### ABSTRACT

The primary goal of the study was to estimate the phylogeny of *Bouteloua* and relatives (Gramineae: Chloridoideae) employing cladistic parsimony analysis of nuclear ribosomal internal transcribed spacer region (ITS1 + 5.8S + ITS2) DNA sequences. Included were *Aegopogon* (2 of 4 species), *Bouteloua* (34 of 42), *Buchloë* (1 of 1), *Buchlomimus* (1 of 1), *Cathestecum* (2 of 4), *Cyclostachya* (1 of 1), *Griffithsdochloa* (1 of 1), *Hilaria* (1 of 7), *Opizia* (2 of 2), *Pentarrhaphis* (2 of 3), *Pleuraphis* (2 of 3), *Pringleochloa* (1 of 1), *Soderstromia* (1 of 1), and five outgroup genera/species for a total of 18 genera, 56 species, and ten varieties. In all, the ITS region of 72 plants was sequenced and analyzed utilizing PAUP. *Aegopogon*, the *Hilaria*-*Pleuraphis* clade, and *Tragus* (an outgroup representative) formed a tetratomy with a clade containing the remaining ingroup taxa. Neither *Bouteloua* nor its two subgenera, *Bouteloua* and *Chondrosium*, were found to be monophyletic. *Bouteloua chondrosioides* was sister to *Opizia*. *Bouteloua rigidiseta* formed a clade with *Buchlomimus* and *Pringleochloa*. *Bouteloua eludens* formed a clade with *Buchloë*, *Cathestecum*, *Griffithsdochloa*, *Pentarrhaphis*, and *Soderstromia*. *Bouteloua annua* and *B. aristidoides* (subg. *Bouteloua*) formed a clade with *B. eriopoda*, *B. eriostachya*, *B. hirsuta*, and *B. pectinata* (subg. *Chondrosium*). *Bouteloua juncea*, which has been included in the *B. curtipendula* complex, was not a member of that clade. No new circumscriptions were proposed, although recognition of *Bouteloua* in the broad sense, with *Chondrosium* reduced to synonymy, was advocated. The findings suggested homoplasy in morphological, anatomical, and breeding system traits.

**Key words:** *Bouteloua*, Chloridoideae, cladistics, dioecy, DNA sequences, Gramineae, internal transcribed spacer (ITS), monoecy, nuclear ribosomal DNA, phylogeny, 5.8S.

### INTRODUCTION

In 1805 Lagasca described the genus *Bouteloua* (nom. cons., originally *Botelua*) and four species: *B. barbata*, *B. hirsuta*, *B. racemosa* (= *B. curtipendula*), and *B. simplex* (Gramineae: Chloridoideae). In the most recent taxonomic treatment of the genus, Gould (1980) recognized 39 species in two subgenera, *Bouteloua* and *Chondrosium* (Desv.) Gould. Since then, three additional species have been recognized (Reeder and Reeder 1981; Beetle 1986; Columbus 1996b) for totals of 25 species in subg. *Bouteloua* and 17 species in subg. *Chondrosium*. Over the years some taxonomists, led of late by Clayton (1982) and Clayton and Renvoize (1986), have chosen to treat *Chondrosium* Desv. as a distinct genus, a decision that Gould (1963) himself contemplated. Reeder and Reeder (1963b) and Estes and Tyrl (1982) argued to maintain *Chondrosium* as a subgenus or section.

The principal differences between the subgenera are shown diagrammatically in Fig. 1 (see Gould [1980] and Clayton and Renvoize [1986] for additional characters). Species in subg. *Bouteloua* usually have 7–80 deciduous branches per inflorescence, each 0.8–2 cm long and bearing 1–10(–20) appressed spikelets,

whereas *Chondrosium* species generally possess fewer branches (1–6) that are persistent (spikelets disarticulating at the base of the fertile [proximal] floret), longer (2–5 cm), and bear more (20–100), spreading (pectinate) spikelets (Gould 1980; Clayton and Renvoize 1986). Not all species, however, conform fully to this general characterization. For example, *Bouteloua chondrosioides* ("like *Chondrosium*") has been placed by most authors in subg. *Bouteloua* in spite of its relatively few inflorescence branches (usually 3–8) and "clearly" (Reeder and Reeder 1963b) or "moderately" (Gould 1980) pectinate spikelets. In subg. *Chondrosium*, *B. eriopoda* and *B. eriostachya* are exceptional in having relatively few (8–18) appressed or ascending spikelets. Other species in possession of atypical characteristics were noted by Gould (1980) and Clayton and Renvoize (1986). These authors, however, were not dissuaded by these exceptions, concluding, "the species of *Bouteloua* comprise two well-defined subgenera" and "divergence within each of the groups has resulted in a slight overlap of characteristics in a few taxa" (Gould 1980), and "though closely related, and with some overlap of individual characters, the two [groups] seem distinct enough" (Clayton and Renvoize 1986).

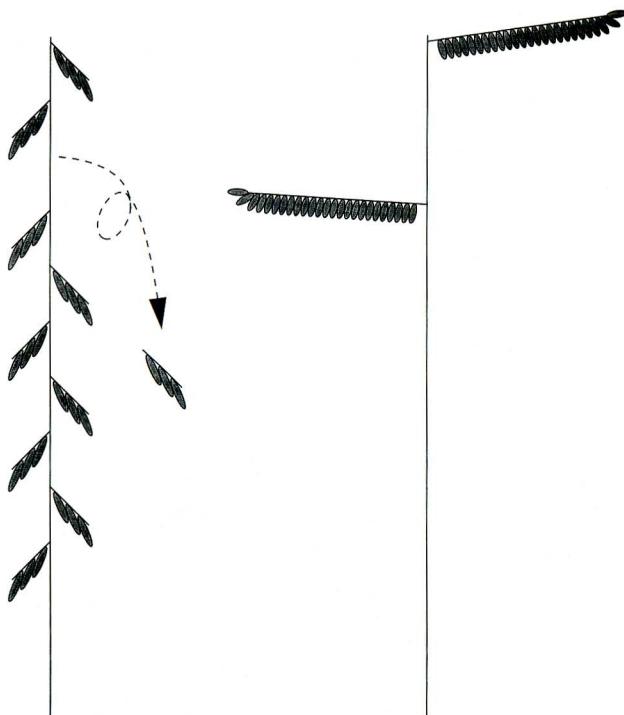

Fig. 1. Diagrams of representative inflorescences of *Bouteloua* subg. *Bouteloua* (left) and subg. *Chondrosium* (right). Shaded ellipses represent spikelets.

Clayton and Renvoize (1986) placed *Bouteloua* s.s. and *Chondrosium* in subtribe Boutelouinae of tribe Cynodonteae. Shown in Fig. 2 are the other genera comprising Boutelouinae, their relationships as suggested by these authors, and numbers of species. The species now treated in the monotypic genera *Buchlomimus* Reeder, C. Reeder, & Rzed., *Cyclostachya* Reeder & C. Reeder, and *Neobouteloua* Gould were transferred out of *Bouteloua* in the 1960s. *Buchlomimus* and *Cyclostachya* were described upon discovery that their constituent species are dioecious and sexually dimorphic (Reeder and Reeder 1963a; Reeder et al. 1965). Reeder and Reeder (1966) also reported "dioecy (or gynodioecy)" in some *Bouteloua chondrosioides*, but refrained from erecting a new genus because correlated characters were lacking. Five other taxa having unisexual flowers distributed in separate inflorescences are *Buchloë* Engelm. (nom. cons.), *Cathestecum brevifolium* (Pierce 1979), *Opizia* J. Presl, *Pringleochloa* Scribn., and *Soderstromia* C. V. Morton. Monoecy (obligate in *Opizia bracteata*, predominate in *Pringleochloa*) and dioecy are known to be expressed in these taxa. Markedly dimorphic are the carpellate (pistillate) and staminate inflorescences of *Buchloë*, *Opizia*, and *Pringleochloa*. Interestingly, the staminate inflorescences of these three genera and *Buchlomimus* and *Cyclostachya* closely resemble one another and inflorescences of species in *Bouteloua* subg. *Chondrosium* (Fig. 1, right), prompting Clayton and Renvoize (1986) to suggest the staminate inflorescences "seem to have been undisturbed by the evolutionary pressures which have shaped the female [= carpellate] plants."

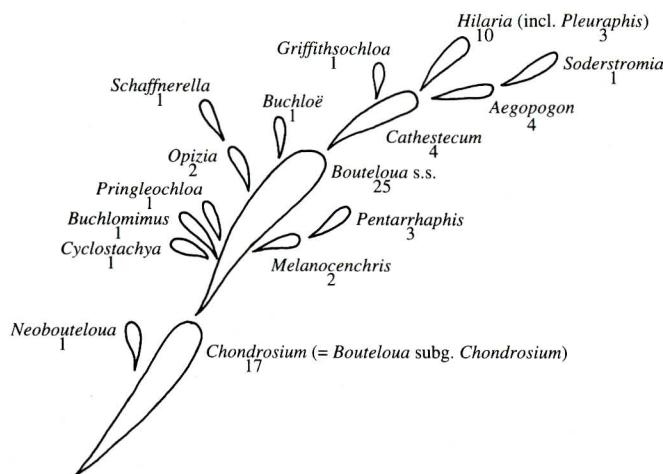

Fig. 2. Relationships among the genera of Boutelouinae as dia-gramed by Clayton and Renvoize (1986) and numbers of species. In Clayton and Renvoize's complete diagram of Cynodonteae, *Chondrosium* is situated near the base of *Chloris*. (Redrawn from a portion of Clayton and Renvoize's [1986] Fig. 16.)

rescences "seem to have been undisturbed by the evolutionary pressures which have shaped the female [= carpellate] plants."

