Abstract. This study investigated the development of biological soil crusts (biocrusts) in an early successional subtropical forest plantation and their impact on soil erosion. Within a biodiversity and ecosystem functioning experiment in southeast China (biodiversity and ecosystem functioning (BEF) China), the effect of these biocrusts on sediment delivery and runoff was assessed within micro-scale runoff plots under natural rainfall, and biocrust cover was surveyed over a 5-year period.

Results showed that biocrusts occurred widely in the experimental forest ecosystem and developed from initial light cyanobacteria- and algae-dominated crusts to later-stage bryophyte-dominated crusts within only 3 years. Biocrust cover was still increasing after 6 years of tree growth. Within later-stage crusts, 25 bryophyte species were determined. Surrounding vegetation cover and terrain attributes significantly influenced the development of biocrusts. Besides high crown cover and leaf area index, the development of biocrusts was favoured by low slope gradients, slope orientations towards the incident sunlight and the altitude of the research plots. Measurements showed that bryophyte-dominated biocrusts strongly decreased soil erosion, being more effective than abiotic soil surface cover. Hence, their significant role in mitigating sediment delivery and runoff generation in mesic forest environments and their ability to

quickly colonise soil surfaces after disturbance are of particular interest for soil erosion control in early-stage forest plantations.

1 Introduction

Biological soil crusts (hereinafter referred to as biocrusts) are a living soil cover, which plays significant functional roles in many environments (Weber et al., 2016). In initial ecosystems, communities of cyanobacteria, algae, fungi, lichens, bryophytes and bacteria in varying combinations are the first to colonise the substrate (Evans and Johansen, 1999). Biocrusts are often dominated by one organism group, with cyanobacterial crusts being indicators of early-stage crusts and drier conditions (Malam Issa et al., 1999, 2007) and bryophyte-dominated crusts being indicators of later-stage crusts and moister conditions (Colesie et al., 2016; Seppelt et al., 2016). These highly specialised communities form a biological crust immediately on top of or within the first millimetres of the soil surface (Büdel, 2005). Biocrusts preferably occur under harsh conditions of temperature or light, where vascular vegetation tends to be rare (Allen, 2010). Therefore, biocrusts are generally widespread under dryland conditions (Berkeley et al., 2005; Belnap, 2006;

Büdel et al., 2009), whereas under mesic conditions they mostly occur as a successional stage after disturbance or in environments under regularly disturbed regimes (Büdel et al., 2014).

In direct competition with phanerogamic plants, biocrusts are generally in an inferior position, and thus their development is limited under closed plant canopies or when leaf litter layers occur (Belnap et al., 2003a). This limitation is due to the competition for light (Malam Issa et al., 1999) and nutrients (Harper and Belnap, 2001). Disturbance of the phanerogamic vegetation layers, however, changes this competitive situation. Such disturbances can occur in forest ecosystems by natural tree fall or human-induced clear-cutting (Barnes and Spurr, 1998). Complete removal of a forest causes a harsh shift in vegetation development and creates a starting point for new vascular plant as well as biocrust communities (Bormann et al., 1968; Keenan and Kimmins, 1993; Beck et al., 2008). Biocrusts are able to quickly colonise natural clearances in tree layers (Belnap et al., 2003a) as well as gaps appearing after human disturbance (Dojani et al., 2011; Chiquoine et al., 2016). Generally, it can be stated that current knowledge on the relation between the development of biocrust cover and vascular plant cover leaves room for further research (Kleiner and Harper, 1977; Belnap et al., 2003b; Zhang et al., 2016). In particular, there are only few studies on the development of biocrusts in early successional forest ecosystems (Su et al., 2007; Zhang et al., 2016), but we assume that biocrusts are able to co-exist in these mesic environments shortly after deforestation. Furthermore, descriptions of different biocrust types in mesic vegetation zones and investigations in southeast Asia are rare (Büdel, 2003; Bowker et al., 2016).

