Brief Report

Is paromomycin the drug of choice for eradication of *Dientamoeba fragilis* in adults?

Diarrhea

ABSTRACT

Dientamoeba fragilis is a debated protozoan parasite that is often detected in stools of patients with chronic gastro-intestinal complaints. A retrospective follow-up study of a large cohort of patients was performed to better understand the natural course of the infection and possible treatment options. *D. fragilis* was spontaneously cleared in 41% of untreated cases. With an eradication rate of 98%, treatment with paromomycin appeared more effective than treatment with clioquinol (83%) or metronidazole (57%).

1. Introduction

Dientamoeba (D.) fragilis is one of the most common protozoan organisms detected in human stools, with reported frequencies up to 30% (Johnson et al., 2004; Stensvold et al., 2007; Schuster and Jackson, 2009; Barratt et al., 2011). *D. fragilis* was originally described as an a-pathogenic protozoan organism, but over the years many reports have provided indications for the pathogenic potential of *D. fragilis* (Johnson et al., 2004; Barratt et al., 2011). Abdominal pain and diarrhea are commonly reported in patients infected with *D. fragilis* in the absence of other bowel pathogens (Barratt et al., 2011). Furthermore, eradication of *D. fragilis* by treatment is frequently associated with clinical improvement of symptoms (Girginkardesler et al., 2003; Bosman et al., 2004; Johnson et al., 2004; Vandenberg et al., 2007). For these reasons, persisting *D. fragilis* infestations are often treated with the intention to eradicate this protozoon from the gut.

Although *D. fragilis* infections are frequently detected and treated, there is no consensus as to the best treatment for dientamoebiasis (Johnson et al., 2004; Barratt et al., 2011). Until now only 11 studies on the efficacy of drugs to eradicate *D. fragilis* have been published (see Table 1 for an overview). These 11 studies investigated the efficacy of 12 distinct drugs, of which eight drugs were

investigated by a single study only. So far, only a single randomized study has been performed in which the treatment efficacy of metronidazole was compared to that of ornidazole (Kurt et al., 2008) and all other studies had a retrospective study design. These studies reported eradication efficacies that were either low (50% for erythromycin (Preiss et al., 1991), 75% for doxycycline (Preiss et al., 1991), and 67–89% for metronidazole (Vandenberg et al., 2006; Stark et al., 2010), or the result of very small retrospective cohort studies involving maximal 27, 12, 9 and 15 patients for clioquinol (81–100% (Bosman et al., 2004; Stark et al., 2010)), iodoquinol (83–100% (Spencer et al., 1982; Millet et al., 1983), diphetarson (100% (Keystone et al., 1983)) and paromomycin (80–100% (Vandenberg et al., 2007; Stark et al., 2010)), respectively. Two compounds, secnidazol and ornidazol, were reported by single studies to have a high eradication efficacy for *D. fragilis* (93% and 97%, respectively) in 56 and 34 patients (Girginkardesler et al., 2003; Kurt et al., 2008). Finally, it is unclear to what extent *D. fragilis* infections are spontaneously cleared, which may further hamper the interpretation of data regarding the eradication rates associated with some drugs. Therefore, the current information on the efficacy of drugs for eradication of *D. fragilis* is surprisingly small and hampers the formulation of unambiguous guidelines for treatment of dientamoebiasis, which is for instance demonstrated by the listing of four recommended drugs for treatment of dientamoebiasis in the latest Medical Letter (2010).

In order to better understand the natural course of the disease and the efficacy of potential treatment options, we analyzed the results of a retrospective follow-up study of a relatively large cohort of 93 patients with a documented *D. fragilis* infection.

2. Materials and methods

This retrospective cohort study was performed at the Institute for Tropical Diseases of the Harbor Hospital in Rotterdam, The Netherlands, which is a national referral center for adult patients who recently visited tropical countries. Patients were included when *D. fragilis* was demonstrated in a stool sample analyzed in the period 2004–2010 by Triple Feces Test (TFT), an all-round and sensitive method for microscopic detection of 'helminth ova and protozoa, among which trophozoites of *D. fragilis* (van Gool et al., 2003). In addition, a follow-up stool sample had to be available for evaluation of an empirical treatment or for evaluation of the natural course of the infestation in case of untreated patients. The majority of the included patients had gastro-intestinal symptoms and all were diagnosed with *D. fragilis* after exclusion of viral, bacterial and parasitological causes of gastro-intestinal illness by thorough investigations including fecal cultures for pathogenic bacteria (*Salmonella*, *Shigella* and *Campylobacter*) and PCR analysis for Rotavirus, Norovirus and Adenoviruses. In the majority of the patients the investigations also included upper and lower GI endoscopy, histological examination of duodenal and colonic biopsy specimens, anti-trans Tissue Glutamate antibodies determination as well as hydrogen breath tests for exclusion of lactose intolerance. Empirical treatment with either paromomycin (3 daily doses of 500 mg for 7–10 days), clioquinol (3 daily doses of 250 mg for 7 days) or metronidazole (3 daily doses of 500 mg for 7–10 days) was prescribed off-label on doctor's declaration and after informed consent of the patient. The patient records of all included patients were retrospectively examined for demographic data, therapy and clinical follow-up data. Patients with an age of less than 18 years and those patients who were treated for another protozoal or helminth infection were excluded. The time interval between two TFT analyses was truncated at 180 days. Parasitological eradication was defined as complete clearance of parasites in the subsequent stool examination.

