POLLUTION SENSITIVITY OF MACROLICHENS ON SOUTHERN LIVE OAK
(*QUERCUS VIRGINIANA*)

by
Christy Folk

This thesis was prepared under the direction of the candidate's thesis advisor, Dr. Jon Moore, and has been approved by the members of her supervisory committee. It was submitted to the faculty of The Honors College and was accepted in partial fulfillment of the requirements for the degree of Bachelor of Science in Liberal Arts and Sciences.

SUPERVISORY COMMITTEE:

Dr. Jon Moore

Dr. James K. Wetterer

Dean Ellen S. Goldey, Wilkes Honors College

Date

ACKNOWLEDGEMENTS

Thanks to everyone who assisted me on my thesis journey, including Dr. Hõim, Dr. McGovern, Dr. April Schimmel, Dr. Wetterer, Dr. Maldonado, and my Field Biology classmates, amongst others. I would also like to thank everyone who has supported me through my college years, including my parents, my friends, my roomies, the Dining Hall staff, and all of the other professors and staff members at the Harriet L. Wilkes Honors College, including but definitely not limited to Dr. Fewkes, Dr. Nur-tegin, Dr. Vazquez, Dr. O'Brien, Kristin Skarie, Devin Herrera, Noelle Parra, and Dean Ellen Goldey. I am grateful for all of the wonderful people who have been my fellow Enviro Club members over the years, the students who care about the condition of our earthly home and share my vision for a more just and sustainable future. It is very "unlucky" that I would have been able to complete a thesis project like the one I did without the constant guidance and support of Dr. Moore, so thank you.

ABSTRACT

Author: Christy Folk
Title: Pollution sensitivity of macrolichens on Southern live oak (*Quercus virginiana*)
Institution: Wilkes Honors College of Florida Atlantic University
Thesis Advisor: Dr. Jon Moore
Degree: Bachelor of Science in Liberal Arts and Sciences
Concentration: Environmental Science
Year: 2018

Lichens in south Florida are poorly documented. I surveyed macrolichens on the bark of Southern live oak trees (*Quercus virginiana*) present on the John D. MacArthur campus of Florida Atlantic University in Jupiter, Florida, to establish a baseline and to determine how automobile pollution may impact lichen species diversity and density. Ten randomly-selected trees in each of two study areas (adjacent to Parkside Drive versus mid-campus, away from any road) were surveyed for lichen species diversity and coverage. Fifteen species of lichens were identified using identification keys and chemical spot tests. Lichen diversity was similar in the two areas of study, but overall lichen coverage was significantly lower in the area adjacent to Parkside Drive, likely due in part to greater exposure to air pollutants from automobile exhaust.

To the “unenlivened” who like to liken lichens to plants

INTRODUCTION

Lichens are a symbiotic association between one or more mycobionts (fungi) and one or more photobionts, such as cyanobacteria or algae (Purvis 2000; Spribille et al. 2016). The fungi provide the main structural component of the lichen, while the photobionts photosynthesize to produce carbohydrates, in addition to providing nitrogen compounds (Richardson 1992). Lichenized fungi, or the species of fungi that are engaged in a symbiotic relationship with a photobiont, differ from non-lichenized fungi because they go through a morphogenesis in which the photobiont activates certain fungal genes to result in a unique structure and appearance (Brodo et al. 2001; Nash 2008). Lichens are classified based on the primary species of lichenized fungus that they contain.

Photomorphs are lichens that include the same fungus species but different photobionts (Purvis 2000).