Functional roles of biocrusts have been investigated for decades, but less attention has been paid to their spatial distribution and characteristics (Allen, 2010). Biocrust cover varies across spatial scales (from centimetres to kilometres), and it could be shown that it depends not only on the surrounding vascular vegetation cover but also on soils, geomorphology, and (micro-)topography or terrain (Evans and Johansen, 1999; Ullmann and Büdel, 2003; Kidron et al., 2009; Bowker et al., 2016) in arid, semi-arid, temperate and boreal environments. Different biocrust distributions have been related to elevation and terrain-influenced microclimatic gradients (Kutiel et al., 1998), different geomorphic zones (Eldridge, 1999), varying aspects (George et al., 2000) and soil types (Bu et al., 2016). We assume that this is also true for mesic subtropical forest environments. To our knowledge, investigations of the influence of small-scale (centimetres to metres) topographic variations in biocrust development are rare, and further studies will help to understand the role of these small-scale factors (Garcia-Pichel and Belnap, 2003; Bu et al., 2016; Bowker et al., 2016). Furthermore, as the development of biocrusts is characterised by a high complexity and spatial heterogeneity with many microclimatic and micro-environmental factors, it is of great significance

to conduct comparative studies on the spatial distribution of biocrusts (Bu et al., 2013).

Biocrusts were recognised as having a major influence on terrestrial ecosystems (Buscot and Varma, 2005; Belnap, 2006) as they protect soil surfaces against erosive forces by both wind and water (Bowker et al., 2008; Zhao et al., 2014). They can absorb the kinetic energy of rain drops (splash effect), decrease shear forces and stabilise soil particles with protonemal mats and fine rhizoids and thus decrease particle detachment and enhance soil stability (Malam Issa et al., 2001; Warren, 2003; Belnap and Lange, 2003). These effects differ with regard to soil texture, surface roughness, water repellency and finally different crust species and developmental stages (Warren, 2003; Belnap and Büdel, 2016). However, studies that directly relate different types of biocrust cover to rates of soil erosion are few (Allen, 2010). Furthermore, the influence of biocrusts on sediment delivery and runoff has mostly been investigated in arid and semi-arid climates and humid climates have been largely disregarded (Belnap and Lange, 2003; Weber et al., 2016).

This study aims to investigate the development of biocrust cover in an early successional subtropical forest ecosystem after human disturbance and the impact of those biocrusts on soil erosion. Therefore, interrill erosion was measured with runoff plots and the occurrence, distribution and development of biocrusts was recorded. The study was conducted in an experimental forest plantation, which aims to study biodiversity and ecosystem functioning relationships in south-east China (biodiversity and ecosystem functioning (BEF) China; for further information see Yang et al., 2013; Bruelheide et al., 2014; Trogisch et al., 2017). During the study, the following hypotheses were addressed:

1. Biocrusts are able to coexist in mesic early successional subtropical forest ecosystems, but crust cover decreases with ongoing canopy closure and decreasing light intensity.
2. The development of biocrusts in mesic subtropical forests is not only influenced by the surrounding vegetation cover but also by major soil attributes which influence biocrust growth and by terrain attributes which affect microclimatic conditions.
3. Biocrusts mitigate interrill soil erosion in early successional subtropical forest plantations.

2 Material and methods

2.1 Study site and experimental design

The study was carried out within the BEF China experiment (Bruelheide et al., 2014) in Xingangshan, Jiangxi Province, PR China (29°06.450' N, 117°55.450' E). The experimental area is located in a mountainous landscape at an elevation of 100 to 265 m a.s.l. with slopes from 15° to 41° (Scholten

et al., 2017). The bedrock is non-calcareous sandstones, siltstones and slates weathered to saprolite, and the predominant soil types are Cambisols with Anthrosols in downslope positions and Gleysols in valleys (Scholten et al., 2017). The particle size distribution was quite homogenous throughout the experimental area, having loam as the main texture class (Scholten et al., 2017). The mean annual temperature is 17.4 °C, and the annual precipitation is 1635 mm with about 50 % falling during May to August (Goebes et al., 2015). The climate is typical for summer monsoon subtropical regions. The potential natural vegetation of this region is a subtropical broadleaved forest with dominating evergreen species. It was widely replaced by tree plantations of mostly *Cunninghamia lanceolata* for the purpose of commercial forestry in the 1980s (Bruehlheide et al., 2014). The experimental area (approx. 38 ha) is structured in 566 research plots (25.8 m × 25.8 m each) at two sites (A and B) and was clear-cut and replanted with 400 tree saplings per plot in different tree species mixtures in 2009 and 2010 (Yang et al., 2013). A selection of 34 research plots was used for this study (cf. Seitz et al., 2016). Shrubs and coppices were weeded once a year from 2010 to 2012 to help the tree saplings grow, following common practice in forest plantations of this area.

