 1995, a Peregrine Falcon (*Falco peregrinus*) shot in Massachusetts was migrating south from Canada or Greenland during hunting season. It suffered neurological damage after being shot in the left wing while it was flying in a wildlife refuge area. The Assistant Director of the State Division of Fisheries and Wildlife, Tom French, stated that it appeared that the bird was not shot accidentally. This was the second shooting of a Peregrine Falcon in as many years. The reintroduction of captive-bred specimens of these birds into the eastern United States has been a success, with over 130 nesting pairs. Their long-term survival, however, will depend on adherence to laws prohibiting shooting or harming them.

For the future, the Migratory Bird Treaty Act would be far more effective if signed with Latin American and Caribbean nations to protect North American birds wintering in those countries. This would be especially important in view of the decline in many of the continent's birds of prey, which are persecuted and killed by pesticides and poisons in their wintering grounds.

The California Condor (*Gymnogyps californianus*), North America's largest bird of prey, once soared over most of the continent. Its bones have been found among Florida's Pleistocene fossils, and 20,000 years ago, it was very common and widespread, feeding on the carrion of mastodons, bison and other large mammals. This giant bird's superb aerodynamic flight makes the most sophisticated man-made aircraft look clumsy by comparison. Condors have a positive role to play in ecosystems, feeding on carcasses and thereby ridding the environment of these potentially infectious contaminants. Although they declined in range over the centuries, condors were still widespread from Baja California, Mexico, north to Washington state, where Lewis and Clark saw them along the Columbia River in the early 19th century. They were often observed scavenging seal and whale carcasses along the California coast, and they nested as far east as the Sierra Nevada Mountains.

Settlers looked on condors as large targets, with their 10-foot wing span, and perhaps thought they were predatory birds. Hundreds were shot. These birds feed exclusively on carrion and do not hunt live animals. When word spread in the last years of the 19th century that the condors were approaching extinction, egg and specimen collectors preyed on the remaining birds. Between 1881 and 1910, 288 birds were killed as museum specimens (ICBP 1981). By the turn of the century, only a few hundred birds remained, yet killing was still legal. The ornithological journal *The Condor* began publication at this time and recorded many instances of these killings. In one case, an individual named Frank S. Daggett reported shooting a California Condor in 1901, wounding it in the wing and then, when it fell to the ground, shooting it three more times, still not killing it. Finally he clubbed it and shot it yet again before the bird died (Daggett 1901).

The California Condor continued its decline until only 60 birds remained in 1939 (Greenway 1967). The last population survived in a wilderness area of southern California. In spite of legal protection and the establishment of the Sespe Condor Refuge, the birds suffered high mortality from shooting, ingestion of lead shot from deer killed by hunters, feeding on animals killed by predator poisons, collisions with power lines, and accidental capture in leghold traps. Biologists from the Fish and Wildlife Service and the National Audubon Society were assigned to study and protect this small population in the 1960s and 1970s, but they did not publicize its precipitous decline or insist on further protection from the threats that continued to kill these birds. As these birds headed toward imminent extinction, nothing was done to stop deer hunting in their refuge, nor to prevent the use of steel jaw leghold traps or predator poisons in their diminishing range.

One of the last nests was in a regal setting befitting this massive bird: a huge natural hole in a giant, old Sequoia tree. The eggs from this nest and others were taken by the Fish and Wildlife Service for captive hatching. In 1980, one of the last wild chicks hatched in a cave and was being weighed and tested by biologists when it suddenly died. It had

been handled for more than an hour, during which time it repeatedly hissed and jabbed at the researcher. Later it was revealed that shock caused its death. The incident was filmed and shown on national television, resulting in the cancellation of the recovery program by the state of California, followed by a long period of re-evaluation and controversy. By 1981, the state reached an agreement with the Fish and Wildlife Service to allow capture of the last nine California Condors, but the program was delayed by lawsuits and wrangling over details. By the time it was finally decided to capture all remaining condors in 1987, only six survived (BI 2000).

The sad decision to remove all wild California Condors turned out to be the correct path to preserve the species, since its wide-ranging behavior exposed it to countless perils that were beyond the control of its protectors. To the amazement of many, the captive-breeding program succeeded beyond all expectations. The eggs laid by the captive condors were artificially incubated, and chicks were fed by workers, with puppets resembling adult condors covering their hands. So many birds were captive-bred at special facilities run by the Los Angeles Zoo and other breeding centers that by 1992, a reintroduction program began with release of captive-bred birds into the wild in southern California. Some of the released birds died after striking electric power wires or were injured and had to be returned to captivity. Several landed in suburban locations, perching on the decks and roofs of private homes and even, in one case, entering someone's home. Most residents did not recognize the birds™ great rarity and protected status, and put out food, such as hot dogs, for them. Finally, wildlife authorities and television news stations learned about the situation, and many Californians became aware of these giant and extremely rare birds. To many ornithologists, the behavior of these young condors indicated that the birds were tame and considered humans a source of food. The puppets apparently had not fooled them into thinking they were being fed by parent birds.

By July 1994, California Condors numbered 89 birds, 85 of which were in captive-breeding facilities, and four released birds (Collar *et al*. 1994). Six young condors were released in the Grand Canyon area in late 1996, with Fish and Wildlife Service personnel staying close to provide food and to radio-track the birds. Within a short time, one of the condors was killed by an eagle, an unexpected setback. The total California Condor population grew to 120 birds by early 1997, and only a year later it had increased to 147 birds, of which there were 97 in captivity, 28 returned to the wild in California's Los Padres National Forest, and 22 released in Arizona (BI 2000). The released birds are provided with livestock carcasses until they are able to find food on their own. The success of this program has not yet been proven by breeding in the wild, as all released birds are too young. Only time will tell whether these birds survive and reach the goal of 150 birds in separate populations. They are being trained to avoid some of the sources of mortality that killed them in the past, such as power lines, but as long as lead shot is used in deer hunting in their range, this will remain a potential threat to them.

Elsewhere in the world, birds of prey receive little or no protection from persecution. In Italy, shooting of migrating birds of prey has long been a "sport" in which gunners position themselves in concrete bunkers on hillsides and kill hawks, falcons and eagles as they fly by. One woman decided to fight the hunters and worked successfully for an official ban on shooting these birds. In spite of this, illegal shooting takes place in Italy, and every year during the migration season, conservationists from many parts of Europe come to help her enforce the ban. The campaign to stop hunting of these birds was described in a film, fiAnna and the Honey-Buzzardsfl (see Video section). In Australia, persecution of eagles and hawks is rampant. After shooting these birds, especially Wedge-tailed Eagles, they are often nailed to fence posts with their wings spread. Few of the ranchers who kill thousands of these birds seem aware of the important role they play in controlling rabbits.

Snakes

The prejudice against snakes may be traced in some cultures to the Biblical story of Adam and Eve, in which the snake represents the evil temptor. For many, snakes inspire great fear and loathing, and they are often killed upon sight. In the American West, rattlesnake hunts are carried out in many towns as an annual event, with thousands of

snakes captured. After being prodded and manhandled, they are killed, often by being skinned alive. The New Mexican Ridge-nosed Rattlesnake (*Crotalus willardi obscurus*) is a threatened species on the US Endangered Species Act, persecuted and overcollected in its limited range. In Eastern states, especially in the South, snakes are also hunted for sport, burned alive with gasoline poured down their dens, and killed in bizarre religious ceremonies. One town in Georgia has an annual war on rattlesnakes, killing as many as possible. For some species, this has resulted in serious declines. The Eastern Timber Rattlesnake (*Crotalus horridus*), the largest snake native to the United States, inhabits forested areas with rock faces, crevices and caves in the Northeast. It has become threatened in many parts of its range. These snakes, which range in size from 35 to 74 inches in length, are vulnerable to persecution because they congregate in large numbers in rocky dens and overwinter with other types of snakes for warmth. They hide under rocks where hunters and collectors find them. Timber Rattlesnakes are long-lived, known to survive 30 years or more. Females give birth only every other year, do not mature until age 4 or 5, and have only 5 to 17 young (Behler and King 1979). With such slow reproduction, they are vulnerable to declines when hunted.

This species has legal protection from hunting in Pennsylvania and New York and is listed on their state endangered laws, yet hunting still kills hundreds each year. One rattlesnake hunter, profiled by CNN, bragged that he had captured 9,000 Timber Rattlesnakes in his lifetime and planned to continue openly flouting laws protecting the species. He claimed that he enjoyed catching and killing these snakes so much that he would never stop, and some herpetologists accuse this man of single-handedly causing declines. He has been arrested many times and jailed for trading in endangered species, but refuses to stop. These snakes do not pose a threat to people unless they are sought out in their retreats.

Biologists point out that snakes are extremely useful ecologically, feeding on squirrels, mice, rats and other rodents, but since laws in the United States and around the world either fail to protect snakes or are not enforced, snakes often are persecuted and killed senselessly.

Rodent Control

Prior to settlement of North America, prairie dogs of many species inhabited towns of burrows that covered some 98 million acres of shortgrass prairies, from southern Canada to Mexico. One prairie dog town in the Texas Panhandle stretched over 25,000 square miles and held an estimated 400 million animals (Dold 1998). Prior to the 19th century, they are thought to have numbered 5 billion animals (DeBlieu 1993). These towns have since been destroyed, the prairie dogs killed, and the habitat used for agriculture, pastureland and development. A keystone species, prairie dogs create habitat for hundreds of other animals who live in their complex burrow systems. These rodents have been driven to endangered status after centuries of persecution and poison campaigns that were based on the belief by cattle ranchers that prairie dogs ate too much grass, depriving cattle of fodder. The US government sponsored the destruction of prairie dog towns beginning in 1900. The poisoning program was bolstered by inaccurate information from the US Biological Survey, which stated in 1902 that prairie dogs decreased productivity of grasslands by 50 to 75 percent (Dold 1998). Poison bait was distributed in the towns, gasoline was poured into their burrows and set afire, and they were shot by the thousands. A highly toxic poison, 1080, was used from the 1960s on, devastating prairie dog towns and killing vast numbers of animals, from foxes to Golden Eagles, who fed on the poisoned prairie dogs. This reduced prairie dog habitat to about 1.5 million acres, a fraction of their original range.

Modern biological research has unveiled the truth about the effect of these rodents on grasslands. Rich Reading, Director of Conservation Biology at the Denver Zoological Foundation, stated flatly that the Biological Survey's figures claiming that prairie dogs reduced grass by up to 75 percent, were "vastly in error" (Dold 1998). Studies by Dan Uresk, a Forest Service biologist, have concluded that prairie dogs eat only a small percentage of grass--from 4 to 7 percent (Dold 1998). James Detling of Colorado State University in Fort Collins has found that prairie dogs are natural fertilizers, whose incessant grass clipping increases the protein content and digestibility of grass (Long 1998).

Other studies have examined the claims of cattle ranchers against prairie dogs and have demonstrated again and again that these rodents actually improve forage quality for livestock and, by cropping the shortgrass prairie, stimulate it to grow, increasing the amount of grasses around the towns (Wuerthner 1996). The American Bison prospered in herds of 50 million, much of the species range lying within prairie dog towns of the short-grass prairies. Their major predator, the highly endangered Black-footed Ferret (*Mustela nigripes*), has been eliminated in the wild as a result of poisoning and shooting campaigns. At least 130 grassland species are associated with prairie dog towns (Godbey and Biggins 1994), and up to 170 vertebrate species have been seen in these towns.

Another complaint of cattlemen, that cattle fall into prairie dog burrows and break their legs, has also been refuted. Don Sharps, a wildlife consultant, asked an audience of 200 ranchers if any of them knew of a case of a horse or cow that had broken its leg in a prairie dog town, and no one said yes (Dold 1998). Such prejudices are passed down from generation to generation and fuel the persecution programs against these ecologically important rodents.

Slow-acting poisons, such as zinc phosphide, are used by many animal damage control programs. This chemical takes up to 12 hours to kill prairie dogs, who suffer extremely painful deaths (Wuerthner 1996). Another technique is the placement of gas cartridges in prairie dog burrows. These are ignited and burn the prairie dogs alive (Wuerthner 1996). On federal lands, these programs are conducted by the Wildlife Services unit of the Department of Agriculture at public expense. In the 1980s, more than $6 million was spent to eradicate 460,000 acres of dog towns on the Pine Ridge Indian Reservation in South Dakota (Line 1997). This was the largest remaining prairie dog town in the United States (Dold 1998) and the site of the only population of Black-footed Ferrets known to exist in the 1970s. In 1993, Animal Damage Control (now called fiWildlife Servicesfl) used, sold or distributed 220,000 fumitoxin tablets, 60,000 gas cartridges, and 21,000 pounds of zinc phosphate baits in the northern plains states to eradicate prairie dogs (Wuerthner 1996).

Studies about prairie dogs have revealed them to be surprisingly intelligent. They communicate in yips and chirps, some of which are warnings to other members of the town. A study by Professor Con Slobodchikoff of Northern Arizona University has revealed that prairie dogs™ calls convey specific information, such as what size a predator is, what type of animal, its speed of travel and level of threat (Dold 1998). Slobodchikoff created experiments in which two people walked through a prairie dog town that had experienced hunting; one carried a simulated rifle, while the other did not. The prairie dogs gave different calls for each person, and when the "hunter" returned in a few weeks without his rifle, they still gave the call for a man carrying a rifle (Dold 1998). Such communication goes far beyond what most people consider rodents to be capable of and shows their ability to react to a variety of threats, including the most serious one, human beings. Unfortunately, their warnings could not protect them from poison, shooting, and even bulldozing of their burrows.

Knowledge about the true role that prairie dogs play in grassland ecosystems has yet to reach most ranchers and others who have a hatred for these rodents that seems to reach no bounds. Many compare notes on how many prairie dogs they have killed, usually by high-powered bullets that cause them to disintegrate on contact (Long 1998). One group in eastern Colorado with 30 members calls themselves the Varmint Militia and kills prairie dogs as a sport. They recently spent two full days shooting prairie dogs until activity in the prairie dog town slowed (Long 1998). One militiaman bragged of having shot 20,000 prairie dogs and wants to retire from his exterminating business to shoot them full time (Long 1998). These shooters recount with glee the story of a recent protest. Some animal rights protesters tried to stop one of these hunts and chained themselves together, refusing to move; the Varmint Militia called the Kit Carson County sheriff, who placed them in jail for the weekend (Long 1998).

Although private shooting may be difficult to stop, many biologists and conservationists have recommended that all government poisoning and shooting on public land be halted and that subsidies be offered to ranchers who do not kill prairie dogs on their property (DeBlieu 1993). Unfortunately, no action has been taken in this direction.

Sport hunting of these rodents is encouraged by state game departments, and many towns organize hunts as a form of recreation. These hunts, which often involve the killing of hundreds of prairie dogs in a single afternoon, are taking a

high toll of these declining animals in many areas (Wuerthner 1996). A South Dakota organization, Varmint Hunters Association, brags that its 45,000 members do society a favor by killing prairie dogs. The vice president, Marc Minkin, told a reporter, "I'd like to be able to step out my back door in the morning and take a couple of shots before my morning coffee" (Dold 1998). The organized prairie dog shoots draw "hunters" from around the country; one hunt held in Nucla, Colorado, obliterated an entire town (Dold 1998). This hunt, which involves taking pot shots at prairie dogs emerging from their burrows, which they must do to feed, is totally unsportsmanlike--a virtual slaughter.

Even in national parks, poisoning takes place as a result of pressure from neighboring ranchers. In spite of abundant habitat in Theodore Roosevelt National Park, Badlands National Park, Wind Cave National Park and various national monuments in the Great Plains, only 6,000 acres of prairie dog towns have been protected (Wuerthner 1996). In most cases, park authorities have been threatened with lawsuits unless they poison prairie dogs. In South Dakota, home of Badlands National Park, a prime potential area for reintroduction of the endangered Black-footed Ferret, the state has declared prairie dogs to be noxious pests and mandates their control (Long 1998). At Devils Tower National Monument in Wyoming, the park rangers use rifles and poison to thin the ranks of its prairie dog colony (Long 1998).

Increasingly, development in the form of housing complexes, malls, highways and industrial centers, has gobbled up millions of acres of land in the West, much of it inhabited by prairie dogs. Some developers merely bulldoze the towns, while others pay to have a company use a giant vacuum cleaner that sucks prairie dogs out of the ground amid deafening noise similar to that of a jet airplane taking off. The proud inventor of this machine bragged that it was non-lethal, and the rodents could then be killed humanely or otherwise disposed of to allow development programs to proceed. In fact, most of the prairie dogs taken in this manner are killed or injured in the process (Dold 1998). The trauma involved for the prairie dogs must be extreme. Many of the prairie dogs removed from their burrows have been offered for sale as pets, advertised in eastern newspapers. Although loveable and cute, these animals are not suitable house pets because they are wild rodents who require extensive dirt to burrow in. They cannot adjust to the unnatural environment of a home. Unfortunately, this new invention has been given favorable publicity in the media. The majority of prairie dogs that survive this operation end up as pet food, according to CNN (December 15, 1996).

A more humane program involves the moving of prairie dogs to safer environments. A Colorado organization, Prairie Ecosystem Conservation Alliance, hoses prairie dog burrows with water and a biodegradable dish soap that creates frothy suds below ground. The suds irritate the eyes of the prairie dogs, who come to the surface where members of the Alliance are waiting to scoop them up and place them in carriers. They then truck them to a safe area, preferably one with empty burrows, and release them (Dold 1998). An even better solution is to save the towns, since the latter method will not save all the other animals inhabiting the burrows. The city of Boulder, Colorado, became the first town in the state to officially designate land to protect prairie dogs. In 1987 it set aside a preserve for prairie dogs, which now covers almost 5,000 acres (Dold 1998). Fort Collins, further north, began with a reserve of 268 acres and now has 1,700 acres (Dold 1998).

A Native American Gros Ventre tribesman, Mike Fox, has come full circle, from sponsoring prairie dog shoots on the Fort Belknap Indian Reservation in Montana to understanding their positive effect on grasslands by watching Bison graze near the towns on the "best grass around" (Long 1998). There are 400 American Bison on the reservation, and Fox, who manages the reservation's wildlife program, has sharply curtailed prairie dog shooting and accepted 23 Black-footed Ferrets to be reintroduced into the 500,000 acres of prairie on the reservation (Long 1998). He tells Indian ranchers, who still kill prairie dogs, that these animals were here before, and the ferret is not a new animal, but an old one returning (Long 1998).

All but 2 percent of original prairie dog populations are now gone, having been poisoned out to make way for livestock or agriculture. The majority of remaining towns are still unprotected, and the poisoning continues. Grasslands with prairie dogs support far higher densities of mammals, birds and other wildlife than those without them.

Several prairie dog species have been driven to near extinction. The Utah Prairie Dog (*Cynomys parvidens*), native to

south-central Utah, became endangered from these programs and the loss of habitat to livestock and agriculture. Listed on the US Endangered Species Act, this species has a restricted range in southwest Utah, and after poisoning programs, its population fell from an estimated 95,000 animals in 1920 to only 3,300 in 1972 (Nowak 1999). Through protection accorded by the US Endangered Species Act, Utah Prairie Dogs began to rebound, and by 1984, the species was downgraded from Endangered to Threatened on the US Endangered Species Act. Populations of prairie dogs fluctuate widely, and counts of Utah Prairie Dogs in the early 1990s ranged from 6,400 in the fall to 24,000 after they had pups in the spring (Nowak 1999). The species has recovered somewhat overall, mainly as a result of the Fish and Wildlife Service program of transplanting prairie dogs from private to public lands (Turbak 1993). Initially, many of the released prairie dogs failed to survive, and not until they began releasing males in the spring, who industriously spent the summer excavating burrows to accommodate other prairie dogs released in the fall, did transplants succeed (Turbak 1993). Utah Prairie Dogs hibernate each winter in compartments in the complex maze of their underground tunnels.

Although some Utah Prairie Dogs have been placed on public land, 60 percent of them still live on private land, where special US Endangered Species Act regulations allow farmers and ranchers to shoot or trap an annual quota of prairie dogs; a high of 6,000 were killed one year, and in 1992, 1,543 were killed (Turbak 1993). Education campaigns and tax incentives to protect prairie dog towns would be far preferable to quota systems.

Mexican Prairie Dogs (*Cynomys mexicanus*) of southern Coahuila and northern San Luis Potos, Mexico, have declined as their habitat has been converted to agriculture and grazing land for livestock, and many colonies were exterminated by poisoning. The largest remaining town covers only 4,400 hectares (Nowak 1999). The species is listed as Endangered by the US Endangered Species Act as well as by the *2000 IUCN Red List of Threatened Species*.

A third species, the Black-tailed Prairie Dog (*Cynomys ludovicianus*) has declined by 98 to 99 percent (Wuerthner 1996) in a range which once extended from Montana and southern Saskatchewan to northern Mexico (Nowak 1999). The Biodiversity Legal Foundation in Colorado filed a petition in October 1994 to list it as a Category 2 species under the US Endangered Species Act, a category just below Threatened. Although the Fish and Wildlife Service's own biologists supported this listing, the petition was denied after political pressure from ranchers (Wuerthner 1996).

Thus, at least three of North America's five species of prairie dogs are in grave danger of extinction, and the remaining two have declined precipitously. Their ecosystems are threatened as well, as are many of the species that depend on them. Although they are extremely photogenic and likeable, prairie dogs are not ecotourist attractions at present. With protection and more publicity, such as nature films and education programs, they could become so, and this would enhance their conservation.

Conservationists have proposed some huge reserves for prairie dogs that would link remnant populations in parts of the West, where much of the land is now under the control of the Bureau of Land Management of the Department of the Interior. The latter department favors cattle ranchers more than prairie dogs, but with outside pressure and publicity, such a plan might become reality. The Fish and Wildlife Service has had difficulty locating prairie dog towns that are protected from poison programs in which to reintroduce captive-bred Black-footed Ferrets.

For their long-term survival, prairie dogs need extremely large territories. At present, fragmented populations, which are often reduced to a few hundred animals widely separated from the nearest prairie dog town, have lost viability from lack of genetic interchange, and some scientists fear that their natural behavior may be altered by this isolation. These loveable animals need more friends to speak out on their behalf and demand that they be protected from poisoning, "sport" hunting and other persecutions, and that sanctuaries be established.

