PROCEEDINGS

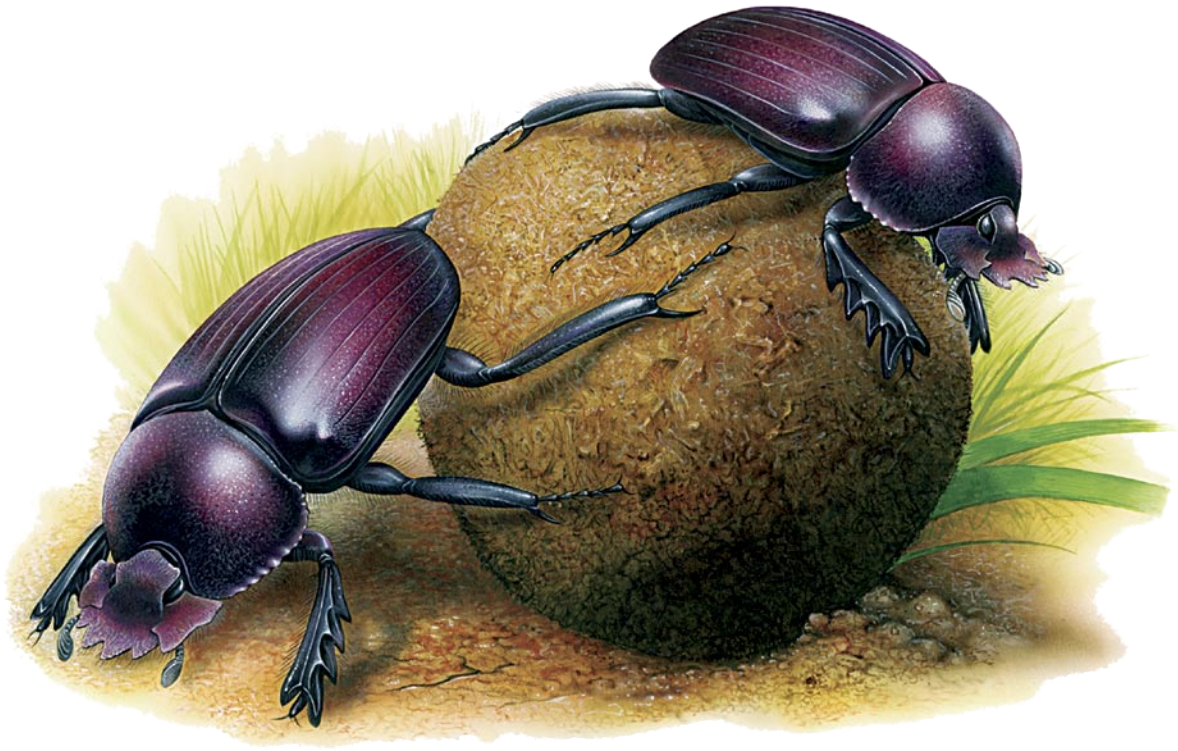
ICE 2008

XXIII International Congress of Entomology

6 - 12 July, 2008: International Convention Centre, Durban

"Celebrating Entomology: Contributions to Modern Science"

ICE 2008: TABLE OF CONTENTS



ICE2008 ORGANIZING COMMITTEES

SOUTH AFRICAN MANAGEMENT COMMITTEE

Congress President

Robin Crewe

Chairman

Gerhard Prinsloo

Deputy Chairman

Schalk Louw

Members

Marcus Byrne
Ahmed Hassanali
Jannette Mitchell
Shirley Hanrahan
John Hoffmann
Margaret Kieser (Secretary)

SCIENTIFIC PROGRAMME COMMITTEE

John Hoffmann (Chair)
Brian Barnes
Jan Giliomee
Cliff Moran

SOCIAL EVENTS COMMITTEE

Marcus Byrne (Chair)
Shirley Hanrahan

FINANCIAL AND SPONSORSHIP COMMITTEE

Jannette Mitchell (Chair)
Steve Mitchell

AFRICAN LIAISON COMMITTEE

Ahmed Hassanali (Chair)
Johnnie van den Berg

DURBAN ORGANIZING COMMITTEE

Des Conlong (Chair)
Various staff members from the following institutions:

ARC-Plant Protection research Institute, Cedara.
Natal Museum, Pietermaritzburg.
Natural Science Museum, Durban.
South African Sugarcane Research Institute, Mount Edgecombe.
University of KwaZulu-Natal, Pietermaritzburg and Durban.

ICE COUNCIL MEMBER

Shirley Hanrahan

The Council - ICE International

The purpose of the Council is to provide continuity and direction for the International Congresses of Entomology, and to serve as the Entomology Section of the International Union of Biological Sciences (IUBS). It may also encourage the holding of smaller inter-Congress meetings.

The Council consists of not more than twenty-three (23) members, who shall represent as wide a field as possible both geographically and by entomological discipline. Membership of the Council shall be limited to distinguished entomologists who are interested in the welfare and future of the International Congresses of Entomology. Members are elected for one term of 8 years. Members can be re-elected for a second term but are not permitted to serve more than two consecutive terms.

Council is able to appoint Honorary members as prescribed in the Constitution. Honorary Members are appointed from among entomologists who have made outstanding contributions to entomological knowledge, who have influenced entomology substantially both within and outside their own countries or regions, and who have made important contributions to the International Congresses of Entomology.

Officers of the Council:

Chairman: Professor Frantisek Sehnal (appointed to Council 1992; Chairman 2004)
Deputy Chairman: Professor Robert Lane (appointed to Council 1998; Deputy Chair 2004)
Secretary/Treasurer: Professor Willem Takken (appointed to Council 1998; Secretary/Treasurer 2004)

Past Chairman: Professor Lynn Riddiford (appointed to Council 1988; Past Chair 2004)

Members of the Council (as of August 2004):

Name	Country	Date of Birth	Year Appointed	Field of Interest
Cheng, Jiaan	China	12 Jul 1942	2000	Pest management, Ecology
Ekbom, Barbara	Sweden	1950	2004	Insect ecology
Hanrahan, Shirley, A	South Africa	11 Jul 1939	2004	Ecophysiology
Hassanali, Ahmed	Kenya (ICIPE)	12 Dec 1941	2000	Chemical Ecology & Physiology
Hoy, Marjorie A	USA	n	2004	Biological Control & Acarology
Kim, Byung-Jin	Korea	25 Apr 2005	2004	Taxonomy & Molecular Phylogeny of ants
Lane, Richard	UK	16 May 1951	1992; 2000	Medical Entomology & Biosystematics
Lane, Robert	USA	07 Mar 1944	1988	Medical & Veterinary Acarology
Moscardi, V.F	Brazil	26 May 1949	1992; 2000	IPM
Napompeth, Banpot	Thailand	20 Feb 1941	1996	IPM, Disease Control
Riddiford, Lyn M	USA	18 Oct 1936	1988;2000	Physiology, Devpt, Biology
Ridsdill-Smith, James	Australia	31 Mar 1942	2004	Experimental ecology, Feeding
Sasaki, M	Japan	27 Jan 1948	2000	Behaviour
Sehnal, Fratisek	Czech Republic	11 Sep 1938	1992; 2000	Physiology, Ecophysiology
Sharma, Hari C	India	15 Jun 1954	2004	IPM
Takken, Willem	The Netherlands	05 Jan 1951	1998	Medical & Veterinary Entomology
Waage, Jefferey	UK	13 Mar 1953	1998	Biological control, Parasitoids
Wysoki, M	Israel	27 Apr 1936	2000	IPM, Acarology, Thrips
Zalukcki, Myron P	Australia	26 May 1954	2004	Ecology, Insect-plant interaction

Honorary Members of the Council:

Member	Country	Date of Birth	Year of Appointment
Adkisson, P	USA	11 Mar 1929	1992
Bacetti, B.	Italy	07 May 1931	1988
Freeman, P.	UK	26 May 1912	1988
Galun, R.	Israel	03 Apr 1926	1996
Hafez, M	Egypt	10 Jan 1912	1992
Ishii, S.	Japan	12 Feb 1915	1996
Lioying, Li.	China	10 Mar 1932	1984
Oliver, J.H.	USA	10 Mar 1931	1992
Pal, R.	Switzerland	10 Oct 1919	1988
Rothschild, M	UK	05 Aug 1908	1984
Sabrosky, C.W.	USA	03 Apr 1910	1984
Saito, T	Japan	29 Sep 1924	1992
Smith, R	USA	20 Jan 1919	1992
Waterhouse, D.F.*	Australia	03 Jun 1916	1988
Whitten, M.J.	Australia	29 Mar 1940	2004

*Doug Waterhouse was elected Honorary Chairman of Council at the August 2000 Congress of Entomology in Iguacu, Brazil. He was awarded this unique honour in recognition of this outstanding contribution to the Congress of Entomology and the cause of international entomology. He died on 7 December 2000 (Obituary in "Historical Records of Australian Science", Vol 13 (4) Pp495 - 519) by M Day, M J Whitten and D Sands.

ICE 2008 recognises the following sponsors for their valued contribution

PREMIER SPONSORS	
agriculture Department: Agriculture REPUBLIC OF SOUTH AFRICA	Department of Agriculture
ARC • LNR	Agricultural Research Council
science & technology Department: Science and Technology REPUBLIC OF SOUTH AFRICA	Department of Science & Technology
E OPPENHEIMER & SON SOUTH AFRICA	E Oppenheimer and Son
	Entomological Society of Southern Africa
Durban Africa's Sporting & Events Capital	The City of Durban
VALUE SPONSORS	
EVERARD READ JOHANNESBURG	Everard Read Gallery
MONSANTO	Monsanto
Leica MICROSYSTEMS	Leica Microsystems
Council for International Congresses of Entomology	Council for International Congresses of Entomology
Dow AgroSciences TM	Dow AgroScience

Section & Symposium Information

SECTION 1	PEST MANAGEMENT: PERENNIAL CROPS	
Convenors	Vaughan Hattingh, Citrus Research International, RSA Jerry Cross, East Malling Research, UK	
Symposium Organisers	**No.**	**Symposium Titles**
Jerry Cross (UK) & Tim Grout (RSA)	**1.1**	IPM on perennial crops
Jim Hardie (UK) & David Hall (UK)	**1.2**	Semiochemicals in IPM on perennial crops
Mark Brown (USA) & Viktor Marko (Hungary)	**1.3**	Functional biodiversity in perennial crops for pest management
Joerg Samietz (Switzerland)	**1.4**	Phenology models and their use in IPM on perennial crops
Nilsa Bosque-Perez (USA) & Sanford Eigenbrode (USA)	**1.5**	Coffee entomology: an international perspective
Paula Shrewsbury (USA) & Rob van Tol (The Netherlands)	**1.6**	Advances in implementing biological control for perennial ornamental crops grown outdoors
Johannes Jehle (Germany) & Patricia Stock (USA)	**1.7**	Microbial and nematode biocontrol agents for pests of perennial crops

SECTION 2	PEST MANAGEMENT: ANNUAL CROPS	
Convenors	Johnnie Van Den Berg, North-West University, RSA Huib van Hamburg, North-West University, RSA John D Mumford, Centre for Environmental Policy, UK	
Symposium Organisers	**No.**	**Symposium Titles**
Megha N. Parajulee (USA), Robert Mensah (Australia) & Lewis Wilson (Australia)	**2.1**	Ecological approaches to cotton IPM: a global perspective
Samuel Waladde (RSA), Johnnie Van den Berg (RSA) & Zeyaur Khan (Kenya)	**2.2**	Pest management: prospects, successes and failures
Sam Cook (UK) & Zeyaur Khan (Kenya)	**2.3**	Habitat management strategies for controlling insect pests of crop plants
Joop van Lenteren (The Netherlands)	**2.4**	Can boundaries between biocontrol and GMOs be overcome?
Mark Stevens (Australia) & Mike Way (USA)	**2.5**	Ecology and management of key rice pests
Vicki Tolmay (RSA) & K.A. Shufran (USA)	**2.6**	Russian wheat aphid management
Joop van Lenteren (The Netherlands) & Martin Hill (RSA)	**2.7**	Critical analyses of successes and failures of biological control in Africa
Malcolm Keeping (RSA) & M.N. Sallam (Australia)	**2.8**	Sugarcane IPM: tough challenges - sweet outcomes
Dionyssios Perdikis (Greece) & Oscar Alomar (Spain)	**2.9**	Predatory Heteroptera: recent advances and future needs
Sunday Ekesi (Kenya) & M. Knapp (Kenya)	**2.11**	IPM in horticultural crops in the tropics

SECTION 3	PESTICIDES, RESISTANCE & TRANSGENICS	
Convenors	Graham Head (USA)	
Symposium Organisers	**No.**	**Symposium Titles**
John Stark (USA)	**3.1**	New pesticides and pest control technologies
Rafael Martinez Pardo (Spain) & Ralf Nauen (Germany)	**3.2**	Insecticide resistance in sucking insects in agriculture
William Moar (USA) & Joseph Huesing (USA)	**3.3**	Development, barriers and use of insect resistant transgenic crops in developing countries
Joerg Romeis (Switzerland) & Tony Shelton (USA)	**3.4**	Integration of insect-resistant GM crops within IPM programs
Srinivas Parimi (India) & Blair Siegfried (USA)	**3.5**	Coffee entomology: an international perspective
Noubar Bostanian (Canada) & J.M. Hardman (Canada)	**3.6**	The effects of pesticides on non-target arthropods

SECTION 4	FOREST ENTOMOLOGY	
Convenors	Andrew Liebhold, USDA Forest Service, USA Michael J. Wingfield, Forestry and Agricultural Research Institute (FABI), RSA Dan Robison, North Carolina State University, USA	
Symposium Organisers	**No.**	**Symposium Titles**
Daniel Doucet (Canada) & Qili Feng (China)	**4.1**	Forest entomology in the era of genomics and post-genomics
Diana Six (USA) & Bernard Slippers (RSA)	**4.2a**	Consequences of environmental change and globalization on insect-microbe symbioses: anthropogenic effects on symbioses
Naoto Kamata (Japan) & Jean-Claude Grégoire (Belguim)	**4.2b**	Consequences of environmental change and globalization on insect-microbe symbioses: ambrosia beetles as affected by environmental factors
Kier Klepzig (USA), Francois Lieutier (France) & Timothy D. Paine (USA)	**4.3**	Mediation of tree-insect interactions by micro-organisms
Joseph Elkinton (USA), Nancy Gillette (USA) & Bernard Slippers (RSA)	**4.4**	Use of molecular techniques to identify and to trace the origin and spread of invasive forest insects
John Spence (Canada), Jari Niemelä (Finland) & Johan Kotze (RSA)	**4.5**	Ecological and conservation implications of linkage between arthropod biodiversity and forestry practices
Patrick Tobin (USA), Brian Aukema (Canada) & Hugh Evans (UK)	**4.6**	Insect invasion dynamics in forest ecosystems
Fred Stephen (USA) & Robert Coulson (USA)	**4.8**	Impacts of insects on forest landscapes: implications for forest health management

SECTION 5	URBAN, STORED PRODUCT & POST HARVEST ENTOMOLOGY	
Convenors	Frank Arthur, Grain Marketing & Production Research Center, USA Frikkie Kirsten, Agricultural Research Council, RSA Michael K. Rust, University of California, Riverside, USA	
Symposium Organisers	**No.**	**Symposium Titles**
Tom Phillips (USA) & Frank Arthur (USA)	**5.1**	Ecology and management of stored-product insects in large-scale facilities
Paul Flinn (USA) & Cornell Adler (Germany)	**5.2**	Biological control of stored product insects
James Campbell (USA) & Marcé Lorenzen (USA)	**5.3**	The stored product pest Tribolium castaneum as a model organism
James Throne (USA) & Brighton Myumi (Zimbabwe)	**5.4**	Ecology of stored-product insects for improving pest management
Brian Forschler (USA) & Vernard Lewis (USA)	**5.5**	Economical, environmentally sensitive termite management: a global perspective

SECTION 6	ECOLOGY	
Convenors	Melodie McGeoch, University of Stellenbosch, RSA Stig Larsson, Swedish University of Agricultural Sciences, Sweden	
Symposium Organisers	**No.**	**Symposium Titles**
Robert Denno (USA) & Matthew Thomas (Australia)	**6.1**	Multiple natural-enemy interactions in natural and managed systems
Robert Knell (UK), Sheena Cotter (UK) & Ken Wilson (UK)	**6.2**	Ecological immunity of insects
Marcel Dicke (The Netherlands) & Louise Vet (The Netherlands)	**6.3**	Omics and ecology and evolution of multitrophic interactions
Jeff Harvey (The Netherlands) & Paul Ode (USA)	**6.4**	Plant chemistry and insect ecology: a multitrophic perspective
Takayuki Ohgushi (Japan), Oswald Schmitz (USA) & Robert Holt (USA)	**6.5**	Trait-mediated indirect effects in insect communities
Nuria Roura-Pascual (Spain/RSA) & Joaquin Hortal (UK)	**6.6**	Sampling and modelling the spatial responses of insects across spatial scales
Connal Eardley (RSA) & Carolin Mayer (Germany)	**6.7**	Pollinators in full bloom
Pedro Barbosa (USA) & Markus Rantala (Finland)	**6.8**	Insect outbreaks revisited
Louise Vet (The Netherlands) & Brian Smith (USA)	**6.9**	Ecology, evolution and application of learning in insects
Jeff Harvey (The Netherlands) & Martijn Bezemer (The Netherlands)	**6.10**	Linking aboveground and belowground multitrophic interactions

SECTION 7	GENETICS, GENOMICS, TRANSGENICS & EVOLUTIONARY BIOLOGY	
Convenors	Ary Hoffmann, University of Melbourne, Australia J. Nagaraju, Centre for DNA Fingerprinting and Diagnostics, India	
Symposium Organisers	**No.**	**Symposium Titles**
J. Nagaraju & H.A. Ranganath (India)	**7.2**	Insect genetics
K. Mita (Japan) & J. Nagaraju (India)	**7.3**	Insect genomics
Chris Klingenberg (UK) & James S. Patterson (UK)	**7.4**	Insect morphometrics
Steve Sinkins (UK)	**7.7**	Wolbachia endosymbionts in invertebrates

SECTION 8	INSECT PATHOLOGY	
Convenors	Justin Hatting, ARC-Small Grain Institute, RSA Patricia Stock, University of Arizona, USA	
Symposium Organisers	**No.**	**Symposium Titles**
Sean Moore (RSA)	**8.1**	Success and failure of microbial control products and businesses: determining factors
Eda Reinot (USA)	**8.2**	Biopesticides: development, formulations, applications

Whitefly resistance potential in different genotypes and cultivars of *Mentha* species

Dwijendra Singh

Central Institute of Medicinal and Aromatic Plants, Lucknow, India

Introduction: *Mentha* species are cultivated commercially as major natural sources of menthol both in tropical and temperate regions globally. Menthol is widely used in the cosmetics, perfumery, beverage, soft drink and pharmaceutical industries etc. The introduction of new chemo-types of mint species is regularly found associated with sweet potato whitefly during last two decades in India.

Methods: Whitefly (*Bemisia tabaci*) adult populations were sampled by applying yellow sticky traps in different plant genotypes of mint species. However, pupae population on menthol-mint leaves was counted with the help of a microscope in laboratory. The *Begmovirus* infection was recorded per m^2 area over healthy twigs during growth and development of mint.

Results: Among 26 entries of *M. arvensis*, 13 entries of *M. piperita*, and seven entries of *M. cardiaca,* two, one, and two entries were found comprising significantly higher resistant potential against whitefly resistance, respectively. Whitefly population build up was found maximum during Ist week of April and mid May in all the menthol-mint genotypes in northern Indian plain conditions. Among ten genotypes and cultivars of menthol mint, variety *Kushal* was found significantly ($P<0.05$) whitefly resistant over other cultivars. The infection of *Begomovirus* was found significantly low in field plots of Kushal and synthesized high oil content in fresh herb over other mint genotypes.

Conclusion: *Mentha* species genotypes and cultivars possessing significant potential resistant to whitefly and *Begomovirus* possibly be recommended further to use in integrated pest management programmes to develop new varieties and studies on insect plant interaction.

The landscape ecology of trophic interactions: Trait- and density-mediated effects

Peter Hambäck

Stockholm University, Stockholm, Sweden

It is becoming increasingly apparent that indirect interactions among species may be caused by changes not only in the abundance of intermediate species but also in their behaviour. This has been observed in a diverse array of interactions, both as behavioural changes in herbivores and as chemical changes in plants. The research on trait-mediated effects has however largely neglected the spatial dimension of species interactions, and how predators may affect the residence time of prey in local habitats. Predators may both cause a freezing behaviour and increased movements in herbivores, which both have direct effects on dispersal rates from host plant patches. Similarly, the spatial dynamics of herbivore-induced chemicals may affect immigration rates of both herbivores and predators into patches. In this talk, I will utilize a recently derived model that accounts for the scaling of migration rates for patches of different size and combine this model with a predator-prey model. In the original model, scaling rules for migration rates depend on the search mode by individuals and the model has successfully predicted variability in density-area relationships for broad groups of insect herbivores. In the predator-prey model, I aim to predict the relative distribution of predator and prey in a patch size gradient and to compare the relative importance of direct mortality and predator-induced changes in herbivore behaviour. This is done both by including different search behaviours by predator and prey but also by including feed-backs between the local predator density and the herbivore movement behaviour.

Population dynamics and management of the mango seed weevil, *Sternochetus mangiferae* (F.) (Coleoptera: Curculionidae), in South Africa

Johan de Graaf

Westfalia Technological Services, Duiwelskloof, Limpopo Province, South Africa

Introduction: *Sternochetus mangiferae* (F.) is quarantine pest of mango in South Africa, preventing exports to several countries. The aim of the study was to investigate the population dynamics and chemical control of the insect.

Methods: The population dynamics were monitored in mango orchards from the onset of weevil egg laying until harvest of fruit. Fruit were sampled randomly every two weeks from trees located in stratified plots. The infestation levels and proportion of infested fruit were recorded for each life stage. The chemical trials used a replicated block design with three replicates. The efficacy of fenthion, fenvalerate, fipronil and thiamethoxam was determined by a similar sampling procedure as the population dynamics trial series, but also noted scale insects on the fruit surface. Analysis of variance (*post hoc* Tukey HSD test) was used to analyse the data
.

Results: Eggs were observed over 12 weeks and showed a long peak through November and December. Small larvae, large larvae, pupae and adults mainly occurred in mid November, early December, mid December and early January. Fruit was the most vulnerable to infestation by eggs laid 4-5 weeks after the onset of oviposition. The weevil was only susceptible to chemical control before larvae entered the seed and the most effective chemicals were thiamethoxam and fipronil, resulting in less than 1% and 10% infestation at harvest, respectively. Fipronil caused the greatest number of fruit infested with scales.

Conclusion: Insecticides is an important control measure as part of a systems approach to manage the mango seed weevil.

Facing the problems of predicting insect distributions

Jorge M. Lobo[1], Alberto Jiménez-Valverde[1], Joaquín Hortal[2]

[1]Museo Nacional Ciencias Naturales, Madrid, Spain, [2]NERC Centre for Population Biology, Imperial College London, London, United Kingdom

Predictive modelling methodologies are commonly thought as being reliable enough to improve significantly the limited information on the distribution of species. However, studies predicting the distribution of insect species are scarce. Here, we review some of the basic problems of predictive modelling, analyzing how they apply to the particular case of insects. First, we discuss the essence and dynamics of the potential and realized distribution of species, making a critic assessment of how predictive models could provide a consistent picture of such dynamic phenomenon. Then, we examine the effects of the quality and bias of distributional data used to feed the models on their performance. In addition, we analyze the influence of the choice and use of predictors in the results and utility of the obtained models as well as the applicability of standard validation procedures. The negative effects of data quality are amplified in the case of insects; information on the distribution, taxonomy and ecological requirements of insect species is scarce and hard to access. This problem is aggravated by the high diversity that insects represent. We provide clues and practical choices for the entomologists to (a) improve the quality of their predictive maps for insect distributions, and (b) assess the limitations and utility of these predictions derived from limited data quality and knowledge about their ecology.

Structure and diversity of dung beetles communities (Coleoptera: Scarabaeoidea) in Southern Larzac (France)

Jean-Philippe Deguine[1], Eric Goze[2], Jean-Pierre Lumaret[3]

[1]CIRAD, Saint-Pierre, La Réunion, France, [2]CIRAD, Montpellier, France, [3]CNRS, Montpellier, France

Introduction: The ecosystems of Southern Larzac (France) have experienced an evolution of pastoral practices which progressively led to a change of landscape structure. With the disappearance of transhumance and the decrease of grazing, the landscape tends to close up and it ancestral equilibrium is changed. Thus, the role of dung beetles (Coleoptera: Scarabaeoidea) and the organization of their communities are strongly modified. The aim of this work is to analyse the structure of these communities and their diversity according to this global evolution.

Methods: The study was carried out during the year 2005. The insects were collected with attractive baited pitfall traps in six sites during four periods of the year. The Motomura model was used to analyse the diversity and the organization of communities. The distribution of the main species was described with correspondence analysis taking into account climatic parameters and pastoral practices.

Results: 4582 insects were collected. The study of the communities showed a wide range of 46 species belonging to four families (Aphodiidae, Scarabaeidae, Geotrupidae, Trogidae). The functional groups differed depending on the seasons, the pedoclimatic characteristics and their breeding requirements.

Conclusion: These preliminary results on the seasonal and spatial structure of the populations of dung beetles highlight the significant role of dung beetle communities in Larzac ecosystems. From a Biological Conservation point of view, our results can help to take decisions for a sustainable management of these ecosystems.

Microorganisms as mediators of tree-insect interactions: Pathogens, saprogens and cofactors

Kier Klepzig

USDA Forest Service, Southern Research Station, Pineville, LA, United States

Introduction: Oleoresin flow is an important factor in resistance of pines to attack by southern pine beetle and its associated fungi. However, little is known of the effects of inoculation with beetle associated fungi on oleoresin flow.

Methods: We measured how constitutive and induced resin yield in loblolly pine was affected by mass fungal inoculation with the southern pine beetle associated fungus *Ophiostoma minus*.

Results: As long as 105 days post-treatment, mass inoculated trees produced higher induced resin yields than control or wounded-only trees. This indicated a localized induced response to fungal inoculation. We noted no systemic induction of host defenses against fungal colonization. Despite mass inoculations, *O. minus* did not kill any host trees. It is unlikely that this fungus functions as a virulent plant pathogen.

Conclusions: While some bark beetle associated fungi can kill trees, numerous inoculation studies have failed to demonstrate a similar role for *O. minus*. Rather, the role of bark beetle associated fungi may be that of 'co-factors' - biotic agents that are not pathogenic in and of themselves but do function in compromising host defenses.

In the bark beetle system, the primary role of the associated fungi may be to aid in exhausting tree defenses and thereby allow beetle establishment. The moderately virulent habit of *O. minus* may, ultimately, be the best strategy for SPB. This allows the beetle to successfully mass attack the tree, but limits the extent to which the fungus can grow during the process of beetle development.

The ubiquity of indirect effects

Peter Price

Northern Arizona University, Flagstaff, United States

An indirect effect occurs when the influence of one species, the donor, is transmitted through a second species, the transmitter, to a third species, the receiver. Since the first food webs about 100 years ago, indirect effects have been evident, and more common than direct effects. This is because species share resources and consumers on each trophic level, so the impact of one influences the other species. Bottom-up and top-down effects cascade through food webs impacting all trophic levels, and “the balance of nature” is tightly linked to indirect effects conceptually, making the subject of central importance in ecology. Apparent competition, multiple-trophic-level interactions, trophic cascades, induced chemical and structural changes, and above and below ground interactions, all contribute to knowledge on indirect effects. Moving from food webs to include indirect interaction webs provides a more holistic and synthetic concept of nature. Because predators kill prey, they influence the density of one species A, and thus indirectly affect the density of another species B interacting with A through competition. This is a density-mediated indirect interaction. But, small herbivores usually act more as parasites on large host plants, seldom killing host plants but altering host traits, such as rolling leaves, or inducing chemical defenses. These traits affect other herbivore species, resulting in trait-mediated indirect interactions. The conceptual development of this large field, and the empirical evidence, contribute importantly to the development of community ecology.

Scolytine beetles and *Ceratocystis* fungi: a deadly interaction for tree health in Africa

Jolanda Roux, Gilbert Kamgan Nkuekam, Ronald Heath, Michael Wingfield

DST/NRF Centre of Excellence in Tree Health Biotechnology, Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, Pretoria, South Africa.

Various insect species have associations with fungal tree pathogens. These associations can be very specific, such as those involving the tree pathognenic fungus *Ceratocystis laricicola* and the bark beetle *Ips cembrae*, or casual as is found in the case of Diptera (*Drosophila melanogaster)* and the oak wilt pathogen, *Ceratocystis fagacearum*. The insects provide the fungi with transport to new trees and also wounds, necessary for infection. Ambrosia beetles (Coleoptera: Playtypodidea), which have very specific associations with fungi, maintain pure cultures of their symbionts, thereby protecting the fungi from competitors and providing food for the vectors. Little is known regarding bark and ambrosia beetles and their fungal associates on hardwood tree species in the Southern Hemisphere. More specifically, studies on *Ceratocystis* spp. and their insect associates in Africa, are limited to a few recent examples. These recent studies have specifically considered the role of wounds emerging from anthropogenic activity, such as pruning and harvesting of bark for medicinal purposes. Insect infestation was found to be common on these wounds and the insects involved included nitidulids (Coleoptera: Nitidulidae), bark (Coleoptera: Scolytinae) and ambrosia beetles. Several species of *Ceratocystis* and other fungi have been isolated from these insects and their tunnels. These included known tree pathogens as well as several previously undescribed species. The results of a small number of studies clearly illustrate the need for further and more detailed investigations on the Coleoptera and their fungal associates in Africa.

Ant use of antibiotics in agriculture

Michael Poulsen, Cameron Currie

University of Wisconsin, Madison, Madison, WI, United States

The dynamics of host-pathogen associations are believed shaped at least in part by evolutionary arms races, in which pathogens evolve to overcome host defenses and hosts are selected to counter-act these through the evolution of new defense mechanisms. Fungus-growing ants appear to have successfully employed antibiotic-producing actinomycete bacteria in the genus *Pseudonocardia* for millions of years to defend their mutualistic fungus gardens from specialized microfungal *Escovopsis* parasites. Here we explore host-pathogen dynamics in the fungus-growing ant symbiosis by evaluating inhibitory capacities of *Pseudonocardia* originating from different ant colonies against a variety of *Escovopsis* strains, in addition to examining the link between *in vitro* inhibition and *in vivo* defense by the *Pseudonocardia* symbionts. Our results suggest that antibiotic resistance has evolved repeatedly in the parasite and that resistant strains are substantially more virulent to fungus-growing ant nests than strains susceptible to the antibiotics. Counteracting antibiotic resistance is the apparent continuous evolution of novel antibiotic compounds in the bacteria. The diversity and specificity in the antibiotics suggest ongoing antagonistic co-evolutionary arms race dynamics in the fungus-growing ant–microbe symbiosis. These dynamics are characterized by defense release of the immediate host (the fungal cultivar), while selection on antibiotic resistance and novel defenses appear to occur between alternative parties in the association (*Pseudonocardia* and *Escovopsis*). Fungus-growing ant use of actinomycete-derived antibiotic production may thus mirror many human pharmaceutical and agricultural practices, where the challenge of maintaining efficient antibiotics against continuously evolving antibiotic-resistance in parasites persists.

Conflict and cooperation in fungus-growing ant mutualisms

Michael Poulsen

University of Wisconsin, Madison, Madison, WI, United States

Potential conflict between partners involved in mutually beneficial associations is predicted to destabilize cooperative relationships. Theoretical and empirical work exploring such conflict has provided significant insight into how it influences relationship dynamics. Here I present results exploring the complexity of conflict within the ancient and coevolved mutualistic associations between attine ants and their fungal cultivar (*Leucoagaricus*) reared for food and actinomycetous bacteria (*Pseudonocardia*) reared to obtain antibiotics against potentially virulent microfungal *Escovopsis* parasites. Both ant-mutualist associations occasionally experience horizontal transmission, potentially decoupling the reproductive interests of host and symbionts and incurring competition between mixed symbiont strains. However, it appears that i) default vertical symbiont transmission aligns the reproductive interests of the partners, and that ii) single symbiont rearing within individual colonies prevents the expression of competitive symbiont-symbiont conflict. The rearing of a single fungal clone within a colony is not expected to pose a cost to the ants in relation to increased colony susceptibility to infection, because the cultivar itself does not have efficient defense against *Escovopsis*. However, the rearing of a single strain of actinomycetes could constrain the effectiveness of the ant-*Pseudonocardia* symbiosis, because rearing multiple strains of antibiotic-producing bacteria would increase antibiotic diversity. The findings presented suggest additional layers of complexity of conflict expression within the fungus-growing ant microbe–symbiosis, through the presence of antagonism between genetically different mutualistic symbionts maintained by different ant colonies, but also through the presence of additional symbiont lineages (*Escovopsis*) that adjust conflict dynamics within an association previously examined in a bipartite framework.

Symbiotic relationships of an invasive psyllid colonizing eucalyptus in California, USA

Allison Hansen, Richard Stouthamer, Timothy Paine

Department of Entomology, University of California, Riverside, Riverside, California, United States

Two endosymbionts, an obligate primary symbiont and facultative secondary symbiont are harbored within the invasive red gum (eucalyptus) lerp psyllid, *Glycaspis brimblecombei*, in California. An extensive survey of diversity and frequency of *G. brimblecombei*'s secondary symbiont was conducted in multiple populations throughout the state of California using PCR detection, restriction enzymes, cloning, and sequencing. A total of 380 *G. brimblecombei* individuals were screened for secondary symbionts among 19 populations. Based on molecular screening results, only one type of secondary symbiont was present among *G. brimblecombei* populations in California. Secondary symbiont infection frequencies among *G. brimblecombei* populations varied dramatically from 0-75%, and were significantly related to parasitism pressure by *Psyllaphaegus bliteus*, a solitary endoparasitoid of the psyllid. *G. brimblecombei* is also associated with a phage which has an intimate relationship with the secondary symbiont. This phage may be a key mechanism in providing potential resistance to parasitism in secondary symbiont infected psyllids.

A new look at beetle-fungus-tree interactions

Timothy Paine

University of California, Riverside, CA, United States

Scolytid bark beetles that colonize living conifers are frequently associated with specific fungi that are carried in specialized structures or on the body surface. These fungi are introduced into the tree during the attack process. The continuing association suggests that there is mutual benefit to the fitness of both beetles and fungi. Extensive research has been directed towards characterizing the interactions of beetle-fungal complexes with live host conifers and determining the advantages for maintaining the associations. The fungal species may benefit from the association with the beetles by transport to new host trees. Beetle species may benefit from the association with fungi by feeding on the fungi, by limiting the impact of potentially detrimental fungi, or by the fungi contributing to the death of the host trees through mycelial penetration of host tissue, toxin release, interactions with preformed and induced conifer defenses, or the combined action of both beetles and fungi during colonization. However, differences among systems and how species interact under different population and environmental conditions make it difficult to generalize about the importance of the separate biological components in successful host colonization. The objective of this evaluation is to describe the paradigms of beetle-fungal-host tree interactions over the last five decades and to establish the historical research context for current efforts.

Genetic identification of forensically important flies

Judith Smith

University of Central Lancashire, Preston, United Kingdom

Insects, in particular members of the Calliphoridae (blowflies) and Sarcophagidae (fleshflies) can be important indicators in a forensic investigation.

Blowflies are attracted to a corpse within minutes of death and the stages and species identified on a body can provide important evidence. Most importantly the stages of the particular species identified can help determine time since death. In addition, the location of maggots on a body can in some cases help determine the cause or manner of death or provide evidence of abuse and the identification of particular insect species may provide evidence as to whether a body has been moved.

Forensic entomology requires and understanding of the ecology, behaviour, developmental biology, and genetics of the species involved. Rates of development can vary even between closely related species thus accurate species identification is critical for an accurate calculation of time since death. Morphological identification is time consuming, complex and highly subjective to the untrained eye, genetic identification could provide a quick and unambiguous way to identify species. We present an analysis of the use of mitochondrial genes for species identification of forensically important blowfly species in the UK.

Induced host-plant volatiles with the aphid sex pheromone using a specific trap design create a highly selective attractant for the male aphid *Dysaphis plantaginea*

Rob van Tol[1], Herman Helsen[2], Frans Griepink[1], Willem Jan de Kogel[1]

[1]Plant Research International, Wageningen, Netherlands, [2]Applied Plant Research, Randwijk, Netherlands

Introduction: All aphid species studied so far share the same sex pheromone components nepetalactol and nepetalactone. Variation by different enantiomers and blends of the two components released by different aphid species is limited and can only partially explain species-specific attraction of males to females. While some host-plant odours are known to enhance more specific attraction of aphid species, herbivore-induced plant volatiles that attract male aphids more specifically to female infested host-plants are unknown.

Methods: Relevant odours of infested apple trees were identified by GC-MS and GC-EAD techniques. Different mixtures of identified plant volatiles and aphid pheromone were tested in an apple orchard on attraction of aphids to different trap types.

Results: We demonstrate that for the host-alternating rosy apple aphid (*Dysaphis plantaginea*) specificity of attraction of males to females on the primary host plant, *Malus* sp. is enhanced by female-induced tree odours in combination with the pheromone. Female aphid infestation induce increased release of four butyrates from apple leaves. These butyrates increase the number of male *D. plantaginea* and decrease the number of other aphid species caught in water traps in the presence of the pheromone components. The butyrate blend alone was not attractive. A further 90% reduction in by-catch of other aphid species was achieved by using an adapted trap allowing aphids to walk after landing. Odour-mediated orientation of male aphids after landing during walking appears to be an important next step in selective attraction to conspecific females.

Conclusions: The demonstration that sexual aphid species use herbivore-induced plant volatiles as a species-specific attractant for mate finding adds a new dimension to our understanding of insect species using or manipulating chemical cues of host plants for orientation.

Populations of lacewings, *Chrysoperla carnea* (Stephens), in relation to sucking insect pests in cotton ecosystems

J.M.Mari, S.M.Nizamani, M.K.Lohar

Sindh Agriculture University Tandojam Pakistan, Hyderabad, Pakistan

The results on population of lacewing in relation to sucking insects pests in cotton ecosystem through direct plant count method was recorded in the vicinity of Sindh agriculture University Tando Jam Pakistan from 8th May to 25th September, at weekly intervals. The consolidated data showed that the sucking insect pest population was highest on 19th July. The regression equation showed that the population growth with time interval was highly significant. The slope rate of population increase was 0.950X. The R-square was 0.98 which explained that about 98 percent variation in population increase was observed by weeks. Thereafter, population decreased and reached its minimum with a declining curve-0.434X it also showed a highly significant relation among population and dates. The R-square was r^2= 0.66. The predator population increased gradually and linearly it was on their peak (6.74) per leaf on 21st September. The regression analysis indicated that the population was highly significant with time interval. The slope of line with increasing trend was 0.4278X. The R-square of model was estimated to be 85. The highest population of predators could be due to easy access of sucking insect pests. The population of lacewing was associated with the sucking insect pests. Lacewing population were positive and highly significant (r=0.863) with aphid. It may be concluded that the population of sucking insect pests was more during the month of July and August, aphid appeared late than the other pests. It was found that increasing population of aphid progressively increased the population of lacewing. For effective control of aphid in cotton spray of any kind of agro-chemicals in and around the cotton crop may be avoided.

Critical analyses of successes and failures of biological control in Africa

Peter Neuenschwander

International Institute of Tropical Agriculture, Cotonou, Benin

Classical biological control has been practiced in Africa since the 19th century. Introductions of insect natural enemies peaked in the 1980s (at around 150). Percentage establishment peaked at 65% in the 1990s, with about 10% contributing to control. Biological control of weeds by insects and later pathogens was practiced mainly in South Africa. Since the 1980s, international collaboration in Africa-wide projects, starting with the control of cassava mealybug and cassava green mite by arthropod predators and followed by a mycopesticide against grasshoppers, brought a new surge in foreign exploration, research, releases, impact assessment and training at all levels.

Documented benefits in crop loss prevention alone – without the concomitant environmental and human health benefits – are huge. Despite these successes, biological control remains controversial and often the last option, when other choices like pesticides and crop varieties have failed to give the expected results. We attribute this reluctance to place resources into biological control to the following factors: 1- continued occurrence of short-term and local pest outbreaks even in successful projects, 2- incomplete coverage of ecological niches by biological control agents, 3- interference with other agricultural techniques (pesticides, but also bad soil and water management), 4- unreasonable requirements on efficiency through low economic thresholds, while full costs of other options are not taken into account, 5- too stringent requests concerning non-target impacts, based on comparisons with the status before the accidental introduction of the pest, instead of the status quo. Priority actions concern foreign exploration, biological control in IPM and public awareness.

Managing mosquito threats using personal protection strategies: Living with mosquitoes in northern New South Wales, Australia

David Durrheim[1], Cameron Webb[3], Richard Russell[3]

[1]Hunter New England Population Health, Hunter New England Area Health Service, Newcastle, Australia, [2]School of Medical Practice and Population Health, University of Newcastle, Newcastle, Australia, [3]Department of Medical Entomology, University of Sydney and ICPMR, Westmead Hospital, Sydney, Australia

The transmission of the disease-causing pathogens, Ross River virus and Barmah Forest virus, results in over 5000 notified cases of mosquito-borne disease annually in Australia. There has been a steady increase in notifications during recent years in northern NSW, as residential and recreational land uses encroach on productive mosquito habitats. Local vector biology and legislative requirements limit the possibility of large scale mosquito control programs, and a newly developed region-wide mosquito awareness strategy emphasises personal protection measures.

The 'Living With Mosquitoes' strategy was developed in conjunction with local, state and federal agencies, and represents the first regionally specific approach to mosquito-borne disease management in NSW. The first stage of this strategy is a coordinated mosquito awareness program with the key element being effective communication of accurate information on personal protection measures, including the appropriate selection and application of insect repellents.

An innovative communications strategy has been developed that addresses the issues of public health and nuisance-biting risks with personal protection measures to complement the overall environmental education messages of the region.

A natural bridged tricyclic sesquiterpene, (–)-Isolongifolenone, is a repellent against ticks and mosquitoes

Aijun Zhang[1], Shifa Wang[2], Jerome Klun[1], John Carroll[3], Mustapha Debboun[4]

[1]Invasive Insect Biocontrol and Behavior Laboratory, Beltsville Agriculture Research Center-West, USDA, Agriculture Research Service, Beltsville, Maryland 20705, United States, [2]College of Chemical Engineering, Nanjing Forestry University, Nanjing, Jiangsu 210037, China, [3]Animal Parasitic Diseases Laboratory, Beltsville Agriculture Research Center-East, USDA Agricultural Research Service, Beltsville, Maryland 20705, United States, [4]US Army Medical Department Center & School, Academy of Health Sciences, Department of Preventive Health Services, Medical Zoology Branch, Fort Sam Houston, TX 78234, United States

Introduction: Human diseases transmitted by blood-feeding mosquitoes represent a serious threat to public health worldwide. More than 700 million cases of mosquito-transmitted diseases have been reported annually. Over 3 billion people live under the threat of malaria, which kills millions annually. Consequently personal protection from mosquitoes is of great importance. A synthetic compound, Deet, is the most widely used insect repellent worldwide. However, it is a synthetic compound and a plasticizer, perceived by as some safety and environmental concerns regarding human usage and water pollution. Therefore, there is clear and good reason to pursue discovery of new chemical tools that might help alleviate above suffering.

Methods: Efficacy of the compound against mosquitoes and ticks was evaluated using the in vitro K&D module bioassay and fingertip bioassay systems.

Results: We discover that (–)-isolongifolenone deters the biting of the yellowfever mosquito, *Aedes aegypti* and *Anopheles stephensi*, a mosquito vector of malaria, more effectively than Deet. We also found that (–)-isolongifolenone repelled the blacklegged tick, *Ixodes scapularis*, and lone star tick, *Amblyomma americanum*, as effectively as Deet. However, at lower concentrations, the (–)-isolongifolenone was more effective against *I. scapularis* than Deet.

Conclusions: Inasmuch as derivatives of isolongifolenone have routinely been used in topically applied cosmetics, we believe that newly discovered properties of the compound give it good potential as a natural product for further development and eventual safe-clinical usage for protection of humans, especially, for military and general public usage against mosquito, tick, and sand fly bites.

Impacts of honeybees on native bumblebees in northern Europe

Dave Goulson

University of Stirling, Stirling, United Kingdom

Honeybees are well known to be non-native organisms in large parts of the globe, but in Europe they are generally regarded at native species. However, in northern Europe they are unlikely to be native and exist at artificially high densities due to assistance from man. I present data that demonstrate a clear effect of honeybees on worker size in a range of bumblebee species in Scotland. Since worker size reflects food return to the colony, and small workers bring back less food, these data strongly suggest that honeybees do have a significant negative impact on the population biology of other social bees in Europe, and that this impact should be considered when deciding on placement of hives and on conservation strategies for native bee species.

DNA barcoding reveals the area of origin of the highly invasive horse chestnut leaf-miner *Cameraria ohridella*

Carlos Lopez-Vaamonde[1], Romain Valade[1], Ferenc Lakatos[2], Sylvie Augustin[1], Marc Kenis[3]

[1]INRA-Orléans, Zoologie Forestière, Olivet, France, [2]University of West-Hungary, Institute of Sylviculture and Forest Protection, Sopron, Hungary, [3]CABI Bioscience Switzerland Centre, Delémont, Switzerland

Introduction: Recent biological invasions usually start with a small number of founder individuals which are likely to be a small fraction of the total genetic diversity found in the original population from which they derive. The aim of our work is to genetically trace the geographical origin of the horse-chestnut leafminer, *Cameraria ohridella*, an invasive microlepidoptera, whose area of origin is unknown. Since its discovery in Macedonia twenty years ago, this insect has experienced an explosive westward range expansion progressively colonizing all central and Western Europe. Here we use DNA barcoding to assess the genetic variability of *C. ohridella* populations and to test the hypothesis that *C. ohridella* comes from the Balkans. The Balkans is the region where the moth was first found and from where the European horse-chestnut originates.

Methods: We use DNA barcoding to study the genetic variability of *C. ohridella*, across its known geographical distribution.

Results: Our results show a reduction in genetic diversity of *C. ohridella* populations sampled from natural stands of horse-chestnuts in the Balkan mountains to *C. ohridella* sampled in parks across Europe.

Conclusions: These findings suggest that European populations of *C. ohridella* may indeed derive from the Balkans.

Taking dengue control from the government to the people: Development of a 'Do it yourself' Lure and Kill technology for dengue control

Scott Ritchie[1], Luke Rapley[1], Brian Montgomery[2], Richard Russell[3]

[1]James Cook Univ., Cairns, Queensland, Australia, [2]Queensland Health, Cairns, Queensland, Australia, [3]Un. Sydney, Westmead, New South Wales, Australia

We have been engaged in a R&D program to develop a “lure and kill” approach (L & K) to control dengue in north Queensland Australia. The basic lethal ovitrap employed (Williams et al. Impact of a bifenthrin-treated lethal ovitrap on *Aedes aegypti* oviposition and mortality in north Queensland, Australia. J Med Entomol 44: 256-262) has proven successful in lab and field trials. Several interventions against dengue have also been successful. Indeed, we have been able to reduce our pesticide usage by at least 90%, and gain access to many more properties, using L & K rather than the previously employed Interior Residual Spraying (IRS). We are currently improving the methodology by using biodegradable lethal ovitraps that leak before they become a breeding site, and thus do not require retrieval by staff. Finally, we have conducted field trials demonstrating that metofluthrin emanaters readily kill *Ae aegypti* within rooms and provide nearly 100% protection from biting. We are developing a "do it yourself" dengue kit composed of LOs and, potentially, metofluthrin emanaters that would allow rapid community engagement for emergency dengue control on a broad scale.

Predator identity and the nature of trait-mediated indirect effects

Oswald Schmitz

Yale University, New Haven, Connecticut, United States

Introduction: Trait-mediated indirect effects propagated by herbivore anti-predator responses to their predators are widespread in ecological food webs. But, trait-mediated effects vary in their nature and strength. Predicting when and how trait-mediated effects arise is important for understanding the role of predators in communities. Such understanding might be derived by knowing predator hunting mode and the spatial domain of predator and prey habitat use.

Methods: A synthesis of literature on predator hunting mode and prey and predator habitat domain led to a framework for predicting the nature of trait-mediated indirect effects.

Results: The nature of trait-mediated indirect effects varied with predator hunting mode (e.g., sit-and-wait vs. active hunting) and habitat domain (narrow vs. broad). Trait-mediated effects arose whenever sit-and-wait predators have a narrow habitat domain and prey have a broad domain that allows habitat switching because the predators emit chronically strong cues of presence. Sit-and-wait predators cause chronic feeding activity reductions (as opposed to habitat sifts) when they face prey with narrow habitat domains. Alternatively, predators that actively hunt throughout the entire habitat (broad domain) will leave very diffuse cues of presence. Prey will thus only respond to imminent predation threat. Such predators tend to cause largely density-mediated indirect effects.

Conclusions: Predator hunting and predator and prey habitat domain provides a useful functional way of predicting the nature and strength of trait-mediated indirect effects.

Selection on the integrated phenotype: Responses in migratory traits of *Gryllus firmus*

Derek Roff, Daphne Fairbairn

University of California, Riverside, CA, United States

Introduction: We investigated the coevolution of the integrated suite of traits associated with migratory capability in insects by imposing selection on two core traits, ovary weight (an index of fecundity) and weight of the dorso-longitudinal flight muscles (DLM) in females of the wing dimorphic cricket, *Gryllus firmus.* Micropters lack significant DLM and have heavier ovaries than macropters. Within macropters, ovary weight is negatively correlated with DLM weight. Wing morphology, ovary weight and DLM weight are all inherited and genetically correlated. We selected for increased ovary or DLM weight, or an increased index (= product of ovary and DLM weight) and then compared the direct and correlated responses with those predicted by an individual-based quantitative genetic model constructed using parameters estimated from a previous half-sib breeding experiment.

Methods: We used 5 generations of family selection, taking the top 25 families out of an average of 60 families/generation, based on the mean of 5 females/family.

Results: All predictions were sustained. Selection for increased fecundity caused a correlated increase in ovary weight and proportion micropterous but decreased DLM weight. Selection for increased DLM weight produced the opposite responses. Selection on the index increased both ovary and DLM weight. In all three cases the intercept of the regression of fecundity on DLM weight increased.