2.2 Field methods

Biocrust cover was determined photogrammetrically in 70 selected micro-scale runoff plots (ROPs; 0.4 m × 0.4 m; Seitz et al., 2015; Trogisch et al., 2017) at five time steps (November 2011, May 2012, May 2013, May 2014 and May 2015). Biocrust species were first described in the field based on appearance and functional groups. Biocrust types were then determined based on the dominating autotrophic component (highest share of total biocrust cover per ROP). During the rainy season in summer 2013, an extended survey together with soil erosion measurements (see below) was conducted in five ROFs on 34 research plots each (170 ROFs in total; Table 1). At each ROP, perpendicular images were taken with a single-lens reflex camera system (Canon 350D, Tokyo, Japan) and processed by the grid quadrat method in GIMP 2.8 using a digital grid overlay with 100 subdivisions (cf. Belnap et al., 2001). Stone cover and biocrust cover were separated by hue distinction. A continuous leaf litter cover, which may impede analyses, was not present during measurements. Biocrusts were collected in 2013, and samples were dried at 40 °C (Dörrex drying unit, Netstal, Switzerland). The identification of these sampled species was carried out by morphological characteristics using a stereomicroscope (Leitz TS, Wetzlar, Germany), a transmitted-light microscope (Leitz Laborlux S, Wetzlar, Germany) and ultraviolet light. Bryophytes (dominating taxa in 2013) were determined to the species level, wherever possible, and separated into mosses (Bischler-Causse, 1989; Moos flora of China: Gao et al., 1999, 2001; 2002, 2003; 2005, 2007; 2008, 2011) and liverworts (Zhu, 2006; Söderström et al., 2016; A.

Table 1. Erosion, soil, soil cover, vegetation and terrain attributes in 170 runoff plots (ROFs) and on 34 research plots (with five ROFs each) in Xingangshan, Jiangxi Province, PR China, in 2013.

Tree height (m)	1.0	2.2	7.4	1.7
Crown width (m)	0.4	1.2	3.0	0.8

Soil cover: proportion of soil surface area covered by biocrusts or stones; crown cover: proportion of soil surface area covered by crowns of live trees; leaf area index: one-sided green leaf area per unit soil surface area; MCCA: Monte Carlo based flow accumulation (Behrens et al., 2008); TRI: terrain ruggedness index (Riley et al., 1999); eastness and northness: state of being east or north (Roberts, 1986); tree height: distance from stem base to apical meristem; crown width: length of longest spread from edge to edge across the crown; min: minimum; max: maximum; SD: standard deviation.

Schäfer-Verwimp, personal communication, 2016). Comparisons were conducted with specimens hosted in the herbarium of the State Museum of Natural History in Stuttgart, Germany (Herbarium STU).

Sediment delivery and surface runoff were measured within 170 ROFs in summer 2013 together with an extended biocrust survey (see above and Table 1), when tree saplings did not exceed 3 years of age and leaf litter fall was still marginal. After four time steps, 334 valid ROP measurements entered the analysis (for detailed information see Seitz et al., 2016). Sediment delivery was sampled, dried at 40 °C and weighed, whereas surface runoff and rainfall amount were measured in situ. At every ROP, crown cover and leaf area index (LAI) were measured with a fish-eye camera system (Nikon D100 with Nikon AF G DX 180°, Tokyo, Japan) and calculated with HemiView V.8 (Delta-T devices, Cambridge, UK). Measurements of tree height and crown width were provided by Li et al. (2014) on a research plot scale ($n = 34$). Tree species richness and tree composition resulted from the experimental set-up of BEF China (Bruehlheide et al., 2014).

Soil attributes (Table 1) were determined for every research plot ($n = 34$, sampling in 2013) using pooled samples from nine point measurements each (sampling depth 0–5 cm). Soil pH was measured in KCl (WTW pH meter with Sentix electrodes, Weilheim, Germany), bulk soil density was determined by the mass-per-volume method, and total organic carbon (TOC) was measured using heat combustion (Elementar Vario EL III, Hanau, Germany). Soil organic matter (SOM) was calculated by multiplying TOC by a factor of 2 (Pribyl, 2010).

2.3 Digital terrain analysis

Terrain attributes (Table 1) were derived from a digital elevation model (DEM; $5\text{ m} \times 5\text{ m}$; Scholten et al., 2017) on a research plot scale ($n = 34$). Attributes were the terrain ruggedness index (TRI; Riley et al., 1999) to describe the heterogeneity of the terrain, the Monte Carlo based flow accumulation (MCCA; Behrens et al., 2008) to diagnose terrain driven water availability, altitude above sea level to address elevation effects, and the eastness and the northness (Roberts, 1986) to describe plant-related climatic conditions. These terrain attributes cover major landscape features of the experimental area and were not correlated. Slope was additionally measured with an inclinometer at every ROP ($n = 170$; see Seitz et al., 2016).