Economically, they may be worth far more alive than dead. The potential for using prairie dogs as a focal point for ecotourism is great. Tourists would be delighted by their behavior and fascinated to see the rich wildlife that inhabits their towns.

Trophy and Sport Hunting
During the late 19th and early 20th centuries, wealthy European and American big game hunters traveled to Asia, Africa and South America to "bag" large animals that they proudly displayed as stuffed animals and heads mounted on the walls of their homes. Maharajahs of India and British hunters took what Vincenz Ziswiler (1967), in his interesting book, *Extinct and Vanishing Animals*, describes as "a morbid pleasure in killing." Lord Ripon, an Englishman who died in 1923, was credited with killing 500,000 game birds and mammals--about 67 creatures for every shooting day of his life (McClung 1976).

One maharajah turned away from hunting and became a famous conservationist. Brajendra Singh, the last Maharajah of Bharatpur, hosted hundreds of hunts on his estate at the Keolada Ghana marsh 100 miles south of Delhi. A shoot organized by an English lord resulted in the killing of 4,323 ducks by 39 hunters in one day. In 1970, Brajendra Singh converted the duck shoot marsh into India's best known bird sanctuary. Singh died in 1995, having presided over the preservation of this vast marsh and its rare resident birds.

Trophy and Sport Hunting: Page 1
The most prestigious trophy for maharajahs and colonial hunters was the Tiger (*Panthera tigris*), largest of all cats. One maharajah shot at least 1,000 Tigers in his lifetime, while another complained that his total bag of Tigers was only 1,150 (McClung 1976). The number of Tigers killed by these two maharajahs equaled the entire population of these cats in India by the late 1960s. Tiger hunts were a royal pastime and employed hundreds of native "beaters," who drove the frightened cat toward a hunter who was perched safely atop an elephant.

Tigers require large territories. Even in the best habitats, their natural density is low. They probably once numbered 50,000 in India alone, however, when forests covered much of the country. Tigers were hunted to extinction on the Indonesian islands of Java and Bali, where each was a separate subspecies, and they have been hunted to endangered status on Sumatra. In the western portion of their range, the Anatolian or Caspian Tiger (*Panthera tigris virgata*) once ranged from Turkey eastward through the Caspian Sea region of Central Asia. Hunting eliminated these Tigers in Central Asia centuries ago, and only a few isolated populations remained in Turkey by 1900. The last individuals in Turkey were shot in 1972. This subspecies was driven to extinction by trophy hunting and persecution by livestock owners. By the 1960s, Indian Tigers were endangered, yet trophy hunting and killing by livestock herders for the fur trade continued. Indian President Indira Ghandi established a conservation program called Project Tiger in the 1970s, which set aside many reserves and accorded strong legal protection. When the species was beginning to increase in numbers, a trade in their body parts for Traditional Chinese Medicine reversed this recovery.

Today, fewer than 5,000 Tigers remain in the wild. At the present rate of killing--one Tiger per day--the species will become extinct in the wild within 30 years or less. Hunting of these magnificent cats intensified in the 1980s and has accelerated everywhere. They are killed by poison, traps and guns wherever they survive. Villagers and professional

hunters sell Tiger pelts, bones and other body parts in a network of smugglers that reaches from rural India, Bangladesh and Indochina to China, Japan and Taiwan. Tiger pelts are openly sold as trophies in many Asian countries, including Pakistan, Cambodia and Vietnam. They are displayed on shop walls, often with head attached. Some Tiger cubs are even part of this trade, killed and stuffed to be sold as tiny curios.

This magnificent cat will not survive long without legions of rangers guarding the remaining animals. Anti-poaching funding is inadequate in almost all its range. Indian parks and sanctuaries, many of them set aside for the Tiger, are understaffed, and dedicated wildlife wardens are underpaid and poorly equipped to combat poachers (Currey 1996). Some Indian park wardens have been bribed by poachers and watch as they skin dead Tigers (Breeden and Wright 1996). Elsewhere in the Tiger's range in Thailand, Cambodia and Burma, for example, few parks and protected areas have been set aside, and wildlife conservation has low priority.

The market for the pelts and stuffed trophies of these last Tigers among wealthy status-seekers in Asia and elsewhere has increased in recent years. One Taiwanese businessman profiled in a *National Geographic* article (Zich 1993) proudly displayed three stuffed Tigers which he had placed in his bedroom; one of the Tigers was standing on a Lion pelt with the head attached. He protested, "I worked so hard to make money. Now I spend it" (Zich 1993).

In spite of what appear to be overwhelming odds, new projects are attempting to turn the tide. Anti-poaching work in Siberia has helped arrest the steep decline of this critically endangered race of the Tiger in a joint United States-Russian program (Galster 1996). An international fund begun by Exxon Corporation, whose logo is a Tiger, has sponsored anti-poaching work and research throughout its range as well as education programs to persuade Asians not to purchase Tiger products. The US Congress appropriated several million dollars for anti-poaching campaigns, and organizations, such as the Wildlife Conservation Society based in New York City, have worked in Cambodia, Indonesia and other countries to survey and aid in conservation of the species. Scientists have cooperated in studies of the Tiger and aided governments in conservation programs, as described in the recent book, *Riding the Tiger. Tiger Conservation in Human-dominated Landscapes* (Seidensticker *et al*. 1999).

The Asiatic Cheetah (*Acinonyx jubatus venaticus*) once occurred throughout the Middle East as far as India. In the 16th century, the Indian emperor Akbar the Great kept more than 1,000 Cheetahs for hunting. Only one litter was produced by his Cheetahs, and the species died out in India and all of its Asian range except Iran, where fewer then 200 animals remain (Hunter 1998). It is classified as Critical, the most endangered category by the *2000 IUCN Red List of Threatened Species*. The Northwest African Cheetah (*Acinonys jubatus hecki*) is listed as Endangered by the IUCN. In reality, it is nearly extinct, with possible survival only in Algeria, Morocco and Niger, having disappeared from Egypt, Libya and Western Sahara. In the Saharan region, nomadic tribes, such as the Tuareg and Toubou, hunt Cheetah in desert areas of Mali, Niger and Chad, using saluki dogs (Hunter 1998). On occasion, Cheetah prey on young camels in the area, their natural prey having been eliminated. The tribes have such a hatred for Cheetah that they pursue them if they see their tracks, with or without proof of predation (Hunter 1998). Being followed for days in the extreme heat, the Cheetahs sometimes die from heat and stress even before the men and dogs reach them (Hunter 1998).

Trophy and Sport Hunting: Page 2

In the stark deserts of the Saudi Arabian Peninsula and the Mideast, wildlife is not abundant. Animals struggle just to survive in the harsh environment. A wild desert equine became a casualty of unrestricted hunting after World War I. The Syrian Wild Ass (*Equus hemionus hemippus*) was hunted to extinction for sport and meat. These wild asses had been hunted out of most of their original range by the 19th century, but in 1850, they were still seen commonly in large herds in the region once known as Mesopotamia, between the Tigris and Euphrates Rivers. Perfectly adapted to the searing desert heat and sparse vegetation, they ran from natural predators at great speed, and their sand-brown

coloration camouflaged them. After thousands of years of adaptation and survival, these delicately hued wild asses found themselves shot at by 20th century soldiers and other hunters. World War I troops and later, civilians in all-terrain vehicles, chased them at high speeds, killing entire herds of these equines for "sport." With no natural cover and unable to outrun jeeps, entire herds were slaughtered. The last known Syrian Wild Ass was shot in 1927 as it came down for water at the Al Ghams oasis in northern Arabia (Day 1981). The surviving populations of this species, the Asian Wild Ass (*Equus hemionus*), are listed as Endangered by the US Endangered Species Act.

After World War II, Arab sheikhs began hunting Arabian Oryx (*Oryx leucoryx*), Arabian Gazelles (*Gazella arabica*) and Arabian Ostrich (*Struthio camelus syriacus*) in all-terrain vehicles and trucks, mowing them down with repeating rifles, shotguns and even machine guns. These macabre and senseless hunts even involved the use of planes and helicopters for spotting. Sometimes animals were pursued until they dropped dead from exhaustion. In 1955, some 482 cars took part in a hunt during the course of a "royal goodwill tour" in northern Saudi Arabia, and every living animal seen was gunned down (McClung 1976). The Arabian Ostrich formerly ranged from Syria to the Arabian Peninsula, and it became a casualty of these forays. The last wild Ostrich was killed and eaten by Arabs near the Trans-Arab oil pipeline north of Bahrain between 1940 and 1945 (Greenway 1967).

The Arabian Oryx nearly followed the Ostrich into extinction when the last three individuals left in the wild were killed off in 1972 in southern Oman (IUCN 1978). This statuesque white antelope, with long, curved horns that arch over its back, once inhabited a wide range in the Middle East, from Syria and Israel to the Arabian Peninsula (Nowak 1999). It was saved from extinction by actions of the Fauna Preservation Society, headquartered in England, and the IUCN, which had undertaken an expedition in 1962 to capture some of the last wild Arabian Oryx for captive breeding. In eastern Aden, four oryx had been taken into captivity, and this herd was augmented from private game farms and zoos by another eight animals, which were transported to the Phoenix Zoo in Arizona. They adjusted easily to the desert climate of the American Southwest and soon bred in captivity. This herd has grown, and several zoos now breed them. Some of these stately animals have been reintroduced successfully into preserves in Oman and other parts of their original range. They have been studied by field biologists who have found that they reverted to wild behavior, with females in separate herds, and males solitary or in bachelor herds defending territories (Nowak 1999). Eighteen breeding herds occupied 14,121 square kilometers in Oman in two 1988 studies (Nowak 1999). In 1990, more Arabian Oryx were reintroduced into Saudi Arabia. There are now about 500 of these oryx in the wild and an additional 300 in captivity on the Arabian peninsula; 2,000 are held in zoos (Nowak 1999). For many Arab conservationists, the return of the Arabian Oryx has been an important event because this species has been very important to the cultures of the Arabian Peninsula for thousands of years. The reintroduced oryx have been guarded zealously to prevent another tragic disappearance.

Gazelles of dryland and open country were at one time abundant throughout North Africa and the Middle East, able to survive in the hottest and dryest of deserts. People have long hunted them for food, and there is little cover where they can hide. In ancient times, stone corrals were constructed into which gazelles were driven for slaughter, and until the early 20th century, these were still in use (Nowak 1999). Some Arab hunters still use captive and trained falcons to harass gazelles in order to frighten and confuse them so they can then be chased down by dogs (Nowak 1999). Two of these small and dainty ungulates have been hunted to extinction, and others have become very rare throughout the region. The Antelope Specialist Group of the IUCN lists the Saudi Gazelle (*Gazella saudiya*) as extinct in the wild and the Queen of Sheba's Gazelle (*Gazella bilkis*) of Saudi Arabia as extinct, with no captive populations. Until the 1990s, the latter species had been classified as Endangered. But the *2000 IUCN Red List of Threatened Species* reports that this delicate animal, which was considered very common in 1951, has not been seen in decades. A survey in 1992 in its range in mountains near Ta'izz failed to find any of these gazelles.

The *2000 IUCN Red List of Threatened Species* categorizes many other gazelles of the region as Threatened and Endangered. The Arabian Gazelle (*Gazella gazella*), native to the Arabian Peninsula, Israel and Palestine, is classified as Conservation Dependent, a category indicating that without strict protection it would decline to Threatened status. Five subspecies of this gazelle are listed in various categories, the most endangered being the Palestine Mountain Gazelle (*Gazella gazella gazella*) (Conservation Dependent) and the Acacia Gazelle (*Gazella gazella acaciae*)

(Critical) of Israel, and the Muscat Gazelle (*Gazella gazella muscatensis*) (Critical) of Oman. Another threatened gazelle is the Arabian Sand Gazelle (*Gazella subgutturosa marica*) (Vulnerable). These little Mideastern gazelles have been heavily persecuted and hunted. Added to the hunting, which is not well controlled, the Arabian Peninsula and much of Israel and Palestine have been heavily overgrazed by livestock, and the scarce oases are used for agriculture and livestock, leaving little natural vegetation for wildlife.

Reintroduced gazelles in Israel's Golan Heights increased to about 4,000 in the late 1980s, and government officials decided to allow the hunting of 2,000 of them by Arabs, who shot to wound rather than kill so that the animals could be killed ritually through throat slitting. This hunt, filmed by Afikim Productions and Survival Anglia in 1990, was a gruesome sight of crippled and dazed gazelles, stumbling about after the shooting.

The most avidly pursued animal by Arab sheikhs is undoubtedly the Houbara Bustard (*Chlamydotis undulata*). The meat of this large, long-legged bird of scrubby desert and sandy grasslands is considered an aphrodisiac by Arabs, although in fact it is a mild diuretic (Weaver 1992). It has been hunted relentlessly on the Arabian Peninsula, causing many populations to disappear. Arab sheikhs have hunted these birds for centuries using a trained falcon that catches the bird as it flies to escape. The great oil wealth accumulated by sheikhs of Saudi Arabia, Qatar, Bahrain, Kuwait and the United Arab Emirates has allowed them to indulge in this "sport" in a manner befitting the bejeweled and pampered rulers of ancient kingdoms. With these bustards so rare on the Arabian Peninsula, they now hunt them in Pakistan. Traditionally, the sheikhs used camels as transport, but today they drive in fleets of 60 or 70 customized all-terrain vehicles, careening through the desert at speeds up to 80 miles per hour, flattening the landscape, vegetation and small animals under their wheels (Weaver 1992). Armed with high-powered guns to shoot any animal that comes into view, the sheikh occupies an elevated seat that swivels 180 degrees to enable him to spot the Houbara Bustards and their tracks in the sand (Weaver 1992). The ecological damage done by the armies of vehicles that flatten vegetation, scar the landscape, and slaughter every animal they see is so severe that it may result in the local extinctions of many rare and delicate species of the Pakistani desert (Hoyo *et al*. 1996).

Many Houbara Bustards winter in Pakistan, converging from breeding areas in Kazakhstan and other countries in the region. Their breeding range extends to North Africa east across Asia to China. In Pakistan and 23 other countries, including India, Iran and Russia, the Houbara Bustard is totally protected from hunting (Weaver 1992). Yet by means of lavish gifts and payments to high government officials and landowners, wealthy Arabs have received special dispensation to pursue and kill thousands of these birds, which are considered endangered and declining in many parts of their range, especially in North Africa, Bahrain, Jordan, Iran, Iraq and India (Hoyo *et al*. 1996, BI 2000).

These extraordinary birds present a spectacular show with their elaborate courtship, strutting and displaying beautiful white puffs of head and body feathers.* Some hunting, mainly illegal, also occurs in their breeding grounds, which greatly disrupts their courtship, nesting and care of chicks.

*"Red Desert," a film in the series fiRealms of the Russian Bearfl described in the Video section, shows these birds displaying and hunting lizards.

The hunts have been carried on for decades in Pakistan, and Houbara Bustards have declined steadily as a result. As early as 1983, scientists and conservationists at a symposium on bustards convened by the International Council for Bird Preservation (now BirdLife International) unanimously called for a five-year ban on hunting (Weaver 1992). Although Pakistan's President at that time supported the symposium, he ignored the appeal and, the following year, allowed 25 parties from the Saudi Arabian Peninsula to hunt; they killed more than 5,000 Houbara Bustards (AWI 1985). Since that time, hunts have continued in spite of changes in administration in Pakistan, and although Arab hunters realize that these birds are heading toward extinction, they have not decreased their kills or practiced conservation. Moreover, they are now hunting in new areas, close to breeding grounds (BI 2000).

One sheikh, the cousin of the ruler of Dubai, found no Houbaras in the tract where he had arranged to hunt. He then moved his camp into Kirthar National Park, where he illegally killed more than 200 Houbaras in 10 days, along with

protected gazelles and ibex (Weaver 1992). As recently as the 1960s, Houbara Bustards were so numerous in Pakistan that they could be counted "like butterflies in a field," but by the 1990s, they became scarce in many areas, and their populations have experienced sharp downward trends (Weaver 1992). No restrictions are placed on the take of Houbaras by the visiting sheikhs.

Some Pakistani conservationists have fought the illegal arrangements made between the Arabs and government officials, and the Society for Conservation and Protection of the Environment (SCOPE), took the issue to the Sind High Court, which ruled in their favor (Weaver 1992). However, because Pakistani government officials rarely follow such provincial court decisions, the hunt did not end. When asked why the government has done so little to protect its wildlife, a well-known Pakistani environmentalist, Wahajuddin Ahmed Kermani, the retired Inspector General of Forests, replied, "Because we lack the moral fibre and the moral courage" (Weaver 1992).

Protests from conservationists in Europe and elsewhere have had no real effect either. Paul Goriup, the bustard expert at BirdLife International in Cambridge, United Kingdom, believes that populations of Houbara Bustards in Sind and Punjab provinces of Pakistan have become "terribly diminished," and hunting of breeding populations has a disastrous effect (Weaver 1992). Goriup contends that the species must be protected by the United Nations' Bonn Convention on Migratory Species to bring the issue to an international level (Weaver 1992). The Houbara Bustard is listed on Appendix I of CITES, which bans all commercial trade between member nations. Yet each year, 500 or more eggs, chicks and adult Houbaras are smuggled from Pakistan, a CITES member, by sheikhs who use them to train their falcons and for captive-breeding programs of dubious effectiveness. Abrar Mirza, the wildlife conservator for the Province of Sind, confiscates many such shipments, but most provincial wildlife officials merely look the other way, especially after receiving diamond-studded, gold Rolex watches and other such gifts from the Arabs (Weaver 1992). The confiscation of so many Appendix I birds in the United States would result in severe penalties, including possible jail sentences, but the effectiveness of CITES depends on the legislation each member country enacts to enforce it and the zeal with which these laws are enforced.

Sheikhs from the United Arab Emirates (UAE) were not so well-received in Turkmenistan in 1995 when they applied to the Ministry of Foreign Affairs to hunt Houbara Bustards. This Ministry forwarded the request to the Ministry of Nature Use which, quite unexpectedly, turned it down because the birds would be breeding (Zatoka 1995). Certain that they would be able to overcome this opposition, the sheikhs arrived in Turkmenistan ready to hunt without official approval, bringing their falcons (Zakota 1995). To their amazement, they were issued an official complaint by the Director of the Department for Animal Conservation and fined $40,000 (Zakota 1995). The sheikhs then turned to Turkmenistan's President Niyaziv, confident that they would be able to overturn the decisions of the wildlife department; instead, he backed up the decision of the Ministry of Nature Use, stating that it had jurisdiction in this issue (Zakota 1995). This was an extremely important precedent and a fine example of a country according its wildlife the respect and protection it deserves. Turkmenistan has a record of combating poaching and conducting environmental research and conservation programs (Zakota 1995).

One sheikh has renounced hunting and fostered environmental programs. Sheikh Zayed of the United Arab Emirates, while hunting gazelles with a rifle, realized that this amounted to "an outright attack on animals" and a cause for their possible extinction (Morgan 1998). He then began a program of setting tracts of land aside for wildlife and setting up breeding herds of endangered oryx, gazelles and other desert ungulates on an island off the coast (Morgan 1998). Other UAE sheikhs have obtained special favors when hunting on the African continent. The government of Tanzania granted exclusive hunting rights in one of the country's most important wildlife areas to a high-ranking official from UAE (Alexander 1993). The agreement was reached in secret with the Deputy Minister of Defense of that country, and he apparently has been allowed to hunt endangered species, such as Cheetah, with automatic weapons (Alexander 1993). The influence of wealthy Arabs in bending wildlife laws has reached to many corners of the world. One of their prime targets is North America for its beautiful Gyrfalcons (*Falco rusticolus*), listed on CITES Appendix I, one of the most coveted of all birds of prey for falconry. Their attempts at bribery, often successful, to obtain these protected birds from Canada resulted in the listing of this species on CITES to prevent any further commercialization of these birds, which was causing declines in their wild populations.

Trophy and Sport Hunting: Page 3
The vast Sahara has been the scene of similar hunts. Scimitar-horned Oryx (*Oryx dammah*) originally had a wide range in arid grasslands from Morocco and Senegal east to Egypt and the Sudan. In historic times, herds of 100 animals were commonly seen, and during wet season migrations, they traveled in groups of 1,000 animals or more. Their white and brown coloration allowed them to blend into the desert, and they were admired for their extremely long, back-curving horns. Their populations and range gradually shrank with hunting, overgrazing and agricultural encroachment on natural grasslands; the species disappeared from Egypt and Senegal in the 1850s. In the 1970s there were still an estimated 6,000 of these spectacular animals in the southern Sahara (Nowak 1999). The Haddad tribe of northern Chad centered their way of life around hunting these oryx, driving them into nets and killing them for their meat (Simon 1995).

Although traditional hunting made inroads into Scimitar-horned Oryx populations, the use of four-wheel-drive vehicles and modern firearms by prospectors and military personnel within the past 30 years drove the species to near extinction (Simon 1995). Groups of wealthy Middle Eastern hunters arrived with all-terrain vehicles and automatic rifles, eliminating these animals from most of their range. Chad's Ouadi Rime-Ouadi Achim Faunal Reserve became one of their only refuges by the 1970s, but the outbreak of war between that government's forces and Libyan-backed rebels in 1978 brought about an unregulated slaughter of the last population of Scimitar-horned Oryx within the reserve, reducing them to only a few hundred animals (Simon 1995). In an attempt to reintroduce these majestic antelope to their original range, 41 were captured in western Chad in 1966 and placed in captivity (Simon 1995). Some 500 of these oryx are part of the American Zoo Association's Species Survival Plan, and another 700 are in other zoos; an unknown number are in ranched herds, especially in Texas (Nowak 1999). A small number of Scimitar-horned Oryx were released into a national park in Tunisia in 1991 (Simon 1995), and others may be released in Niger (Nowak 1999). The IUCN listed this species as Critical in 1996, Extinct in Algeria, Egypt, Libya, Mauritania, Senegal, and Western Sahara, and Probably Extinct in Burkina Faso, Chad, Mali, Niger, and Sudan. The *2000 IUCN Red List of Threatened Species* listed the Scimitar-horned Oryx as Extinct in the wild.