Conclusions: Selection produced quantitatively predictable changes in both the focal traits and the suite of correlated traits, indicating that quantitative genetic parameters adequately capture the short term coevolutionary dynamics of this complex suite of integrated traits.

Introduction to the structure and function of termite mounds

Jo Darlington

University of Cambridge, Cambridge, United Kingdom

When termites build nests in the soil, they are exposed to soil predators. One response is to concentrate the nest into a single populous hive and so minimise soil contact. A side effect of this is that metabolic products (gases and heat) cannot easily disperse through the soil pores. The extreme case is in fungus-growing termites, where the biomass of the termites themselves is augmented by that of the fungus combs, so that overall nest metabolism is at least trebled. Improved ventilation is supplied by the structure of the hive, surrounding passages, and the soil mound above it. This is a passive ventilation system because the nest is built of soil, and so its structure is rigid. There are several different designs. The simplest and commonest type consists of open vertical shafts that link up underground. External wind draws ambient air through the shafts in response to the height and structure of their rims. A rare type of nest has a single tall chimney through which air vents directly from the nest. This is the only outflow, and enables us to make direct measurements of metabolic products from the nest. The most complex type consists of a structured passage system inside a closed mound, where gas exchange takes place through the outside wall. This has proved more difficult to interpret than the mounds with open ventilation systems, and new work from several sources will be presented in this section.

The air-conditioned termite nest revisited

Scott Turner

SUNY College of Environmental Science & Forestry, Syracuse, New York, United States

Termites of the genus *Macrotermes* are renowned for the building of spectacular mounds. In 1960, the Swiss entomologist Martin Lüscher proposed that these mounds provide "air-conditioning" (i.e. temperature and humidity control) for the metabolically effervescent nest. Lüscher's beautiful conception is, to this day, a textbook example of "superorganismal physiology." In recent years, however, Lüscher's conception has come under criticism: his proposed mechanism for the air-conditioning appears to be wrong; it is unclear precisely what property of the nest is being regulated, and it says little about how such a remarkable structure comes to be built in the first place. In my presentation, I will outline recent work on the mechanisms of nest ventilation, nest temperature and nest moisture of *Macrotermes michaelseni*, a species that is widespread through sub-Saharan Africa. I will argue that it is nest water balance, rather than regulation of nest gas exchange or temperature, that drives mound construction and repair, and that the mound's respiratory function is a secondary adaptation that has evolved on this foundation.

Community dynamics of *Ips typographus* - associated fungi in spruce stands following storm disturbance

Rimvydas Vasaitis[1], Bo Långström[2], Halvor Solheim[3], Ylva Persson[1], Katarina Ihrmark[1], Jan Stenlid[1]

[1]Department of Forest Mycology and Pathology, Swedish University of Agricultural Sciences, Uppsala, Sweden, [2]Department of Ecology, Swedish University of Agricultural Sciences, Uppsala, Sweden, [3]Norwegian Forest and Landscape Institute, Ås, Norway

Ips typographus is economically most important insect pest of mature spruce in Eurasia. Normally, it prefers to reproduce in dead and/or dying trees, but following large-scale storm disturbances, its outbreaks kill waste areas of living stands. One factor triggering such epidemics is a surplus of broken and uprooted trees with non-existent, or weak, defence. While infesting vigorous spruce, blue-stain fungi carried by *I. typographus*, play important role for success of beetle attack. In Europe, *I. typographus* is associated with about 30 fungal species, among which primary invaders *Ceratocystis polonica* and *Ophiostoma europhioides* are the most pathogenic: artificial inoculations with those fungi kill healthy spruce even in absence of the insect. During the rise of beetle outbreak, living trees are increasingly attacked and pathogenic primary invaders gain habitat in which they are more competitive than other fungi, e.g. due to ability to grow through resin-impregnated sapwood under oxygen deficient conditions. During non-outbreak periods, the beetles utilize dead wood, more accessible to saprotrophic fungi. Consequently, the dynamics of *I. typographus* outbreak might influence the incidence and frequency of the pathogens, which could play a major role in further development of the epidemics. We hypothesize that during non-outbreak periods pathogenic blue-stain fungi occur at low frequencies in overall fungal community, but their frequencies increase gradually when living trees are attacked, enhancing future dieback. In Sweden, the storm on January 2005 resulted in approximately 164 million of downed spruce. Here, we present preliminary results on community dynamics of blue-stain fungi during the subsequent outbreak of *I. typographus*.

To free or not to free: the New Zealand experience

Libby Harrison[1], Rachel Helson[1], Barbara I.P. Barratt[2]

[1]Environmental Risk Management Authority, New Zealand, Wellington, New Zealand, [2]AgResearch, Invermay, Mosgiel, New Zealand

New Zealand is a South Pacific archipelago with a classic island ecology. It was first settled by Polynesians – ancestors of today's Māori – less than 1000 years ago, followed by Europeans in the late 1700s. Most of its native fauna and flora are endemic and highly valued by New Zealanders. Agriculture makes an important contribution to the national economy, which means the agricultural landscape, too, is highly valued. In 1996, the Hazardous Substances and New Organisms Act (HSNO Act) was passed to prevent or manage adverse effects on the environment, and on the health and safety of people, from the introduction of either hazardous substances or new organisms. In the Act the principal definition of a new organism is a species not established in New Zealand before 1998, when the Act came into force. An important feature of the regulatory process is that when the decision to approve or decline the introduction of an organism is being made, the beneficial effects of the organism are weighed against the adverse effects. This presentation uses case histories of approved introductions of invertebrate biological-control agents to demonstrate how New Zealand evaluates beneficial and adverse effects across the board – on the environment, on the health and safety of people, on societies and communities, on the economy and on Māori culture.

Priming of inducible defenses by volatiles from neighboring plants and endophytic bacteria

Ted Turlings[1], Jurriaan Ton[2], Matthias Erb[1], Marco D'Alessandro[1]

[1]University of Neuchatel, Neuchatel, Switzerland, [2]Rothamsted Research, Harpenden, United Kingdom

Plants have evolved an elaborate arsenal of physical and chemical defenses that allow them to cope with their numerous attackers. An increasing number of studies suggest that, if properly understood, these natural plant defenses can be manipulated and exploited for the control of insect pests. We have been studying a form of indirect plant defense, whereby, in response to insect feeding, plants emit various volatile compounds that attract the natural enemies of their attackers. Using maize as our model plant, we recently found that such induced volatiles affect defense responses in neighboring plants. This effect is only evident when the exposed plants themselves are attacked, at which point defense genes show rapid and enhanced expression and direct, as well as indirect defense compounds are produced faster and in larger quantities. This so-called priming for defense has now been demonstrated in several plant species and is expected to primarily function in within plant communication. We have also found that endophytic bacteria contribute to a plant's volatile emissions and thereby enhance the resistance of the host plant to other pathogens. I will give an overview of our work in these areas with an emphasis on the possibility to manipulate volatile emissions in crop plants in order to enhance direct and indirect resistance against pests.

Outbreak dynamics of geometrid moths in climatic gradients in sub-arctic birch forest

Jane U. Jepsen[1], Snorre B. Hagen[1], Rolf A. Ims[1], Nigel G. Yoccoz[1], Helena Bylund[2]

[1]University of Tromsø, Tromsø, Norway, [2]Swedish University of Agricultural Sciences, Uppsala, Sweden

Periodic population outbreaks of geometrid moths constitute the most pronounced disturbance factor in sub-arctic birch forest in Fennoscandia. The most important insect herbivores in the system are winter moth, *Operophtera brumata* and autumnal moth, *Epirrita autumnata*, both of which experience cyclic outbreaks every 9-10 yrs, with severe impacts on the birch forest ecosystem. Historically outbreaks by winter moth have been restricted to low-altitude, coast-near forest in W-NW Norway, while outbreaks by autumnal moth have occurred throughout northern Fennoscandia with the exception of the coldest inland regions.
We present evidence that suggests that distinct, climate-change related shifts in geometrid outbreak ranges are now taking place in northern Fennoscandia. Coinciding with a period of increasingly earlier springs, winter moth has expanded its outbreak range to reach the altitudinal and latitudinal forest limit in NE Finnmark County. There the winter moth now overlaps with the normal outbreak range of the autumnal moth as to cause intense and long-lasting defoliation leading to extensive forest death. During the same period autumnal moth outbreaks have for the first time been recorded in the most continental regions. Furthermore, during the last 3 years, a novel geometrid for northern Norway, *Agriopis aurantiaria*, has rapidly become abundant as to inflict forest damage locally in the coastal birch forest in Troms County. *A. aurantiaria* is known as a forest pest species further south in Europe and it may thus represent a putative new pest in the sub-arctic birch forest.

Distribution, habitats, taxonomy and ecological niche models of malaria vectors, *Anopheles hyrcanus* group (Culicidae: Diptera), from Asia

Pollie L.M. Rueda[1], Desmond Foley[1], Richard Wilkerson[1], Terry Klein[2], Heung-Cheul Kim[2]

[1]Smithsonian Institution/WRAIR, Suitland, Maryland, United States, [2]18th MEDCOM, US Army, Seoul, Republic of Korea

Mosquito collections were carried out from1999-2007 from various parts of Asia including China, Japan and Korea. The distribution records of *Anopheles* Hyrcanus Group species in selected Asian countries were updated based on published records and original observations. In China, 21 out of about 30 known species of the Old World Hyrcanus Group (*Anopheles* subgenus *Anopheles*) are found in 24 provinces and 2 cities including *An. belenrae* Rueda. In Korea and Japan, about 6 species of the Hyrcanus Group were collected. *Anopheles sinensis* Wiedemann is the most widely distributed species in all countries surveyed. The habitats of known and potential malaria vectors (e.g. *An. lesteri* Baisas and Hu*, An. sinensis, An. kleini* Rueda*, An. pullus* Yamada*, An. kunmingensis* Dong and Wang*, An. hyrcanus* [Pallas]) included rice paddies, irrigation ditches, irrigated sugar cane and vegetable fields, ground pools, permanent ponds, and others. The taxonomy, including the status of the type specimens of some Hyrcanus Group species and their importance in disease transmission were also noted. Ecological niche models were constructed to predict the potential distribution of selected vector species in various parts of the Asian region.

Hazard assessment of fipronil and spinosad to aquatic organisms

John Stark[1], Roger Vargas[2]

[1]Washington State University, Puyallup, Washington, United States, [2]USDA, ARS PBARC, Hilo, Hawaii, United States

Introduction: Two of the newer insecticides being marketed for control of various pest species are spinosad, a natural product, and fipronil. Spinosad, in particular has been shown to be a selective insecticide which in general is more toxic to pest species than to their biological agents. Fipronil also is supposed to be less detrimental to the environment than the previous generation of insecticides.

Methods: In this study, spinosad was evaluated for toxicity to the Cladocerans, *Daphinia pulex*, *D. magna* and *Ceriodaphnia dubia* and Coho salmon, *Oncorhynchus kisutch*. Toxicity data for fipronil was developed for *D. pulex*. Hazard assessments were developed for both insecticides with the quotient method where the expected environmental concentration (EEC) for each product was divided by the acute LC50.

Results: The LC50 estimates for spinosad were: *C. dubia* - 1.8 µg/l, *D. pulex* - 129 µg/l, *D. magna* - 4.8 µg/l. No mortality was observed when the Coho salmon were exposed to spinosad concentrations as high as 500 mg/l. The LC50 estimate for *D. pulex* exposed to fipronil was 15.6 µg/l. USEPA EEC's for spinosad and Fipronil are 0.092 and 2 µg/l, respectively.

Conclusions: Hazard assessments based on EEC'c and LC50 estimates indicate that both spinosad and fipronil pose no hazard to Daphnids or Coho salmon.

Beyond Bt: alternative strategies for insect-resistant GM crops

Louise Malone[1], Angharad Gatehouse[2], Barbara Barratt[3]

[1]Horticulture and Food Research Institute of New Zealand Ltd, Auckland, New Zealand, [2]University of Newcastle, Newcastle, United Kingdom, [3]AgResearch, Invermay, New Zealand

Bacillus thuringiensis (Bt)-plants dominate today's commercial market for insect-resistant transgenic crops. However, not all pests are susceptible to Bt Cry toxins and there are concerns that even susceptible species may evolve to become resistant to these crops. The search for alternatives is well under way, with significant progress already made towards producing transgenic crops expressing insecticidal compounds from plants, such as protease inhibitors, lectins and alpha-amylase inhibitors. New types of proteins from *B. thuringiensis*, such as the vegetative insecticidal proteins, are also being exploited. At an earlier stage of development but attracting much research interest are other insecticidal compounds, such as chitinases, defensins, enhancins, biotin-binding proteins, proteases and toxins, sourced from bacteria, viruses, plants and arthropods. Fusion proteins, combining the features of different insecticidal proteins, have significant potential for extending the range of insect species which could be controlled via transgenic plants. In the future, metabolic engineering of plants could allow us to alter with great precision the ways in which plants and insects interact. The compatibility of these novel insect control strategies with biological control and integrated pest management is discussed.

Lessons from the development of Green Muscle® for the future of microbial insect control in Africa

Christiaan Kooyman

Fondation Agir pour l'Education et la Santé, Dakar, Senegal

Introduction: Like in most other parts of the world, insect pests are still mainly controlled by means of chemical insecticides in Africa. However, progress has been made over the last 20 years to develop alternative means of control. The case of Green Muscle®, a *Metarhizium*-based biopesticide for locust control, is presented to highlight some of the problems with biopesticide development and some of the lessons learnt.

Methods: The LUBILOSA program brought together a group of researchers with a wide diversity of expertise to be able to go through all the necessary steps for the development of an effective product, these being the search for isolates, bioassays to select the best ones, field testing, (eco)toxicological testing, mass production and storage studies, formulation, application and commercialisation. Licensing agreements were signed with two African producers that have registered the product under the name Green Muscle® in different parts of Africa.

Discussion: One of the main lessons learnt is that end users can often live with the delayed effects of a biopesticide but that it has to be supplied in an easy-to-use formulation. Another is that the requirement of separate registration in each African country will slow down the spread of biopesticides.

Conclusion: Green Muscle® is well on its way to become an established commercial product. Though the commercialisation of new microbial products remains difficult, the current demand for biological or residue-free food has created a much better climate.

Invasive alien species, Classical Biological Control and the Convention on Biological Diversity.

Fabian Haas, Bernhard Loehr

icipe, Nairobi, Kenya

The Convention on Biological Diversity (CBD) introduced Access and Benefit Sharing (ABS) to promote the concept of ownership to biodiversity and to ensure that owners receive benefits from biodiversity use. Basically, this approach assumes that biodiversity products are marketed by private businesses to generating continuous income and benefits to owners.

Also, Invasive Alien Species (IAS) pose a major threat to the well-being of millions of people. Classical Biological Control (CBC) combats IAS by the controlled release and establishment of natural enemies from the home of the IAS in the invaded regions. Thus, a public good is created with no income to a business but with benefits to all.

However, after the CBD entered into force ABS legislation was introduced that seriously impedes scientific studies including the search for natural enemies. The ABS regulations apply to CBC, despite the fact that CBC already successfully works along the lines of benefit sharing, capacity building and conservation, as requested by the CBD.

The workshop will bring together experts from organizations (such as FAO, IOBC, IUCN), regulating authorities, and practitioners to discuss these issues and to inform the policy makers on the special situation and value of CBC. A concluding statement of the workshop will be drafted and be presented to the CBD, to raise awareness of decision-makers at CBD's top level.

Do dietary constraints promote intraguild predation and antagonistic interactions among predators in complex-structured food webs?

Robert Denno[1], Rachel Goeriz[1], Masaya Matsumura[2], Deborah Finke[1]

[1]University of Maryland, College Park, Maryland, United States, [2]National Agricultural Research Center, Nishigoshi, Kumamoto, Japan

Introduction: Given the important consequences of intraguild predation for prey suppression and food-web dynamics, it becomes essential to identify factors that promote its occurrence. Here we contrast food resource stoichiometry (C:N) and prey behavior as potentially important food characteristics that influence predator performance.

Methods: We fed an intraguild predator (the spider *Pardosa littoralis*) and an omnivore (the katydid *Conocephalus spartinae*) diets from multiple trophic levels and measured their performance and nitrogen intake.

Results: Weight gain and nitrogen intake in *Pardosa* were highly correlated with the biomass of prey consumed. However, there was little evidence that the C:N stoichiometry of specific prey items contributed to *Pardosa* growth. For *Pardosa*, behavioral characteristics of prey played a significant role in prey capture and predator performance. However, *Pardosa* performed best when fed a mixture of herbivores and intraguild prey suggesting that dietary supplementation with N-rich prey may be a foraging compromise between satisfying high-nitrogen demands and reducing the risk of counter attack. Likewise, the consumption of prey from higher trophic levels enhanced the growth and survival of *Conocephalus*.

Conclusions: Dietary constraints associated with nitrogen limitation may contribute to the strategy of diet mixing and promote the frequent occurrence of omnivory and intraguild predation in complex-structured food webs.

Changing landscapes, predator subsidies, and altered biodiversity at higher trophic levels: Consequences for plant-herbivore interactions

Robert Denno[1], Deborah Finke[2], Danny Lewis[1]

[1]University of Maryland, College Park, Maryland, United States, [2]University of Missouri, Columbia, Missouri, United States

Introduction: Climate change and anthropogenic disturbance are contributing to fragmented habitats, altered species distributions and the increased exchange of species across habitat boundaries. In particular, the composition of the predator complex (proportion of intraguild predators) at higher trophic levels is highly subject to habitat change. Thus, it becomes imperative to assess how compositional changes in the predator complex influence herbivore suppression and food-web dynamics. Here we investigate how the spatial subsidy of an intraguild predator (*Pardosa* wolf spiders) from neighboring habitats interfaces with the composition of the resident predator complex to influence the suppression of herbivorous insects.

Methods: After documenting the occurrence of an extensive incursion of an intraguild predator, we employ a factorial experiment to explore the consequences of increasing the proportion of intraguild predators in the natural-enemy complex on prey suppression.

Results: We found that increasing the proportion of intraguild predators in the natural-enemy complex results in reduced herbivore suppression.

Conclusions: In fragmented landscapes, the exchange of consumers across habitat boundaries can have drastic consequences for resident herbivores. In particular, the incursion of intraguild predators, the composition and diversity of the resident predator complex, and habitat structure interact to affect the strength of top-down control on herbivores.

Population dynamics and biological control

H Charles J Godfray

Dept. Zoology; University of Oxford, Oxford OX1 3PS, United Kingdom

Introduction: Biological control is applied population dynamics, an attempt to change artificially the abundance of a detrimental organism. Biological control can be improved by a better understanding of population dynamics, while fundamental population biology can be informed by an analysis of successful and failed biological control attempts. My talk will explore the exchange of ideas between biological control and population dynamics, concentrating on host-parasitoid interactions.

Content: The study of host-parasitoid interactions is one of the most highly-developed branches of population dynamics. It was initially spurred by the need to understand biological control, though subsequently parasitoids became in their own right a model system for exploring general issues in population biology. I will first explore how the interplay of applied and fundamental questions have moulded the development of the field, and then look in more detail at a series of questions of interest to both ecologists and pest managers. First, what is the evidence that the density of natural populations of insect herbivores is determined by natural enemies in general and by parasitoids in particular, and the degree to which information from agricultural systems may be useful in studying more complex natural systems. Second, what are the biological processes responsible for damping the intrinsic propensity of host-parasitoid systems to oscillate unstably. Third, the complexities that arise in host-parasitoid interactions with overlapping generations. Fourth, the question whether ecological theory can help practitioners decide which and how many natural enemies it is best to release.

Resource partitioning and the relationship between natural-enemy diversity and the strength of prey suppression

Deborah Finke[2], William Snyder[1]

[1]Washington State University, Pullman, Washington, United States, [2]University of Missouri, Columbia, Missouri, United States

Introduction: Resource partitioning is often implicated as a mechanism leading to greater resource consumption with increasing consumer biodiversity, but empirical studies explicitly examining its importance have proven difficult.

Methods: We conducted this study using a community of parasitoids (*Aphidius colemani, Aphidius matricariae,* and *Diaeretiella rapae*) which attacks three aphid species (*Brevicoryne brassicae, Lipaphis erysimi,* and *Myzus persicae*) on radishes (*Raphanus sativus*). To isolate the impact of resource partitioning among natural enemies on the strength of herbivore suppression, we factorially manipulated parasitoid species diversity (1 versus 3 species) and resource-use differentiation (complete overlap in resource use versus complementarity in resource use among parasitoid species) while controlling for parasitoid species identity. To manipulate the breadth of resources used by a single parasitoid species, and thus resource-use differentiation among species, we took advantage of the host fidelity expressed by parasitoids. Parasitoids were reared on single versus multiple aphid hosts to create populations of wasps within a single species that exhibited narrow (1 aphid species attacked) or broad (3 aphid species attacked) resource-use breadth.

Results: We found that the relationship between enemy species diversity and herbivore suppression is mediated by differentiation in resource use among consumers, with the benefit of diversity only occurring when there is complementarity among consumers in resources exploited.

Conclusions: Resource partitioning among natural enemies is an important mechanism which can lead to enhanced herbivore suppression with greater enemy diversity.

Tracing the origins of the invasive maritime pine bast scale *Matsucoccus feytaudi* in Corsica and Italy: use of mitochondrial and microsatellite markers

Carole Kerdelhué, Christian Burban

INRA UMR1202 BIOGECO, Cestas, France

Introduction: The bast scale *Matsucoccus feytaudi* (Hemiptera: Coccoidea: Margarodidae) is a specific pest of the maritime pine (*Pinus pinaster*). It is naturally present in the western part of the Mediterranean basin, i.e. in the Iberian Peninsula, Morocco and Southwestern France, where its impact on the host tree is neglictable. On the contrary, the scale is supposed to have been introduced in southeastern France where it caused severe outbreaks responsible for the decline of 120 000 ha of maritime pine in the 1960s. It reached Italy in the late 1970s and is still expanding southwards there. Moreover, *M. feytaudi* was detected in Corsica in 1994 where its range is continuously growing, causing heavy tree mortality.

Methods: Males were caught from pheromone trapping in the natural range of the species as well as in Southeastern France, Italy and Corsica. 30 individuals per population were genotyped using 8 microsatellite markers. Data were compared to phylogeographic data obtained by PCR-RFLP and SSCP for part of the mitochondrial COI-COII and cytochrome b genes.

Results and discussion: Mitochondrial data showed that the populations are highly structured in space, with intra-population variability in the natural range of the species. However, the invasive populations were all monomorphic for the chosen marker and bear the most frequent haplotype. Microsatellite markers were useful to trace the most plausible invasion events and expansion pathways, as the successive bottlenecks did not lead to complete allelic fixation.

Allochronic differentiation of a phenologically atypical population of the pine processionary moth *Thaumetopoea pityocampa* (Lepidoptera: Notodontidae)

Carole Kerdelhué[1], Helena Santos[2], Jérôme Rousselet[3], Maria-Rosa Paiva[4], Manuela Branco[2]

[1]INRA UMR1202 BIOGECO, F-33612 Cestas, France, [2]ISA/DEF, Universidade Técnica de Lisboa, Tapada da Ajuda, 1349-17, Lisboa, Portugal, [3]INRA, URZF, F-45166 Olivet cedex, France, [4]DCEA/FCT, Universidade Nova de Lisboa, 2829-516 Campus de Caparica, Portugal

Introduction: Allochronic speciation refers to a mode of sympatric speciation in which the differentiation of populations is primarily due to a phenological shift without habitat or host change. *Thaumetopoea pityocampa* is a Mediterranean insect with winter larval development. A phenologically atypical population with early adult activity and summer larval development was detected ten years ago in Leiria, Portugal (hereafter summer population). We used neutral genetic markers to test the hypothesis of allochronic differentiation and we measured several ecological parameters to determine the ecological impacts of the phenological shift.

Methods: Larvae were sampled from the summer population of Leiria as well as from surrounding winter populations. We used mitochondrial and nuclear sequences as well as microsatellite markers to test the divergence of the summer population and to compare the allelic richness. For both populations, male flight was monitored by pheromone trapping and egg mortality and parasitism rates compared.

Results: Sequences strongly suggest that 'summer' individuals are closely related to the sympatric winter population, while microsatellite data show a reduction in allelic richness, a distortion of allelic frequencies and significant genetic differentiation. Monitoring of adult flight suggests that reproductive activity does not overlap. Furthermore, significantly different egg mortality and parasitism rates were observed between populations.

Discussion: The summer population probably appeared after a sudden phenological shift of some individuals, leading to a founder effect and complete reproductive isolation. Given that the individuals showing this new phenology are subjected to different selection pressures, the observed allochronic differentiation may rapidly lead to deeper divergence.

Cross-effects between below- and aboveground tritrophic interactions in maize

Ted Turlings[1], Sergio Rasmann[2], Matthias Erb[1]

[1]University of Neuchatel, Neuchatel, Switzerland, [2]Cornell University, Ithaca, United States

Plants under attack by arthropod herbivores have been shown to employ a strategy of indirect defense by attracting natural enemies of the herbivores. Such interactions have been intensively investigated for aboveground tritrophic systems, whereby leaf-feeding insects induce the emissions of specific volatiles that attract predatory and parasitic arthropods. Recently it was found that similar interactions also occur belowground when insects-damaged roots release compounds that attract entomophatogenic nematodes. We have investigated such root signals for maize plants under attack by larvae of *Diabrotica virgifera virgifera*, a ferocious pest on maize. It was found that *D.v.virgifera*-damaged roots produce large quantities of the (E)-β-caryophyllene and that this sesquiterpene is highly attractive to the entomophatogenic nematode *Heterorhabditis megidis***.** Using a setup of interconnected above- and belowground olfactometers we have studied how root feeding may affect aboveground signaling and the attraction of parasitoids, and *vice versa* how leaf feeding affects the belowground signal and the attraction of nematodes. Such double infestation renders maize plants less attractive to both types of natural enemies. Measurements of volatile emissions showed that the principal root attractant was indeed reduced due to double infestation, but this was not evident for the leaf volatiles. The parasitoid showed an ability to learn the differences in odour emissions and increased its response to the odour of a doubly infested plant after experiencing this odour during an encounter with hosts. Investigations into the molecular mechanisms into the cross-effects between above- and belowground signaling are underway.

Share the resources or displace the natives: different strategies in invasive *Megastigmus* seed insects

Marie-Anne Auger-Rozenberg, Alain Roques

INRA, Orléans, France

Introduction: Because of the rapidly- increasing, and often unregulated, seed trade, exotic seed chalcids in the genus *Megastigmus* invaded Europe where they presently represent 9 out of the 21 species recorded from tree seeds. We investigated their impact on both the native chalcid entomofauna exploiting seed resources and the potential of natural regeneration of trees.

Methods: Using a standardized procedure, seeds of firs (*Abies* spp.), true cedars (*Cedrus* spp.) and wild roses (*Rosa* spp.) were sampled all over Europe in order to assess the relative importance of the native and invasive species, and their specific impact on tree seed yield. Experimental trials consisted in offering enbagged cones to the attack of *Megastigmus* spp. using various ratios of invasive/ native species. Using X-rays and rearings of infested seeds, we analyzed the spatial distribution of the different species in the cones with and without competition for seed resource

Results: In firs, the exotic *M. rafni* became over the last 10 years the dominant species in most stands, replacing the native species rather than sharing the seed resources within the cone. The decrease in seed yield thus remained equivalent when only one exotic species was present instead of the native species or together with the native. However, seed yield significantly decreased as soon as 2 or more exotic species were present. In this case, all the zones of the cone were attacked. The cone resources were similarly shared in cedars and wild roses when 2 exotic species were present with large consequences on the potential of natural regeneration of the trees.

Conclusions: Research has now to focus on the biological traits susceptible to be involved in the competitive superiority of the exotic seed chalcids with regard to the native ones.

Population genetics of the larch budmoth *Zeiraphera diniana* (Lepidoptera: Tortricidae)

Sophie Delamaire, Alain Roques

INRA, Orleans, France

Introduction: Population densities of larch budmoth, *Zeiraphera diniana* (LBM), exhibit cyclical outbreaks in the Alps. Outbreaks usually occur at 8-10 year intervals, larval populations increasing by ca. 10^5 times during the 3-4 years following a short latency phase. In addition, outbreaks are subject to travelling waves across the Alps. We hypothesized that there is a link between changes in the genetic structure of the populations and the outbreak development.

Methods: LBM adults and larvae were sampled for 3 consecutive years at several sites of France, Switzerland and Italy showing delayed outbreak patterns.
We use mitochondrial and nuclear molecular markers (mtDNA sequences and AFLPs) to study the spatial and temporal changes in the genetic structure of LBM populations, and try to relate it to the demography.

Results: mtDNA sequencing results suggested that the demographical explosion at the onset of an outbreak is associated with an increase in populations genetic diversity. Spatial comparisons also showed that outbreaking populations present a higher genetic diversity than populations in latency. The star-like shape of the haplotype network obtained by mitochondrial sequences is congruent with the sudden demographic expansion.

Conclusions: This study is a first step towards the understanding of its population dynamic via genetic tools. Additional data will be supplied during the presentation. Nuclear data are expected to confirm this trend, and temporal data that are in process should give more information on the underlying phenomena of this particular cyclic outbreak pattern.

Newest quick scan and comprehensive evaluation methods of environmental risks for exotic natural enemies

Joop C. van Lenteren, Antoon J.M. Loomans

[1]Laboratory of Entomology, Wageningen, Netherlands, [2]Section Entomology Plant Protection Service, Wageningen, Netherlands

First, we summarize the international situation concerning environmental risk assessment for biological control agents. Next, we illustrate a new, comprehensive risk evaluation method consisting of a stepwise procedure, which can be used for all types of biological control agents used in augmentative and classical biological control programmes, and for native and exotic natural enemies. The new comprehensive method solves weaknesses that we encountered when using the previous assessment methods: decision criteria are more clear and the decision to advise a release is taken at relevant steps in the process, thus preventing unnecessary research.

We applied the new procedure to about 100 species of natural enemies used in Europe. The elimination of obviously risky species early in the process, and the acceptance of other species that previously wrongly scored a high index, clearly show improvements of the new procedure.

For those natural enemies that have been in use for many years in certain ecoregions of the world, we propose that environmental risks are evaluated by using a quick scan method, based on available information only. We have applied this method to all 150 species of natural enemies that are currently commercially available in Northwest Europe and concluded that 80% of the species were expected to cause no problems, while about 5 % of the species (all exotic) were considered too risky for release in this region. Information was not sufficient for another 15% of the species, but the necessary information to make a final decision could usually be obtained easily.

Cheating honey bee workers produce royal offspring

Lyndon A Jordan[3], Michael H Allsopp[1], Theresa C Wossler[2], Benjamin P Oldroyd[3], Madeleine Beekman[3]

[1]Honey bee Research Section, ARC-Plant Protection Research Institute, Stellenbosch, South Africa, [2]University of Stellenbosch, Stellenbosch, South Africa, [3]University of Sydney, Sydney, Australia

The Cape bee (*Apis mellifera capensis*) is unique among honey bees in that workers can lay eggs that instead of developing into males develop into females via thelytokous parthenogenesis. We show that this ability allows workers to compete directly with the queen over the production of new queens. Genetic analyses using microsatellites revealed that 23 of 39 new queens produced by seven colonies were offspring of workers and not the resident queen. Of these, eight were laid by resident workers, but the majority were offspring of parasitic workers from other colonies. The parasites were derived from several clonal lineages that entered the colonies and successfully targeted queen cells for parasitism. Hence, these parasitic workers had the potential to become genetically reincarnated as queens. Of the daughter-queens laid by the resident queen, three were produced asexually, suggesting that queens can 'choose' to produce daughter-queens clonally and thus have the potential for genetic immortality.

What has the 'selected anarchist' line told us about reproductive parasitism in honey bees?

Benjamin Oldroyd

University of Sydney, Sydney, NSW, Australia

The 'selected anarchist' (SA) line of honey bees maintained at Sydney University has been developed by 10 years of recurrent selection for worker reproduction. In the SA line about one third of 10-day-old workers have activated ovaries and lay eggs that produce males. This is in stark contrast to wild-type (WT) workers in which almost no workers are reproductive. The SA line offers the opportunity to investigate the pheromonal and genetic mechanisms that regulate worker sterility in WT honey bees.

Pheromonal studies have shown that SA queens have similar mandibular pheromones to wild-type queens, but that ovary activation in SA workers is less inhibited by exposure to queen mandibular pheromones. Similarly, SA workers are less inhibited by brood pheromones than WT workers, but the brood of SA queens is less inhibitory than the brood of WT queens.

Microarray studies have revealed a number of genes that are differentially expressed between young, age-matched WT and AN workers. These include key regulatory proteins including Major Royal Jelly proteins and vitellogenin.

Backcrosses between WT and SA lines reveal that there are several genes of both small and large effect that control expression of worker sterility. Our goal is to elucidate the molecular genetic mechanisms that regulate worker sterility in honey bees, and to show how reproductive parasitism by individual workers is controlled.

The SA line can also be used as an independent test of the 'reproductive ground plan hypothesis' (RGPH) for the regulation of reproductive potential in honey bee workers. The RGPH suggests that workers with higher than normal reproductive potential are likely to forage early in their life and to focus on pollen foraging (Amdam et al *Nature* 439: 76). Our studies of the SA line show that in contrast to the predictions of the RGPH, SA workers are significantly older than WT workers when they commence foraging, and the proportion of pollen foragers does not differ significantly from the proportion of pollen foragers among WT workers.

‘Wallacea’ – The origin of diversity for butterflies (Lepidoptera) in the Indo-Pacific? Biogeographic patterns across three co-occurring tropical genera

Chris Muller, Luciano Beheregaray

Macquarie University, Sydney, Australia

Introduction: This work is a comparative molecular phylogenetic and biogeographic analysis of separate co-occurring genera in the Indo-Pacific. The subjects studied included all known species of the butterfly genera *Cethosia* (48 taxa) and non-African *Charaxes* (51 taxa) (both Nymphalidae) and representatives from all recognized species groups within the genus *Delias* (72 taxa) (Pieridae). The focus was to determine the biogeographical importance of ‘Wallacea’, in central Indonesia, a biological hotspot which is poorly understood.

Methods: Sequence data from three genes (mtDNA: 650 base pairs COI, 410 bp ND5; nuclear DNA: 430 bp wingless gene) were used to reconstruct the molecular phylogenies for each genus. Phylogenetic analysis included Maximum Parsimony, Maximum Likelihood and Bayesian Inference methods.

Results: Several clades within each genus were consistently resolved and showed strong concordance between phylogenetic relationships and morphology. Morphologically divergent species had longer branch lengths between taxa and formed basal clades, whereas more recently derived species displayed similar phenotype. For each of the three genera the tree topology indicated that basal clades consisted of species largely confined to Wallacea.

Conclusions: The biogeographical histories of the three genera are consistent with the interpreted geological evolution of the region. Long term isolation and hence higher genetic diversity of taxa within Wallacea likely parallels the independent formation and drifting of microplates during the Tertiary. Repeated connection/isolation of land masses and mountain ranges during Pleistocene inter glacial periods in Sundaland and New Guinea, respectively, resulted in the recent evolution of numerous taxa with lesser genetic divergence.

Using population modelling to assess the risk of pesticides to non-target arthropods with different life history strategies

John Stark

Washington State University, Puyallup, Washington, United States

Introduction: Traditionally, estimation of the ecological impacts of chemical toxicants has been done by comparing individual-level endpoints of toxicity to an expected, or range of expected environmental concentrations. However, the ability of this approach to protect nontarget species has been questioned. The use of population modeling has been suggested as a more feasible means to ascertain the fate of populations under stress. In this talk I will discuss the use of matrix models to estimate the effects of pesticides on non-target arthropods.

Methods: The advantages and disadvantages of matrix models will be discussed. Results from Hazard Ratios (ratio of expected environmental concentration and LC50), a commonly used approach used to determine the hazard of a pesticide to nontarget organisms will be compared to modeling results using examples with tephritid fruit flies and *Daphnia*. Lethal and sublethal effects will be modeled.

Results: Matrix models can be used to make better assessments of pesticide effects on populations compared to the Hazard Ratio method.

Conclusions: Hazard assessments based on expected environmental concentrations and the LC50 can provide estimates of risk but are limited because they do not take into account multiple effects of pesticide and differences in life history traits.

Post-release evaluation of risks of a biocontrol agent: a New Zealand case study

Barbara Barratt[1], John Kean[2]

[1]AgResearch, Mosgiel, New Zealand, [2]AgResearch, Lincoln, New Zealand

Introduction: The parasitoid *Microctonus aethiopoides* Loan (Hymenoptera: Braconidae) was introduced into New Zealand in 1982 to control the lucerne pest, *Sitona discoideus* Gyllenhal (Coleoptera: Curculionidae). Previous studies have shown that a number of non-target weevil species are attacked in the field by this parasitoid. A field study was carried out over a seven-year period to investigate non-target parasitism by *M. aethiopoides* in native grassland.

Methods: Sampling was carried out at three locations in Otago. Parasitism of *S. discoideus* in lucerne growing in the valley floor was assessed, and at progressively higher altitude grassland sites, weevils were sampled monthly and dissected to determine parasitism levels. Simple population models were used to estimate the likely impacts of the observed parasitism rates on non-target population densities.

Results: Of the 36 species of weevils identified, eight were found to be parasitized, including *S. discoideus* which was found at all sites. Parasitism of the target pest in lucerne ranged from 17-78% and for non-target species was 2% overall but this varied with location, site, and season. Substantial nontarget parasitism was found at only one location, with up to 24% parasitism of a native weevil, *Nicaeana fraudator* Broun recorded. Modelling suggested that impacts of non-target parasitism are likely to vary between species and sites.

Conclusions: The target host has the potential to transport parasitoids to native grassland areas. There was no apparent relationship between nontarget parasitism by *M. aethiopoides* and weevil density or between altitude or distance from lucerne. Post-release studies can be of value to regulatory agencies for future decision support.

Terrors from beyond space: Alien arthropods in the movies

Richard Leskosky

University of Illinois at Urbana-Champaign, Urbana, Illinois, United States

Most science fiction films with arthropod menaces (Insect Fear Films) have earthly settings and terrestrial arthropod antagonists, but many of them feature extraterrestrial arthropods of one sort or another. In fact, from its very beginnings, the cinema has relied on arthropods as models for alien creatures because of both their intrinsic otherness with respect to humans and the social behavior exhibited by various species. Such alien arthropods belong to three major categories: arthropods encountered in extraterrestrial settings, extraterrestrial arthropods invading the Earth, and earth-based arthropods turned into menaces by extraterrestrial forces. This presentation will trace the history of alien arthropods in Insect Fear Films, examine the reasons for their popularity with filmmakers, and relate their appearances in films to their depictions in other popular media.

Too hot to handle: Ecophysiological responses of the southern green stink bug *Nezara viridula* (Heteroptera: Pentatomidae) to climate warming

Dmitry I. Musolin, Daisuke Tougou, Kenji Fujisaki

Lab. of Insect Ecology, Grad. School of Agriculture, Kyoto University, Kyoto, Japan

Introduction: The climate warming promotes northward expansion of *N. viridula*'s range by providing favourable overwintering conditions close to the species' range limit. We present results of an experiment in which this species responds to the simulated climate warming.

Methods: Adults collected in Kochi (33.6ºN, 133.6ºE) were transferred to Kyoto (35.0ºN, 135.8ºE), close to the current species' north range limit. The progeny was divided into two groups and reared over a year under outdoor conditions and in a specially constructed transparent incubator which simulated climate warming by adding in real time 2ºC to the outdoor temperature.

Results: The moderate temperature increase (2ºC) affected many life history traits. In summer, nymphs suffered higher mortality, their development was significantly more retarded and emerged adults were significantly smaller under simulated warming conditions than outdoors. In late autumn, on the contrary, warming resulted in a shorter nymphal period and, thus, earlier emergence of adults. These adults successfully changed colour, entered diapause and survived winter, while their siblings failed to change colour and suffered high winter mortality outdoors. Simulated warming affected overwintering mortality directly (by increasing survival) and indirectly (by advancing adult emergence). It also advanced the beginning of reproduction in spring.

Conclusions: The effect of even moderate warming is complex. In summer, it might affect performance even at the northern limit of the species' range, likely because of the deleterious effects of daily maximum temperatures. In other seasons, warming might advance phenology and enhance survival, thus promoting range expansion and establishing in newly colonized areas.

Biological control of *Chromolaena odorata* in Africa: some progress made but much more is needed

Costas Zachariades

Agricultural Research Council, KwaZulu-Natal, South Africa

The two biotypes of *Chromolaena odorata* invading Africa continue to spread. The Asian/West African biotype is spreading into East Africa, while the southern African biotype is spreading north. Although research into the biological control of chromolaena was initiated by Nigeria in the 1960s, and several species of biocontrol agents were released in West Africa in the 1970s, the first establishment in Africa only occurred in the 1990s. To date, agents have been established on chromolaena in two countries: *Pareuchaetes pseudoinsulata* (Lepidoptera: Arctiidae) in Ghana, and *P. insulata* and *Calycomyza eupatorivora* (Diptera: Agromyzidae) in South Africa. These agents are effecting a degree of control but more agents are needed. The introduction of the host-specific, damaging stem-galler *Cecidochares connexa* (Diptera: Tephritidae) into one or more countries where the Asian/West African biotype is present, is recommended. Because this fly cannot develop on the southern African *C. odorata* biotype, other potential agents are under consideration, with a particular emphasis on those adapted to the severe dry season typical of much of the invasive range of this biotype. The conflict of interest in West Africa concerning the useful versus harmful attributes of *C. odorata* has not yet been resolved and still acts as a block to international funding for chromolaena biocontrol there. The South African programme on *C. odorata* biocontrol is the only one world-wide investigating new agents, and hopes to supply these not only to African countries but also to the drier parts of South-East Asia where *C. connexa* has not performed well.

Immunogen-induced anorexia in locusts

Graham Goldsworthy, Khadijo Osman, Mary Lightfoot, Ilona Wenzel

Birkbeck College, London, United Kingdom

Illness-induced anorexia is a widespread phenomenon in animals, and infection is known to inhibit feeding activity in locusts. Anorexia can be induced by injecting immunogens such as bacterial LPS or the ∃ 1,3-glucan, laminarin. After a 2 h period of food deprivation, Ringer-injected locusts feed with latency of 1-2 min and continue to eat for *c.* 4 min. During a test period of 1 h, they may take up to three meals. The effect of injecting immunogens on feeding behaviour of adult and nymphal *Locusta* is apparent immediately: adult locusts injected with >10 µg of laminarin, or nymphs injected with >1 ug, do not eat at all during a 1 h test period starting 10 min after treatment with the immunogen. They perch on the wheat seedlings provided, but do not palpate the leaf surface and do not attempt to eat. Sub-optimal doses of laminarin allow some locusts to feed, but with an increased latency and normal first meal duration.

The anorectic effect of laminarin or LPS is modulated by injection with a serotonin antagonist such as Mianserin, or by injection of adult locusts with Adipokinetic Hormone (AKH-I) 2h before the immune challenge: latency to feed increases relative to that in controls, while meal duration is unaffected. Injection of AKH-I into nymphs does not block the anorectic response to laminarin, suggesting that increased lipid mobilisation, which occurs in adults but not nymphs in response to AKH, is implicated in modulation of the anorectic response to this immunogen. Experiments in which serotonin or octopamine is injected suggest strongly that serotonin receptors are involved in the mechanism of sickness-induced anorexia in locusts.

A locust model can be used to study virulence determinants of *Escherichia coli* K1

Graham Goldsworthy, Behzad Mokri-Moayyed, Naveed Khan

Birkbeck College, London, United Kingdom

E. coli K1 meningitis involves invasion of the CNS by the bacterium *Escherichia coli*, and results in 50,000 human deaths per year worldwide. Understanding of the pathogenesis of this disease has, until now, relied on vertebrate models, but parallels between the innate immune responses of mammals and insects, and the fact that *E. coli* K1 meningitis occurs mostly in neonates, suggest that insects could be useful models for studying the pathogenesis of *E. coli* K1. The physiology of *Locusta migratoria*, the African migratory locust, has been studied extensively in our laboratories, and was chosen as a model to study *E. coli* K1 pathogenesis *in vivo*. The aim of this study is to determine how well *E. coli* infection can be modelled by testing in the locust some of the virulence factors known currently to be required for *E. coli* K1 pathogenesis in mammals.

The *E. coli* K12 strain HB101, which is non-pathogenic in mammals, has also very low pathogenicity to locusts and does not invade the locust CNS, whereas the *E. coli* K1 strain RS218 (O18:K1:H7; isolated from a meningitis patient) kills almost 100% of locusts within 72 h, and invades the brain. After injection of *E. coli* K1 into adult male locusts, both mortality and invasion of the locust brain require at least two of the known virulence determinants shown for mammals. Deletion mutants that lack OmpA (Outer membrane protein A) or CNF1 (cytotoxic necrotizing factor 1) have reduced abilities to kill locusts and to invade the locust brain compared with the parent *E. coli* K1. The locust model can be used to examine the dynamics of invasion of the brain and to test the virulence in locusts of *E. coli* K1 mutants in which known pathogenicity islands in the K1 genome have been deleted. In this way, as yet unknown virulence determinants may be identified.

Insect conservation in practice: lessons in the real world

Michael Samways[1], Timothy New[2]

[1]Stellenbosch University, Matieland, South Africa, [2]La Trobe University, Melbourne, Australia

Insect conservation comprises both theoretical and practical exercises, the latter drawing on the accumulated wisdom of both these facets. With massive current and future threats (ranging from habitat and resource loss, influences of invasive species, and effects of climate change) to insects, the practice of insect conservation is increasingly important. In this symposium, we emphasize practice, and examine a variety of cases and scales through which practical conservation is contributing to insect well-being, and how the mutual lessons from theory and practice are being tested and will apply in the future.

Assessing freshwater health using macroinvertebrate surrogates, especially adult dragonflies

Rembu Magoba[1], Michael Samways[2], John Simaika[1]

[1]Stellenbosch University, Matieland, South Africa, [2]Stellenbosch University, Matieland, South Africa

In many countries, benthic macroinvertebrates are being used to assess the quality of freshwater ecosystems. This is also the case in South Africa, where, in addition, adult dragonfly assemblages are being matched to them, with excellent concordance. However, adult dragonflies, as surrogates for biodiversity, have the distinct advantage that they can be used at the more sensitive, species level, rather than at the more general higher taxonomic level, as in the case of macroinvertebrates. Thus, dragonflies can be used at both fine spatial scales and for measuring compositional biodiversity i.e. ecological integrity, as well as freshwater health. Furthermore, adult dragonflies are much easier and more practical to sample than benthic macroinvertebrates, and therefore are an excellent practical tool for conservation managers. A scoring system for adult dragonflies has been developed which will enable national implementation of dragonfly surrogates for various uses, including measuring the success of the national clearing of invasive alien riparian trees.

Implementing ecological networks using grasshoppers as indicators

Corinna Bazelet, Michael Samways

Stellenbosch University, Matieland, South Africa

The forestry industry in South Africa has implemented a very large scale mitigation measure for the conservation of biodiversity. This involves setting aside about a third of forestry land, a total of 500,000 hectares, in the form of interconnected corridors and nodes of remnant habitat, together called an ecological network (EN). Most of these ENs are grasslands, at various elevations and often following the hydrological landscape. Previous research has shown that an EN can fulfill a habitat function for a range of taxa, if large enough. Since the majority of the ENs fall below this size threshold, guidelines must be developed to optimize the structure and management of the ENs. Surrogates are also necessary to measure the mitigation success of the EN and to use as a monitoring tool for adaptive management. Possible surrogates include landscape, vegetation and management variables, and bioindicators. Of the potential bioindicators, grasshoppers may prove to be a prime practical tool for quantifying the conservation success of the ENs.

Shading by agricultural and natural plants affects growth and development of malaria mosquito larvae in Western Kenya

Susan Imbahale, Richard Mukabana, Willem Takken

[1]Kenya Medical Research Institute, Kisumu, Kenya, [2]University of Nairobi, Nairobi, Kenya, [3]Wageningen University and Research Centre, Wageningen, Netherlands

Malaria in tropical Africa is a major cause of illness and death, and its control depends on drugs and vector control. The latter is accomplished by reducing populations of malaria mosquitoes. We have investigated the effect of crop plants on larval growth and development in a peri- urban environment, using locally available plants. Larval habitats were created in agricultural fields in Kisumu, western Kenya. The fields are used for irrigated rice production and vegetable production. Small plots of 1 x 1m were dug and filled with water naturally by seepage and rainfall. 5, 1 by 1 m plots were provided with canopy cover from the following plants, Napier grass (*Pennisetum purpureum*), rice (*Oryza sativa*), yams (*Dioscorea batatas*), papyrus reeds (*cyperus papyrus*) and one open plot which acted as a control. Larval sampling was done once on weekly basis from the 7th week to 25th week of 2007.

The results show that plots provided with Napier grass had the lowest larval densities, followed by rice, yams, and papyrus reeds and finally the open/ control plots had highest anopheline larval densities

Biological control as a component of IPM for cowpea

Manuele Tamo[1], Cyriaque Agboton[1], David Arodokoun[2]

[1]International Institute of Tropical Agriculture (IITA), Cotonou, Benin, [2]Institut des Recherches Agricoles au Benin (INRAB), Cotonou, Benin

For many years, biological control has been considered of marginal importance to IPM of cowpea pests. This fact was based on the assumption that, cowpea being an indigenous crop to Africa, all pests were also native to Africa, and hence less amenable to be targets for biological control. Critical issues in developing biological control for cowpea can be summarized as 1) the complexity of the cropping system, with multiple pests attacking different stages of the plant, and sharing a wide range of alternative host plants; 2) the evidence that each pest would need at custom-tailored solution; and 3) interactions with other IPM interventions including pesticides.

Using three case studies involving three major cowpea pests, the flower thrips *Megalurothrips sjostedti*, the pod borer *Maruca vitrata*, and the aphid *Aphis craccivora*, various aspects of the above issues are presented. All these key pests have naturally-occurring alternative host plant, which, in many areas, are far more important for their population dynamics than cowpea, the cultivated host. On-going investigations have revealed that the introduced thrips parasitoid *Ceranisus femoratus* was able to establish on shrubs such as *Tephrosia candida*, and leguminous trees such as *Pterocarpus santalinoides* in the three countries it was released, Benin, Ghana and Nigeria. On the latter host plant, preliminary observations indicate that it was able to reduce the thrips population by up to 43%. Similar studies are being carried out for the exotic parasitoid *Apanteles taragamae* attacking *M. vitrata*, and *Aphidius colemani* attacking *A. craccivora*.