2.4 Statistical methods

The temporal development of biocrust cover (hypothesis 1, above) from 2011 to 2015 was assessed at five time steps within 70 ROPs (see above) by an analysis of variance (ANOVA) and Tukey's honestly significant difference (HSD) test ($n = 350$).

The influences of vegetation, soil and topographic attributes on biocrust cover (hypothesis 2) in 170 ROPs (see above) were assessed by linear mixed effects (LME) models ($n = 334$). Crown cover, bulk soil density, SOM, pH, altitude, slope, MCCA, TRI, eastness, northness and tree species richness were fitted as fixed effects and biocrust cover as a response variable. The attributes were tested with Pearson's correlation coefficient before fitting. LAI was fitted individually in exchange with crown cover due to multicollinearity. The experimental site and research plot were fitted as random effects, and hypotheses were tested with an ANOVA type 1 with a Satterthwaite approximation for degrees of freedom.

The influences on soil erosion (hypothesis 3) were assessed by LME models with a restricted maximum likelihood ($n = 334$) and sediment delivery and surface runoff as response variables. Crown cover, slope, surface cover, SOM, rainfall amount and tree species richness were fitted as fixed effects. Surface cover was then split into surface cover by biocrusts and by stones, which entered the analysis as fixed conjoined factors. Precipitation events nested in plot, tree species composition, experimental site and ROP nested in

Figure 1. The development of biological soil crust cover in runoff plots of the BEF China experiment from 2011 to 2015 in Xingangshan, Jiangxi Province, PR China ($n = 350$). Horizontal lines within box plots represent medians, and diamonds represent means with standard error bars. Points signify outliers and small letters significant differences ($p < 0.001$).

plot were fitted as random effects. Attributes were not correlated. The hypothesis was tested with an ANOVA type 1 with a Satterthwaite approximation for degrees of freedom. Moreover, the Wilcoxon rank sum test was applied to test for differences between biocrust cover and stone cover on sediment delivery and surface runoff. Therefore, the dataset was split into data points where biocrust cover exceeded stone cover ($n = 281$) and data points where stone cover exceeded biocrust cover ($n = 53$).

All response variables were log-transformed before modelling. The dataset was tested for multicollinearity and met all prerequisites to carry out ANOVAs. All analyses were performed with R 3.1.2 (R Core Team, 2014). LME modelling was conducted with “lmerTest” (Kuznetsova et al., 2014) and rank sum tests with “exactRankTests” (Hothorn and Hornik, 2015). Figures were designed with “ggplot2” (Wickham, 2009).

3 Results

3.1 Temporal development of biocrust cover

Biocrusts occurred in 94 % of all ROPs, and their cover within ROPs ranged between 1 and 88 % over the course of 5 years. The mean biocrust cover of all ROPs more than tripled from their installation in 2011 to the last measurement in 2015 (Fig. 1). The increases were significant from 2011 to 2015 and from 2012 to 2013, 2013 to 2014 and 2014 to 2015 ($p < 0.001$).

Whereas a clear bryophyte dominance of biocrusts was evident at the time of sampling in 2013 (average ROP surface cover 24 %), different successional stages were identified in