In *Aegopogon* Humb. & Bonpl. ex Willd., *Cathestecum* J. Presl, *Griffiths ochloa* G. J. Pierce, *Hilaria* Kunth, and *Pleuraphis* Torr. (often treated as a subgenus of *Hilaria*, e.g., Hitchcock 1951; Sohns 1956; Clayton and Renvoize 1986), each inflorescence branch bears three spikelets, the terminal or central spikelet containing a hermaphroditic or carpellate floret (with or without staminate, neuter, and/or rarely hermaphroditic florets above) while the two lateral spikelets (one often not developed in *A. bryophilus* Döll) usually contain staminate florets (sometimes neuter, rarely hermaphroditic). *Aegopogon* and *Pleuraphis*, with hermaphroditic central spikelets, are andromonoecious, and *Hilaria*, possessing a carpellate central spikelet, is monoecious. As described by Pierce (1978, 1979), sexuality in *Cathestecum* and *Griffiths ochloa* is quite labile; both andromonoecy and monoecy are known in *Griffiths ochloa* and two species of *Cathestecum*, while *C. brevifolium* may be monoecious or dioecious and *C. varium* may be andromonoecious, monoecious, or trimonoecious (staminate, carpellate, and hermaphroditic flowers all present; Cruden and Lloyd 1995). Other than sexuality, the lateral spikelets of *Aegopogon*, *Cathestecum*, and *Griffiths ochloa* primarily differ from the central in being smaller and possessing fewer florets (in *Cathestecum* the first glumes also differ), whereas the spikelets of *Hilaria* and *Pleuraphis* are quite dimorphic. Clayton and Renvoize (1986) grouped these genera plus the monoecious/dioecious *Soderstromia* together in their diagram of relationships (Fig. 2) because all possess three spikelets per inflorescence branch (in *Soder-*

*stromia* each lateral spikelet is represented by a sterile bract).

Except for the facultatively dioecious or gynodioecious *Bouteloua chondrosioides*, the remaining species of *Bouteloua*, *Melanocenchrus* Nees, *Neobouteloua*, *Pentarrhaphis* Kunth, and *Schaffnerella* Nash lack unisexual spikelets. A staminate floret, however, may accompany the hermaphroditic floret in spikelets of some species, mainly species in the *Bouteloua repens* complex (Gould 1969), *Melanocenchrus*, and *Pentarrhaphis*.

Clayton and Renvoize's (1986) diagram of generic relationships in subtribe Boutelouinae (Fig. 2) was based in part on "strong trends towards deciduous abbreviated racemes [= inflorescence branches] and di-clinny [= monoecy and dioecy]." Situated at the base of the diagram are *Chondrosium* and *Neobouteloua*, which have relatively long, persistent branches bearing relatively numerous, hermaphroditic spikelets (Reeder and Reeder [1963b, 1969], however, reported deciduous branches in *Bouteloua* [*Chondrosium*] *karwinskii*). The remaining taxa have deciduous branches, except for *Schaffnerella*, that are usually shorter and typically bear fewer, sometimes unisexual, spikelets.

Apart from *Melanocenchrus*, distributed from Chad to India and Sri Lanka, and a single collection of *Aegopogon* from an isolated mountain top in Papua New Guinea (Veldkamp 1985), the genera in subtribe Boutelouinae have a natural distribution in the New World. Ten of the 16 genera and 58 of the 75 species are restricted to North America and the West Indies. With 14 genera (five endemic) and 64 species (27 endemic), Mexico is the center of diversity. Only *Aegopogon* (two species, one endemic), *Bouteloua* (nine species representing both subgenera, one endemic), *Neobouteloua* (one endemic species), and *Pentarrhaphis* (two species) are represented in South America. The most widespread species is *Bouteloua curtipendula*, extending from southern Canada to Argentina and Uruguay.

*Bouteloua* and relatives occur in areas, including deserts, characterized by relatively high temperatures and low precipitation. They are grassland associates or grow in openings in other vegetation types such as scrub and woodland. *Bouteloua curtipendula*, *B. gracilis*, *B. hirsuta*, and *Buchloë* are common prairie elements on the North American Great Plains; *Bouteloua gracilis* and *Buchloë* dominate the western, shortgrass region (Sims 1988). These and many of the other taxa are associated with and sometimes dominate semidesert grasslands, which extend in North America from the southwestern U.S.A. to southern Mexico (Rzedowski 1975; Brown 1982).

In his taxonomic revision "The grama grasses: *Bouteloua* and related genera," Griffiths (1912) wrote, "it is doubtful whether there is another group of native pasture grasses which is of as much economic impor-

tance as this, when both quality and quantity are considered." Stubbendieck et al. (1992) included nine species of *Bouteloua* and relatives among their 75 most important North American native range grasses.

#### OBJECTIVES

In their classification of the world's grass genera, Clayton and Renvoize (1986) explained that "the diagrams are intended to give a visual impression of phenetic relationships, progressing from simple to complex structures; they obviously have phylogenetic implications, but no attempt has been made to treat these rigorously." Nonetheless, Fig. 2 represents the only explicit hypothesis of relationship that has been published for *Bouteloua* and relatives. In addition, insights into possible intrageneric relationships have been largely confined to remarks concerning a few species. The principal goal of this study, therefore, was to improve upon our limited understanding of the evolutionary relationships among *Bouteloua* and relatives. Some specific objectives were to ascertain the monophyly of the genera, intrageneric taxa, and informal groups (i.e., *Bouteloua curtipendula* complex [Gould and Kapadia 1964], *B. repens* complex [Gould 1969]) and to determine the phylogenetic distribution of the various sexual phenotypes (andromonoecy, monoecy, dioecy, etc.). The method chosen for this investigation was cladistic parsimony analysis of internal transcribed spacer (ITS) region sequences of nuclear ribosomal DNA (Baldwin et al. 1995).

#### MATERIALS AND METHODS

##### Taxa and Collections

The taxa and collections used in this study are listed in Table 1. Included were 72 collections representing 18 genera (five outgroup), 56 species (five outgroup), and ten varieties. All genera in subtribe Boutelouinae were sampled except *Melanocenchrus*, *Neobouteloua*, and *Schaffnerella*. Living material of these three genera was not obtained and attempts to amplify the ITS region from herbarium specimens were unsuccessful. Most species of *Bouteloua* were sampled; those not sampled included six species that are undisputed members, based on morphology and leaf blade anatomy (Columbus 1996a), of the *Bouteloua curtipendula* complex of 12 species (Gould and Kapadia 1964), *B. quiriegoensis* Beetle (scarcely distinct from *B. hirsuta*), and the South American endemic *B. megapotamica* (Spreng.) Kuntze.

Gould (1980) and Clayton and Renvoize (1986, their Fig. 16) suggested that *Bouteloua* s.l. is closely related to *Chloris*; *C. virgata*, therefore, was chosen as an outgroup species. Other outgroup species, likewise members of subfamily Chloridoideae, included: *Cy-*

Table 1. Taxa, collections/vouchers, and origin of collections utilized in cladistic parsimony analysis of ITS region sequences. Asterisks denote those taxa not included in *Boutelouinae* by Clayton and Renvoize (1986) and employed herein as the outgroup. In bold are members of *Bouteloua* subg. *Chondrosium*. Collection/voucher numbers are those of Columbus unless indicated otherwise. Vouchers are deposited in RSA unless indicated otherwise.

*nodon dactylon* and *Microchloa kunthii*, placed by Clayton and Renvoize (1986) along with *Chloris virgata* in tribe Cynodonteae, subtribe Chloridinae; *Tragus racemosus*, Cynodonteae, subtribe Zoysiinae; and *Leptochloa dubia*, tribe Eragrostideae.

Most plants were grown in a controlled environment chamber, screenhouse, and/or greenhouse at Rancho Santa Ana Botanic Garden (RSABG) from seed (caryopses) or transplants. Frank Axelrod kindly sent live material of *Bouteloua juncea* from Puerto Rico. *Bouteloua americana* was grown from caryopses removed from a specimen recently accessioned at RSA. For some plants, at least 1 g of healthy living leaves and young shoots was removed while in the field, wrapped in aluminum foil, and immediately plunged into a dewar of liquid nitrogen; these samples were transported to RSABG and transferred to a -80°C freezer. Tissues removed from plants growing at RSABG were immediately placed in a -80°C freezer or used directly for DNA extraction. Samples of *Bouteloua chasei* and two collections of *Cyclostachya stolonifera* (Columbus 2206 and 2601) were obtained from herbarium specimens. Determinations of all collections were made by the first author and, other than the *B. juncea* material, vouchers were deposited at RSA (Table 1).

#### DNA Extraction

About 1 g from each sample was ground to a powder in liquid nitrogen with a mortar and pestle. From

the pulverized tissues total genomic DNA was extracted using a 2X CTAB buffer protocol (Doyle and Doyle 1987) with the following modifications: after addition of isopropanol the sample was kept at -20°C overnight to enhance precipitation, centrifuged, and the resultant pellet was washed for 10 min with 5 ml of 76% ethanol containing 10 mM ammonium acetate. Pellets were dried in a vacuum oven and resuspended in 0.2–1.0 ml of 10 mM Tris-HCl and 1 mM EDTA at pH 8.0. For samples taken from herbarium specimens, DNA extraction followed a 2X CTAB microprep protocol (Cullings 1992). All samples were diluted with sterile deionized water to a final concentration of 10 ng/μl.

#### Amplification and Sequencing

The ITS region (ITS1 + 5.8S + ITS2) was amplified using the polymerase chain reaction (PCR). Equal proportions of primers ITS4 and ITS5 (White et al. 1990) and 4–40 ng of total genomic DNA were included in each 100 μl reaction; for most taxa 20 ng of DNA resulted in the best amplification. A PTC-100™ (MJ Research) or Robocycler™ 96 (Stratagene) was used to carry out PCR: an initial denaturing step of 1 min at 97°C was followed by 40 cycles of 1 min at 97°C, 1 min at 48°C, and 2 min at 72°C, and concluded with a final extension step of 7 min at 72°C. The double-stranded PCR product was electophoresed

on a 1.5% agarose gel to verify amplification. Purification of the PCR product was accomplished via filtration through Millipore Ultrafree-MC™ filters or a polyethylene glycol precipitation protocol (Morgan and Soltis 1993), followed by resuspension in sterile deionized water. The template DNA was then cycle-sequenced using the PRISM™ DyeDeoxy™ Terminator Kit (Perkin Elmer) following the manufacturer's recommendations. The primers used for sequencing were ITS2, ITS3, ITS4i, and ITS5i (White et al. 1990; Porter 1997). Sequencing products were read by an Applied Biosystems 373A automated DNA sequencer using a Sequagel-6 polyacrylamide gel (National Diagnostics).