Effect of temperature on the viability and toxicity of *B. bassiana* and *M. anisopliae* on *P. rapae*

Cipriano Garcia-Gutierrez[1], Hiram Medrano-Roldan[2], Isaias Chairez-Hernandez[1]

[1]CIIDIR COFAA IPN, Sinaloa, Mexico, [2]ITD, Durango, Mexico

Introduction: The temperature, humidity and sunlight have influence on the growth of *Beauveria bassiana* and *Metharhizium anisopliea*; the cabbage worm *Pieris rapae* (L.) is controlled with native strains of fungus applications on cauliflower *Brassicae oleraceae* (L.) in in many sites with different ranges of temperature and altitude.

Methods: A contamination leaf bioassay was used to calculate the CL_{50} for 10 isolates, then these spore concentrations were used to study the effect of different temperature conditions (25,30,35, and 40^0C) in the spore viability and strain´s toxicity on 1-3 old-day *P.rapae* larvae, using a factorial design 10x4x3.

Results: The LC_{50} to *B.bassiana* and *M. anisopliae* ranged from 10^{7-6} conidia/ml, respectively. There were significant statistical differences between mean larvae mortality of all strains (F= 34.45, p = 0.001), but not between the same strains (MSD=2.3). The highest larval mortality was present in the isolate code *B.b*4 ($1.2x10^9$ spores/ml) at 30ºC, while the lowest mortality was to Mtz3 ($2.3x10^7$) at 25ºC; the better spore viability percentage was obtained by the isolate Bb1(98±0.6 $_{C.V\ 0.3}$) at 30 ºC, and the lowest to Mtz2 (76±2.1 $_{C.V\ 0.6}$) at 40 ^{0}C. In all *B.b* strains the highest viability spores were observed, as well as the better toxicity values at temperatures between 30-35ºC, while for *Mtz* these same results were obtained at 25-30 ºC; the strain origin, altitude and temperature, were also important.

Conclusions: The results showed that *B. bassiana* strains had better tolerance to high temperatures than *M. anisopliae*, preserving the spore viability and toxicity, this characteristic allows a selective choice of *B.bassiana* strains as first candidates to use it in cabbage worm control in sites with maximum temperatures around 30^0C in Mexico.

Functional roles of short neuropeptide F in the brain of Drosophila

Dick R. Nassel, Lina E. Enell, Elisabeth Gustafsson, Helena A. D. Johard

Department of Zoology, Stockholm University, Stockholm, Sweden

The expression of the gene *snpf* and its neuropeptide products (short neuropeptide Fs; sNPFs) is widespread in the CNS of larval and adult *Drosophila.* We studied the distribution by means of in situ hybridization and antisera against sequences of the precursor and two of the encoded peptides (Johard et al., J Comp Neurol, in press). sNPF expression is seen in Kenyon cells of the mushroom bodies and in various chemosensory neurons, as well as interneurons and neruosecretory cells of different types. A previous report has shown that *snpf* plays a role in feeding in larvae and adults of Drosophila (Lee et al., J Biol Chem 279:50781, 2004). This was shown by global (pan-neuronal) interference with *snpf* expression. Here we analyze the role of different subpopulations of sNPF expressing neurons in feeding and locomotor activity. This is done by neuron-specific interference with sNPF expression using the binary Gal4-UAS system to drive RNA interference, followed by behavioral tests.

Expansion of pine processionary moth in Europe: patterns and predictive model

Christelle Robinet[1], Alain Roques[1], Jérôme Rousselet[1], Andrea Battisti[2]

[1]INRA Forest Zoology, Olivet, France, [2]University of Padova, Legnaro, Italy

Introduction: Many species are already affected by the warming up of climate. Their distribution is expanding or retracting depending on climatic tolerance, dispersal capabilities and response to environmental changes. During the last decades, the pine processionary moth, *Thaumetopoea pityocampa*, has expanded northwards and upwards in Europe. We investigated the role of climate warming in this expansion and developed a predictive model with regard to climatic scenarios for the future.

Methods: Experimental studies have been carried out to determine the effects of low temperatures on the survival of larvae during the cold period, and climatic thresholds for development. A reaction- diffusion model relying on these thresholds has been developed. The effects of climatic anomalies have also been considered.

Results: We found close relationships between the increase in winter temperatures and feeding activity and survival of larvae. By including these relationships into a diffusion model, we successfully reconstructed the range expansion in the southern Paris Basin since the early 1990s. Under moderate hypotheses for average winter warming during the next 50 years (+3°C), model predictions suggest a colonization of downtown Paris by 2025. However, climatic anomalies such as the heat wave which occurred in August 2003 in Western Europe are likely to modulate such expansions because of contrasting effects: extremely high temperatures in the Italian Alps enhanced the range expansion in higher elevations whereas processionary populations collapsed at the same time in the Paris Basin.

Conclusions: In the future, the impact of climatic anomalies should be explored and included in predictive models. Because of its northwards expansion, this forest insect is likely to become an urban pest, causing serious troubles to public health due to its urticating properties.

Termites and Namibian fairy circles: No connection

Walter R. Tschinkel

Florida State University, Tallahassee, FL, United States

The sandy plains of the Pro-Namib Desert are punctuated by thousands of bare areas 3 to 15 m in diameter edged by a circle of taller grasses. The cause of these “fairy circles” is unknown, although several hypotheses have been advanced. We tested the hypothesis that the circles are caused by the termite *Baucaliotermes hainsei*, a harvesting termite endemic to southern Namibia. Excavation of 10 fairy circles to a depth of 1.5 to 2 m revealed no evidence of termites. We then exposed the underground foraging tunnel systems of two nests using a soft brush and a petrol-powered lawn blower. Areas containing nests of this termite are underlain by complex, interconnecting underground highway systems with risers to the surface at regular intervals. The tunnels themselves are not simple tubes, but consist of a raised central portion serving as a runway, and lateral pockets and grooves in which foragers deposit cut grass pieces for eventual transport to the nest. The extent and complexity of this foraging/transport system is extreme. We also censused a nest of this species, finding it to be occupied by about 40,000 individuals, including all castes and stages.

Pest management: An emergent property of biodiversity

Mark Brown

USDA, ARS, Appalachian Fruit Res. Sta., Kearneysville, WV, United States

A number of studies have demonstrated that increasing the diversity of agricultural ecosystems can allow for a reduction in insecticide applications without an increase in insect damage to the crop. However, it has been very difficult to demonstrate the specific mechanism involved in producing the pest management benefit: interspecific competition, biological control, plant resistance, etc. Several examples of habitat diversification studies in apple ecosystems will be used that demonstrate a reduction in pest damage but no identification of specific mechanisms responsible for pest control. Pest management is an emergent property of the ecosystem, an ecosystem service, resulting from the interactions among all the components in the system. Diversification of the ecosystem affects each trophic level making it difficult to isolate one specific mechanism. Traditional agricultural research experiments are good at detecting treatment effects but are not the best method for explaining emergent properties that are a result of system-level interactions. An appropriate analysis should include a combination of resource limitation, landscape and food web analyses. Before landscape analysis is performed, basic biology of the pests and natural enemies is needed to identify what resources, if any, are limiting. Then the spatial range of key pests and natural enemies must be known to evaluate the availability of limited resources. Landscape analysis can then be applied to evaluate how and where limiting resources can be supplemented. Food web analysis is needed to evaluate the resulting interactions when selected species are provided resources in preference of other species. Such complex analyses are needed to provide sufficient data for predicting the result of ecosystem modifications, whether for pest management or any other objective.

Novel resistance response of a perennial vine crop (kiwifruit) to armoured scale insect (Diaspididae) feeding

Garry Hill, Nicola Mauchline, Midori Jones, Paul Sutherland

Horticulture and Food Research Institute of New Zealand, Auckland, New Zealand

Introduction: The polyphagous sibling diaspidid species, latania scale (*Hemiberlesia lataniae*) and greedy scale (*H. rapax*), shown major differences in survival and growth on kiwifruit (*Actinidia* spp.) genotypes. The responses of petiole, bark and fruit from 'resistant' kiwifruit genotypes to feeding by both species is described.

Methods: Crawlers of both scale species were settled onto petiole, bark (1 year-old canes) and fruit of 5 kiwifruit genotypes in an experimental orchard in New Zealand. Insect growth and survival were monitored and samples of challenged plant material taken at weekly intervals over a 5-week period. The histological responses of the plant to insect feeding were characterised using light microscopy.

Results: On bark and fruit, the vines responded to latania scale by developing, over a 5-week period, a bowl-shaped neoplasm in the collenchyma, 200-400 µm from the settled insect, caused by massive cell proliferation (hyperplasy). Cell growth (hypertrophy) and the deposition of lignin on cell walls occurred within this hyperplasic bowl, isolating the insect's stylet from unmodified collenchyma and parenchyma cells beneath, leading to stunted growth and death of the insect within 1-2 weeks. Fruit from one genotype responded to latania scale with cell death (hypersensitive response) occurring directly beneath the insect. Greedy scale initiated no plant response and developed normally. Petiole tissue showed no response to either species.

Conclusions: Selected kiwifruit germplasm shows strong and unique resistance responses to latania scale but not to its equally polyphagous sibling species, greedy scale. The latania-kiwifruit interaction appears to fit the gene-for-gene model of plant defence.

Comparative toxicity of neem seed powder with three local leaf powders to *Sitophilus zeamais* and the influence of drying regime and particle size on insecticidal efficacy

Elias Nukenine[1], Florence Chouka[1], Cornel Adler[2], Christoph Reichmuth[2]

[1]University of Ngaoundere, Ngaoundere, Cameroon, [2]Federal Biological Research Centre for Agriculture and Forestry, Berlin, Germany

Introduction: *Sitophilus zeamais* is a serious pest of maize in the tropics. Peasant farmers in Cameroon can not afford chemical insecticides. The toxicity of neem seed powder and leaf powders from *Plectranthus glandulosus*, *Steganotaenia araliacea* and *Annona senegalensis* to adult *S. zeamais* was determined in the laboratory. The influence of drying regime and particle size on the insecticidal efficacy of *P. glandulosus* and *S. araliacea* was also assessed.

Methods: The seeds and leaves were harvested in northern Cameroon, dried under shade or sunlight, pulverized until they passed through a 1 mm or 0.2 mm sieve. Maize grains were admixed with the powders at four rates (5, 10, 20 and 40 g/kg) for the assessment of mortality over a 14-day or 30-day period, as well as for population increase and damage.

Results: *S. zeamais* mortality increased with ascending contents for all the powders. Within two weeks exposure, *P. glandulosus* powder caused the highest weevil mortality followed by *A. indica* (powder. Neem seed powder was by far more efficacious in reducing grain damage and population increase compared with all the leaf powders within three months of storage. The leaves dried under shade compared with those dried under sunlight and the larger compared with the smaller particle size powders, caused higher mortality of the weevil.

Conclusions: Neem seed powder and powdered leaves of *P. glandulosus* could be of value in the protection of maize against weevil attack in the subsistence storage systems of northern Cameroon.

Managing a mountain in a biodiversity hotspot for maximizing arthropod diversity

James Pryke, Michael Samways

Stellenbosch University, Matieland, South Africa

Table Mountain, Cape Town, South Africa, is a very significant mountain in terms of biodiversity, being a hotspot within a global biodiversity hotspot (Cape Floristic Region). Recent research on the mountain, and the Cape Peninsula in general, has identified some management procedures which are feasible and should be implemented. The arthropod fauna is very sensitive to various environmental variables, including aspect, elevation, fynbos type and presence versus absence of alien trees such as pines and of the Argentine ant. General concern that accidental fires on the mountain are too frequent is borne out by new, quantitative data. Evidence is accumulating that in the future, one mitigation measure would be well-planned patch burning. Removal of the alien trees, which is currently taking place, is clearly very beneficial for indigenous plant and arthropod diversity. A management priority for the future is to give particular attention to the lower elevations on the mountain which are under extreme anthropogenic pressure.

Integration of new insecticides into apple pest management programs in Washington

Jay F. Brunner

Washington State University, Wenatchee, WA, United States

The US-EPA has determined a phase-out schedule for the use of azinphosmethyl in apple by 2012. This insecticide has historically been the key chemical control for codling moth, *Cydia pomonella* (L.). Several new insecticides have been registered as organophosphate (OP) replacements; some classified as reduced risk. The number of new products, differing modes of action, and target stage brings added complexity to pest control decisions. Concentration response and field-aged bioassays coupled with replicated field trials were used to assess the inherent toxicity, residue longevity, and efficacious rates and timings of different insecticides. Base-line data provided by concentration response bioassays have been used to assess the potential of OP-mediated cross-resistance or resistance development after new insecticides have been in use for a period of time. There are nine insecticides that are OP alternatives for codling moth control, eight for leafroller control and five that will control both pests. Efficacies of insecticides against codling moth and leafrollers differ but combining them into a seasonal program can provide acceptable control. A new on-line Decision Aids System has been developed to help practitioners make the best possible decisions on when to use new insecticides. Resistance to some insecticides has been detected after only 6 years use in the field. OP mediated cross-resistance may be an issue for some new insecticides limiting their efficacy and useful life before they are introduced. A resistance management program is being stressed in educational programs to help delay the development of resistance to new insecticides.

GrubPlan: A greyback canegrub monitoring program in Australian sugarcane fields

Mohamed Sallam, Peter Samson

BSES Limited, Queensland, Australia

Introduction: The GrubPlan program was developed to encourage proactive management of the greyback canegrub (*Dermolepida albohirtum*) and advise growers on best management strategies.

Methods: The program relies on large scale pest monitoring in selected areas of North and Central Queensland. Monitoring involves counting grub numbers in these fields, assessing crop damage before harvest and monitoring adult beetle densities on the regional scale.

Results: Results from Far North Queensland over 5 years showed that pesticide use was an effective means of combating grub damage, however, growers' attitude tends to be reactionary, where rates of pesticide application drop considerably when grub damage declines, and this causes damage to start rising again which in turn leads to a rise in pesticide application. The GrubPlan program is designed to "fine tune" this process, where, based on thorough monitoring, growers can strategically treat their most vulnerable crops and on the same time be prepared to increase their treatment levels if grub populations start to surge. Monitoring results are shared with growers to keep them informed of the pest's population levels and this enables them to maintain sustainable grub management on the local and the regional level.

Conclusion: Queensland canegrowers can improve their grub management and reduce reliance on chemical treatment by committing to a thorough, long-term monitoring program.

Enhancing sugarcane biosecurity measures in Australia

Mohamed Sallam, Peter Allsopp

BSES Limited, Queensland, Australia

Introduction: Invasive pest and disease species pose an ongoing threat to agricultural industries world wide. In Australia, a sugarcane biosecurity scheme has been initiated, whereby Incursion Management Plans are developed for major exotic pests and diseases such as species of moth borers and sugarcane smut.

Methods: The plans detail steps to be taken following an incursion of a sugarcane pest or a disease into Australia, with specific information on the pest's biology, identification, geographical distribution, economic impact and control strategies. All plans are continuously updated in light of new information on changing pest status and recent expansions. The plans also provide information on the "pest risk category", which places the pest into one of four categories depending on its economic status in its area of distribution, with predicted levels of damage that might be incurred in Australia in case of incursion. These categories assist in deciding on sharing eradication and compensation costs between the state government and the industry(s) concerned.

Results: Our preparedness has been tested when an unknown moth borer was found on Thursday island north of the Australian mainland. The moth species was found to be *Chilo crypsimetalla*, which is not a pest of sugarcane and unlikely to cause any economic damage.

Conclusion: Our detection, quick diagnosis and response confirms our good level of preparedness for any possible exotic pest or disease introduction.

Belowground mycorrhizal endosymbiosis and aboveground insects: can multilevel interactions be exploited for a sustainable control of pests?

Emilio Guerrieri[1], Maria Cristina Digilio[2]

[1]Institute for Plant Protection, National Research Council of Italy, Portici, Naples, Italy, [2]Department of Agricultural Entomology and Zoology, University of Naples, Portici, Naples, Italy

More than 20 years have passed from the first report of a multilevel interaction between an arbuscular mycorrhizal fungus and an aboveground insect herbivore. Since then, this intriguing topic has been developed by including other partners, such as the natural enemies of insect pests and by considering top-down interactions, i.e. the effect of insect herbivory on mycorrhizal development. As for bottom-up interactions, it appears that their final outcome mainly depends on the species-specificity of the effects induced by AM fungi on plant responses. In other words, through AM symbiosis more nutrients are transferred to the plant, but whether this leads to an improvement (e.g. tolerance) or a reduction (e.g. better performance of herbivore) of plant resistance depends on the partners involved. Moreover, the alteration of plant volatiles induced by AM symbiosis can play a role in the attractiveness towards the natural enemies of insect pests (indirect defence). However, many aspects of these interactions remain to be elucidated before considering AMF-insects interaction as a new tool to be exploited for the sustainable control of agricultural pests. In this view, the use of modern techniques could be of great help in unravelling the inner mechanisms regulating the interaction between AM symbiosis and aboveground insects. This ambitious result can only be achieved by following a multidisciplinary approach that involves plant physiologists, geneticists, microbiologists, chemists, mycologist, entomologists and ecologists.

Male morph predicts investment in larval immune function in the dung beetle, *Onthophagus taurus*

Sheena Cotter[1], Leigh Simmons[3], Sheena Cotter[2]

[1]University of Cambridge, Cambridge, United Kingdom, [2]CSIRO Entomology, Perth, WA, Australia, [3]The University of Western Australia, Perth, WA, Australia

Investment in immunity is costly, so that resource-based trade-offs between immunity and sexually-selected ornaments might be expected. The amount of resources that an individual can invest in each trait will be limited by the total resources available to them. It would therefore be informative to investigate how investment in immune function changes during growth or production of the sexual trait as resources are diverted to it. Using the dung beetle, *Onthophagus taurus*, which displays both sexual and male dimorphism in horn size, we examined changes in one measure of immune function, phenoloxidase activity, in the haemolymph of larvae prior to, and during horn growth. We found that phenoloxidase levels differed between small and large horned males throughout the final instar prior to the point where investment in horn growth was taking place. PO levels in females were intermediate to the two male morphs. These differences could not be accounted for by differences in condition, measured as haemolymph protein levels and weight. We suggest that the observed differences might be associated with sex and morph specific variation in juvenile hormone levels.

The role of chemical cues on host selection by female sunflower moth, *Homoeosoma electellum* (Hulst) (Lepidoptera: Pyralidae), and banded sunflower moth, *Cochylis hospes* Walsingham (Lepidoptera: Tortricidae).

Maboko Mphosi, Stephen Foster

Agricultural Research Council, Potchefstroom, South Africa

The sunflower moth, *Homoeosoma electellum* (Hulst), and banded sunflower moth, *Cochylis hospes* Walsingham are important economic pests of cultivated sunflower, *Helianthus annuus* L., in North America. The role of chemical cues on female sunflower moth and banded sunflower moth host selection was investigated. *H. electellum* females used volatile chemical differences in order to distinguish between two different stages of sunflower heads. In contrast, *C. hospes* females do not appear to distinguish between the odours of the different head stages, but rather do so when in contact with the head. The presence of conspecific larvae on a head influenced oviposition by females, with females of both species laying fewer eggs on heads infested by conspecific larvae, than on uninfested heads. Larvae of both species also showed preferences for material from different stage sunflower heads, corresponding to the head stage they would normally feed on. *H. electellum* neonate larvae preferred florets from R5 heads over bracts from R2 heads, while *C. hospes* neonate larvae preferred bracts from R2 heads over florets from R5 heads. This study demonstrated that chemicals produced by different stages of sunflower are likely important for the selection of appropriate head stage by both adult females and larvae of both *H. electellum* and *C. hospes.*

Influence of biodiversity in the bio-control of African rice gall midge, *Orseolia oryzivora* H & G (Diptera: Cecidomyiidae)

E. O. Ogah, J. A. Odebiyi, F. E. Nwilene

Ebonyi State University, University of Ibadan, Africa Rice Centre (WARDA), IITA, Abakaliki, Ebonyi state, Ibadan Oyo State, Ibadan, Oyo State, Nigeria

Introduction: The bio-control of African rice gall midge (AfRGM) in the tropical rice over the past 30 years using *Platygaster diplosisae,* an indigenous endoparasitoid*,* has not given the desired results, despite high level of parasitism recorded. This has been attributed to late arrival of this parasitoid in the field. The current management efforts are directed at integrating biodiversity with bio-control agents.

Methods: We tested the hypothesis that diversifying the rice ecology will conserve *P. diplosisae* in alternative host, *Orseolia bonzii* in *Paspalum scrobiculatum* weeds, in the management of AfRGM. The strategy adopted in the study was to plant raised seedlings of *P. scrobiculatum* on a strip of land at the border of each plot one metre around it early in the season and allowed to be fully established before planting of the rice plants inside each plot. The control experimental plots were planted with only rice seedlings leaving the border empty without any weed. All infestations were natural. The responses of *P. diplosisae* to AfRGM infestations were monitored in two ecologies. The host transfer experiment to ensure that *P. diplosisae* can transfer from the alternative host to rice midge was conducted in a screen house.

Results: The results of the statistical analysis indicated that field diversification was the most important sources of early season peak of alternative host insects, which provided a highly consistent, abundant and well dispersed food sources for *P. diplosisae*. This allows parasitoid population to develop early in advance of rice pest population, thereby consistently keeping pests well below economically damaging levels. The host transfer experiment confirmed this result followed by the significant positive correlation recorded, which justifies its economic usefulness.

Conclusions: The results of the study therefore demonstrate the role of biodiversity in the management of AfRGM, and provide a mechanistic understanding of the important contribution of conservation in the bio-control of AfRGM.

Foraging behaviour of the African honey bee (*Apis mellifera adansonii*) on *Combretum nigricans, Erythrina sigmoidea, Lannea kerstingii* and *Vernonia amygdalina* flowers

Fohouo Fernand-Nestor Tchuenguem[1], Jean Messi [2], Dorothea Bruckner[3]

[1]*University of Ngaoundéré, Ngaoundéré, Cameroon,* [2]*University of Yaoundé I, Yaoundé, Cameroon,* [3]*University of Bremen, Bremen, Germany*

Introduction: In Cameroon, demand for hive products is growing. Honey and pollen yields are low in this country, partly because of the poor knowledge of the apicultural value of the flora. In orther to determine the apicultural value of *Combretum nigricans, Erythrina sigmoidea, Lannea kerstingii* and *Vernonia amygdalina*, a study of the activity of the African honey bee, *Apis mellifera adansonii*, were carried out on the flowers of these plant species, from December 2001 to May 2002, then from December 2002 to May 2003.

Methods: Flowers of each plant species were prospected at least four days per month, between 7 am and 6 pm, for the registration of the nectar and/ or pollen foraging behaviour of *A. m. adansonii* workers.

Results: *A. m. adansonii* harvested nectar of each plant species. In addition, *L. kestingii* and *V. amygdalina* were visited for pollen. The greatest number of workers foraging on a plant at the same time varied from 26 in *E. sigmoidea* to 4200 in *V. amygdalina*. *A. m. adansonii* workers were faithful to the flowers of each plant species. During foraging, *A. m. adansonii* increased the pollination possibilities of visited flowers.

Conclusions: Each of the studied plant species could be cultivated and protected to increase honey production. *L. kestingii* and *V. amygdalina* could enable beekeepers to increase their pollen production.

Sustainable management of pests of vegetable crops in Ghana with neem insecticides

Daniel Obeng-Ofori

University of Ghana, Legon, Accra, Greater-Accra, Ghana

Introduction: The production of vegetables is a major all-year-round agricultural activity of small and medium-scale farmers in Ghana and has a great potential to increase the income level and standard of living of growers. However, vegetable production is constrained by attack by insects, diseases, nematodes and the declining soil fertility, necessitating the use of high rates of pesticides and artificial fertilizers. Currently, the main method of controlling pests and diseases of vegetable crops is the use of synthetic pesticides. This sole dependency on pesticides to control pests is posing serious environmental and health problems. There is, therefore, the need to develop a sustainable and environmentally sound alternative pest management strategy to combat insect pests and diseases of vegetable crops in Ghana. Native to India and Burma, the neem tree, *Azadirachata indica* A. Juss was introduced to Africa earlier this century and is now well established in at least 30 countries, including Ghana where it has become an important source of fuel, lumber and biopesticide. Calneem oil is cold pressed, double filtered, pure and natural oil derived from high quality neem seeds, produced and marketed in Ghana by AQUA AGRIC Community Projects (AACP), Accra. It contains about 0.3% azadirachtin as its major active ingredient. It is a broad spectrum insecticide which is effective against several pests of vegetables, food crops, fruit and other tree crops.

Methods: The efficacy of different concentrations of Calneem oil and 'home made' neem seed extract against major pests of okra, cabbage, pepper, garden egg and cucumber were carried out in different locations in Ghana namely: Weja Irrigation Site, Ashman Irrigation Site and the University Farm, Legon.

Results: Both Calneem oil and 'home made' neem seed extract were effective in controlling the major pests of okra, cabbage, pepper, garden egg and cucumber. The major target species included the diamondback moth, fruit files, mealy bugs, aphids, pod borers, bud borers, bud worms, leafhoppers, plant bugs, beetles, grasshoppers and other defoliators. The neem products were also less harmful to some beneficial organisms such as certain ant species, lady bird beetles and dragon flies.

Conclusion: The practical utilization of neem insecticides for sustainable protection of vegetables against pest infestation in Ghana has been demonstrated in the field.

Herbivore-induced bottom-up trophic cascade

Takayuki Ohgushi, Shunsuke Utsumi

Center for Ecological Research, Kyoto University, Otsu, Shiga, Japan

Introduction: In ecological communities prey-predator interactions are potentially affected by the phenotypic plasticity of plants. If plant traits influence community structure of herbivores and predators, then the bottom-up effects would alter the outcomes of multiple prey-predator interactions. Insect herbivores induce a diversity of trait changes in plants, which, in turn, greatly affects the abundance and species richness of insect herbivores. These bottom-up effects produced by insect herbivores through changes in plant traits will extend upward to the third trophic level, altering the abundance and species richness of natural enemies.

Methods: we experimentally examined how the secondary regrowth of willows in response to the swift moth boring and artificial herbivory affects the abundance and species richness of higher tropic levels on three willow species.

Results: The swift moth boring and artificial cutting induced the rapid regrowth of lateral shoots followed by increased new leaves with high nutritious status. In response to the secondary regrowth, species richness and relative abundance increased not only in herbivorous insects but also in predators. Note that specialist herbivores increased in response to the secondary regrowth but generalists did not. Also, the numerical response of predators largely depended on predator taxa, such as ants and spiders.

Conclusions: We revealed the herbivore-induced bottom-up trophic cascade induced by swift moth boring and artificial herbivory. Feeding mode of herbivores and predator taxa are important in determining the community consequences of the herbivore-induced bottom-up trophic cascade.

What can chemical neuroanatomy tell us about signalling in the lamina of the *Drosophila* visual system?

Dick Nassel, Agata Kolodziejczyk

Stockholm University, Stockholm, Sweden

Synaptic connections of neurons in the *Drosophila* lamina, the most peripheral synaptic region of the visual system, have been comprehensively described. Thus the lamina is not only an excellent model for the development and plasticity of synaptic connections, but also a neuropil in which functional circuits can be analyzed with particular clarity. To unravel neurotransmitter circuits in the lamina of *Drosophila* we combined Gal4 driven green fluorescent protein in specific lamina neurons with antisera to g-aminobutyric acid (GABA), glutamic acid decarboxylase, a $GABA_B$ type of receptor, a vesicular glutamate transporter (vGluT), ionotropic and metabotropic glutamate receptors, choline acetyltransferase and a vesicular acetylcholine transporter. We furthermore analyzed distribution of serotonin and two of its receptors in the lamina. Whereas acetylcholine, GABA and glutamate appear to act within synaptic circuits of the lamina neuropil (classical short-range synaptic transmission), serotonin seems to signal non-synaptically by volume transmission. Surprisingly the two types of serotonin receptors were detected on glial cells in the lamina, not on neurons. The neuron-specific expression patterns of neurotransmitters and receptors will be discussed in the light of known synaptic connections and proposed visual processing elements.

Population structure and the conservation of bumblebees in western Europe

David Goulson, Gillian Lye, Ben Darvill

University of Stirling, Stirling, United Kingdom

Bumblebees (*Bombus* spp.) are among the most important pollinators in western Europe, but have undergone major declines in the last 60 years. We review causes of these declines, which can largely be attributed to changes in agricultural practices. However, populations of bumblebees continue to go extinct in protected areas which have not been directly affected by agricultural change. Recent molecular studies have revealed much about the population structure of declining bumblebee populations. These data suggest that many surviving populations may be doomed to extinction through breakdown of metapopulation structure and the effects of inbreeding, the latter exacerbated by the social nature of bumblebees which renders their effective population size low (most bees are sterile workers). It has become clear that effective conservation of bumblebees requires concerted action at a landscape-scale, and that most existing nature reserves are too small to conserve viable populations of bumblebees in the long term. Strategies for the conservation of bumblebees in Europe are discussed.

A fixed spray system for applying pesticides to high-density apple plantings

Arthur Agnello, Andrew Landers

Cornell University, Geneva, New York, United States

Introduction: Pesticide application to tree fruits using airblast sprayers can be inefficient and inaccurate, resulting in spray drift, off-target contamination, and ineffective pest control. A spray system fixed into the tree canopy was used to apply all seasonal pesticide sprays to a commercial planting and compared with results using a conventional sprayer.

Methods: A high-density Gala apple planting received all its pesticide and thinning sprays through a system of microsprinkler nozzles attached to polyethylene tubing running through the row middles and supplied by a central tank and pumping station. Insect and disease control, thinning results, and spray deposition data were compared with those taken in a section of the orchard treated using a tractor pulling an airblast sprayer.

Results: Sprays were applied quickly and efficiently, each taking only a few minutes to completely cover all the trees in the fixed-spray section of orchard. In-season sampling sessions revealed identical zero-damage levels in both spray treatments from leaf- or fruit-infesting insects. The fruit harvest evaluation showed comparable levels of clean fruit (96-97%) in the two halves of the block, with the fixed-spray half receiving slightly more late leafroller damage, and the grower's comparison showing more apple maggot and plum curculio damage. Spray deposition in different canopy sectors, as measured by a dye tracer, was comparable using the fixed-spray or airblast application methods.

Conclusions: A fixed nozzle plus tubing arrangement could offer benefits in pesticide application efficiency and accuracy while maintaining crop protection efficacy and production quality in modern apple plantings.

Functional and phylogenetic implications of the sting apparatus of solitary wasps

Silke Mosel, Michael Ohl

Museum of Natural History, Department of Research, Berlin, Germany

The sting apparatus of solitary wasps is one of the most prominent apomorphic characters of the Aculeates. It is of importance for an understanding of phylogenetic and evolutionary processes of the aculeate Hymenoptera. Derived from the ovipositor it serves as a tool for prey paralysis in addition to its defense function. It can be presumed that the sting apparatus has evolved in close functional association to its specific biological meaning, for example in adjustment to reproduction strategies. Apoid wasps exhibit a great diversity of foraging and parental behaviours as well as a great variation of morphological characters. Modifications of the sting apparatus may be expected to result from variation in the prey utilized and the precision of the stinging action. These modifications are particularly pronounced in the shape and structure of the stylet and lancets and may reflect a correlation with the mobility and physical strength of the prey. The presence of barbs on the distal parts of the lancets can be correlated with a less sclerotized body wall of the prey. This morphological diversity can be found on all systematic levels and is of great significance for the phylogeny of solitary wasps. A representative set of morphological characters taken from the sting apparatus has been examined. A comprehensive cladistic analysis based on these characters was performed in order to investigate the relationships among apoid wasps. The results combined with the different behavioural strategies will give rise to a scenario of the evolution of the sting apparatus of solitary wasps.

Vibrational communication in the new insect order Mantophasmatodea

Monika J. B. Eberhard[1], Mike D. Picker[2], Guenther Pass[1]

[1]Department of Evolutionary Biology, Faculty of Life Sciences, University of Vienna, Vienna, Austria, [2]Zoology Department, University of Cape Town, Rondebosch 7700, Cape Town, South Africa

Introduction: In Mantophasmatodea, both sexes produce vibrational communication signals. Two sympatric species, *Karoophasma biedouwensis* and an undescribed species, were used to determine the role of communication in a) species identity and b) potential mate location.

Methods: Vibrational signals were recorded from laboratory-reared adults drumming directly onto the membrane of a loudspeaker. The digitized signals were analyzed using Sound Forge Software and were used in one-sided stimulation playback experiments. The responses of males and females to different calls were monitored on a Y-shaped apparatus.

Results: Each sex produced a distinctive call. The female call consisted of repeated single pulses, whereas the more complex male call comprised repeated pulse trains. The calls of males and females of the two species were of similar general structure, but differed in most temporal characters such as pulse and pulse train repetition time. Females reacted to the call of conspecific males by calling and becoming less active, but did not react to the call of heterospecific males. Males exhibited abdominal rubbing, high tapping rates, increased activity and characteristic searching behaviour at the fork of the Y apparatus when presented with the call of a conspecific female. These responses were significantly depressed when males were stimulated with the call of a heterospecific female, or of a conspecific male.

Conclusions: Temporal features of the vibrational signals used by duetting male and female Mantophasmatodea convey cues for both mate location and species recognition.

Coexistence of *Aphidius* species: Does interspecific competition structure the parasitoid community?

Joan van Baaren, Cécile Le Lann, Pauline Le Guigo, Liliane Krespi, Yannick Outreman, Jean-Sébastien Pierre, Jacques van Alphen

[1]*University of Rennes 1, Rennes, France,* [2]*Agrocampus Rennes, Rennes, France*

Introduction: Three species of *Aphidius* parasitoids exploit the wheat aphid *Sitobion avenae* in western Europe. *Aphidius rhopalosiphi* is a habitat specialist and the only species present in wheat fields in winter. It is the commonest species throughout spring. Two generalists, *A. avenae* and *A. ervi,* invade wheat fields by the end of spring. Wheat aphids defence themselves actively when attacked by parasitoids and emit alarm pheromone when attacked.

Methods: Behavioural analyses of interspecific host discrimination, competition, patch exploitation were realized.

Results: *A. rhopalosiphi* is sensitive to host defensive behaviour, and exploits host patches only partially. *Aphidius avenae* displays a particular behaviour, with wing fluttering before attacking a host, which results in suppression of defensive behaviour. This allows them to exploit patches with alerted aphids abandoned by *A. rhopalosiphi*. *Aphidius ervi* has a fecundity twice that of *A. rhopalosiphi*, is less sensitive to the host defence behaviour and is a better competitor than *A. rhopalosiphi* in multi-parasitized hosts. Interactions between *A. avenae* and *A. ervi* are limited due to the low densities of these species. When females of the three species encounter each other in a host patch they display no aggressive behaviour to each other.

Conclusions: We showed that the three species can coexist with little overlap in host use, because they have different phenologies and densities, different host exploitation strategies and different life histories.

Spatial co-occurrence networks couple with DNA analysis to reveal the dynamics and feeding histories of polyphagous predators

James R. Bell, R. Andrew King, David A. Bohan, William O.C. Symondson

[1]Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, United Kingdom, [2]Cardiff School of Biosciences, Cardiff University, Biomedical Sciences Building, Museum Avenue, Cardiff CF10 3US, United Kingdom

Explaining the relationships between complex polyphagous feeding histories and pest suppression is essential for sustainability in those agricultural systems that rely heavily on the role of beneficial invertebrates for pest control. For some time it has been argued that univariate predator-prey relationships may be an abstract and simplistic model of polyphagous predator behaviour. Selection may therefore have led to the evolution of patterns of behaviour or prey detection systems that require multivariate approaches. In this presentation we demonstrate the utility of a spatially explicit, ecological-network model that uses spatial co-occurrence to link above-ground and below-ground species in winter wheat. In addition, we include extra layers for within-field environmental gradients. Spatial co-occurrences were computed for all pairwise relationships between polyphagous beetles and spiders and key pests, which included orange blossom wheat midge, slugs and aphids and a range of alternative prey that have either beneficial (e.g. worms) or negligible (e.g. springtails) effects on crop production. From these spatial co-occurrences we infer important interactions between species groups and effects on winter wheat productivity, with support from DNA analysis of the gut contents of selected predators.

Unraveling a chalcidoid wasp complex associated with galls in the seed capsules of *Eucalyptus camaldulensis* in South Africa

Hildegard Klein[1], Stefan Neser[1], Ottilie Neser[1], John Hoffmann[2]

[1]*Agricultural Research Council, Plant Protection Research Institute, Pretoria, South Africa,* [2]*University of Cape Town, Cape Town, South Africa*

Introduction: Five chalcidoid species were reared from galls in the flower buds and seed capsules of river red gum (*Eucalyptus camaldulensis*) in South Africa: *Megastigmus zebrinus* (Torymidae: Megastigminae); *Quadrastichodella nova*, *Aprostocetus* sp., and two species belonging to different, undescribed genera (all Eulophidae: Tetrastichinae). All five species are probably inadvertent introductions from Australia. Both *M. zebrinus* and *Q. nova* were previously described as gall inducers elsewhere. We aimed to determine the roles of each of the five species (gall inducer, parasitoid or inquiline) and the impact of galling on seed numbers.

Methods: Hymenopterans found as juveniles during dissection of, or reared from, flowerbuds and seed capsules of *E. camaldulensis*, were recorded, and correlated with the development stage of tagged flower buds and capsules. Gene sequencing was used to match juveniles with adults. The oviposition behaviour of wasps was observed in the laboratory. The insects were also sleeved on reproductive shoots on the trees, and the ensuing capsules examined for galling. Viable seed numbers were plotted against gall numbers per seed capsule.

Results: Two of the chalcidoid species had distinct emergence peaks, and the others emerged throughout the year. Some species diapaused for a year or longer. The biological role of some of the insect species could be deduced. Capsules containing more than one gall produced hardly any viable seeds.

Conclusions: Present indications are that only *Q. nova* initiates galls, which originate in the placenta. No indication of endoparasitism was found, and at least one of the species is entomo-phytophagous.

Application of statistical models for efficient monitoring of invasive insects

Gudeta Sileshi, Gerson I. Nyadzi

[1]World Agroforestry Centre (ICRAF), Lilongwe, Malawi, [2]UN Millennium Villages Project, Tabora, United Republic of Tanzania

Introduction: Rapid and accurate estimation of abundance patch occupancy is critical to understanding the spatial and temporal dynamics of invasive insects and their management. An inherent problem associated with monitoring small and often abundant species is the time and resources required to collect a sufficient number of sampling units to obtain a reliable estimate of abundance or patch occupancy (occurrence probability).

Methods: This paper describes a synthetic method for estimation of abundance and occupancy of invasive insects. The method uses nonlinear mixed modelling (NLMM) approach for estimating parameters of abundance and occupancy as functions of environmental covariates. It also applies conventional and non-standard occupancy–abundance models to estimate abundance from presence-absence data.

Results: The proposed approach allows rigorous testing of adequacy of habitat models and more realistic predictions of abundance from records of presence-abundance for zero-inflated, time-series and clustered data. Parameter estimation and statistical inference are demonstrated using field data on the invasive species *Heteropsylla cubana* collected in Zambia and Tanzania. Potential applications of the approach in large-scale monitoring of site colonization and establishment by alien invasive species are also discussed.

The genetic basis of a plant–insect coevolutionary key innovation

Heiko Vogel[1], Hanna Fischer[1], Cristopher Wheat[2]

[1]Max Planck Institute for Chemical Ecology, Jena, Thuringia, Germany, [2]Pennsylvania State University, PA, United States

The unresolved central tenet of Ehrlich and Raven's theory is that evolution of plant chemical defenses is followed closely by biochemical adaptation in insect herbivores, and that newly evolved detoxification mechanisms result in adaptive radiation of herbivore lineages. Using one of their original butterfly-host plant systems, the Pieridae, we identify a pierid glucosinolate detoxification mechanism, nitrile-specifier protein (NSP), as a key innovation. This unique host adaptation system, not based on universal detoxifying enzymes (eg P450), offers the opportunity to serve as a model system to study molecular evolution events leading to the gain of new traits. Butterfly NSP activity matches the distribution of glucosinolates in host plants across Pieridae. Moreover, by using five different temporal estimates, NSP seems to have evolved shortly after the evolution of the host plant group (Brassicales) (10 Myr). An adaptive radiation of these glucosinolate-feeding Pierinae followed, resulting in significantly elevated species numbers compared with related clades. Mechanistic understanding in its proper historical context documents more ancient and dynamic plant–insect interactions than previously envisioned. Moreover, these mechanistic insights provide the tools for detailed molecular studies of coevolution from both the plant and insect perspectives.

Natural repellents from human hosts against biting insects

James Logan[1], Michael Birkett[1], Gregor Devine[4], Ahmed Hassanali[3], A. Jennifer Mordue[2], Elvira Perea[5], John Pickett[1]

[1]Rothamsted Research, Biological Chemistry Department, Harpenden, Hertfordshire, United Kingdom, [2]Aberdeen University, Aberdeen, United Kingdom, [3]International Centre of Insect Physiology and Ecology, Nairobi, Kenya, [4]Naval Medical Research Center Detachment, Trujillo, Iquitos, Peru, [5]Laborotorio Referencial, Direccion de Salud, Iquitos, Peru

Introduction: Haematophagous insects show differential behavioural responses to odours from individual human hosts with some hosts being much less attractive than others. Such hosts are known to produce compounds that attract haematophagous insects as well as compounds that can interfere with host attraction. In a previous study, we identified behaviourally-active compounds that are associated with low human attractiveness to mosquitoes and midges. These compounds significantly affect host location behaviour and cause a reduction in flight activity of host-seeking female mosquitoes in behavioural studies.

Methods: Recently, we have tested several putative human-derived repellents in laboratory and field trials, as topically applied repellents, against several species of biting flies, including *Anopheles*/*Aedes/Culex* spp. mosquitoes and *Culicoides* spp. midges. Single compounds and mixtures (including different combinations and specific ratios) were tested in dose response assays. Additionally, we have investigated the potential of using the compounds as spatial repellents in a chemical dispenser, which maintains ratio integrity of the active compounds upon release.

Results: Two of the human-derived compounds, released in the correct ratio, show effective topical and spatial repellency against mosquitoes and midges. Despite the high volatility of the active compounds, some persistence over time has been achieved.

Conclusions: This study provides an insight into how biting insects respond to naturally produced human-derived repellent compounds, and how such compounds could be exploited as new, topically applied or spatial repellents.

On the frontier of risk management: Potential nontarget effects of classical biocontrol agents stimulate innovation by entomologists in the U.S.A.

Keith Douglass Warner, Waide Hicks

Santa Clara University, Santa Clara, California, United States

Introduction: Biological control practitioners worldwide now encounter difficulties obtaining permits to import exotic control agents due to nontarget concerns. Practitioners in the U.S.A. have devised strategies, individual and collective, to address risk concerns.

Methods: Bibliometric analyses and semi-structured interviews with U.S. practitioners, critics and regulators provided data describing how entomologists have responded to concerns regarding potential nontarget effects.

Results: Entomologists report developing: new molecular analytical tools to identify sub-species of candidate control agents, new rearing methods which make more natural enemies available as classical biocontrol agents, new partnerships with international scientists to conduct nontarget studies of agents in their countries of origin, and new modeling strategies to understand probable specificity of action on hosts. Practitioners repeatedly referred to the international code of conduct for weed biocontrol, and arthropod biological control practitioners are considering one. Many individual practitioners are increasing public outreach about their work and responding to public interest in proposed agent introductions.

Conclusion: Concern about risks associated with nontarget impacts of introduced control agents has prompted changes in practice by individuals, their laboratory groups, and research-sponsoring organizations. These have generally been voluntary in character, but some policy development is occurring as well. Entomologists also report conducting public outreach efforts. Nontarget concerns have been acute in the U.S.A. and will likely become more so in other countries. The innovations developed here may be applicable to other entomologists confronting concerns about the risks of nontarget effects.

Potential leafhopper vectors associated with potatoes in Alaska

Alberto Pantoja[1], Aaron M. Hagerty[1], Susan Y. Emmert[1], Joseph Munyaneza[2]

[1]United States Department of Agriculture, Agricultural Research Service, Fairbanks, Alaska, United States, [2]United States Department of Agriculture, Agricultural Research Service, Wapato Washington, United States

Leafhopper transmitted phytoplasma diseases are an emerging problem for potato and vegetable producers in the conterminous United States of America (USA)**.** Due to its geographical isolation and climatic constrains, Alaska is considered relatively free of diseases and insect pests. Potato growers in the state are exploring the potential of producing seed potato for export. However, the biology of agricultural insect pests in the circumpolar region is lacking or poorly understood. Research conducted from 2004 to 2006 in the main potato (*Solanum tuberosum* L.) production areas of Alaska resulted in the identification of 33 leafhopper species associated with agricultural settings. Fourteen species were associated with potato. Two species, *Macrosteles facifrons* (Stål) and *Davisonia snowi* (Dorst) made up approximately 60% of the total number of individuals collected. Four of the species collected are known vectors of phytoplasma diseases of potatoes and other agricultural crops or have the potential to cause mechanical damage to potatoes. Data on vectoring capacity, population dynamics, and geographic distribution will be presented.

Resistance and physiological differences among three species of stored product beetle pests exposed to diatomaceous earth

Charles Adarkwah, Paul. G Fields, Christoph Reichmuth, Carmen Buttner, Daniel Obeng-Ofori

Humboldt University of Berlin, Berlin, Germany

Dosages of diatomaceous earths (DE) killed approximately 70% of the beetle populations. DE-susceptible and DE-tolerant adult insects were compared for: water loss, speed of movement and progeny production. For all the tests, the diatomaceous earth Protect-It™ was used at the following dosages and exposed for 7 days**:** red flour beetle *Tribolium castaneum,* 0.6 g/kg wheat; rice weevil *Sitophilus oryzae,* 0.3 g/kg wheat and rust-red grain beetle *Cryptolestes-ferrugineus*, 0.15 g/kg, wheat respectively. The use of different dosages reflected the different susceptibilities of the three species towards the DE.

Tolerant strains lost significantly less water when exposed to DE-treated grain; they moved more quickly through grain and two tested insect species, *Tribolium castaneum* and *Sitophilus oryzae* produced less progeny. Tests with measurements of the movement and activity in Petri dishes were similar to the movement through grain for *T. castaneum*, but not for the other two species. If this level of increased tolerance towards exposure to DE was present in insect populations found in commercial stores, it would probably cause control failures. However, if tolerant species produced fewer offspring, as in these strains, tolerant strains would probably diminish with time.

Insects in western art

Marcel Dicke

Wageningen University - Laboratory of Entomology, Wageningen, Netherlands

Insects have been a source of inspiration to artists throughout the centuries. From the 13th century until present artists have depicted insects in two-dimensional and three-dimensional works. Insects have often been used as symbols for the brevity of life, for the transcendence of the soul, but also because of the beauty of their forms and colours. Some artists paint or sculpt with insects themselves, either dead or still alive.

Over the past seven years I have visited 180 art museums and recorded the representation of insects in the works on display. As a result I have gained an entomological view of the history of art. This has provided insight both in the history of art itself as well as in the role of insects in its development.

At present I have seen more than 3,700 works of art in which insects are represented. The majority occur in the Netherlandish still-lifes of the 17th and 18th centuries, in surrealistic works and in art nouveau works. Some artists have depicted only a single insect while others have represented over 100 insects in a single work of art. Of some artists I know only a single work with insects, while of others more than 100 works are known.

The value of omics to community ecology

Marcel Dicke

Wageningen University - Laboratory of Entomology, Wageningen, Netherlands

Insects comprise the most diverse group of organisms that attack plants and plants have evolved a diverse array of induced defenses against insects, including direct and indirect defenses. These defenses can be investigated at various levels of biological organization and integrating such approaches from genes to community ecology is an exciting challenge to biologists. Recent developments have shown a rapid expansion of mechanistic knowledge of plant-insect interactions in terms of induced resistance and induced attraction of carnivorous enemies of herbivorous insects. In the laboratory the effects of certain genes on individual plant-insect interactions can be investigated. An exciting development is that plants that have been altered in the expression of specific genes involved in induced defenses are exposed to their natural ecological community. By integrating approaches aimed at understanding subcellular mechanisms with those on addressing ecological functions in a natural environment the field of molecular ecology of insect-plant interactions is rapidly expanding our understanding of the intricate phenotypic plasticity that plants exhibit in their contest with the large number of herbivorous insect species. In this presentation the added value of integrating transcriptomics, metabolomics, phenomics and community ecology will be highlighted.

Using GM to enhance bodyguard attraction in crops

Marcel Dicke

Wageningen University - Laboratory of Entomology, Wageningen, Netherlands

Almost half of all insect species are carnivorous and attack herbivorous insects. Thus, plants are surrounded by a multitude of potential bodyguards. In crop protection two main strategies are employed, i.e. (i) host plant resistance aimed at making plants that are toxic or repellent to herbivorous insects and (ii) biological control aimed at releasing the best natural enemy of an insect pest. Plants generally respond to herbivory with the production of volatiles that attract carnivorous insects such as parasitoids or predators as bodyguards. This allows for plant breeders to select for plants with an enhanced attraction of bodyguards through classic methods. Moreover, now that genes underlying the biosynthesis of bodyguard attractants are being uncovered (e.g. Kappers et al. 2005, Science 309: 2070-2072; Schnee et al. 2006, PNAS 103: 1129-113), also genetic modification may be used to produce crops with enhanced bodyguard attraction. In this presentation I will highlight the potentials and the questions related to this new development.