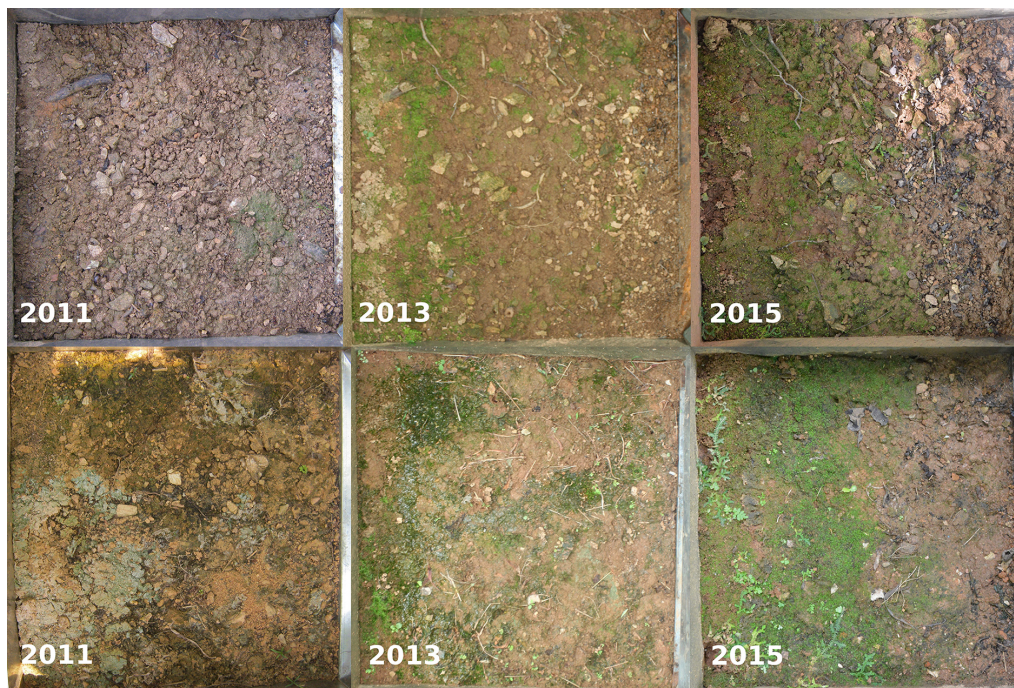

Figure 2. Successional stages of biological soil crusts in two exemplary runoff plots (top row and bottom row, 0.4 m × 0.4 m each) in 2011, 2013 and 2015 (from left to right) at the BEF China experiment in Xingangshan, Jiangxi Province, PR China.

Figure 3. The influence of runoff plots dominated by biological soil crust cover ($n = 281$) and stone cover ($n = 53$) on sediment delivery and surface runoff in Xingangshan, Jiangxi Province, PR China, in 2013. Horizontal lines within box plots represent medians, and diamonds represent mean with standard error bars.

the field and on ROP photos from 2011 to 2015 (Fig. 2). In 2011, a smooth, light cyanobacteria- and algae-dominated crust with few lichens and bryophytes indicated an earlier stage of biocrust development (Colesie et al., 2016). In 2013, 25 moss and liverwort species were classified (Table 2) and formed a bryophyte-dominated crust, with some cyanobacteria, algae, lichens and micro-fungi still observed within ROPs. The same was true in 2015, but the first evidence of vascular plants (*Selaginella* and *Poaceae*) indicated a further change in the vegetation cover of the soil surface.

3.2 The influence of vegetation, soil and terrain on biocrust cover

The development of biocrust cover in 2013 was positively influenced by crown cover and LAI as attributes of the surrounding vegetation (Table 3). Furthermore, it was negatively affected by slope and northness and slightly positively affected by the altitude of the research plots as terrain attributes (Table 3). Further terrain attributes or any soil attributes did not affect the development of biocrust cover.

3.3 The impact of biocrust cover on soil erosion

Results reveal that biocrusts strongly affect soil erosion. ROPs with biocrust cover below 10 % showed a mean sediment delivery of 302 g m^{-2} and a mean runoff volume of 39 L m^{-2} , whereas ROPs with biocrust cover above 50 % showed a mean sediment delivery of 74 g m^{-2} and a mean runoff volume of 29 L m^{-2} . Both biocrust and stone cover, as well as total soil surface cover (comprising both biocrust and stone cover; $p < 0.001$) negatively affected sediment delivery (Table 4). In addition, soil surface cover negatively affected surface runoff ($p = 0.003$). However, only biocrust but not stone cover mediated the effect of runoff.

Furthermore, crown cover, SOM and rainfall amount affected sediment delivery, whereas runoff was affected by crown cover and rainfall amount. ROPs with increased stone cover showed higher sediment delivery and surface runoff compared to those with increased biocrust cover (Fig. 3).

4 Discussion

4.1 Temporal development of biocrust cover

Biocrusts were detected widely within the experiment and occupied a considerable area in the interspaces of the growing tree community. Thus, the first part of hypothesis 1, stating that biocrusts are able to coexist in mesic early successional subtropical forests, can be confirmed, as they successfully colonised the newly created habitats originating from the disturbance by forest clear-cutting and weeding (Bruehlheide et al., 2014). Although biocrusts have been mainly defined to occur in dryland regions (Weber et al., 2016), they can also appear as a transient feature in mesic environments after major singular or repeated disturbance events (Büdel et al., 2014; Fischer et al., 2014). In the current study, deforestation provided a local arid micro-environment, which initiated early biocrust development. At this young stage of forest development, biocrusts were able to coexist with up-