The Addax (*Addax nasomaculatus*), a desert antelope which once ranged from Western Sahara and Mauritania to Egypt and Sudan, is now nearly extinct in the wild as a result of heavy hunting combined with loss of its grassland and shrubland habitat to agriculture and competition with livestock. Perfectly adapted to life in the desert, Addax are able to spend their lives without drinking water, deriving moisture from plants on which they feed (Nowak 1999). Instead of the long, arched horns of the Scimitar-horned Oryx, the Addax has horns that grow outward, then bend inward and upward. A stocky antelope that is not able to run quickly enough to flee men on horses, it has been easy prey for hunters and feral dogs. In recent years, remnant populations literally have been run to death by tourists in four-wheel-drive vehicles who pursue them until the animals fall dead in the sand (Nowak 1999). A herd in northeastern Niger was reduced to 50 to 200 animals when, according to some reports, they were wiped out by hunting. Fewer than 200 remained in north-central Chad, and another 50 along the border of Mali and eastern Mauritania in 1994 (Nowak 1999). The *1996 IUCN Red List of Threatened Animals* listed the Addax as Endangered, Extinct in Algeria, Egypt, Libya, and probably Sudan. The *2000 IUCN Red List of Threatened Species* upgraded its status to Critical. A small reintroduced population survives in Tunisia, but the wild population is at risk of disappearing altogether. More than 400 animals are in captivity, including a herd in a large dryland safari park in Texas called Fossil Rim.

Other Saharan animals have been ruthlessly pursued. Pelzeln's Gazelle (*Gazella dorcas pelzelni*) have been pushed to Vulnerable status by hunting. They are listed on the US Endangered Species Act. The Slender-horned Gazelle (*Gazella leptoceros*), native to North Africa, is now endangered throughout its range, according to the *2000 IUCN Red List of Threatened Species*. The hunting of these desert animals by men in all-terrain vehicles, some armed with

machine guns, reached such heights in the 1970s that they nearly became extinct, and their status has not improved in the intervening years. The endangered Dama Gazelle (*Gazella dama*), also a heavily hunted species, is extinct in Algeria, Libya, Mauritania, Morocco and Western Sahara; it has been reintroduced into Senegal, and populations are now confined to Chad, Mali, Niger and Sudan (Baillie and Groombridge 1996). Cuvier's Gazelle (*Gazella cuvieri*), another North African species, is also extinct in the Western Sahara and survives in endangered populations in Algeria, Morocco and Tunisia, according to the IUCN. In some cases, antelope and gazelles have been pursued by hunters in helicopters who shoot at them with rockets, a method also used to kill African Elephants in Chad, where the last Greater Kudus (*Tragelaphus strepsiceros*) were destroyed in 1976 (Anon. 1977).

Trophy and Sport Hunting: Page 4

Poachers have caused the extinction in Somalia of the endangered Hunter's Hartebeest or Hirola (*Damaliscus hunteri*), which now survives only in a restricted portion of scrubby desert of south-eastern Kenya. Looking somewhat like an Impala, this delicate, dryland antelope can live for weeks on very little water. This species is considered an evolutionary relic, having lived on earth for 15 million years, and is a progenitor of other hartebeests and the Topi; fossil evidence indicates that the Hirola's range once extended to South Africa (McKinley 1996). Kenyan populations totaled 14,000 in 1976, living along the Tana River and in the arid Garissa region to the east (McKinley 1996). In the 1980s, poachers killed off the region's African Elephants, who had kept the land clear of thorn bushes for grazers, such as the Hirola (McKinley 1996). A rinderpest epidemic brought in by cattle herders wiped out half the region's antelope between 1983 and 1985.

In the early 1990s, Somali refugees and troops fleeing from civil war in Somalia crossed into Kenya and began slaughtering the Hirola (McKinley 1996). By 1993, only 2,000 Hirola survived, and with unregulated hunting, a 1995 census found a total of 306 animals scattered in small groups over 45,000 square miles (McKinley 1996). Rangers from the Kenya Wildlife Service decided to capture and move as many as possible of the remaining animals to Tsavo National Park, where they could be guarded against illegal hunting. One hundred animals were moved to the park in 1995, and a year later, about 57 survived. In 1996, more were chased by helicopter into nets, sedated, blindfolded, and then taken by truck to a small plane which airlifted them to Tsavo. The habitat in Tsavo is lusher and greener than their native desert shrub, and the Hirola may not thrive there. Only time will tell. The *2000 IUCN Red List of Threatened Species* lists the species as Critical.

Trophy and Sport Hunting: Page 5

In South Africa, the Quagga (*Equus quagga*), a zebra-like equine, became extinct from hunting. Some zoologists consider these animals to have been a race of Burchell's Zebra (*Equus burchelli*), but others classify them as a full species. They had black, vertical stripes on the head and neck, while their back and haunches were uniform grayish or faintly striped. Native to the Cape Colony grassy plains, their limited and open habitat made them vulnerable to the Boer settlers, who killed them by the thousands (Day 1981). Many were tamed and used to guard domestic livestock at night because they gave loud alarm calls upon seeing predators (Day 1981). Some were even shipped to London and used as harness animals. The Boers used their skins for sacks and other practical purposes. By the 1850s, it had nearly disappeared from the Orange River area from relentless hunting (Nowak 1999). The last wild Quagga was killed in 1878, and in 1883, the last captive Quagga died in the Amsterdam Zoo (Day 1981). Photographs (Nowak 1999) and specimen skins exist with DNA that has been compared with living zebras. There has been talk of restoring a Quagga-like animal through selective breeding with Plains Zebras.

Many other South African species were reduced to endangered status or eliminated from the country altogether by

Boer hunting and their policy of clearing the land for livestock and agriculture. Although many parks have been set aside, wildlife as a whole has been crowded out of its natural environments in South Africa. Elephants became restricted to an area in the northeast that later became Kruger National Park, and only recently have they been reintroduced into a few parks elsewhere. Zebras have become extremely rare, with several races critically endangered (see Grasslands, Shrublands and Deserts chapter).

The high-altitude Simien Mountains National Park (6,234 to 14,535 feet) has many endangered endemics. A Survival Anglia film, fiEdge of the Abyss,fl records many of these species, including the Walia Ibex (*Capra walie*), a mountain goat found only in Ethiopia. It has a population of about 300 in the park and stays above 10,000 feet, browsing in the giant heath. These goats were common until the 1930s when hunting decimated their numbers. They also have lost habitat to agriculture and livestock. By the 1960s, there were only 200 Walia Ibex in the park, and although they have recovered somewhat, they still are poached for their magnificent, massive curved horns, hides and meat. Poachers enter the park and place nooses on the narrow mountain trails they must use to travel from one part of the park to another.

Trophy and Sport Hunting: Page 6

Local villagers in Kankani, India, have turned the tables on hunters of the threatened Blackbuck. This town, located in the Rajasthan desert of western India, has a history of preserving nature, refusing to allow an 18th century maharajah to cut their trees by encircling them and vowing to be killed rather than let the maharajah's men cut the trees (Bearak 1998). When hunters in all-terrain vehicles awoke the villagers with gunshots in October 1998, the villagers chased them off and got the license plate number of the driver (Bearak 1998). Some bucks of these striking black-and-white antelope had already been killed. "These animals are considered sacred to us, and we consider their lives more important than even our own," said a village elder of the Bishnoi people (Bearak 1998). The license turned out to belong to a famous movie actor, Salman Khan, star of many high-action, violent films (Bearak 1998). The story was told in many newspapers, and public opinion turned against Khan, who came to symbolize the callous rich who take pleasure in poaching endangered species like the Bengal Tiger and Sarus Crane (Bearak 1998). The week before, he had hunted Chinkara (*Gazella bennetti*), a Conservation Dependent species, according to the IUCN. On October 12, 1998, the actor was arrested, but he was unlikely to go to jail, as a result of his fame and wealth. The village elder said: "Between us and the animals there is complete trust. Our teachings tell us that we must serve as protectors and nurturers of all living things" (Bearak 1998).

Trophy Hunting Clubs

The US-based Boone and Crockett Club keeps records of trophy animals for North American mammals, and Safari Club International (SCI) maintains international records and promotes trophy hunting of animals worldwide. US state wildlife departments tend to favor sport hunting, and many earn large license fees from the trophy hunting of Bighorn Sheep, Elk, Grizzly Bear, Gray Wolf and other mammals. Trophy hunters in North America vie with one another to receive the "Outstanding Hunting Achievement" trophies awarded each year, primarily for having killed one each of 29 big game animals, some of which are on the US Endangered Species Act list (Williams 1991). Trophy hunting organizations have "master measurers" who check the size of horn, antlers and other measurements of animals killed for record books. SCI gives awards to those who kill at least 13 of the world's 22 species of "available" wild sheep (Williams 1991).

Rifles that fire at distant targets with telescopic lenses, elaborate blinds, heat sensors, and other technological gadgetry have weighted the contest so much in favor of the hunter that animals have become mere targets, with virtually no

hope of escape. Hunters using these high-powered rifles revel in recounting their experiences in hunting publications, whose writing fees help pay for their trips. One hunter's 1997 account recorded his delight in seeing the look of total shock of an Alaskan Dall Sheep (*Ovis dalli*) as it died from a shot he fired without it even having been aware of his presence. The hunter had selected the largest male with the most massive horns, which curved into a complete circle. Such hunting can so terrify animals that they run off cliff edges or flee into places from which they cannot escape.

Bernard Grzimek's *Animal Life Encyclopedia* recounts a hunt in the Canadian Rockies of Mountain Goats (*Oreamnos americanus*), in which five animals were pursued by hunters. They fled in terror, becoming entrapped on the ledge of an overhanging cliff, unable to move in any direction (Grzimek 1968). The hunters returned to their camp where they could see the goats as they stood on the ledge. The next day, the goats were still standing on the spot, but during the following days, they gradually became weakened and fell, one after another, usually at night, to their deaths. The last of the animals fell after 10 days (Grzimek 1968).

One US trophy hunter, Donald G. Cox, has hunted in 68 countries, taken 208 different species, including 125 from Africa, and has killed 23 of the world's spiral-horned antelope (Williams 1991). Trophy hunters try to kill as large a number of species as possible and as many trophy-sized animals as they can shoot. Many trophy hunting organizations claim to have made major contributions to conservation, but documentation is often lacking. SCI has published brochures in which it claims that it purchased habitat for endangered species. As it turned out, on investigation these claims were unsubstantiated (Williams 1991). Endangered animals are often the prime targets of trophy hunters. Safari Club International makes regular applications to the Fish and Wildlife Service to import trophies of endangered species. A 1978 application was particularly stunning because it requested permits to import 1,120 animals of a wide range of species, including Orangutans, various species of monkeys and crocodiles, and 39 species of endangered deer, gazelles, wild sheep, antelope, rhinoceroses, and 12 species of endangered wild cats. After a public outcry, the Safari Club withdrew its application, but in 1982, it was successful in its long battle to allow importation of Leopard trophies.

Trophy hunting clubs have made financial contributions to officials in foreign countries to receive permission to hunt endangered species and have convinced wildlife officials in countries such as Pakistan, Zimbabwe and Botswana that trophy hunting fees pay for conservation and should form the basis of wildlife management programs. The profits from trophy hunting pale beside those of ecotourism, however (see Trophy Hunting vs. Ecotourism Revenues section below).

Illegalities

Trophy hunting organizations have lobbied the US Department of the Interior for decades to weaken law enforcement "overzealousness" and have, on occasion, been successful. The Law Enforcement Division of the US Fish and Wildlife Service has tended to be strict in prosecuting trophy hunters for violations. In one case that inflamed Safari Club International members, it subpoenaed pages of the SCI™s *Record Book*, which listed many endangered species, to determine the details of the killing of various protected animals. To shield its members from prosecution, SCI returned information to their members on trophy animals killed at a time when they could not have been imported legally, and deleted this information in the SCI database to avoid further investigations (Williams 1991).

In another case, however, SCI influence won favors from the Department of the Interior. A highly placed official with the Fish and Wildlife Service, Richard Mitchell of the Office of Scientific Authority, allegedly accepted money from SCI in exchange for facilitating permits to get endangered species trophies into the United States (Williams 1991). Correspondence between Mitchell and SCI members included advice on registering as an institution with CITES on behalf of the trophy museum that the organization maintains in Arizona. Mitchell suggested that he would arrange to register several institutions in China and Pakistan in order to trade endangered species "specimens" with them

(Williams 1991). Another official, Assistant Secretary of the Interior G. Ray Arnett, who later co-founded a lobbying organization for trophy hunters, helped a fellow hunter caught importing an endangered species in the early 1980s by ordering agents to return the trophies to the smuggler, Thornton Snider (Williams 1991). Rick Parsons, who founded the Permit Office within the Fish and Wildlife Service, which gave permits to trophy hunters and others wishing to import endangered species, later became the Washington Counsel to Safari Club International, using his government experience to facilitate the permit process for trophy hunters and also lobbying at CITES Conferences on behalf of trophy hunters.

Ted Williams, in a 1991 article in *Audubon* magazine, tells of an appraiser for the Safari Club, R. Bruce Duncan, who arranged for many members of the club to mislabel the trophy animals they killed in foreign countries in order to import them into the United States without prosecution under the US Endangered Species Act (Williams 1991). One Club member imported a Jaguar (*Panthera onca*) pelt from Venezuela, labeled as a "goat hide" under Duncan's advice, and valued at $60; Duncan had appraised it at $11,000 (Williams 1991). Another SCI trophy hunter, Andrew Samuels, was the winner of the 1990 "Weatherby Award" given by a firearms company to the hunter who kills the greatest number of average, as well as record-sized, game animals throughout the entire world and whose character and sportsmanship are "beyond reproach" (Williams 1991). An undercover Fish and Wildlife Service Law Enforcement investigation revealed that Samuels had confided having illegally killed a Bighorn Sheep and numerous endangered foreign animals and smuggled them into the United States by falsifying shipping documents (Williams 1991). These included Jaguars, endangered wild Markhor goats (*Capra falconeri*), rare African antelope, Jentinck Duikers (*Cephalophus jentinki*), Ocelot (*Leopardus pardalis*), and a wild Asian sheep, the Punjab Urial (*Ovis orientalis punjabiensis*) (Williams 1991). Samuels paid $100,000 in fines, spent 30 days in jail, and performed 800 hours of community service; he also forfeited his world hunting rights for three years (Williams 1991).

In another case, John Funderburg, the curator of the North Carolina Museum of Natural Sciences in Raleigh, acquired more than 1,800 animals as "specimens," many of them endangered, that had been killed by trophy-hunting acquaintances (Williams 1991). They were donated to the museum as tax-exempt, but had little scientific value because they lacked information about the location or date where they were killed, and many were merely heads mounted for hanging on walls. Scientific specimens consist of the skins of entire animals, or their skeletons. A number of the donated trophy animals mysteriously disappeared from the collection, apparently returned to the donors (Williams 1991). In exchange for financial "donations" to the museum, the trophy hunters received the title of "associate curator," with certificates that allowed them to misrepresent themselves to foreign wildlife officials in order to obtain permits to kill protected animals (Williams 1991). Funderburg urged the hunters to send him the trophy animals via private taxidermists to avoid the attention of authorities, but a five-year undercover investigation by Fish and Wildlife Service Law Enforcement revealed all the details of this scam (Williams 1991).

The highly respected Smithsonian Institution has not been invulnerable to such unprincipled arrangements. A wealthy real estate developer, Kenneth Behring, pledged $20 million to the Institution's National Museum of Natural History in 1999, the largest donation in the 151-year history of the museum (Golden 1999). Behring, a trophy hunter and past president of Safari Club International, donated the remains of four endangered Central Asian wild sheep, including the Kara-Tau Argali (*Ovis ammon nigrimontana*) of Kazakhstan, listed as Critical by the *2000 IUCN Red List of Threatened Species*, to the museum. This animal cannot be imported legally because it is listed on the US Endangered Species Act, but on behalf of Behring, the Smithsonian petitioned the Department of the Interior to waive the ban in order to have the trophy shipped into their collection (Golden 1999). This action set an unfortunate precedent for this august institution. Behring is also under investigation for illegally killing three bull elephants in Mozambique, in spite of a $20,000 "donation" he made to a local hospital in the province (Golden 1999). The head of Mozambique's wildlife department, Arlito Cuco, said that the hunt was illegal, "Because according to the law in Mozambique, you cannot hunt for sport" (Golden 1999).

Hunting magazines often glorify the pursuit of endangered species. An article in *Sports Afield* encouraged the hunting in Mexico of Jaguar, Ocelot, and "crested Guan," or Horned Guan (*Oreophasis derbianus*), a highly endangered pheasant-like bird (Anon. 1981). It noted parenthetically, "However, United States laws prohibit bringing in skins"

(Anon. 1981).

Effects of Trophy Hunting on Animals

Among the most coveted of the "Grand Slam," or the most prestigious trophy animals, is the Brown Bear. The Kodiak Bear (*Ursus arctos middendorffi*) of Alaska represents a major trophy for hunters who come from all around the world to kill large males. This bear exceeds other subspecies in size, weight and skull size. These bears have been isolated since the end of the last Ice Age, and the abundant food supply of salmon runs, berry bushes and other edible plants in their habitat has produced this giant bear (Chadwick 1990). Trophy hunters pay $20,000 or more to private hunting guides for the privilege of shooting these bears. A recent study has revealed a potentially disastrous effect on the species of this trophy hunting. According to *The Kingdom. Wildlife in North America*, by the respected author and National Geographic Society correspondent Douglas Chadwick, "Continued harvesting of the biggest animals by trophy hunters has caused a decline in the average size of Kodiak Bears over the years" (Chadwick 1990). Thus, this record-size animal is gradually becoming smaller and smaller as a result of trophy hunting.

The pressure of hunters on some populations of Alaskan bears is so intense that it has altered the behavior of males, preventing their normal feeding on salmon runs. On Admiralty Island in southeastern Alaska, part of the Tongass National Forest, tourists watch female Brown Bears fishing with their cubs, but rarely see males because they have become so wary of people after years of being hunted; even females without cubs can be hunted on Admiralty Island (Crittenden 1997). The rich salmon rivers on this island are among the world's most productive, and since clearcutting of timber has been banned, salmon thrive in the clear water. Salmon is an important portion of the diet of male bears, yielding a great deal of protein and helping to fatten them for the winter. By frightening the male bears from the salmon rivers, which they have fished for thousands of years, humans may be affecting the health, survivability and size of these bears. Each year more than 40 Brown Bears are killed on Admiralty, and hunters are lobbying to reopen hunting in areas such as Pack Creek that are now closed to protect the fishing spots (Hanson 1998). This island deserves to be declared a National Park, which would protect these bears from hunting.

Another effect of hunting male bears has recently been documented by Swedish and Norwegian biologists, who found that in areas where resident adult male Brown Bears had been killed to thin the population, bear cubs suffered very high mortality for several years until dominant males reoccupied the territory (O'Neil 1997). Male bears, who have traditionally been considered threats to cubs, may be a danger only to cubs they have not fathered. Thus, the killing of bears by sport and trophy hunters may also result in the deaths of hundreds of bear cubs.

Russian Brown Bears have been hunted heavily in recent years. When a prominent government official, Prime Minister Viktor S. Chernomyrdin, announced early in 1997 that he wanted to trophy hunt a Brown Bear, local guides bulldozed a path to the den of a sleeping female bear (Filipov 1997). Tractors plowed a campsite for a large tent with mobile kitchen and cafeteria, and the Prime Minister flew in by helicopter (Filipov 1997). Chernomyrdin, accompanied by 12 hunters, rode a skimobile to the site, roused the bear and killed her two cubs and the mother. This incident received much adverse publicity in Russia. When the Prime Minister was criticized for his lack of sportsmanship, he replied: "What's wrong with that? Hunting of bears is not banned; it's a normal thing . . . I'd like to watch those who are writing about this meet those bears eye to eye to see their reaction" (Filipov 1997).

In Greece and Turkey, where Brown Bears are avidly hunted in spite of their dwindling numbers, cubs orphaned when their mothers are killed are often sold to zoos or to gypsies who treat them abusively. This trade is illegal in both countries, and the World Society for the Protection of Animals (WSPA) has saved many of these gypsy bears, who are dragged through the streets with nose rings and made to perform tricks. WSPA has placed several hundred of these abused bears in large wooded compounds, unfettered for the first time in their lives. Some had to be euthanized because of severe infections that had caused them extreme pain and serious physical disabilities that they had endured

for many years without veterinary treatment. The majority suffered the effects of malnutrition.

The animals trophy hunters seek--the finest specimens--are the very ones that should be left in the wild to maintain the species. Killing the largest specimens of a species, subspecies or population is likely to diminish it in size and survivability. This would seem elementary, but trophy hunters, state game departments, many in the Fish and Wildlife Service, the World Wildlife Fund and other organizations in favor of trophy hunting do not discuss or acknowledge this fact. Claims are made on behalf of trophy hunters that only old and non-breeding adults are killed, but this contention has been proven wrong in case after case. Brown and Grizzly Bears continue to breed until an advanced age. Other trophy animals have also been shown to be at their prime when shot.

Lions are a prime target of trophy hunters, who select the largest male specimens, especially those with enormous manes. Two filmmakers, Derek and Beverly Joubert, in producing their dramatic series, fiLions of Darknessfl for the National Geographic Society, followed three exceptionally large males for a long period. These magnificent Lions spent most of their lives in a national park in Botswana, but made the fatal mistake of leaving the park and entering a wildlife management area where trophy hunting was allowed. All were shot within a short time at the prime of their lives by trophy hunters.