The biological significance of the shape of magnetic termite mounds

Judith Korb[1], Peter Jacklyn[2], Anna Schmidt[1]

[1]University of Regensburg, Regensburg, Germany, [2]Charles Darwin University, Darwin, Australia

The “Magnetic Termite” *Amitermes meridionalis* is restricted to a small part of northern Australia where it occurs in seasonally flooded areas and builds famous wedge-shaped mounds with an elongated axis that is orientated in a striking north-south direction. This shape is unique among all other termite mounds which are always more or less radially symmetrical and many hypotheses have been advanced to explain the remarkable shape and orientation. Most of these investigations focus on the orientation, but the biological significance of the shape is rarely explored. The currently accepted hypothesis considers shape and orientation as adaptation to maintain a thermo-stable eastern face. We tested the importance of seasonal flooding to explain the unique shape of these mounds. We hypothesized that elongated mounds with a large surface area and thin walls offer more favourable conditions (a) to dry the grass storage, on which the termites depend during the floods, (b) to increase mound stability by drying the mounds quickly after heavy rainfalls, and (c) to facilitate respiratory gas exchange when dampness decreases the porosity of the walls. These hypotheses were tested by manipulating mound shape and ambient temperature conditions to test their influence on the termite colonies. The results of this still ongoing project will be presented.

Spatial and temporal patterns in the abundance of beech bark disease-associated organisms in North America: evidence for negative feedback within the subcontinental landscape

Jeff Garnas[1], Celia Evans[2], Mark Twery[3], David Houston[4], Matthew Ayres[1]

[1]Dartmouth College, Hanover, NH, United States, [2]Paul Smiths College, Paul Smiths, NY, United States, [3]USDA Forest Service, Burlington, VT, United States, [4]USDA Forest Service, retired, Danville, VT, United States

Beech bark disease (BBD) in North America is a cankering disease complex of American beech (*Fagus grandifolia* Ehrh.) arising from the association of an introduced scale insect (*Cryptococcus fagisuga* Lind.) and one of several species of ascomycete fungi of the genus *Neonectria*. To test alternative hypotheses regarding the epidemiology of beech bark disease, we evaluated spatial patterning in populations of the insect and fungus at three different spatial scales: (1) trees within stands, (2) stands within forests, (3) forests within the subcontinental landscape. We found no evidence for spatial autocorrelation at either of the two smallest spatial scales; trees and stands that were close together were no more likely to harbor similar population densities of scale insects or fungi than those farther apart. Across the landscape however, disease agent populations were significantly related to the estimated time since local introduction of BBD organisms to a stand. Scale insect densities peak soon after infection and decline thereafter, whereas fungal densities are highest in long-infected stands and forests. This indicates that disease ontogeny follows a predictable trajectory and suggests the existence of negative feedback among the associated organisms at a broad spatiotemporal scale. This finding contradicts the conventional wisdom that BBD associates function as mutualists. Instead, it raises the possibility that the fungal symbiont is actually an antagonist at the scale of the landscape and may therefore mitigate the long-term effects of the disease on North American forests.

Mapping *Drosophila* color-vision circuits

Chi-Hon Lee, Shuying Gao, Chun-Yuan Ting

NIH, Bethesda, MD, United States

Introduction: *Drosophila* color vision is mediated by three types of photoreceptor neurons, each of which has a distinct spectral response. Visual information gathered by all three types of R-cells converges to the medulla ganglion. The post-receptoral mechanism by which color information is processed in the medulla is not known.

Methods: By combining molecular genetic, histological, and behavioral approaches, we determined (a) the connection patterns of the first-order interneurons in the medulla, (b) their dendritic and axonal compartments, and (c) their expression of neurotransmitters and receptors, and (d) their requirement for discriminating different wavelengths of lights.

Results: We analyzed five types of the first-order interneurons, including one distal medulla cell type (DM5) and four types of transmedullar neurons (projection neurons). The projection neurons extend dendritic arbors in specific medulla layers and project axons to the lobula neuropil to form a topographic map. The projection neurons, including TM5 and TM20, appear to receive inputs from two color-channels, suggesting that they might function as color-opponent or summation neurons. The DM5 neurons, which receive direct inputs from multiple R7s, are required for ultraviolet phototaxis behavior.

Conclusions: The flies' innate preference to ultraviolet light is driven by a single subset of neurons. True color vision might be mediated separately by the color-opponent/summation neurons, which directly output to the higher visual center lobula.

Surfactants, but not fatty acid amides contribute to caterpillar defence against predators

Michael Rostás[1], Katrin Blassmann[2]

[1]University of Würzburg, Würzburg, Germany, [2]University of Basel, Basel, Switzerland

Introduction: Plants respond to insect attack by releasing volatile organic compounds that attract the herbivores' natural enemies. Fatty acid amides are potent elicitors of such plant volatiles and have been isolated from the oral secretions of caterpillars. The question why herbivores produce these elicitors, despite the negative selection pressure, remains obscure. We assessed the role of fatty acid amides as potential defence compounds against predators because regurgitation of oral secretion is a widespread mode of self-protection in many caterpillars. Commonly, the effectiveness of herbivore oral secretion has been ascribed to the presence of deterrent secondary metabolites sequestered from the host plant. However, this notion also implies that generalists are particularly vulnerable on plants with low levels of chemical defences. A defensive function of ubiquitous primary compounds such as fatty acid amides could resolve this dilemma.

Methods: A combination of contact angle measurements to assess the physicochemical properties of oral secretion and behavioural assays using caterpillars of *Spodoptera exigua* were applied to test the hypothesis that amphiphilic fatty acid amides in the oral secretion provide protection by wetting the hydrophobic cuticle of predatory ants and forcing the attacker to engage in intensive cleansing.

Results: Our data confirm that surfactants alone can sufficiently explain the defensive character of oral secretion and we speculate that this novel mechanism may be widespread among caterpillars. However, proteins rather than fatty acid amides caused the wetting effects.

Conclusons: Detergency can provide a base level of protection which may or may not be further enhanced by plant-derived secondary metabolites.

Managing harvester termites: the ecosystem approach

Jannette Mitchell

ARC-PPRI, Pretoria, South Africa

The harvester termite, *Hodotermes mossambicus*, is an important component of semi-arid grassland ecosystems of southern and eastern Africa where it occupies a central position in the food chain. It has a wide range of natural enemies, many of them highly specialised. Harvesting is most intense during winter months when little other prey is available. When predators are present in sufficient numbers their impact on the foraging worker population is potentially enormous. Termite populations fluctuate depending on rainfall. Populations are low (± 9,000 workers/ha/yr) following seasons of above average rainfall, while following dry summers numbers can be as high as ± 0.26 x 10^6/ha/yr. Eruptive population growth with consequent high off-take of grass during seasons of low primary productivity brings termites into competition with large herbivores (domestic stock and game). High termite populations also remove all litter, exposing the soil surface and leading to compaction, low infiltration, erosion and loss of nutrients. Ignorance of ecosystem functioning has resulted in mismanagement of these grasslands. Declining predator numbers were also noted as early as the 1930's. These factors favour the development of large residual populations in degraded areas.

Evidence suggests that seasonally appropriate management of herbivore numbers, adequate grassland restoration and conservation measures, and even reintroduction of a suite of predators suited to the area may prove beneficial tools for the management of termite infestations in rangeland. The use of poison bait in areas of high residual population at appropriate times may need to be part of a successful management strategy.

SPLAT formulations: Optimization of semiochemical IPM tools

Agenor Mafra-Neto, Reginald Coler

ISCA Technologies, Inc, Riverside, California, United States

Introduction: SPLAT is a semiochemical technology that has spawned a series of new insect control agents that have been marketed or are going to be marketed in the near future, with the promise of being highly efficacious, compatible with biological control agents, and exhibiting low environmental impact thus making them excellent candidates for integrated pest management programs. We will introduce to the public several of the current SPLAT formulations and describe their modes of application and resulting modes of action. The novel SPLAT formulations their uses in integrated pest management programs will be discussed.

Results: SPLAT is a monolithic and long lasting formulation, but it is amorphous and flowable, allowing for easy mechanization of its application. SPLAT is rainfast and biodegradable. SPLAT has been formulated with different active ingredients, including insecticides and semiochemicals, and successfully biologically and chemically tested both in the laboratory and in the field. Mechanization allows the application of the same mass of SPLAT in either a few large point sources that last for a very long time in the field, or in a multitude of very small point sources allowing management of high density populations. It is possible, therefore, to use SPLAT applications to achieve the density of point sources necessary to control insect pest populations at the density that they are found in the field. This plasticity has allowed SPLAT to be successfully used as a mating disruption agent as well as an attract and kill agent in field trials around the world, which in turn has resulted in a host of successful commercial products.

Conclusions: SPLAT is a long lasting, flowable formulation that allows for easy mechanical application, thus increasing the utility and commercial feasibility of semiochemical pest control formulations.

Amalgamative action of phytoextract and synthetic insecticide against the larvae of the filaria vector, *Culex quinquefasciatus*

Lalit Mohan, Preeti Sharma, C. N. Srivastava

Dayalbagh Educational Institute (Deemed University), Dayalbagh, Agra, Agra, India

Mosquitoes are referred as “Public Enemy Number One”, by WHO, 1996, due to the most common and nuisance-creating dipteran-vector responsible for transmitting various dreadful diseases. It continues to pose the major public health problems in India as well as in other countries with resurgence of chiefly malaria, encephalitis and dengue fever.

Chemical insecticides used in mosquito management, though are quite effective but have some drawbacks like environmental pollution, toxic to non-target organisms and emergence of resistant vector varieties. This deleterious effect caused by the insecticidal applications encouraged the scientific professionals towards the development and advancement of novel, ecofriendly and non-hazardous insecticides of plant origin. Plant products are successfully tested for various biological control activities of different insect pests but the availability and development of bio-pesticides are so far limited. For the effective field applications of phyto-pesticides, plant materials are required in huge quantity to get sufficient amount of the phyto-pesticides. In recent years, the scientists related to pest management have, therefore, diverted their approach from the application of either pure synthetic pesticides or pure phyto-pesticide towards the combined application of both for more effective vector management. In the present correspondence, it is a step forward in the direction of combined application of *Solanum xanthocarpum* and Temephos for the control of *Culex quinuefasciatus* larvae.

Effect of temperature on toxicity and persistence of *Artemisia annua* against *Anopheles stephensi* larvae

Preeti Sharma Rawat, Lalit Mohan, C. N. Srivastava

Dayalbagh Educational Institute, Agra, Uttar Pradesh, India

Synthetic insecticides, on account of their efficiency and fast action, have been constantly used all over the world for more than five decades. It has led to the series of problems of precipitation of resistance in the vector population jeopardizing all important insect control programmes worldwide. In addition, the danger of environmental contamination related with persistence and high toxicity of these insecticides has necessitated the search for newer methodologies in various insect control programmes. The alternative advances in this direction are towards the selection of ecofriendly and cost effective pesticides and propagating the idea of using effective biodegradable chemicals of plant origin. Botanical pesticides in general, possess low mammalian toxicity and thus constitute least health hazards and environmental pollution and there is practically no risk of developing pest resistance to these products, when used in natural forms. Further, these cause less hazards to non-target organisms and insect resurgence has not been reported except synthetic pyrethrins. In view of these facts, under the present study, an attempt has been made to study the larvicidal activity of certain botanical extracts against the vector for urban malaria in India.

Further, the effect of temperature, a very important physical parameter affecting the activity of chemical and botanical insecticide, has been investigated for *Artemisia annua*, one of a potent extract, against the anopheline larvae. The extract was found to be stable within the temperature range of 15-30 ^{0}C. However, above 30 its efficacy was reduced depicting biodegradable the effect of temperature on this botanical insecticide.

Multiple origins of social parasitism in the bee subgenus *Dialictus* (Halictidae: *Lasioglossum*) identified using morphology and DNA barcodes

Jason Gibbs, Laurence Packer

York University, Toronto, Ontario, Canada

Introduction: The sweat bee subgenus *Dialictus* displays an incredible array of social systems and is an ideal group for studying the evolution of social behaviour. Solitary, communal, primitively eusocial and socially parasitic behaviours have been identified. We take advantage of the large numbers of DNA barcodes currently being generated for alternate purposes to examine the evolution of social parasitism in these bees using a phylogenetic approach.

Methods: DNA barcode and morphological data were analysed in isolation and in combination using TNT to generate most parsimonious phylogenetic trees of North American *Dialictus* species. Character mapping was used to examine the origin of social parasitism in this group.

Results: Phylogenetic analyses of morphology and DNA barcodes used with character mapping suggest that social parasitism has arisen multiple times in the subgenus *Dialictus.* The origins of parasitism in *Dialictus* follow the loose form of Emery's rule (ie. parasites are not sister taxa to their hosts). DNA barcode data provides superior resolution of the phylogeny to morphology alone.

Conclusions: Current DNA barcoding efforts are generating a pool of data that may be utilized to aid in phylogenetic inference and improve the density of taxonomic sampling. Since DNA barcoding is in many ways external to mainstream systematics, these data might be used to improve phylogenies at essentially no cost. The discovery that *Dialictus* species have evolved a parasitic lifestyle multiple times may generate new avenues of research into the evolution of social systems in the sweat bees.

Estimating the economic injury level and the economic threshold for the use of α-cypermethrin against the sugarcane borer, *Eldana saccharina* Walker (Lepidoptera: Pyralidae.)

Graeme Leslie

South African Sugarcane Research Institute, Mt Edgecombe, Kwa Zulu - Natal, South Africa

Introduction: The sugarcane borer *Eldana saccharina* Walker (Lepidoptera: Pyralidae) is the most serious pest of sugarcane in South Africa. Approaches to control comprise several practices including insecticide use. To enable more effective management of insecticide use, estimates the Economic Injury Level (EIL) and the Economic Threshold (ET) were developed.

Methods: Five years of results from field–scale insecticide trials assessing the value of α–cypermethrin (Fastac®) against this pest, were used to estimate the EIL and ET. The analysis was based on estimates of borer damage (percent internodes bored) and larval numbers, and the impact of these on crop yield, as estimated by percentage recoverable sugar (ERC%) and tons ERC /ha.

Results: The estimated EIL, based on percent internodes bored and ERC%, was more reliable than estimates based on larval numbers and ERC% and was calculated to be 6.3%IB (± 1.00) or 7.9% IB (± 1.24), depending on the level of treatment efficacy selected (50% and 40% respectively). Where tons ERC/ha was used, estimated EIL was 8.3% IB (± 1.51) or 10.5% IB (± 1.88) for efficacy levels of 50% and 40% respectively. Least reliable were estimates based on larval numbers. Using estimates of damage accumulation over time, the ET, based on %IB and ERC%, was estimated to be 3% IB, assuming a 40% treatment efficacy.

Conclusions: The EIL and ET were estimated to be 7%IB and 3%IB respectively, derived from data on crop damage. Such estimates provide measures that can aid in deciding whether or not the use of an insecticide is justified.

Plant-mediated interactions between rhizobacteria, herbivorous insects and parasitoids

Si-Jun Zheng[1], Jeroen P. van Dijk[2], Anna Costa[1], Marcel Dicke[1]

[1]Laboratory of Entomology, Wageningen University, Wageningen, Netherlands, [2]RIKILT-Institute of Food Safety, Wageningen University and Research Centre, Wageningen, Netherlands

Plants are members of complex communities. Yet, most studies of plant defences against herbivorous insects are made in simple systems usually consisting of the plant and the herbivorous insect and one of its natural enemies. It is well-known that non-pathogenic rhizobacteria can influence aboveground anti-pathogen defences. To understand whether and how anti-insect defence is affected by rhizosphere microorganisms, a multitrophic system consisting of microorganism-plant-herbivore-parasitoid interactions was established. The system consists of two caterpillar species, i.e. the specialist *Pieris rapae* and the generalist *Mamestra brassicae*; the parasitoids *Cotesia glomerata* and *Diadegma semiclausum* and the non-pathogenic rhizobacteria *Pseudomonas fluorescens.* We investigated *P. fluorescens*-mediated plant-insect multitrophic interactions and *P. fluorescens*-mediated gene expressions in cabbage plants through transcriptomics, behavioural ecology and life history analysis. The results indicate that *P. fluorescens* inoculation affects herbivore-induced gene expression and plant-insect interacdtions. This is the first finding that *P. fluorescens* mediates microorganism-plant-herbivore-parasitoid multitrophic interactions. These results may provide novel insights for biological control of insect pests in the future.

Benefits and fitness costs of learning in insects

Frederic Mery

CNRS, Gif sur Yvette, France

Learning and memory play a crucial role in the development of an animal's behavior within its lifespan and are important for its survival and reproductive success. They are products of evolution and the degree to which information is learned and maintained in the brain varies among species and among different types of behavior. Recently these differences in learning ability and memory capacities among species and populations began to be studied in the context of their natural environment and analyzed in terms of fitness benefits and costs. While fitness benefits of learning are relatively well understood, we know little about fitness costs of learning ability, constraints on its evolution, and the nature of heritable variation on which natural selection can act. As with any fitness-related trait, knowledge of these aspects is essential to understanding why, how, and when learning ability evolves under natural selection. Some authors have proposed that learning and memory may trade off with other fitness related traits. In the evolutionary context it is important to distinguish between the costs of inducing memory and the costs of memory capacities.

Studies on Drosophila have greatly advanced our understanding of learning and memory, especially in the context of associative classical (Pavlovian) conditioning and represent an interesting model for the study of the evolutionary biology of learning and memory. From different experiments on this model I will present some evidence of fitness costs and benefits of learning and memory.

Diversity of Agromyzidae and associated parasitoid species in the Afrotropical region

Robert Musundire[1], Benhard Lohr[1], Kerstin Kruger[2]

[1]icipe, Nairobi, Kenya, [2]University of Pretoria, Pretoria, South Africa

Introduction: The Agromyzidae (mining flies) are a diverse dipteran family of exclusively phytophagous species. A number of species are of economic importance, especially those feeding on Fabaceae and some horticultural plants. The economic challenges posed by these species have brought about the need for them to be managed through sustainable methods of which biological control by parasitoids is a key aspect. In the Afrotropical region, there is a need to provide harmonised information about agromyzid and parasitoid diversity to aid in the implementation of biological control.

Methods: The existing knowledge from published information and museum records on species diversity and distribution of agromyzids and associated parasitoid species within the Afrotropical region was reviewed. Information on agromyzid species, origin, associated host plants, parasitoids, and species distribution was captured. An analysis was undertaken to examine the diversity and distribution patterns of agromyzids and how they may have affected parasitoid assemblage size within this region.

Results: Approximately 265 species of agromyzids have been recorded in the Afrotropical region, representing only 10 percent of the world diversity. A total of 42 parasitoid species including introduced species are associated with agromyzids in this region.

Conclusions: Intensive regional collaborative effort on the biodiversity of agromyzids and associated parasitoid species in the Afrotropical region is needed to ascertain whether the apparent paucity of the Afrotropical agromyzids and associated parasitoid species is real or an artefact caused by a lack of sampling effort.

Bemisia tabaci biotype B manipulates its host to suppress effective defenses

Linda Walling, Sonia Zarate, Louisa Kempema

University of California, Riverside, CA, United States

Introduction: The basal defense mechanisms that deter phloem-feeding insect performance are largely unknown. The genetic and genomics resources from *Arabidopsis thaliana* were used to identify the defense pathway that controls basal resistance to *Bemisia tabaci* biotype B.

Methods: Affymetrix ATH-1 GeneChips were used to determine the RNA profiles changed after *B. tabaci* feeding. Defense gene RNAs that controlled by salicylic acid (SA), jasmonic acid (JA) and ethylene (ET) were monitored by RT-PCR or qPCR after adult or nymph feeding. The percentage of nymphs in each instar was measured after 24 d of infestation in wild-type and six defense mutants (*cim10, NahG, npr1, coi1, cev1, pad4* and *ein2*).

Results: There were differences in RNA profiles after *Bemisia tabaci*, aphid and caterpillar feeding. The changes in defense RNAs to *B. tabaci* were biphasic. Responses to adult feeding were distinct from nymph feeding. After nymph feeding, SA-responsive gene transcripts accumulated locally and systemically and SA levels increased. In contrast, JA- and ET-dependent RNAs were repressed or not modulated by *B. tabaci*. Nymph development was accelerated on *cim10* and *coi1* and delayed on *cev1*, *npr1,* and NahG plants. *npr1* plants treated with MeJA displayed a dramatic delay in nymph development. Unlike *Myzus persicae*, *B. tabaci* performance on wild-type, *ein2* and *pad4* mutants were similar.

Conclusions: *B. tabaci* nymphs suppress JA-regulated defense genes. Nymphs develop most rapidly when JA-defenses are impaired. Collectively, these data indicate the *B. tabaci* avoids or suppresses effectual JA defenses.

Circadian and circannual oscillators share the same mode in phase resetting

Hideharu Numata[1], Yosuke Miyazaki[1], Tomoyosi Nisimura[2]

[1]Osaka City University, Osaka, Japan, [2]The University of Shiga Prefecture, Hikone, Japan

Introduction: In circadian rhythms, the shape of the phase response curves (PRCs) depends on the strength of the resetting stimulus. Weak stimuli produce Type 1 PRCs with small phase shifts and a continuous transition between phase delays and advances, whereas strong stimuli produce Type 0 PRCs with large phase shifts and a distinct break point at the transition between delays and advances. A stimulus of an intermediate strength applied close to the break point in a Type 0 PRC sometimes produces arrhythmicity. In the circannual pupation rhythm of the varied carpet beetle *Anthrenus verbasci*, we constructed PRCs to long-day pulses on a background of constant short days, and examined the relationship between phase resetting of the circannual rhythm and the strength of long-day stimuli.

Methods: Larvae of *A. verbasci* kept under LD 12:12 were exposed to LD 16:8 for 2 or 4 weeks (long-day pulse) at various phases of the rhythm at 20ºC.

Results: The PRC to 4-week long-day pulses was similar to circadian PRCs of Type 0. However, the PRC to 2-week long-day pulses was Type 1, and a 4-week long-day pulse administered close to the PRC's break point induced arrhythmicity in pupation.

Conclusions: The phase response of the circannual rhythm in *A. verbasci* closely resembles circadian phase responses reported in various organisms.

Honeybee learning of complex scents: from behaviour to odorant receptors

Judith Reinhard, Charles Claudianos, Michael Sinclair, Julie Lim, Mandyam Srinivasan

The Queensland Brain Institute, St Lucia, QLD, Australia

Introduction: Honeybees (*Apis mellifera* L.) are exposed to countless floral scents in their natural foraging environment, most of which are complex chemical mixtures. While processing of single odorants has been well studied in honeybees, it is still unclear how bees learn and process scent mixtures.

Methods: Using the well-known Proboscis-Extension-Reflex Assay (PER), we investigated olfactory learning of floral scent mixtures. We also examined learning preferences of individual floral scent components, and determined expression patterns of olfactory receptor proteins (OR) potentially involved in floral scent processing using qRT-PCR and microarrays.

Results and Conclusions: (1) Honeybees use one of two strategies to learn a scent mixture, depending on the type of mixture. They either learn key compounds as representative of the entire mixture, or they learn the mixture as a unit. The first strategy keeps scent recognition flexible, while the second strategy enables bees to discriminate even between subtly different scents. We will discuss under which circumstances bees might employ which strategy, and propose a hypothesis of the neural mechanisms underlying complex scent processing. (2) Honeybees learn certain floral odorants better than others, however the preferences are in no correlation to the molecular structure or physico-chemical properties of the tested odorants. Behavioural data and OR expression patterns indicate that sensory exposure in the foraging environment may cause olfactory preferences, suggesting that honeybee olfaction is not entirely hard-wired, but subject to experience-based modulation at the molecular level.

Funded by CSIRO Food Futures Flagship.

Sensory driven synaptic remodelling in the honeybee brain

Charles Claudianos[1], Sunita Biswas[2], Judith Reinhard[1], John Oakeshott[3], Robyn Russell[3], Alexandre Dos Santos Cristino[4], Mandyam Srinivasan[1]

[1]The Queensland Brain Institute, St Lucia, QLD, Australia, [2]The Australian National University, Canberra, ACT, Australia, [3]CSIRO Entomology, Canberra, ACT, Australia, [4]The University of Sao Paulo, Sao Paulo, Ribeiro Preto, Brazil

Introduction: Precise cell-to-cell contact is fundamental to proficient synapse connectivity. Several vertebrate studies highlight the post-synaptic neuroligins and pre-synaptic neurexins (cell adhesion binding partners) as critical to proper synapse development and function. Aberrations to the neuroligin/neurexin complex have been associated with a number of neuro-psychiatric disorders such as autism, Aspergers and schizophrenia. Our honeybee study represents the first comprehensive study of these molecules in invertebrates.

Methods: Isolation and characterisation of five neuroligins and one neurological neurexin provided the basis for examining localisation and developmental expression of these molecules in the honeybee. To investigate the role of *neuroligins* and *neurexin I* in the adult honeybee brain, we conducted a quantitative expression analysis using three different experimental paradigms: environmental deprivation, associative learning, and unilateral or bilateral amputation of the antennae.

Results and conclusion: *Neuroligins* and *neurexin I* were found to be highly expressed throughout the adult honeybee brain including the higher order processing centre, the mushroom bodies. This suggests that the neuroligin/neurexin system has a broadly similar role in synaptogenesis in insects as in vertebrates, with the scope to generate substantial functional diversity through alternative splicing. Experiments using environmental deprivation, associative learning, and antennal amputation all showed that *neuroligin 1* expression was highly correlated with sensory input, suggesting a critical role in synapse development associated to sensory processing, learning and memory. This study is one of the first to investigate a role for these molecules at an organismal level.

Plant-mediated interactions between gall-formers and leaf-chewers

Lilach Zexer[1], Efraim Lewinsohn[2], Einat Bar[2], Moshe Inbar[1]

[1]University of Haifa, Haifa, Israel, [2]Newe Ya'ar Research Center, Ramat Yishay, Israel

Introduction: Indirect, plant-mediated interactions (negative or positive) between herbivores might be common and important. We investigated such interactions between a leaf-galling aphid, *Smynthurodes betae* (Fordinae), and the folivorus moth (*Thaumetopoea solitaria*) both feeding exclusively on *Pistacia atlantica* trees. The aphids induced leaf galls in early spring in which they reproduce until the fall. In the spring the moth caterpillars feed on the same leaves; occasionally, leavening the plant totally defoliated. It is expected therefore, that both insects will be engaged with complex interactions.

Methods & Results: In Field and laboratory experiments we found that: 1. The caterpillars repeatedly avoid the galls while consuming the leaves creating intact "trimmed galls". 2. The galls are protected physically, but primarily chemically from the moth. 3. In GC-MS analysis we found higher levels of mono- and sesquiterpenes in the galls that may contribute to such defence. 3. In the field, gall density on defoliated shoots increased (X 4) comparing to caterpillar-free shoots, due to compensatory tree growth which extended the availability of young leaves. 4. Trimmed galls maintained strong sink for nutrients from alternative sources as reflected by the unaffected reproduction of the aphids in these galls.

Conclusions: Plant-mediated effects between the caterpillars and the aphids are complex and involve various mechanisms. The aphids manipulate the host plant (gall tissue) to avoid gall consumption and draw assimilates from alternative sources. The aphids also utilize plant response to defoliation to their own benefit.

Megachile unbripennis Smith: Leaf cutting behaviour on rose leaves (*Rosa*)

Dita Nurtjahya

SMAN 1 Senior High School, Sungailiat, Bangka Belitung, Indonesia

The research was carried out based on being unsatisfied with the previous research results. The objective was to identify the leafcutter bee species that cuts the leaves of roses (*Rosa* sp.) that grow in Sungailiat, Bangka Island; secondly it was to study its leaf cutting behaviour. The information might be useful to uncover the role of leaf-cutter bees in ecology. Identification was carried out at Entomology Laboratory, LIPI (Indonesian Science Research Institute) in Cibinong. By observing the *Megachile* spp. collection, doing some morphological research especially on the fourth tooth of the mandibles, and by examining the position of its cutting edge, the 1.0 – 1.5 cm the bee belongs to *Megachile unbripennis* Smith. This species prefers to cut the young healthy reddish leaf (97.1%). The average time for selecting the leaf is 19.3 seconds, cutting the leaf is 14.8 seconds, and perching after cutting is 97.2 seconds. The bee prefers to cut at 12:00 – 13:00, but its cutting time is from around 07:00 – 17:30 and they avoid rainy days. The average number of cuts in every leaflet is 1.1, the average of the cut area is 98.2 mm^2, the cut position away from the main leaf vein is 57.3%, and only 6.1% through the main vein. The number of leaflets which is unsuccessfully cut is 3.8%. The nest is in the form of hole.

Macadamia IPM: A Southern African perspective

Schalk Schoeman

Agricultural Research Council, Nelspruit/Mpumalanga, South Africa

Introduction: Macadamia production is currently centred in Southern Africa, Hawaii and Australia. These areas account for more than 90% of the global production and pest complexes generally consist of nut borers (Tortricidae) and stinkbugs (Pentatomidae & Coreidae). The Southern African tortricid complex consists of, *Thaumatotibia leucotreta*, *Thaumatotibia batrachopa* and *Cryptophlebia peltastica* (Meyrick) while the stinkbug complex consist of *Nezara viridula* as well as ± 45 indigenous species. Currently the tortricid complex is of relative minor importance, but the stinkbug complex was responsible for a monetary loss of ± R20 million (US$ 3 million) during the previous production season. The pentatomid *Bathycoelia natalicola* is particularly troublesome because its relative long mouthparts (12mm) enable it to feed on the kernel at any time during the development of the nut.

Methods: Damage profiles of both pest complexes were studied in relation to phenological development of macadamias. This study was conducted over three years on 10 farms in the Mpumalanga province of South Africa

Results and conclusion: Field trials successfully demonstrated that withholding commonly applied “clean up sprays” immediately before and after flowering had no effect on kernel yield or quality at harvest. This reduced the spray frequency of disruptive foliar applied synthetic pyrethroids from ± 6 – 4/season. Although tortricids are not generally economically important, the availability of suitable host plants can induce severe localised outbreaks. A large component of immature kernels was linked to late season infestation of the fruit. Spray timing is critical and depends on the main oviposition period. Larvae normally feed inside the nuts effectively out of reach of contact insecticides. The main oviposition period of the moths was determined and was subsequently linked to possible physiological changes in the plant at the end of premature nut drop. Uptake of research is normally a slow process therefore the second phase of this project currently focuses on extension. Methods used to assist all sectors of South African agriculture are briefly discussed.

Trait-mediated indirect effects on the structure of insect communities through herbivore-induced changes in plants

Takayuki Ohgushi

Center for Ecological Research, Kyoto Univesity, Otsu, Shiga, Japan

One of the most fundamental problems in ecology is determining the causal mechanisms that shape the structure of ecological communities. Ecologists have long focused on constructing traditional food webs that have less appreciated the potential importance of nontrophic, indirect, and facilitative interactions in structuring communities. Recently, there is a growing appreciation that trait-mediated indirect effects have important community consequences. Thus, we need to start combining these effects with trophic effects to create indirect interaction webs as an alternative to traditional food webs. In terrestrial systems there is a strong contrast between the effects of herbivory and predation: predators kill prey, but instead of killing mature plants herbivores usually alter a wide variety of plant traits such as secondary substances, growth, physiology, morphology, and phenology. There is rapidly increasing evidence that such herbivore-induced responses of plants are common and widespread in nature. Plant responses following herbivory substantially influence the structure of arthropod communities by creating indirect connections among herbivore species. These herbivore-induced plant responses act as mediators of interactions among species by linking multiple plant-insect interactions. As a result, they can increase not only abundance and species richness, but also the number of direct, indirect, and facilitative interactions involved in higher trophic levels. Consequently, plant-centered insect communities are largely organized by nontrophic, trait-mediated indirect, and facilitative interactions that have been little underscored in insect community ecology.

Functional studies of ORN populations on the antennae and maxillary palps of *Anopheles gambiae*

Yu Tong Qiu, Joop J.A. van Loon, Larry Zwiebel, Willem Takken

[1]Wageningen University, Wageningen, Netherlands, [2]Vanderbilt University, Nashville, TN, United States

Introduction: The malaria mosquito *Anopheles gambiae* is a highly human-specific blood feeding mosquito. Host seeking and oviposition site location behaviour are mainly odour-mediated and 79 putative olfactory receptor genes have been identified in this mosquito. Understanding the function of the olfactory receptor neurons is essential for developing strategies to disrupt odour-mediated behaviour with the aim to diminish malaria transmission.

Methods: We mapped functional groups of olfactory receptor neurons (ORNs) on the antennae and maxillary palps of female *A. gambiae*. Single sensillum recording was used to study the function of trichoid and grooved peg sensilla on the antennae and capitate peg sensilla on the maxillary palps.

Results: Based on the responses of ORNs to 44 human- or oviposition site-related odours, two functional types were found for E-type trichoid sensilla, three types for type C trichoid sensilla and five types for grooved peg sensilla. After a blood meal, a new functional type was found for E trichoid sensilla, which was highly responsive to indole and 3-methylindole, known as mosquito oviposition stimuli. All the tested capitate peg sensilla on the maxillary palps house three neurons belonging to three functional types based on their responses to 97 odours; and all of these sensilla are innervated with neurons highly sensitive to the known mosquito kairomone CO_2 and 1-octen-3-ol.

The influence of the parasitoids on the development of their aphid hosts

Amalia Kati, Jim Hardie

Imperial College London, Silwood Park, Ascot, Berks, United Kingdom

Changes in wing formation and development of the black bean aphid *Aphis fabae* (Scopoli) (Homoptera: Aphididae) are examined after parasitisation by *Aphidius colemani* (Viereck) (Hymenoptera: Aphidiidae) along with an investigation of the mechanisms of how changes are effected.

Parasitisation of nymphs of presumptive winged gynoparae of *A. fabae* induced by short days show that wing development is inhibited and the earlier parasitism takes place, the stronger the effect. Consideration of the timing of events indicates that the active component(s) is most likely injected along with the egg during oviposition and is not related to the parasitoid larva.

When saline extracts of female parasitoids or venom glands are injected into late-second stadium aphids they develop to fourth-stadium nymphs with rudimentary wingbuds, show developmental arrest and die usually in an attempt to moult to the adult stage. Injections in later stadia gave similar results. Injected late-fourth stadium insects develop normally.

Experiments with long-day winged virginoparae reveal similar results in regard to developmental arrest but injections into long-day wingless aphids, which develop more rapidly, had this effect only when treated during the early-third stadium. There seems to be a correlation between the time remaining to the final moult and the effect of the injected extract on preventing adult development.

The results indicate that there is an active factor(s) in the parasitoid's venom that disrupts wingbud development and/or inhibits moulting; the loss of activity after heat or protease treatment makes it likely that it is a protein.

In search of monophyly: the Ctenopelmatinae (Hymenoptera: Ichneumonidae) and its included tribes

Jacques Dubois[1], Matt Yoder[2], Debra Murray[3], Aubrey Colvin[4], Mika Cameron[4], Robert Wharton[4]

[1]Department of Invertebrate Zoology, American Museum of Natural History, New York, New York, United States, [2]Department of Entomology, Ohio State University, Columbus, Ohio, United States, [3]Department of Entomology, North Carolina State University, Raleigh, North Carolina, United States, [4]Department of Entomology, Texas A&M University, College Station, Texas, United States

Introduction: Ichneumonidae is the most speciose family of Hymenoptera with over 23,000 valid species assigned to approximately 40 subfamilies. Members of the subfamily Ctenopelmatinae are primarily parasitoids of sawflies and are characterized by an apical tooth on the fore tibia. This feature is also present in members of at least three other subfamilies, leading to concerns about characterization of the subfamily and support for its monophyly.

Methods: Ctenopelmatines and various out-group taxa were extracted from Malaise trap samples, and hind legs were removed for DNA analysis. Specimens were then pinned, labelled, databased, and their identification confirmed. DNA was extracted from exemplar taxa, amplified, and sequenced for three gene regions: 28S D2-D5, CAD, and RNA Polymerase II (POL). Data were analyzed using cladistics and Bayesian methods.

Results: Sequence data were obtained for over 100 in-group (ctenopelmatine) and out-group (other subfamilies) taxa. Although 28S has been used in prior assessments of ichneumonoid relationships, this gene was insufficient for resolving issues of monophyly at the subfamily and tribal levels, despite dense sampling. Not surprisingly, both better resolution and stronger support were obtained when all three gene regions were employed. Mesoleiini, perhaps the most poorly defined tribe morphologically, was consistently resolved as monophyletic, with strong support, in our analyses.

Conclusions: For Ichneumonoidea, a superfamily with approximately 40,000 species, the use of molecular data for resolving higher order relationships is still in its infancy.

Nocturnal oviposition in forensically important flies (Diptera: Calliphoridae, Sarcophagidae): laboratory and field studies

Kirstin Williams[1], Martin Villet[2], Nkosinati Mazungula[2]

[1]Durban Natural Science Museum, Durban, South Africa, [2]Rhodes University, Grahamstown, South Africa

Introduction: Nocturnal oviposition by blowflies is a debated factor that can affect the precision of forensic estimates of a post mortem interval (PMI) by more than 14 hours, depending on latitude and season.

Methods: Field and laboratory experiments involving forensically important African flies were conducted using rat carcasses and pieces of rotting meat to determine if these flies were able to lay eggs at night.

Results: It was found that *Lucilia sericata* could lay at night in the field, and that *L. sericata*, *Chrysomya chloropyga, C. albiceps* and *C. putoria* could do so in the laboratory, especially at temperatures above 22°C. This brings the number of species that have been found to be able to lay at night to thirteen species in three subfamilies. Thus, the forensic issue is not whether nocturnal oviposition occurs, but rather whether the environmental conditions of a particular case are more or less conducive to it.

Conclusions: The circadian rhythms and physiological thresholds (e.g. minimum temperature for flight and laying, and minimum humidity for laying) of each species of fly involved in a case are likely to need simultaneous consideration. The significance for experimental design of carcass size, freezing of carcasses, handling of carcasses and comprehensive quantification is discussed, and recommendations are made for future experiments. When estimating a PMI, it is recommended that the likelihood of nocturnal oviposition is considered probabilistically, and even empirically, for each forensic case, rather than on the basis of a categorical generalization.

Neuropeptides, receptors and innate behaviors in the silkmoth *Bombyx mori*

Dusan Zitnan, Ladislav Roller, Ivana Daubnerová, Inka Zitnanová, Young-Joon Kim, Michael E. Adams

[1]Institute of Zoology, SAV, Bratislava, Slovakia, [2]Institute of Medical Chemistry and Biochemistry, Comenius University, Bratislava, Slovakia, [3]Institute of Molecular Pathology, Vienna, Austria, [4]Depts of Entomology & Neuroscience, University of California, Riverside, United States

Introduction: The *Bombyx* model is becoming attractive with availability of its genome, the growing utility of gene transformation and suitability for physiological and behavioural studies, including ecdysis. The moth ecdysis sequence is composed of different movements (pre-ecdysis, ecdysis and post-ecdysis) necessary for shedding of the old cuticle. It is controlled by ecdysis triggering hormones (ETH) from endocrine Inka cells and multiple neuropeptides from neurons expressing ETH receptor in the central nervous system (CNS).

Methods: We cloned two subtypes of ETH receptor (ETHR-A and ETHR-B) and detected their expression in peptidergic neurons by in situ hybridization and immunohistochemistry. We used electrophysiology techniques, various bioassays and molecular approaches to determine functions of neuropeptides expressed in specific ETHR neurons.

Results: Our data showed that each behavioural phase during ecdysis sequence is under control of a specific set of neuropeptides. Central release of these neuropeptides from identified neurons results in initiation of pre-ecdysis, switch from pre-ecdysis to ecdysis, and activation and termination of ecdysis. Peripheral actions of the same neuropeptides involve regulation of water balance and contractions of skeletal muscles and hindgut. Electrophysiological analysis of the CNS from pharate pupae and pharate adults indicates considerable functional shift of neuronal networks and neuropeptides during metamorphosis.

Conclusions: Our data provide evidence that the ecdysis sequence is a very complex process controlled by multiple neuropeptides centrally and peripherally released from the CNS upon ETH action on specific neurons expressing ETHRs. Each neuropeptide may control different functions depending on timing of their release and site of action.

This work was supported by a grant from the National Institute of Health, USA (GM 67310), and Slovak grant agencies, Agentúra na podporu výskumu a vývoja (APVV-51-039105) and Vedecká grantová agentúra (VEGA 2-6090-26).

GM crops and biological control: What are the concerns and how to address them.

Nick Birch

SCRI, Dundee, United Kingdom

The presentation will focus on GM pest-resistant crops to discuss the development, testing and use of environment- and scale-sensitive biosafety testing procedures. An overview will be given of the potential risks and benefits (direct and indirect) for using GM pest-resistant crops in Integrated Pest and Disease (IPDM) crop protection systems. The risk:benefit approach will be discussed in relation to hypothesis-driven, functional ecology based methodologies for GM trait and crop assessment. These methods are designed to address the main concerns surrounding the compatible use of GM crop technologies with biocontrol agents, as part of IPDM frameworks in varying geographic regions. The GM biosafety methods are developed and tested at different scales (laboratory, glasshouse / mesocosm, field) in the EU and several developing countries. They assess impacts of GM crops on above- and below-ground agro-ecosystems, in relation to existing crop protection options. The effectiveness of biosafety testing methods to measure GM crop impacts on non-target biocontrol agents and on other components of biodiversity which provide valuable 'ecological services' will be discussed in terms of predictability and 'ecological context setting'.

Community response of phytophagous and transient non-target canopy insects associated with eastern hemlock, *Tsuga canadensis* (L.) Carrière, to imidacloprid and horticultural oil applications

Carla Dilling[1], Paris Lambdin[1], Jerome Grant[1], Rusty Rhea[2]

[1]University of Tennessee, Knoxville, Tennessee, United States, [2]USDA Forest Service, Forest Health Protection, Ashville, North Carolina, United States

Introduction: Hemlock woolly adelgid, *Adelges tsugae* Annand, is an invasive species reducing populations of eastern hemlock, *Tsuga canadensis* (L.) Carrière, throughout the eastern United States. While systemic imidacloprid and horticultural oils are the primary chemicals used to control infestations of this pest, their impact on non-target canopy insects is unknown. A study was initiated in November 2005 to assess the effects of imidacloprid soil drench, soil injection, and tree injection applications, and horticultural oil applications on multiple levels of organization within the phytophagous and transient insect community.

Methods: Eastern hemlocks were arranged in a split plot 2 x 5 factorial complete randomized block design consisting of three blocks of ten trees each. Treatments were made in the fall and spring with monthly sampling methods consisting of: canopy malaise traps, beat sheet, direct observation, and branch sampling.

Results and Conclusions: Analysis of similarity of Bray-Curtis distances infer significant differences between community composition and treatments. Mean species richness and abundance were significantly reduced by one or more application methods. Species richness was significantly reduced among detritivore and phytophaga guilds by soil drench applications. Species abundance was significantly lower across all guilds when compared with the control trees, with the exception of the haematophaga guild. From 293 species evaluated, 35 were found to be directly effected by one or more of the chemical treatments. Of the 35 species, 27 were lepidopterans that directly consume needles of eastern hemlock. The remaining eight species were psocopterans that feed on micro-fungi found on the needles.

The relevance of economic thresholds in transgenic corn: Does IPM affect IRM?

Michael Gray, David Crowder, David Onstad

[1]University of Illinois, Urbana, Illinois, United States, [2]University of Arizona, Tucson, Arizona, United States, [3]University of Illinois, Urbana, Illinois, United States

Introduction: The use of transgenic crops is increasing rapidly worldwide, particularly in the midwest of the United States. Questions have arisen regarding the necessity of economic thresholds used in conjunction with transgenic crops such as Bt maize. We conducted a simulation model to determine the benefits of scouting and economic thresholds in improving resistance management programs.

Methods: A population model for the western corn rootworm, *Diabrotica virgifera virgifera* LeConte, was used to elucidate resistance development to transgenic maize and crop rotation. A diploid genetic system with the following assumptions was utilized: autosomal inheritance, two-locus, and two-alleles per locus. The simulated model landscape was comprised of 100 hectares with a maximum of four crop rotation schemes and six fields.

Results: Unless transgenic maize was planted each season without a refuge, along with a simulated high dose, durability of transgenic maize was greater than 15 years (assuming allele for resistance to transgenic Bt maize is recessive). If the allele for resistance is partially recessive or dominant, the time for resistance development was generally well below 15 years, particularly at the medium and lose dose simulations across each of the four management strategies. Using economic thresholds only slightly delayed the onset of resistance to transgenic maize by corn rootworms.

Conclusions: Due to the effectiveness of transgenic maize and favorable economic returns, escalating use of Bt hybrids is anticipated in the United States. Concurrent with this trend, producers may be increasingly inclined to use transgenic maize each year without the use of traditional IPM tactics such as scouting and economic thresholds.

Differences between thermal requirements of native and exotic insect species

Vojtech Jarosik, Marc Kenis, Alois Honek

[1]Department of Ecology, Faculty of Science, Charles University, Vinicna 7, 128 44 Prague 2, Czech Republic, [2]CABI Europe - Switzerland, Rue des Grillons 1, CH-2800 Delemont, Switzerland, [3]Research Institute of Crop Production, Drnovská 507, 161 06 Prague 6-Ruzyne, Czech Republic

Introduction: Temperature determines the rate of development and survival of insects, and thus enables predictions of the effects of climate change on the distribution of insects, and on the spread of invasive species. We ask whether two basic thermal requirements for insect development, the lower developmental thresholds (LDTs), i.e. temperatures at which development ceases, and sums of effective temperatures (SETs), i.e. numbers of day degrees above the lower developmental thresholds necessary for a completion of the total pre-imaginal development, differ among European native and invasive species.

Methods: Because the thermal requirements are similar for related taxa, pairs of closely related species, native vs. exotic in Europe, were compared for their LDTs and SETs by paired t-tests, using a database of thermal requirements, systematically gathered from original studies by Alois Honek.

Results: LDTs were higher for exotic comparing to native species, but only if exotic store product pests were included. SETs were systematically less for exotic than native species, meaning that closely related exotic species develop faster than their native congeners.

Conclusions: As LDTs systematically change with latitude, which in turn changes with temperature, similar LDTs for closely related exotic and native species suggest a good climatic match of introduced species with their new environments. That the exotic species develop faster than their related native congeners correspond to the results in other invasive taxa, in which fast development also belongs to characteristic traits of successful invaders.

Managing *Helicoverpa* spp. and *Creontiades dilutus* on cotton crops: Role of entomopathogenic fungus, semiochemicals and trap crops

Robert Mensah, Leah Austin

Australian Cotton Research Institute, NSW Department of Primary Industries, Narrabri, NSW, Australia

Introduction: *Helicoverpa* spp. is a major pest in cotton in Australia, but, with the introduction of transgenic (Bollgard II®) cotton crops *Creontiades dilutus* (green mirid), populations have increased to economically important levels resulting in an increase in insecticide use against green mirids. Consequently, there is the need to reduce insecticide use to minimise the risk of insecticide resistance to green mirids. The goal of this study was to search for and develop IPM compatible tools to minimise synthetic insecticide use against *Helicoverpa* spp. and green mirids.

Method: Studies were conducted in commercial Bollgard II® cotton surrounded by conventional cotton crops. The study assessed (1) different rates of entomopathogenic (fungal) insecticides (Beauveria and Metarhizium spp.) (2) trap cropping with lucerne crop to control green mirids on cotton crops and (3) attract and kill technique using attracticide applied to transgenic cotton crops to reduce *Helicoverpa* spp. population on the surrounding conventional cotton crops.

Result: The study showed that application of entomopathogenic (fungal) insecticides controlled green mirids on cotton crops. In addition, interplanting lucerne crop in cotton reduced green mirid numbers on the cotton crops. Application of attracticide onto transgenic cotton crops reduced Helicoverpa moth population on the adjacent conventional cotton crops by 91.5 per cent resulting in insecticide savings of $11.40 per ha on the conventional cotton crops.

Conclusion: The programme that involves the use of entomopathogenic fungi, semiochemicals and trap cropping can be used to manage cotton pests, reduced synthetic insecticide use and increase crop yield and profitability.

Unexpected relicts – Eocene insects indicate former widespread distribution of various insect groups

Sonja Wedmann

Senckenberg Research Institute, Research Station Grube Messel, Messel, Germany

Various insect groups presently restricted to certain biogeographic regions were once much more widely distributed. This is documented by a wide range of fossils, which are found in areas distant from where their extant relatives occur. Recent fossil evidence from the 47-million-year-old Eocene deposit of Messel in Germany shows that this list continues to grow.

For instance, the extant austral group of genera closely related to *Comptosia* (Diptera: Bombyliidae) has long been regarded as Gondwanan disjuncts. *Comptosia* fossils recently discovered in Messel and in the Eocene North American fossil site Florissant show that their present distribution is relictual rather than disjunct. The first fossil record of a leaf insect from Messel shows that their former geographical range was distinctly larger. Currently, all species of leaf insects (Phasmatodea: Phylliinae) are distributed primarily in south-east Asia and adjacent regions. Another record from Messel is a fossil belonging to a subgroup of mantidflies (Neuroptera: Mantispidae: Symphrasinae) which today occur only in South America, Central America and southern North America.

In the Eocene, the geographical range of many insect groups was substantially more encompassing than it is today. This is most likely connected with the warm and equable climate in the Eocene. The fossil insects from Messel indicate a high diversity of taxa comparable to the present tropical level of biodiversity. Seemingly, many insect groups retreated south as the Northern Hemisphere began to cool and their habitats began to recede. They became extinct in their former geographical ranges and now have a relict distribution.

Determining the efficacy curve of thiametoxam (Actara™ 240SC) with regards to the intensity and duration of oviposition of the mango seed weevil, *Sternochetus mangiferae* F. (Coleoptera: Curculionidae)

Cornelia Estelle Louw

Bavaria Fruit Estates / Westfalia, Hoedspruit, Limpopo, South Africa

Introduction: The mango seed weevil (MSW), *Sternochetus mangiferae*, is a serious phytosanitary pest, restricting South African export to certain foreign markets. Thiamethoxam, a neo-nicotinoid with a long residual activity, is effective in controlling MSW. However, since varying opinions exist regarding the onset and length of oviposition, the efficacy curve of thiamethoxam, applied at different times in the mango season, were investigated and compared to MSW oviposition and larval development.

Methods: Oviposition was ensured by enclosing bags containing adult weevils around fruit. Efficacy was expressed as the percentage MSW free fruit, out of the total number of fruit with induced egg-laying, compared to the chemically untreated fruit. This data was plotted over time to determine the efficacy curve. At the end of the season infestation levels due to natural seed weevil oviposition, as well as infestation levels of mango scale (*Aulacaspis tubercularis*) and mealybugs (*Planococcus citri* & *Pseudococcus longispinus*) were determined.