The four sequences obtained per sample were assembled, edited, and a consensus sequence constructed using Sequencher™ version 3.0 (Gene Codes Corporation). The bounds of ITS1, 5.8S, and ITS2 were determined by comparison with sequences in Hsiao et al. (1994) and Buckler and Holtsford (1996; sequences in GenBank). The latter authors included four more bases on the 3' end of ITS2, a decision we followed.

#### *Cladistic Analysis*

The consensus sequences were aligned visually and analyzed utilizing Phylogenetic Analysis Using Parsimony (PAUP) version 3.1.1 (Swofford 1993). The entire ITS region, including 5.8S, was analyzed. Characters (nucleotide sites) were treated as unordered, weighted equally, and optimized via accelerated transformation. Gaps were treated as missing data. For a particular taxon, a site having multiple nucleotides was interpreted as a polymorphism. The heuristic option was used to search for all most parsimonious (minimum-length) trees. Starting trees were obtained via random stepwise addition, with one tree held at each step. Tree bisection-reconnection was employed as the branch-swapping algorithm. The steepest descent option was not in effect. Zero-length branches were collapsed. One hundred replicates were performed.

Also computed using PAUP were the character status, pairwise distance matrix, strict consensus tree, consistency index (CI), rescaled consistency index (RC), and retention index (RI). The trees were drawn by PAUP.

To assess support for clades, a bootstrap analysis of 100 replicates was performed employing the same settings as above except that a closest addition sequence was used. In addition, decay indices (Bremer 1988; Donoghue et al. 1992) were calculated following the method of Baum et al. (1994) using a PAUP block appended to the file to automate the procedure (Leigh Johnson pers. comm.).

#### RESULTS

The aligned sequences are provided in Appendix 1. Alignment necessitated insertion of gaps, resulting in a length of 705 base pairs (bp), 94 (*Pleuraphis mutica*) to 121 (*Soderstromia*) bp longer than the unaligned sequences. In some regions alignment was not straightforward; in these cases, an alignment was arrived at that minimized variation. Of the 705 characters, 387 (55%) vary and 324 (46%) are potentially phylogenetically informative. Most variable is ITS2 (182 of 266 characters vary, or 68%), followed by ITS1 (179/274, 65%) and 5.8S (26/165, 16%). The percentage of variable characters that are potentially informative is nearly the same, ca. 84%, in each of ITS1, 5.8S, and ITS2. The pairwise distance matrix is shown in Appendix 2. Mean distances (proportions of divergent nucleotide sites to total sites, excluding gaps and polymorphic sites) range from 0 between several conspecific samples to 28% (162 sites) between *Bouteloua simplex* and *Hilaria ciliata*.

The heuristic search located 4747 most parsimonious trees of 1817 steps (nucleotide substitutions). The trees have a CI of 0.43, RC of 0.31, and RI of 0.73. The strict consensus of these trees is shown in Fig. 3, including bootstrap percentages and decay indices. Figure 4 is one of the most parsimonious trees drawn as a phylogram with branch lengths (numbers of nucleotide substitutions) indicated. As seen in the strict consensus tree (Fig. 3), a tetratomy is formed among *Tragus racemosus* (an outgroup representative), the *Aegopogon* clade, the *Hilaria-Pleuraphis* clade, and a poorly resolved but well-supported clade comprising the majority of the ingroup taxa. With the aim of improving the resolution of this last clade, a second analysis was carried out after removing *Aegopogon*, *Hilaria*, *Pleuraphis*, and the five designated outgroup species. This search found 376 most parsimonious trees of 1293 steps, each tree with a CI of 0.50, RC of 0.39, and RI of 0.77. Figure 5 is the strict consensus tree and Fig. 6 is one of the most parsimonious trees, upon which are mapped the insertions/deletions (indels) identified and enumerated in Appendix 1. Only unambiguous indels shared by two or more taxa are identified; these can be regarded as another measure of support for clades. Rooting of these trees was accomplished by designating *Bouteloua kayi* and *B. trifida* as the outgroup; common to these species and *Aegopogon*, *Hilaria*, *Pleuraphis*, and the five outgroup species in the more inclusive analysis are a single base (indel 11) and a string of six bases (indel 25) lacking in the remaining taxa (Appendix 1; Fig. 6).

#### DISCUSSION

##### *Aegopogon*

Circumscription of *Aegopogon* has never been disputed and monophyly of the genus is strongly sup-