The entire structural body of the lichen is known as the thallus (plural: thalli). Most of the cells of a lichen are fungal cells in the form of threads known as hyphae. In addition, lichens have a single layer of photobiont cells (Brodo et al. 2001). Basic lichen anatomy includes the cortex, which is the protective outside layer of fungal cells, with the photobiont layer of algal cells below, and then the medulla, a thick and often white layer composed of hyphae (Brodo et al. 2001). Characteristics used to identify different lichen species include cilia (hair-like growths at the edges of the thallus), maculae (white patches visible on the surface from a natural break in the photobiont layer), and pseudocyphellae (bumps on the surface as a result of hyphae growing through a break in the cortex) (Brodo et al. 2001). Different lichens produce unique secondary metabolites, or the by-product compounds of metabolism (Brodo et al. 2001). The metabolites react

with chemicals to give different colors, so spot tests in which a small drop of chemical is applied to the cortex or medulla of a lichen are used to distinguish between species (Brodo et al. 2001). Reproductive structures of lichens are also used to differentiate species. Four structures commonly used for identification are pycnidia (structures that contain spores that appear as black dots; Figure 1), apothecia (cup-shaped fruiting bodies that contain spores; Figure 1), soredia (clumps of fungal cells surrounding algal cells; Figure 2), and isidia (finger-like outgrowths of the cortex) (Brodo et al. 2001).

Figure 1. *Parmotrema subrigidum* with pycnidia (black dots) and apothecia (arrow).

Figure 2. *Dirinaria picta* with soralia composed of clumps of soredia (arrow).

In addition to their taxonomic classifications, lichens are generally categorized into one of three major types based on their physical structure: fruticose, foliose, and crustose (Hale 1969). The term macrolichens refers to fruticose and foliose lichens because their thalli have a greater surface area that is not as firmly attached to their substrates compared to the thalli of the crustose lichens (Brodo et al. 2001). Macrolichens also have a lower cortex or cortical layer on the side that attaches to the substrate, whereas crustose lichens do not have a lower cortical layer and attach via their medulla layer (Brodo et al. 2001).

It is particularly difficult to distinguish between different crustose species due to their similarities in appearance. Identification often requires additional chemical tests using techniques such as thin layer chromatography or spore analysis. Therefore, I

narrowed the scope of this project to macrolichen species, identified through the use of keys and simple chemical spot tests. A fourth type of lichen, squamulose, is characterized by a mixture of traits associated with crustose and foliose lichens. Squamulose lichens differ from foliose lichens in that they do not have a lower cortex, but they are also not as firmly attached to their substrate as crustose lichens, so very few species fall into the squamulose category (Hale 1969). However, some foliose species appear squamulose, so the classification is relevant to the current research.

Lichens play multiple, important ecological roles, including the creation of soil in primary succession, which allows for the growth of plants and all other species that rely on producers (Nash 2008). They are present in most terrestrial habitats all over the world as a result of their ability to tolerate a wide range of temperatures and environmental conditions (Nash 2008). To satisfy their hydration needs, lichens absorb water from dew, rain, and humidity. They grow very slowly, from one to five millimeters per year on average, due in part to the fact that they undergo metabolism and photosynthesis only when moist and become inactive when dry (Richardson 1992).

Automobile exhaust from internal combustion engines is a major source of air pollution in urban areas. A few examples of primary air pollutants found in car exhaust include nitrogen oxides, sulfur dioxide, soot, and carbon monoxide (Richardson 1992). Sulfur and nitrogen compounds react with oxygen and water vapor to give sulfuric and nitric acids, which are main components of acid rain and industrial smog. Dissolved sulfur dioxide and particulates get absorbed and accumulated by lichens, disrupting their metabolic processes and damaging chloroplasts and mitochondria (Richardson 1992). Consequently, lichens tend to be more sensitive to air pollution than larger plants and

animals (Brodo 1966). Macrolichens are particularly sensitive to airborne pollutants because much of the thallus is exposed to the air (Cameron et al. 2007). Researchers take advantage of lichens' tendency to accumulate air pollutants by using them as a low-cost alternative to expensive techniques to measure air pollution (Nash 1973; Richardson 1992; Asta et al. 2002; Cameron et al. 2007; Will-Wolf et al. 2017).