Results: Induced weevil infestation levels in fruit from trees treated during mid August or mid September were comparative and remained low throughout the trial period. Infestation levels in fruit treated in mid October were comparative to the other treatments 3 weeks after application. With natural oviposition, significantly fewer MSW were found in treated fruit, with no significant differences between treatments (time of application), although a time response did show earlier applications to be slightly more effective. Thiamethoxam had, contrary to registration data, no noticeable effect on mango scale, but mealybug numbers were significantly reduced, with a time response showing slightly better control with later applications.

Investigating mango seed weevil (*Sternochetus mangiferae* F. (Coleoptera: Curculionidae)) development in order to determine the most appropriate time for control measures

Cornelia Estelle Louw

Bavaria Fruit Estates / Westfalia, Hoedspruit, Limpopo, South Africa

Introduction: In order to control any insect pest, it is imperative to understand its biology. For the mango seed weevil (MSW), *Sternochetus mangiferae*, varying opinions exist regarding oviposition and development. It is therefore important to know the onset and duration of oviposition, as well as the duration of each developmental stage, to determine the most appropriate time for intervention. In order to ensure effective chemical control, it is important to determine the time elapsed from oviposition to the eggs hatching, and the time it takes for the larvae to penetrate the fruit and reach the safety of the seed.

Methods: Weevil oviposition on 'Keitt' fruit was artificially induced by enclosing adult weevils with bags around the fruit. Oviposition was induced during October, November and again in December. Exposed fruit were sampled at weekly intervals after oviposition to determine the developmental stage(s) present at subsequent time intervals. Every egg present on the fruit skin was inspected and counted and resultant developmental stages, where eggs had hatched, were noted. Further larval development stages were also recorded.

Results: During the October induction all the eggs were intact after 7 days, with a very small percentage (<1%) still intact after 14 days. Fourteen days after egg-laying 38% of the hatched larvae had already penetrated the seed. For the November induction, development appeared somewhat faster. One week after oviposition 9% of eggs had hatched, while 45% of hatched larvae had reached the seed by week 2. For the December induction 64% of the eggs, on average, did not develop. Initial hatching was comparative to the October induction, but no larvae were noted up to 5 weeks after oviposition.

Biotypic diversity and distribution of Russian wheat aphid *Diuraphis noxia* (Hemiptera: Aphididae) in the eastern and central Free State

Astrid Jankielsohn

ARC-Small Grain Institute, Bethlehem, South Africa

Introduction: Since the release of the first RWA resistant cultivar in 1992 wheat farmers in the eastern and central Free State relied on wheat cultivars with resistant genes to manage Russian wheat aphid (RWA). In 2005 a new biotype RWASA2 was described based on its ability to damage wheat with the resistant genes *Dn*-1 and *Dn*-2. To effectively manage RWA in the future it is important to know the biotype composition in the major wheat producing areas.

Methods: Russian wheat aphid was collected from 12 different localities in the central and eastern Free State. Between one and four samples were collected at each locality, depending on infestation level and size of the collection area. Russian wheat aphid clone colonies were made from these samples. Clones were screened against Betta (susceptible), Elands (*Dn*-1 resistance gene), Halt (*Dn*-4 resistance gene) and PAN 3144 (*Dn*-5 resistance gene). If the clones were able to damage the wheat with resistance gene *Dn*-1 but not wheat with resistance gene *Dn*-4 and *Dn*-5 they were considered to be RWASA2.

Results: RWASA2 was the dominant biotype across all the collection sites.

Conclusion: Based on the predominance of RWASA2 in the eastern and central Free State wheat with the *Dn*-1 resistance gene will have little value in controlling RWA in these areas.

Root-feeding insects as agents of change in agroecology

Scott Johnson, Carolyn Mitchell

Scottish Crop Research Institute, Dundee, United Kingdom

Introduction: Necessary reductions in pesticide usage have resulted in some crops being challenged by multiple pests, both above- and below the soil surface. It has been known for some time that root and foliar-feeding insects can interact via changes to their shared host plant, but comparatively less is known about how these interactions vary with genetic resistance and crop phenology. We investigated the interactions between root- and foliar-feeding insects in an annual (barley, *Hordeum vulgare*) and a perennial crop (raspberry, *Rubus idaeus*).

Methods: In laboratory and glasshouse experiments, we investigated how root-feeding vine weevils (*Otiorhynchus sulcatus*) affected genetic resistance in raspberry and how this in turn affected the large raspberry aphid (*Amphorophora idaei*). We measured changes to plant chemistry, most notably epicuticular waxes. We also measured how wireworms (*Agriotes* spp) changed the nutrient profile of barley at different time points and assessed how this affected the bird-cherry oat aphid (*Rhopalosiphum padi*).

Results: There was no interaction between vine weevils and aphids in raspberry cultivars containing single A10 gene resistance, but root herbivory by vine weevils promoted aphid populations in cultivars with multigenic resistance. Wireworms and aphids caused specific changes in P, K, Ca, S and soluble amino acids. At one time point, aphid populations were promoted by wireworm herbivory.

Conclusions: Root and foliar-feeding insects interact in both an annual and a perennial crop. Genetic resistance aboveground can be compromised by belowground herbivory in raspberry. In barley, temporal shifts in mineral and amino acid nutrients underpinned interactions between the two herbivores.

Plant mediation of intraspecific interactions and population dynamics

Timothy Craig

University of Minnesota Duluth, Duluth, Minnesota, United States

A central theme of the study of ecological interaction has been the role of competition for resources in determining the evolution and ecology of species. For herbivorous insects host plants are not just a fixed quantity of food that is competed for until it is exhausted, instead they are a dynamic resource that is continuously altered by herbivory. Modification of plant resources can have a positive or negative impact on subsequent generations of conspecifics. Herbivore damage can have a positive effect if it induces the plant to re-grow tissues where herbivore performance is high. For example, on the willow, *Salix lasiolepis*, the damage by the gall-inducing sawfly *Euura lasiolepis*, induces the growth juvenile tissue where sawfly performance is high. As a result sawfly population densities are continuously maintained at high densities on some plants. In contrast the lacebug, *Corythuca marmorata,* has a more complex intergenerational interaction mediated by the host plant within a growing season. These lacebugs are group feeders on rapidly senescing tissue. Initially, ovipositing females are attracted to plants where previous feeding has induced leaf senescence. However, at high population densities plant damage is so high that resources deteriorate in quality and females avoid ovipositing on them. When these plants are released from attack they can resume growth and become preferred host plants again. Thus there is a complex interaction of the oviposition preference, feeding damage, and host plant quality that determines the distribution and population dynamics of the lacebug.

A change for the better: Resurgence in biocontrol agents associated with the adoption of Integrated Fruit Production (IFP) in New Zealand apple orchards

Peter W. Shaw[1], Roger D. Wallis[2], James T.S. Walker[3]

[1]HortResearch, Old Mill Road, RD3 Motueka, New Zealand, [2]HortResearch, Old Mill Road, RD3 Motueka, New Zealand, [3]HortResearch, PO Box 1401, Havelock North, New Zealand

Introduction: Biological control of orchard arthropod pests has become a key component of the Integrated Fruit Production (IFP) system developed by the NZ apple industry in the 1990's to reduce reliance on agrichemicals and demonstrate environmental responsibility.

Methods: Yellow sticky traps and trays to collect insects knocked from branches were used to record the relative abundance of bio-control agents in apple blocks treated with either organophosphate (OP) or IFP based insecticide programmes.

Results: Apple blocks in Nelson, New Zealand, during 1995-1996, sprayed with a calendar programme of organophosphate (OP) insecticides, typical of production practice at the time, had very little arthropod fauna. Some beneficial arthropods were recorded in transitional IFP blocks treated with selective Insect Growth Regulator (IGR) insecticides during the same season. By comparison, the same monitoring methods revealed that by 2006-2007, bio-control agents were more varied and numerous in established IFP apple blocks using selective insecticides in a threshold-based pest management programme.

Conclusions: The change by the NZ apple industry from a calendar-based broad spectrum OP insecticide programme to an IFP system based on targeted use of selective insecticides has resulted in an associated increase in the diversity and abundance of arthropod bio-control agents in apple orchards. This has resulted in a marked decrease of some previously important pests while maintaining similar levels of control of key pests.

Molecular evidence of a rapid radiation and divergence times in carabid beetles

Karen Ober, Thomas Heider

College of the Holy Cross, Worcester, Massachusetts, United States

Evolutionary radiations are often considered to have been times of rapid origination of major clades as represented by their sudden appearance in the fossil record. Explosive evolution can, in principle, be tested by molecular estimates of divergence times. The fossil record indicates a rapid tempo of cladogenesis of major lineages early in the evolutionary history of beetles in the carabid subfamily Harpalinae. Lack of resolution in the molecular phylogeny at the base of Harpalinae may be evidence for rapid radiation in this clade. The beetle subfamily Harpalinae is the largest subfamily in Carabidae with approximately 19,000 species, most of carabid diversity. Its sister group, Brachininae, has about 655 species. Molecular clock estimates of divergence dates of major harpaline lineages were estimated. Temporal variations in estimated diversification rates in harpalines and it sister group were analyzed. Preliminary results suggest a rapid increase in evolutionary diversification in the subfamily Harpalinae compared to other related carabid beetle clades.

Disasters by design: Why pests outbreak in the urban forest

Michael Raupp, Adrianna Szczepaneic, Scott Creary

Department of Entomology, University of Maryland, College Park, MD, United States

The purpose of this presentation is to provide a synthesis of our knowledge of the many mechanisms underlying pest outbreaks in managed urban landscapes. We will provide evidence that several factors, either individually or in concert, act to uncouple trophic relationships in managed landscape systems, thereby altering ecosystem function. These factors include a critical lack of plant diversity and complexity in our cities and residential landscapes, failure to consider evolutionary relationships between plants and their pests in the selection of plant material, management practices such as elevated levels of fertilization that predispose plants to increased frequency and intensity of attack by pests, application of pesticides that uncouple natural enemies from their prey and hosts, thereby enabling pest outbreaks. These factors underlie a majority of arthropod outbreaks in managed landscapes ranging from residential gardens to large public parks and urban forests. In some cases the solutions will be very expensive and require paradigm shifts in the way urban forests are designed and planted. Other problems can be resolved through reductions in chemical inputs including fertilizers and insecticides. It is our hope that this synthesis will act as a catalyst for entomologists to work with urban planners, landscape managers, and the general public to create more sustainable landscapes. Our goal is to reduce dependence on inputs such as fertilizer and pesticides while providing enhanced levels of services including beauty, recreation, biodiversity, biological remediation, and ecosystem function in urban settings.

Neurohormonal control of diuresis in *Rhodnius prolixus* (the vector of Chagas' disease)

Ian Orchard, Jean-Paul Paluzzi, Juan Ianowski, Victoria Te Brugge

University of Toronto Mississauga, Mississauga, ON, Canada

Introduction: Diuresis in *Rhodnius prolixus* is under the neurohormonal control of neuropeptides and serotonin. These neurohormones act on the crop and Malpighian tubules to stimulate salt and water transport. These, and other factors, are also involved in a range of feeding-related physiological events, including cuticle plasticization, contraction of muscles of the digestive system, salivation, and increases in rate of heart-beat. The cessation of diuresis has been less studied, but is an essential phenomenon that prevents excessive loss of water and salts. It has been suggested that an anti-diuretic hormone, with properties similar to *Manduca sexta* cardioacceleratory peptide 2b (Manse CAP2b; pELYAFPRVa), might be present in *R. prolixus*.

Methods and Results: Using molecular biology in combination with MALDI-TOF/TOF tandem mass spectrometry, we have determined the sequence of the CAP2b/CAPA-related peptides in *R. prolixus*. Rhopr CAP2b is indeed an anti-diuretic factor, inhibiting serotonin-stimulated secretion from crop and Malpighian tubules. In addition, we have characterized the expression of mRNA encoding these peptides in various developmental stages and have also examined the tissue-specific distribution in fifth instars.

Conclusions: The overall control of events associated with gorging on a blood meal is complex, involving a range of neuropeptide families and serotonin that act upon a variety of tissues to bias them towards a new physiological state. The parasite causing Chagas' disease is transmitted during diuresis / excretion, and therefore neuropeptides and serotonin control the timing of transmission of this disease. Understanding these processes might lead to strategies for preventing the transmission of Chagas' disease.

Central neurons expressing multiple chemical factors are involved in the neural control of reproductive tissues in the female locust, *Locusta migratoria*

Angela Lange, Rosa da Silva

University of Toronto Mississauga, Mississauga, ON, Canada

Introduction: The spermatheca in the female acts as a repository for spermatazoa deposited by the male, and in the locust is situated dorsal to the lateral and common oviducts. In the locust, eggs mature in the ovaries and are ovulated into the lateral oviducts where they are held till a suitable oviposition site is found. At that time, aided by muscular contractions of the lateral oviducts, the eggs are propelled through the common oviduct and genital chamber and deposited in the soil. Contractions of the spermathecal sac lead to spermatozoa release, resulting in fertilization of eggs in the genital chamber. Coordination of the oviducts and spermatheca is clearly critical to the production of viable eggs.

Methods: Immunohistochemistry, neurobiotin backfilling and neurophysiological techniques have been used to examine the neural control of both the oviducts and spermatheca and the integrative actions of these two visceral muscles.

Results: Both structures are under central neuronal control incorporating neurons that express an array of peptide and amine phenotypes. Many of the phenotypes are common to both reproductive tissues. A neural loop ensures the coordinated release of spermatozoa when an egg passes into the genital chamber.

Conclusions: Central neurons control the muscular activities of the spermatheca and oviducts of the locust, allowing these tissues to work independently or in a coordinated and integrated fashion. This paper will discuss our understanding of the neural control of these reproductive tissues and their coordination.

‘Push-Pull’ - a chemical ecology-based IPM strategy for smallholder farmers in Africa

Zeyaur Khan

International Centre of Insect Physiology and Ecology (ICIPE), Nairobi, Kenya

With recent advances in our understanding of the chemical ecology of plant-insect and plant-plant interactions, we have developed new semiochemicals-mediated crop protection strategies to control insect pests and parasitic weeds in subsistence African farming system. Specifically, the presentation will highlight practical use of plants releasing semiochemicals to attract and/or ward off pest attack, to ensnare the attackers, to attract beneficial insects that will attack the pests, and, at the same time, to cause very effective suicidal germination and control of the African witchweed, *Striga hermonthica,* in cereals. Typically, the plants are deployed in a ‘push-pull’ (stimulo-deterrent diversionary) arrangement with rows of an attractive plant at the border and a repellent plant as an inter-crop with cereals like maize. The intercrop (e.g. the cattle fodder legume *Desmodium uncinatum*) was primarily selected because of novel allelopathic effects of flavonoid compounds in its root exudates on striga, some of which cause germination of striga seeds and others their subsequent development. There are now more than 12,000 smallholder families using the 'push-pull' approach in eastern Africa. The technology is improving their livelihood through increased agricultural productivity and improved environmental sustainability. In addition, it opens up significant opportunities for smallholder growth and represents a platform technology around which new income generation and human nutritional components, such as livestock keeping, can be added. To ensure long-term sustainability of the system, we are currently developing quality control protocols to monitor any potential changes in the semiochemicals produced by existing trap and repellent plants, and allelopathic agents produced by roots of desmodium intercrops. We are also exploring the possibility of broadening options to different farming communities through biotechnological transfer of biochemical traits associated with the systemic release of the defense chemicals from repellent plants to maize itself and those associated with striga allelopathy to edible legumes and, perhaps in the long term, to maize itself to create a new generation of weed-free maize plant.

The entomofauna of Greenland and its zoogeographical status

Jens Böcher

Zoological Museum, Copenhagen, Denmark

Greenland is an arctic area with a comparatively depauperate biota, the origins of which have been a subject of much interest and debate for more than a century. The expectation that the distribution and abundance of insects and arachnids at high latitudes will prove particularly susceptible to global climate change has recently added extra momentum to studies of the Greenland entomofauna, giving an updated stock-taking and continuous inventory of this fauna high priority. As a basis for such work the compilation of an identification manual of this fauna has been undertaken by the Entomology staff of the Natural History Museum of Denmark in collaboration with a large international specialist team. The revision of available museum holdings and new field work carried out in preparation for this publication have provided massive new information about the composition and distribution patterns of the Greenland entomofauna, now known to consist of about 1100 species.

Geological evidence points to a ”tabula rasa” at the height of the last glaciation, so that all Greenland taxa had to immigrate during the only 10.00 years of the Holocene. In spite of the position of the island, close to the North American continent, the Greenland faunas of particularly soil-bound taxa like Coleoptera, Collembola, Oribatida and Mesostigmata have sizable components of species of Palaearctic origin. A number of explanations of this strong Palaearctic element in the Greenland biota have been suggested, and these will be discussed in the light of the extensive new data and evidence from recent palaeo-entomological work.

Tracking butterfly flight with harmonic radar: Linking genotype, phenotype and performance

Kristjan Niitepõld, Otso Ovaskainen, Ilkka Hanski

University of Helsinki, Helsinki, Finland

Introduction: Many insects, including butterflies, use flight for both everyday purposes and dispersal. Flight ability may thus have fitness consequences in several ways. It has been suggested that certain phenotypes would be more likely to disperse, which clearly is the case in wing-dimorphic insects. We have been studying dispersal mechanistically in a wing-monomorphic butterfly species. We link together genetic variation in the *Pgi* locus, flight metabolic rate and flight in field conditions.

Methods: We measured the flight metabolic rate of common garden-reared Glanville fritillary butterfly (*Melitaea cinxia*) females using flow-through respirometry. On the following day an ultralight transponder was attached to the thorax of individuals which were released in an open heathland and followed using a harmonic radar. We recorded the flight paths of 66 females moving freely for several hours. A wing sample taken before the release was used to genotype the individuals for the polymorphic *Pgi* locus.

Results: Lab-measured flight metabolic rate was highly correlated with butterfly mobility in the field. An interaction between *Pgi* genotype and temperature was found both in the respirometry measurements and in radar-measured mobility. Also, mobility peaked at intermediate ambient temperatures in the field.

Conclusions: We have shown how variation at the genetic level may be correlated with flight in the field through the link of metabolic rate. The genotype being active in cool temperatures has in previous studies been shown to be most common in newly-established local populations in Finland. This supports the idea of mobile individuals establishing new populations, and suggests a mechanism for maintaining genetic polymorphism in a metapopulation.

Females do it better: Superior conditions for female development in a gall-inducing wasp

Netta Dorchin[1], John Hoffmann[2], Wendy Stirk[3], Miroslav Strnad[4], Johannes van Staden[3]

[1]Museum Koenig, Bonn, Germany, [2]University of Cape Town, Cape Town, South Africa, [3]Research Centre for Plant Growth and Development, University of KwaZulu-Natal, Pietermaritzburg, South Africa, [4]Palacky University and Institute of Experimental Botany, Olomouc, Czech Republic

Introduction: The pteromalid wasp, *Trichilogaster acacialongifoliae*, is a gall-inducing biological control agent introduced from Australia to South Africa against the invasive weed *Acacia longifolia*. Galls are induced in inflorescence and vegetative buds, and show striking differences in the abundance, position, and shape of larval chambers between the sexes. Females are found in spherical chambers at the center of the gall, whereas males, when present, are found in oval and much smaller chambers along the gall periphery.

Methods and Results: In a histological study of the galls we found significantly larger amounts of vascular tissues and stored metabolites around female chambers than around male chambers. These findings attest to an improved food supply and a higher metabolic activity around female chambers, a condition we attribute to the presence of phytohormones. To test this assumption, we used bioassays comparing Auxin- and Cytokinin-like activity in extracts of male and female larvae, and found significantly higher activity in females. Gall tissues originating from female chambers likewise showed higher phytohormone activity than tissues originating from male chambers.

Conclusions: Our data show that *T. acacialongifoliae* females are significantly more efficient than males in eliciting the gall induction response, resulting in improved nutritional conditions for their development. These physiological differences between the sexes are most probably responsible for the sexually dimorphic gall structures observed in this species. However, the source of the elevated phytohormone levels in the insect and gall tissues is currently unknown.

Larval-pupal parasitoids of the African wild silkmoth, *Gonometa postica* (Lepidoptera: Lasiocampidae) in the Mwingi Forests, Kenya

Ken Fening[1], Esther Kioko[2], Suresh Raina[3], Jones Mueke[4]

[1]ICIPE/Kenyatta University, Nairobi, Kenya, [2]ICIPE, Nairobi, Kenya, [3]ICIPE, Nairobi, Kenya, [4]Kenyatta University, Nairobi, and Democratic People's Republic of Korea

Introduction: *Gonometa postica* produces high quality silk, but is affected by parasitoids. This study seeks to assess the extent to which wild silk cocoon production is affected by parasitism and to study the development behavior of these parasitoids.

Methods: A survey of parasitism of *G. postica* larvae and pupae on host and non-host plants, and development of parasitoids were undertaken for two generations in 2006 at six field sites, three each in Imba and Mumoni forests of Mwingi, eastern Kenya. All freshly spun cocoons of *G. postica* were sampled at each site from a total of one hundred trees of the host plants and other non-host plants where they have migrated before pupation. The cocoons were kept individually in fine net-sealed plastic vials to determine percentage parasitism.

Results: Two dipterans and four hymenopteran larval-pupal parasitoids were identified from the two forests. They were all gregarious, endoparasitic koinoboints. The most common ones were *Palexorista* sp. (Diptera: Tachinidae) and *Goryphus* sp. (Hymenoptera:Ichneumonidae) with parasitism ranging from 1.8 – 32.7 % and 2.2 – 7.5 %, respectively. Parasitism varied significantly according to host or non-host plants, generations and sites. *Eurytoma transvaalensis* Cameron was thought to be a facultative hyperparasitoid of *Goryphys* sp. Multiparasitism was demonstrated for some species, as both *Pimpla* sp. and *Goryphus* sp. were obtained from the same cocoon of *G. postica.*

Conclusions: The current study has identified six larval-pupal parasitoids of *G. postica*.

Residual efficacy of aerosol insecticides in mills and warehouses

Frank Arthur, Thomas Phillips

USDA-ARS, Manhattan, Kansas, United States

Aerosol insecticides are receiving increased usage with the impending phase-out of methyl bromide in milling facilities. Some of these aerosols are also being applied in food warehouses. Questions arise as to the distribution of these aerosols and their residual persistence. Both of these components were examined to determine implications for insect pest management.

Concrete treatment arenas were constructed using the bottom portions of a plastic Petri dish, approximately 62cm2 in total area. These arenas were shipped to industrial cooperators, who exposed them to the label rates of aerosol insecticides, and then shipped these dishes back to the Grain Marketing and Production Research Center, Manhattan, Kansas, USA.. Residual efficacy was assessed by exposing different life stages of either *Tribolium castaneum*, the red flour beetle, or *Tribolium confusum*, the confused flour beetle.

Results show that the aerosols containing either methoprene or pyriproxyfen, both of which are insect growth regulators (IGRs), were highly effective on immature stages of both beetle species. The organophosphate diclhorvos offered little residual control.

Farmers' ethno-ecological knowledge of termites and their management in southern and eastern Africa

Gudeta Sileshi[1], Philip Nyeko[2], Philip O. Y. Nkunika[3], Benjamin M. Sekamatte[4], Festus K. Akinnifesi[1], Oluyede C. Ajayi[1]

[1]World Agroforestry Centre (ICRAF), Lilongwe, Malawi, [2]Makerere University, Kampala, Uganda, [3]University of Zambia, Lusaka, Zambia, [4]RIU (Research Into Use), Nkoola Institutional Development Associates, P.O. Box 22130, Kampala, Uganda, [5]World Agroforestry Centre (ICRAF), Lilongwe, Malawi, [6]World Agroforestry Centre (ICRAF),, Lilongwe, Malawi

Introduction: Termites are 'keystone' species in Africa as they play a dominant role in the way that managed and natural ecosystems function. Although less than 5% of the approximately 1000 termite species known in sub-Saharan Africa cause serious damage to crops and tree species, termites generally are regarded as "pests" in agriculture and forestry. Non-specialists approach their control as if a single pest were to be dealt with, which is often in sharp contrast with farmers' attitudes towards termites. Therefore, farmers' ethno-ecological knowledge may be valuable in designing more sustainable strategies for pest management and sustainable agriculture.

Methods: Data on farmers' knowledge, attitudes and management practices were collected using community meetings, participatory rural appraisal (PRA), individual interviews using structured questionnaires and direct observation by the authors in Zambia, Malawi, Mozambique and Uganda.

Results: Farmers perceived specific termites as the major causes of tree mortality and damage to staple crops such as maize, cassava and groundnuts, and they identified most of those that damage their trees and crops using local names, and applied various indigenous termite control practices. The strengths and limitations of farmers' ethno-ecological knowledge and termite control practices are discussed and recommendations for future research are given.

Phoretic arthropods of the red imported fire ant (*Solenopsis invicta*, Hymenoptera: Formicidae) in Central Louisiana

John Moser

USDA Forest Service, Pineville, LA, United States

A total of 4665 phoretic arthropods comprising 29 species were taken from red imported fire ant, *Solenopsis invicta* Buren (RIFA) alates that were preparing to fly from nests in Pineville, Louisiana. A wide variety of taxonomic groups were represented, including 2 insect- and 14 mite families. The arthropods fell into two classes -- those that may be truly phoretic with more than four specimens collected [13 species] and those appearing to be accidentally phoretic with 1-3 specimens collected [16 species]. The fact that over one-half of the species may have been "accidental" may mean that the alates were picking up mites from adjacent sources, such as grass, soil, tree bark; this suggests that many small arthropods may routinely be using phoresy as a dispersal mechanism. The arthropod with perhaps the highest total numbers was *Cyphoderus similis* Folsom a wingless insect, and the only phoretic species belonging to the Collembola. Twenty-three of the 29 species may be new; five of the common species are currently being described; another five species are future candidates for descriptions. Data analyses indicate that the more common species may actively persist in nests for the entire year. The scutacarid and pygmephorid associates may be associated with fungi. These and common associates from other families carried many types of hyperphoretic spores of fungi from inside the fire ant nests. All three of the laelapid mites may be important predators or parasitoids of individuals within the nests. *Histiostoma* n. sp. is a filter feeder consuming microorganisms, and the collembolan is possibly a general feeder. RIFA is native to Brazil, and we speculate that most of the common mite associates may also have originated there. *Trachyuropoda whitkombi*, at least, has been documented from RIFA nests of that country.

Area-wide IPM for commercial wheat storage

Paul Flinn[1], David Hagstrum[2], Carl Reed[2], Thomas Phillips[2]

[1]USDA-ARS, GMPRC, Manhattan, Kansas, United States, [2]Kansas State University, Manhatan, Kansas, United States

The USDA, Agricultural Research Service funded a demonstration project (1998-2003) for area-wide IPM for stored wheat in Kansas and Oklahoma. The project utilized two elevator networks, one in each state, for a total of 28 grain elevators. These elevators stored approximately 843682 metric tonnes of wheat, which was harvested from approximately 324000 hectares. During this study, thousands of grain samples were taken in concrete elevator bins. A vacuum-probe sampler was used to take ten 3-kg grain samples in the top 12 meters of each bin at grain elevators. Decision support software, Stored Grain Advisor Pro (SGA Pro) was developed. This software interprets insect sampling data, and provides grain managers with a risk analysis report that describes which bins are at low, moderate or high risk for insect-caused economic losses. Recommended treatment strategies and economic analysis are presented to the manager. The area-wide IPM program was superior to calendar-based management because it ensured that the grain in each bin was only treated when insect densities exceeded economic thresholds. This approach reduced the frequency of fumigation while maintaining high grain quality. Elevators that followed our recommendations reduced the number of bins they normally fumigated by at least 50%. A new grain-scouting company was started that is using SGA Pro and the sampling tools that were developed in this project.

Insect pest management in pulses in India

Chandra Srivastava

Banaras Hindu University, Varanasi, Uttar Pradesh, India

Introduction: Chickpea (*Cicer arietinum* L.) and pigeon pea [*Cajanus cajan* (L.) Millspaugh] are the two important pulse crops grown in India and are the major source of vegetarian protein to the millions of people in Indian sub-continent. Insect pests are the major biotic constraint to increase the production and productivity of pulses in India. These two pulse crops are attacked by more than 300 insect pests (> 60 on chickpea and > 250 on pigeon pea). *Helicoverpa armigera* Hubner is the most serious insect pests on chickpea and pigeon pea. Whereas *Melanagromyza obtusa* Malloch is also a serious pest of pigeon pea.

Methods: Experiments were conducted on larger plots and different modules were tested in farmers fields on both the crops. The treatments included cultural control, bio-rationals and judicious use of eco-friendly synthetic insecticides.

Results: Application of Neem Seed Kernel Extract (NSKE) at 5% concentration and HNPV @ 400 LE/ha managed the *H. armigera* on chickpea. Whereas on pigeon pea adjustments in sowing dates and crop maturity, application of eco-friendly synthetic insecticide and NSKE 5% minimized the damage *of H. armigera* and *M. obtusa*.

Conclusions: *H. armigera* on chickpea can be managed by combining the cultural control and use of bio-rationals. Whereas on pigeon pea, in addition to cultural control and bio-rationals, one spray of eco-friendly synthetic insecticide is required. By managing *H. armigera* on chickpea, the yield can be increased by 30-40%, whereas in pigeon pea the yields can be doubled by the successful management of *H. armigera* and *M. obtusa*.

The relative importance of snags and logs to the saproxylic beetle community in two forest types of the southeastern United States

Mike Ulyshen[1], Jim Hanula[2]

[1]University of Georgia, Athens, Georgia, United States, [2]USDA Forest Service, Athens, Georgia, United States

Numerous studies from Europe and Canada have demonstrated that saproxylic insects are sensitive to forest management practices that reduce the abundance and variety of dead wood. Yet this diverse community continues to receive little attention in the southeastern United States, a region supporting some of the most diverse, productive and intensively managed forests in North America. Research is needed to better understand the habitat requirements of saproxylic insects in this region if these species are to be retained for future generations. The primary purpose of this study was to compare the beetle communities inhabiting snags (i.e., standing dead trees) and logs of three common tree species (*Pinus taeda*, *Quercus nigra* and *Liquidambar styraciflua*) to determine the relative importance of these habitats to saproxylic beetles. Sampling took place in stands dominated by loblolly pine (*P. taeda*) as well as in mixed bottomland hardwood forests in the upper coastal plain of South Carolina.

The community ecology of tropical rainforest termites: a spatial analysis considering environmental and biotic interactions

Olivia Scholtz[2], Mairi Knight[2], Rod Blackshaw[2], Sarah Donovan[2], Paul Eggleton[1]

[1]Natural History Museum, London, United Kingdom, [2]University of Plymouth, Plymouth, United Kingdom

Introduction: Termites feed on organic material at various stages of decomposition, and as ecosystem engineers, their influence on soil properties may feedback into the termite community. We examined the spatial structure of termite feeding groups, soil and micro-habitat properties and other soil faunal groups, to consider the ecological interactions that are occurring within the termite community.

Methods: A one hectare plot, divided into 2 m x 2 m contiguous sample points, was surveyed in a tropical rainforest in Sabah, Borneo. At each sample point, termites were sampled from a soil pit (25cm x 25cm x 10cm deep), along with earthworms (considered their ecological analogues) and ants. Several environmental variables were also recorded. Spatial patterns for these variables were quantified, and spatially explicit associations analysed, using SADIE.

Results: The termite community was dissociated with soil moisture levels and under-storey vegetation. Soil feeding (SF) and non-soil feeding (NSF) termites, were associated with their respective food material, i.e. organic rich soil, and logs and sticks. The oral and/or faecal products on NSF that are worked into the soil profile, may provide a food material to SF, however no association was detected between the two groups. Predatory ants were associated with the termites, and a weak (non significant) association was found between SF and earthworms. The spatial scales of these variables indicate the complex interplay of environmental and biotic interactions.

Conclusions: It appears that food quality and availability is an important factor in structuring termite communities. However, this effect may be reduced by negative affects such as predation pressure.

Repellent activity of alligator pepper, *Aframomum melegueta* (Zingiberaceae) and ginger, *Zingiber officinale* (Zingiberaceae), against the maize weevil, *Sitophilus zeamais* (Coleoptera: Curculionidae)

Donald A. Ukeh[1], Michael A. Birkett[2], John A. Pickett[2], A. Jennifer Mordue (Luntz)[1]

[1]*School of Biological Sciences, University of Aberdeen, Aberdeen, Scotland, United Kingdom,* [2]*Centre for Sustainable Pest and Disease Management, Biological Chemistry Department, Rothamsted Research, Harpenden, England, United Kingdom*

Introduction: Maize, *Zea mays* L. (Poaceae), is an important source of carbohydrate in Nigeria. *Sitophilus zeamais* is a major insect pest of stored maize in the tropics. Essential oils and oleoresins extracted from seeds of alligator pepper, *Aframomum melegueta*, and rhizomes of ginger, *Zingiber officinale* were evaluated for their repellent activity against *S. zeamais* in the laboratory.

Methods: Vacuum distilled oils and oleoresins were tested against *S. zeamais* in a Pettersson olfactometer using 3 day old adults at 25 ºC, 65 % rh. The mean time spent and the mean numbers of entries made by the weevil to the test and control arms were assessed in 10 min duration.

Results: Olfactometer assays showed that *S. zeamais* adults were significantly repelled by vacuum distillates and oleoresins of *A. melegueta* and *Z. officinale* when tested individually ($p < 0.001$), and in combination with maize grains ($p < 0.05$). Bioassay-guided liquid chromatography of the distillates showed that the fractions containing polar compounds accounted for the repellent activity. Coupled gas chromatography-mass spectrometry (GC-MS), followed by GC peak enhancement and enantioselective GC using authentic compounds, revealed the identity of the 3 major compounds in the behaviourally active *A. melegueta* fraction to be (*S*)-2-heptanol, (*S*)-2-heptanyl acetate and (*R*)-linalool. A synthetic blend of the 3 compounds, prepared in a ratio (1:6:3) found in the distillate, was shown to account for repellent activity.

Conclusions: This research provides the scientific basis for the potential use of *A. melegueta* and *Z. officinale* in stored-product protection at the small-scale farmer level in Nigeria.

Odorant-binding proteins in insect vectors

Linda Field, John Pickett, Jing-Jiang Zhou

Rothamsted Research, Harpenden, United Kingdom

When insects respond to semiochemicals such as pheromones or host odours the first step is detection of the volatile cues by sensilla on the antennae. The odour molecules enter the sensilla via pores on the surface and are transported to the odour receptors (ORs) by odorant-binding proteins (OBPs). Many different putative OBPs have been identified in a range of insect species and there is some evidence of specificity between the proteins and the odour ligands.

We have used a 'MotifSearch' algorithm to identify genes encoding putative OBPs in the vectors *Anopheles gambiae* and *Aedes aegypti*. This had revealed a large number of genes for different classes of OBP some of which are specific to mosquito species and some of which show expression specific to female antennae and are therefore likely to be involved in the location of the correct host for the blood meal.

We will present data on the mosquito putative OBPs and techniques being developed to study their interactions with ligands. Preliminary experiments to identify similar genes/proteins in tsetse are also underway.

A first view of gall-inducer beta diversity in South America

Milton Mendonça

Departmento de Ecologia, UFRGS, Porto Alegre, RS, Brazil

Gall-inducing arthropods are useful for diversity sampling allowing recognition of arthropod and plant species through gall morphology. Galler diversity is almost always studied for alpha diversity only (species richness). Beta diversity (species composition) is nearly unexplored, and I provide examples where it can reveal important patterns. A dataset of 429 gall morphotypes from Rio Grande do Sul (RS) in subtropical south Brazil is analysed along with a few examples of data from the literature. RS gallers were sampled across 5 years in 8 localities and 42 trails with standardised 1h30min censuses, usually repeated visits (2 to 8 times) to trails with homogeneous vegetation. Samples covered 7 vegetation types: grassland, steppic savannah, restinga shrublands, humid forests, riparian forests, riparian forest edges (with grassland) and peat forest. Space is more important than vegetation type for beta diversity, although both factors were significant (ANOSIM tests: only savannah significantly differs from riparian forests, but most localities have significantly distinct species compositions). However, even between nearby (1 km apart) trails, galling fauna similarity can be low (20-40% species in common), except for savannahs (50-80% common species). Low similarity among close-by sites was found for cerrado and Pantanal in tropical Brazil, and Chaco in Argentina. Insufficient sampling is unlikely: for RS galls correlations between measures of sampling effort (trails and samples per locality) and similarity between nearby sites are non-significant (better sampled localities or vegetation have equally low similarities). This first assessment uncovers interesting ecological patterns that should be explored and considered in galler diversity hypotheses.

Control and modulation of salivary secretion in *Periplaneta americana*

Wolfgang Blenau[1], Britta Troppmann[1], Jeannine Witte[1], Otto Baumann[1], Arnd Baumann[2], Bernd Walz[1]

[1]University of Potsdam, Potsdam, Germany, [2]Research Centre Jülich, Jülich, Germany

The acinar salivary glands of the cockroach *Periplaneta americana* receive a dual innervation from the subesophageal ganglion and the stomatogastric nervous system. Acinar cells are surrounded by a plexus of dopaminergic and serotonergic varicose fibers. In addition, serotonergic terminals lie deep in the extracellular spaces between acinar cells. Recently, we could show that the gland is also innervated by neurons that contain GABA. Secretion in cockroach salivary glands is stimulated by dopamine and serotonin. Serotonin stimulates the secretion of protein-rich saliva, whereas dopamine causes the production of protein-free saliva. These observations are consistent with the view that protein-producing central cells of the acini respond only to serotonin, ion-transporting peripheral cells to serotonin and dopamine, and most duct cells only to dopamine. Thus, two elementary secretory processes, namely electrolyte/water secretion and protein secretion, are triggered by different aminergic transmitters. We characterized the pharmacological properties of dopamine- and serotonin-induced secretory responses by using receptor agonists and antagonists. PCR experiments with degenerate primers were performed in order to clone dopamine and serotonin receptor genes from *Periplaneta.* We obtained four PCR fragments of putative biogenic amine receptors. Meanwhile, three of them were cloned in full length. Here, we will focus on the serotonin 5-HT_1 receptor (Pea5-HT_1). Functional properties of Pea5-HT_1 were studied in stably transfected HEK 293 cells. Serotonin reduced cyclic AMP production in a dose-dependent manner. Pea*5-ht1* mRNA has a widespread distribution in various tissues including the salivary glands as shown by different techniques. In addition, we have cloned a cDNA fragment coding for nitric oxide synthase (NOS). NOS expression was proven in the salivary glands by using RT-PCR and NADPH diaphorase staining. Dopamine-induced salivary secretion was reduced by the application of NO donors.

Nest inheritance in the social wasp *Polistes dominulus*

Thibaud Monnin, Alessandro Cini, Vincent Lecat, Pierre Federici, Claudie Doums

Laboratoire Fonctionnement et évolution des systèmes écologiques CNRS UMR 7625, Université Pierre et Marie Curie, Paris, France

Introduction: We studied the potential conflict over nest inheritance in the social wasp *Polistes dominulus*. Colonies are initiated by 1 to 8 foundresses, of which 1/3 are unrelated. The alpha foundress monopolises reproduction, but one of the subordinate foundress may inherit the nest if alpha dies. Workers are daughters of alpha. Because workers can mate in *Polistes* they may oppose to an unrelated subordinate inheriting the nest, by favouring a sister worker instead.

Methods: We investigated this potential workers-subordinates conflict by analysing egg-laying and egg destruction in three sets of colonies: controls, colonies where brood was regularly removed to mimic the ageing of alpha, and colonies where alpha was removed. Colonies were video recorded continuously for 22 days. Relatedness was determined using microsatellites analysis.

Results: In control colonies alpha laid most eggs, and destroyed most of the few eggs laid by subordinates and workers. When brood was removed all wasps laid more eggs, especially workers. However, alpha retained a near-reproductive monopoly by destroying the other wasps' eggs. When alpha was removed, beta became the new alpha. She laid most eggs and destroyed the few eggs laid by other wasps. There was no difference between control colonies and colonies where alpha was removed, and no effect of relatedness.

Conclusions: There is no evidence of a conflict over nest inheritance, despite the potential high relatedness costs to workers. Colony level costs of conflict may favour a conventional nest inheritance by beta. Also, workers may leave the nest to initiate their own.

Monitoring phytosanitary insect pests and sharing pest information in tropical areas

Yulu Xia[1], Ronald Stinner[1], James Vankirk[1], Aunu Rauf[2], Merle Shepard[3], Michael Hammig[3], Phillip Chung[4], Shelby Fleischer[5], Stephen Crawford[5], Jon Voortman[5], Carltle Brewster[6], Jean Cobb[6], Pat Hipkins[6], Donald Mullins[6], James Westwood[6]

[1]North Carolina State University, Raleigh, NC, United States, [2]Bogor Agricultural University, Bogor, Indonesia, [3]Clemson University, Clemson, NC, United States, [4]Rural Agricultural Development Authority, Kingston, Jamaica, [5]The Pennsylvania State University, University Park, United States, [6]Virginia Polytechnic Institute and State University, Blacksburg, United States

Introduction: Fruit flies, whiteflies, and the cocoa pod borer (CPB) (*Conopomorpha cramerella* Snellen), are among some of the worst agricultural insect pests. It is critical to share information about these pests and monitor their distribution and populations on a regional, and global basis.

Methods and Results: This collaborative effort has involved three tropical regions: Southeast Asia (SA), the Caribbean Basin (CB), and West Africa (WA).

SA Project. This study focuses on sharing pest information about the CPB. CPB is a destructive cocoa pest in Southeast Asia only. It would be devastating to world cocoa production if it spreads to other cocoa production areas. Our efforts involve five areas: a) creating a knowledgebase of CPB; b) collecting and distributing CPB pest management technology; c) developing databases such as a Global CPB Expert Database, d) mapping of CPB worldwide; e) databasing general pest management information.

WA Project. Study scope includes a) developing a knowledge base of whitefly biology and dynamics, including alternative host plants, b) a pesticide residue and safety training website, c) developing an online mapping tool to provide dynamic descriptions of whitefly distribution in the region.

CB Project. Our effort is to develop an online fruit fly surveillance system for monitoring the five species of tephrid fruit flies in the region. An online data reporting and mapping system has been developed. Training sessions on sampling procedures and methods have been conducted and data collection is in progress. The current effort is focused on sampling and data reporting.

Phylogeny and antiquity of the bees based on combined molecular, morphological and paleontological datasets.

Sophie Cardinal[1], Atsushi Kawakita[2], Bryan Danforth[1]

[1]Cornell University, Ithaca, NY, United States, [2]Kyoto University, Kyoto, Japan

The traditional view of phylogenetic relationships of bee families has been recently contested by molecular data in favor of a topology where a paraphyletic Melittidae is sister to the remaining bees instead of Colletidae. In this study, we have expanded the molecular dataset to include 7 genes and all major lineages of bees with appropriate outgroups. The molecular dataset was combined with morphological data for a total evidence analysis. Phylogenetic relationships were estimated under parsimony, maximum likelihood and Bayesian optimality criteria. Increased taxon sampling within the family Apidae allowed us to incorporate fossil data to robustly estimate the antiquity of bees for the first time. Divergence dates were also estimated for all major bee clades. The antiquity of eusocial and cleptoparasitic behavior within bees is discussed as well as major shifts in diversification rates.

Simulation of mating disruption and mass trapping with competitive attraction and camouflage

John A. Byers

US Arid-Land Agricultural Research Center, USDA-ARS, Maricopa, AZ, United States

Introduction: Computer simulation was used to explore variation of key model parameters such as effective attraction radius (EAR) of lures, lure density, and female/male density on efficacy of mating disruption and mass trapping of moths and other insects.

Methods: QuickBASIC and Java program languages were used to simulate male moth movement as a correlated random walk during random encounters with EAR of lures of variable radius and density. Calling female moths of variable EAR and density were in competition with lures in attracting males that oriented in the EAR for various periods. Females could be camouflaged by lure EAR but were allowed to move positions at various rates.

Results: When male orienting time was constant regardless of EAR, the models indicated no difference in mating disruption efficacy between either a higher density of dispensers with smaller EAR, or a lower density of dispensers with a compensating larger EAR. However, when the orienting time was increased in proportion to dispenser EAR, then fewer dispensers with larger EAR were more effective in reducing female mating than were more numerous ones with smaller EAR. When costs of pheromone are substantial, however, more numerous dispensers of smaller EAR would be more economical since dose-response curves in previous studies indicate release rate must increase exponentially to achieve a linear increase in EAR. Mass trapping reduced mating more than mating disruption given equivalent conditions.

Conclusions: The models are useful in understanding which variables need be measured to predict a successful mating disruption or mass trapping program.

Possibilities and constraints to breeding potatoes resistant to aphids and aphid-transmitted viruses

Edward B. Radcliffe[1], Jeffrey A. Davis[2], Kathy L. Flanders[3]

[1]Department of Entomology, University of Minnesota, St. Paul, Minnesota, United States, [2]Department of Entomology, Louisiana State University, Baton Rouge, Louisiana, United States, [3]Department of Entomology and Plant Pathology, University of Alabama, Auburn, Alabama, United States

Advances in biotechnology over the past quarter century have transformed our understanding of insect plant interactions. Molecular and biotechnological approaches are now routinely used to supplement conventional plant breeding methodologies. These technologies provide opportunities for exploitation of genetic traits in wild solanaceous species not previously accessible by conventional breeding methodologies. We seek to develop potato breeding lines incorporating durable resistances to aphids (*Myzus persicae*, *Macrosiphum euphorbiae*) and viruses (*Potato leafroll virus*, *Potato virus Y*). Wild potato species (~190 spp. are recognized) represent a vastly underutilized resource, e.g., *M. persicae*-resistant genotypes are reported in ~40 potato spp. Somatic fusions offer one way to overcome these incompatibilities. Somatic fusions created to incorporate late blight resistance from *S. etubersum* and *S. bulbocastanum* yielded some progeny concurrently resistant to *M. persicae* and *M. euphorbiae*. Past progress in breeding potato for virus/vector resistance has been stymied by our inability to identify resistance except by using phenotypic screens. Gene mapping and identification of molecular markers can facilitate selection of quantitative traits. However, the practicality of using marker assisted selection to concurrently introgress multiple resistances, especially of traits quantitatively inherited (e.g. *M. persicae*, *M. euphorbiae*, PLRV) has yet to be demonstrated. For purposes of validating resistance, vector resistance is best measured in the laboratory using life table studies to measure antibiosis and EPG (electronic penetration graph) to measure antixenosis and elucidate feeding behaviors associated with virus acquisition and transmission. Virus resistance is best measured by field screening in the presence of inoculated viruses and augmented aphid populations.

Integration of *Heterorhabditis indica* with other biorationals for managing chickpea pod borer, *Helicoverpa armigera* (Hüb.)

Aralimarad Prabhuraj, Girish K. S, Shivaleela Shivaleela, Patil B.V

University of Agricultural Sciences, Dharwad, Karnataka, India

Introduction: A successful management strategy was developed against chickpea pod borer, *Helecoverpa armigera* (Hüb) by integrating locally isolated entomopathogenic nematode, *Heterorhabditis indica* (RCR) with other entomopathogens like *Helicoverpa* Nuclear polyhedrosis virus (HaNPV) and *Bacillus thuringiensis* (Bt) and botanicals.

Methods: Preliminary laboratory studies were conducted, to standardize the optimum dosage of nematodes required for field application, to evaluate the compatibility of nematode with entomopathogens and botanicals and their combinations. The optimum dosage of infectives was standardized to third (LC_{50} of 145 IJs/larva) and fourth (LC_{50} of 195 IJs/larva) instars based on the concentration mortality response.

Results: Persistence study on chickpea foliage in field condition indicated that, infectives along with 0.1 % glycerol survived better (80%) compared to other antidessicants. In compatibility studies, though nematode was compatible with other entomopathogens, but was susceptible to higher concentrations of aqueous leaf extracts of some selective botanicals. A series of laboratory bioassay was carried out to select best combinations of *H. indica* with other entomopathogens and botanicals against third and fourth instar *H. armigera* and these were tested in field for two consecutive years. Two year field evaluation indicated that, sequential application of *H. indica* + *Prosopis juliflora* (1 lakh IJs/l + 10%) at 50 and 75 days after sowing was superior with highest larval reduction (23.47%), minimum pod damage (11.27%) and maximum seed yield (19.24 q/h).

Conclusions: Combination of two biorationals either in sequential or simultaneous application resulted in better management of *H. armigera* compared to insecticidal application alone.

Study on insectivorous bats as potential predator of moths of sugarcane borers

Sunaryo Sunaryo, Koko Widyatmoko

PT Gunung Madu Plantations (Sugar Plantation), Bandar Lampung, Lampung, Indonesia

Introduction: Sugarcane moth borers (pyralids, Lepidoptera) are predominant pests of Gunung Madu sugarcane plantation, Lampung, Indonesia. Major control measures include augmentative releases of lab reared parasitoids. However, alarming peaks of borer population still exist occasionally, which shall be characterized by abundant moth flying at 1900-2100 hrs. Within such time some insectivorous bats were observed preying on borer moths and a significant predation was presumed to take place. This brought about the present study.

Methods: Net trapping was used to capture the bats for identification. Twenty specifically designed shelters were made and installed near water reservoirs in sugarcane fields. Monthly observations on shelter occupation were done to study bats' roosting habit. Feces of the predominant species were collected and examined to recognize and quantify the predation.

Results: Three predominant species captured by the net were *Taphozous longimanus, Pipistrellus javanicus*, and *Scotophilus kuhlii*. However, only *S. kuhlii* was observed occupying the shelters. An average of 4.4 bats occupied each shelter and 77% of total shelters installed were occupied. Examination on feces collected from *S. kuhlii* as supplied from net-trapping showed remains of organs of eight insect orders which include Lepidoptera, Coleoptera, and Orthoptera.

Conclusions: The study suggests that bats may settle down in man-made shelters, which may be manipulated to increase their role in controlling moth population. It also suggests that lepidopteran moth is an important constituent of bats' diet. The insectivorous bats could complement the ecological approach of controlling sugarcane moth borers at times when moth population is abundant.