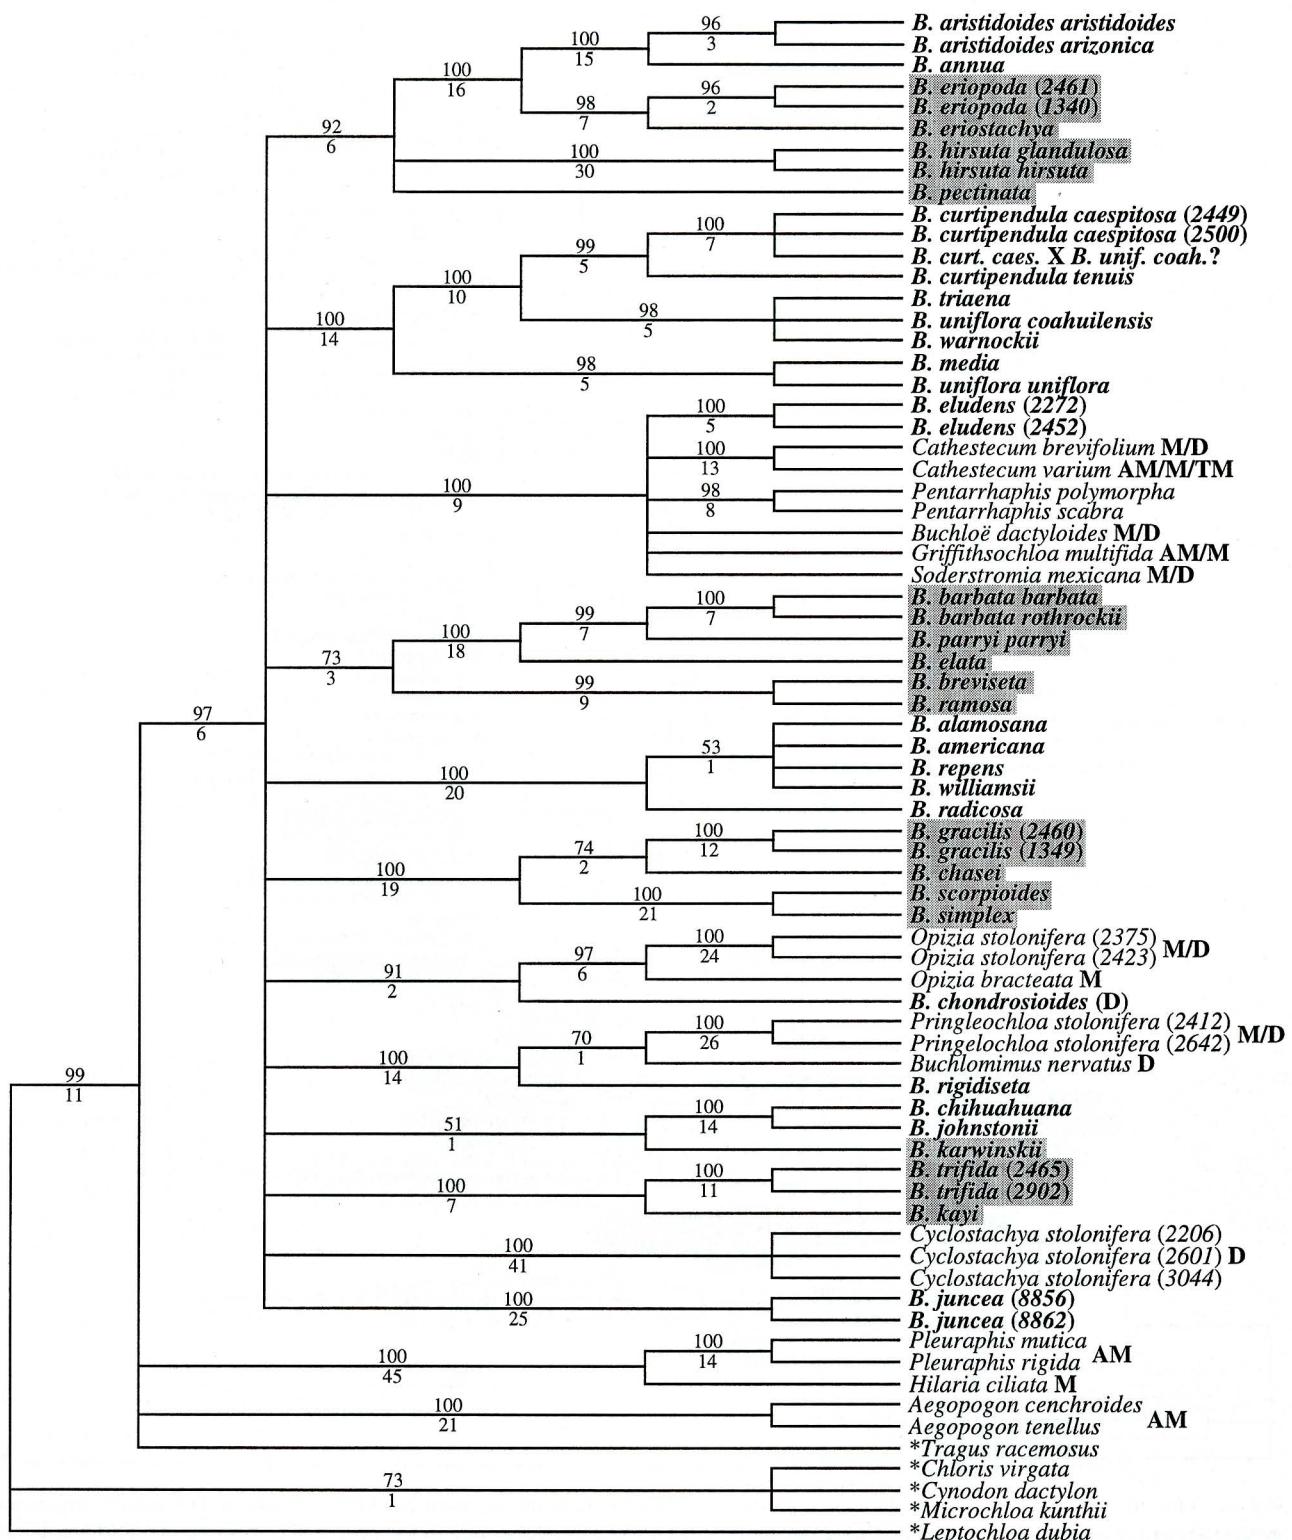

Fig. 3. Strict consensus of 4747 most parsimonious trees resulting from a PAUP analysis of ITS region sequences of representatives of *Bouteloua* and related and outgroup genera. Asterisks precede species designated as the outgroup. In bold are members of *Bouteloua*. Shaded are members of *Bouteloua* subg. *Chondrosium*. Numbers above and below branches are bootstrap percentages and decay indices, respectively. AM = andromonoecious, D = dioecious, M = monoecious, TM = trimonoecious. Tree length = 1817, CI = 0.43, RC = 0.31, RI = 0.73.

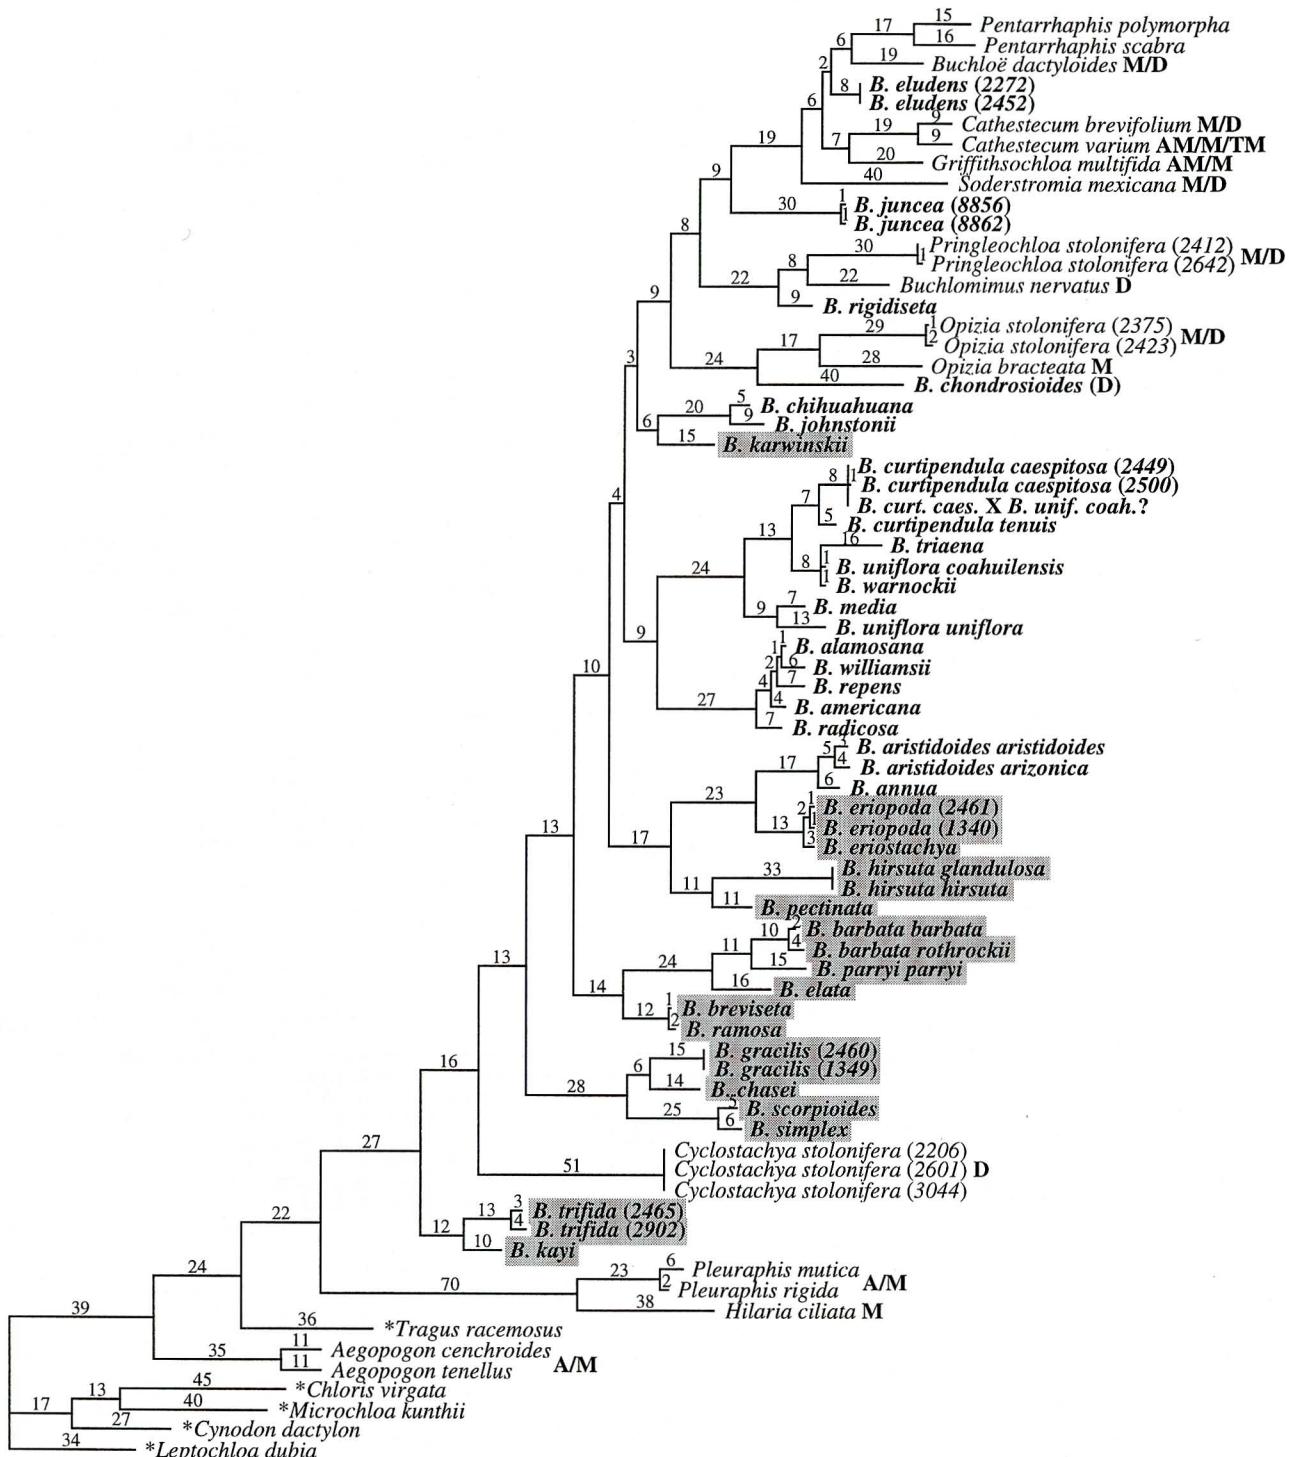

Fig. 4. One of 4747 most parsimonious trees, drawn as a phylogram, resulting from a PAUP analysis of ITS region sequences of representatives of *Bouteloua* and related and outgroup genera. Asterisks precede species designated as the outgroup. In bold are members of *Bouteloua*. Shaded are members of *Bouteloua* subg. *Chondrosium*. Numbers above branches are branch lengths. AM = andromonoecious, D = dioecious, M = monoecious, TM = trimonoecious. Tree length = 1817, CI = 0.43, RC = 0.31, RI = 0.73.

ported in this study (Fig. 3). *Aegopogon* is one of six genera, grouped together by Clayton and Renzvoize (1986), having spikelets arranged in triads. In the ITS region phylogeny, *Aegopogon* does not form a monophyletic group with any of these genera (*Cathestecum*, *Griffithsdochloa*, *Hilaria*, *Pleuraphis*,

*Soderstromia*). Columbus (1996a) found that *Aegopogon* is unlike these and the other genera in subtribe *Boutelouinae* in microscopic features of the abaxial epidermis of the lemma and in leaf blade trans-sectional structure. In the strict consensus tree (Fig. 3), *Aegopogon*, along with the *Hilaria-Pleuraphis*

