## ABSTRACT

The cerambycid beetle borers play an important role in Hawaiian forests, both in the natural and disturbed environments. Their significance is enhanced by the disharmonic nature of the fauna, such as the lack of leaf beetles and june beetles, in the native fauna. There are about 120 known species of endemic cerambycids, almost entirely restricted to native trees and shrubs, and 17 species of established exotic cerambycids, which with few exceptions bore in exotic trees. The seasonal occurrence, as far as known, of the adult cerambycids is tabulated. Altitudinal range and latest year of collection (native) or earliest year of record (exotic) are also tabulated. In a further tabulation, the species for which host associations are known are presented by host genera under plant families, and by islands. The introduced species are treated in similar manner.

## INTRODUCTION

The native fauna of the Hawaiian Chain is highly disharmonic in nature, meaning that because of the extreme isolation, many prominent groups of animals failed to reach the islands before the recent arrival of man. Certain groups, however, reached the island early and speciated extensively. The family Cerambycidae (longhorned beetles - adults; rounded-head wood-borers - larvae) represents one of these groups. About 120 endemic species are known, and probably considerably more exist or formerly existed and became extinct. These beetles bore in the wood of over one-third (38 out of 102) of the native genera of woody plants. It is puzzling, however, that only a minority (23.8%) of the endemic genera of trees and shrubs have confirmed host records for cerambycids. Some of the very common trees have few or questionable records. This situation may be related to chemical or physical properties of the living trees, such as the nature of the sap. An important point is that all of the endemic cerambycids are closely related (except Parandra and Megopis which bore in dead wood). The main group, called the plagithmysines, to a great extent bore in living trees as larvae. They evolved from a single immigrant ancestor. Although several genera have been named, representing considerable divergence in form, we now consider that they constitute a single genus, with five of the former genera to be retained as subgenera. Native Araliaceae, with gummy sap, have no confirmed plagithmysine records, but Parandra bore in rotting-araliads.

In connection with the period of adult occurrence, data are as yet insufficient to express a view on seasonality. For some species, it would appear that adults occur the year around, and that there are completely overlapping generations. On the other hand, pupae and adult emergence seem to be more prevalent between March and July. In captivity, adults live up to 6 or 8 weeks,

but the average span may be less in nature, with birds, rat and mongoose predation.

In the first tabulation, altitude range and latest year of collection are given for endemic species and earliest year of record for exotic species. For both, the numbers of dated specimens examined is also presented. In the second tabulation, host genera are listed under the plant families and are indexed at the end.

Monoinsular endemicity is the rule with the plagithmysines--that is, no one kind is known to occur on more than one island. However, there are closely related species on different islands, particularly as between Molokai, Lanai and Maui. Host associations are largely narrow as far as known, and often related species have the same host genera. More species are being discovered by investigating gaps in host/island records.

In this family, the greatest number of known species occur on the island of Hawaii (44) and the next greatest on Maui (30). This is in contrast to the situation in the weevils where Kauai has the greatest number of species and Oahu the next greatest.

A large proportion of the specimens which have been collected have been utilized in constructing the following tables. It is expected that much additional data to be collected will shortly render these tables out of date. We trust that this presentation may prove useful. We also hope that it may encourage other workers to help us to fill the many gaps in our present knowledge. The material here comprises background and comparative data for the "Island Ecosystems" IBP studies on the joint transects, and on the biologies of some of the involved species, as well as of the evolution of the cerambycids and their host relationships in the Hawaiian Chain.

We wish to gratefully acknowledge the assistance and advice of J. W. Beardsley, F. A Bianchi, E. J. Ford, Jr., Lynnette Fuller, Bruce Furmidge, Wayne Gagne, D. E. Hardy, Carol Higa, F. W. Howarth, James Jacobi, Ronald Lau, Rebecca G. Lau, Steve Montgomery, Barbara Myers, Noah Pekelo, Thane Pratt, G. A. Samuelson, Dr. Harold St. John, Donald Sugawa, Rene Sylva and Ernest Yoshioka.

All of these species are associated with introduced plants and therefore occur primarily at low altitudes. None of them have been found to our knowledge above the altitude of 900 meters. Additional species with isolated records, which are probably not established in Hawaii, are the following:

*Semanotus amethystinus* (Lec.) Nov. 1931 (1 specimen); *Clytus pilosus* Forst. subsp. *glabromacultatus*, June 1938 (6); *Xylorechus colonus* (F.), Apr. 1947 (1); *Monochamus* sp., Oct. 1971 (1); *Batocera davidis* Fairm., July 1969 (1); *Aerenicopsis championi* Bates, Apr. 1960 (1).