The effects of pyrethroid resistance on transcription of metabolic enzymes in a major African malaria vector, *Anopheles funestus*

Riann Naguran[1], Hilary Ranson[3], Maureen Coetzee[1], Lizette L Koekemoer[1]

[1]Vector Control Reference Unit, National Institute for Communicable Diseases, Johannesburg, Gauteng, South Africa, [2]Division of Virology and Communicable Disease Surveillance, School of Pathology of the National Laboratory Service and the University of the Witwatersrand, Johannesburg, Gauteng, South Africa, [3]Vector Research Group, Liverpool School of Tropical Medicine, Liverpool, United Kingdom

Introduction: *Anopheles funestus* Giles is a major malaria vector in Africa, specifically South Africa. Insecticide resistance in this species had a major impact on malaria transmission in South Africa. Very little is known about the genes responsible in detoxification of insecticides in *An. funestus*. We aimed firstly to determine if the microarray *(*detoxification chip) developed for *An. gambiae* could be used on *An. funestus*. The microarray detoxchip was then used to investigate the effects of pyrethroid resistance in *An. funestus* on transcription of metabolic enzymes.

Methods: The pyrethroid resistant *An. funestus* colony used in this study, originates from Mozambique (Fumoz-R) while the susceptible colony (FANG) originates from Angola. RNA extractions, dye labeling, hybridization, scanning and data analysis were performed.

Results: This study showed that the detoxchip can be used to study transcriptional differences in other insecticide resistant species such as *An. funestus*. A number of genes were over-expressed in the pyrethroid resistant and susceptible strain of *An. funestus*.

Conclusion: This study showed that the *An. gambiae* detoxchip can be used to study transcriptional differences in other insecticide resistant species such as *An. funestus.* Overall the outcomes of this research identified differentially expressed genes in a pyrethroid resistant *An. funestus* strain. The results will provide information on alternative enzymes associated with pyrethroid resistance in this important malaria vector and aid in our understanding of this complex resistance mechanism.

Fossils and phylogeny: The evolution of termites

Michael Engel, David Grimaldi

[1]University of Kansas Natural History Museum, Lawrence, Kansas, United States, [2]American Museum of Natural History, New York, New York, United States

A study of phylogenetic relationships among major lineages of Isoptera is provided based on morphological and ethological data. For the first time an extensive sampling of fossil termites from the Tertiary and Cretaceous periods, including an abundance of "primitive" termites newly discovered and described during the last year. This comprehensive paleontological and neontological analysis recovers major patterns of diversification of termites during the Cretaceous and again in the middle Tertiary. Most Cretaceous taxa are found to represent stem groups to either the modern families or as intermediate between groups of families, including one genus as a stem group to all other Isoptera. Mastotermitidae falls relatively basal in the order, among a diversity of fossil taxa. Termopsidae and Hodotermitidae as widely defined were not recovered as monophyletic with components of these families emerging from a grade of living and fossil termites lineages leading to Kalotermitidae as closely related to the higher termites (Rhinotermitidae + Termitidae). There is relatively tight stratigraphic-rank correlation, with the earliest fossils falling more basal in the order. The analysis indicates that the higher termites, particularly the ubiquitous Termitidae radiated during the Tertiary.

Does temporal synergism increase the efficacy of natural pyrethrins against insect pests?

Anna Khot, Lin Field, Graham Moores

Rothamsted Research, Harpenden, UK

Insecticide resistance is a growing problem around the world. Resistance can be caused by a number of mechanisms, one of which is enhanced detoxification of the insecticide by metabolic enzymes.

Temporal synergism using piperonyl butoxide (PBO) has been found to inhibit some resistance-associated esterase enzymes, overcoming insecticide-resistance in different agricultural pests. This PhD project investigates the use of temporal synergism to increase the efficacy of natural pyrethrins against insect-pests.

In vivo bioassays have been performed to calculate the lethal concentration of natural pyrethrins required to give 50% mortality in the studied population (LC_{50}). These bioassays have demonstrated that the presence of PBO in a tank mix with natural pyrethrins can reduce the LC_{50} for natural pyrethrins. Experiments have also been performed using a pre-application of PBO prior to exposure to pyrethrins, although these results need further investigation. Results will be discussed.

Botanical extracts and other compounds have been screened for their ability to inhibit esterase enzymes using a novel assay. Extracts showing potential to inhibit esterase enzymes have been screened for their ability to inhibit mixed function oxidase activity and will be screened for their ability to inhibit glutathione *S*-transferases. Compounds performing well will be selected for trials *in vivo.*

Ground-dwelling spiders in two Quebec vineyards

Noubar J. Bostanian[1], Christopher M. Buddle[2], Charles Vincent[1], Elise Bolduc[2]

[1]Hortic.Dev.Centre, Agric.Agri-Food Canada, St.Jean-sur-Richelieu, Canada, [2]Dept. of Natural Resources, McGill Univ., St. Anne de Bellevue, Canada

Introduction: Spiders are important predators in almost every imaginable habitat. In vineyards the spider community is composed of arboreal and ground dwelling species. Most spiders are generalist predators. Individual species may not exhibit classic density-dependent control of pests. Nevertheless assemblage of spiders do regulate pest insect populations.

Materials and Methods: Spiders were collected in pitfall traps weekly from May to mid September in two vineyards. All spiders were identified to species. All data were compared using a mean number of spiders collected on a per-trap basis. Diversity comparisons were done using rarefied estimates of species richness (Ecosim software). Community composition was elucidated by analyzing individual pitfall data with detrended correspondence analysis (DCA). Species turnover was evaluated by completing a matrix of shared species by sample period. Temporal distribution of web-building species to hunting species was also evaluated.

Results: A total of 4600 spiders belonging to 97 species from 16 families were collected. Assemblages were similar between the two vineyards independent of environmental differences. Fallow fields and adjacent apple orchards is believed to result for a higher abundance of certain agrobiont species in one of the vineyards. *Tennesseellum formicum* (Emerton) Linyphiidae, showed high phenotypic variation and possibly its multvoltine life cycle is an adaptive behavior to be present in vineyards that are frequently disturbed. Species turnover was high between sample dates. Data on activity and species richness indicated that many species that differ in forraging mode are active all months of the growing season.

Conclusion: spiders in vineyards are well placed to prey on phytophagous pests and their populations should be conserved in vineyards.

Spatial synchrony in forest insect outbreaks: Why is it so ubiquitous?

Andrew Liebhold[1], Ottar Bjørnstad[2], Derek Johnson[3], Christelle Robinet-Makdoud[4]

[1]US Forest Service Northern Research Station, Morgantown, WV, United States, [2]Department of Entomology, Pennsylvania State University, University Park, PA, United States, [3]Department of Biology, University of Louisiana at Lafayette, Lafayette, LA, United States, [4]INRA, UR633 Zoologie Forestière, Orléans, France

Spatial synchrony refers to the coincident temporal variability in the abundance of geographically disjunct populations and is a characteristic of virtually all species of forest insects. For those forest insects that occasionally reach epidemic densities, it is the characteristic of spatial synchrony that determines their pest status because outbreaks occurring synchronously over large areas are likely to result in more substantial ecosystem and sociological impacts. Spatial synchrony can result from 1) dispersal of individuals among populations, 2) synchronous trophic (e.g., parasitism) effects and 3) synchronous stochastic (e.g., weather) effects. Unfortunately it is often difficult to identify the relative contribution of these mechanisms and synchrony observed in real populations is likely the result of several mechanisms. Temporal variability in weather is universally synchronous and this is a plausible explanation of the ultimate ubiquity of synchronous population dynamics. However, understanding synchronous dynamics requires identifying both the factors contributing to synchrony as well as those processes that desynchronize populations. These latter processes are poorly understood but geographical variation in density dependence and nonlinear dynamics are both probably important. In this paper many of these issues are explored using the gypsy moth, *Lymantria dispar*, in North America as a model system.

A mutualistic herbivore? Increased yield through herbivore specific cues

Katja Poveda[1], Maria Isabel Gomez[2], Andre Kessler[3]

[1]Göttingen University, Göttingen, Germany, [2]Universidad Nacional, Bogotá, Colombia, [3]Cornell University, Ithaca, NY, United States

Introduction: Herbivores are known to be an important ecological force via their typically negative effects on plant fitness, which have devastating economic consequences in agriculture. In a few cases, overcompensation has been shown to provide an apparent benefit to attacked plants, but the actual fitness consequences have been controversial and the mechanisms by which overcompensation occurs are unknown. Here we demonstrate that larval feeding by the Guatemalan potato moth (*Tecia solanivora*, Lepidoptera: Gelechiidae), one of the most economically important potato pests in Latin America, leads to a dramatic increase in potato tuber production.

Methods: In the field we evaluated the effect of *T. solanivora* larval feeding on potato tuber production. In greenhouse experiments we tested if larval feeding induces the growth of damaged (local response) or undamaged (systemic response) potatoes. We also tested if herbivore specific cues (regurgitant) in opposition to mechanical tissue damage are causing an increased potato production.

Results: Field-grown potato plants in the Colombian Andes attacked by low numbers of potato moth larvae produce a 2.5 fold higher marketable potato yield than undamaged plants. Greenhouse experiments indicate that this effect is induced by compounds in the larval regurgitant, rather than by mechanical tissue damage.

Conclusions: The possibility of using induced overcompensation mechanisms to increase the per-hectare yield of a major crop has the potential to yield high economic returns. This is particularly true for potato production, as potatoes are the world's fourth most important crop and generate global revenues in excess of 6 billion USD per year.

Reproductive success of subfamilies in the honeybee colony (*Apis mellifera*)

Robin F.A. Moritz

Institut für Biologie, Martin-Luther-Unniversität Halle-Wittenbegr, Halle/Saale, Germany

The honeybee queen (*Apis mellifera*) mates with an excessive number of males and has been reproted to store the semen of up to 50 males in her spermatheca throughout her lifetime. Consequently, the colony is composed of a large number of half-sib subfamilies sired by different fathers but having the same mother queen. This sets the stage for a high potential of intercolonial conflict among these subfamilies. Many adaptations have evolved to prevent conflict both between queen and workers and among workers. Nevertheless, intracolonial selection is a strong factor considerably affecting reproductive success of the various subfamilies in the colony. I will show how this process interferes at the various levels of intracolonial selection determining the selection of queens and reproductive workers. I will argue that this is an inevitable process and highlight how an evolutionary stable strategy can emerge in spite of sometimes huge selection intensities at the individual level in the colony. The interplay between individual, family and colony level selection, a multilevel inclusive fitness, is the key to understanding natural selection processes in honeybees.

Peptidomics of pheromone biosynthesis activating neuropeptide (PBAN)-expressing neurons of an insect

Susanne Neupert[1], Wolf Huetteroth[2], Joachim Schachtner[2], Reinhard Predel[1]

[1]Institute of Zoology, Friedrich-Schiller-University,, Jena, Germany, [2]Fachbereich Biologie, Tierphysiologie, Philipps-University Marburg, Marburg, Germany

Pheromone biosynthesis activating neuropeptide (PBAN) is a member of the FXPRLamide/pyrokinin (PK) peptide family and is encoded on the diapause hormone (DH)-pheromone biosynthesis activating neuropeptide (PBAN) gene. It belongs to the most extensively studied neuropeptides of insects and regulates pheromone biosynthesis in female moths by direct activation of receptors of the pheromone gland cells. Totally, five peptides (PBAN, DH, and α-, β-, γ-SGNP), all of which share a common FXPRL sequence at the C-terminus, were predicted from the *Manduca sexta*-DH-PBAN precursor.

In this study, we analysed the cellular expression of the PBAN and structurally related neuropeptides from neuroendocrine cells in the SEG of the adult tobacco hawk moth, *M. sexta,* for subsequent MALDI-TOF mass spectrometric analysis. Neuropeptides of the DH-PBAN gene were found to be expressed in cells of the mandibular (4), maxillary (10) and labial (2) neuromeres along the ventral midline in the SEG. The mass spectrometric analysis revealed the expression of numerous peptides from the DH-PBAN gene in all neuroendocrine FXPRL synthesizing neurons of the SEG. In contrast to the neurons of the mandibular and maxillary neuromeres which express only the products of the DH-PBAN gene, the cells in the labial neuromere also express products of the CAPA gene, which contains an additional FXPRLamide, CAPA-PK.

Delimiting baridine weevil evolution (Coleoptera: Curculionidae)

Steve Davis

University of Kansas, Lawrence, Kansas, United States

Weevils (family Curculionidae) are one of the most diverse groups of extant organisms, with approximately 60,000 described species. They are extremely important economically, being of great agricultural significance because they are associated with all major groups of plants and plant parts. The weevil subfamily Baridinae is one of the larger weevil lineages. It is distributed worldwide, consists of 548 genera, approximately 9,000 described species, and is considered most in need of systematic study. Most baridine taxa have not been studied since their original description and the generic definitions are in need of much refinement. Although the baridines undoubtedly form a cohesive group, the delimitations of this group also remain uncertain. In order to provide stability to the group and to define the major lineages, the first phylogenetic hypothesis, based on morphology, has been constructed. Because of the rather broad scale of this undertaking, examination of the evolution of many interesting characters has also been made possible.

Introduced bees in Australia – a control regime for integrated weed management.

Caroline Gross

The University of New England, Armidale, NSW, Australia

Introduction. *Apis mellifera* L. was introduced into Australia in the 1800s. The Apiary Industry is an integral part of the domestic and export market as Australian bee products and pollination services are in demand worldwide. Feral colonies of honeybees are present over much of Australia and in the last 20 years there has been much concern over the impacts of honeybees on native biota. In addition, the pressure of introduced pollinators on natural systems is considerable because increasingly apiarists require access to native vegetation to agist their colonies over winter. The impact of honeybees on weed invasiveness is an unquantified area in Australia and a novel area for investigation.

Methods. An evaluation of the impacts of honeybees on weed fecundity was undertaken using two key weed species, Scotch Broom (*Cytisus scoparia*) and Lippia (*Phyla canescens*) in the field and in a glasshouse.

Results. Feral honeybees are having a demonstrable impact on seed set in these weeds — in Scotch Broom a single worker bee is capable of effecting over 6000 seeds in one day; in *Phyla canescens* (Lippia) a pollen vector is also required to effect seed set and honeybees are the primary cause of a seed bank that can reach 100,000 germinable seeds/m^2 per year in dense infestations.

Conclusions. The incorporation of pollinator control is the next step for the integrated weed management of these species and one that will require cooperation from local apiarists. A design for a baiting station and protocols for installation are discussed.

Development of diagnostic dose for monitoring resistance of the Asian corn borer *Ostrinia furnacalis* Guenee to Bt corn in the Philippines

Edwin Alcantara

National Institute of Molecular Biology and Biotechnology, University of the Philippines (Los Baños), College, Laguna, Philippines

Introduction: One of the most critical components of a resistance management strategy for Asian corn borer (ACB) populations is the ability to effectively monitor the development of resistance to Bt corn.

Methods: Artificial diet surface overlay assays were carried out to estimate baseline susceptibility of ACB populations to Cry1Ab protein. Mortality data were analyzed by probit analysis. The upper fiducial limit of the LC_{99} was used as diagnostic dose for monitoring ACB resistance to Bt corn. The same ACB populations were bioassayed in the laboratory to validate the diagnostic dose of Cry1Ab protein.

Results: There was no significant difference in LC_{50} values estimated from bioassays of eight ACB populations collected from Luzon. The LC_{50} values ranged from 0.42 ng/cm^2 to 1.5 ng/cm^2. Likewise, three ACB populations from Mindanao had similar susceptibility to Cry1Ab protein. The Mindanao populations had LC_{50} values ranging from 1.44 ng/cm^2 to 2.37 ng/cm^2. The susceptibility of all the populations was not significantly different from the susceptible ACB reference strain maintained in the laboratory. Each of the twelve ACB populations responded with at least 99% mortality when assayed with the diagnostic dose (104 ng/cm^2) of Cry1Ab protein.

Conclusions: The Philippine ACB populations are homogenous in mortality response and are highly susceptible to Cry1Ab protein. A diagnostic dose of 104 ng/cm^2 Cry1Ab protein can be used for nationwide monitoring for ACB resistance to Bt corn.

Clues to the evolution and speciation of the *Diplolepis* (Hymenoptera: Cynipidae) complex provided by the world's most structurally complex gall on rose hips in eastern Turkey

Joseph Shorthouse, Aban Güçlü, Rüstem Hayat

[1]*Laurentian University, Sudbury, Ontario, Canada,* [2]*Atatürk University, Erzurum, Turkey*

Each of the approximately 42 species of Holarctic cynipid wasps of the genus *Diplolepis* induce structurally distinct galls on wild roses. *Diplolepis* are organ specific, with galls of most species occurring either on the leaves or stems. One of these wasps, *Diplolepis fructuum* (Rübsaamen), induces galls within the flowers and hips of the wild roses *Rosa canina* L. and *R. villosa* L. in northeastern Turkey. Eggs are attached to all organs within immature flowerbuds resulting in galls induced from achenes (seeds), anthers, the hypantium (hip walls), sepals, and petals. Oviposition errors result in galls induced on leaves and tips of shoots. Achene and anther galls are frequently so abundant they cause hips to rupture and turn flowers into masses of tissue four times their natural size. Consistent gall anatomy, regardless of the tissues attacked, illustrates the control gallers have over the development of their hosts. *D. fructuum* is closely related to the first galler of roses and the occurrence of its galls within all tissues of flowers and hips provides clues as to how current species of *Diplolepis*, with their anatomically distinct galls, may have evolved.

Colony relocation in the ant *Aphaenogaster senilis*: role of foragers and reminiscence of acquired experience

Aurore Avargues-Weber, Thibaud Monnin

Laboratoire Fonctionnement et évolution des systèmes écologiques CNRS UMR 7625, Université Pierre et Marie Curie, Paris, France

Introduction: We studied the pattern of colony emigration of the ant *Aphaenogaster senilis*, which reproduces by colony fission, and its ability to improve at emigrating through acquired experience.

Methods: Emigrations were triggered in the laboratory by opening the nest while providing a new nest 1.5 m away (n=10). We video recorded foragers and nurses entering or exiting this arrival nest. Six to eleven weeks later a second emigration was triggered to determine whether colonies improved their performance.

Results: Nest relocation was characterized by a synchronised emigration: the number of workers present in the arrival nest increased following a sigmoid curve. The duration of emigration was relatively constant between colonies, while the delay before emigrating varied. The queen relocated in the middle of the emigration, when many workers were on the move. When emigrations were repeated, the duration of emigration was unchanged but the delay before the emigration was much shorter.

Conclusions: *Temnothorax albipennis* colonies gain experience through migrating. This experience results from the individual experience acquired by foragers and lasts six days. In *A. senilis* the experience acquired lasted several weeks, and it was not due to experienced foragers since these had been removed. These differences may stem from *T. albipennis* nurses being transported by foragers while *A. senilis* nurses actively walk to the destination nest, so that only the latter gain experience by emigrating. This would also explain the longer reminiscence of experience in *A. senilis*, where experienced individuals are not only short lived foragers but also young nurses.

Islands in the Australian savannah: Population genetics of magnetic termite mounds

Judith Korb[2], Anna Schmidt[1]

[1]University of Regensburg, Biology I, Regensburg, Germany, [2]University of Osnabrück, Behavioral Biology, Osnabrück, Germany

The “Magnetic Termite” *Amitermes meridionalis* is restricted to a small part of northern Australia where it occurs in seasonally flooded areas and builds famous wedge-shaped mounds with an elongated axis that is orientated in a striking north-south direction. Despite its popularity not much is known about this species’ biology. Due to its restriction to seasonally flooded areas, it has a very patchy distribution. ‘Islands’ sizes range from a few m² with less than 10 mounds to several km² with several thousands of mounds all differing by their degree of isolation. We used nine variable microsatellite markers, specifically developed for this species, to (1) describe the colony structure of mounds and (2) to test how population size and degree of isolation influence the population structure of *A. meridionalis*. The genetic analyses revealed that each mound was inhabited by a single colony and that colonies were not polydomous. The number and distribution of alleles and relatedness estimates indicated that colonies were founded by one pair of reproductives which was often replaced by its inbreeding offspring. Within the islands, the observed heterozygosity was lower than expected and F-statistics indicated that there was a significant degree of inbreeding. How population size and degree of isolation influence population structure will be discussed in this still ongoing study.

Termites and mites: adaptive behavioural responses to infestation

Judith Korb[2], Alexander Fuchs[1]

[1]University of Regensburg, Biology I, Regensburg, Germany, [2]University of Osnabueck, Osnabrueck, Germany

Rapid adaptation to their hosts' defence systems usually allows parasites to keep the upper hand in the co-evolutionary arms race between hosts and parasites. However, although morphological and physiological adaptations are generally far slower in hosts than in their parasites, the former can rapidly respond to a parasite challenge by dispersal-related, adaptivechanges in their behaviour. We investigated whether the drywood termite *Cryptotermes secundus* altered its behaviour in response to an infestation with parasitic, astigmatic mites.

The frequency of the vital, dispersal-related behaviours allogrooming and proctodeal trophallaxis did not differ between colonies or between individuals with mites compared to without mites. However, activity levels were lower in mite-infested colonies and individuals spent more time resting and feeding when mites were present in the colony, irrespective of whether they were infested themselves or not. This behavioural pattern shown by individuals from infested mite-colonies is known to be associated with a development of *C. secundus* workers into winged dispersing sexuals. As dispersing individuals were less likely to have mites, this behavioural response to the mites' infestation might be an adaptive response to escape the deteriorating nest conditions.

The use of *Solanum oplocense* as a source of resistance to the Colorado potato beetle, *Leptinotarsa decemlineata* (Say)

Yvan Pelletier, David De Koeyer

Potato Research Centre, Fredericton, NB, Canada

The objectives of this study were to evaluate the genetic variability for insect resistance and to gather information on the mechanism of resistance to the Colorado potato beetle (CPB) of *Solanum oplocense*. Further information on the genetics and nature of the resistance was also gathered by studying hybrids during a few generations.

In field plots, the population density of all developmental stages of the CPB tended to be lower on *S. oplocense*. There was a reduction in "feeding" frequency for all larval stages and adults on *S. oplocense*. All larval stages tended to spend more time "resting" and "walking" on *S. oplocense* foliage than on potato. Adults "walked" more on *S. oplocense* foliage than potato. All five CPB life stages consumed much less foliage of the wild *Solanum* species than of potato. When caged with *S. oplocense*, the population of CPB decreased and egg production was greatly reduced compared to potato. Data on the evaluation of resistance in *S. oplocense* hybrid populations will also be presented.

Trypsin Modulating Oostatic Factor (TMOF), from reproduction to digestion

Dov Borovsky

University of Florida, IFAS, Vero Beach, FL, United States

Trypsin Modulating Oostatic Factor, a decapeptide (YDPAPPPPPP), was isolated from the ovaries of *Aedes aegypti* female mosquitoes. Initially the hormone was thought to stop ovarian development and act like a 'birth control pill' because injection of the hormone into blood fed females caused the arrest of ovarian development. When female guts were dissected and assayed, it became apparent that the hormone directly inhibits blood digestion and acts like a 'diet pill' and indirectly inhibits ovarian development.

TMOF has 7 prolines and resists proteolysis in adult and larval guts. The hormone easily penetrates the gut epithelial cells when it is fed to larvae and adult mosquitoes and binds a specific receptor that resides on the hemolymph side of the gut. After binding, the hormone turns off trypsin biosynthesis in the gut epithelial cells by stopping the translation of the trypsin message. TMOF was found to be effective against mosquito larvae, and several other agricultural pest insects, i.e. *Heliothis virescens* and *Diaprepes abbreviatus,*

The hormone was genetically engineered and expressed on the coat protein of TMV, in *Chlorella sp.* and *Chlorella desiccate*, in *Saccharomyces cerevisiae* and *Pichia pastoris* and in alfalfa plants. Feeding tobacco plants that were infected with recombinant TMV expressing TMOF or recombinant alfalfa plants to several agricultural pest insects caused inhibition of larval growth and trypsin biosynthesis. Feeding recombinant chlorella and yeast cells to mosquito larvae caused anorexia starvation and larval death.

These results, the genetic engineering of the hormone and the characterization of its receptor will be discussed.

Advances in the semiochemistry of cerambycid beetles

Jocelyn G. Millar[1], Lawrence M. Hanks[2], Emerson S. Lacey[1], Jardel Moreira[1], James Barbour[3], J Steven McElfresh[1]

[1]University of California, Riverside CA, United States, [2]University or Illinois, Urbana-Champaign IL, United States, [3]University of Idaho, Parma ID, United States

Introduction: The Cerambycidae are a large and diverse beetle family, with >25,000 described species. A number of species are important pests, both in their native ranges, but increasingly in new regions of the world where they have been accidentally introduced. Despite their importance, very little is known of their use of pheromones, and the chemistry of those pheromones.

Methods: Pheromones of a number of cerambycid species were collected from the headspace of confined beetles, and identified by spectroscopic methods. A matrix of likely pheromone chemicals was also synthesized and screened in field trials.

Results: Sex and aggregation pheromones of a number of cerambycid species were identified by the tandem strategy of isolation and identification of compounds from beetle extracts supplemented by screening of possible pheromone components. Most pheromones were male-produced, with males of some species producing >0.1 mg of pheromone per day. The species for which pheromones have been fully or partially identified will be summarized, along with the chemistry of the pheromone compounds. Some general trends and patterns of pheromone use in this family are beginning to emerge, and will be discussed.

Conclusions: Both contact and long-range attractant pheromones are widely used by cerambycid beetles. These compounds have enormous potential for use in IPM programs, particularly for detection of invasive species.

Chemistry and practical applications of pheromones of mealybugs infesting vineyards

Jocelyn G. Millar[1], J. Steven McElfresh[1], Jardel Moreira[1], Kent M. Daane[2], Walt Bentley[3]

[1]University of California, Riverside CA, United States, [2]University of California, Berkeley CA, United States, [3]Kearney Agricultural Center, Rarlier CA, United States

Introduction: Obscure, longtailed, vine, and grape mealybugs constitute some of the most important pests of viticulture worldwide. Their sex attractant pheromones have the potential to be of major use in detection, sampling, and possibly control of these pests. We report the identification, synthesis, and testing of the sex pheromones of each of these species.

Methods: Pheromones of all 4 species were collected in microgram amounts from cohorts of unmated females, identified by spectroscopic and microchemical methods, and synthesized for field bioassays.

Results: The pheromone of each species consists of a single component, and each pheromone has proven to be a highly unusual chemical structure, with all of them being molecules new to science. The pheromones are extremely attractive, with microgram doses attracting males for >8 weeks in the field. Quirks in the reproductive biology of each species may have major implications in the use of these pheromones in IPM programs.

Conclusions: The pheromones of pest mealybugs are likely to become important new tools for IPM, with pheromone lures being extremely attractive to male mealybugs for extended periods under field conditions.

Plant-mediated interactions linking foliar-feeding insects and root-feeding nematodes: ecological significance and underlying mechanisms

Ian Kaplan[1], Robert Denno[2]

[1]Cornell University, Ithaca, New York, United States, [2]University of Maryland, College Park, Maryland, United States

Introduction: Roots play a critical, but largely unappreciated, role in aboveground anti-herbivore plant defenses and root-leaf connections may therefore result in unexpected coupling between above- and belowground consumers.

Methods: Using the tobacco (*Nicotiana tabacum*) system we highlight two examples of this phenomenon. First, using nicotine-deficient mutant plants we tested the role of nicotine, a secondary compound that is synthesized in root tissue, in nematode-induced effects on aboveground herbivorous insects. Second, we used pulse-labeling (^{13}C) of plants followed by stable isotope analysis to assess the impact of foliar insect herbivory on the performance of root-feeding nematodes via plant source-sink dynamics.

Results: Although recent studies emphasize the role of induced defenses in plant-mediated competition between foliar and root herbivores, we demonstrate that leaf-root connections can generate the opposite effect, with positive interactions linking foliar and root consumers. Nematode root herbivory interfered with foliar nicotine expression, resulting in positive effects on aboveground phytophagous insects. Notably, nematode-induced facilitation only occurred on nicotine-expressing plants, and not on nicotine-deficient mutants. Foliar insect herbivory elicited a putative tolerance response whereby aboveground nutritional reserves were allocated to roots, resulting in facilitation of phytoparasitic nematodes co-occurring on the same host-plant.

Conclusions: Plants integrate roots in resistance and tolerance mechanisms for leaf defense, and such root-leaf connections inherently link the dynamics of above- and belowground consumers.

Potential of the wasp *Habrobracon hebetor* (Say, 1836) (Hymenoptera: Braconidae) as a biological control agent for *Corcyra cephalonica* (Stainton, 1865) (Lepidoptera: Pyralidae) in stored rice

Charles Adarkwah, Daniel Obeng-Ofori, Sabine Prozell, Mathias Schoeller, Christoph Reichmuth, Carmen Buettner

[1]Humboldt University of Berlin, Berlin, Germany, [2]University of Ghana, Crop Science Department, Accra Legon,, Ghana, [3]Biological Consultants Ltd, Berlin, Germany, [4]Federal Biological Research Centre for Agriculture and Forestry, Berlin, Germany

Habrobracon hebetor is a gregarious larval ectoparasitoid of several species of pyralids attacking stored grains. The potential of using *H. hebetor* for the biological control of *C. cephalonica* was assessed in rice stored in jute bags. 1 kg of uninfested rice grains was introduced into small jute bags measuring 18 cm x 16 cm. A total of 8 bags (4 bags treated with *H. hebetor* and 4 untreated) were included into the test in separate two chambers. Treated and untreated bags were placed in climatized chambers at the same climatic conditions of a temperature of 25°C and relative humidity of 65%. Sixty first instar larvae of *C. cephalonica* were released into all of the bags that were subsequently sealed and kept for 10 days to allow for the larvae to develop inside the jute bags. The individual bags were placed on a small pallet. Ten *H. hebetor* adults aged 2 days old were exposed for 12 days to four of the bags containing rice infested with larvae of *C. cephalonica,* respectively, within one chamber. Each treatment was repeated five times with control without parasitoids in a separate chamber. After the exposure period, the rice was transferred from the jute bags into 250 ml glass jars. The emergence of *C. cephalonica* was recorded daily in both *H. hebetor* treated and untreated rice samples until the 21st day. *H. hebetor* was able to locate its host in the bags with infested rice kernels and produced F_1 progeny. In the four untreated bag samples, the pest population developed normally into adult moths: on average out of five replicates 91.3% adults were found out of 60 introduced larvae. *H. hebetor* was able to significantly reduce the emergence of *C. cephalonica* in rice stored in jute bags. On average a percentage reduction of emergence (PRE) of 61.6 % was observed. The implications of these results with respect to the suitability of *H. hebetor* for the biological control of *C. cephalonica* in jute bags are discussed.

Seasonal abundance of *Cephonodes hylas* (Linnaeus) (Lepidoptera: Sphingidae) on Robusta Coffee in Ibadan, Nigeria.

Feyisare Okelana, Adebayo Odebiyi

[1]*Cocoa Research Institute of Nigeria, Ibadan, Nigeria,* [2]*University of Ibadan, Ibadan, Nigeria*

The Oriental bee-hawk moth *Cephonodes hylas* (L) (Lepidoptera: Sphingidae) is one of the major defoliator insect pests of robusta coffee *(Coffea canephora* Pierre ex. Froehner) in Nigeria.

Seasonal abundance of the eggs and caterpillars of the insect vis-a-vis the influence of some climatological factors (rainfall, temperature and relative humidity) was monitored by weekly random sampling of 100 coffee stands at two well-established and routinely managed robusta coffee experimental plots under different shade regimes. The plots are located at the southern block of the Headquarters of Cocoa Research Institute of Nigeria, Idi-Ayunre, Ibadan. The study period covered five years (1990-1994).

The results showed a marked seasonal variation in the population of the two life stages of the pest. Incidence of eggs and caterpillars of the moth was from March, which usually followed the onset of the early rains and commencement of leaf flushing in coffee. The insect is bivoltine, having two reproductive cycles per annum; the major population peak occurring in any of the months between March and July which coincided with the period of peak rainfall in the South-Western part of the country and minor peak around October/November when the minor rainfall peak occurred. Irregularity, cessation and decline of the early rains after its onset, often resulted in drastic drop in the population of the pest. Generally, there was a positive correlation between the prevailing temperature and incidence of the eggs and caterpillars at the two plots. Furthermore, the comparative"t" test analysis showed that significant differences ($P>0.05$) in the number of eggs and caterpillars of the moth existed in 1990 at the two plots and in 1991 for the eggs. A higher population of the two stages was often recorded in the unshaded (open) and actively rejuvenating coffee plots which abound in young flushes than in the heavily shaded plot where old leaves predominate, probably because the new flushes produced by the open plot made it more attractive to ovipositing females and more nutritive to young larvae of the pest.

While heavy shading adversely affected the yield of robusta coffee, appropriate shade regime which will minimize attack by *C. hylas* but result in optimum coffee yield needs to be investigated.

Manipulating butterfly wing patterns using over-expression and knock-down of candidate genes using transgenics

Antonia Monteiro[1], Diane Ramos[2], Bin Chen[1], Firdous Kamal[2], Ondrej Podlaha[1]

[1]Yale University, New Haven, CT, United States, [2]University at Buffalo, Buffalo, NY, United States

Many genes involved in wing development in *Drosophila* are expressed in novel domains in the butterfly wing that correlate with adult color patterns. In order to move beyond correlative studies in implicating a gene in the development of a color pattern, we have been exploring the effect of over-expressing or down-regulating several of these genes in the African butterfly *Bicyclus anynana*. We developed a novel piggyBac vector plasmid where candidate genes can be either inserted once, and used in over-expression studies, or inserted twice, in opposite orientation, and used in RNAi based knock-down approaches. We are using the heat-shock promoter from *Drosophila Hsp70* to activate gene expression in a controlled temporal fashion in *Bicyclus*, and also a laser-assisted heat-shocking system to provide localized over-expression of genes on the developing pupal wing. Our results show that global over-expression and down-regulation of candidate wing pattern genes have opposite effects on the adult color pattern, suggesting a functional role for these genes in wing pattern development. In addition, local heat-shocks can produce a different class of phenotypes relative to global heat-shocks, suggesting that juxtaposing cells with and without gene expression is an important parameter in the development of butterfly color patterns.

The evolution of eyespot number in *Bicyclus* butterflies: developmental mechanisms, sex, and imprinting

Antonia Monteiro[1], Kendra Robertson[2], Jeffrey Oliver[1], Andrea Hodgins-Davis[1], Andrew Goldman[2], Mayank Lahoti[2]

[1]Yale University, New Haven, CT, United States, [2]University at Buffalo, Buffalo, NY, United States

Bicyclus butterflies have diversified in mainland Africa and have evolved different wing patterns. Most wing pattern differences between species occur on the dorsal surface of the wings, a surface believed to be mostly functioning in sexual selection. Eyespot patterns are sometimes present on this surface, and their current species distribution implies that they have been “switched on” or “off” multiple times during the evolution of the genus. Here we propose both a developmental mechanism that can account for these “switches” as well as an ultimate sexual selection mechanism that allows new wing pattern mutations, involving variation in eyespot number, to be favored by members of the ancestral species. This mechanism can lead to assortative mating, and may facilitate speciation.

The importance of line thinning to arthropod conservation and ecosystem management in Japanese cedar (*Cryptomeria japonica* D. Don) plantations

MD. Abdul Maleque, Kaoru Maeto, Hiroaki Ishii, Shingo Taniguchi

Kobe University, Kobe, Hyogo Prefecture, Japan

Introduction: Overstocked conifer plantations in Japan, where management is lacking, support low understory biodiversity. Therefore, we investigated the effectiveness of a new silvicultural technique, line thinning (cutting trees in lines), on biodiversity restoration in overstocked *Cryptomeria japonica* plantations.

Methods: We investigated the effects of line thinning on microclimate, understory plant species diversity and insect assemblages. We compared the abundance and diversity of Coleoptera and Hymenoptera captured with Malaise traps from a line-thinned stand and an adjacent unthinned stand in two plantations: a low-elevation *Sugi* site (4 years since thinning) and a high elevation *Kuchiotani* site (6 years since thinning).

Results: In both plantations, more open canopy conditions resulted in higher maximum temperatures on the forest floor. The thinned stands supported greater understory plant species richness and biomass than the unthinned stands. Important functional groups of Coleoptera (*e.g.*, plant feeders, wood borers, rotten-wood feeders, root feeders, fungus feeders, dung feeders, and scavengers) and Hymenoptera (*e.g.,* pollen feeders, parasitoids, and predators) as well as many families of both orders were more abundant in the thinned stand than in the unthinned stand. Some coleopteran families were absent from the unthinned stands. There were strong positive relationships between coleopteran abundance and understory vegetation across sites. Most hymenopteran functional groups were positively correlated with both species richness and understory plant biomass in the plantations where understory vegetation was rich.

Conclusions: Our results indicate that line thinning increases the diversity of understory plants and arthropods, thereby enhancing ecosystem integrity in overstocked *C. japonica* plantations.

Microstructural characters in the systematics of Bostrichidae (Coleoptera)

Lan-Yu Liu[1], Klaus Schönitzer[2], Jeng-Tze Yang[1]

[1]Chung Hsin University, Taichung, Taiwan, Province of China, [2]Zoologische Staatssammlung München, Munich, Germany

Introduction: In order to find more taxonomically useful characters in the family Bostrichidae, we used an Environmental Scanning Electron Microscope (ESEM) to examine the micro-structural characters, such as hairs, punctures and tubercles of the middle part of the elytral disc. We expected to find new useful characters from these micro-structures.

Methods and Materials: We examined 78 species belonging to 3 subfamilies and 4 tribes by low vacuum ESEM. In order not to damage the old museum specimens, we did not dismount them and did not coat the surface of the specimens with gold or other metals.

Results: We studied the structures of the punctures, tubercles and hairs under the ESEM and described them in relation to their shape, density and the location of the insertion of the hairs.

Conclusions: Our work not only found more taxonomical useful characters in the micro-structures on the surface of specimens, but showed that we can now examine the specimens under ESEM without any damage.

Ecology and management of three rice planthopper species in the Yangtze Delta, China

Jia-an Cheng, Zeng-rong Zhu

Institute of Insect Sciences, Zhejiang University, Hangzhou, Zhejiang, China

Introduction: Modern agriculture relying on high yielding variety and agri-chemicals has resulted in more secondary pests, including *Laodelpdx striatellus* (SBPH), *Nilaparvata lugens* (BPH) and *Sogatella furcifera* (WBPH). The simultaneous outbreak of the three species in the new century indicates even higher risk in Yangtze Delta is coming. Ecological mechanisms and management strategy for reducing the risk were studied.

Methods: Field investigations and lab experiments were carried out to study interactions among the three species and environmental factors, understand mechanisms of mutualism causing simultaneous outbreaks and develop ecological strategy for managing rice planthoppers.

Results: Field investigations indicated that field competitions for food and space among the three species could be reduced by differentiations of seasonal development pattern and food nutrition. Coexistence of BPH and WBPH at certain level could promote their population parameters because of the changes of plant nutrition. Field evaluations on predation using McAb showed that time-lag of peak populations among the three species provided better chance for a late species to escape from predation. Differences in sensitivities of the three species to pesticides and effects of insecticides stimulating planthopper fecundity and reducing natural control made chemical controls for one species become alternative way causing resurgence for another species in same season. Therefore, one to one strategy for controlling planthopper resulted in outbreaks of three species simultaneously.

Conclusions: Planthopper management program should be designed based on understanding of interactions among three planthopper species and key strategy could be reduction of initial population size and growth rate using cultural practices.

Ghosts of invasions past: Non-target acquisition of native lepidoptera by parasitoids released to combat exotic tussock moths in North America

Dylan Parry

State University of New York, College of Environmental Science and Forestry, Syracuse, New York, United States

Introduction: The introduction of gypsy moth (*Lymantria dispar*) to North America in 1867 launched an ecological experiment still ongoing. Subsequent introductions of two additional lymantriids (*Euproctis chrysorrhea* in 1896 and *Leucoma salicis* in the 1920's) elicited an unprecedented biological control program that continued for more than 80 years. At least 50 parasitoids were released for control of these invasive tussock moths. I examined the acquisition of native North American Lepidoptera by these exotic parasitoids relative to their life-history strategies (generalist/specialist).

Methods: To assess non-target acquisition, I used controlled rearing of field-collected native Lepidoptera from natural and experimental populations coupled with analysis of literature. Field collections were also made from satin, browntail, and gypsy moth populations to survey the parasitoid complex.

Results: Of more than 50 parasitoids released for control of these invasive tussock moths, 14 species appear to be still extant in North America. Six are unique to gypsy moth, three to browntail moth, one to satin moth, and four species are shared by all three lymantriids. Acquisition of native hosts was dependent on life-history strategy and ranged from apparently zero in the tachinid *Townsendielliomyia nidicola* to nearly 200 species (*Compsilura concinnata*: Tachinidae).

Conclusions: Despite their presence in North America for 30-100 years, most parasitoids released as part of exotic tussock moth control programs have acquired few native species. The two notable exceptions (*C. concinnata* and the ichneumonid *Pimpla disparis*) are highly polyphagous in their native range and thus their effect on native biodiversity was predictable.

Overcoming host plant resistance and parasitoid attack: tri-trophic challenges for the large raspberry aphid

Carolyn Mitchell, Scott Johnson, Stuart Gordon, Nicholas Birch, Stephen Hubbard

[1]SCRI, Invergowrie, Dundee, United Kingdom, [2]University of Dundee, Dundee, United Kingdom

Introduction: This study investigated how the relative roles of bottom up and top down influences can be affected as the insect herbivore overcomes host plant resistance. This model system used the large raspberry aphid (*Amphorophora idaei*), the parasitoid (*Aphidius ervi*) and the red raspberry (*Rubus idaeus*). The resistance within the plant is underpinned by a single gene (A_{10}) which is absent in susceptible cultivars.

Methods: A survey of *A. idaei* in a raspberry plantation compared the number of aphids found on both resistant and susceptible cultivars. A series of laboratory experiments firstly compared the aphid performance on a resistant-challenged cultivar and a susceptible cultivar and secondly observed parasitoid performance and aphid behaviour on three cultivars with varying degrees of resistance.

Results: In the field, no aphids were found on the resistant-challenged cultivar but were regularly observed on the susceptible cultivar. In the laboratory, all four parameters studied: pre-reproductive period, total number of nymphs produced, longevity and r_m showed that the aphid preformed significantly better on the susceptible cultivar. Parasitoid attacking behaviour increased with aphid density but was lower on the resistant-challenged cultivar. The attack rate on the partially resistant cultivar was significantly higher than on the other cultivars. Aphids showed a greater tendency to drop from the resistant-challenged cultivar.

Conclusions: This study suggests there is a trade-off between bottom-up and top-down forces as insect herbivores become adapted to host plant resistance mechanisms.

The diminutive supercolony: Argentine ants of the southeastern United States

Grzegorz Buczkowski[1], Jules Silverman[2]

[1]Purdue University, West Lafayette, IN, United States, [2]North Carolina State University, Raleigh, NC, United States

Introduction: Native to Argentina and Brazil, the Argentine ant (*Linepithema humile*) is an invasive species that has become established on six continents and many oceanic islands. In several parts of its introduced range, including the western U.S., southern Europe, and Chile, the Argentine ant is unicolonial, forming extensive supercolonies.

Methods: We examined population genetic structure and intercolony aggression in two regions of the introduced range of this species in the United States: California and the southeastern U.S. Our results show that the southeastern *L. humile* population has high genotypic variability and strong intercolony aggression relative to the California population.

Results: In the California population, intercolony aggression was absent and 23 alleles were found across seven polymorphic microsatellite loci. However, in the Southeast, aggression between colonies was high and 47 alleles were present across the same seven loci in an equal number of colonies.

Conclusions: We suggest that distinctly different colonization patterns for California and the Southeast may be responsible for the striking disparity in the genetic diversity of introduced populations. Southeastern colonies may have descended from multiple, independent introductions from the native range, undergoing a bottleneck at each introduction. In contrast, the California supercolony may have originated from one or more colonies inhabiting the southeastern U.S., thus experiencing a double bottleneck. The differences in present-day distribution patterns between California and the Southeast may be due to the combined effect of two factors: lower winter temperatures in the Southeast and/or competition with another successful and widely distributed ant invader, the fire ant *Solenopsis invicta*.

Permethrin aerial ULV spray efficacy for controlling salt marsh mosquitoes and potential impacts on fish

He Zhong[1], Ed Hunter[2], Max Feken[3], Cate Brock[1]

[1]Public Health Entomology Research and Education Center, Florida A&M University, 4000 Frankford Avenue, Panama City, Florida 32405, United States, [2]Beach Mosquito Control District, 1016 Cox Grade Road, Panama City Beach, FL 32407, United States, [3]Florida Department of Agriculture and Consumer Services, Bureau of Pesticides, 3125 Conner Boulevard, Bldg. #6,Tallahassee, FL 32399, United States

Aerial ultra-low-volume (ULV) application of insecticides is widely used by mosquito control programs to control adult mosquitoes and reduce mosquito-transmitted diseases. Although permethrin is sprayed by truck as an adulticide in Florida, aerial applications currently are not permitted based on potential effects to field aquatic organisms, including fish. In 2007, we investigated the impact of permethrin residue on laboratory-reared mosquitofish, *Gambusia holbrooki* (Girard), following exposure to ULV aerial applications in Panama City Beach, Florida. The efficacy of the 5 field aerial spray trials was validated using adult salt marsh mosquitoes, *Ochlerotatus taeniorhynchus* (Wiedemann), placed in cylindrical exposure cages (over 50 female adult mosquitoes per cage) with 1 cage placed at each of the 12 sampling stations (9 treatment and 3 control stations). Non-target bioassays were conducted using 25 adult fish and 30 juvenile fish placed in separate plastic bins at each station. The ULV aerial applications were conducted by the Beach Mosquito Control District using a helicopter equipped with a high pressure nozzle spray system. Excellent mosquito control (> 90% efficacy) was obtained for all five trials. Also, no mortality differences were observed between treatment and control groups for either adult or juvenile fish after 120 hours. This research demonstrated that aerial applications of permethrin were effective against adult mosquitoes and did not result in adverse impacts on either adult or juvenile fish under the conditions of the study. We believe that when properly conducted aerial ULV application of permethrin should pose minimal risk to fish in the field.

Bees in bonnets, butterflies in stomachs, and ants in pants; how insects creep into culture

May Berenbaum

University of Illinois, Urbana, IL, United States

In some respects, it is remarkable that insects, a group that in real life is at best studiously avoided and at worst actively reviled, figure prominently metaphorically in most cultures around the world. Among the possible explanation for such cultural ubiquity is that, irrespective of location, it is virtually impossible on this planet to live an insect-free life, given their abundance, ubiquity, and close association with humans. Despite staggering differences in outward appearances and in lifestyle that may assail human sensibilities, remarkable similarities between humans and insects, particularly social species, have not escaped notice around the world. They are the only organisms that have colonized the planet to the extent that humans have, living everywhere people live (even on occasion hitching a ride on our bodies to do so). Historical and contemporary uses of insect societies to mirror aspects of human societies are provided.

A history of insect outbreaks — from Genesis to GIS

May Berenbaum

University of Illinois, Urbana, IL, United States

Insect outbreaks by their very nature command attention but, due to their inherently intermittent nature, they have proved difficult over the years to investigate experimentally. Although early hypotheses accounting for outbreaks tended to be essentially untestable (often involving in one form or another divine wrath or punishment), more recently a multitude of scientific hypotheses have been advanced--yet these, too, can be difficult to falsify. Cyclic variations in insect populations strongly suggest that some regulatory factor is in force, but just which regulatory factor remains an open question. A problem with many studies of population cycles in eruptive species is that they're pursued (and funded) at the peak of outbreaks and interest often disappears in the troughs. Moreover, dynamics of outbreak species, like many other aspects of insect life, might be idiosyncratic and difficult to generalize. Thus, it is not surprising that the nature of the forces affecting population sizes of insects has been the subject of some of the most polarized and vitriolic debates in insect ecology. As is often the case in insect ecology, however, both sides of each of the arguments may have merit, depending on species and circumstances.

All we are saying is give bees a chance — citizen scientists and pollinator decline

May Berenbaum

University of Illinois, Urbana, IL, United States

Worldwide, concern about pollinator declines has increased, and, where pollinator status has been monitored over time, as in Europe, reductions in numbers have been documented. The U.S. National Academy of Sciences Committee on the Status of Pollinators in North America, charged to evaluate apparent pollinator declines, concluded in October 2006 that, for most pollinators, there are simply no baseline data to allow assessments of changes in abundance and distribution. Among their principal recommendations was to begin monitoring programs with bees as a top priority due to their prominence as pollinators. This committee recommended involving citizen-scientists in such monitoring efforts, providing an extraordinary and timely opportunity for informal science education, particularly given the widespread attention in the popular media on colony collapse disorder and the nationwide disappearances of bees. Although the general public has an appreciation for bees and pollination, the level of detailed knowledge is low. Monitoring and conservation efforts require an educated public to differentiate between pollinating bees and predaceous stinging wasps. All too often, the typical reaction to the presence of anything striped and buzzing is to kill it. Thus, recruiting citizen scientists to pollinator monitoring efforts requires visual recognition and user-friendly color-guided keys rather than the more traditional collection and dissection to identify species. Such an approach is better suited in any case to conservation efforts. Components of a workable partnership between citizen-scientists and the professional science community that educates the public about pollinators and engages them in useful data collection are suggested.

Talking bugs — insects and ventriloquism

Hannah Leskosky

University Laboratory High School, Urbana, IL, United States

Ventriloquism is an ancient art form that, like magic, relies on misdirection to create the illusion that non-humans can engage in conversation. Despite the fact that some insects can actually communicate by sound, they rarely are used as ventriloquial figures. The main reason is most likely that the majority of the public don't usually think of "bugs" as "cute" or "funny" and ventriloquism is generally performed to entertain. In addition, because people generally don't know very much about their behavior, insects can be difficult for some audiences to relate to. However, insect ventriloquism has great potential not only for entertainment purposes but also to teach people about insects in an engaging way. Some entomological ventriloquism techniques will be demonstrated.

Efficacy of chemical insecticides in controlling the pea beetle (weevil) *Bruchus pisorum* L. (Coleoptera: Bruchidae) on field pea (*Pisum sativum* L.) in Ethiopia

Birhane Asayehegne, MC van Der Westhuizen

University of the Free State, Bloemfontein, Free State, South Africa

Introduction: The *Bruchus pisorum* L. has became very important insect pest on Pisum sativum L. in the northwest and northeast Ethiopia. For this newly occur insect pest for the region and the country on the crop and which is expanding its infestation in alarming rate to more field pea growing areas of the country, finding any control option was an urgent task.