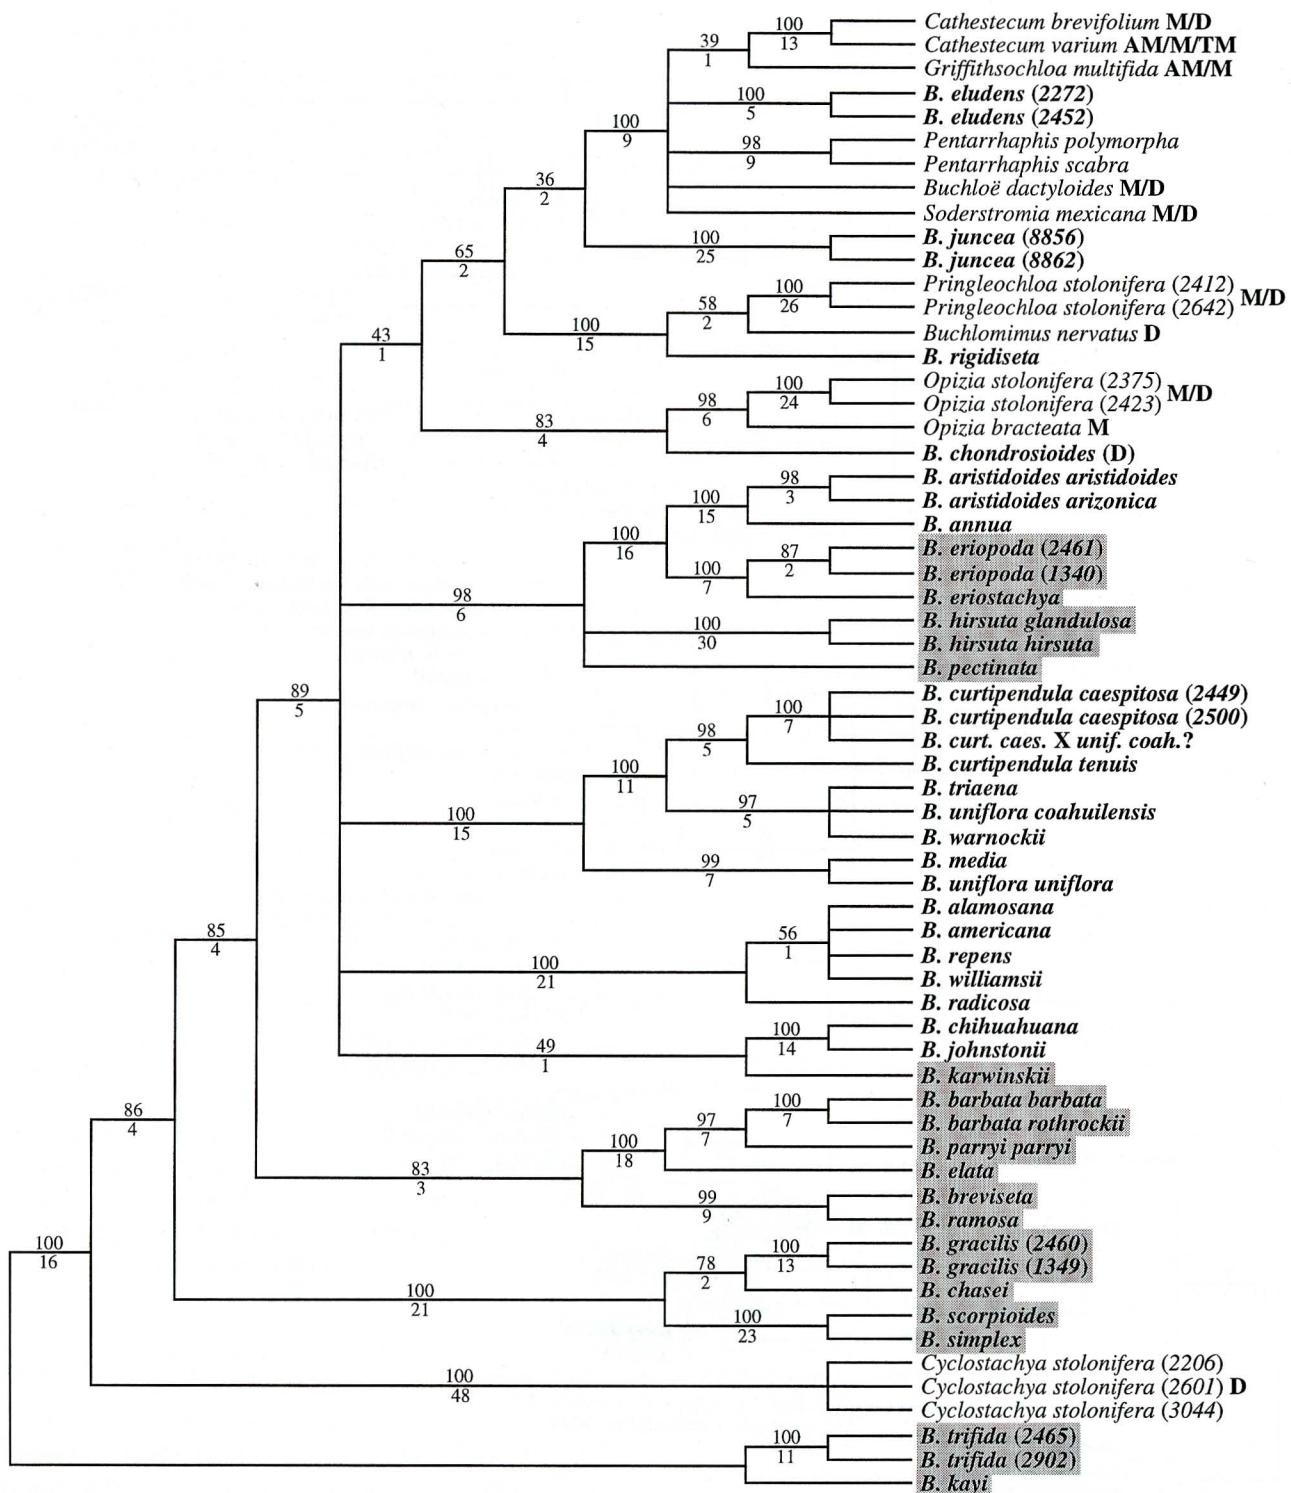

Fig. 5. Strict consensus of 376 most parsimonious trees resulting from a PAUP analysis of ITS region sequences of representatives of *Bouteloua* and related genera, but excluding *Aegopogon*, *Hilaria*, *Pleuraphis*, and five species designated as the outgroup in the more inclusive analysis. In bold are members of *Bouteloua*. Shaded are members of *Bouteloua* subg. *Chondrosium*. Numbers above and below branches are bootstrap percentages and decay indices, respectively. AM = andromonoecious, D = dioecious, M = monoecious, TM = trimonoecious. Tree length = 1293, CI = 0.50, RC = 0.39, RI = 0.77.

clade, *Tragus racemosus* (an outgroup representative), and the clade comprising the remainder of the ingroup taxa, form a tetratomy. Noteworthy, following Bentham's (1881) lead, until the mid 1900s *Ae-*

*gopogon*, *Hilaria*, and *Pleuraphis* were routinely placed, along with *Tragus* and *Soderstromia*, in tribe Zoysieae, separate from the other genera included in this study.