3. Results and discussion

In the study period 5491 outpatients were examined for gastro-intestinal parasites by TFT and *D. fragilis* was demonstrated in stools of 451 patients (8%) of which 93 patients fulfilled the inclusion criteria. General demographic and clinical characteristics of the included patients with *D. fragilis* at presentation are shown in Table 2. Diarrhea (42%), abdominal pain (37%) and malaise (51%) were frequently observed. The laboratory parameters C-reactive protein, leukocyte and eosinophil counts were not elevated (Table 2). Patients with *D. fragilis* frequently had co-infestations with *Blastocystis* sp. (74%) and a-pathogenic protozoa (<10% for individual species) (Table 2).

The 93 included patients received a total of 102 treatments. Three patients received two treatments (first no treatment followed by paromomycin treatment) and another three patients received three subsequent treatments (one received no treatment first, then metronidazole treatment and finally paromomycin treatment, another received paromomycin treatment first, followed by two treatments with metronidazole, and the third patient received paromomycin treatment first, then no treatment and then paromomycin treatment combined with doxycycline). Therefore, results could be examined of 102 treatments with either paromomycin ($n = 61$), clioquinol ($n = 12$), metronidazole ($n = 7$) or no treatment ($n = 22$). This 'wait and see' policy was considered to represent the natural course of *D. fragilis* infestation. In 30 treatment cases (paromomycin $n = 27$, clioquinol $n = 2$, metronidazole $n = 1$) treatment was combined with doxycycline. Mean time between analysis of subsequent stool samples was 62–76 days and did not differ significantly between treatment regimens. Because treatment was not started directly after laboratory diagnosis of

Table 2
Characteristics of patients at presentation with a *Dientamoeba fragilis* infestation.

Demographic data	n	%
Patients	93	
Age (median, IQR)	41 (29, 49)	
Male gender	27	29
Female gender	66	71
Visit to the (sub) tropics ($n = 78$) ^a	72	92
Clinical symptoms	n	%
Duration of complaints ($n = 70$) ^a		
0–1 month	7	10
1–3 months	6	9
3–6 months	11	16
More than 6 months	46	66
Type of complaints ($n = 83$) ^a	Present (n)	Present (%)
Abdominal pain	31	37
Diarrhea	35	42
Malaise	42	51
Weight loss	17	20
Laboratory findings	Median (IQR)	N
Blood leukocyte count, $\times 10^9/L$	6.5 (5.7, 7.5)	77
Blood eosinophil count, $\times 10^9/L$	0.1 (0.1, 0.2)	42
C-reactive protein, mg/L	2 (1, 5)	75
Erythrocyte sedimentation rate, mm/h	7 (3, 11)	72
Stool examination	n	%
<i>Blastocystis hominis</i>	69	74

<i>Entamoeba hartmanni</i>	1	1
<i>Iodamoeba butschlii</i>	2	2

^a Specified data on travel history, duration of complaints and type of complaints was available in the medical records for 78, 70 and 83 patients, respectively.

the initial stool sample but after the subsequent outpatient clinic visit, the second stool sample was collected shortly after completion of treatment, which minimizes reinfection as a cause of persisting *D. fragilis* infections.

D. fragilis was spontaneously cleared in 41% of the untreated cases. Treatment with paromomycin, clioquinol and metronidazole was associated with eradication rates of 98%, 83% and 57%, respectively (Fig. 1). Although patient numbers in each treatment group are uneven, statistical analysis showed that paromomycin treatment had superior eradication rates compared to both metronidazole and no treatment ($P < 0.005$) and a trend towards superiority over clioquinol ($P = 0.06$) (Fig. 1). Treatment with clioquinol was significantly more effective when compared to “wait and see” ($P < 0.05$). Metronidazole treatment was not significantly more effective than a ‘wait and see’ policy ($P = 0.667$). Statistical analysis showed that the eradication rates of paromomycin, clioquinol or metronidazole were not affected by a *Blastocystis sp.* co-infection or a combined treatment including doxycycline. Furthermore, the time interval between the first and subsequent follow-up stool examination did not significantly differ between the patient groups.

The retrospective design of this study may hamper the generalizability of the findings of this study, because (1) the various treatment modes were not assigned randomly, (2) an all-round microscopic detection method was used instead of a more sensitive *D. fragilis* PCR method (Bruijnesteijn van Coppenraet et al., 2009), and (3) a placebo-control was lacking. Since in this study gastro-intestinal complaints were not systematically recorded nor evaluated, this study focused on eradication of *D. fragilis* as a hard end-point in relation to various treatment modes but not on resolution of gastro-intestinal complaints or evaluation of the pathogenic potential of *D. fragilis*. However, even within this framework of limitations, the following clinical relevant observations could be made. First, the natural course of *D. fragilis* infestation in untreated patients is characterized by a spontaneous clearance in 41% of cases. Second, this study suggests the superior efficacy of paromomycin for eradication of *D. fragilis* in adults (98%) as compared to treatment with metronidazole and possibly also to clioquinol. In this study the eradication efficacy of metronidazole was low (57%), but the relatively small number of included patients treated with metronidazole ($n = 7$) prohibits firm

conclusions on the eradication efficacy of this drug. Although the eradication efficacies might be lower when a more sensitive PCR method had been used, the observed relative differences in drug efficacy are not dependent on the sensitivity of the detection method.

The high efficacy of paromomycin was suggested by previous reports for small numbers of patients (maximal 15) comprising predominantly children (Vandenberg et al., 2006, 2007; Stark et al., 2010). This study now showed that paromomycin is a highly effective drug for treatment of *D. fragilis* in a large group of adult patients, since 60/61 (98%) patients cleared *D. fragilis* after paromomycin treatment. Our observations seem to justify validation of the treatment efficacy of paromomycin for eradication of *D. fragilis* in properly designed placebo-controlled trials in adults and may be of help in evaluating the pathogenic potential of *D. fragilis* in the etiology of persistent gastro-intestinal complaints.