Methods: The timely spraying of synthetic chemicals, one insecticide from each of, from carbamate, organochloride and organophosphate groups and three from pyrothroids group were used. The experiments were conducted on-farms for two consecutive years in randomized complete block design applying the insecticides with knapsacks.

Results: In the field control efficacy of the chemical insecticides among the groups and with in a group varied. Carbaryl 85% WP and Endosulfan 35 % EC more effective while Diazinon 60 % EC was less effective. From the pyrothroids, Alpha Cypermethrin and lambda cyhalothrin more effective compare to Deltamethrin.

Conclusions: In Ethiopia, where the small scale farming system dominant, in the absence of any immediate available means of control option it is revealed that a proper measure to use the lesser hazard to the environment but effective chemical insecticide(s) on the insect pest. Considering effective and economically sound chemical insecticide sprays at appropriate time based on the economic threshold level for the insect pest on the crop with proper operation of the sprayer in use is important.

New reduced risk control approaches for area-wide pest management of fruit flies in the Pacific

Roger Vargas, Ronald Mau, Jaime Pinero, John Stark, Eric Jang

USDA-ARS-PBARC, Hilo, Hawaii 96720, United States

Introduction: In 1999, the United States Department of Agriculture, Agricultural Research Service, in cooperation with the University of Hawaii and the Hawaii Department of Agriculture, initiated the Hawaii Fruit Fly AWPM program to suppress fruit flies (Diptera: Tephritidae) below economic thresholds while reducing the use of organophosphate insecticides. Historically, protein-bait sprays and the highly attractive male lures, methyl eugenol and cue-lure, have been used with organophosphate insecticides (malathion and naled) for area-wide fruit fly control throughout the Pacific region. Through the AWPM program an effective Spinosad protein bait spray (GF-120 Fruit Fly Bait), a sprayable Spinosad male annihilation treatment (SPLAT ME and C-L) and a fipronil male annihilation station (Amulet ME and C-L) were developed and investigated as organophosphate insecticide substitutes for AWPM of melon and oriental fruit flies.

Methods: In field trials, GF-120, SPLAT, and Amulet were tested against oriental and melon fruit fly populations.

Results: Data suggested GF-120, SPLAT and Amulet reduced fruit flies, and in many cases were as effective as organophosphate treatments.

Conclusions: These fruit fly treatments offer environmentally friendly alternatives to present organophosphate formulations for area-wide suppression/eradication of fruit flies.

Addressing capacity needs in medical entomology for national disease vector control programmes in the Eastern Mediterranean Region

Abraham Mnzava

World Health Organization, Regional Office for the Eastern Mediterranean, Cairo, Egypt

Countries of the Eastern Mediterranean Region contribute disproportionately to the global burden of disease due to vector-borne diseases (VBDs). The Region is also experiencing the emergence/re-emergence of VBDs – including their seasonal and geographical expansion. Some of the factors responsible for this expansion: include climatic and technical (e.g. insecticide resistance) factors, rapid urbanization, population movement and inappropriate policies. For example, as a result of successful control of malaria, some countries withdrew vector control resources, both human and financial. In 2005, the 52nd session of the WHO Regional Committee for the Eastern Mediterranean – the highest policy decision body on health in the Region – reviewed this situation and took a number of decisions. While the Committee endorsed integrated vector management as the recommended strategy for rational use of vector control resources, it also recognized the need to strengthen national capacity in medical entomology and vector control for the successful implementation of integrated vector management. Through resolution EM/RC.52/R.6, the Committee requested the Regional Director of WHO to establish a regional MSc course in medical entomology and vector control in an attempt to address this problem. After a series of consultations with key national control programmes and regional and international research and training institutions, a course curriculum was developed and finalized. A hosting institution was identified and the first group of students will start the course in June 2008 at the University of Gezira, Sudan. With the continued support of partners and Member States, including their political commitment, it should be possible to start establishing capacity in medical entomology to meet the needs for successful implementation of integrated vector management in the Region.

Genomic analysis of chemical communication in honey bees

Christina Grozinger, S Kocher

North Carolina State University, Raleigh, NC, United States

Pheromonal communication is often considered to be stereotyped and innate, in terms of both the production and response to pheromones. However, production of pheromonal cues and responses to pheromones can be modulated by environmental context, physiological changes and/or the genotype, but the molecular mechanisms underlying these processes are relatively uncharacterized. *We are using genomic approaches to characterize the molecular mechanisms and pathways underlying modulation in the production of and response to queen mandibular pheromone (QMP).* QMP is rather unusual pheromone, in that it can cause both short-term changes in behavior and long-term changes in behavior and physiology. QMP also causes profound changes in brain gene expression, in a manner that correlates with its long-term effects on behavior and physiology. Furthermore, the short- and long-term responses QMP can be uncoupled; thus, they appear to operate by different mechanisms. We are now expanding our studies to characterize how physiological and genotypic factors modulate response to QMP. Additionally, we have found that modulation of the mating process in honey bee queens alters the pheromone blend that is produced, and workers are responsive to differences in these blends. Finally, we are beginning to address the roots of pheromone-mediated behavior in social insects, by monitoring expression of QMP-regulated genes in other hymenopteran species with different social organizations, to determine if there are common underlying pathways related to queen control.

Ancient rapid radiations of insects: a major challenge for phylogenetics

James Whitfield

University of Illinois, Urbana, IL, United States

The phylogenies of many major groups of insects have been difficult to resolve using either molecular or morphological data, in part due to shortness of time spans between divergences for evolution to occur, and very long time spans after divergences for subsequent evolutionary changes to obscure the earlier ones. Another reason for difficulty in resolving some of the relationships using molecular data is the limited spectrum of genes so far developed for phylogeny estimation. For this latter issue, there is cause for current optimism based on rapid increases in our knowledge of comparative genomics. For morphological studies, fossil evidence has been helpful at times, but some critical periods of insect evolution are more poorly documented than others. Our knowledge of insect fossil history continues to improve and to be more effectively integrated with morphological knowledge of extant taxa and with estimates of divergence times based on molecular data. At least some historical patterns of divergence may, however, continue to defy our attempts to completely reconstruct them with confidence, at least using current strategies.

Does the bumblebee trade have a sting in its tail?

Thomas Ings, Lars Chittka

Queen Mary, University of London, London, United Kingdom

Bumblebees are second only to honeybees in their economic importance as crop pollinators. Increased global demand for bumblebees has been met by year-round production of a limited number of species (4 to 5 out of approx. 250 species). Even though these commercially reared species are targeted towards particular regional markets, there are many cases where importation of bumblebees for pollination involves introducing non-native species. While many bumblebees are used to pollinate crops grown under glass (e.g. tomatoes), they readily escape into the wild, and are increasingly being used to pollinate open field crops (e.g. fruit trees and strawberries). Such observations have lead to a number of concerns being raised about the trade in bumblebees.

Therefore, we examine some of the ecological risks associated with the seemingly indiscriminate movement of non-native bumblebees around the globe. We focus on one of the main commercial species, *Bombus terrestris,* as it has been introduced into countries where it is a non-native genus, species and subspecies. Case studies of bumblebee introductions are used to illustrate three major ecological risks associated with importation of non-native bumblebees: parasites/disease, competitive exclusion and hybridisation.

The evidence presented clearly indicates that the commercial trade in bumblebees does carry a real ecological risk. However, it is important to evaluate how significant that risk actually is before any meaningful recommendations can be made. Therefore, we finish with a discussion on how we might attempt to evaluate, and potentially mitigate, the three major ecological risks associated with importing non-native bumblebees for pollination.

Juvenile hormone in reproductive physiology and behavior of Lepidoptera: Intra- and interorganismal co-ordination

Maciej Pszczolkowski[1], Sonny Ramaswamy[2]

[1]Missouri State University, MO, United States, [2]Purdue University, IN, United States

Traditionally, juvenile hormone (JH) is regarded as a *status quo* factor of metamorphosis. In adults of many species, however, JH is a primary coordinator of reproductive processes. In our paper we present how JH co-ordinates reproduction of a promiscuous lepidopteran female in two ways: during interaction between two conspecifics (JH transfer from male to female) and within the organism of mated female (ovarial patency and egg development upon JH action).

We also address functional and evolutionary aspects of JH action in promiscuous Lepidoptera, and speculate on its contribution to species richness of this order.

Independent gains or reversals of highly eusocial behavior in the corbiculate bees? Visualizing conflict among multiple gene trees

Sydney Cameron

University of Illinois, Urbana, Illinois, United States

Introduction: The corbiculate bees comprise four tribes, three of which represent the major groups of highly social bees, including the stingless bees (Meliponini), bumble bees (Bombini) and honey bees (Apini). Orchid bees (Euglossini), the fourth tribe within the clade, are solitary or communal. Understanding the historical pattern of relationships among these taxa is important for a full understanding of the evolution of highly social behavior in bees. Yet their phylogeny has been a difficult problem to solve. In particular, rooting the corbiculate bee tree has been difficult, even with large numbers of nucleotide characters and multiple outgroups. Thus, the direction of social evolution in the group has been obscure.

Methods: Bayesian analyses of each of 12 nuclear and two mitochondrial gene fragments were run for phylogenetic inference. To visualize the conflict among the gene trees, the filtered supernetwork method was used to extract the most common recurrent phylogenetic signal from a set of taxonomically overlapping gene trees.

Results and Discussion: At mintrees = 6, the supernetwork is already greatly simplified, but still contains some splits that place an outgroup (*Centris*) within the ingroup. At mintrees=9, all reticulation within the network is gone, and the outgroups are seen to root the tree at the base of the Apini + Euglossini split. The most recurrent splits among the 14 gene trees, despite outgroup “noise”, are consistent with previous findings that Meliponini and Bombini are sister taxa, with the relationships still uncertain for Apini and Euglossini.

Wolbachia effects on insect hosts: evolving from a symbiont to a mutualist

Ary Hoffmann, Andrew Weeks

The University of Melbourne, Melbourne, Victoria, Australia

Wolbachia commonly spread through host insect populations by causing cytoplasmic incompatibility, often expressed as reduced egg hatch when uninfected females mate with infected males. Infected females are frequently less fecund as a consequence of Wolbachia infection. However, theory predicts that because of maternal transmission, these ‘‘parasites’’ will tend to evolve towards a more mutualistic association with their hosts. In *Drosophila simulans* in California, which represents the classic case of a *Wolbachia* infection spreading in nature, cytoplasmic incompatibility allowed the infection to spread through individual populations within a few years and from southern to northern California (more than 700 km) within a decade, despite reducing the fecundity of infected females by 15%–20% under laboratory conditions. Here we show that the Wolbachia in California *D. simulans* have changed over the last 20 y so that infected females now exhibit an average 10% fecundity advantage over uninfected females in the laboratory. The data demonstrate that fecundity-increasing Wolbachia variants are currently polymorphic in natural populations but the variants exhibiting a fecundity advantage are expected to become fixed over time.

Wolbachia effects on insect hosts: evolving from a symbiont to a mutualist

laboratory. The data demonstrate that fecundity-increasing Wolbachia variants are currently polymorphic in natural populations but the variants exhibiting a fecundity advantage are expected to become fixed over time.

Predicting the ability of insets to counter the effects of climate change through adaptation

Ary Hoffmann, Michael Kearney

The University of Melbourne, Melbourne, Victoria, Australia

Shifts in the distribution, abundance and phenology of invertebrate species in response to climate change are now well documented in the literature, particularly in Europe. In Australia climate envelope models predict changes in the distribution of many invertebrates including pests and threatened species currently restricted to high elevation sites. Yet insects and other invertebrates have the potential to counter the effects of climate change through physiological acclimation and through evolutionary adaptation. There are now several examples of evolutionary shifts taking place in response to climate change in flies and mosquitoes. Patterns of clinal variation highlight the potential of many widespread insect species including pests to evolve. New mechanistic models that consider the way environmental conditions predict the growth and reproduction of organisms can accurately incorporate the potential for adaptation and evolution. These models when coupled with quantitative genetic information can be used to accurately assess distribution and shifts persistence of threatened populations under climate change.

Attraction of male vine mealybug to the female structurally related pheromone components

Anat Zada, Hofit Kol-Mimon, Ezra Dunkelblum, Fabienne Assael, Alex Protasov, Zvi Mendel

Department of Entomology, Volcani Center, ARO, Bet Dagan 50250, Israel

Introduction: The vine mealybug (VM) *Planococcus ficus* (Signoret) is a worldwide pest, mainly of grapevine and figs. Two pheromone components, (*S*)-lavandulyl senecioate and (*S*)-lavandulyl isovalerate were identified in Israel from VM reared for several generations on potato sprouts, while in California only (*S*)-lavandulyl senecioate and (*S*)-lavandulol were identified.

Methods: Enzymatic separation of racemic lavandulol enabled us to assess the response of VM males in the field to the two enantioenriched pheromone components and lavandulol.

Results: A positive correlation between peak mealybug density and male capture was observed using racemic lavandulyl senecioate as bait, strengthening the usefulness of the pheromone traps for monitoring the pest. However, addition of racemic or the two enantiomers of lavandulyl isovalerate to lavandulyl senecioate decreased the capture of VM males in the field, while in the lab, this component attracted males. Both enantiomers of lavandulyl isovalerate displayed the same antagonistic activity. The addition of (*S*)-lavandulol to the pheromone resulted in shut-down of the traps while inhibition by its antipode, (*R*)-lavandulol, was moderate indicating a certain degree of chiral discrimination.

Conclusions: Racemic lavandulyl senecioate can be used for field work since the unnatural enantiomer of lavandulyl senecioate is benign and does not affect the activity of the pheromone. Recently, we found that in some vineyards males are also attracted to lavandulyl isovalerate, indicating the existence of VM pherotypes in the field.

The role of competition in structuring an insect metacommunity on oak (*Quercus robur*)

Ayco Tack, Sofia Gripenberg, Tomas Roslin

University of Helsinki, Helsinki, Finland

Introduction: Herbivore densities in nature are generally very low, perhaps reflecting the importance of indirect interactions mediated by the host-plant. To test this hypothesis, we investigate the relative importance of direct and indirect interactions in structuring the herbivore community on the pedunculate oak (*Quercus robur*).

Methods: We address indirect interactions at different spatial and temporal scales, and among both herbivorous insects and a pathogenic fungus. Experimental work on the strength of interactions is combined with observations on spatiotemporal patterns of co-occurrence of different taxa in nature.

Results: Both direct and indirect interactions among leaf-mining species seem to result in slightly elevated mortality rates. Nevertheless, the species do not seem to repel each other: long-term surveys reveal that leaf miners occur more often than predicted by chance on the same leaf, shoot, branch and tree.

Conclusions: This study does not support any major role for direct and indirect interactions in shaping local insect densities or local community structure. While such effects are certainly present, they do not seem strong enough to leave any significant imprint on what species occur where and at what densities. In contrast, there appears to be a strong role for spatial processes in shaping the structure of local insect communities.

The legacy of Melrose Highlands: Parasitoid drift and its unintended consequences for lepidopteran diversity in New England forests

Dylan Parry[1], George Boettner[2], Jennifer Selfridge[1], Brian Hoven[1], Joseph Elkinton[2]

[1]State University of New York, College of Environmental Science and Forestry, Syracuse, New York, United States, [2]University of Massachusetts, Amherst, Massachusetts, United States

Introduction: Decline and extirpation of numerous giant silk moth species (Saturniidae) has been apparent for several decades in New England. Several explanations have been proposed, but a seminal study [Boettner et al. (2000), Conservation Biology] strongly implicated an exotic parasitoid, *Compsilura concinnata*, introduced a century ago to control burgeoning gypsy moth populations in Massachusetts. To determine how robust these results were, we experimentally established populations of several additional lepidopterans within and outside of Massachusetts and quantified mortality.

Methods: Parasitism by *C. concinnata* was assessed in experimental populations of four saturniids (*Hemileuca maia*, *Anisota senatoria*, *Antheraea polyphemus*, *Callosamia promethea*) and a notodontid, *Datana ministra*. The saturniid experiments were conducted at multiple sites in both Massachusetts and New York.

Results: Parasitism of *A. polyphemus* and *C. promethea* by *C. concinnata* was very high in Massachusetts, validating the results of Boettner et al. (2000) but was significantly lower in New York, suggesting limitations to this hypothesis. For *H. maia* and *A. senatoria*, parasitism was low in both regions indicating that alternative single-factor or interactive mechanisms may be driving populations declines. Finally, parasitism in the gregarious notodontid *D. ministra* was very high suggesting that the effects of this parasitoid need to be assessed in other less charismatic lepidopterans.

Conclusions: *Compsilura concinnata* plays an important role in the decline of native macrolepidopterans in northeastern North America but high regional variance in its parasitism suggest that it is unlikely to be the only factor underlying the decline of this biodiversity.

Local ecological effects on the rate of spread of Argentine ants: Interspecific behavioral interactions and aggregation sites

Deborah M Gordon, Katherine Fitzgerald

Stanford University, Stanford, CA, United States

Introduction: The Argentine ant, *Linepithema humile*, is invasive in Mediterranean climates worldwide, with substantial ecological impact on native arthropod and plant communities. The factors that determine its rate of spread are not well understood. Argentine ants are seasonally polydomous, aggregating in the winter and dispersing into many nests linked by trails, in the summer. A colony, or set of connected nests, occupies about 200 m2 in northern California. Previous work suggests that the native winter ant, *Prenolepis imparis*, is one of few native species that effectively resists elimination by the Argentine ant. Both the Argentine and winter ants nest at the base of woody plants and tend scale insects to consume their honeydew.

Methods: We have monitored the distribution of Argentine and native ants in a 500-ha preserve in northern California for 15 years. Observations and experiments examined competition between *L. humile* and *P. imparis* and the formation of new colonies.

Results: Survey results show that competition between Argentine and winter ants is intense at the edge of the invasion front, where the distribution of ants at many sites alternates between the two species. We will discuss how priority of access to foraging area, and seasonal factors, influence the distribution of the two species, and how the availability of winter aggregation sites affects the rate of formation of new clusters of associated nests, or colonies.

Conclusions: The availability of sites for new colonies, and the dynamics of interspecific competition, influence the rate of spread of Argentine ant invasions.

Consequences of environmental change and globalization for *Dendroctonus valens* and its fungal symbionts: A case study

Nancy Gillette, Jianghua Sun, Donald Owen, Min Lu, Mike Wingfield, Diana Six, Xudong Zhou

USDA FS, PSW Research Station, Berkeley, California, United States

Dendroctonus valens and its fungal symbionts may become globally catastrophic as invasives riding a tide of climate fluctuation. *D. valens,* native to North America, is a polyphagous subcortical feeder adapted to collecting fungal spores; it is difficult to control using biological, cultural, insecticidal, or behavioral insect pest management methods. It feeds on all pine species within its range, where it vectors *Leptographium terebrantis* and related fungi to its hosts. It was accidentally introduced into China, where feeds on all pines with which it has come into contact, and is now expanding its range there. There are no apparent barriers to its spread westward across Eurasia, where there is a continuous, transcontinental corridor of pines. In addition, *D. valens* in North America has already acquired a European species of *Leptographium* from a beetle introduced from Europe, and is expected to acquire more new associations as it expands its Asian range. The consequences of these new associations for native and exotic pine forests are difficult to predict, but even in the absence of such new associations *D. valens* is expected to become a more serious pest with warmer and dryer global climates. In an effort to respond to these potentially disastrous new associations, we have embarked upon an international collaboration to characterize the existing *D. valens*/fungal symbioses using molecular methods to build a baseline of information so that future new associations can be more rapidly detected. This case study may provide a useful model for other new beetle/fungal associations.

Conserving narrow range endemic insects in the face of climate change: Options for some Australian butterflies

Timothy New

La Trobe University, Melbourne, Victoria, Australia

Many southern hemisphere butterflies of conservation interest appear to be 'point endemics' or 'narrow range endemics', and vulnerable because of ecological specialisation and poor dispersal capability or opportunity. Short–term, site-focused conservation efforts, however successful they may be, do not cater for range alterations likely to occur with climate change. Greater attention to assessing potential future distributions of such species along ecological gradients, predominantly of latitude and altitude, may help to counter this lack by selecting sites for translocations to be made decades or more into the future. Consideration of such assisted colonisations for selected species may be a worthwhile addition to current conservation planning, with the possible options differing according to the species' current distribution pattern within the possible range.

Some possibilities for this approach are discussed, using examples from narrow range endemic butterflies in Australia. Such long-term strategies pose formidable problems in logistics and regulation, and may not be practicable widely. Designing and including conservation on this extended temporal scale, however, may help to focus current conservation efforts for wider beneficial effects.

Comparing Argentine (*Linepithema humile*) to big-headed (*Pheidole megacephala*) and native ants in their interactions with an extrafloral nectary plant: Who benefits?

Lori Lach[1], Richard J. Hobbs[1], Jonathan D. Majer[2]

[1]Murdoch University, Murdoch, WA, Australia, [2]Curtin University of Technology, Bentley, WA, Australia

Though Argentine ants (*Linepithema humile*) are strongly attracted to carbohydrate-rich resources, few studies have investigated relationships between Argentine ants and plants with extrafloral nectaries (EFNs). We compared benefits conferred upon and received from the EFN plant *Acacia saligna*, among Argentine ants, the invasive big-headed ant (*Pheidole megacephala*), and native ants. Twelve pairs of *A. saligna* were planted in each of eight urban bushland sites: two with Argentine ants, two with big-headed ants, and four matched nearby uninvaded sites. Argentine ants were observed on 83-92 %, big-headed ants on 30-80%, and native *Iridomyrmex* spp. on 58-92% of plants in their respective sites. Trophobionts were only observed in sites with native ants. In sites with Argentine and big-headed ants, ant-allowed trees grew more phyllodes and branches than their paired ant-excluded trees, but these differences were not seen in sites with native ants. In laboratory experiments, we compared worker survival of Argentine, big-headed, and native *Iridomyrmex chasei* workers exposed to herbivorized or non-herbivorized *A. saligna* or controls. Ants given herbivorized plants had 7-11 times greater worker survival relative to unfed ants, but there were no differences in survival among the three ant species exposed to the same treatments. Ants with access to non-herbivorized plants had the same survival as unfed ants. Results suggest that the invasive Argentine and big-headed ants are more beneficial to *A. saligna* growth than native *Iridomyrmex*, possibly due to the native ants' mutualistic relationships with trophobionts on the plants; however, all three taxa can benefit from *A. saligna* extrafloral nectar.

Circatidal rhythm of locomotor activity in the mangrove cricket *Apteronemobius asahinai*

Aya Satoh[1], Eiji Yoshioka[2], Hideharu Numata[3]

[1]University of the Ryukyus, Okinawa, Japan, [2]Kobe Yamate University, Kobe, Japan, [3]Osaka City University, Osaka, Japan

Introduction: Mangrove forests are influenced by tidal flooding and ebbing with a period of about 12.4 h (tidal cycle). Mangrove crickets (*Apteronemobius asahinai*) forage on mangrove forest floors during low tide and rest on stems during high tide. The endogenous rhythm in their locomotor activity was examined.

Methods: Locomotor activity was recorded under constant darkness (DD) for 25 days and under a 12-h light/12-h dark cycle (LD) for the subsequent 22 days for 24 collected males, and under LD for 14 days and under DD for the subsequent 12 days for 18 collected males. The temperature was maintained at 25ºC.

Results: Under DD, most crickets showed a clear bimodal daily pattern in their locomotor activity for at least 24 days; the active phases of about 10 h alternated with inactive phases of about 2 h. The free-running period was 12.56 ± 0.13 h (mean ± SD, n = 11). Under LD, the activity was not entrained by the light–dark cycle; the bimodal rhythm was expressed in the scotophase but suppressed in the photophase. This endogenous rhythm was assumed to be a circatidal rhythm. On the other hand, the activity under constant darkness subsequent to a light-dark cycle was more intense in the active phase continuing from the scotophase than from the photophase of the preceding light–dark cycle; This indicates the presence of circadian components.

Conclusions: Two clock systems, i.e. circatidal and circadian, are involved in controlling locomotor activity in mangrove crickets.

Conservation of biodiversity using shelterbelts: consequences for biological control at local and landscape scales

Sagrario Gamez-Virues[1], Geoff Gurr[2], Anantanarayanan Raman[2], David Perovic[3], Helen Nicol[2]

[1]Pest Biology and Management Group, The University of Sydney, Orange, New South Wales, Australia, [2]E. H. Graham Centre for Agricultural Innovation, Charles Sturt University, Orange, New South Wales, Australia, [3]Pest Biology and Management Group, Charles Sturt University, Orange, New South Wales, Australia

Introduction: As a result of biodiversity lost from farmlands, shelterbelts and related non-crop habitats have become the main refuge and source of food for wildlife. This study investigated the effects of shelterbelt characteristics and landscape elements on the abundance and activity of arthropods within shelterbelts and adjacent pastures, both types of perennial crop.

Methods: Pitfall and sticky traps were used to assess diversity of arthropods within 18 shelterbelts of different plant diversity and habitat structure. Arthropods were also collected along transects from shelterbelts to adjacent pastures using vacuum sampling. Predation of pest arthropods was measured using sentinel baits along the same transects. Generalised linear models were used to analyse data. Area covered by isolated trees, cropped trees and dams, at three landscape scales, were also included in the analysis.

Results: Effects of plant diversity and habitat structure on the abundance of arthropods varied between species. However, diversity of arthropods was not significantly different between shelterbelts when using Shannon's diversity index. The abundance of minute parasitic wasps such as Mymaridae (2 spp.) and Trichogrammatidae (1 sp.) decreased when the distance from shelterbelts increased, but the abundance of other arthropods such as Aeolothripidae (1 sp.) and Formicidae (1 sp.) increased. Predation of pest arthropods significantly decreased with increasing distance from shelterbelts. Effects of landscape elements on the abundance of arthropods varied between species.

Conclusions: Shelterbelts offer the possibility to improve biological control of arthropods that attack trees and adjacent crops via manipulation of plant diversity and habitat structure.

Studies on the reproductive capacity and intraspecific competition of *Holepyris sylvanidis* (Hymenoptera: Betylidae), a larval parasitoid of *Tribolium confusum*

Cornel Adler, Cornelia Frielitz

JKI, OPV, Berlin, Germany

Introduction: *Holepyris sylvanidis* (BRETHES 1913) is a parasitoid on larvae of *Tribolium confusum*. The present study was carried out to gain information for mass cultivation.

Methods: 1-5 up to 4 d old mated females were placed into a plastic petri dish (diam. 55 mm) together with 5 larvae of *T. confusum* and hollow wheat grains for shelter at 25°C and 55 % r.h. After 24 h the females were transferred to fresh larvae and grains. The total experimental time was 4 d or covered the lifetime of females.

To determine the optimum number of hosts, a batch of 5, 10, 15 or 20 *T. confusum* larvae and hollow wheat grains were offered to one mated female in a plastic petri dish. Twice weekly the larvae and grains were replaced, the experiment was carried out for three weeks.

Results: With 1.6 eggs per day and female the highest oviposition rate was achieved when a single female was kept in the petri dish. This value dropped to 0.9 with two females and 0.4 with five females. Up to 52 eggs were laid per female in the presence of a male.

The highest number of eggs was laid with 10 larvae and wheat kernels present at a time. Within one week (and a total of 20 larvae offered) an average of 9.5 eggs was laid per female.

Conclusions: *H. sylvanidis* is a promising candidate to suppress mass development of *T. confusum* in the grain industry.

Studies on the reproductive capacity and intraspecific competition of *Holepyris sylvanidis* (Hymenoptera: Betylidae), a larval parasitoid of *Tribolium confusum*

Cornel Adler, Cornelia Frielitz

JKI, OPV, Berlin, Germany

Introduction: *Holepyris sylvanidis* (BRETHES 1913) is a parasitoid on larvae of *Tribolium confusum*. The present study was carried out to gain information for mass cultivation.

Methods: 1-5 up to 4 d old mated females were placed into a plastic petri dish (diam. 55 mm) together with 5 larvae of *T. confusum* and hollow wheat grains for shelter at 25°C and 55 % r.h. After 24 h the females were transferred to fresh larvae and grains. The total experimental time was 4 d or covered the lifetime of females.

To determine the optimum number of hosts, a batch of 5, 10, 15 or 20 *T. confusum* larvae and hollow wheat grains were offered to one mated female in a plastic petri dish. Twice weekly the larvae and grains were replaced, the experiment was carried out for three weeks.

Results: With 1.6 eggs per day and female the highest oviposition rate was achieved when a single female was kept in the petri dish. This value dropped to 0.9 with two females and 0.4 with five females. Up to 52 eggs were laid per female in the presence of a male.

The highest number of eggs was laid with 10 larvae and wheat kernels present at a time. Within one week (and a total of 20 larvae offered) an average of 9.5 eggs was laid per female.

Conclusions: *H. sylvanidis* is a promising candidate to suppress mass development of *T. confusum* in the grain industry.

Simulating causes and remedies for spider mite outbreaks in Canadian apple orchards

John Hardman[1], Wopke Van der Werf[2], Jeff Franklin[1]

[1]Atlantic Food and Horticulture Research Centre, Agriculture and Agri-Food Canada, Kentville, Nova Scotia, Canada, [2]Crop and Weed Ecology, Plant Sciences Department, Wageningen University, Wageningen, Netherlands

Introduction: In Nova Scotia, Canada, successful biological control of the European red mite, *Panonychus ulmi,* by the phytoseiid predator, *Typhlodromus pyri*, was soon followed by outbreaks of the two-spotted spider mite, *Tetranychus urticae*.

Methods: A combination of simulation modelling and orchard experiments were used to explore causes of outbreaks and to assess potential remedies (cultural, biological and chemical controls). The model is a modified Leslie matrix, which simulates the effects of weather, pesticides applications, immigration of mites into trees, and predation on the dynamics of *T. urticae* and *T. pyri* in apple trees.

Results: Orchard trials and simulations indicated that warm weather, higher rates of *T. urticae* immigration from the ground cover, and application of pesticides toxic to phytoseiids all contribute to rapid growth of *T. urticae* populations in trees. A major predisposing factor for outbreaks was the near absence in the tree canopy of *Neoseiulus fallacis,* an effective predator of *T. urticae*, likely because of competition from *T. pyri*. Furthermore, simulations indicated that failure of *T. pyri* to aggregate in prey patches greatly reduces the effectiveness of this predator. Also application of non-selective acaricides, those less toxic to *T. urticae* than to phytoseiids and to *P. ulmi*, the preferred prey of *T. pyri*, can actually worsen outbreaks.

Conclusions: Remedies suggested by the model include managing ground cover vegetation so as to minimize *T. urticae* immigration into trees and properly-timed application of selective acaricides, which are more toxic to *T. urticae* than to *P. ulmi* and phytoseiids.

Phenology of the European spruce bark beetle (*Ips typographus* (L.) (Coleoptera: Scolytidae) as the basis for modelling outbreak risk assessment in Triglav National Park, Slovenia

Maja Jurc, Nikica Ogris

University of Ljubljana, Biotechnical Faculty, Department of Forestry and Renewable Forest Resources, Ljubljana, Slovenia

Introduction: Large scale sanitary fellings due to spruce bark beetles (mostly *I. typographus*) were carried out in 1986/1987 and have increased since 1999; in 2003/2004 populations greatly increased in all parts of Slovenia. We developed a model of population dynamics and phenology of *I. typographus* for outbreak risk assessment as a tool for spruce bark beetle management in mountainous parts of Slovenia.

Methods: The research area was in a 130 years old forest community *Aposeri-Piceetum* on the plot of an intensive monitoring programme in Slovenia's Triglav National Park, 1397 m a.s.l.. We measured temperatures and moisture (T button, H button, Dallas Semioconductor) under the bark of old Norway spruce trees that were felled and left in stand gaps, from Feb. 2007 to Feb. 2008. We systematicaly collected 200×200 mm squares of bark from the felled trees and through analysis of bark beetles galleries we tracked spring swarming, start of parental, sister and filial generations, and brood development, as well as the beetle's natural enemies; we isolated entomopathogenic fungi from the beetles. We also collected data about direct solar radiation and other GIS data relevant to the research area. We developed a model using an M5' regression tree for better understanding of the complex ecological interactions involved in bark beetle outbreaks.

Results: The most important factor for brood development is the temperature under the bark, which changed drastically during the year, as well as during the day, and depended strongly on the position where measurements were taken on the log. We also found out that there is a significant influence of entomopathogenic fungi on the development of the beetles analyzed.

Conclusions: These modelling procedures can be used for simulation of the developmental stages of bark beetles if accurate data about their biology and phenology are available. A risk assessment of outbreaks, in combination with retrospective analysis of population dynamics, a topoclimatic model, and spatial visualization of the potential development and associated risks of *I. typographus* outbreaks, can be a useful tool for spruce bark beetle management in mountainous parts of Slovenia.

Humanity hastens host expansion: the autumn gum moth as an Australian example

Martin Steinbauer[1], Fredrik Östrand[2]

[1]Department of Zoology, La Trobe University, Melbourne, Victoria 3086, Australia, [2]Department of Ecology, Lund University, Lund SE-223 62, Sweden

Introduction: In the 1960s foresters identified *E. globulus* and *E. nitens* as preferred for pulpwood production and began greatly extending both species' geographic range. Coincidentally, both species are preferred hosts of the autumn gum moth, *Mnesampela privata* (Geometridae). Since then, *M. privata* has gone from uncommon to outbreak species and expanded its host range in the wild.

Methods: Field observations of oviposition on different species and families of eucalypts and generational changes in body weight were conducted in two experimental arboreta. These data were supplemented with laboratory bioassays of oviposition preference and larval survival and analyses of physical and chemical traits of leaves of different species and families of eucalypts.

Results: In both arboreta, the numbers of eggs on preferred and novel hosts increased between parent and offspring generations. This coincided with an increase in the weight of females between consecutive moth seasons. Field and laboratory studies revealed that females would oviposit on novel hosts if foliar monoterpenes and epicuticular waxes were comparable to those of preferred hosts. Some larvae pupated on all novel hosts tested with one exception (*Corymbia eximia*). Larval mortality was high on novel hosts whose leaves contained high concentrations of sideroxylonal as well as high concentrations of monoterpenes. These hosts may present larvae with toxic loads greater than those ingested when eating *E. globulus* or *E. nitens*. Only high leaf toughness was universally detrimental to larvae but such leaves are usually avoided by females.

Conclusions: Synchronicity of time of planting provides a superabundance of the leaf type (juvenile) preferred for oviposition. Plantations of non-endemic hosts sustain atypically large populations and facilitate generational increases in fitness. The dispersal of numerous, highly fecund females from localised outbreaks creates greater opportunities for oviposition on less preferred families and species growing near plantations. Exaptation of larvae for ubiquitous eucalypt secondary metabolites means that some will eclose on novel species only somewhat similar to *E. globulus* and *E. nitens*. Whether or not host races have arisen is unknown but the potential for further host expansion continues to grow.

The contribution of ecological insights to pest management of the larger grain borer *Prostephanus truncatus* (Coleoptera: Bostrichidae) in Africa

Rick Hodges

Natural Resources Institute, Chatham Maritime, Kent, ME4 4TB, United Kingdom

Prostephanus truncatus arrived in Africa from meso America in the late 1970s. It was a new beetle pest of stored maize grain and dried cassava roots with a distinctly different ecology and behaviour from the more familiar storage insects. It also caused much greater storage losses.

The development of pheromone traps for *P. truncatus* soon demonstrated that the pest was unusual in having major populations away from stores on woody hosts in the bush. Evidence that greater numbers of beetles dispersing by flight increased the likelihood of stores becoming infested emphasised the importance of large populations in the bush as a source of infestation of stored products; an apparently unique situation for a storage pest. This finding supported the use of a predatory histerid, *Teretrius nigrescens*, as a classical biological control agent. Although this predator is relatively ineffective in reducing the pest in infested stores, it offers considerable benefits by limiting populations in the bush and consequently lowering the scale of cross-over from the bush into stores.

The pest shows strong inter-annual variation in flight activity and a rule-based model has been developed to predict flight activity using climatic variables. Warning of years with higher flight activity indicate when there is greater risk of *P. truncatus* attack and this can be used to alert farmers to take pest management action before food losses become significant.

The effect of a blood meal on insecticide resistance in *Anopheles funestus*

Belinda Spillings, Lizette Koekemoer, Basil Brooke

Vector Control Reference Unit, National Institute for Communicable Diseases, NHLS;; Division of Virology and Communicable Disease Surveillance, School of Pathology of the National Health Laboratory Se, Sandringham, Johannesburg, South Africa

Introduction: Insecticide resistance has been detected in the southern African malaria vector *Anopheles funestus*, raising concerns for current vector control programs. At present, indoor residual spraying (IRS) using DDT and pyrethroids is an effective method for reducing the numbers of malaria vectors in South Africa. However, the portion of the population most affected by IRS is the blood feeding females, which is responsible for the transmission of malaria.

It has been suggested that blood fed females are able to tolerate higher levels of insecticide due to their increased body weight (vigor tolerance). Furthermore, the process of blood digestion activates a suite of enzymes responsible for detoxifying potentially toxic compounds present in the blood. We hypothesized that this period of increased detoxification could result in increased levels of insecticide resistance.

Methods: Cohorts of *An. funestus* females were divided into blood fed and unfed groups and exposed in Permethrin coated glass bottles. The blood fed group were given a blood meal 4 hours prior to exposure. Percent mortality was scored 24 hours post exposure and statistical analyses carried out.

Results: Our data shows that a significant increase in insecticide tolerance occurs in blood fed females from a pyrethroid resistant strain of *An. funestus.* A comparison of blood fed and unfed females from a fully insecticide susceptible *An. funestus* strain did not show any significant increase in insecticide tolerance.

Conclusions: The elevated level of resistance detected in blood fed females of the insecticide resistant strain suggests that the resistance mechanism may be directly enhanced by detoxification processes that are stimulated by the presence of the blood meal. These increased levels of resistance are currently being quantified through molecular techniques such as qPCR and microarrays.

Immunity and insect social systems

Rob Knell[1], William Hughes[2]

[1]Queen Mary, University of London, London, United Kingdom, [2]University of Leeds, Leeds, United Kingdom

Intuitively, we expect disease incidence and therefore investment in immunity to be greater in social than in solitary insects, because the increased contact rates with conspecifics in social groups will lead to higher transmission rates. Theory disagrees, however, suggesting that reduced contact rates between social groups can counter the increased contact rates within groups, leading to lower disease incidence in social species. A review of empirical data finds support for both points of view. We discuss the relationship between social system and contact rates in detail, and propose that the relationship between immunity and sociality will depend on the details of the social systems in question. In particularly, the longevity of the groups and the movement patterns of the animals in the groups will vary between different types of social insect and will have a pronounced effect on the patterns of disease incidence and therefore immune investment.

Period gene plays a role in circadian rhythm and photoperiodism in crickets

Kenji Tomioka, Yoshiyuki Moriyama, Tomoaki Sakamoto

Okayama University, Okayama, Japan

Introduction: Periodic expression of clock genes is now believed to be an essential part of the circadian clock in *Drosophila* and the circadian clock has been hypothesized to be involved in insect photoperiodism. However, these are still to be examined. In this study we investigated the role of *per* gene in circadian rhythm generation and photoperiodism using two cricket species, *Gryllus bimaculatus* and *Modicogryllus siamensis.*

Method:.We measured *per* mRNA levels with quantitative real time RT-PCR and knocked-down *per* mRNA levels by injecting *per* double-stranded RNA (dsRNA).

Results: In *G. bimaculatus*, *per* mRNA levels in the optic lobe showed a rhythmic expression both in light/dark cycles and in constant darkness (DD), with a peak in the late day to early night. Knocking-down of the *per* mRNA levels mostly resulted in a loss of circadian locomotor rhythms. The electrical activity of optic lobe efferents also became arrhythmic in the *per* dsRNA treated crickets. We next examined the role of *per* in the photoperiodic regulation of nymphal development in *M. siamensis*. We collected the eggs laid by *per* dsRNA injected females and examined development of the nymphs hatched from the eggs under long-day or short-day conditions. Under both photoperiodic conditions, the nymphs showed an adult emergence pattern neither for those of long-day nor for short-day conditions but similar to those kept in DD conditions.

Conclusion: These results strongly suggest that *per* plays an important role not only in the circadian rhythm generation but also in the photoperiodic time-measurement in the crickets.

An early-warning system for *Heteronychus arator* Fabricius (Coleoptera: Scarabaeidae)

Thomas Drinkwater

ARC-Grain Crops Institute, Potchefstroom, South Africa

H. arator adults that emerge from pupal cells during late summer and autumn overwinter as adults in maize fields and damage maize seedlings during the following spring. By capturing adult black maize beetles (BMB) during February to April in light traps and entering these numbers into a mathematical model, the size of the subsequent spring population could be estimated and used as an early-warning system. The occurrence of two severe pest outbreaks over the past six decades, namely in the late 1940's and late 1970's was also incorporated into the model. During February to April of the latter period more than 72 000 adults were captured in a single light trap in the affected area. This is the magnitude that could be considered an outbreak. Following this period a limited number of light traps were placed in the Heidelberg area, which provided sufficient data to successfully advise producers in that region for nine consecutive years. This advisory service was expanded in 2002 to include producers in all affected areas by placing light traps in a quarter degree grid pattern over the whole area. An inverse distance-weighted analysis with four nearest-neighbouring localities was done with the *Arcview 3.2* computer programme, based on the actual number of beetles captured every year at each locality. BMB has now been monitored through this early-warning system for 16 years. Lately the seasonal mean number of adults captured fluctuated between 190 and 2 150, which remains far below the levels expected to cause an outbreak. Producers were continuously advised accordingly and could therefore save up to R110/ha every year.

Evolutionary origins and local adaptations of a novel host-plant detoxification gene in butterflies

Hanna Fischer[1], Christopher Wheat[2], David Heckel[1], Heiko Vogel[1]

[1]Max-Planck-Institute for Chemical Ecology, Jena, Germany, [2]Pennsylvania State University, PA, United States

Introduction: The interactions between plants and their specialist insect herbivores provide an excellent opportunity to study the evolution of species interaction on a molecular level. Here we investigate a novel detoxifying enzyme (Nitrile-specifier Protein: NSP) in the butterfly family Pieridae. NSP redirects the hydrolysis of plant chemical defense glucosinolates to nitriles rather than toxic isothiocyanates in caterpillar guts, enabling them to feed on plants in the order Brassicales. The appearance of NSP coincides with the emergence of the Brassicales family and was followed by significantly increased diversification rates identifying NSP as a key evolutionary innovation.

Methods: Generation of cDNA libraries and genomic data sets allowed us robust phylogenetic analysis. Population studies on four wild *P. rapae* populations permitted us concluding on population structure of this butterfly species and on selection pressure acting on NSP.

Results: We found NSP to be a member of an insect specific gene family we characterized and named NSP-like gene family. Members of this family can be found across insecta. The NSP-like gene family evolution is a dynamic, ongoing birth death process. NSP and its ortholog are still subject to high rates of change, reflecting dynamic properties and possible adaptation to their plant counter part.

Conclusions: We have generated a broad sketch of the evolutionary origins and ongoing selection pressures of an adaptive trait, which facilitated an ecologically important host shift and the diversification of the Pieridae butterfly family. We provide direct evidence that gene duplication is one of the driving forces for speciation and adaptation.

The evolution of control strategies for trypanosomiasis and tsetse flies (*Glossina* spp.) in Africa (1908-2008)

Charles Kyorku

University for Development Studies, Northern Region, Ghana

Trypanosomiasis is a protozoan disease transmitted by blood sucking tsetse flies (*Glossina* spp.) in man and other vertebrate animals in sub -Saharan Africa. Owing to its debilitating and fatal effects on man and his animals, especially cattle, it is one of the major constraints on socio-economic development in the region.

The importance of this disease was realized by the colonialists at the turn of the 20th century. Since then various strategies have been employed to mitigate the situation. These included chemo-therapeutic and chemo-prophylactic treatment infections and attacks on the vector populations including vegetation (habitat), wild host (food source) destruction and insecticidal spraying of vector populations. The paper reviews the gradual changes in the control strategies for this disease over the century

For the first half of the century, the results of control campaigns have varied widely from total failure in most places to limited success in a few. To a large extent, this was due to the fact that there was very little knowledge on the biology, ecology and behaviour of the whole vector-parasite-host relationship.

The failure of insecticides, especially DDT, to achieve permanent control and other drawbacks, prompted scientists to intensify research into finding more acceptable, sustainable and long-lasting alternative control strategies.

Thus, over the past fifty years scientists have put in concerted efforts to achieve this. Today efficient odour-baited attracting mechanical killing devices have been developed. These have proved, through community based pilot control projects, to be very effective in drastic reduction of vector populations and hence disease prevalence. The one problem encountered by most of these small scale projects is reinvasion of the control areas by tsetse from neighbouring populations.

In the light of above, the African Union (AU) has formulated a policy for adoption by all African countries for the eradication of tsetse and trypanosomiasis – The African Tsetse and Trypanosomiasis Eradication Campaign. (PATTEC). The programme was launched in 2007 in many parts of Africa including Ghana.

The prospects for this giant undertaking are discussed.

Habitat manipulation in cotton IPM: Host plant utilization, host sequence, and host preference of *Lygus hesperus*

Megha N. Parajulee

Texas AgriLife Research and Extension Center, Lubbock, Texas, United States

A comprehensive research on ecology and behavior of *Lygus hesperus* (Hemiptera: Miridae) has been conducted at the Cotton Entomology Program Laboratory in Lubbock, Texas, USA, for the last seven years, with a focus on quantifying the biological parameters in relation to host plant utilization, non-cotton host plant sequence, and host preference affecting the likelihood of *Lygus* damage severity in cotton in vulnerable stages. The presentation will examine a multi-year regional survey work that elucidates the habitat complexity and intercrop relationship in *Lygus* movement between cotton and non-cotton hosts. Field surveys showed that several non-cotton hosts (alfalfa, Russian thistle, pigweed, sunflower, and grain sorghum) serve as sink for *Lygus* during the early summer months while *Lygus* move to adjacent cotton when these alternate host sources senesce or are less favorable for *Lygus*. Laboratory studies also showed that nymphal development and survivorship were better in non-cotton hosts compared with that in cotton fruits, particularly the young bolls. Immunological assays of field-marked *Lygus* also indicate that the non-cotton hosts such as alfalfa may serve as both sink and source for *Lygus* depending on the phenological stages of these hosts. Large, regional research is currently underway in the western United States to develop a predictive model to estimate *Lygus* severity in cotton fields as a function of non-cotton host plant diversity based on a source-sink relationship with cotton.

Commercial use of transgenic crops, their effect on biodiversity and natural enemies

Graham Head

Monsanto Company, St Louis, Missouri, United States

Over the past 11 years, the use of transgenic crops has grown dramatically, and now exceeds 100 million hectares on a global basis with substantial adoption in both developed and developing countries. Corn, soybeans, cotton and canola make up most of this area, and the most commonly used traits are insect resistant and herbicide tolerance. Over the past five years, the use of transgenic crops with multiple traits has grown particularly rapidly. This rapid adoption has brought many changes to agricultural systems, including significant changes and reductions in conventional insecticide use, reductions in tillage, and changes in cropping practices. In addition, ecological changes have occurred in these agro-ecosystems, with apparent suppression of a number of major plant pests through direct and indirect effects of the transgenic traits, increases in some important natural enemy populations, and flare-ups of several previously uncommon pest species. The reasons for these changes and their implications for the future will be discussed, with a particular focus on interactions between transgenic crops and biological control functions in agro-ecosystems.

A private sector perspective on IRM strategies for transgenic Bt crops

Graham Head

Monsanto Company, St Louis, Missouri, United States

Transgenic Bt crops were first approved for commercialization in 1995 and now have been commercialized in more than 15 countries. Insect resistance management (IRM) is an important part of the stewardship of these Bt crops, and therefore technology providers have proactively implemented IRM practices wherever these products have been introduced (making this the first technology for which IRM has been routinely and proactively practiced). The IRM plans for Bt crops include a number of standard elements, such as an appropriate refuge for the production of susceptible target insects, a program to monitor for resistance, and broad-based education for growers and other relevant groups. However, there also has been an increasing recognition that the IRM needs for Bt crops vary among countries because of differences in pest biology, farming practices, and farmer literacy and experiences. Locally adapting IRM plans has required local scientific studies and surveys of grower practices, and has resulted in a number of novel approaches being developed. Smallholder systems in developing countries have posed a particular challenge because of the scale and diversity of these agricultural systems. In such cases, IRM strategies are most effectively implemented through the technology providers rather than requiring individual farmers to carry out novel practices. Going forward, it is heartening that no instances of resistance evolution to Bt crops have yet been observed, but significant scientific and logistical challenges will continue to arise.

Bionomics of *Aedes albopictus* (Skuse) vector of chikungunya and dengue in the Indian Ocean

Delatte Hélène[1], Gimonneau Geoffrey[1], Triboire Aurelie[2], Fontenille Didier[3]

[1]IRD, Saint Pierre, Reunion, [2]CIRAD UMR PVBMT, Saint Pierre, Reunion, [3]IRD, Montpellier, France

Introduction: *Aedes albopictus,* is a worldwide invasive mosquito originating from Asia, considered as competent in transmission of arboviruses. It was first described in La Réunion (an island of the South West part of the Indian Ocean (SWIO)) in 1913. Since, it has become the dominant *Aedes* species and a serious threat to public health, especially during the two last arboviruses outbreaks of Dengue and chikungunya. Despite its pest status, data on the biology of this vector are scarce, especially the population present in SWIO.

Methods: Biological parameters in controlled conditions were studied for this population at 8 constant temperatures (5, 10, 15, 20, 25, 30, 35 and 40°C). Biological data obtained were modeled.

Results: The minimal threshold of immature stages development was found at 10.4°C and its optimum at 29.7°C. The shortest periods for immature development were found at 30°C, with in average of 8.8 days. The optimum intrinsic rate of growth (*r*) was observed between 25 and 30°C. The trophogonic cycles were also evaluated and the shortest cycles were found at 30°C (in average 3.5 days).

Conclusions: Those results pinpointed the ability of a female to take a blood meal, at a minimum 2 days after its emergence. This ability, its good vectorial competence for CHIKV and DENV, the high (ideal) temperatures of subtropical summers, plus the presence of enough viremic travellers with an arbovirus, can partly explain the two explosive epidemic transmitted by *Ae. albopictus* for DENV and CHIKV in the Indian Ocean in 1997-8 and 2005-6, respectively.