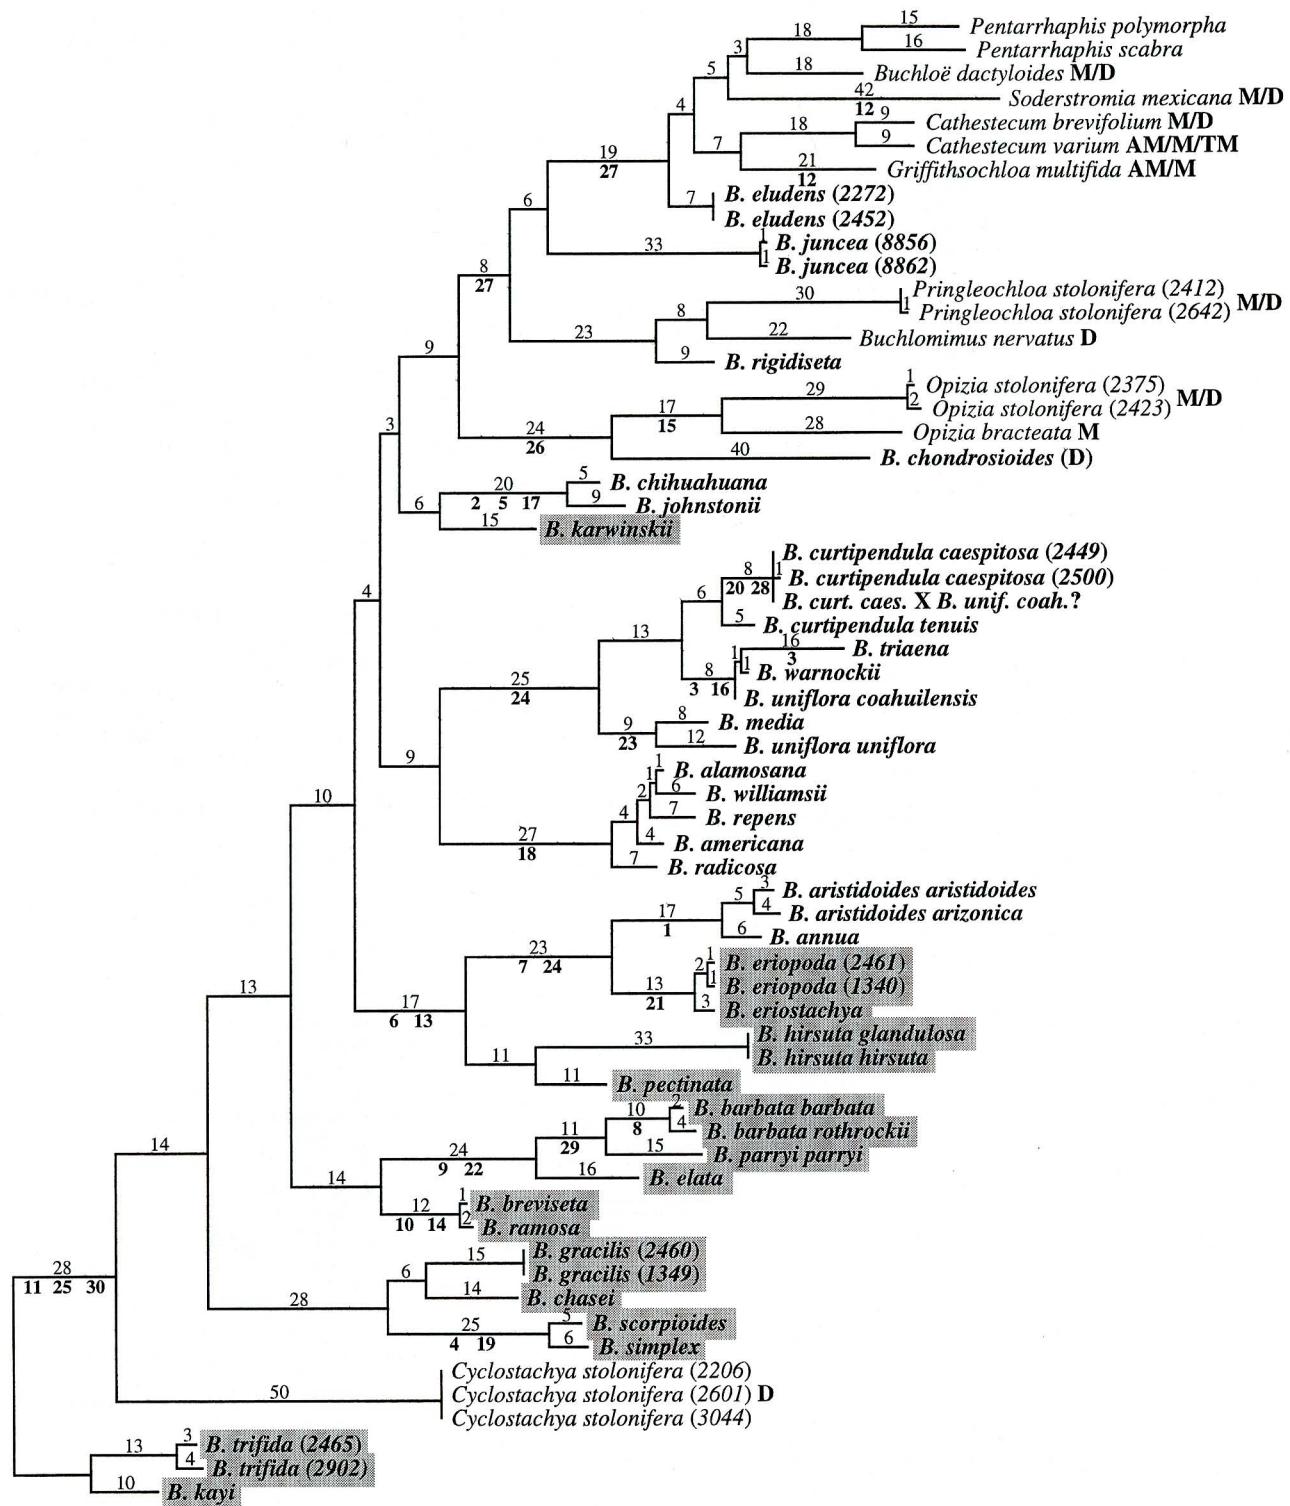

Fig. 6. One of 376 most parsimonious trees, drawn as a phylogram, resulting from a PAUP analysis of ITS region sequences of representatives of *Bouteloua* and related genera, but excluding *Aegopogon*, *Hilaria*, *Pleuraphis*, and five species designated as the outgroup in the more inclusive analysis. In bold are members of *Bouteloua*. Shaded are members of *Bouteloua* subg. *Chondrosium*. Numbers above branches are branch lengths. Numbers in bold below some branches represent indels, identified and enumerated in Appendix 1, shared by two or more taxa and mapped onto the tree. AM = andromonoecious, D = dioecious, M = monoecious, TM = trimonoecious. Tree length = 1293, CI = 0.50, RC = 0.39, RI = 0.77.

### Hilaria-Pleuraphis Clade

Not surprisingly, *Hilaria* and *Pleuraphis* form a strongly supported clade (Fig. 3). A close relationship between these taxa, often treated as congeneric, has never been questioned. Clayton and Renvoize (1986) remarked that *Hilaria* (including *Pleuraphis*) is "rather isolated but its "spikelet triads strongly suggest a link with the *Cathestecum* group of genera." Such a link is not evident from the ITS region phylogeny (Fig. 3), save possibly with *Aegopogon*. Among the most divergent sequences are those of *Hilaria-Pleuraphis* (Appendix 2) and the branch leading to these genera is by far the longest in the entire phylogeny (Fig. 4), mirroring the numerous morphological synapomorphies that set them apart from the other members of subtribe Boutelouinae. *Hilaria* and *Pleuraphis* also differ in basic chromosome number from the other genera in the subtribe (Avdulov 1931; Nielsen 1939; Brown 1950; Gould 1958, 1960, 1965, 1966, 1968, 1980 and refs. therein; Tateoka 1962; Pratt 1965 and refs. therein; Reeder et al. 1965; Anderson 1965; Reeder 1966, 1967, 1968, 1971, 1977, 1984, unpubl. data; Roy 1970; Pohl and Davidse 1971; Davidse and Pohl 1972; Holmgren and Holmgren 1977; Pierce 1979 and refs. therein; Reeder and Reeder 1981, 1988, 1990; Löve and Löve 1981; Windham and Schaack 1983). These reports suggest a basic number of nine for *Hilaria* and *Pleuraphis* and ten for the other genera except *Melanocenchrus* (one report of  $2n = 24$ , Swami 1963) and *Neobouteloua* and *Schaffnerella* (no reports).

A significant amount of sequence divergence has also occurred between the sole representative of *Hilaria* in this study and the two *Pleuraphis* species (Fig. 4; Appendix 2), paralleling morphological and anatomical divergence (Columbus 1996a: lemma micromorphology, leaf blade anatomy). In contrast, the *Pleuraphis* sequences differ relatively little from one another.

### Bouteloua

Monophyly of *Bouteloua*, either s.s. or s.l., is unsupported by the findings of this study (Fig. 3–6). *Bouteloua* subg. *Chondrosium* is also not monophyletic. What follows is discussion of those clades comprised entirely of *Bouteloua* species. *Bouteloua chondrosioides*, *B. eludens*, and *B. rigidiseta* will be discussed later in conjunction with the genera they form clades with.

*Bouteloua kayi-B. trifida clade*.—As indicated in the results section, *Bouteloua kayi* and *B. trifida* are the only species in the genus that share indels with *Aegopogon*, *Hilaria*, *Pleuraphis*, and the five outgroup species in the more inclusive analysis. The two species

constitute a strongly supported clade (Fig. 5, 6). The two plants of *B. trifida* used in this study, collected in Arizona and Texas, were substantially less divergent in sequence than either one was from *B. kayi* (Fig. 6; Appendix 2), a narrow endemic known only from Brewster Co., Texas, lending no support to Correll and Johnston's (1970) assertion that *B. kayi* is "probably only a form" of *B. trifida*. These species are atypical in subg. *Chondrosium* because they possess relatively few spikelets per branch (6–24[–32], Gould 1980), the spikelets are appressed or ascending rather than spreading, and the base of the sterile (distal) floret lacks a tuft of hairs.

*Bouteloua gracilis-B. simplex clade*.—*Bouteloua chasei*, *B. gracilis*, *B. scorpioides*, and *B. simplex*, all members of subg. *Chondrosium*, form a strongly supported clade (Fig. 5). *Bouteloua simplex*, an annual distributed in both North and South America, is sister to the perennial *B. scorpioides*, endemic to central Mexico. A close relationship between these two species is also suggested by morphology and leaf blade anatomy (Columbus 1996a). *Bouteloua scorpioides* and *B. simplex* are unique in *Bouteloua* in consistently developing only one branch per inflorescence.

A single polymorphic site (529) in ITS2 is the only difference between the sequences of the two *Bouteloua gracilis* plants sampled, from Arizona and Durango (Appendix 2; Fig. 6). The species is distributed from southern Canada to central Mexico. Its sister species is *B. chasei*, restricted to gypsum soils in northeastern Mexico. Support for the *B. chasei-B. gracilis* clade is not as strong as that for the *B. scorpioides-B. simplex* clade (Fig. 5, 6). The infolded, cylindrical leaf blades of *B. chasei* and *B. scorpioides* differ little and share a unique combination of anatomical features (Columbus 1996a).

*Chondrosium procumbens* (Durand) Desv. (= *Bouteloua simplex*) is the type species of *Chondrosium*.

*Bouteloua barbata-B. breviseta clade*.—*Bouteloua barbata*, *B. elata*, *B. parryi*, *B. breviseta*, and *B. ramosa* are members of subg. *Chondrosium* and constitute a well-supported and well-resolved clade (Fig. 5). The first three species form a clade sister to a clade formed by the last two species, each clade also strongly supported (Fig. 5, 6).

*Bouteloua barbata* and *B. parryi* in turn comprise a strongly supported clade that is sister to *B. elata* (Fig. 5, 6). Close relationships among these species have been suggested previously. Watson (1883), in describing var. *vestita* (= *B. parryi* var. *parryi*) of *B. polystachya* (Benth.) Torr. (= *B. barbata* var. *barbata*), treated *B. barbata* and *B. parryi* as conspecific. Gould (1949) compared *B. parryi* var. *gentryi* (Gould) Gould (not included in our study) to *B. barbata*. Reeder and Reeder (1963b) recognized the morphological similar-

ties between *B. elata* and *B. parryi* var. *parryi*, although the former is a large perennial and the latter a smaller annual. A close relationship among the three species is also suggested by lemma micromorphology and leaf blade anatomy (Columbus 1996a); lemma micromorphology supports a closer relationship between *B. parryi* and *B. elata* while leaf anatomy supports a closer relationship between *B. parryi* and *B. barbata*. Contrary to Gould (1980), Griffiths (1912) treated the perennial *B. barbata* var. *rothrockii* as specifically distinct from the annual var. *barbata*. While the perennial *B. elata* is restricted to southern Mexico, the annuals *B. barbata* var. *barbata* and *B. parryi* var. *parryi* are more widespread, distributed in the southwestern U.S.A. and Mexico, the former also disjunct in Argentina. The two perennial varieties of *B. barbata*, var. *rothrockii* and var. *sonorae* (Griffiths) Gould (not included in this study), have narrower distributions in southwestern U.S.A.-northern Mexico and western Mexico, respectively.

The sequences of *Bouteloua breviseta* and *B. ramosa* differ by only three nucleotide substitutions (Fig. 6; Appendix 2). Gould (1980) treated these species as conspecific, but Reeder and Reeder (1981) effectively argued, based on morphology, ploidy level, geography, and habitat, that the two are distinct. *Bouteloua breviseta* is restricted to gypsum soils in southeastern New Mexico and adjacent Texas and Mexico, whereas *B. ramosa* occurs farther south on calcareous substrates in the Chihuahuan Desert of western Texas and northern Mexico.