Trophy hunting took a tragic and highly controversial turn when the government of Tanzania sold trophy hunting rights for African Elephants at more than $4,000 per animal in the early 1990s. The *2000 IUCN Red List of Threatened Species* classifies this species as Endangered. The government claimed that the largest animals, which for trophy hunters were the most desirable, were not active breeding males, but past the breeding age and, therefore, "excess." Tanzania issued 50 permits a year for trophy-hunted elephants (Brody 1994). At least four very tame bull elephants that had been studied for decades in Amboseli National Park in southern Kenya by biologist Cynthia Moss, author of two classic books, *Echo of the Elephants* and *Elephant Memories*, wandered into Tanzania in 1994, where they were shot at point-blank range by trophy hunters (Moss 1995). The hunters had received CITES permits from the Tanzanian government to export the tusks as hunting trophies (Moss 1995). Northern Hunting Enterprises, which organized the Tanzanian elephant hunt, is run by Rick Trappe, a German Tanzanian; the hunters were two Germans and an American (Brody 1994). One of the bulls killed, called "R.B.G.," was 47 years old at the time of his death, based on aging of the jaw--not old in elephant years--and so habituated to vehicles that he could be easily approached to within a few feet (Moss 1995). Cynthia Moss said she was "devastated" by the loss of the animals, who had come to trust researchers, tourists and rangers. She stated: "The message they got from us was, 'It's OK, we're not going to hurt you, you can trust us.' Then one day they walk two kilometers into Tanzania, where they'd been going for most of their lives, and they're blown away . . . I feel as if was lying to them" (Brody 1994). A spokesperson for the African Wildlife Foundation said: "The ethics of shooting these virtually tame animals is appalling. You can't call this a hunt of any kind" (Brody 1994). Had R.B.G. not been shot, he would have lived another 18 years, according to Moss (Brody 1994).

These were among a relatively small number of large, old bull elephants left in East Africa, protected through the ivory slaughters of the 1980s by the presence of field researchers and tourists. The assertion that they were non-breeding males was refuted by Moss, who had documented that they were active breeders and, in fact, among the top breeding bulls in the Amboseli population (Brody 1994). This disputes the view that they were not contributing to the gene pool and were "excess," worthy only of being used as targets. After protests and adverse publicity on television programs that reached the United States and elsewhere, Tanzania announced a ban on trophy hunting of elephants near the Tanzania/Kenya border on December 13, 1994, and initiated an investigation into the granting of permits to shoot the Amboseli bull elephants.

In spite of the supposed ban, two other big bulls of the Amboseli, Sleepy and Beach Ball, both in their 50s, were killed in Tanzania by trophy hunters in 1996. Both had fathered calves that were born after their deaths. The largest bull in Cynthia Moss's study area is the gigantic Dionysus who, at 55 years old, weighs some 6,000 kilograms, with 100-pound tusks. He probably owes his life to Cynthia Moss and other researchers who have deterred poachers, but should he wander into Tanzania, he may be killed. The females in the family, headed by Echo, an old matriarch, prefer

Dionysus above all the males, and he has fathered many calves. In a BBC film about her work in Africa, fiEcho of the Elephants. The Next Generationfl (PBS--WNET 1996), Moss pledged that she would spend the rest of her life watching over these elephants.

Another effect of trophy hunting of elephants and many other animals is an imbalance that is created between the sexes. The largest elephant bulls of both the African and Asian species have been killed off, leaving far too few males for the number of adult females. In some parts of Africa where the ivory massacres were the most intense during the 1970s and 1980s, virtually no adult males remained prior to the 1989 CITES ban on ivory. In Asia, adult male Asian Elephants (*Elephas maximus*), also listed as an Endangered species by IUCN, have become extremely rare because they were killed by ivory poachers. Females do not have tusks, and most have been spared by ivory hunters. In parts of Asia, males without tusks, a recessive trait, have come to dominate some populations, since they are not valuable for their ivory. This is altering the traits of the species.

After the largest bull African Elephants were killed off, trophy and ivory hunters turned to the older females, who have large tusks. They are essential in maintaining and leading family groups, providing experience, protection and guidance (Moss 1995). These older females, or matriarchs, have accumulated survival lore over many decades, acquired from previous matriarchs and their long life experiences. They also know the location of scarce water holes in the dry season, where to find minerals in clay they need for their nutrition, what plants are poisonous and other bits of survival lore that can mean the difference between life and death of herd members. Yet these matriarchs also were killed in the 1980s, leaving young, traumatized teen-aged females, who wandered in disarray, without the knowledge or authority of the older females. Females as young as 10 years old found themselves matriarchs of bands of orphan calves, many just weaned. Without direction, they often blundered, placing the calves at risk.

Scientists studying elephants over the past 30 years have documented hundreds of cases of trauma and apparent mourning when family members were killed. The elephants that suffer the most are the young who see their mothers and relatives butchered in front of them. Researchers in the 1990s have noted that many of these young elephants fail to develop normally and are extremely shy, unable to find food and cope with predators as effectively as adults. Some young males, who were calves when they watched as their families were slaughtered by poachers or in culls in South Africa, were released in national parks where they later became unruly and destructive to property and to other animals. Only when older elephants were released to lead and discipline them did they calm down and assume the peaceful personality that characterizes the species.

Zimbabwe, Botswana and Namibia submitted proposals in 1997 to the CITES Conference that the African Elephant's population in their countries be down listed from CITES Appendix I to Appendix II to allow export of trophy-killed elephants. Zimbabwe requested commercial trade in trophies, and Namibia, non-commercial trade. This proposal was amended to read "for non-commercial purposes" and adopted by the CITES members at the 1997 Conference. This is a step in the wrong direction, as hunters will arrive in these countries from around the world to kill the largest, prime elephants as trophies. Shooting elephants in open country where they have no cover is hardly sport, yet the hunting companies tout their massacre as a feat of bravery. Killing them as they come to drink at the few water holes that remain in the dry season in southern Africa is also unsportsmanlike. Matupula Hunters of Texas calls such hunting "exciting and rewarding." Their brochure states, "With the country dry and surface water limited, the elephant bulls can be tracked going to and from water, or in amongst the woodlands and forest where they feed and lay up" (Scully 1997).

Trophy Hunting vs. Ecotourism Revenues

The irony of the slaughter of elephants and other large mammals for trophies is that the funds accrued from trophy hunting or ivory are miniscule in comparison to the value of these animals as ecotourist drawing cards. In Kenya, a

1989 analysis on the viewing value of elephants found that between $25 and $30 million per year was earned in tourist dollars from people attracted to the elephants alone (Brody 1994). A new project provides a local Maasai tribe with about $23,000 a year from tour operators who camp there primarily to show visitors the big bull elephants that are now so rare in East Africa (Brody 1994). During the long life of an African Elephant, it may produce tourist revenue worth $1 million, distributed to a wide range of recipients, from airlines to travel companies, and to local economies (Currey and Moore 1994). By contrast, a trophy-hunted elephant brings a one-time fee of $4,000 to $20,000. Estimates for African Lions are similar. A fully maned male Lion, according to Lee Durrell (1986) in *State of the Ark*, is worth $500,000 as a tourist attraction, whereas a Lion shot for sport or trophy is worth between $3,500 and $8,500, and its skin about $1,000.

Ecotourism has shown an astronomic rise within the past decade, with magazines, books and films aimed at the ecotourist and soaring revenues accruing to countries that protect their natural heritage. Most tourists prefer to come to a country where the animals are tame and where senseless killing is not carried out. Countries that allow hunting of the largest specimens of their wildlife, whether elephants or Leopards, are likely to suffer loss of tourist revenue because they have fewer larger animals and the hunted species often become either shy, hiding from tourists, or belligerent, charging them. A recent article in *Africa. Environment and Wildlife*, a magazine affiliated with World Wildlife Fund South Africa, gave advice to tourists coming to Okavango. Daryl and Sharna Balfour (1998) recommended that tourists avoid coming during hunting season, which runs from early April to mid-September, because game is "scarce in this areas, skittish and almost impossible to approach." They further noted that the sound of gunfire and the sight of carcass-laden vehicles can be disconcerting (Balfour and Balfour 1998). Wildlife can remain shy throughout the year, especially sensitive, gun-shy animals like elephants, and even beyond the suffering caused to the animals, this trophy hunting potentially deprives the country of far greater revenues that tourists could contribute. Several tourists have been killed recently by charging African Elephants in areas where the animals had been trophy hunted.

Tourists coming to South Africa have increased in number in recent years, producing revenues totaling $6 billion in 1995; a large percentage of this total derives from tourists coming to see scenery and wildlife. By contrast only $2 million in trophy hunting fees for rhinos, and a few million dollars more for other animals, were earned in that year, according to the Natal Parks Board (Hughes and Brooks 1996).

Botswana earns $100 million per year from tourism and only a tiny fraction from trophy hunting, yet the government actively promotes the latter activity and has failed to give national park status to its crowning jewel, the Okavango Delta. Portions of this superb wildlife area have been designated as game reserves which allow hunting, but most remains unprotected (Balfour and Balfour 1998). By contrast, Kenya has designated vast areas as national parks and has encouraged ecotourism for decades, with the result that the government earned $500 million in 1996, up from $452 million in 1995. A new organization, Okavango Peoples' Wildlife Trust, in Botswana, is pressing for a complete ban on trophy hunting in the immense Okavango Delta wetland (Jackman 1997). As a result of livestock fencing in the area, African Buffalo are declining 18 percent a year, and Lion, zebra, Sable Antelope and waterbucks are also becoming scarce (Jackman 1997). This organization has proposed that all hunting, except for subsistence or problem animals, be banned and that the Delta be promoted as an ecotourism center, with low-impact camps for luxury visitors (Jackman 1997). New fencing has blocked about one-fourth of the Okavango to wildlife, who migrate to this oasis from surrounding desert areas as a vital refuge for many months during the year. These fences also have blocked wildlife migrations between Namibia and Angola, a disastrous event for many thousands of animals (Jackman 1997). This region has enormous potential for ecotourism that would far outweigh the revenues from cattle ranching or trophy hunting.

In general, funds from trophy hunting end up in government coffers and in the pockets of a few tour operators; the people of a country receive little of the revenues. By contrast, ecotourism funds are spread throughout the local economies, with hotels, taxis, buses, restaurants, souvenir shops and others benefiting from the greater number of tourists than hunters. In fact, the number of trophy hunters is miniscule in comparison to the number of ecotourists. In most countries, hunters amount to a few hundred or thousand, versus hundreds of thousands--or even millions--of

tourists. In some countries, a portion of trophy fees and the meat from slaughtered animals are shared with local villagers, but if they were given the same share of tourist money, it could be very profitable. This trend of sharing tourist revenues or park fees with local people is making an enormous difference in the lives of people around the world.

Meat Hunting

Three Asian wild cattle are endangered from hunting, and one of these is on the verge of extinction. The Kouprey (*Bos sauveli*), discovered in 1937, is classified as Critical by the *2000 IUCN Red List of Threatened Species*. Native to open lowland forests of Southeast Asia in Cambodia, Laos, Thailand and Vietnam, it is the size of a steer. Adult males weigh up to 1,980 pounds and stand 6 feet tall at the shoulder (Nowak 1999). Originally, the Kouprey's habitat consisted of low, rolling hills interrupted by patches of forest; it grazed in herds of up to 20 animals, covering some 15 kilometers a day in the open areas and entering the forest for shelter from the sun and refuge from predators (Nowak 1999).

Page 1 (Asia)
Page 2 (Africa & Logging)
Page 3 (Markets)

Meat Hunting: Page 1

Today, much of the Kouprey's habitat has become a battleground for bands of guerrillas who have planted land mines throughout the region and hunt and snare wildlife for food. After the Vietnam War and the Khmer Rouge occupation of Cambodia, Kouprey were only seen rarely (Stewart-Cox 1995). A 1986 survey found fragmented, small populations remaining in most of its range (Nowak 1999). A few Kouprey were seen in the 1980s trying to migrate through the steep escarpment separating Cambodia and northeast Thailand, but they apparently died in booby-traps set for people (McNeely and Sochaczewski 1988). The skull and horns of a female Kouprey were offered for sale in a shop in Poipet, Cambodia, in 1994 for $400, according to biologists surveying illegal trade in the country (Martin and Phipps 1996). The Kouprey has little chance of surviving without protection from hunting unless a large sanctuary is set aside for it. No strong conservation measures have been taken to date. No Koupreys are in zoos. It is possible that this species is already extinct.

The Banteng (*Bos javanicus*) is similar in size to the Kouprey, with upturned horns and an extremely stocky build. Brown to bluish-black, Bantengs have white legs and a white rump patch. Their range is larger than that of the Kouprey, extending from India to Myanmar (Burma), Thailand and Indochina, south through the Malay Peninsula to Java and Borneo. These animals are being crowded out of their forest and shrubland habitat by settlements and logging, and they are extremely vulnerable to hunting. They have become wary and shy, and large herds are now rare. Banteng have been domesticated in Indonesia and bred with domestic cattle, producing fertile offspring (Nowak 1999). Wild, genetically pure Bantengs are extinct in Bangladesh, Brunei, and probably India as well, according to the *1996 IUCN Red List of Threatened Animals*. The 2000 version of this list also classifies the species as Endangered.

The Gaur (*Bos gaurus*), largest of the three Asian wild cattle, is the most numerous, yet it is listed as Vulnerable by the *2000 IUCN Red List of Threatened Species*. Ranging from Nepal and India to the Malay Peninsula, these massive animals weigh up to 1,000 kilograms (2,200 pounds) (Nowak 1999). They have become extremely rare to absent in all

but protected national parks, and their populations have been estimated as extremely low, only about 1,000 animals (Nowak 1999). These animals are killed whenever possible for their meat throughout their range.

The Annamite Mountains extend along the border between Laos and Vietnam, rising to more than 6,000 feet in some areas, where stands of wet evergreen broadleaf forest harbor some of the strangest and rarest mammals on earth. Not until the 1990s were these remote forests explored by scientists, who examined skins and horns of rare animals killed by Hmong tribespeople. First to come to light in 1992 was the extraordinary Sao la or Vu Quang Ox (*Pseudoryx nghetinhensis*), a beautiful, gray, goat-like antelope. Its genus, *Pseudoryx*, meaning false oryx, indicates its superficial resemblance to oryx because of its long, straight, backward pointing horns. Weighing up to 200 pounds and 35 inches tall, this relatively large animal somehow had escaped the attention of scientists. (See photo in Nowak 1999.) Soon after discovery of several pairs of its horns, rewards were offered for live specimens. Two young calves were captured in Vietnam and placed in the Hanoi Zoo; within weeks, both were dead (Rabinowitz and Schaller 1994). Others were captured by villagers hoping to receive rewards, and some of the animals died (Nowak 1999).

The Hmong people know the Sao la well and hunt them whenever they can. They believe these antelope number at most a few hundred animals (Rabinowitz 1997). Many have been killed since their discovery, and hunters indicate that it has disappeared from some areas (Nowak 1999). Only a few hundred Sao las are thought to exist in Vietnam and Laos, where heavy hunting presents a major threat to them in spite of official protection by the Vietnamese and Laotian governments (Nowak 1999). Wildlife Conservation Society biologist Alan Rabinowitz (1997) estimates that they are restricted to an 800-square-mile portion of the rugged mountain forests along the border. In 1994, soon after this animal was given its scientific name, it was listed on Appendix I of CITES to prevent international commercial trade. The *2000 IUCN Red List of Threatened Species* lists it as Endangered. Vietnam set aside the Vu Quang Nature Reserve for these very rare animals and prohibited snaring in the reserve (Rabinowitz and Schaller 1994).

Other rare and newly discovered or rediscovered animals of the Annamite Mountains include two species of muntjac, or barking deer, one of which is the largest of all muntjac species; a long-snouted, yellowish wild hog rediscovered from a skull fragment; a striped rabbit, based on fur pelts found in a local village, which may be the same species or related to the endangered Sumatra Short-eared Rabbit (*Nesolagus netscheri*); and a very endangered palm civet (Rabinowitz 1997). The muntjacs and palm civet were discovered as captive animals, but nothing is known of the others, and searches for the wild hog have been unsuccessful (Rabinowitz 1997). Had these intriguing and unusual animals been discovered in a wilderness area in North America, they would be the subjects of field surveys and strict protection, as well as extensive media coverage. In Asia, where diversity is far greater and conservation a luxury few can afford, even such fascinating species may fade into extinction for lack of funding for conservation programs.

Throughout the region, much of the larger wildlife, from deer to large predators, has been hunted out, and guerrilla warfare has left the land marked with bomb craters and land mines. Alan Rabinowitz (1997), who has lived in Southeast Asia and witnessed overhunting in many countries, says, "The killing of wildlife in Laos was unlike anything I had seen elsewhere." Even within the Nakai Nam Theun Reserve, "walls of death" were constructed of thatch, bamboo and small trees, with openings rigged with snares; animals walking along the wall would be caught when trying to pass through an opening, snared by a leg or the neck, to "die a slow death" (Rabinowitz 1997).

Meat Hunting: Page 2

A wildlife slaughter of enormous proportions is taking place in Central and West African countries. Rural people who once killed animals only for personal consumption now hunt professionally, and markets in villages and cities now sell thousands of monkeys, antelope, wild cats, pangolins and even endangered apes (Pearce 1995, McRae 1997). Hunters use wire snares and leghold traps, high-powered rifles and dogs to track down animals. The tropical rainforests of west-central Africa, which once teemed with wildlife and echoed with their calls, are now falling silent.

For miles surrounding villages, wildlife has largely disappeared as local peoples throughout this vast region are killing every animal to sell its meat and body parts. Professional hunters have taken so much wildlife that little is left for local tribes. Logging corporations based in Europe have launched this commercialization of bushmeat by opening up previously impenetrable wilderness areas with logging roads and offering to buy animals that local people kill. Both the forests and the wildlife are being devastated.

Logging companies have taken advantage of these impoverished countries' national debts, buying rights to clearcut the majority of the remaining primary tropical rainforest in West and central-west Africa at bargain prices. The last primary forests in Cameroon, the Congo, the Democratic Republic of Congo and the Central African Republic are being cut and bulldozed, and their wildlife exterminated. Five-hundred-year-old trees with massive trunks 20 feet around, standing more than 100 feet tall, fall daily. The old-growth forests that provide homes for a myriad of wildlife will soon be gone at the present rate of cutting. In some areas, the logging is selective for certain species of trees, but this reduces forest diversity, and hundreds of trees are destroyed in the process of obtaining a few. When great trees fall, they bring down others, and logging roads and entry roads into forest tracts take thousands more trees.

In a shocking and moving report, *Slaughter of the Apes. How the Tropical Timber Industry is Devouring Africa's Great Apes* (Pearce 1995), the World Society for the Protection of Animals documents the tragic and gruesome slaughter of hundreds of Gorillas, Chimpanzees and other wild animals in Central African countries in this trade. The commercialization of wildlife and environmental devastation that have resulted are activities totally antithetical to the legislation and conservation ethics of the European countries--France, Germany, Italy, the Netherlands, Belgium and Denmark--that are sponsoring the logging (Pearce 1995). Several documentary films shown on the National Geographic Explorer program and CNN have shown the markets with thousands of small antelope, Chimpanzees, Gorillas, monkeys and other mammals lying dead on tables, offered for sale. fiAfrica Extremefl and fiNdoki Adventurefl are National Geographic films shown in March 2001 that document the discovery of poachers' camps with dead forest antelope, Leopard skins and other wildlife. One incident of snaring was filmed. A hunter filmed in the remote Ndoki Forest of the former Zaire found a Forest Pig struggling in a wire snare. The hunter began hitting the pig in the head to cause death, while the animal screamed and kicked. Only after hitting the animal about six times did death finally occur. Local hunters interviewed by the photographers said they regularly killed Bongos (*Boocercus euryceros*), rare and extremely beautiful rainforest antelope that are closely related to giraffes. These films traced the 1,500-mile voyage by Wildlife Conservation Society biologist Michael Fay through the last rainforests of the Democratic Republic of Congo and Gabon to publicize the fact that these magnificent wildernesses are being logged and their wildlife killed, and urgent action is needed to stop these activities.

Hundreds of Lowland Gorillas are being killed for the meat trade and sold for $40 per animal. Loggers place orders for Gorilla meat, which encourages the snaring and shooting of virtually every Gorilla that local people are able to procure for this grisly trade. WSPA found that in one district of the Cameroon, 800 Gorillas a year were being killed (Pearce 1995). Swiss photographer Karl Ammann has spent years fighting this trade (McRae 1997), and in the late 1990s, conservationists from around the world began efforts to save these beleaguered apes from slaughter.

In the forests of southeastern Cameroon, Ammann and Michael McRae, a journalist, found an infant Gorilla being kept in a dark mud-hut; the tiny animal was cowering in the corner, grinding its teeth and straining against its tether. The owner explained that the Gorilla™s parents had been shot two weeks earlier by a village hunter, the male having been wounded as he charged to defend the family, but escaping. The mother Gorilla died clutching her baby; she was then gutted and carried out of the bush, cooked and eaten (McRae 1997). Malnourished baby Gorillas are kept to be sold to passing trucks, but usually die within days. Ammann, after years of witnessing these tragedies, concluded, "Chimpanzees have the will to live if they're separated from their family, but Gorillas fall into a depressive state, and just give up on life" (McRae 1997). One baby Gorilla photographed by WSPA had been stuffed into a suitcase, where the Gorilla died of starvation after days of suffering (Pearce 1995). Another baby Gorilla was filmed lying dead in a battered cardboard box. CNN reporter Gary Streiker filmed an orphan baby Gorilla, tied on a string leash, being kicked and taunted. Huge cargo boats chug along the Congo River and other waterways of the Central African rainforest that serve as highways, carrying hundreds of orphan Chimpanzees and Gorillas to markets, stuffed in boxes

and bound with rope. fiDown the Dark River,fl a 1996 film by CNN, captured the squalid and cruel conditions that baby Chimpanzees endured on these boats. When sold as pets, baby Chimpanzees are often placed in outdoor dirt yards, lonely, solitary little gnome-like figures with sad eyes, hugging themselves or clinging to dirty cotton cloths. When they grow older and become strong and difficult to manage, they are usually killed and eaten (McRae 1997).