The objectives of my research are to create a baseline of the species of macrolichens on the bark of Southern live oak trees (*Quercus virginiana*) that are present on the John D. MacArthur campus of Florida Atlantic University in Jupiter, Florida, and to compare species coverage between two areas of study in varying proximity to a major road to determine how automobile pollution impacts lichen density and diversity.

Relatively little research has been conducted on lichens in southeastern Florida, except in the Everglades region (Moore 1968; Harris 1995; Kaminsky 2011; Seavey and Seavey 2011, 2012, 2014; Lücking et al. 2011), so my project aims to document the species that occur on campus and to collect data on coverage of different classifications of lichens.

Such identification and coverage data will create a baseline, or the necessary starting point, from which future studies can be designed on topics such as changes in biodiversity and lichen density over time or in response to anthropogenic alterations to the environment.

MATERIALS AND METHODS

Site Description

The project takes place in two areas of study in varying proximity to Parkside Drive, a major thoroughfare that borders the west side of the John D. MacArthur campus (hereafter referred to as campus) (Figure 3).

Figure 3. Areas of study on the John D. MacArthur campus.

The first area of study (AOS1) is in the central part of campus, in the corridor between the Honors College (MC01), Administration (MC02), and Student Resources (MC03) buildings (Figure 4).

Figure 4. Area of study one (AOS1) with live oak trees (*Quercus virginiana*) labelled.

The second area of study (AOS2) is adjacent to Parkside Drive, a main thoroughfare that runs north from Donald Ross Road (Figure 5).

Figure 5. Area of study two (AOS2) with live oak trees (*Quercus virginiana*) labelled.

To minimize complicating factors such as variations in bark acidity for different species of tree and various ages of trees, one species of tree (Southern live oak) was chosen, and the trees selected were all planted in the same year. Based on an analysis of aerial maps of the campus and surrounding development in the years that it was first built, two areas of study were designated as containing Southern live oak trees that were planted around the same time, i.e. 1999 (aerial photos from original Abacoa Development Company). Southern live oak trees were identified and assigned a number from 1 to 21 in the first area of study and 1 to 29 in the second area of study. Ten sample trees in each area of study were designated using an online random number generator (random.org). Duplicate numbers were excluded, so numbers were generated until there were ten different sample trees designated (Table 1).

Table 1. Designated sample tree numbers

Data Collection

One transparency sheet with a 10 cm² quadrat printed on it along with three colors of water soluble markers (blue, green, and red) were used to trace different types of lichens for coverage to be calculated (Figure 6). The red marker was used to trace fruticose lichens, the green marker was used to trace foliose lichens, and the blue marker was used to trace what I described as squamulose lichens, which were later identified as small-lobed foliose lichens. Each quadrat was assigned a label indicating the sample tree number, the cardinal direction, and vertical position of the quadrat, with 1 being the

highest quadrat in a given direction and 3 being the lowest (e.g., T2N1 refers to the first quadrat on the north side of sample tree 2).

Figure 6. First quadrat on the east side of sample tree nine in AOS1.

The first quadrat was attached to the trunk of each mature tree about 1.5 m above the ground using four thumb tacks. The next quadrat was 20 cm lower, and the third quadrat, 20 cm below the second. Thus, there were 10 cm between each of the three quadrats in a given cardinal direction in vertical alignment for a total of twelve quadrats

per sample tree. The height of the quadrats was chosen to avoid the influence of the sprinkler irrigation system, which may artificially stimulate lichen growth at the base of the trunk.

To calculate the coverage of the different types of lichen within the quadrat, the transparency sheet was scanned for the samples in AOS1, but photographed for the samples in AOS2 due to the greater distance I needed to travel from the site to my computer scanner. Images of the transparency sheets were then uploaded to an online irregular shape area calculator (sketchandcalc.com) to determine the coverage area (mm²) of each type of lichen (fruticose, foliose, and squamulose) within each quadrat.