*Bouteloua aristidoides*-*B. eriopoda*-*B. hirsuta* clade.—*Bouteloua annua* and *B. aristidoides* (members of subg. *Bouteloua*) form a well-supported clade with *B. eriopoda*, *B. eriostachya*, *B. hirsuta*, and *B. pectinata* (members of subg. *Chondrosium*) (Fig. 5, 6). The first four species make up a strongly supported and well-resolved clade that in turn forms a tritomy with *B. hirsuta* and *B. pectinata* in the strict consensus tree (Fig. 5). In 78% of the most parsimonious trees, including the tree in Fig. 6, *B. hirsuta* and *B. pectinata* form a clade that is sister to the *B. aristidoides*-*B. eriopoda* clade.

*Bouteloua annua*, *B. aristidoides*, *B. eriopoda*, and *B. eriostachya* (originally described as a variety of *B. eriopoda*) are similar in spikelet orientation and form, including lodicules and the abaxial epidermis of the fertile lemma, and in transectional structure of the leaf blade (Columbus 1993, 1996a, 1999). The two most widely distributed species, *B. aristidoides* (southwestern U.S.A., Mexico, South America) and *B. eriopoda* (southwestern U.S.A., northern Mexico), differ considerably in general appearance. *Bouteloua eriopoda* usually has 2–6 branches per inflorescence, each 2–5 cm long and persistent (characteristics of subg. *Chondro-*

*sium*), while *B. aristidoides* typically has more numerous (7–20), shorter (1–3 cm), deciduous branches (characteristics of subg. *Bouteloua*). In addition, branches of *B. eriopoda* usually bear 8–18 spikelets (exceptionally few for subg. *Chondrosium*) and are usually distichous and ascending or spreading (see Griffiths 1912, Plate 74B), whereas branches of *B. aristidoides* usually have fewer spikelets (2–10) and, in var. *aristidoides*, are frequently pendulous along one side of an ascending or arching main axis (rachis), rendering the inflorescence secund (see Griffiths 1912, Plate 77A). The differences between the inflorescences, along with the fact that *B. eriopoda* is a stoloniferous perennial with pubescent internodes while *B. aristidoides* is a nonstoloniferous annual with glabrous internodes, have long masked their close relationship and led to the two species being placed in separate subgenera. In the ITS region phylogeny (Fig. 5, 6), the annuals *B. annua* (endemic to Baja California Sur) and *B. aristidoides* form a clade that is sister to a clade comprised of perennials *B. eriostachya* (endemic to Coahuila) and *B. eriopoda*; each clade is strongly supported. See Columbus (1999) for a more detailed discussion of these four species.

The nomenclatural combinations *Bouteloua hirsuta* var. *pectinata* (Feath.) Cory and *B. hirsuta* subsp. *pectinata* (Feath.) Wipff & S. D. Jones attest to the morphological similarity between *B. hirsuta* and *B. pectinata*. Each of these taxa has been advocated as a close relative of *B. gracilis* (Roy 1968; Correll and Johnston 1970; Roy and Gould 1971). Although the second (distal) glume of *B. hirsuta*, *B. pectinata*, and often *B. gracilis* (as well as *B. elata* and *B. parryi*) bears long, bulbous-based hairs, the spikelet of *B. gracilis*, especially the fertile lemma, differs considerably from those of the other species (see Griffiths 1912, Fig. 34, 35). Lemma micromorphology and leaf blade anatomy also suggest a relationship more distant than believed by the above authors (Columbus 1996a). A conspicuous feature of *B. hirsuta* and *B. pectinata*, often employed in keys to distinguish these taxa from *B. gracilis*, is that the inflorescence branch axis is prolonged beyond the terminal spikelet node. The branch axis is also prolonged in the four species comprising the *B. aristidoides*-*B. eriopoda* clade. In fact, *B. eriopoda*, *B. eriostachya*, *B. hirsuta*, *B. pectinata*, and *B. quiriegoensis* (not included in this study, but unequivocally closely related to *B. hirsuta* based on morphology and leaf blade anatomy [Columbus 1996a]) are the only members of subg. *Chondrosium* that exhibit this feature.

No author has hypothesized that *Bouteloua hirsuta* or *B. pectinata* is closely related to any of the species in the *B. aristidoides*-*B. eriopoda* clade as is suggested in the ITS region phylogeny. This is for good reason. Other than the prolonged axis of the inflorescence

branch, obvious morphological similarities are lacking (see figures and plates in Griffiths 1912). The two groups also differ markedly in leaf blade transectional structure (Columbus 1996a).

With regard to the two varieties of *Bouteloua hirsuta*, the plants used in this study came from the same population. Their sequences were found to be identical except for a polymorphism at a single site (469) in ITS2 of var. *hirsuta* (Appendix 1). The varieties, recognized by Gould (1980), are distinguished simply by the presence (var. *glandulosa*) or absence (var. *hirsuta*) of pubescence on culm internodes. Expressing doubt and citing a mixed collection, Griffiths (1912) nonetheless recognized *B. hirticulmis* Scribn. (= *B. hirsuta* var. *glandulosa*) as a distinct species. We assert that if these taxa are to be recognized at all, it should be at the rank of form.

*Bouteloua karwinskii*.—Although this species, a member of subg. *Chondrosium*, is sister to the *Bouteloua chihuahuana*-*B. johnstonii* (subg. *Bouteloua*) clade in the strict consensus tree (Fig. 5), the relationship is weakly supported by a bootstrap percentage of 49 and decay index of 1.0. Lacking are obvious morphological and anatomical (leaf blade x. s., Columbus 1996a) similarities between *B. karwinskii* and *B. chihuahuana*-*B. johnstonii* that would suggest a close relationship. Swallen (1943), Reeder and Reeder (1963b, 1969), and Gould (1980) considered *B. karwinskii* to be closely related to *B. chasei*, a member of the *B. gracilis*-*B. simplex* clade discussed above. *Bouteloua karwinskii* and *B. chasei*, both endemic to northern Mexico, have similar distributional ranges. Reeder and Reeder (1963b, 1969) pointed out differences between the species, however, including deciduous inflorescence branches and the absence of a tuft of hairs at the base of the second floret in *B. karwinskii*, features that Gould (1980) and Clayton and Renvoize (1986) associated with subg. *Bouteloua*. Columbus (1996a) found that *B. karwinskii* is most similar to *B. gracilis*, *B. scorpioides*, and *B. simplex* based on lemma micromorphology and to *B. gracilis* and *B. rigidiseta* (subg. *Bouteloua*) based on leaf blade anatomy.

*Bouteloua chihuahuana*-*B. johnstonii* clade.—A sister relationship between these species in subg. *Bouteloua* is strongly supported (Fig. 5, 6). These little-collected species are known only from Chihuahua and Coahuila, respectively. *Bouteloua chihuahuana* grows on calcareous substrates while *B. johnstonii* is an obligate gypsophile. The close relationship is also suggested by morphology and leaf blade anatomy (Columbus 1996a).

*Bouteloua americana*-*B. repens* clade.—This strongly supported clade is a group of species recognized by Griffiths (1912) and Gould (1969) plus *Bouteloua ala-*

*mosana*, which Gould (1980) eventually discovered also belongs to this group. The species are members of subg. *Bouteloua*. Although there is considerable sequence divergence among the species (Fig. 6; Appendix 2), the relationships are unresolved (Fig. 5). In 79% of the most parsimonious trees, including the tree in Fig. 6, this clade is sister to the *B. curtipendula* clade (discussed below). Columbus (1996a) found the groups to be very similar in microscopic features of the abaxial surface of the fertile lemma.

*Bouteloua curtipendula* clade.—Gould and Kapadia (1964) recognized 12 species and five varieties in the *Bouteloua curtipendula* complex (subg. *Bouteloua*). Included in our study were six species, four varieties, and a possible interspecific hybrid inferred from morphology. All but *B. juncea* (discussed below) comprise a strongly supported and well-resolved clade (Fig. 5, 6). Incongruent with morphology, the two varieties of *B. uniflora* are quite divergent in sequence (Appendix 2) and the species is polyphyletic (Fig. 5). The sequence of *B. uniflora* var. *coahuilensis* scarcely differs from that of *B. warnockii* (Fig. 6; Appendix 1, 2), although the latter species is morphologically more similar to *B. curtipendula*. Sequences from the two *B. curtipendula* var. *caespitosa* plants from Arizona and the putative hybrid from Coahuila are nearly identical, differing at only three nucleotide sites (249, 438, 693, the last two polymorphic; Appendix 1). As an interesting aside, Griffiths (1912) positioned *B. triaena* in the monotypic genus *Triaena* Kunth (under the misapplied name *T. juncea* [Desv. ex P. Beauv.]) Griffiths [= *B. juncea*].

*Bouteloua racemosa* Lag. (= *B. curtipendula*) is the type species of *Bouteloua*.

*Bouteloua juncea*.—This species in subg. *Bouteloua*, endemic to the West Indies, was suspected by Columbus (1996a), based on morphology (including lemma micromorphology) and leaf blade anatomy, to be misplaced in the *B. curtipendula* complex (Gould and Kapadia 1964; discussed above). The sequence divergences (Appendix 2) and phylogeny (Fig. 5) lend support to this hypothesis.

#### Cyclostachya

Clayton and Renvoize (1986; Fig. 2) suggested that the monotypic and dioecious *Cyclostachya*, endemic to central Mexico, is closely related to the dioecious *Buchlomimus* and monoecious/dioecious *Pringleochloa*. The ITS region phylogeny (Fig. 5), however, supports Reeder et al. (1965) who contended, based on morphology of bicellular microhairs on the abaxial surface of the leaf, that *Cyclostachya* does not appear to be closely related to either of these genera. In the phylogeny, *Cyclostachya* is situated among members

of *Bouteloua* subg. *Chondrosium* (all having hermaphroditic flowers), but note its numerous autapomorphies (Fig. 6). Although the staminate and carpellate inflorescences of *Cyclostachya* consist of a single *Chondrosium*-like branch, the branches are deciduous, unlike most species of *Chondrosium*. Also noteworthy is the lack of sequence divergence among the three plants originating from widely separated sites throughout the range of the species (Fig. 6; Appendix 2).