The total Lowland Gorilla population is not known with any certainty, and "guesstimates" of 100,000 put forth in 1985 are probably greatly exaggerated. Their true numbers are probably half that, and in steep decline (McRae 1997). Several bushmeat hunters were interviewed in fiThe Bush Meat Trade,fl a film shown on the National Geographic Explorer television series in 1995. When asked why they shoot these magnificent and protected animals, the hunters defended themselves by saying: "What's wrong with killing a Gorilla? They're fierce." One of the hunters told McRae that he was sure Gorillas were plentiful: "In Cameroon there are a million Gorillas. Three weeks ago, I saw sixty in one day. I shot three and then stopped . . . Why should I feel bad for a Gorilla? He is just a stupid animal" (McRae 1997). The West African country of Gabon also has markets where huge amounts of bushmeat are offered for sale, including Chimpanzee heads and Gorilla parts (Walters 1996).

Monkeys are killed on sight by the hundreds by hunters for sale in meat markets. Traders on the boat trip filmed in fiDown the Dark Riverfl were transporting some 30 or more dead monkeys, strung together with cord wrapped around their necks. These colorful and delicate rainforest primates are rapidly disappearing throughout their range. Monkeys from the forests surrounding the Congo River are bought by traders from hunters along the boat routes, or by logging truck drivers, and sold for $1 each in cities such as Kinshasa to be smoked for human consumption. Some traders traveling on riverboats specialize in bushmeat and barter with local people for monkeys, apes, turtles and other animals, some kept alive for the journey to preserve freshness of the meat, and others dead, stacked in piles.

WSPA has launched a campaign called EscAPE to encourage African governments to enforce existing hunting laws and police the trade in ape meat and body parts. WSPA personnel have rescued baby Chimpanzees and Gorillas from being sold as pets or abandoned, placing them in zoos or sanctuaries. A conference organized by WSPA invited loggers, conservationists, government representatives and organization representatives to discuss the bushmeat market and possible ways of ending it. The loggers boycotted the meeting, but others attended and, after two days, drafted a long list of resolutions, including enforcing existing laws, instilling conservation ethics, and restricting the logging trade (McRae 1997). In December 1995, Ammann and WSPA presented information on the trade to a committee of the European Parliament, distributing their report (Pearce 1995), and at a subsequent meeting of Afro-Caribbean-Pacific nations and the European Union, 140 delegates passed a resolution urging action (McRae 1997).

The bushmeat trade has become the foremost threat to wildlife in Central and West Africa's forests, an even greater threat than logging (McRae 1997). Urgent action to substitute other sources of income is needed. Ecotourism has been suggested, as well as employing hunters to conduct wildlife counts and become rangers. To date, no coherent program has been set into place, and hunters claim that they will continue to kill large numbers of animals until they find an adequate substitute.

Bonobos (*Pan paniscus*), or Pygmy Chimpanzees, number only about 13,000 in a restricted area of the former Zaire's dwindling rainforests. As the most endangered of the apes, exploitation could cause their extinction. WSPA documented illegal trade in these primates (Pearce 1995).

A study of the bushmeat trade in western Cameroon found serious declines in several other species of primates, caused by the meat trade. The rare Preuss's Guenon (*Cercopithecus preussi*) and the highly endangered Drill (*Mandrillus leucophaeus*), a large monkey listed on the US Endangered Species Act and Appendix I of CITES, are also being hunted for market sale. In one hunt alone, 30 Drills were killed (King 1994). Troops in the area have declined in number. One monkey, the Russet-eared Guenon (*Cercopithecus erythrotis camerunensis*) has been hunted to extinction there, and all primates from the Mount Manenguba region have declined dramatically (King 1994). In Sierra Leone, 300 tons of monkey meat are exported to Liberia each month, decimating wild populations of Red

Colobus (*Procolobus badius*) and Diana Monkeys (*Cercopithecus diana*). All these primates are listed by the *2000 IUCN Red List of Threatened Species* as Endangered. Scientists predict extinction in the region for the Red Colobus in 10 years, and the Black and White Colobus (*Colobus guereza*) in 20 years. Gabonese markets also offer various species of monkeys for sale. In one market, three small monkey heads were lined up on a gutter curb. Two of the faces were expressionless, and the third was open-mouthed, its eyes staring under furrowed brows, "as if frozen in a final, terrified gaze" (Walters 1996).

The Gabonese bushmeat trade, while not linked to commercial logging, has nevertheless grown in size and, in 1993, accounted for almost 11 percent of the country's gross domestic product (Walters 1996). A 1993 study found that, in a single city, more than 5,000 animals of 43 species of mammals, reptiles and birds were sold per year. Guenons; the magnificent and colorful Mandrill (*Mandrillus sphinx*), a Vulnerable species; Black Colobus; Chimpanzees; Gorillas; four species of duiker antelope; pangolins; Brush-tailed Porcupines; mongooses; genets; civets; and African Golden Cats are among the mammals killed for sale in Gabonese markets (Walters 1996). Birds being sold in these markets include crowned eagles, vultures, hornbills, guineafowl and plaintain eaters (a type of turaco). Pythons, Gabon Vipers, Nile Monitors, hinge-back tortoises and even threatened West African Dwarf Crocodiles (*Osteolaemus tetraspis*) were being marketed. Even animals protected under Gabonese law as endangered species are offered openly for sale. In addition to Gorillas and Chimpanzees, the Giant Pangolin (*Manis gigantea*), a race of the Potto (*Perodicticus potto*), and Demidoff's Dwarf Galago (*Galagoides demidoff*), nocturnal primates, all threatened species, could be obtained clandestinely (Walters 1996). In some areas of Gabon, high-ranking government--as well as local--officials supply hunters in villages with rifles and ammunition. Hunters then decimate wildlife and exchange the dead animals with traders for beer or soap. The traders then sell them for large amounts in city markets (Walters 1996). Hunting takes place throughout the forests, which still cover much of the country, and even in protected reserves where hunting is not allowed (Walters 1996).

An environmental organization, ECOFAC, has set up an ecotourism project to attract visitors to one of Gabon's wildlife havens, the Lope Reserve. Paths have been made through the forests, and 24 elevated observation posts have been built by members of the Scottish Primate Research Group, who have spent years habituating mangabeys and Chimpanzees to human contact (Walters 1996). The goal is to provide local communities with an alternate form of income from tourism and, perhaps, to spread the concept throughout the country and elsewhere in tropical forests where viewing wildlife is not as easy as in open savannah habitats.

The wild animal trade of Central and West Africa is obliterating populations of small forest antelope, such as various species of duiker. Twelve species of central and west African duiker are listed in the *2000 IUCN Red List of Threatened Species*. The meat trade and unregulated hunting, accompanied by destruction of forests, are the major threats. These animals are killed by capture in snares, where they may struggle for days. Two small, delicate antelope, both on CITES Appendix II, the Blue Duiker (*Cephalophus monticola*) and Bay Duiker (*Cephalophus dorsalis*), are trapped in wire snares or taken in pit traps in the Cameroon (King 1994). Dismembered duikers were seen in a market in Libreville, the capital of Gabon, in 1995 (Walters 1996).

Illegal snaring for antelope meat in national parks has been a major threat to Mountain Gorillas (*Gorilla (gorilla) beringei*), who number only about 650 animals. Many have lost their hands to snares, but some have now learned to recognize these traps and spring them. In 1995, however, a baby Mountain Gorilla strayed from the group and became snared, crying and struggling in terror for almost 24 hours while family members watched helplessly until Virunga National Park guards cut him free. Others have died in these snares.

Congo's national park, Odzala National Park, an area of 1,000 square miles, until recently had the region's only unexploited populations of African Elephants, African Buffalo and other mammals. Because of a lack of guards, poachers are now invading the park. The European Economic Community has agreed to fund the hiring and training of guards, with help from the Congolese army. This country is nearly bankrupt, like neighboring countries, making wildlife protection extremely difficult. Private hunting safaris enter the Congo rainforest and, for a fee, a foreign hunter can kill rare species of antelope and other wildlife.

Those who eat African monkeys and apes may be risking death. Several people who ate a dead Chimpanzee they found in the forest in Gabon died of the dreaded ebola virus, and the disease threat is not well-known to those who eat the meat of primates. Sooty Mangabeys harbor a virus related to HIV-2, an AIDS-like virus, and McRae (1997) saw a hunter carrying dead mangabeys, dripping blood into scratches on his leg.

In the Amazon, primates are avidly hunted for meat. Russell Mittermeier, head of the IUCN Primate Specialist Group, states that thousands of primates are killed by hunters, causing local extinctions of woolly monkeys (*Lagothrix* spp.) and spider monkeys (*Ateles* spp.) in Peru and Brazil. Forest tribes in Suriname kill very large numbers of primates for food, selling the meat in many local markets. The Wildlife Conservation Society (WCS) has been working with several native tribes in South America, evaluating the effect of their hunting on wildlife. They have found that in many cases, natives were overhunting many animals, causing local extinctions, even when only killing for subsistence. Peccaries of various species have been extremely vulnerable.

Meat Hunting: Page 3

Fruit bats of Asia and Pacific islands are killed in large numbers for food, sold by the tens of thousands to markets in Southeast Asia. Two species of the western Pacific, the Little Mariana Fruit Bat (*Pteropus tokudae*) of Guam and the Mariana Fruit Bat (*Pteropus mariannus mariannus*) of Guam, Rota, Tinian, Saipan and Agiguan have both been exploited so heavily that they are nearly extinct. Both bats are listed on the US Endangered Species Act as Endangered, yet the trade continues. On Sulawesi Island in Indonesia, thousands of bats are caught by young boys using kites to entangle them as they fly overhead. These bats are vital as pollinators of many species of commercially important fruit.

Bushmeat hunters in Indonesia and Malaysia are wiping out the populations of many animals. On the island of Borneo, a study conducted by the Wildlife Conservation Society found that hunting, legal and illegal, was the single greatest threat to wildlife (Bennett 1994). In Sarawak and Sabah, two northern states on Borneo, Elizabeth Bennett and her assistants conducted a three-year study of native hunting. These rural people, who previously had hunted only for subsistence, now hunt to sell the meat to town markets (Bennett 1994). Areas that had been inaccessible were opened up by logging roads, and hunters now swarm in the forests, killing any animal they see (Bennett 1994). Except in the most remote areas, all local people now possess shotguns. Squirrels, which have a great diversity of species on Borneo, nearly disappeared in some areas, along with leaf monkeys (Bennett 1994). Bearded Pigs, macaques, deer and porcupines are hunted, speared and trapped by some tribes (Bennett 1994). The only taboo involves the killing of Orangutans, who are protected by legend. Hunting pressures were so great that Bennett predicted extinctions for many animals, and the effects on the forest ecology were equally dire, as seed dispersers are killed off (Bennett 1994). WCS is working with local peoples to educate them about the effects of their hunting, with the cooperation of the Forest Department of Sarawak and the Wildlife Department of Sabah (Bennett 1994).

On the neighboring island of Sulawesi, formerly known as Celebes, WCS conducted a similar study in the Tangkoko-DuaSudara Nature Reserve. The study found that in the past 15 years, populations of the endemic Bear Cuscuses (*Ailurops ursinus*), bear-like marsupials who hang by their prehensile tails from branches, had declined by 95 percent from hunting (Kinnaird and O'Brien 1996). Crested Black Macaques or Celebes Apes (*Macaca nigra*), tailless, all-black monkeys found only on Sulawesi and listed as Endangered by the *2000 IUCN Red List of Threatened Species*, have declined by 90 percent, due in large part to meat hunting (Kinnaird and O'Brien 1996). An extraordinary turkey-like bird that incubates its eggs in large, leaf mounds, the endemic Maleo (*Macrocephalon maleo*), a Vulnerable species (BI 2000), has declined 75 percent from hunting (Kinnaird and O'Brien 1996). Other endemic species affected by this hunting are the Mountain Anoa (*Bubalus quarlesi*), a CITES Appendix I threatened dwarf buffalo found only on Sulawesi that is on the verge of local extinction, and the threatened, gargoyle-headed

Babirusa (*Babyrousa babyrousa*), a tusked wild pig, whose total wild population is about 5,000 (Kinnaird and O'Brien 1996). Highly organized networks hunt and trade the meat from these threatened species. Some dealers acquire animals on order for traders in North Sulawesi by driving up to 375 miles to buy Babirusa and other meat from forest hunters (Kinnaird and O'Brien 1996).

When native peoples cease hunting for subsistence only and begin hunting for markets, wildlife can be decimated quickly. Even subsistence hunting has been shown to be detrimental in some areas, but when wild animal meat becomes an economic commodity, overhunting usually results. Market hunting in the United States caused the extinction of the Passenger Pigeon (*Ectopistes migratorius*) and Labrador Duck (*Camptorhynchus labradorium*). The Eskimo Curlew (*Numenis borealis*), heavily hunted for meat in the 19th century, is probably extinct as well. The American Bison, Elk, White-tailed Deer and many waterfowl species also nearly disappeared. Following the 19th century slaughters that decimated these animals, laws banning the sale of wild meat from mammals and birds were enacted and remain in force today. In other parts of the world, only extinctions may bring about strong legislation banning market hunting of wildlife.

Persecution and Hunting

Roman Slaughters

The tradition of killing animals for pleasure has a long history in Asia and Europe. So popular was hunting in ancient Rome that mosaics and paintings often depicted this pastime as a heroic activity. Slaughtering animals was considered a form of entertainment, and people scoured the countryside for bears, Lions, stags and boars to pursue with spears and dogs (Attenborough 1987). As the Roman Empire grew to encompass the entire Mediterranean basin, its citizens traveled throughout the region to hunt and bring back animals to be killed in primitive contests in the coliseums of Rome and other cities. The coliseum games continued for more than 400 years in more than 70 amphitheaters, the largest seating up to 50,000 people on stone benches arranged around a central arena (Attenborough 1987).

Roman emperors curried favor with the public by upstaging their predecessors in killing more animals and producing more spectacular displays of slaughter (Morris 1990). Emperor Titus inaugurated the Roman Coliseum by declaring 100 days of celebration, during which enormous numbers of animals were speared by gladiators. On the opening day, 5,000 animals were slaughtered, and over the next two days, 3,000 more were killed (Morris 1990). The caged animals were kept underground in dungeons where they were not fed, and on the day of the festival, they were hauled in their cages onto lifts that brought them into the center of the arena. As the crowd roared with excitement, drums were beaten, trumpets blown, and the terrified animals were set loose (Attenborough 1987). Sometimes the animals were goaded to attack one another, and at other times, men armed with spears and tridents pursued them around barriers made from shrubs in imitation of hunts in the wild (Attenborough 1987). One arena hunt resulted in the killing of 300 Ostriches and 200 Alpine Chamois (Morris 1990).

Lions, Tigers, bears, bulls, Leopards, Giraffes and deer died after being tormented, stabbed and gored (Morris 1990). Big cats that had been starved were released into the ring where a human slave or prisoner of war was lashed to a post; the animals clawed at the person before they themselves were speared and stabbed by gladiators (Attenborough 1987). In some of the larger slaughters, 500 Lions, more than 400 Leopards, or 100 bears would be killed in a single day (Morris 1990). Hippos, even rhinoceroses and crocodiles, were brought into these arenas, and sometimes gladiators employed bizarre methods of killing such as decapitating fleeing ostriches with crescent-shaped arrows (Morris 1990).

The Roman audiences cheered these brutal slaughters enthusiastically as a rule, but when 20 elephants were pitted against heavily armed warriors, the screaming of these gentle animals as they were wounded caused the crowd to boo the emperor for his cruelty (Morris 1990). This did not stop their use in the games however. These slaughters virtually eliminated large mammals from the Mediterranean area. North African Elephants (*Loxodonta africana*) were exterminated, having been hunted and captured to die in these arenas (Leakey and Lewin 1995). Elephants were also used by the Romans for transport and even conscripted for battle by Hannibal, a Carthaginian general who used them in a deadly march across the Alps, in which all the elephants died of exposure. Romans were probably the key element in the disappearances of the Asian Elephant (*Elephas maximus*) from West Asia as well (Leakey and Lewin 1995).

Prior to the expansion of the Roman Empire, Atlas Bears (*Ursus arctos crowtheri*) lived in the mountains and forests of North Africa, the only bears on the African continent. Named for their last refuge in the Atlas Mountains of Morocco, they were a race of the Brown Bear which is native to Eurasia and North America. North Africa was the species' most southerly distribution. When Romans entered North Africa, they cut the forest habitat of this bear and slaughtered thousands for sport. Others were collected for coliseum combat, where they were attacked by smaller animals, or gladiators wielding axes, spears and other weapons. Over the centuries, the Atlas Mountain forests were leveled for building materials, and colonial landowners used the cleared land for grazing livestock (Day 1981). The

Atlas Bear became restricted to Mount Atlas, where an 18th century French naturalist discovered a fresh skin, upon which the first scientific description was based (Day 1981). Even as late as 1830, the bears were common enough to be captured and sent to French zoos. In 1840, an English scientist concluded that this bear, smaller than the American Black Bear (*Ursus americanus*), was a distinct subspecies. It was stocky, with a short face, blackish-brown, shaggy fur on its back, and orange-rufous fur on its belly (Day 1981). This differentiates it so much from the Brown Bear that modern taxonomists might consider the two distinct species. Although Atlas Bears became increasingly rare, they received no protection from hunting, and the last of these bears were shot around 1870 (Day 1981).

Herodotus and Aristotle, philosophers of ancient Greece, wrote that Lions once lived in that country (Attenborough 1987). Two thousand years ago, the range of these big cats extended eastward in a continuous band to India and Pakistan and throughout the African continent. The Lion disappeared at an early time from Italy and Greece after being hunted and captured by the thousands for gladiator spectacles. When European Lions had been killed off, Romans turned to North Africa. The Barbary or Atlas Lion (*Panthera leo leo*), once distributed through much of the region north of the Sahara, fell victim to hunting and Roman Coliseum games. Known for its enormous mane, which covered virtually half its body, the male Barbary Lion was one of the largest of all races of Lions (Day 1981). It was also the nominate, or first subspecies named. This massive animal weighed as much as 500 pounds and measured up to 10 feet long from the tip of his nose to the tip of his tail (Day 1981). After centuries of hunting, persecution and habitat loss, these Lions withdrew to remote forests, where the last of them were systematically hunted down. Arabian tribesmen in Tunisia and Algeria chased them for sport, and later, French colonial governments paid bounties for their skins; by the 19th century, hunters had exterminated the last of the lions in Algeria (Day 1981). Government lists recorded the bounty fees paid, with fewer each year; only one skin was submitted for payment in Algeria in 1884 (Day 1981). Their final refuge, like the Atlas Bear's, was the wilderness forest of Morocco's Atlas Mountains, where hunters killed the last one around 1922 (Day 1981). Although officially extinct, some of these Lions may still survive in captivity. Certain circus and zoo Lions resembling the original Barbary Lion have been identified, and an effort is being made to gather a breeding colony of these animals. Whether they are, in fact, direct blood lines from the original North African Lions remains to be seen.

By the 13th century, Lions had been eliminated in the eastern Mediterranean; they disappeared from Iraq, Iran and Pakistan by the 1800s (McClung 1976). The last Lion in the Saudi Arabian peninsula was killed in 1923. For most ancient cultures of the Middle East and West Asia, killing one of these great cats, especially a large male, was considered a heroic deed worthy of being recorded in paintings and mosaics. Many such art works remain from Assyrian and other West Asian cultures. By the mid-19th century, Asiatic Lions (*Panthera leo persica*) had become confined to India, but were still widespread in that country (McClung 1976). During the last half of the 19th century, however, Indian Lions came under siege by British Colonial officers, who traditionally proudly took a Lion pelt back to England; a single hunter boasted of shooting 300 Indian Lions in 1860 (IUCN 1978). Under such pressure, Lions disappeared from all of India, save the Gir Forest in the southwest, by 1884 (IUCN 1978). In 1900, protection was finally accorded the last of these Lions, when their populations had been reduced to fewer than 100 animals (McClung 1976). Today, the Gir Forest Lions number a few hundred animals, all that remain of these proud cats on the Eurasian continent. Confined to a habitat that was rapidly being whittled away by villagers cutting firewood, and overgrazed by livestock, the Gir Lions are now protected in the Sasan Gir National Park of western India where, in recent years their population has increased.

Hunting by Romans and later peoples, combined with capture for the colosseum games, devastated the wildlife of North Africa and the entire Mediterranean region. Large predators, as well as deer and other ungulates, disappeared altogether or become endangered. Few conservation programs exist to protect remaining populations from hunting and persecution.

Predator Prejudice

The Roman tradition of persecuting predators spread throughout Europe and intensified in proceeding centuries, reaching superstitious depths in the Middle Ages. Beliefs that fiwerewolvesfl existed resulted in the persecution of wolves in Europe and Russia that continues today. Fairy tales are still recounted to children, in which wolves and bears are depicted as voracious killers. These stories, especially those by the Grimm brothers, frighten small children with tales of wolves, that pursued and ate small children and adults alike. "Little Red Riding Hood" and other stories instilled horror and hatred of predators. In Russia, the destruction of wolves was considered a great benefit to people, as well, with folklore embodied in tales such as "Peter and the Wolf." Persecution of wolves in that country continues to this day. With the spread of domestic livestock throughout Europe, official programs were instituted to destroy wolves (McIntyre 1995). Wolves were not the only animals killed in these programs. Lynx and Brown Bear were also eliminated from all but the most remote areas of Western Europe.

When Europeans settled in America, they brought these prejudices with them, treating native predators as vermin. Most colonies passed laws similar to Massachusetts' 1630 law requiring that "every English man that killeth a wolf . . . shall have allowed him one penny" (McIntyre 1995), and South Carolina's 1695 "Act for Destroying Beasts of Prey," which mandated that all Native American braves be required to bring in one skin of a wolf, panther, or bear, or two Bobcat skins each year. If he failed to do so, he would be "severely whipped," but if more than one skin was provided, he would receive a reward (Nowak 1972). In the East, these programs systematically killed off Gray Wolves, bears and Cougars. Large predators were effectively eliminated in the eastern states by the early 1800s, except for the Black Bear, which became greatly reduced in range and numbers.