Fruticose and foliose specimens were collected from each of the ten sample trees in the two areas of study for identification. To prevent the removal of the only specimen of a given species from a sample tree, photographs were often taken of the fruticose species and sometimes taken of the foliose species for identification rather than collecting a specimen. Small segments of a solitary specimen were occasionally collected to conduct spot tests if the species could not be identified using the photographs alone. The identification keys from *Lichens of North America* and “Field oriented keys to the Florida lichens” were the primary keys used to identify specimens (Brodo et al. 2001; Rosentreter et al. 2015). Spot tests consisted of the application of a single drop of 10% potassium hydroxide (abbreviated as K), sodium hypochlorite solution or bleach (abbreviated as C), or *para*-phenylenediamine solution (abbreviated as PD) using drawn-out capillary tubes under a dissecting microscope (detailed descriptions on how to make chemical solutions found in Brodo et al. 2001).

Data Analysis

After uploading the scans or photographs of the quadrats to the online area calculator tool to determine coverage area (mm²) of each type of lichen, data were recorded in a Microsoft Excel spreadsheet for analysis (Appendix I and II). Total lichen coverage (mm²) was calculated for each quadrat by summing the coverage for each of the three lichen types. A total of twenty-one Student's t-tests were conducted on various subsets of data.

Identification

Identification of species of lichens started with the assignment of a specimen to one of four categories (crustose, foliose, squamulose, and fruticose) in the field while coverage data were collected. The lichens that were identified as crustose species were excluded from the coverage calculations as beyond the scope of the project (not macrolichens). The lichens that were described as foliose and marked with a green marker in the quadrats included the seven *Parmotrema* species that were later identified with spot tests when specimens were collected. The lichens that were identified as squamulose and marked with a blue marker to distinguish them from the foliose lichens included the three *Dirinaria* species, which were later identified as foliose as well. For the purposes of this project, they are described as squamulose, but it should be noted that very few lichen species fall into the squamulose category and that *Dirinaria* species are recognized as small-lobed foliose in identification keys. The lichens that were identified as fruticose and marked with a red marker included the five *Ramalina* species.

Once the squamulose specimens were identified as belonging to the genus *Dirinaria*, physical characteristics were sufficient for distinguishing between species using the descriptions found in the identification keys of *Lichens of North America*. The specimens of *D. picta* are characterized by soredia, the asexual reproductive structures previously described and depicted in Figure 2. The *D. confusa* and *D. purpurascens* specimens have black and purple apothecia, respectively.

The foliose lichen *Parmotrema praesorediosum* produces no color change in reactions with the medulla during spot tests because of the presence of caperatic acid (Brodo et al. 2001). Therefore, when the three spot test reactions with potassium hydroxide (K), bleach (C), and *para*-phenylenediamine (PD) were negative for color changes, the species was identified as *P. praesorediosum*. The color of the underside of the specimen and the presence of cilia, pycnidia, and/or maculae initiated spot tests to distinguish between species that have similar sets of physical characteristics. A few of the physical differences between the specimens of *P. praesorediosum* and *P. tinctorum* were the presence of soredia and a mottled ivory underside (*P. praesorediosum*) versus isidia and a brown underside (*P. tinctorum*), as well as a positive reaction to bleach, which turned the medulla red. An example of physical differences among specimens of *P. praesorediosum*, *P. hypoleucinum*, and *P. subrigidum* was absence of cilia (*P. praesorediosum*) versus presence of cilia (*P. hypoleucinum* and *P. subrigidum*). The specimens of *P. perforatum* and *P. subrigidum* differed from *P. praesorediosum* by the presence of apothecia rather than soredia.