#### *Bouteloua chondrosioides*-*Opizia* Clade

The monophyly of *Opizia* is strongly supported by the ITS region phylogeny (Fig. 5, 6), validating McVaugh's (1983) decision to position his new species, *O. bracteata*, in *Opizia*. The monoecious and nonstoloniferous *O. bracteata* is known only from southwestern Michoacán while its monoecious/dioecious and stoloniferous sister species, *O. stolonifera*, is much more widespread (southern Mexico, Honduras, West Indies). Both species have markedly dimorphic staminate and carpellate inflorescences (Columbus 1994). Sister to *Opizia* is the nonstoloniferous *Bouteloua chondrosioides* (subg. *Bouteloua*), a relationship well supported by a bootstrap percentage of 83, decay index of 4, and a three-base insertion in ITS2 of all three species (Fig. 5, 6; Appendix 1). A close relationship between *B. chondrosioides* (Arizona, Texas, Mexico, Central America) and *Opizia* has never been hypothesized. Interestingly, *B. chondrosioides* is the only species of *Bouteloua* known to be dioecious (or gynodioecious), although the condition is facultative and without associated dimorphism (Reeder and Reeder 1966). Note also the long branches in this clade.

#### *Bouteloua rigidiseta*-*Buchlomimus*-*Pringleochloa* Clade

Based on morphology, including copossession of linear bicellular microhairs on the abaxial surface of the leaf, Reeder et al. (1965) suggested that the dioecious *Buchlomimus* and monoecious/dioecious *Pringleochloa* are closely related, a hypothesis supported by the ITS region phylogeny (Fig. 5). These two stoloniferous monotypic genera have small distributional ranges in central Mexico, the former known only from the states of Hidalgo and Mexico and the latter from Puebla. The other member of this strongly supported clade is the caespitose, perfect-flowered *Bouteloua rigidiseta*, a member of subg. *Bouteloua* and distributed in Oklahoma, Texas, Coahuila, and Tamaulipas. A close relation of *B. rigidiseta* to *Buchlomimus* and *Pringleochloa* has not previously been suggested.

#### *Bouteloua eludens*-*Buchloë*-*Cathestecum*-*Griffithsochloa*-*Pentarrhaphis*-*Soderstromia* Clade

This strongly supported clade, though backing monophyly of both *Cathestecum* and *Pentarrhaphis*, is poorly resolved (Fig. 5). In 1978 Pierce segregated the monotypic and andromonoecious/monoecious *Griffithsochloa* from the andromonoecious/monoecious/tri-monoecious/dioecious *Cathestecum*. These genera plus the monotypic and monoecious/dioecious *Soderstromia*, along with *Aegopogon*, *Hilaria*, and *Pleuraphis* (discussed above), constitute a group of genera that Clayton and Renvoize (1986) considered to be related (Fig. 2). These authors also situated *Pentarrhaphis* (perfect-flowered, although the second floret may be staminate) next to the Old World genus *Melanocenchrus* (not included in our study) and apart from the above genera (Fig. 2), although earlier Clayton and Richardson (1973) wrote that *Aegopogon*, *Cathestecum*, and *Soderstromia* "are clearly related to *Melanocenchrus* Nees and *Pentarrhaphis* H. B. K., and they to *Bouteloua* Lag."

*Bouteloua eludens*, a member of subg. *Bouteloua* having hermaphroditic flowers, has never been postulated to be closely related to any of the other members of this clade. Gould (1980) and Reeder and Reeder (1990) considered *B. eludens* to be closely related to *B. chondrosioides* (discussed further below).

Of the members of this clade, the monotypic, monoecious/dioecious, and markedly dimorphic *Buchloë* has been compared only to *Soderstromia* because each possesses unisexual flowers (Reeder and Reeder 1963a; Reeder et al. 1965). Inflorescence morphology, however, does not indicate a close relationship. In fact, the staminate and carpellate inflorescences of *Buchloë*, which are *Chondrosium*-like and burrlike, respectively, not only differ markedly from each other but from the inflorescences of all the other taxa in this clade.

#### CONCLUSIONS

Although monophyly of *Bouteloua* s.l. or s.s. and *Chondrosium* is not supported by cladistic parsimony analysis of ITS region sequences, no new circumscriptions are proposed herein. This study represents one line of evidence in a larger systematic investigation, and additional phylogenetic estimates, particularly from the nonrecombining chloroplast genome, are needed before taxonomic changes, if any, are proposed. Columbus (1999), however, presents morphological and anatomical evidence corroborating the close relationship between *Bouteloua aristidoides* and *B. (Chondrosium) eriopoda* (Fig. 5). He recommends that for now *Bouteloua* be treated in the broad sense, with *Chondrosium* reduced to synonymy and no subgeneric divisions, a position we also advocate.

If the ITS region phylogeny provides an accurate

estimate of the organismal phylogeny, then some intriguing cases of parallel or convergent morphological, anatomical, and breeding system evolution have taken place, although retention of plesiomorphic traits is a less parsimonious alternative. For instance, inflorescence branches of *Aegopogon*, *Cathestecum*, *Griffithsdochloa*, *Hilaria*, *Pleuraphis*, and *Soderstromia* each bear a triad of spikelets, the central spikelet differing in some manner from the laterals, but *Aegopogon*, *Hilaria*, and *Pleuraphis* appear distantly related to the other genera (Fig. 3). Also, inflorescence branches of *Bouteloua hirsuta*, *B. karwinskii*, *B. pectinata*, species in the *B. barbata*-*B. breviseta* and *B. gracilis*-*B. simplex* clades, *Buchlomimus*, *Cyclostachya*, and the staminate branches of *Buchloë*, *Opizia*, and *Pringleochloa* all bear numerous spreading spikelets (Fig. 1, right), but these taxa are scattered throughout the phylogeny (Fig. 5).

While a close relationship among *Bouteloua chihuahuana*, *B. chondrosioides*, *B. eludens*, and *B. johnstonii* has been advanced by Swallen (1943), Gould (1980), Reeder and Reeder (1990), and Columbus (1996b), the ITS region phylogeny supports a close relationship only between *B. chihuahuana* and *B. johnstonii* (Fig. 5). *Bouteloua eludens* commonly grows sympatrically with *B. chondrosioides* and their inflorescences are so similar that the two species can be difficult to distinguish in the field. In addition, the leaf blades of these two species and *B. chihuahuana* are virtually identical in transsectional structure to one another and to the blades of *B. hirsuta*, *B. pectinata*, *B. quiriegoensis*, and *Pentarrhaphis scabra* (Columbus 1996a). Also similar are the blades of *B. johnstonii*, *Griffithsdochloa*, *Opizia*, the two other species of *Pentarrhaphis*, and *Soderstromia*. Examination of the ITS region phylogeny (Fig. 5) reveals that these taxa are distributed in four separate clades, suggesting homoplasy at the anatomical level.

Taxa possessing unisexual spikelets are distributed throughout the ITS region phylogeny. The andromonoecious *Aegopogon* and *Pleuraphis*, monoecious *Hilaria*, and dioecious *Cyclostachya* are more distantly related to the other taxa, which are distributed in three separate well-supported clades (Fig. 3, 5). However, the relationship among these three clades is unclear as evidenced by the weak bootstrap and decay index support for the branches linking the clades in the strict consensus tree (Fig. 5). Interestingly, hermaphroditism, monoecy, and dioecy are expressed in each of these clades. These data suggest, therefore, that spikelet unisexuality and its various manifestations are homoplastic, and that *Bouteloua* and relatives appear to be predisposed to this condition.

Some of these genera deemed divergent on the basis of cryptic data are remarkably convergent morphologically. For instance, *Aegopogon* resembles the distantly

related *Cathestecum* and *Griffithsdochloa*, all having spikelets arranged in triads and exhibiting andromonoecy. More striking, however, is the likeness between the distantly related *Buchlomimus* and *Cyclostachya*, each stoloniferous and dioecious and "might almost be included in the same genus" (Clayton and Renvoize 1986).

#### ACKNOWLEDGMENTS

Kelly Allred, Sandra and Cassie Columbus, Oscar Dorado, Alfonso and Maria Munoz, Mark Porter, Andrés Rodriguez, Octavio Rosales, and Jesús Valdés facilitated field work. Field work was supported in part by the 1992 G. H. M. Lawrence Memorial Award; a Grant-in-Aid of Research from the National Academy of Sciences (Alexander Bache Fund), through Sigma Xi, The Scientific Research Society; and a grant from the Sigma Xi Chapter at the University of California, Berkeley; all to J. T. Columbus. Rosa Cerros, Mary Debacon, Matilda Low, and Shana Stein assisted in the lab. Leigh Johnson set up the decay index analysis in PAUP. Vanessa Ashworth, Elizabeth Friar, Mark Porter, Eric Roalson, and Tim Ross provided helpful input. We thank all for their support.

Appendix 1. Aligned ITS region sequences of representatives of *Bouteloua* and related and outgroup genera. Nucleotide sites are numbered 5' to 3'. Polymorphic sites are coded as follows: K = G/T, M = A/C, R = A/G, S = C/G, W = A/T, Y = C/T. Dashes represent gaps. ITS1, 5.8S, and ITS2 correspond to positions 1–274, 275–439 (ends marked by asterisks), and 440–705, respectively. Plus signs denote indels shown in Fig. 6. Unaligned sequence lengths are given at the end.

Appendix 2. Pairwise distances (divergence) between ITS region sequences of representatives of *Bouteloua* and related and outgroup genera, calculated using PAUP. Numbers representing taxon names correspond to those in Appendix 1. Absolute distances (numbers of divergent sites) appear below the diagonal and mean distances (proportions of divergent sites to total sites) appear above the diagonal. Gaps and polymorphic states were excluded from the comparisons.