The US government ran predator control programs throughout the country. Traps and poisons were the major tools used. Poison was liberally spread over most of the West. Thallium sulfate, strychnine, Compound 1080, and cyanide were distributed in great quantities, killing not only wolves, bears, and Coyotes, but foxes, weasels, ferrets, eagles and other birds. Any animals that ate the poisoned bait died, as well as those feeding on their carcasses. All these poisons caused a painful death, and most killed slowly. Poisoned animals could take hours to die from Compound 1080, and sometimes days after ingesting thallium sulfate. Strychnine, an extremely painful poison, can make water supplies lethal, killing humans, dogs and livestock. The wild predators that consumed Strychnine would vomit while dying from convulsions. Their bodies spread more poison, which remained toxic for a year or more.

Trapping was equally indiscriminate in its victims. Irrational prejudices against predators resulted in the total extermination, even in remote wilderness areas, of America's wolves and almost all its bears through bounty systems, federal subsidies and government control programs. Trappers and poisoners combed the countryside, randomly placing poison and traps.

Prejudice against predators affects a wide spectrum of animals, from foxes and bears to bats and birds of prey. Although the number of species that have become threatened as a result of control programs and random killing is less than those threatened by habitat destruction, the ecological consequences have affected a host of species within their habitats. These animals have co-evolved with their prey, the wolf making the deer fleet; wild cats making gazelles, zebras and hundreds of other ungulates agile. Although there is dispute as to the effect that predators have on the populations of their prey, overpopulations of deer and other ungulates have occurred in many parts of the world where predators have been eliminated. When ungulates overpopulate, they tend to overgraze their habitats, eliminating many types of vegetation, as well as birds and other wildlife dependent on that vegetation for feeding and habitat. Thus, thousands of species may be adversely affected when predators are destroyed.

Many species of snakes, as well as small carnivores such as foxes, eat large numbers of rodents, performing

important roles in preventing population explosions of these prey animals. Bats, as the most important predator of insects, control insect populations, as documented by many scientific studies. These mammals, although more abundant in number and diversity than carnivores, have declined radically in recent years, as evidenced by the enormous number now listed in the *2000 IUCN Red List of Threatened Species*. From a humane point of view, predator control has brought out the worst in human character, suppressing reason and compassion to allow fear and hate to dominate. As science has learned more about the importance of predators, and they are being protected and reintroduced in a growing number of areas in the world, prejudices remain, as do centuries-old ways of raising livestock that involve killing predators. These latter problems need to be addressed with the same vigor that has elevated predators to their rightful place at the top of their food chains in the eyes of conservationists and scientists.

Wolves, Wild Dogs and Foxes

Wolves have suffered more inhumane treatment and loss of range and populations than any other predator. The history of their survival and disappearance in various parts of the world is a reflection of the overwhelming importance of people's attitudes toward animals. When emotions, especially fear and negative superstition, rule people's minds, wolves can be destroyed on the basis of ignorance about their real threats to people and livestock. On the other hand, when people are aware of biological facts about the wolf and its ecological role, behavior, value to ecosystems, and the truth about its history of not attacking people, prejudices tend to dissipate. Native Americans had a natural affinity and respect for wolves, calling them "brother." The wolf's very survival as a species depends on its being treated with tolerance and respect. Gradually, this is happening in many parts of the world. Education and a change in government attitudes in many countries are needed to conserve this species, along with better ways of raising livestock.

Wolves, Wild Dogs and Foxes: Page 1

Prior to European settlement of North America, two wolf species lived throughout the forests of the East: the widespread Gray Wolf (*Canis lupus*), the same species that is native to Eurasia, and the Red Wolf (*Canis rufus*), a uniquely American species of the Southeast. Some biologists estimate that there were 2 million wolves on the continent at this time. European settlers entered the American wilderness and set about killing off these animals. The book, *War Against the Wolf. America's Campaign to Exterminate the Wolf*, by Rick McIntyre (1995), chronicles the history of this extermination program, based on historical and modern documents. Colonists dug pit traps and filled them with vertical stakes, which impaled wolves falling onto them. When hunters found an animal in the pit, they would leap in and ham-string the cowering wolf. John James Audubon described a farmer who captured wolves in a pit trap, severed the tendons in their hind legs, then tossed the crippled animals into a pack of dogs which tore them

apart (McIntyre 1995). The new colonists and their professional hunters set toothed traps that held the animal's leg while the teeth broke through its skin, wounding and breaking bones. Some who captured wolves cut off the lower jaw and turned the animal free to starve (Laycock 1990). Others set them afire, or started forest fires to rid the woods of wolves (Laycock 1990). Strychnine and thallium were placed in meat baits. Wolf pups were ripped apart by dogs, stomped to death, or burned alive in their dens. One predator hunter threw baited fish hooks, attached to lines, into wolf dens, waited until the pups swallowed the hooks, which embedded in their stomachs, then dragged them out of the den and killed them (McIntyre 1995).

Europeans were convinced that wolves hunted humans, even entering towns to kill children as they slept. In truth, wolves are neither ferocious nor killers of people. No case of a non-rabid North American wolf killing a human has ever been documented (McIntyre 1995, Nowak 1999). Very passive when trapped, they do not even attack the trapper as other predators might. Native Americans took wolf pups out of dens for pets without ever being attacked by the parents.

Red Wolves, named for their reddish-brown coats, had other color phases as well. Prior to their near-extinction, they exhibited a range of colors from black to gray and brown. The genes for these color phases were eliminated along with the wolves themselves in predator-control programs. Originally, this wolf inhabited the United States as far west as Oklahoma and eastern Texas, north to Indiana, as well as the southeast. The Red Wolf is the only surviving wolf that evolved in North America. This species and its ancestor, *Canis edwardii*, had been resident in forests as far north as Pennsylvania since the middle Quaternary epoch (Nowak 1979). Dr. Ronald Nowak, an expert on wild canids, maintains that the Red Wolf is a far more ancient species than the Gray Wolf. The latter species is thought to have evolved more recently in Eurasia, during the early Pleistocene, and migrated into North America across the Bering land bridge that linked the continents (Nowak 1979).

Weighing only 20 to 40 kilograms (44 to 88 pounds), and 660 to 790 millimeters (26 to 31 inches) tall at the shoulder, the Red Wolf is larger than the Coyote (*Canis latrans*), but smaller than the Gray Wolf. Mating for life, it breeds in February or March, producing two to six pups in March or April. The pair dens in hollow logs or along banks of canals or ditches. These wolves did not usually form packs, but were most often seen in pairs or small family groups. They were systematically trapped, shot and poisoned out of their range. From the 17th century onward, in state after state, these wolves were exterminated to the last animal, pushing this species toward extinction. Federal predator-control programs took some 50,000 Red Wolves from 1937 onward, until they were virtually extinct in the wild (Laycock 1990). It was not until 1962 that this wolf's highly endangered status received any attention from biologists and wildlife officials. Still, no action was taken to stop state trapping and predator-control programs for another 11 years.

By the 1970s, the Red Wolf had been completely exterminated, except a small population that survived in one county in southwestern Louisiana and in adjoining areas of eastern Texas (Carley 1975). Coyotes had moved into the range of the Red Wolf and interbred with some of the last members of the species. This hybridization spelled the demise of wild Red Wolves. It has been suggested that this interbreeding occurred only because Red Wolves had become so rare that they were unable to find mates of their own species. A live-trapping program to capture the last, pure-blooded specimens, as the only way of saving the species, began in 1973 in Texas, funded by the US Endangered Species Act (ESA). Fewer than 100 animals remained. After capture, X-rays were taken of these animals' skulls to determine which were pure-bred and which were hybrids, based on their skull shape and dimensions.

A number of these hybrids, as well as the pure-blooded Red Wolves, were in poor health from mange, heartworm and other parasites when captured (Carley 1975). Their last attempt to survive in the wild had obviously been a difficult one. Their remaining habitat in Texas and Louisiana had become a mosaic of agricultural and residential development, leaving little natural forest. Moreover, they were under constant threat from trappers and hunters. After five years of live-trapping, only 40 pure-blooded Red Wolves were identified, and they were sent for captive breeding at the Point Defiance Zoo in Tacoma, Washington. No further Red Wolves were found, and in 1979, Howard McCarley and Curtis Carley of the Red Wolf Recovery Team, authorized under the US Endangered Species Act, announced in a status

report, "Recent findings indicate that the only extant subspecies (*Canis rufus gregoryi*), once occurring from eastern Texas to eastern Mississippi, for all practical purposes is extinct in the wild" (McCarley and Carley 1979). The other subspecies of the Red Wolf, the Florida Red Wolf (*Canis rufus floridanus*), had become extinct by 1917 (Day 1981). So many wolves of the Florida race, which once ranged into Georgia and southern Tennessee, were black, that this wolf was originally named the Black Wolf. This genetic strain is now lost.

Of the 40 captive Red Wolves, 14 were selected to form the nucleus of a Fish and Wildlife Service-sponsored captive-breeding colony (Nowak 1999). In 1977, offspring were successfully produced, and by 1989, there were 83 descendants, and the last surviving wild-caught Red Wolf died (Nowak 1991). In 1993, the captive colony consisted of more than 187 animals in 31 breeding facilities. By 1995, there were 289 living descendants from the original wild Red Wolves, the majority in Point Defiance Zoo in Tacoma, Washington (Nowak 1999). In the mid-1980s, reintroduction programs began with the release of several of the captive-bred wolves to the wild. This was the first time the American government had ever sought to introduce and protect wild populations of wolves, instead of eliminating them. Since the Coyote is now present throughout the Red Wolf's original range, attempts were made to find reintroduction areas without Coyotes to prevent hybridization and competition. In 1987, four pairs of Red Wolves were reintroduced into the 120,000-acre Alligator River National Wildlife Refuge, an island in North Carolina without resident Coyotes. A pair released on Bulls Island in Cape Romain National Wildlife Refuge in South Carolina produced two pups in 1988. These pups were captured and released in the Alligator River Refuge in 1989. Another pair, introduced to Horn Island off the Mississippi Coast, produced seven pups in May 1989. By the close of 1993, 46 to 60 animals survived in these newly wild populations by Fish and Wildlife Service counts.

In 1991, a pair of Red Wolves and their two pups were set free in Great Smoky Mountains National Park in Tennessee. Jan DeBlieu, a writer on endangered species, witnessed the release of the wolf family (McIntyre 1995). This area has resident Coyotes, which arrived in the mid-1980s, and the interaction between the two species will be closely watched. Several Coyotes and the adult Red Wolves have radio transmitters and were tracked by a number of biologists after their release. DeBlieu was present when, soon after their release, the male and pups traveled 2 miles away from the female, who lay quietly in a field. Suddenly the researchers heard the prolonged, low howl of the male wolf and high-pitched yaps of the pups, a song "not heard in the Smokies for one hundred years" (McIntyre 1995). They were calling the female, who ran toward them. This national park receives 8.6 million visitors a year--more than any other park in the system. The visitors tend to stay near roads, however, and most of the park is roadless wilderness. Prey is abundant, and both the adults and pups began catching rodents and rabbits, hunting at dawn to avoid tourists during the day (McIntyre 1995). By late summer 1994, there were seven Red Wolves in Great Smoky Mountains National Park. Two more family groups were released the following year, but the available prey in Great Smoky Mountains National Park is limited in the mountainous terrain (Rancourt 1997). As many as 26 wolves lived in the park in 1997 (Rancourt 1997). A few pairs have produced young.

For the most part, these reintroduced wolves have survived with few conflicts with local people, mainly due to the extensive education programs and hearings held by the Fish and Wildlife Service in each area prior to releases. Some private landowners in North Carolina became apprehensive about the potential threat to children and livestock. The Fish and Wildlife Service has paid claimants for losses even when no proof was submitted that it was, in fact, a wolf at fault. One livestock owner admitted that the Red Wolves had become "good neighbors." Yet even these limited reintroductions have provoked resentment in some local communities which harbor ancient prejudices about wolves. The North Carolina state legislature passed a law early in 1995 that defied the US Endangered Species Act, allowing people to kill wolves that attacked livestock. The Fish and Wildlife Service accommodated these concerns by changing its policy in April 1995 to allow killing of Red Wolves thought, but not proven, to be attacking livestock in North Carolina and Tennessee. One of the first wolves killed, male number 464, was shot in 1995 in North Carolina by a landowner who caught him digging under his dog's pen. This wolf had been released the previous year near Alligator River National Wildlife Refuge, but prey was scarce, so Fish and Wildlife Service personnel recaptured him and freed him on the mainland. Number 464 had not been guilty of preying on livestock.

Further incidents between residents and Red Wolves occurred in 1997 and 1998, with wolf pups that were attempting

to disperse into new territory being trapped. One young wolf that had been taken in a leghold trap in North Carolina was rescued by the Fish and Wildlife Service and returned to a penned enclosure in 1998. The local county representative stated that wolves were unwanted intruders and would be dealt with by residents. This does not bode well for reestablishment of these wolves.

If the Red Wolf survives this irrational prejudice, it may reoccupy many of its original haunts. The threat of hybridization with the Coyote will remain, however, and without corridors of habitat to link reintroduced populations, these wolves risk becoming inbred. With education of the public, one day the Red Wolf may be restored as a natural predator, benefiting its prey and ecosystem.

Wolves, Wild Dogs and Foxes: Page 2

Unlike the Red Wolf, Gray Wolves traveled in large packs in the Great Plains of the West. Many of the wolves painted by George Catlin, the great 19th-century artist of Native Americans and wildlife of the Plains, were beige or pure white, as are many of the wolves of the grasslands of northern Canada. Early hunters killed wolves for their pelts by trapping, poisoning and shooting. Many were used for target practice in the open country. When livestock ranchers took over huge tracts of land in the West, the Gray Wolf became a target for total extermination. Cowboys often roped wolves and dragged them to their deaths across rough ground (McIntyre 1995). Federal trappers used even more brutal killing methods (McIntyre 1995).

James Josiah Webb, who wrote a memoir of events in the Santa Fe, New Mexico, area from 1844 to 1861, recounted that two men conducted a wolf-killing operation by spreading strychnine bait placed in chunks of bison meat around the prairie. The number of wolves that once inhabited the region was so dense that they found 64 dead wolves within 1.5 miles of their camp in a single day after a poisoning; they bragged that they earned $4,000, an enormous sum in those days, by selling wolf pelts (McIntyre 1995).

As wolves were exterminated in one state or territory after another, a few of these intelligent animals managed to escape traps, guns and poison, earning the label of "outlaws." These wolves ranged alone or in small packs, and in the last days of the western wolf, some trappers spent months or years in determined pursuit of them. The ability of these wolves to elude their persecutors were truly amazing. One of the most famous such cases was described by Ernest Thompson Seton, an English artist and writer, in *Wild Animals I Have Known* (1899). Based on fact and documented by photographs, it concerned Lobo, an enormous wolf, called "The King" by Mexican residents who lived near a huge cattle ranch in northern New Mexico. For many years in the 1890s, Lobo led a pack of five wolves. He had a distinctive, deep howl that ranchmen recognized among the howls of the other wolves. He was by far the largest wolf in the pack and exceeded the size of other wolves in the region. Whereas most wolf paws measured 4 3/4 inches, Lobo's were 5 1/2 inches long. His mate, whom the Mexicans called Blanca, was a large, magnificent white wolf.

These wolves, like many others of the West during this period, had been deprived of their natural prey, White-tailed and Mule Deer and Elk, which had been hunted out by settlers and replaced with livestock. The wolves turned to livestock as the only large prey available and, in doing so, became the target of ranchers' wrath. Western ranchers, like many livestock owners in Europe, believed that they should be able to release cattle to roam free without herding them into shelter at night. This situation had existed in Western Europe after large predators were eliminated from all but the most remote areas. In their new ranches, allocated to them by the government, ranchers sought to recreate the European model. This required the destruction of large predators.

Lobo and his pack refused to eat dead animals that they encountered, apparently to avoid poison, and survived on calves and sheep that they killed themselves. When Lobo and his pack killed a cow, ranchers immediately put poison in the carcass. But when the wolves returned the next day to eat, they somehow knew which parts of the carcass were

poisoned, and pulled out the poisoned chunks, throwing them aside, eating only the unpoisoned portions. Lobo also avoided the traps set for him and hid from hunters on horseback who pursued him. Trappers came from great distances to claim the high bounty on Lobo, but all failed to kill him. Ernest Thompson Seton decided to try to kill Lobo himself for the $1,000 bounty. He scattered poisoned baits, covering the human scent with other odors, and the following day, found that one after another of the baits was gone. Assuming that he would come upon the body of Lobo, he was surprised to find his five baits in a pile. Lobo had picked them up, one after another without eating them, and left them as a message to Seton. Seton obtained special steel jaw leghold wolf traps and set them in concealed places in Lobo's territory. When he came out to check the traps, he found Lobo's tracks leading from trap to trap. The canny wolf had discovered each of the traps during the night, scratching earth away to reveal the chain and trap, continuing from trap to trap until he encountered one in the center of the trail. Lobo then retraced his steps, placing each paw exactly in its old track until he found no more traps, using his paw to flip stones and earth clods to spring every trap.

Seton finally succeeded in trapping Blanca by setting hidden traps among parts of a cow carcass and covering the area with Coyote scent. Lobo avoided the traps, but Blanca made a fatal error and blundered into one. When Seton and the others found her dragging the heavy trap, she turned to fight, howling across the canyon. Lobo howled back, while Seton and the others brutally killed her. Throwing lassos over her neck and holding the ends of the ropes, they galloped horses in opposite directions until her body was torn apart. When he wrote of the event years later, Seton (1899) called the killing a tragedy. They heard the howls of Lobo for days afterward. Seton described it as having "an unmistakable note of sorrow in it, now. It was no longer the loud, defiant howl, but a long, plaintive wail." When they found Lobo's tracks at the spot where Blanca had been killed, Seton reflected, "Now, indeed I truly know that Blanca was his mate."

Soon afterward, Lobo came near the ranch house. His tracks showed that he had galloped about in a reckless manner before he blundered into a trap set in a pasture. He was able to pull out of it, but Seton then set 130 steel jaw leghold wolf traps in groups of four on every trail leading into Lobo's home canyon, and dragged Blanca's body around the area to leave her scent. He even removed one of her paws, with which he made a line of tracks on the soil covering each trap. Within days, Lobo was caught with all four legs in a trap set, having followed Blanca's scent and forgetting all caution. When Seton approached the trapped wolf, Lobo managed to stand, in spite of severe injuries, and howled his deep call, but no members of his pack responded. Seton and others wrapped ropes around his neck, put a stick in his mouth and lashed his jaws closed. His feet were tied, and when he was placed on Seton's horse, he refused to look at any of his captors. At the ranch, Seton placed a collar around his neck, secured him to the pasture with a strong chain, and Lobo lay calmly, gazing across the prairie.

When Seton came out the next morning, Lobo was dead. On measuring his body, Seton found that Lobo weighed 150 pounds and was 3 feet tall at the shoulder. He was one of the largest wolves ever trapped in the Southwest. The largest Gray Wolves are native to northern Canada and Alaska and weigh up to 176 pounds, but most wolves of the Southwest were far smaller and lighter (Nowak 1991). Scientists who measured the skulls of the pair estimated that Lobo was 4 to 5 years old when he was killed, and Blanca was 7 (McIntyre 1995). Photos of Lobo and Blanca caught in traps are reproduced in Rick McIntyre's 1995 book, *War Against the Wolf*. Lobo and Blanca were exceptional specimens, and their slaughter represented an irreplaceable genetic loss. The treatment they received will remain a blot on human "kind." Lobo was killed on January 31, 1894, near Currumpaw, and his pelt is kept at the Ernest Thompson Seton Memorial Library and Museum at the Philmont Scout Ranch near Cimarron, New Mexico (McIntyre 1995). This experience changed Seton's attitude, and he expressed strong feelings of guilt in his description of his treatment of these wolves.

Government programs did not reflect Seton's newfound sympathy for wolves. In fact, predator-control programs intensified in the early years of the 20th century. Ranchers convinced the federal government to launch an all-out attack on predators, primarily wolves. The Forest Service and the Bureau of Biological Survey used poisons and traps to kill adult animals and many cruel methods to kill the pups in dens in their efforts to try to exterminate the wolf. In 1907 alone, the Forest Service killed more than 1,800 Gray Wolves and 23,000 Coyotes, among other animals

(Laycock 1990). After the US Congress authorized the first substantial appropriation for hiring government hunters in 1915, federal wolf-control programs achieved an unprecedented level. Hundreds of agents combed the most remote wildernesses, spreading poison even where no cattle or livestock grazed. A point system was established; the highest number of points, 15, was accorded for killing a Mountain Lion or a Gray Wolf (Laycock 1990). Hired hunters earning high point totals made the Honor Roll, while others might be fired; they were expected to kill virtually every predator in their assigned area (Laycock 1990).

Within a few decades, many thousands of Gray Wolves had been killed. They were eliminated from more than 95 percent of their range in the lower 48 states by the 1930s (Robbins 1997). A few wolves, using their intelligence and survival senses, managed, like Lobo and his pack, to survive somewhat longer, but they were killed in the end. The Custer Wolf, a large female also known as "Old Three-Toes" because she had lost a toe in a steel jaw leghold trap set by a government trapper, became as infamous as Lobo and Blanca. After her mate and pups were killed, the Custer Wolf survived until caught in a trap that became snagged on rocks (McIntyre 1995).

Vernon Bailey, a biologist with the US Biological Survey, the government agency that later became the Fish and Wildlife Service, conducted wildlife and plant studies as well as predator-control programs. He noted early in the century that the Biological Survey had conducted "the most systematic and successful war on these pests ever undertaken" (McIntyre 1995). The loss of virtually all wolves in the vast area encompassing the lower 48 states may be the most devastating predator-control campaign in history.

If not for the fact that the predator-control programs of the territorial and provincial governments of Alaska and Canada did not succeed in totally exterminating the wolf, the species might be extinct on the continent. Although wolves were persecuted and trapped for their fur in the latter areas, they survived in the far north and in the eastern forests of Ontario and Quebec and have now reoccupied most of their original range in Canada.