coming tree saplings and formed a pioneer vegetation on the soil surface (Langhans et al., 2009), which provides the basis for the growth of other plants by the input of carbon and nitrogen (West, 1990; Evans and Johansen, 1999). Biocrusts are known to facilitate the succession of vascular plants to more advanced stages (Bowker, 2007), but tree growth and thus crown cover can also lead to an advancement in biocrust development, e.g. due to the protection from direct sunlight (Zhao et al., 2010; Tinya and Ódor, 2016). The bryophyte dominance of biocrusts in 2013 documented this development into a later and somewhat moister successional stage. Later-stage bryophytes have received comparatively little attention in forest understorey (Gilliam, 2007) and biocrust studies (Weber et al., 2016), and in Asia only 23 different species have been reported within biocrusts up to now (Sepelt et al., 2016). Thus, this study with 25 recorded moss and liverwort species, most of them being new records within Asian biocrusts (Burkhard Büdel, personal communication, 2016), substantially increases the knowledge on biocrusts of this region.

The extent of biocrusts has been strongly increasing since 2012, i.e. 3 years after tree replantation, and was still gaining coverage in the sixth year after the experimental set-up. Thus, the second part of hypothesis 1, stating that crust cover decreases with ongoing canopy closure, has to be rejected. Even if single trees were already up to 7.4 m high (Li et al., 2014) and LAI was up to 5.35 in 2013, biocrusts still remained coexisting within the early-stage forest ecosystem. Furthermore, increasing crown cover and LAI seemed to foster the development of bryophyte-dominated biocrusts at this ecological stage. By the end of this study in summer 2016

(LAI up to 6.18), there were indications that biocrust cover may start to be pushed back, as the first vascular plants appeared in between. This is in line with the existing literature, demonstrating that continuing tree growth will cause biocrust communities to adapt with an altered composition of moss and liverwort species (Eldridge and Tozer, 1997; Fenton and Frego, 2005; Goffinet and Shaw, 2009). It has been shown that bryophytes switch from species favouring sunny habitats to more shade-tolerant species (Zhao et al., 2010; Müller et al., 2016). In addition, there might also be a reduction in bryophyte diversity due to shady conditions, where only a smaller number of species could prevail. In later stages, biocrust cover will be replaced by vascular vegetation (in light forests) or buried under persisting leaf litter (under darker conditions). In this context, the ecological roles of biocrusts in succession models and plant restoration are of interest (Hawkes, 2004; Bowker, 2007). In particular, biocrust succession in temperate climates has received limited scientific attention (Read et al., 2016). Furthermore, there are several projects underway to establish successful restoration techniques in arid and semi-arid environments (Rosentreter et al., 2003; Bowker, 2007; Chiquoine et al., 2016; Condon and Pyke, 2016), which could be adapted to mesic environments. Nevertheless, it has to be stated that biocrust restoration might be dispensable in some mesic systems, as natural reestablishment appeared to be very fast in this study.

4.2 The influence of vegetation, soil and terrain on biocrust cover

In the current study, the development of biocrusts was influenced by vegetation and terrain but not by the three soil attributes investigated in this study. Thus, hypothesis 2, stating that the biocrust development is not only influenced by surrounding vegetation but also by soil and terrain, can only partly be confirmed for this ecosystem. As demonstrated above, high crown cover and LAI positively affected the development of biocrust cover in 2013. This increase in biocrust cover is likely caused by successional alteration of biocrusts towards bryophyte dominance. Mosses and liverworts profit from humid conditions and a higher protection from light compared to cyanobacteria- or lichen-dominated crusts (Ponzetti and McCune, 2001; Marsh et al., 2006; Williams et al., 2013). The successional development of biocrusts within the BEF China experiment was faster than reported by Zhao et al. (2010) for Chinese grasslands (Loess Plateau), who claimed biocrusts from a 3-year-old site were early successional and dominated by cyanobacteria. The recovery rate was also faster than described by Eldridge (1998) and Read et al. (2011) for semi-arid Australia, two of the very few studies on biocrust recovery under woodland. In the study presented here, the rapid change in biocrust community composition is mainly linked to the growth rates of surrounding trees in this subtropical forest. As functions of biocrusts, such as erosion reduction, are species-dependent, the rapid change in species composition might also lead to considerable variations in functional responses. Further studies are required to investigate species changeover times in different environments and particularly in disturbed mesic ecosystems.