Many of the acids that the fruticose species contain give negative spot test results for the chemicals that were used, so identification of fruticose species relied heavily on

analysis of photographs and observation of specimens under a dissecting microscope. The physical differences used to differentiate amongst fruticose species include patterns of pseudocyphellae, the presence or absence of apothecia, and the size and shape of branches. The most evident physical difference between specimens of *R. complanata* and those of *R. stenospora* was the number and shape of pseudocyphellae, which were abundant on thicker branches for the former species and elongated on narrower branches for the latter species. Identification using published keys was conducted as accurately as possible, but the lack of prior experience and training on lichen identification may have resulted in some incorrect identifications.

RESULTS

Identification

Fifteen different foliose and fruticose lichen species were identified using keys and a combination of photographs and chemical spot tests on collected specimens. Five species were only found in the first area of study and four species were only found in the second area of study (Table 2). I photographed all identified species except *Parmotrema hypoleucinum* (Appendix III).

The most commonly identified species of foliose lichen was *Parmotrema praesorediosum*, while the most commonly identified fruticose lichen species was *Ramalina complanata*, followed closely by *R. stenospora*. A single specimen was identified for each of the two species *R. peruviana* and *R. cf. americana*, both in the second area of study adjacent to Parkside Drive.

Pollution impacts

Mean lichen coverage for the three documented types of lichens was 1937 mm² (SD = 1549 mm²) for AOS1 (n = 120) and 1227 mm² (SD = 1538 mm²) for AOS2 (n = 120). I calculated individual, total, and mean coverage for each cardinal direction in the two areas of study (Table 3 and 4).

Fruticose	0.052	74	34
Squamulose	0.016	1006	735
Foliose and squamulose	0.002		

DISCUSSION

Previous studies show that fruticose and foliose lichen species have lower tolerances for air pollution, and macrolichen coverage and diversity tends to increase on a gradient as one travels away from areas with high concentrations of sulfur dioxide and other air pollutants (Brodo 1966; Nash 1973; Richardson 1992; Cameron et al. 2007). Species absent from the second area of study could be indicator species with a lower tolerance for air pollution: *D. purpurascens*, *P. hypoleucinum*, *P. perforatum*, *P. reticulatum*, and *R. denticulata*. Contrary to expectations, only one of the five species identified from the first area of study that was not identified in the second area of study was fruticose, while two species of fruticose lichens, *R. cf. americana* and *R. peruviana*, were identified from the second area of study but not the first.

One possible explanation for such results is that species that were not identified in one area of study or another are not necessarily absent from that area, but instead they were left unidentified due to specimen collection being restricted to sample trees and the non-comprehensive nature of the study. On the other hand, the results may indicate that fruticose species such as *R. complanata* and *R. stenospora* are present in both areas of study because they can tolerate pollution levels adjacent to the road to an extent. Although the Student's t-test comparing fruticose coverage in both areas of study was not significant at the $\alpha = .01$ level, the results were close to being statistically significant at the $\alpha = .05$ level with a value of 0.052, indicating that the likelihood of the two groups showing differences in coverage due to chance is lower than that of many of the other groups that were tested. The mean coverage of each of the three types of lichens for the quadrats in which they were present in the first area of study, which was farther from the

road, was greater than the mean coverage of each of the lichen types in the second area of study (Table 6).

Species belonging to the fruticose lichen genus *Usnea* are common in Florida but were not identified in either area of study. Species of *Usnea* have thin branches with a comparatively large surface area exposed, so their sensitivity to sulfur dioxide levels may preclude them from colonizing urbanized regions, which include both of the areas of study (Richardson 1992). Many of the previous studies on lichens and air quality, which recognize a decrease in coverage along a gradient, involved data collection in sites that were kilometers apart (Brodo 1966; Richardson 1992; Cameron et al. 2007). The current project's areas of study were located less than a kilometer apart, which may explain the similarity of species diversity between the two areas.