The Gray Wolf is able to adapt to a wide variety of habitats and climates, whether searing deserts, shrublands, grasslands, forests of all types, frozen tundra or even marshlands. It had the largest range of any terrestrial mammal on Earth, other than humans (Nowak 1999). Wolves had lived for thousands of years on the continent, their environment and prey altering drastically through the Ice Ages, needing only the presence of large prey to survive. Wolf intelligence, in fact, exceeds that of the domestic dog, which has a brain 31 percent smaller (Busch 1995). In spite of the wolf™s survival abilities, the fragmentation of packs by predator-control agents prevented them from hunting normally and hastened their disappearance soon after control methods began. This need to live in a pack for hunting and companionship made the species vulnerable to extermination. When persecuted, Gray Wolves do not desert one another, and many cases have been documented of wolves sacrificing their lives in an effort to save a pack mate. This altruistic trait also contributed to their extermination. The traits that humans most admire about domestic dogs were inherited from the wolf--loyalty, intelligence, playfulness and affection. Wolf pups were first domesticated by hunter gatherers tens of thousands of years ago, and even after selective breeding by humans in the intervening centuries, they still retain many of the wolf's best qualities.

Wolf packs have a lead pair, known to biologists as the alpha male and female, who are the only members of the pack that produce cubs. They mate for life, and dominate other wolves in the pack. They are usually the fittest and largest. Other pack members challenge for leadership, which can result in a change in the alpha pair. The entire pack, which includes adult females and males and pups from the previous year's litter, cares for the pups, ensuring that the strongest pass on their genes to future generations. Young unmated females and males "baby-sit" the pups when the alpha pair and the rest of the pack are out hunting. When the pups are about six weeks old, their baby-sitters spend hours with them in wrestling matches, games of tag and other rambunctious activities. Within the pack, wolves are extremely friendly and devoted to one another, barking and yipping with delight on meeting, and before and after hunts. They howl at night, communicating with other wolf packs which howl back. Bonds between wolves, especially mated pairs, are very strong, as illustrated by the saga of Lobo and Blanca, and many other cases of wolves in apparent mourning for lost mates have been documented. For many days, one male Mexican wolf, howling plaintively, followed a government trapper who had killed the wolf™s mate and carried off her pelt.

Other species of canids show similar behavior. The African Wild Dog (*Lycaeon pictus*), a highly endangered wild canid, hunts on the African plains in even larger packs than Gray Wolves, numbering up to 26 animals, yet only one female in the pack has pups. The alpha female might have 16 pups, and if another female in the pack has a litter, the alpha female will steal the cubs and nurse them, even if the litter size reaches 20 or more. Fewer than 5,000 of these beautiful animals, sometimes called Painted Wolves because of their black-and-yellow spotted coats, remain in the wild, and they are in steep decline (Nowak 1991). In Zimbabwe, where there are only about 300 to 500 animals, they are still persecuted by farmers. Even in national parks, they often lose prey when chased off by Spotted Hyenas or Lions.

The ecology of the Gray Wolf has been studied since the 1940s, revealing it to be completely different from the prejudicial folklore of Europe. Adolph Murie, one of America's greatest biologists, conducted studies of wolves in Mount McKinley (now known as Denali) National Park, where they were neither persecuted nor hunted. In his study, *The Wolves of Mount McKinley* (Murie 1944), he revealed: "It appears that wolves prey mainly on the weak classes of sheep, that is, the old, the diseased, and the young in their first year. Such predation would seem to benefit the species over a long period of time and indicates a normal prey-predator adjustment in Mount McKinley National Park." By examining the carcasses of Caribou and other mammals killed by wolves in the park, Dr. Murie found that most were in poor physical condition. Wolf packs test their prey by isolating and then chasing individual animals to detect weaknesses, and the majority of their chases do not result in a kill.

In spite of more than 50 years of biological studies of wolves that have shown them to be a positive rather than a negative influence on their prey, there are still many who disagree. Predator-control programs have been authorized in Alaska, Canada and parts of Eurasia in misguided attempts to protect deer, Elk, Moose, American Bison and Caribou. A trophy hunting organization, Safari Club International, paid the British Columbia government to kill wolves in that province (Williams 1991). The real motivation for these eradication programs is often to promote artificial increases in populations of ungulates, such as Moose, Caribou and deer, for sport hunting.

Over the ages, prey species of wolves have evolved to survive their attacks by becoming faster and stronger. The largest and healthiest deer on the North American continent have been found in areas where wolves are resident predators. The number of wolves in a pack varies according to the size of the prey: packs of up to 15 are needed to bring down bison, while packs of seven or fewer hunt deer (Nowak 1999). Wolves hunting large prey run in shifts, with tired members of the pack replaced by rested wolves. They will sometimes need to run for many miles after Caribou, Moose, American Bison or deer before they succeed in singling out one they are able to bring down; an average of only one in 10 chases is successful. Native Americans have always been aware of the important relationship between the wolf and its prey. The Keewatin Inuits have an ancient saying: "The caribou feeds the wolf, but it is the wolf who keeps the caribou strong" (Busch 1995). The healthiest members of each prey species are able to fend off wolf packs, and only in unusual circumstances can wolves kill them. For the vast majority of prey species, wolves sense weakness in their prey, evidenced by body stance, uncoordinated movements, the smell of wounds or, most often, by their lack of endurance when being chased (McIntyre 1995).

When wolves are hunted out of an area with deer and other ungulates, the latter animals often increase in numbers to such great levels that they strip their habitat of vegetation. The overpopulation of White-tailed Deer in many parts of the northeastern United States, especially in suburban locations, has resulted from a lack of natural predators. Their absence has created a major imbalance in eastern forest ecosystems, where they have become so numerous that they consume young trees and new growth on mature trees.

Wolves, Wild Dogs and Foxes: Page 3
Although Gray Wolves were completely eliminated from the eastern states south of Canada and east of Minnesota by 1930 (McIntyre 1995), a few remnant populations survived in northern Minnesota and northern Montana. The first US Endangered Species Act in 1967 listed all wolves in the lower 48 states and Mexico as Endangered. In 1973, another Endangered Species Act was enacted, replacing the 1967 Act. Five years later, the category for the wolves of Minnesota was changed to Threatened. In subsequent years, wolves were reintroduced to the southwest, Wyoming, Montana and Idaho, listed as Threatened experimental populations. All other wolves south of Canada are still listed as Endangered. Wolves have wandered from Minnesota and south from Canada to neighboring Wisconsin and Michigan, with about 50 wolves living in each state (Nowak 1999). Prior to eradication programs beginning in the 19th century, between 9,000 and 16,000 wolves were estimated to have occupied these three states (Savage 1996). Bounty programs killed 150 wolves a year in Minnesota alone between 1949 and 1954, and this state did not withdraw its bounty until 1965; Wisconsin stopped bountying wolves in 1957, and Michigan in 1960 (Savage 1996).

The wolves of Minnesota have gradually increased in range in the past 30 years, but they remain thinly distributed in the northern portion of the state. State regulations allow them to be killed if found preying on domestic livestock, with little or no proof of depredation. Minnesota has a compensation program for livestock owners but does not attempt to relocate wolves, even though depredations have occurred on only 1 percent of farms in that state (Savage 1996). In Wisconsin, large areas have been closed to Coyote hunting during the deer season, which has greatly decreased wolf mortality there, since many wolves were shot--either mistakenly or intentionally--by hunters (Savage 1996). Unlike Minnesota, Wisconsin relocates wolves found preying on livestock and compensates owners of livestock killed by wolves; Michigan's Upper Peninsula, where wolves are found, has no livestock (Savage 1996).

Although many Minnesota residents consider wolves to be threats to livestock and resent the protection they receive from the US Endangered Species Act, for others, they are a thrilling symbol of wilderness and the America that existed several hundred years ago. Ellen Hawkins and her husband Gary live in a wilderness cabin surrounded by Superior National Forest land, prime wolf country in northern Minnesota. Because they are avid wildlife watchers, they put out food for birds, foxes, Fishers, Martens and weasels, and state officials bring the couple road-killed deer which they place in a clearing 200 yards below their house for wildlife to feed on. They saw wolves very rarely and felt lucky to hear their howls or find their tracks (Hawkins 1988). One December day, they spotted a wolf feeding on a deer carcass on their property and noticed that he was wearing a radio collar, placed by the Fish and Wildlife Service to track many of Minnesota's wolves.

Their excitement at seeing the wolf, who brought "magic to the place," dimmed when they realized he was injured. He limped, holding up his right front foot, and they saw him fall in the snow (Hawkins 1988). He kept his tail down, a sign of subservience and fear, and moved stiffly and awkwardly. He spent five days feeding on the deer, lying in the snow near it, and seemed weaker each day. On the sixth day, he disappeared from the clearing, and in the middle of the night, an amazing event occurred: "We were confronted by his face pressed against our window" (Hawkins 1988). As they stood gaping at him, they heard him thump his nose on the glass, still staring at them. The wolf then went to another window, and they found themselves again eye-to-eye with him. He had climbed a snowdrift onto their greenhouse roof and now sat leaning against the window, looking back over his shoulder at them. The Hawkinses found some chicken and tossed it onto the roof next to him, while offering him a pan of gravy. The wolf looked at the food, and then at them, but did not eat.

The temperature was 25 degrees below zero F., and they decided the wolf needed warmth. Gary got a blanket and put it around the wolf, who jumped at first, and then quieted down. His passive response made them think that he should be brought indoors. They got an old quilt, and Gary picked up the sick wolf, carrying him into their living room. The wolf was somewhat dazed, but hardly moved. They called their neighbor, who came 12 miles to see the frail and sickly wolf sitting near the stove in their living room. Uninterested in food, the wolf looked about and seemed to warm up, leaning against the stove until his fur singed. They saw that he had lost part of his front foot, and they heard him wheezing as he breathed. Within minutes, his condition deteriorated, and he began pawing at his mouth. His wheezing grew into a "terrible, deep gurgling" (Hawkins 1988). Gary moved close to the wolf and began to stroke its

head. The wolf stood up with effort, but then slumped down to lie beside the stove. Gary removed the collar so that the wolf could breathe more easily, and they saw that it had a number--6530--with the address of the Fish and Wildlife Service. The wolf suddenly staggered into the middle of the room, spasmed and struggled for breath. Gradually they saw his eyes become unfocussed, and the light faded out as he died (Hawkins 1988).

They later learned that Wolf 6530 left his pack when he was nearly 2 years old and wandered for eight months before he returned to his family. He stayed with them only two months before walking 40 miles to another hunting area. Finally, fatally ill, he came to the Hawkins' house, which was 45 miles from his pack. An autopsy revealed that he had died of a fungal pneumonia, the first such case of wolf mortality. The disease may have been brought on by stress and lack of nourishment (Hawkins 1988). Although his coat was thick, he was emaciated, weighing only 55 pounds. At his age he should have weighed at least 75 pounds. He had a tear on his lower lip, had lost three pads on his right foot, and one pad was mutilated on his left foot (Hawkins 1988). A biologist with the Fish and Wildlife Service was contacted about Wolf 6530 and, in his opinion, the wolf's foot wounds were probably the result of getting caught in a fox trap and dragging the trap about until its toes rotted off (Hawkins 1988). As long as he was dragging the trap, he was unable to hunt with the pack, and this may have explained why he was forced to wander in search of carrion.

Many Minnesota wolves and those dispersing to neighboring states and southern Canada have been trapped in leghold traps. In fact, Wolf 6530's brother had been killed by a trapper in Ontario, 115 miles to the northeast, at the age of 18 months (Hawkins 1988). Wolf 6530 had suffered for many months, and his life ended prematurely. Wolves can live 10 years or more in the wild. Only because he had turned to people during his last days did his story come to light. Ellen Hawkins reflected on the extraordinary event: "We'll never know what motivated him to come our way. I can only say that I'm grateful to Wolf 6530 for sharing his last, desperate moments of life. His act gave us a sense of connection with his world that we would never have had, and our commitment to live in harmony with that world has been strengthened. We will always carry with us the vivid image of the wolf at the window" (Hawkins 1988). The dying wolf may have sensed that the Hawkinses were friends of wildlife, having seen them put out food and watch him without taking any aggressive action toward him. Because he was a highly social animal who had been forced into solitude for most of his short life, he may have sought their company, sensing that he was close to death, preferring humans to an isolated and painful death without his pack mates. Whatever his motivation, his appeal to the Hawkinses' prior to dying was evidence of the complexity of this fascinating creature, and an indictment of the continued use of the inhumane steel jaw leghold trap.

Wolves, Wild Dogs and Foxes: Page 4

To counter the strong anti-wolf prejudice, a new organization called the International Wolf Center in Ely, Minnesota, has live wolves in an enclosure, museum exhibits and field classes. The 50,000 visitors it has received in the past few years brought $3 million to the local economy (Chadwick 1998). But wolves in Minnesota and elsewhere continue to be taken in traps set for other types of animals, causing injury or death. One study on wolves taken in various types of traps was published in the *Journal of Wildlife Management* (Ballenberghe 1984). It investigated injuries and mortality of 126 wolves trapped in northeastern Minnesota and Alaska. Traps used included steel jaw leghold traps of various types, some with teeth, others with smooth offset jaws; steel cable foot snares; and cable neck snares equipped with devices that prevented the loop from fully closing (Ballenberghe 1984). The results confirmed that steel jaw leghold traps caused the greatest number of injuries and mortalities: 41 percent of 109 adults, yearlings and pups caught in these traps incurred serious foot and leg injuries, defined as lacerations, damage to tissue, bone breakage, and joint dislocations (Ballenberghe 1984). Three wolves, including a pup, had broken leg bones; two others lost front feet after they were nearly amputated by the trap. One young male with broken radius and ulna bones in his foreleg was released in this study to stumble off; this wolf was caught by a trapper several months later (Ballenberghe 1984).

Other injuries resulted when trapped animals gnawed their own feet off and chewed on the traps, breaking teeth and

splitting lips. The steel jaw leghold traps caused tissue, muscle and tendon injuries, even when checked daily (Ballenberghe 1984). Since the observations carried out were not done by a veterinarian, or with aid of X-rays and other sophisticated tools to arrive at diagnoses, many unnoticed or undetectable damage to nerves, ligaments and other body parts almost certainly went undetected. Other effects of trapping noted in his study were heat and water stress; stress from risk of discovery and killing by people happening upon them; killing by other predators finding them trapped; and undiagnosed trauma (Ballenberghe 1984). In the same study, a wolf was killed by a cable neck snare when it passed over his chest and closed around his stomach. Long-term effects from broken teeth, severed tendons and poorly healed bones made survival unlikely. This was the case with Wolf 6530, described above, who suffered for many months with an injured paw after pulling free from a leghold trap, becoming weaker and weaker until he died.

Another method tested involved darting animals with tranquilizers from helicopters, which resulted in the euthanizing of a wolf after it became paralyzed when the dart penetrated its spinal column (Ballenberghe 1984). Of the animals darted, 85 percent sustained injuries and soft tissue damage. The Ballenberghe study also cited other research projects with even higher mortalities, and commented, "None of the wolf capture methods discussed here resulted in study animals that were free of injuries, but some methods clearly had more potential to inflict serious injuries than others."

The steel jaw leghold traps that Ballenberghe found to be the most injurious are the very traps that are still used by the Fish and Wildlife Service, Animal Damage Control (ADC)*, state game departments and others, killing wolves and many non-target animals. The US Department of Agriculture's Animal Damage Control program, which traps hundreds of thousands of Coyotes, Cougars and other predators for the benefit of livestock owners, has been responsible for the incidental trapping of endangered and threatened species, from Bald Eagles (*Haliaeetus leucocephalus*) to Gray Wolves.

*Animal Damage Control (ADC) has since been changed to fiWildlife Services.fl

---

Many wolves are trapped by wire snares. A loop of wire pulls tight and cuts through the skin when the animal steps into it or, in the case of a neck snare, it is placed a few feet off the ground and strangles and cuts through the flesh of an animal blundering into it. Most US states allow wire snares, and wolves are taken in them in Alaska. The Alaska Department of Fish and Game has sponsored various control programs or "studies" on wolves, using airplanes, steel jaw leghold traps and, most often, wire snares. The avowed purpose of recent state research, which involved trapping wolves in a large wildlife management area near Fairbanks, was to determine their population and effect on ungulate prey, such as Moose, Caribou and Elk. In fact, this and similar "studies" have been launched after hunters urged the state to eliminate wolves in order to leave more prey species. The rationale of the trapping program is based on the premise that killing wolves will result in increases in the population of these prey animals. A program in the 1970s involved the elimination of wolves from a 3,000-square-mile area, but according to Warren Ballard, a retired game biologist from Alaska, the Moose population did not rebound after wolves were exterminated (Egan 1992). Moreover, it creates an imbalance in the ecosystem. Killing of ungulates by human hunters does not cull the sick and old, but rather the fittest and largest.

In 1992, such a wolf "research" program, involving the setting of thousands of wire snares, was carried out south of Fairbanks. Gordon Haber, a conservationist and wolf biologist who has worked for decades on behalf of Alaska's wolves, brought television crews to film the snaring operation in December 1994. They were shocked by the scene that awaited them. Four wolves had been caught in wire snares, two of them pups. One was dead, and three were still alive, terrified and in great pain. A 6-month-old pup, with its paw caught in a neck snare, had chewed off its foreleg in a futile effort to escape. Another had been snared around the chest, causing deep wounds. The other two had been snared by the leg. All these snares had been set to catch the wolves by the neck and kill them, yet none did. Members of the pack milled about nearby, unwilling to leave their fellows. Two snared Caribou were lying dead nearby. A trapper was filmed as he attempted to shoot the wolves, repeatedly missing or wounding them because he used the wrong caliber ammunition in his gun. He shot one pup five times in the head and body at point-blank range with the

wrong gauge ammunition. The pup, wounded, remained standing. The trapper then reloaded with other ammunition, and this time shot all three wolves fatally.

The film of this massacre was shown on national news programs, causing outrage around the country. Alaska Governor Tony Knowles called off the hunt, ordered a review and stated, "That's no way to treat an animal." Six hundred and eighty-five snares set for this program were removed from state lands, but not before 12 more wolves had been killed. More than 1,000 snares had been set by the state for this "study," which lasted two years. On February 2, 1995, Governor Knowles made public the results of the Gray Wolf kill review. During the program, 134 wolves were snared, 37 of which were found alive and had to be shot. Also caught in the neck snares were Moose, Caribou, Grizzly Bears, Wolverines, Coyotes, Red Foxes, Arctic Hares, Common Ravens and Golden Eagles (AWI 1995). This gruesome haul of non-target animals is typical of the indiscriminate nature of snares.

Governor Knowles canceled the wolf kill indefinitely and ordered a review of Alaska's entire predator-control policy. This "research" program was permanently canceled in February 1995. A biologist with the Alaska Department of Fish and Game admitted in 1997, while appraising the program, that it had been ill-conceived, poorly run and politically motivated. He insisted, however, that wolves had suffered no pain from the snaring and even from chewing off their own paws. This failure to acknowledge proven neurological effects of such injuries is not unusual among state game department officials.

In 1996, the Alaska Department of Fish and Game began a new program to curtail the wolf population in the Fortymile region near Fairbanks. This time, the program consisted of sterilizing the alpha male and female of each of the 15 wolf packs in the area, with plans to relocate all "subordinate" wolves (Trost 1998). The plan to reduce all 15 packs to a single sterile pair was intended to increase the number of Caribou for hunters (Trost 1998). The Alaska Wildlife Alliance strongly opposed this project, and Gordon Haber expressed the opinion that it would reduce the wolves of the area to the brink of extinction (Trost 1998). This research program was described as "based on assumptions" by the National Academy of Sciences.

Alaska's trapping regulations are the laxest in the country, with no visitation requirement, meaning that trappers are not required, as in most states, to check traps daily for animals. Animals suffer in steel jaw leghold traps or snares for days. One case is known of a trapped Lynx--brought food by its mate--that lived for six weeks with its leg caught in a leghold trap.

No state regulations govern the manner in which trapped animals are killed, and trappers often stomp trapped animals to death to obtain pelts without damage--such as that caused by bullet holes--to the pelt. The Alaska Game Department takes advantage of the strong ties between wolf pack mates by requiring trappers of wolves to count the number of wolves in the packs of the animals they trap. Pack mates will usually remain by their trapped pack mate, even when it is dead in a trap.

Wolves, Wild Dogs and Foxes: Page 5

Aerial hunting of wolves was carried out for decades in Alaska by private parties and the Alaska Department of Fish and Game itself. Prior to 1972, wolves could be hunted from airplanes for sport, or by state predator-control agents. Federal legislation was enacted in that year to ban such hunting, with high penalties including confiscation of aircraft, large fines and even jail terms. In fact, Director of Wildlife Conservation David Kelleyhouse, known as "Machine Gun Kelleyhouse," suggested that the best way to control wolves was to machine-gun them. In 1991, a state law was passed in Alaska that allowed shooting of wolves if the aircraft landed 330 feet away from the animals. This legislation was virtually impossible to enforce. Many hunters flew over wolf packs, hazing them until the wolves were too exhausted to escape. Then they would land and kill the wolves. The law failed to protect wolves from this type of

harassment and killing. Among the misuses alleged were trappers checking their trap lines by flying from one set to another, and killing wolves and other predators they saw. Another common practice that was targeted was the "recreational" aerial hunting of wolves. Conservationists in Alaska began a petition campaign to change the law through voter ballot referendum for the November 1996 national election, having failed to persuade the legislature to enact a stricter law. This ballot was openly opposed by many members of the Alaska Department of Fish and Game, who were then chastised for this lobbying by the Governor. The ballot was voted into law by the Alaskan public. The new law states that no one who flies an aircraft to an area and lands, may shoot a Gray Wolf, fox, Lynx or Wolverine on the ground the same day. This closed the loophole left by the previous law.

Wolf hunting is carried out by snowmobilers in many parts of Alaska. Brenda Peterson, an eyewitness to one of these hunts, described it, and photos taken of the event documented the wolves being chased into a tight group and killed (McIntyre 1995). Six black wolves, an entire family, died "splayfooted against one another," having run for their lives at a gallop of 35 miles per hour as the snowmobilers herded them into a terrified, dense mass, and then shot them at point-blank range (McIntyre 1995).