Furthermore, several terrain attributes affected biocrust cover. Slope was the most prominent of those factors, causing a considerable decline in biocrust cover with increasing slope. This finding was explained by their decreasing ability to fix themselves on the soil surface at high slope angles and thus their tendency to erode from the soil surface when large surface water flows occur during rainfall events (Chamizo et al., 2013; Bu et al., 2016). Thus, the surface-protecting effect of biocrusts decreases at steep plantation sites and during heavy monsoon rainfall events, which frequently occur in the broader research area in Jiangxi Province, PR China (Yang et al., 2013; Goebes et al., 2015). Moreover, microclimatic factors played a role in the development of biocrusts. Northness showed a positive impact on biocrust cover and indicated that slope orientations towards the incident sunlight directly influence the biocrust development. This was also observed in other studies in arid and semi-arid areas (Bowker et al., 2002; Zaady et al., 2007). Furthermore, biocrust development depended on the altitude, which probably also affects microclimatic conditions (Kutiel et al., 1998; Chamizo et al., 2016; Bu et al., 2016). Those microclimatic factors are additionally altered by the growing tree vegetation itself.

Interestingly, SOM and pH did not affect biocrust cover in this study, whereas generally, underlying substrates are a main factor for bryophyte development (Spitale, 2017) and soil attributes are known to strongly influence biocrust cover (Bowker et al., 2016). In the experimental area, increased organic matter contents and acidic conditions have been determined (Scholten et al., 2017) which favour the development of bryophyte-dominated biocrusts (Eldridge and Tozer, 1997; Seppelt et al., 2016). Nevertheless, the variation between the research plots was small and apparently not large enough to cause prominent differences in biocrust development. Comparisons between forest plantations on different substrates would help to clarify the influence of soil attributes on biocrust development in those environments and to assess their effect in a broader environmental context (Spitale, 2017). Furthermore, a broader range of soil parameters should be included in future studies.

4.3 The impact of biocrust cover on soil erosion

Biocrust cover clearly mitigated interrill soil erosion in this early-stage ecosystem, and thus hypothesis 3 was confirmed. Sediment delivery was strongly reduced with increasing biocrust cover. For arid environments, Cantón et al. (2011) and Maestre et al. (2011), for example, showed that sediment delivery from soil surfaces covered with biocrusts decreases compared to bare soil surfaces with physical crusting (from 20 to $< 1 \text{ gm}^{-2}$ and 40 to $< 5 \text{ gm}^{-2}$, respectively), both studies using micro-scale runoff plots (0.25 m^2). Bu et al. (2015) and Zhao and Xu (2013) found similar erosion-reducing patterns for the subarid temperate Chinese Loess Plateau. The study presented here shows that biocrusts fulfil this key ecosystem service also within a particular mesic habitat, even if their biomass and soil penetration depth is low compared to trees. This functional role is due to the fact that biocrusts attenuate the impact of raindrops on the soil surface and greatly improve its resistance against sediment detachment (Eldridge and Greene, 1994; Goebes et al., 2014; Zhao et al., 2014). Moreover, they have the ability to glue loose soil particles together with polysaccharides extruded by cyanobacteria and green algae (Buscot and Varma, 2005). In the current study, protonemata and rhizoids of mosses and liverworts were observed to be most effective by weaving and thus fixing the first millimetres of the topsoil, as also described by Bowker et al. (2008). *Pogonatum inflexum* and *Atrichum subseriatum*, for example, have shown positive effects on erosion control due to their sustained protonema system (present authors' personal observation, 2014). Furthermore, bryophytes increase the formation of humus, which in turn assists with binding primary particles into aggregates (Scheffer et al., 2010; Zhang et al., 2016).

Whereas a partial stone cover did not decrease surface runoff in this study, bryophyte-dominated biocrusts positively influenced the hydrological processes in the topsoil layer regarding erosion control. Thus, they actively mitigated