The common factor that returned significant results when comparing general lichen coverage was coverage on the east side of sample trees in the second area of study. In both areas of study, there was higher lichen concentration on the north and west sides than on the east and south sides of the trees, as shown by the total and mean coverage data for the four directions in Tables 3 and 4. Unlike vascular plants, lichens do not have a mechanism to retain water, and they rely on precipitation to satisfy their hydration needs, as previously mentioned. Because they undergo metabolism and growth only when hydrated, lichens that are exposed to higher temperatures dry out more quickly and grow more slowly (Nash 2008). The east and south sides of the trees therefore have less lichen coverage because they are subjected to more sunlight, which dries out the lichens, making those orientations of the tree less habitable. Despite the west side of the trees more directly facing the source of air pollution from the passing traffic, the east side of

the trees in the second area of study contained the least amount of lichen coverage due to the physiology of the lichens in relation to sun exposure.

In comparing the two areas of study in terms of the coverage of individual lichen types, the results of the t-tests showed that the tests comparing the species that were designated as squamulose and the species that were designated as foliose and squamulose together were significant. As previously mentioned, the squamulose designation included the three species that were later identified as *Dirinaria confusa*, *D. picta*, and *D. purpurascens*, which are three species of foliose lichens that have smaller lobes and therefore resemble crustose lichens. Upon testing of the overall foliose coverage, which included the species that were designated as foliose and squamulose that were later identified as *Parmotrema* and *Dirinaria* species, the results are significant at the $\alpha = .01$ level, indicating that it is not likely that the difference in lichen coverage between the two areas of study is due to chance (Table 6). The results show that the difference in foliose coverage between the two areas was statistically significant while the difference in fruticose coverage was not, possibly signifying that that the foliose species that were present in the two areas of study exhibit greater sensitivity to air pollution between shorter distances away from the source.

The result of the Student's t-test that aimed to compare overall lichen coverage between the two areas of study produced significant results that clearly show that there is a difference that is probably caused in large part by proximity to a source of air pollution (Table 5). In addition to air pollution, another factor that may explain the difference in lichen density between the two areas is the amount of shade versus sun exposure based on the canopy size of the trees and proximity to buildings as an additional source of

shade. Further research on concentrations of sulfur compounds in lichen specimens and the identification and collection of coverage data for crustose lichens may contribute to a greater understanding of lichen sensitivity to air pollution.

CONCLUSION

A baseline of lichen species that are present on campus was created through identification of specimens collected from each of ten sample trees in two areas of study for a total of twenty Southern live oak trees. The expected number of lichen species to be identified prior to conducting the study ranged from ten to twenty, so the final results in which fifteen species were identified and documented conformed to expectations.

The Student's t-tests that produced significant results at the $\alpha = .05$ level included the tests that compared general lichen coverage between the east and west sides and north and east sides of the trees in the second area of study next to the road, the east sides of the trees in both areas of study, and overall lichen coverage between the two areas of study on all sides of the trees. The tests that produced significant results at the $\alpha = .05$ level when comparing the coverage of individual lichen types included squamulose or *Dirinaria* species coverage in the two areas of study and both squamulose and foliose or *Dirinaria* and *Parmotrema* species coverage in the two areas of study.

Lichen diversity was similar between the two areas of study, with eleven species identified from the first area of study and ten species identified from the second area of study with six species in common. The number of species that were identified may not necessarily reflect the lichen diversity in the two areas of study, as specimen collection was limited to sample trees. According to the results, the amount of lichen diversity did not differ between the two areas of study, but overall lichen density differed significantly, probably in part due to proximity to air pollution from automobile exhaust.

Appendix III. Photographs of identified species

Dirinaria confusa

Dirinaria picta

Dirinaria purpurascens

Parmotrema cristiferum

Parmotrema perforatum

Parmotrema praesorediosum

Parmotrema reticulatum

Parmotrema subrigidum

Parmotrema tinctorum

Ramalina cf. americana

Ramalina complanata

Ramalina denticulata

Ramalina peruviana

Ramalina stenospora