The total kill of wolves by hunters and trappers in Alaska in recent years has declined from 1,600 taken in the winter 1993 to 1994 to 1,180 taken in 1995 to 1996, according to the Alaska Department of Fish and Game. With a total wolf population in the state in late 1995 estimated at about 7,000, the kill represents 17 percent of the total population. This is probably threatening some populations. One race of Alaskan wolves, the Alexander Archipelago Wolf (*Canis lupus ligoni*), an extremely rare subspecies, resides in the heavily logged Tongass National Forest. In spite of various threats, the US Department of the Interior has refused to list the wolf on the US Endangered Species Act (see Forests chapter).

Within the past few decades, wolves have again become resident in several western states. Beginning in the 1970s, a few Gray Wolves crossed the border from Canada into Montana's Glacier National Park where a population of about 100 wolves in 10 packs now lives (Stevens 1997).

Wolves, Wild Dogs and Foxes: Page 6

In the 1990s, the Fish and Wildlife Service began a reintroduction program of wolves into Yellowstone National Park and portions of Idaho and Montana to the north. Historically, wolves were killed to the last individual in Yellowstone National Park by park service personnel under predator-control laws. Their return is a vindication of their importance in the ecosystem. From the start, the project was fraught with difficulties and controversy, with conservationists pitted against one another as to methods and regulations, and many cattle and sheep ranchers opposing the entire project, vowing to kill any wolves that strayed out of the park. Defenders of Wildlife began a fund to repay ranchers for lost livestock, which helped convince some ranchers to accept the project. Of the 14 Canadian wolves released in 1995 in Yellowstone National Park, almost all remained within the park. Two packs produced a total of nine pups, and 17 more wolves from Canada were set free in the park in 1996. The largest of the reintroduced wolves and his mate left the park, and he was gunned down by a drunken man for sport; he skinned this big male and threw the carcass into the brush. Later, the wolf's pregnant mate found the skinless carcass and dug a den beside it. The hunter who, in defiance, sported a shirt reading "Northern Rockies Wolf Reduction Project," spent six months in jail and a year of supervised probation after being found guilty of deliberately killing the wolf.

These Canadian wolves, taken from areas where they were hunted and trapped, experienced a trap- and gun-free environment in Yellowstone National Park. They have adapted well, preying mainly on Elk, which had become overpopulated. Only a few Bison have been taken. Within a few years, the wolves have had major effects on the park's ecosystem. Grizzly Bears have benefited by feeding off the remains of wolf kills, as have ravens, foxes, Bald Eagles and Golden Eagles. The park's aspen trees have also benefited. Researchers from Oregon State University determined

that until the late 1920s, young aspens were able to survive and mature within existing groves, but after the last wolves were killed off about 1926, the aspens began to die out because the overpopulated Elk browsed on these trees in the winter, stunting them. Another change that resulted from the absence of wolves was the disappearance of smaller birds, such as the Calliope Hummingbird (*Stellula calliope*) and Willow Flycatcher (*Empidonax traillii*), from brushy areas that were heavily browsed by the large populations of Elk and other ungulates. Wildlife Conservation Society (WCS) biologists have been researching the many effects of the return of wolves on the park's ecology (WCS 2000).

By 1996, three packs of wolves occupied the park, and a fourth pack of four wolves lived on the park's northwestern border. Their total population in Yellowstone has risen to about 185, exceeding the expectations of scientists (Murphy 2000). Although detractors remain, wolves have garnered a great deal of support. Scientists have come to Yellowstone National Park to study the wolves, some saying it is the best place in the world to see these animals in an open habitat, exhibiting natural behavior. Tourists, likewise, have flocked to see the Yellowstone wolves, bringing $43 million a year to the area, according to Defenders of Wildlife (Rembert and Motavalli 1998). Visitors have been thrilled to see these wolves streak across the grasslands, meet in affectionate, playful groups and raise their melodious voices in group howls. The wolves are expected to be a major tourist attraction in the future, perhaps rivaling the world-renowned geysers. Television films have been made of the wolves, chronicling their reintroduction and pack behavior, and *The Return of the Wolf to Yellowstone*, a book by Thomas McNamee (1997), recounts their reintroduction.

The wolves were released under a special designation of the US Endangered Species Act known as "non-essential, experimental populations," a category that permits authorities to kill them if they are found preying on livestock, or even if they cause adverse effects on wild ungulates such as deer and Elk. It is not legal to kill them for sport deliberately (FWS 1994). As a result, many wolves straying outside Yellowstone National Park have not fared well. One pack of 13 that roamed the plateaus north of the park declined to a single wolf in one year; all but three, who are now back in captivity, died or were shot (Murphy 2000). Several conservation organizations sued the Fish and Wildlife Service to appeal the non-essential designation, stating that there were already some wolves present that would be killed at will because of the designation. Livestock owners also sued the government, requesting that the program be stopped and the wolves be removed. These lawsuits were not heard in federal court until late 1997, after 66 wolves had been brought from Canada to Yellowstone and Idaho in 1995 and 1996.

In December 1997, the lawsuits from both sides of the wolf issue were finally heard in a US District Court, which came to the stunning decision that the Fish and Wildlife Service had violated the US Endangered Species Act by declaring the wolves an experimental population because wolves that might already be present would be denied full protection of the law. The judge ordered that the reintroduced wolves be removed from the park, but stayed his own decision pending appeal. Secretary of the Interior Bruce Babbitt expressed the Department's support for keeping the wolves in the wild. The Fish and Wildlife Service stated that should the decision be upheld on appeal, the wolves would have to be euthanized, as there was no area where they could be released (Chadwick 1998). The decision was appealed and overturned in January 2000, allowing the wolves to remain as part of Yellowstone's ecosystem for the indefinite future.

For the long-term success of the reintroduction of Gray Wolves into this region, the entire Yellowstone ecosystem, which extends well beyond the limits of the national park and other federal lands, should be protected. Already, much prime habitat that was once occupied by wildlife has been converted for agriculture, livestock and homes. Growth of housing and spread of the urban landscape in Jackson, Wyoming, are gobbling up thousands of acres each year. At least one cattle ranch has recently been purchased as a buffer for wolves and bison straying out of Yellowstone National Park. Efforts should be made to acquire more habitat so Yellowstone's wolves and those to the north could be linked through forest corridors to avoid inbreeding and provide space for expanding populations. The Greater Yellowstone Coalition has proposed a program called Y to Y, or Yellowstone to Yukon, that seeks an even more ambitious goal: to link reserves and parks between the two areas, providing a vast wildlife corridor. Much of the land in this linkage area is already federally owned. Grizzly Bears and wolves are among the many wildlife species that

require enormous amounts of habitat, and unless action is taken now, populations of these and other wide-ranging animals will become isolated and inbred.

Central Idaho has 12 million acres of national forest land and was chosen as a release site because of the enormous potential habitat. Opposition to the reintroduction in Idaho was strong, and the state legislature blocked the involvement of the state wildlife department (Robbins 1997). The Nez Perce tribe, which has a strong commitment to preserving the wolf, stepped into the void and became the first Indian tribe to manage an endangered species in an entire state (Robbins 1997). The project is headed by a tribal leader, Jaime Pinkham, a forest biologist who returned to his tribal roots and became manager of the Nez Perce Department of Natural Resources (Robbins 1997). Conservation groups, such as the Gray Wolf Education and Research Center in Idaho, are attempting to change the anti-wolf opinions of local ranchers with films, several penned wolves and other programs. Unfortunately, wolves have been released in Idaho and in Montana, where many have been shot, trapped or died from other causes. They lack the protection of a large national park where hunting and trapping are prohibited, and many ranchers graze cows and sheep in and near the national forests.

Most wolves prefer wild prey, but because of the large number of livestock in the region, the success of these releases may depend on whether the wolves can be conditioned to keep away from livestock. Several of the reintroduced wolves have killed calves in Idaho and Montana, resulting in anger from ranchers who have convinced the Governors and many state delegates to legislate against the program. Fears have even become irrational. Some ranch mothers sent letters to Idaho's Congressional delegation demanding that children be guarded from wolf attacks at school bus stops (Corbett 2000). The Republican delegation from Idaho passed a unanimous resolution at their convention, calling for the immediate removal of all reintroduced wolves (Corbett 2000). Signs urging that wolves be killed were placed in store windows in Idaho. Fish and Wildlife Service biologists killed 82 wolves during the first five years of the program, after complaints from livestock owners (Corbett 2000). Several wolves were shot under questionable circumstances. After a calf was killed, for example, the Service ordered three adult males of the pack killed from a helicopter; sharpshooters, unable to kill the adults, ended up shooting three pups (Murphy 2000). After ranchers reported that a pack had backed a group of his horses against a cliff, the alpha male was removed, leaving his mate alone and the pack without a leader (Murphy 2000).

Some environmentalists protested these killings and threatened to interfere before more wolves were shot (Corbett 2000). David Gaillard of the Predator Conservation Alliance questioned the wisdom or purpose of introducing wolves that needed to be controlled and trained (Murphy 2000). Experiments are underway using electric shock collars that shock a wolf when it comes close to a cow or calf wearing a collar that sets it off. This is a crude approach, which inflicts pain on the wolves and may not even succeed in its intent. Some humane organizations that have protested these collars have rightly stated that almost no efforts have been made to teach ranchers to protect their livestock with sheepherding dogs, pen them in at night and before calving and lambing, and use other means of preventing predation.

Wolves, Wild Dogs and Foxes: Page 7

Historically, the critically endangered Mexican Gray Wolves (*Canis lupus baileyi*) roamed montane woodlands and drylands in northwestern Mexico and extreme southern Arizona, New Mexico and Texas. After centuries of persecution, they disappeared altogether from the United States and verged on extinction in Mexico. In 1976, the subspecies was listed on the US Endangered Species Act, and in 1982, the Fish and Wildlife Service approved a recovery plan in which a professional trapper was hired to capture the last few wild wolves in Mexico. Only five of these wolves were found, and in this 11th-hour rescue, they were live-trapped in Chihuahua and Durango for captive breeding (Brown 1995). They have bred well in captivity and, in 1998, numbered 175 distributed in a number of American zoos (Bass 1998). Through genetic testing, new strains of pure Mexican Wolves have been identified in

Mexican Wolves already in captivity; this adds to the subspecies™ known diversity (Brown 1995). Smaller than northern wolves, males weigh 60 to 70 pounds and females 50 to 60 pounds.

The recovery plan's major goal was to reintroduce Mexican Gray Wolves into portions of their original range in a joint project by the Fish and Wildlife Service, the ADC program which had been responsible for their demise, the US Army, and the state wildlife departments of Arizona and New Mexico (Brown 1995). Surveys conducted in the region determined that most people favored the reintroductions (Brown 1995). Ted Turner, the founder of Cable News Network (CNN) and other cable stations, is New Mexico's largest landowner with more than 1 million acres. He offered one of his ranches, Ladder Ranch, which is near the Blue Range mountains release site, as a holding area and paid an employee to oversee construction of holding pens (Bass 1998). This was supported by his organization, the Turner Endangered Species Fund (Bass 1998).

Although the public as a whole supported the wolf reintroduction, many New Mexican ranchers expressed great antipathy. The national forest release sites allow hunting and trapping. Many volunteers and a grassroots organization, Preserve Arizona's Wolves (PAWS), have worked for decades to bring about this reintroduction and volunteered their time to help on Ted Turner's ranch preparing for the arrival of wolves from two zoos (Bass 1998). In December 1997, four wolves, two sisters and two brothers from separate zoos, arrived at Turner's ranch and were paired off male-and-female in separate pens, where they stayed for several months (Bass 1998). More arrived and spent time in acclimatization pens before release. The release program failed. Of 11 Mexican wolves released in the area, five died, one disappeared and is presumed dead, and five have been returned to captivity near Alpine, Arizona (Sink 1998). One pup born in the wild is missing and presumed dead, since its mother was shot in August 1998 (Sink 1998). A New Mexican rancher is said to have offered $35,000 to anyone who would kill all the wolves returned to the wild (Sink 1998).

Among the wolves that were shot was one of a newly formed--but strongly bonded--pair, Val and Minnie (Bodo 1999). Soon after release from the holding cage, Val was shot by a camper who claimed that the wolf charged at him; a necropsy revealed that the wolf had been killed standing still, broadside to the man (Bodo 1999). The female, Minnie, who had been born at the Rio Grande Zoo in Albuquerque, was pregnant with four pups when her mate was killed. She was returned to her holding pen and began to try frantically to dig and leap her way out of the pen (Bodo 1999). Her pups were born, but all died. At the end of 1998, she was shipped to the Living Desert Wildlife and Botanical Park in Palm Desert, California, where she paced or remained curled up in a spot of dirt, failing to interact with her surroundings or a male put in her pen (Bodo 1999). She was spayed and will remain in captivity for the rest of her life. As for the other deaths, no examples of livestock predation were found. About 140 of these wolves remain in captivity (Nowak 1999).

The reintroduction of Mexican Gray Wolves will be far more difficult than the Yellowstone National Park reintroduction, which involved transplant of wild Canadian wolves. These captive-born wolves have no knowledge of wild survival. They will need to learn how to hunt large prey as a pack, as well as how to survive the many threats humans pose to them. Their intelligence and instincts may be the deciding factors for their survival.

The legal status of the Gray Wolf in the lower 48 states seems destined to change in the near future. The Fish and Wildlife Service wants to change the status of the species from Endangered to Threatened in all but the southwest, where the Mexican subspecies is being reintroduced, and remove the Minnesota wolves altogether from the US Endangered Species Act (Revkin 2000). Minnesota wolves continue to be persecuted, and suffer from parasitic heartworms and deadly canine parovirus disease spread by domestic dogs (Nowak 1999). Delisting undoubtedly will unleash unrestricted hunting and trapping of these animals. Total legal control will revert to the state of Minnesota should this proposal be finalized.

The wolves in the West, from Yellowstone National Park to Idaho, Montana and Washington, would be listed as Threatened when removed from the experimental category. This category has much more flexibility concerning how much protection a species receives. Penalties are lower, and species may be hunted and trapped under the category.

Some ranchers in the West are prepared to eliminate wolves outside national parks. One rancher in Montana installed loud alarms that are triggered by the radio collars used to monitor most of the area's wolf packs (Revkin 2000).

The approximately 3,500 wolves south of Alaska, most of which are in Minnesota, occupy only about 5 percent of their original range, and as a result of prejudice and unfounded fear, these wolves are still being persecuted. Several states have enacted laws banning reintroduction of wolves, which would also apply to wolves crossing over the state's borders. Proposals to reintroduce wolves into Maine or New York have also been met with opposition by many (Higgins 2000). A major education program is needed to allay these fears and to train ranchers to protect their herds and flocks, compensating them for any losses. Although the detractors speak more loudly than the defenders of wolves, the latter probably far outnumber the former in the United States as a whole. It may fall to private conservation and humane organizations to turn the tide in favor of the wolves to return them to a greater percentage of their original range in the lower 48 states.

Wolves, Wild Dogs and Foxes: Page 8

Elsewhere, the history of the Gray Wolf is similar. As early as 300 B.C., Celtic people in the British Isles began breeding wolfhounds for chasing and killing wolves (McIntyre 1995). The King of Scots decreed in the second century B.C. that anyone killing a wolf would be rewarded with an ox (McIntyre 1995). In Anglo-Saxon England, January was designated Wolf Month, to be devoted to the slaughter of wolves; during the reign of King Edgar of England, beginning in 953, a tribute of 300 wolf skins per year was demanded. In 1281, King Edward I hired a man to devote himself entirely to killing wolves (McIntyre 1995). Over the next centuries, wolf extermination campaigns continued in the British Isles, and forests were leveled for livestock grazing and agriculture. The last wolf in Ireland was killed in 1821, and a wolf killed in Scotland in 1848 resulted in the extinction of the species throughout the British Isles (McIntyre 1995).

In France, Emperor Charlemagne founded an order of knights for killing wolves, called the Louveterie, about A.D. 800 (McIntyre 1995). Wolves were exterminated 1,000 years ago in all but remote forests of the French Pyrenees on the border with Spain. By the 20th century, only a handful of Gray Wolves survived in these forests, and apparently they were killed off in the 1950s. In the early 1990s, small numbers of Gray Wolves crossed over the Alps from Italy into southeastern France. In 1999, the French government decided to remove these 40 wolves, killing or caging them, after complaints by herdsmen that the wolves were killing sheep (Newman 1999). Environmentalists claimed the sheep were being killed by feral dogs (Newman 1999).

The last wolf in what is now Germany was killed in 1847 (McIntyre 1995). Within the past decade, a few wolves have entered eastern Germany from Poland, which has a population of about 1,000 wolves (McNamee 1997). Polish wolves have been heavily persecuted for centuries, and only in 1998 did the species receive official protection (Nowak and Myslajek 1999). They occur mainly in eastern mountains where they have come into conflict with livestock owners. An organization, Wolfnet, has been working with livestock owners to compensate them for losses and protect them against predation by wolves (Nowak and Myslajek 1999). Wolfnet travels around the country educating the public, government officials and students about the behavior, biology and intelligence of wolves, attempting to undo the mistaken beliefs that result in many killings of wolves (Nowak and Myslajek 1999).

Scandinavia has nearly wiped out its wolves, with only about 25 in Norway and Sweden and fewer than 100 in Finland (McNamee 1997). In 2001, the Norwegian government allowed the killing of some of the few remaining wolves because of complaints by livestock owners, despite protests from wildlife organizations in the country. An unknown--but small--number also survive in Greenland (McNamee 1997).

In Spain, wolves may total from 1,500 to 2,000, the largest population in Western Europe (McNamee 1997, Binder

2000). They are heavily persecuted there, however. At one time wolves were found throughout the Iberian peninsula, but they are now confined to the northern portions of Spain and Portugal (Bergman 1997). In Portugal, only about 150 survive. The wolves of Spain and Portugal are listed by the *2000 IUCN Red List of Threatened Species* as Conservation Dependent. At least half of rural people in areas where wolves remain in Iberia believe the animals should be exterminated altogether, while another 35 percent want them "controlled," allowing only a few to survive (Bergman 1997). Wolves may be sport hunted in Spain, resulting in the deaths of at least 300 animals a year; added to this mortality, the practice of denning, or killing pups in a den, is legal, and 25 percent of wolves are killed in this manner (Bergman 1997). Luis Mariano Barrientos, a biologist studying Spain's wolves, has documented that they kill relatively few sheep, which are usually protected by mastiff dogs and shepherds. He says that the wolves are killed because of prejudice and persecution, and laments, "It's a national disgrace. A barbarity" (Bergman 1997). A recent study recommended that a strict compensation program be set up. At present, indemnities are paid only if local administrations choose to do so, and many do not (Bergman 1997). This results in great resentment toward wolves. The wolves of Spain survive by stealth, hiding in fallow fields and moving about at night, and when they howl, they risk their lives (Bergman 1997). For long-term survival in Spain, they need a large sanctuary with natural prey species.

Small populations of Gray Wolves still remain in pockets of the Mediterranean region. About 500 wolves survive in Italy, listed as Vulnerable by the International Union for the Conservation of Nature (IUCN). Very little wilderness remains in the country, and wolves have been squeezed into agricultural and livestock grazing areas (McNamee 1997). Their survival until the 20th century is due to an attitude of tolerance, unlike the prejudice and hatred toward wolves so common in Europe. No national extermination campaign was ever launched, and herders corral their sheep at night and protect their flocks with guard dogs (McNamee 1997). Because of a lack of natural prey, such as deer, in the region, these wolves occasionally kill livestock. When this happens, herders put out poison or shoot the wolves. Italian wolves live in pairs or groups of three in most areas because there are no large ungulates to hunt in packs. This has made them quiet, nocturnal and shy. These wolves also prey on small mammals, such as rabbits and marmots (McNamee 1997). Only in a few national parks, such as the Abruzzi east of Rome where about 20 to 30 wolves hunt deer, do they exhibit natural behavior, forming packs and howling (McNamee 1997). Even there, however, sheep are allowed to graze within park boundaries, and sheep owners have been soliciting members of the public to "adopt" a sheep to contribute to the cooperative farm (Stanley 2000). By the 1970s, wolves numbered only a few hundred, but after the government accorded the species full protection in 1976, they began to increase in numbers and range (McNamee 1997). They now occupy the entire country, and if there are livestock losses, owners are compensated and are not allowed to kill the wolves (McNamee 1997). Professor Luigi Boitani, a wolf biologist at the University of Rome, commented at a wolf conference that most of the Italian public is in favor of wolves and more opposed to control programs than some wildlife managers, like himself (Binder 2000). The official protection given to these wolves is far stronger than that given to either the Gray or Red Wolf in the United States.

Southeastern Europe's wolf populations are fragmented, but increasing in some countries. The former Yugoslavia has about 930; Hungary, 50; Romania, which protects the species, 2,500; Bulgaria, fewer than 100; Slovakia, 350; and Greece, 300 to 500 (McNamee 1997). Romania is the only one of these countries where people have a tradition of honoring wolves; sheep in the country are protected by guard dogs, and wolves prey mainly on native ungulates. In some areas the wolves have taken to ranging through city trash piles for food (Binder 2000). Croatia allowed unlimited killing of wolves until 1995 when fines of up to $6,000 were imposed for killing wolves (Binder 2000). This had the counter-effect of encouraging wolf killing, resulting in the deaths of more than 40 wolves, and no one has paid a fine; about 100 wolves remain in the country (Binder 2000).

In the eastern Mediterranean, there are estimates of a few wolves remaining in Lebanon; about 30 in Egypt; 200 in Jordan; 150 to 300 in Israel; several thousand in Turkey; and about 1,000 in Iran (McNamee 1997). In Saudi Arabia, where wolves are killed to protect livestock, hunters often string up a wolf carcass on a pole for all to see (Binder 2000). Dr. Iyad A. Nader of the King Khalid Wildfire Research Center in Riyadh, estimated that up to 700 wolves remain in three protected areas of Saudi Arabia, but elsewhere in the country they have no legal protection (Binder 2000). Wolves are persecuted by livestock herders in all the latter countries.