initial soil erosion compared to abiotic components such as stones and pebbles. Biocrusts have been frequently shown to influence hydrological processes such as surface runoff and infiltration rates (Cantón et al., 2011; Chamizo et al., 2012; Rodríguez-Caballero et al., 2013). Recently, Chamizo et al. (2016) showed that biocrusts decrease runoff generation on a larger scale ($> 2 \text{ m}^2$), but the converse behaviour has also been found (Cantón et al., 2002; Maestre et al., 2011). Reducing effects on runoff are related to biocrusts species composition (Belnap and Lange, 2003), and later developmental biocrust stages with higher biomass levels provide more resistance to soil loss (Belnap and Büdel, 2016). Bryophyte-dominated crusts in particular have shown to enhance infiltration and reduce runoff due to their rhizome system, causing soil erosion rates to stay low (Warren, 2003; Yair et al., 2011). Other field studies also revealed that later-stage biocrusts, containing both lichens and bryophytes, offer more protection against soil erosion than cyanobacterial crusts (Belnap and Gillette, 1997) as they provide a higher infiltration potential (Kidron, 1995). On the other hand, Drahorad et al. (2013) found an increase in water repellency and a decrease in water sorptivity with ongoing biocrust succession in a temperate forest glade, which could also strongly affect runoff and sediment transport on subtropical forest soil surfaces. Moreover, biocrusts dominated by bryophytes increase surface roughness and thus slow down runoff (Kidron et al., 1999; Rodríguez-Caballero et al., 2012). Finally, biocrusts also absorb water and provide a comparably high water storage capacity (Warren, 2003; Belnap, 2006). For example, *Leucobryum juniperoideum*, which was widely found in the study area, showed a high water absorbing capacity (present authors' personal observation, 2014). Thus, the observed rapid change in biocrust composition from cyanobacteria to bryophyte dominance improved soil erosion control in this forest environment. This effect should be considered for the replantation of forests in regions endangered by soil erosion.

5 Conclusions

This study investigated the development and distribution of biocrusts in an early-stage subtropical forest plantation as well as their impact on interrill soil erosion after human disturbance. The following conclusions were drawn:

1. Biocrusts occurred widely in this mesic early successional forest ecosystem in subtropical China and were already dominated by bryophytes after 3 years of tree growth (25 bryophyte species classified). After 6 years of continuing canopy closure, biocrust cover was still increasing. Further monitoring under closing tree canopy is of importance to detect changes in biocrust cover and species composition. As this study discusses a very particular subtropical forest environment, where trees were replanted after clear-cutting, results have to

be viewed with this particular set-up in mind. Further studies on biocrust development in different disturbed forest ecosystems appear to be of high interest.

2. The surrounding vegetation and underlying terrain affected biocrust development, whereas soil attributes did not have an effect on this small experimental scale. Besides high crown cover and LAI, the development of biocrusts was favoured by a low slope gradient and slope orientations towards the incident sunlight and altitude. Further research appears to be necessary to explain effects of terrain attributes such as aspect or elevation and effects of underlying soil and substrates.
3. Soil surface cover of biocrusts largely affected soil erosion control in this early stage of the forest plantation. Bryophyte-dominated crusts showed erosion-reducing characteristics with regard to both sediment delivery and surface runoff. Furthermore, they more effectively decreased soil losses than abiotic soil surface covers. The erosion-reducing influence of bryophyte-dominated biocrusts and their rapid development from cyanobacteria-dominated crusts should be considered in management practices in early-stage forest plantations. Further research is required on functional mechanisms of different biocrust and bryophyte species and their impact on soil erosion processes.

Data availability. Data are publicly accessible and archived at the BEF China data portal (<http://china.befdata.biow.uni-leipzig.de/datasets/376>, <http://china.befdata.biow.uni-leipzig.de/datasets/598>, Seitz, 2016a, b).

Author contributions. SS and TS designed the experiment, and SS, ZS, KK and CLW carried it out. MN and KK classified biocrust types and determined bryophyte species. SS, PG and KS performed the statistical models. SS, XS and BW prepared the manuscript with contributions from all co-authors.

Competing interests. The authors declare that they have no conflict of interest.

Special issue statement. This article is part of the special issue "Biological soil crusts and their role in biogeochemical processes and cycling". It is a result of the BIOCRUST3 conference, Moab, USA, 26 to 30 September 2016.

Acknowledgements. We are grateful to the BEF China research group and especially to our students Mario Ahner, Milan Daus, Marlena Hall, Madeleine Janker, Paula Kersten, Vera Müller and Andrea Wadenstorfer for assistance in fieldwork. We also thank Alfons Schäfer-Verwimp for assistance in the determination of

bryophytes, Karl Forchhammer for giving us first insights into the world of cyanobacteria and the participants of BioCruz3 for helpful comments on the results. We are indebted to five anonymous referees for a very constructive and helpful review.

This work was funded by the German Research Foundation (DFG FOR 891/2 and 891/3). We also benefitted from travel grants from the Sino-German Centre for Research Promotion (GZ 699 and GZ 785) and from funding by the Max Planck Society. We acknowledge support by the Open Access Publishing Fund of the University of Tübingen.