Biogenic amine action on motor circuits in *Drosophila* and other insects

Hans-Joachim Pflueger[1], Natalia L. Kononenko[2], Ricard Vierk[1], Bjoern Brembs[1], Frauke Christiansen[3], Carsten Duch[4], Heike Wolfenberg[1]

[1]Free University, Berlin, Germany, [2]NTNU, Trondheim, Norway, [3]Universitaet, Wuerzburg, Germany, [4]Arizona State University, Tempe, AZ, United States

Biogenic amines are important modulators of behaviour both in vertebrate and invertebrate animals, and act on the central and peripheral nervous system. In *locusts*, we examined the functional role of octopamine which is released from a special class of efferent neuromodulatory neurones innervating peripheral muscles, sense organs and glands. Octopamine released from these neurones (i) modulates the efficacy of neuromuscular transmission, (ii) regulates the energy metabolism (activation of glycolysis), and (iii) increases the sensitivity of mechanoreceptors. Thus, the whole organism is primed for more dynamic, long lasting actions.

Consistent with this hypothesis, different types of efferent octopaminergic neurones are differentially recruited (activated or inhibited) during motor behaviour in parallel to the motor networks, and that those which activate glycolysis in muscles are inhibited during behaviours in which energy is generated by lipid oxidation. *Drosophila* tßh-mutants which cannot synthesize octopamine from tyramine, exhibit severe flight deficits, and the results suggested a combined effect of both tyramine and octopamine onto the flight system of *Drosophila*.

Correspondingly, the effects of octopamine and tyramine on the alternating motor patterns of a fictive flight preparation of *Manduca sexta* were tested. If tyramine is perfused then a similar alternating rhythm like that from octopamine is evoked but the depressor motoneurones show a different firing pattern sensitive to yohimbine, a tyramine-receptor-antagonist. This suggests that both octopamine and tyramine differentially affect elevator and depressor motoneurones.

Finally, immunocytochemical studies reveal pure tyraminergic cell populations and an interesting compartmentalization within octopaminergic neurones dependent on behavioural activity.

Caste polyphenism in bees: New phenotypes from tinkering with old genes and conserved signaling pathways

Klaus Hartfelder

Universidade de São Paulo, Ribeirão Preto, SP, Brazil

The two basic questions, *why* and *how* alternative phenotypes such as the caste of social insects can arise have, so far, mostly been formulated under quite distinct perspectives. This has left a wide gap between approaches that explain the origin of the worker caste in Hymenoptera and the soldier/worker castes in termites in terms of fitness gains (ultimate reasons) on the one hand, and developmental regulation and reproductive physiology (proximate mechanisms) on the other. The current fusion of developmental and evolutionary biology, driven by the advances in developmental genetics of model organisms, now start to provide a common framework on how caste phenotyes can be built from basic mechanisms for insect development. I will illustrate this by examples on endocrine system functions in social bees (juvenile hormone and insulin signaling) and from comparative functional genomic approaches. Obviously, the latter are only first incursions into a novel field of research, but one of the main conclusions already emerging is that metabolic regulation is a key factor in caste development. A particularly interesting question is that of gene regulatory networks, that is, how gene expression patterns are integrated by the architecture of their cis-regulatory regions in the development and reproduction of the female castes. I will show how this question can be approached through position-specific matrix analysis and network theory.

Population biology of the lucerne flea, *Sminthurus viridis*, with applications for control

John Roberts, Andrew Weeks, Ary Hoffmann

Centre for Environmental Stress and Adaptation Research, University of Melbourne, Parkville, Victoria, Australia

Introduction: The lucerne flea is a major agricultural pest of crops and pastures throughout southern Australia and New Zealand. As control methods for this pest rely heavily on pesticides, there is a need for a sustainable IPM strategy. To provide the necessary biological information for such an approach, we are currently examining the lucerne flea's population biology and life-cycle, as well as investigating chemical and biological control methods.

Methods: Genetic markers were used to examine the population structure, migration potential and mode of reproduction throughout Australia. Laboratory bioassays were used to assess the efficacy of several chemicals against lucerne fleas. Field experiments investigating the life-cycle of the lucerne flea were also conducted.

Results: Allozyme markers indicate that Victorian lucerne flea populations reproduce sexually and have significant structure due to limited gene flow. Microsatellite markers have been developed for greater resolution of the population biology throughout southern Australia as variability in allozyme loci was low. Pesticide testing has found lucerne fleas to have high tolerance to several registered chemicals when compared to the co-existing redlegged earth mite, also a major agricultural pest. Longitudinal sampling of several populations suggests at least two generations per season with numbers peaking in autumn and spring. Experiments examining summer diapause in the lucerne flea are in progress to determine when over-summering eggs are laid during a season.

Conclusions: High pesticide tolerance in the lucerne flea supports the need for an IPM strategy. Further insights into this pest's biology will lead to more effective and sustainable control.

Assessing the impact of the spatial arrangement of non-crop vegetation in Australian cotton landscapes: incorporating connectivity in spatially specific landscape complexity analysis

David Perovic[1], Geoff Gurr[2], Anantanarayanan Raman[2]

[1]Charles Sturt University, Orange, New South Wales, Australia, [2]E.H. Graham Centre for Agricultural Innovation, Charles Sturt University, Orange, New South Wales, Australia

Introduction: Landscape complexity at a scale of several kilometres has previously been shown to strongly affect natural enemy conservation in cropping land. Our study investigated ecological insights which may be gained by including measures of connectivity into landscape analysis.

Methods: The relationship between non-crop habitats and natural enemy abundance in crops was compared using generalised linear models at scales of 120, 750, 1500 & 3000 m surrounding crops. Cost-distance measures were included in regressions to test the effects that the connectivity of these habitats have on the abundance of natural enemies in crops. Further, the degree to which each land-use type impedes, or facilitates, the movement of natural enemies through the matrix was tested by comparing cost-distance models with different cost structures.

Results: Connectivity metrics explained the majority of variation observed within crops for all taxa observed. 'Linear' elements such as shelterbelts and 'dispersed' elements such as isolated native trees on farms were shown to be important for creating connectivity between non-crop habitats and cotton crops. Cost-distance models which considered arable land to be more resistant to movement than other land-uses fitted arthropod data most significantly. Spatially specific analysis indicated that landscape structure affects different taxa at different scales: these differences reflected the dispersal capacity of each taxon.

Conclusions: While non-crop areas provide important habitats for natural enemies in agroecosystems; the spatial arrangement of these elements can greatly enhance ecosystem services by facilitating the movement of natural enemies into crops.

Astounding success in dengue control in Vietnam, using *Mesocyclops* and community-based methods

Brian Kay

Australian Centre for International and Tropical Health, Queensland institute of Medical Research, Brisbane, Australia

Introduction: In 2005 in Lancet 365 : 613-617, we reported a mosquito control strategy which incorporated four elements; (i) a combined vertical and horizontal approach which depended on community understanding and leadership, (ii) prioritized control according to the larval productivity of major habitat types, (iii) the usage of predacious copepods of the genus *Mesocyclops* as a biological control agent, delivered by (iv) communal activities of health collaborators, school children and the public.

Methods: From 1998-2000, we reported that our community based vector control program in six communes in the northern provinces of Nam Dinh, Hung Yen and Hai Phong had resulted in extension to another 37 communes by 2000-2003. From 2000-2003, we set up similar interventions in central Vietnam provinces of Quang Nam, Quang Ngai and Khanh Hoa and from 2004-2007, worked in the southern provinces of Long An and Hau Giang. In 2007, our team evaluated program sustainability in Nam Dinh, 7 years after project completion.

Results: For all interventions, eradication of *Aedes aegypti* was achieved in 40 of the 48 communes, with only small numbers of larvae detected in the others. In Nam Dinh province in 2007, these community-based programs were strongly led by local leadership and eradication status maintained. The setting up of micro-enterprise schemes towards the end of project completion in 2000 was used to stimulate community action and was thought to have played a role in ensuring sustainability. The direct cost of locally run programs in Nam Dinh was estimated to be 4 US cents per person per year.

Conclusion: This strategy is affordable and sustainable in northern Vietnam at least but should have application to other countries where large water storage containers are major contributors of *Aedes aegypti* and where there are local leaders and communities willing to take responsibility for controlling dengue.

Postembryonic development of Mantophasmatodea, with reference to antennal development

Mike Picker, Dorit Hockman

University of Cape Town, Cape Town, South Africa

Introduction: The first description of the life cycle of Mantophasmatodea is provided. Antennal development and structure are described and used as characters for an evaluation of interordinal relationships.

Methods: Newly hatched nymphs of field-collected *Lobatophasma redelinghuysense* were reared, providing a time sequence of head capsule measurements. SEM and light microscopy tracked the mode of antennal growth.

Results: The life cycle comprised six instars, with females having significantly larger head capsules from instar II onwards and a greater rate of development than males. Antennae of first instars comprised a smooth 4-segmented basiflagellum and a 7-segmented, sensillae-rich distiflagellum. Increase in number of annuli occurred in the basiflagellum only. Lengthening of the antennal flagellum was achieved by division of the first basal annulus, adding two annuli at each moult. Both number of annuli and unique segmentation pattern of the distiflagellum (alternating short and long annuli) remained constant until adulthood. The segmentation pattern of the adult antennae (comprising basiflagellum and a distiflagellum of 14 and 7 annuli respectively) was consistent for all 10 species examined, and thus considered to be stable within the order. Secondary subdivision of terminal basiflagellar annuli occurred from segment 8 onwards. The position of the secondary annular divisions was variable, and corresponded with intraordinal clades defined by molecular studies.

Conclusions: The mantophasmatodean antenna provided a number of characters, autapomorphic within Hexapoda. It bears little resemblance to that of putative sister-groups viz. Grylloblattodea, Mantodea and Phasmatodea. Instead, the mode of flagellar elongation and annulation is the same as that of Isoptera, Blattodea and Dermaptera.

Understanding the nutritional ecology of *Anopheles gambiae* in western Kenya and its possible impact on malaria transmission

Hortance Manda[1], Louis Clement Gouagna[2], John Beier[3], Woodbridge Foster[4], Ahmed Hassanali[1], John Githure[1]

[1]International Centre of Insect Physiology and Ecology, Nairobi, Kenya, [2]Institut de Recherche pour le Développement, Ouagadougou, Burkina Faso, [3]University of Miami, Miami, Florida, United States, [4]The Ohio State University, Columbus, Ohio, United States

Introduction: To provide for their energy needs, both sexes of adult mosquitoes require sugars which they acquire mainly from plants. This study investigated plant-feeding behaviour of *Anopheles gambiae* and its impact on their fitness and vector competence.

Methods: In Suba district, western Kenya, indoor resting *An. gambiae* were sampled and tested for their plant-feeding status. Their feeding responses on common plants growing around human dwellings and mosquito larval habitats were determined in choice and no-choice bioassays. Survival and fecundity were evaluated when feeding on plants. Mosquitoes fed on each plant species were experimentally infected and their infectivity determined.

Results: Up to 12% of females *An. gambiae* sampled had recently fed on plants. There was a preferential feeding pattern of *An. gambiae* on specific plants species. Flower was the most preferred part for feeding, but leaves and stems were most preferred in some plants species. Survival and fecundity of *An. gambiae* were increased when they fed on almost all preferred plants. This was positively correlated with the quality and quantity of sugars on those plants. Two plants species impeded the development of *Plasmodium falciparum* in the mosquito midgut, significantly reducing the prevalence of infection in mosquitoes, at a magnitude of >50% below mosquitoes fed on the control glucose. The adverse effects of plants on parasite development in the mosquito midgut increased on post-infection plant-feeding and were optimum on continuous plant-feeding.

Conclusions: The availability of certain plants species to *Anopheles* mosquito in endemic areas may affect mosquito population dynamics and malaria transmission.

Spatio-temporal distribution of Coleoptera in food mills

Pasquale Trematerra

University of Molise, Campobasso, Italy

Introduction: Geostatistical methods and spatio-temporal analisys can be a powerful tool for the understanding of many spatially-related phenomena.

Methods: By utilizing food-bait traps we evaluated the presence and the spatio-temporal distribution of insect-pests in an industrial semolina-mill.

Results: Insect specimens captured in the traps belonging to 14 *taxa*, mainly Coleoptera. The most abundant were *Tribolium confusum*, followed by *Typhaea stercorea* and *Tribolium castaneum*. *T.confusum* was collected on all the sampling dates, with peaks in the second half of June-beginning of July and in the first half of August. *T.stercorea* was most abundant from the second half of May to the beginning of July and in the first half of September. The presence of *T.castaneum* had a peak in June. For *T.confusum* the highest abundance foci were confined to the corners of the milling area and in the base of the adjacent walls of every floor. *T stercorea* was confined in the I and the II floors, the main moisture areas of the mill contaminated with mould. *T. castaneum* was observed in the upper floors of the mill. Of interest was the presence in the food-bait traps of *T.confusum* and *T.castaneum* adults in a mixed population with equal numbers of males and females; analysis of the spatio-temporal dynamics suggested that the distribution of the two sexes was almost the same during the sampling period.

Conclusions: The indications obtained were used in precision IPM procedures after the fumigation, based essentially on the improvement of good sanitation practices.

Precision IPM and spatial distribution of Lepidoptera pests of pome, stone and grape fruits

Pasquale Trematerra, Andrea Sciarretta

University of Molise, Campobasso, Italy

Introduction: Geostatistical methods can be a powerful tool for the understanding of many spatially-related phenomena.

Methods: The main objectives of our studies (from 1998 to 2007) were to determine, by pheromone traps, the temporal and spatial variation in distribution and abundance of *Cydia funebrana*, *Cydia pomonella*, *Cydia molesta*, *Anarsia lineatella* and *Lobesia botrana* inside and outside orchards, and to evaluate the importance of the presence of several host plants.

Results: *C.funebrana* (250 ha), kriging procedures showed that the number of males was lowest in the interior of plum orchard and highest around a ravine, near irrigation channels and hedgerows in the orchard surroundings.

C.pomonella (100 ha), spatial characterizations obtained illustrate that the high trap capture foci were confined to the productive apple orchards or in a small groups of apple trees. *C.molesta* and *Alineatella* (250 ha), were investigated inside small plots of stone fruit, plum, apple, pear and kiwi orchards, and outside in field crops, irrigation channels, hedgerows and a river. The main hot spot for both pests was in a stone fruit orchard. The river and the irrigation channels seem to act as barriers.

L.botrana (50 ha), was monitored in a hilly ecosystem where vineyards are surrounded by hedgerows, small woodlots, alternated with cereal and olive groves. The presence of males was not limited to vineyards, particularly at the beginning of the season, when most of the individuals were caught inside olive groves, while during the II and the III flight they concentrated in vineyards.

Mechanisms of insecticide-resistance in hemipteran species: An overview

Graham Moores, Georgina Bingham, Ian Denholm, Lin Field, Kevin Gorman, Martin Williamson

Rothamsted Research, Harpenden, Herts, United Kingdom

Too often in the past various insecticide-resistance mechanisms have been specifically aligned with pest species. Hence, 'Dipterans possess target-site insensitivity whilst homopterans possess metabolic resistance'. The agricultural sucking pest insects are a prime example to repudiate the old adages, with populations from aphid and whitefly species demonstrating the full spectrum of resistance mechanisms.

Main consideration is given here to the Sternorrhyncha, in particular the global whitefly pest, *Bemisia tabaci,* and the prinicipal UK crop pest, *Myzus persicae*. Both species exhibit target-site resistance in the forms of modified acetylcholinesterase (MACE) conferring insensitivity to carbamates and organophosphates as well as knockdown resistance (kdr) conferring insensitivity to pyrethroids. Furthermore, both species exhibit metabolic resistance in the forms of enhanced/ modified enzyme activity due to esterases and/ or microsomal oxidases.

Molecular, biochemical and synergist studies using piperonyl butoxide and analogues have been utilised to characterise these resistance mechanisms. The latter allow informed decisions on the contributions from each metabolic component and have indicated the possible presence of target-site resistance to neonicotinoids in some strains of *B. tabaci*.

Synergistic enhancement of plant activators

Georgina Bingham, Lesley Smart, Toby Bruce, Barry Pye, John Pickett, Glen Powell, Simon Hodge, Graham Moores

Rothamsted Research, Harpenden; and Imperial College, Kent, United Kingdom

The development of insecticide resistance in a wide range of important insect pest species, together with the withdrawal of several widely used insecticides in Europe, poses a serious challenge to effective crop protection, leaving an urgent need for alternative control strategies.

A number of natural and synthetic compounds (plant activators) are able to induce effective plant resistance against insect pests by increasing the plant-defense chemistry. Such plant activators include DL-β-aminobutyric acid (BABA) and *cis*-jasmone.

Insects have metabolic enzyme systems that enable them to metabolise plant xenobiotics. These same enzyme groups may be enhanced, resulting in pesticide-resistance. Inhibitors of these enzymes can act as xeniobiotic synergists, and by allowing sufficient time for these inhibitors to fully inhibit the enzymes (temporal synergism), insect pests can be made sensitive to either conventional pesticides or activator-derived plant xenobiotics.

Since activator-primed plants have an enhanced ability to produce defensive xenobiotics and enzyme inhibitors leave the insect defenceless, a combined approach has demonstrated enhancement of the potency of plant activators. In crops that have relatively toxic secondary metabolites (such as potatoes, cotton, tomatoes and black mustard), the use of temporal synergism in conjunction with plant activator priming has resulted in low survival of *Myzus perisicae, Aphis gossypii* and complete control of *Bemisia tabaci* (insecticide resistant and susceptible strains) without the use of pesticides.

Vegetation context and the emergence of multi-predator effects

Andrew Wilby[1], Linda Anglin[2], Khalid Asiry[2]

[1]Lancaster University, Lancaster, Lancashire, United Kingdom, [2]University of Reading, Reading, Berkshire, United Kingdom

Introduction: Mechanisms underlying both positive (prey risk enhancement) and negative (prey risk reduction) effects of increasing predator species richness have been identified, and it has been argued that the relative expression of these mechanisms may be affected by the broader ecological context. Here we test whether plant density and species composition can alter the strength or sign of emergent multi-predator effects.

Methods: We subjected caged populations of the aphid *Metapolophium dirhodum* to *Chrysoperla carnea* larvae alone, *Adalia bipunctata* adults alone, and a combination treatment including both predator species. These predator treatments and a no-predator control where applied in three different vegetation contexts: low-density wheat, high-density wheat and a wheat and field bean mixture. Comparisons of control and treatment cages allowed calculation of the per-capita impact of each predator treatment on population growth in *M. dirhodum*.

Results: Both *A. bipunctata* and *C. carnea* caused a significant reduction in *M. dirhodum* population size. Prey suppression was not affected by plant density, but was significantly reduced in the wheat/bean mix compared with the wheat monocultures. Comparison of prey-suppression in mixed-predator treatment with expected suppression based on the single-species predator treatments revealed positive emergent effects in the wheat monoculture treatments (risk enhancement), but negative emergent effects (risk reduction) in the wheat/bean mix.

Conclusions: Plant species composition can not only affect prey population suppression, but can also moderate the sign and strength of multi-predator effects. Benefits of increased predator species richness may be determined, in part, by the vegetation context.

The evolution of termites: Fossils and phylogenetic patterns

Michael Engel[1], David Grimaldi[2]

[1]University of Kansas Natural History Museum, Lawrence, Kansas, United States, [2]American Museum of Natural History, New York, New York, United States

A study of phylogenetic relationships among major lineages of Isoptera is provided based on morphological, ethological, and paleontological data. An extensive diversity of fossil termites from the Tertiary and Cretaceous have been newly synthesized with living termite diversity, including an abundance of "primitive" termites. Most Cretaceous genera are stem groups to either the modern families or as intermediate between groups of families, including one genus as a stem group to all other Isoptera. Mastotermitidae falls relatively basal in the order, among a diversity of fossil taxa. Termopsidae and Hodotermitidae as widely defined were not recovered as monophyletic, with components of these families emerging from a grade of living and fossil termite lineages, leading to Kalotermitidae as closely related to the higher termites (Rhinotermitidae + Termitidae). A relatively tight stratigraphic-clade rank correlation was recovered, with the earliest fossils falling more basal in the order. The phylogenetic patterns have implications for the diversification of termites and their impact on the surrounding environment as they are the most efficient recyclers of carbon and breakdown the most abundant biomolecule – lignocellulose. Although termites arose early, perhaps in the latest Jurassic, and diversified into numerous primitive lineages, they remained a small component of the insect fauna and with apparently minimal environmental influence. Termites only appear to have begun to rise in diversity slowly after the origin of the Rhinotermitidae + Termitidae clade. The analysis indicates that the higher termites, particularly the ubiquitous Termitidae with their enormous, perennial colonies did not truly explosively radiate until the Tertiary and may have altered global patterns of carbon recycling.

Establishment of *Harmonia axyridis* in North America: A case for the enemy release hypothesis?

Ted Cottrell, David Shapiro-Ilan

USDA, Agricultural Research Service, Southeastern Fruit and Tree Nut Research Laboratory, Byron, GA, United States

Introduction: The establishment and quick spread of the exotic coccinellid *Harmonia axyridis* across much of North America has possibly been facilitated through reduced susceptibility to endemic pathogens. Susceptibility of the exotic coccinellid to pathogens was compared with susceptibility of native coccinellids.

Methods: We tested the laboratory susceptibility of endemic and exotic species of North American Coccinellidae to *Beauveria bassiana* derived from different sources and to different species and strains of entomopathogenic nematodes.

Results: Three endemic coccinellid species were susceptible to an isolate of *B. bassiana* originally isolated from one of the native species. However, another endemic coccinellid and the exotic *Harmonia axyridis* were not susceptible to this isolate. Similarly, the exotic *H. axyridis* was less susceptible to nematode infection than native species. Nematode reproductive capacity data also indicated lower host suitability in the exotic *H. axyridis*. **Conclusions:** Overall, our hypothesis was supported, i.e., low susceptibility to pathogens may have contributed to successful establishment and spread of *H. axyridis*.

Allozyme studies on *Helopetis theivora* (Hemiptera: Miridae) from Peninsular Malaysia

Rita Muhamad Awang, Tan Soon Guan, Siti Hajar Latipp

[1]Universiti Putra Malaysia, 43400 UPM Serdang, Selangor, Malaysia, [2]Universiti Putra Malaysia, 43400 UPM Serdang, Selangor, Malaysia, [3]Universiti Putra Malaysia, 43400 UPM Serdang, Selangor, Malaysia

Introduction: *Helopeltis theivora* is known as a pest of cocoa and tea in Malaysia. Polyacrylamide gel electrophoresis (PAGE) was used to determine the metabolic enzymes (25) involved in the development of resistance in *H. theivora*

Methods. Adults of *Helopeltis theivora* were collected from three geographical populations namely Bukit Cheeding, Banting, Selangor, Sg. Palas, Cameron Highlands and MARDI, Cameron Highlands, Pahang.

Results: 9 enzymes were detectable in *H. theivora*: α- and β- esterase (EST), xanthine dehydrogenase (XDH), leucine aminopeptidase (LAP), glutamate oxaloacetate transaminase(GOT), superoxide dismutase (SOD), glucose 6-phosphate dehydrogenase (G6PDH), aldehyde oxidase (ALDOX) and alkaline phosphatase (ALKP). Based on the phenotypes observed for these nine enzymes, alleleic frequencies were obtained which were in turn used to calculate the Nei's (1978) genetic distance coefficients among the three populations. The genetic distance coefficients were then used to cluster the populations by using UPGMA (unweighted pair group method with arithmetic averaging).

Conclusions: Dendogram cluster analysis grouped the Banting, Selangor and MARDI, Cameron Highlands populations together while the Sg. Palas, Cameron Highlands population clustered by itself. This clustering pattern could be due to the frequent spraying of insecticides at Sg. Palas over the past 5 years. For the Banting and MARDI populations, insecticides were not frequently sprayed when compared with the Sg. Palas, Cameron Highlands population. Our insecticide sensitivity studies showed that the Sg. Palas population was more resistant to insecticides than the Banting and MARDI, Cameron Highland populations.

Field performance of transgenic crops: do they frustrate biological control?

Gary Fitt

CSIRO Entomology, Brisbane, Qld, Australia

IPM must be founded on a thorough understanding of the ecology of pest and beneficial species and their interaction with the crop and surrounding non-crop environments. Biological control is often a focal component of IPM in crop production systems, although key pests often escape the control of natural enemies and require other interventions. Transgenic crops targeting key pests, such as Bt cotton, are rapidly emerging as one of those key interventions, particularly control for noctuid pests such as *Helicoverpa* spp.

This emerging era of insect resistant GM crops with potentially high efficacy against target pests has raised concerns among some IPM practitioners about direct or indirect impacts on natural enemies in ways which disrupt the synergy of biological control and partial host plant resistance, often regarded as an ecologically stable approach.

Experience in many parts of the world with Bt cottons, suggest in contrast that these GM crops offer real prospects for more sustainable, economically acceptable IPM with the integration of a range of non-chemical tactics. With the potential for dramatic reductions in pesticide, natural enemies clearly continue as an important component of these systems. Examples from Australia and other systems will be discussed.

Maintaining an appropriate balance and retaining the benefits of Bt cottons requires vigilant resistance management, sustained efforts to enhance beneficial species and non-disruptive, short residual pesticides for key sucking pests. Overall the stability of these systems will require mobilization of the whole farm environment and greater understanding of the flows of impacts and services between intensive cropping systems and the surrounding landscape.

Have Bt crops led to changes in insecticide use patterns and impacted IPM?

Gary Fitt

CSIRO Entomology, Brisbane, Qld, Australia

GM crops have now been commercialised for over ten years and currently over 100 million hectares are grown in 22 countries. By incorporating a powerful pest management tactic within the plant these *Bt* crops overcome some, but not all of the problems with timing and variable rates of application of insecticides, which reduce efficacy and often result in higher than necessary concentrations being applied than is necessary. This paper will present the current evidence for impacts of *Bt* crops, largely *Bt* cotton and *Bt* maize, on insecticide use and will reflect on their role in IPM. Analyses of *Bt* crop performance across a range from large-scale intensive production to smallholder production systems of varying levels of sophistication indicate significant reductions in insecticide input and in some systems, highly significant improvements in yield. However, economic performance is highly variable and seems dependent more on the market characteristics, support structures and culture of the systems in which *Bt* crops are deployed than on the *Bt* crops themselves. Given their specificity for key target pests and well demonstrated lack of impact on beneficial insects, *Bt* crops provide an important new platform for sustainable IPM systems, one that is compatible with a full range of other tactics. However, achieving that IPM outcome will often require ongoing education and extension support for farmers, particularly in smallholder systems, to ensure they can build confidence and gain sustainable benefit from a mix of new and established technologies in pest management.

On a temporal model for the Chikungunya disease: application for vector control

Frédéric Chiroleu[1], Yves Dumont[2], Caroline Domerg[1]

[1]Cirad, Saint-Pierre, Reunion, [2]Université de la Réunion, Saint-Denis, Reunion

Introduction: We propose a compartmental model to study the time course of the Chikungunya outbreak of 2005 in Reunion Island. Our aim is to take into account the effect of larvicide or destruction of breeding sites to control vector population, and estimate the possible influence on the epidemics of 2006.

Methods: We use a SEIR model with host population constant along time and compartments corresponding to the epidemiological states. We add a supplementary compartment for vectors, the larval stage, corresponding to the productivity of breeding sites. We calculate the basic reproduction number, R_0, and a function of R_0, R_C. We present simulations for some cities, considering the great number of micro-climates, and compare them to real data.

Results: R_0 can be written as the product of a host-vector acquisition rate, R_{HV} and a vector-host inoculation rate, R_{VH}. We show that a free disease equilibrium exists that is globally asymptotically stable under a threshold condition on R_C. It means that we can control the epidemics if, at any time, efficient vector control interventions are realised to lower R_C enough.

From the simulations, we explain why no outbreak appeared in 2005: R_{HV} was very small, and so R_0, corresponding, for instance, to a small transmission rate from infectious host.

Conclusion: From our model, and knowing the evolution of some biological parameters, like the transmission rate from an infectious host, we link the episode of 2005 with the big outbreak of 2006. Finally, we show that efficient interventions could have been useful to prevent the epidemic of 2006.

Evidence of a recent outbreak range expansion in winter moth in Fennoscandia

Jane U. Jepsen, Snorre B. Hagen, Rolf A. Ims, Nigel G. Yoccoz

University of Tromsø, Tromsø, Norway

The winter moth, *Operophtera brumata* is one of the most important insect herbivores in sub-arctic birch forest in Fennoscandia. The winter moth experiences cyclic outbreaks in parts of the species' distribution range every 9-10 yrs, with severe impacts on the birch forest ecosystem. Historical records indicate, that winter moth invasion into northern Norway is a recent event (first occurrences in Troms County around 1900). However, throughout the twentieth century the area experiencing regular outbreaks by winter moth (e.g. the species' outbreak range) has been restricted to low-altitude, coast-near forest in W-NW Norway. Through analysis of outbreak records covering more than a century, we document a recent north-eastern expansion of the outbreak range of winter moth, most noticeably occurring during the last two decades. Regular outbreaks now occur at the northern and alpine forest limit in NE Norway overlapping the outbreak range of the autumnal moth (*Epirrita autumnata*). Since population peaks of winter moth tend to lag 1-2 yrs behind those of autumnal moth, an increase in range overlap can be expected to lengthen duration of outbreaks. Satellite monitoring and ground data, obtained during the most recent (2000-2007) outbreak cycle in NE Norway, confirms that this is indeed happening.

Are there patterns in above and belowground insect herbivore interactions?

Katy Clark[1], Scott Johnson[1], Sue Hartley[2]

[1]Scottish Crop Research Institute, Dundee, United Kingdom, [2]University of Sussex, Brighton, United Kingdom

Introduction: An increasing amount of literature over the last decade has focussed on interactions between above and belowground insect herbivores. However, identification of patterns within the data has proved difficult owing to the wide range of both study systems and experimental setup. Meta analyses were conducted to answer questions relating to the effect above and belowground insects have upon one another.

Methods: A literature search was conducted, from which 62 observations in 22 relevant papers were identified. The data collected was used to determine: 1) How do belowground insects respond to aboveground herbivory on a shared host plant? 2) How do aboveground insects respond to belowground herbivory on a shared host plant? 3) How are different above and belowground feeding guilds influenced by herbivory through a shared host plant? and 4) How are different above and belowground orders influenced by herbivory through a shared host plant? Analyses were conducted using insect performance parameters.

Results: Preliminary results indicate that relative growth rate (RGR) and survival of belowground insects are negatively affected by aboveground insect herbivory; however, weight/size gain and abundance are not influenced. Insect herbivores aboveground had a negative impact on belowground root chewing insects, but did not affect belowground insect suckers.

Conclusions: Meta analyses provide useful insights into the overall interactions between above and belowground insect herbivores, however, further research in the field will strengthen the results.

Diapause termination in overwintering larvae of the peach twig borer *Anarsia lineatella* (Lepidoptera: Gelechiidae)

Petros T. Damos, Matilda Savopoulou-Soultani

Aristotle University of Thessaloniki,Faculty of Agriculture,Laboratory of Applied Zoology and Parasitology, Thessaloniki, Greece

The course of diapause development under field conditions for overwintering larvae of *Anarsia lineatella* (Zeller) (Lepidoptera: Gelechiidae) was studied in Northern Greece. For 3 years (2005-2007) hibernacula with overwintering larvae of *A. lineatella* were collected during the winter and early spring from peach orchards of the most important peach production regions of northern Greece (Veria: 40.32^{o}N and Velvendo: 40.16^{o}N). Each hibernaculum was considered as a sampling unit and on the day of sampling, all the collected material was transferred to the laboratory and placed individually in plastic cells at 20^{0}C, under long-day (16:8h L:D) or short-day (8:16h L:D) photoperiods. In all cases photoperiod had a significant influence on diapause development. Duration in days, from transfer from the orchard to the laboratory until first molt and pupation of larvae was significantly affected by sampling date. In addition, photoperiod and sampling date had also a significant effect on the number of molts until pupation and especially on early-collected larvae (mid and late December). In most cases short-day photoperiod maintained diapause for larvae sampled until late January. Thus, *A. lineatella* may complete diapause development in late January, but it will not break diapause until spring, when region specific temperatures are sufficiently high to induce diapause break.

Development and validation of models in forecasting the seasonal emergency and population dynamics of the peach twig borer *Anarsia lineatella* (Lepidoptera: Gelechiidae) in northern Greece

Petros Damos, Matilda Savopoulou-Soultani

Aristotle University of Thessaloniki,Faculty of Agriculture,Laboratory of Applied Zoology and Parasitology, Thessaloniki, Greece

Effective management of the peach twig borer *Anarsia lineatella* (Zeller) (Lepidoptera Gelechiidae) in Northern Greece's IPM orchards, depends mostly on successful timing of biorational insecticide application. The objective of this study was to develop and validate species-specific phenological models that reliably predicted male moth emergence and population dynamics of *A. lineatella* in Northern Greece. Male moths caught in pheromone traps and temperature data were collected over a 4 year period in the two most important peach production regions of northern Greece (Veria lat. 40.32^{o} N and Velvendo lat. 40.16^{o} N). The relationship between the cumulative percentage of males caught in pheromone traps and the relative degree-days was modeled. A 3rd order polynomial equation, a Weibull distribution function and a 3-parameter sigmoid equation were fitted to the data. Field data were compared with developmental and emergence data coming from an *A. lineatella* laboratory strain. Predicted versus observed data were compared and the model performance statistics of root mean square error (*RMSE*) and index of agreement (*d*) were applied in order to validate the models. According to the 3-parameter sigmoid model, approximately 90, 250 and 460 *DD* must be completed, after the first moth caught in early spring, for a 10, 50 and 90% of the overwintering population moth emergence, while for the second flight, approximately 1100, 1300 and 1600 *DD* must be completed, for a 10, 50 and 90% cumulative moth caught, respectively. Degree-day forecasting models significantly improve present strategies of IPM in providing an early prediction of the moth emergence and population course during cultivation season.

Intraguild predation and selection of best species of biological control agents for release

Jacques Brodeur

Université de Montréal, Montreal, Quebec, Canada

Guild interactions occur among species within the same trophic level. Considerable attention has been given to intraguild predation among natural enemies in natural and agricultural ecosystems over the past decade. A common approach in biological control is the use of ecological theory to better interpret the prevalence, nature and outcome of guild interactions and, from a more applied perspective, to implement biological control programs. Of significance, understanding intraguild interactions is important to determine (i) the number and composition of species to release, (ii) the most suitable developmental stages of arthropods to be used, (iii) the timing of multiple releases, and (iv) the impact of biological control agents on non-target species.

Cotton pest management in Argentina

Oscar Antonio Peterlin

INTA, Santiago del Estero, Argentina

In Argentina pest management varies according to cotton production systems. It can be differentiated the pest management between small and large producers, and among crops in semiarid, wet and irrigation conditions. The cotton crops of small producers surrounded by a rich flora and fauna biodiversity in general show less pest problems because the pest population's level does not require insecticide applications. The case for big producers is totally different since the biodiversity of their ecosystems is extremely low because the area used for cultivation is very large. In arid conditions, characteristics that affect the survival chances of predators and micro-hymenoptera, markedly increase pest problems. In conditions of high humidity, the more benign environmental conditions allow greater survival of beneficial fauna, and usually have less pest problems. In the areas of irrigation, the planting dates are very diverse (either early, intermediate, or late cotton crops). This situation increases the proliferation of some pests from early to late crops.

The recommended IPM for cotton crops varies for different situations, but generally it is based on the rotation of crops with soybeans and corn, reducing the crop cycle by using narrow and ultra narrow rows, creating conditions that increase the natural control from beneficial insects, planting cultivars that contains a protein from *Bacillus thuringiensis* (Bt) that protects the cotton plants from specific lepidopteron insect pests and using a systematic monitoring of the presence of pests to establish timely control with insecticides.

New Zealand as a Noah's Ark for British bumblebees

Gillian Lye[1], Roddy Hale[2], Dave Goulson[1]

[1]University of Stirling, Stirling, United Kingdom, [2]Lincoln University, Christchurch, New Zealand

British bumblebees were introduced into the South Island of New Zealand in ~1895 for the pollination of red clover (*Trifolium pratense*). Four British species became established (*Bombus hortorum*, *B. ruderatus, B. terrestris* and *B. subterraneus*) and all four spread rapidly throughout large areas of the South Island. Their success is largely attributed to the availability of several non-native plant species including many that are known to be favoured forage species of these insects within their native range. As a result, the increasing drive towards the eradication of non-native weed species in New Zealand is posing a huge threat to the bumblebees.

Due to their non-native status, there appears to be little concern over the loss of these species from New Zealand. However, these non-native bees are potentially of great importance in terms of conservation. New Zealand has been become a stronghold for *B. ruderatus*, a bumblebee that has suffered severe declines elsewhere, and since the recent extinction of *B. subterraneus* in the UK, the New Zealand population of this species now constitutes the only remaining individuals of British stock in the world. As a result, New Zealand bumblebee populations have been suggested as potential source populations for reintroduction into the UK.

However, this suggestion is based on the assumption that the New Zealand population is ecologically and genetically similar to the original UK population. I will present ecological and genetic data comparing these populations in order to assess the potential of New Zealand bumblebees for use in a reintroduction attempt.

Global distribution patterns of termite (Isoptera) evolutionary feeding groups

David Jones, Paul Eggleton

Natural History Museum, London, United Kingdom

Introduction: Recent molecular phylogenetic studies have revealed repeated acquisition, loss and reacquisition of major feeding habits among termites. Species can now be assigned to one of 40 evolutionary feeding groups (EFG) defined by independent acquisition of feeding habit, rather than using traditional non-taxon-specific feeding groups. Using this new framework, how does the number of species in each EFG vary within and among regions? What is the impact of land-use change on EFG composition within termite assemblages, and the consequences for termite-mediated ecosystem services?

Methods: Termite assemblages were sampled at 110 tropical and subtropical forest sites in five continents. The standardised sampling method gives a representative measure of the species density and composition of the local assemblage. A range of environmental variables were also recorded.

Results: Multivariate analyses show that assemblages in different regions have very different EFG structures, and significant differences in species density. "Region" is the main factor structuring assemblages, whereas ecological factors such as rainfall or altitude account for only a small amount of the variation. However, some EFG, particularly soil-feeders, are very sensitive to land-use change.

Conclusions: The use of EFG uncovers patterns that are not seen when using the traditional feeding groups. The greater resolution offered by EFG reveals distinct trajectories of termite assemblages within each region, and provides new insights into the links between termite cladogenesis, dispersal ability and the ecological constraints of different feeding habits. Furthermore, the loss or reduction of some EFG caused by land-use change will have negative impacts on soil processes.

Use of Google Earth to strengthen public health capacity and facilitate management of vector-borne diseases in resource-poor environments

Saul Lozano-Fuentes[1], Darwin Elizondo-Quiroga[1], Jose Arturo Farfan-Ale[2], Maria Alba Lorono-Pino[2], Julian Garcia-Rejon[2], Salvador Gomez-Carro[3], Victor Lira-Zumbardo[3], Rosario Najera-Vazquez[3], Ildefonso Fernandez-Salas[4], Joaquin Calderon-Martinez[5], Marco Dominguez-Galera[5], Pedro Mis-Avila[5], Michael Coleman[6], Natashia Morris[6], Chester Moore[1], Barry Beaty[1], Lars Eisen[1]

[1]Department of Microbiology, Immunology and Pathology, Colorado State University, Fort Collins, Colorado, United States, [2]Laboratorio de Arbovirologia, Universidad Autónoma de Yucatan, Merida, Yucatan, Mexico, [3]Servicios de Salud de Yucatan, Merida, Yucatan, Mexico, [4]Laboratorio de Entomología Medica, Facultad de Ciencias Biologicas, Universidad Autonoma de Nuevo Leon, San Nicolas de los Garza, Nuevo Leon, Mexico, [5]Servicios Estatales de Salud de Quintana Roo, Chetumal, Quintana Roo, Mexico, [6]Malaria Research Programme, Medical Research Council, Durban, South Africa

Introduction: Novel solutions are needed for improved management of vector-borne diseases in resource-constrained environments. Emerging free software providing access to satellite imagery and simple editing tools (e.g., Google Earth) complement existing Geographic Information System (GIS) software and provide new opportunities to: 1) strengthen public health capacity through development of information for city infrastructure; and 2) display public health and vector data directly on an image of the physical environment.

Methods and Results: We used satellite imagery freely accessible through Google Earth and a set of feature-making tools included in the software (allowing for production of polygons, lines, and points) to generate information for city infrastructure and to display disease data in a Dengue Decision Support System framework. Two cities in Mexico (Chetumal, Merida) were used to demonstrate that a basic representation of city infrastructure useful as a spatial backbone in a Dengue Decision Support System can be developed at minimal cost using Google Earth. Data layers generated included labeled polygons representing city blocks, lines representing streets, and points showing the locations of schools, health clinics etc. City blocks were color-coded to show presence of dengue cases. Google Earth-generated data (KML file format) were successfully imported as shapefiles into a GIS software. Benefits and limitations of using Google Earth are discussed.

Conclusion: The combination of Google Earth and free GIS software (e.g., The HealthMapper, SIGEpi) has tremendous potential to strengthen public health capacity and facilitate Decision Support System approaches to prevention and control of vector-borne diseases in resource- constrained environments.

Spatial modelling of human risk of exposure to vector-borne pathogens based on epidemiological versus arthropod vector data

Rebecca Eisen[1], Lars Eisen[2]

[1]Division of Vector-Borne Infectious Diseases, Centers for Disease Control and Prevention, Fort Collins, Colorado, United States, [2]Department of Microbiology, Immunology and Pathology, Colorado State University, Fort Collins, Colorado, United States

Introduction: Understanding spatial patterns of human risk of exposure to arthropod vectors and their associated pathogens is critical for targeting limited prevention, surveillance, and control resources (e.g., spatial targeting of vaccination, drug administration or education campaigns; use of sentinel sites to monitor vector abundance; identifying areas for most effective use of pesticides). Vector-borne disease risk can in many cases be modeled with high predictive accuracy using Geographic Information System (GIS)-approaches because abundances of vectors and pathogen reservoirs often are associated with environmental factors. Spatial risk models for human exposure to vector-borne pathogens, which ideally should have high accuracy for predicting areas of elevated risk without overestimating risk coverage, can be constructed based on epidemiological data or abundance of vectors or infected vectors.

Methods and Results: We will use four bacterial or viral vector-borne diseases occurring in the United States and with pathogen transmission by fleas (plague), ticks (Lyme disease), or mosquitoes (dengue, West Nile virus disease) to: 1) examine how spatial risk of human exposure to vector-borne pathogens typically is presented to the public health community and public; and 2) evaluate the utility of basing spatial risk models on epidemiological data relative to data for arthropod vectors or infected vectors.

Conclusion: Recommended future directions for vector-borne disease risk modeling in the United States include development of sub-county level spatial risk models combining epidemiological and vector data and use of simulation or analytical models to assess critical vector abundance thresholds required for enzootic pathogen maintenance.

Sex determination in the housefly: Variations on a common theme?

Daniel Bopp, Nicole Meier, Christoph Quinter, Regina Perez, Caroline Henggeler, Monika Hediger

University of Zurich, Zurich, Switzerland

Sexual development is based on a simple binary decision between two alternative developmental programs, male or female. Still, we only have begun to understand the underlying genetic control in a few model systems. In insects, this pathway has been most extensively studied in *Drosophila melanogaster*, and this work has provided deep insights into the molecular mechanisms that specify the sexual fate. However, it appears that an astounding diversity exists at the level of the instructive signal. Alone in the housefly, *Musca domestica*, several types have been described in natural populations, ranging from dominant male or female determiners to maternal cues. Since this spectrum, to a certain extent, reflects the dissimilitude of sex-determining cues described in insects, the *Musca* system appears particularly well suited for studying evolutionary diversification of this pathway. The different mechanisms in *Musca* are considered to have evolved in a relatively short period suggesting that the observed variations are discrete changes in an otherwise well conserved pathway. By identifying the components and their molecular functions in the *Musca* pathway, and by comparing them to those found in other fly species, we were able to define a basic mechanism that operates in most dipteran insects. This conserved core mechanism provides an ideal target for developing effective sexing strategies in programs that use the Sterile Insect Technique to control the spreading of pest fly species of medical and agricultural relevance.

Insecticide and fungal susceptibility of laboratory-reared *Anopheles gambiae* s.s. and *Anopheles arabiensis*

Christophe K. Kikankie[2], Lizette L. Koekemoer[1], Basil D. Brooke[1], Bart Knols[4], Maureen Coetzee[3]

[1]Vector Control Reference Unit, National Institute for Communicable Diseases of the National Health Laboratory Service, Johannesburg, South Africa, [2]School of Animal, Plant and Environmental Science, University of the Witwatersrand, Johannesburg, South Africa, [3]Department of Virology and Communicable Diseases Surveillance, School of Pathology, University of the Witwatersrand, Johannesburg, South Africa, [4]Laboratory of entomology, Plant sciences group, University of Wageningen, Wageningen, Netherlands

Introduction: Control of the main African malaria vectors *Anopheles gambiae sensu lato* and *Anopheles arabiensis* continues to rely heavily on the application of insecticides either by indoor residual house spraying or bednet impregnation. The development of insecticide resistance can undermine theses control strategies. Therefore, alternatives such as vector control with biological agents may be effective. Entomopathogenic fungi are being considered as a biocontrol agents for adult African malaria vectors. We carried out a study to assess the level of susceptibility to fungal infection of insecticide susceptible and resistant colonies of laboratory strains of *Anopheles gambiae* and *Anopheles arabiensis.* The entomopathogenic fungal strain tested was *Beauveria bassiana* under laboratory conditions.

Methods: Insecticide susceptibility tests against all four classes of insecticides recommended by WHO for vector control was performed according to the standard WHO bioassay protocol. Fungal susceptibility tests using hair rollers brushed with dry spores of *Beauveria bassiana* was performed on laboratory reared colonies of *Anopheles gambiae* and *Anopheles arabiensis*.

Results: Our data showed that there is no relationship between insecticide susceptibility and fungal susceptibility. All colonies showed complete susceptibility to fungal exposures despite some of them showing high resistance levels to insecticide.

Conclusions: These results provide hope for alternative control strategies other than use of insecticides. Investigations are underway to determine whether mosquitoes can be killed by fungi within the 14 day period before they become infective.

Biogeography and biology of the New Caledonian Chrysomelidae (Coleoptera)

Pierre Jolivet[1], Krishna K. Verma[2]

[1]Nat. Museum of Nat. Hist., Paris, France, [2]MP. Govt. P. G. Colleges, Borsi, Durg, India

Introduction: Probably 150 to 200 species of Chrysomelidae exist in New Caledonia and around 120 have been recorded and described. The majority of them belong to Eumolpinae. Endemism is extremely high, 10 subfamilies are represented and at least 3 species seem to be the result of vicariance. Eumolpinae seem to be polyphagous in majority, but Spilopyrini, as are many non-eumolpine genera, oligophagous and restricted to some plant families.

Methods: Most of the Chrysomelidae were collected with beating sheets, sweeping nets, Malaise, pitfall and interception traps in the plains and also in the mountains. Their biology has been studied on the spot and in the laboratory.

Results: As in Madagascar, New Caledonian fauna is disharmonious, but being smaller the island is much poorer in genera and species as compared to neighbouring land masses. Some subfamilies, as Sagrinae, Donaciinae and Clytrinae, are missing and Cassidinae are represented only by one species. Donaciinae are represented in Northern Australia, Southern New Guinea and in Indonesia. More subfamilies are missing in New Zealand, but archaic Sagrinae which are so abundant in Australia and, even represented in Madagascar, are missing in New Caledonia and New Zealand. As regards the Spilopyrini, those eumolpines are typically part of an old Gondwanan distribution and the tribe is represented in New Caledonia. Among other chrysomelids, Criocerinae, Cryptocephalinae, Chrysomelinae, some cases of vicariance (*Zira*) could be suspected, but most of the affinities of the fauna are with Australia, Sunda islands, and New Guinea. Passive introductions seemed to have been taking place since the Miocene. Affinities with New Zealand probably in some cases exist, since both archipelagoes are believed to have been linked for a short period in the past. An Eumolpine genus, must diversified in New Caledonia, *Dematochroma*, is spread from Lord Howe and Norfolk islands up to Timor in the north. As usual, quasi-polyphagy or oligophagy is the rule for many genera, but strict monophagy also exists. Development of archaic and Gondwanan Spilopyrini larvae have special features.

Conclusions: Biodiversity is high in New Caledonia, but the fauna is disharmonious, as it seems to include products of both vicariance and dispersal.

Studies on a major vector *Anopheles arabiensis* from Gwave, a malaria endemic area in Zimbabwe

Givemore Munhenga[1], Ron. T. Masendu[1], Basil. D. Brooke[2], Richard. H. Hunt[4], Maureen Coetzee[4], Lizette. L. Koekemoer[2]

[1]Department of Biological Sciences, University of Zimbabwe, P.O. Box MP 167, Mount Pleasant, Harare, Zimbabwe, [2]Vector Control Reference Unit, National Institute for Communicable Diseases, NHLS, Private Bag X4, Sandringham, Johannesburg, South Africa, [3]Division of Virology and Communicable Diseases Surveillance, School of Pathology of the National Health Laboratory Service and the University of the Witwatersrand, Johannesburg, South Africa, [4]School of Animal, Plant and Environmental Sciences, University of the Witwatersrand,, Johannesburg, South Africa

Introduction: A major obstacle that has evolved from malaria control programmes that utilize insecticides for vector control is the development of insecticide resistance. Despite decades of pesticide usage in Zimbabwe limited information on the susceptibility status of major malaria vectors is available. We investigated the susceptibility status and underlying resistance mechanisms in *Anopheles arabiensis* from a malaria endemic area in Zimbabwe.

Methods: Standard WHO bioassays, using 0.75% permethrin, 4% DDT, 5% malathion, 0.1% bendiocarb and 4% dieldrin were performed on wild-collected adult anopheline mosquitoes and F_1 progeny of *An. arabiensis* reared from wild-caught females. Molecular assays were carried out to identify *kdr* mutation. Biochemical assays to determine relative levels of non-specific esterases, monooxygenases, glutathione-S-transferases and presence of an altered acetylcholinesterase (AChE) were performed.

Results: *Anopheles arabiensis* was identified by PCR. Among the *An. arabiensis* females, 0.5% (n = 436) were positive for *Plasmodium falciparum*. WHO diagnostic tests showed 47% mortality on permethrin and 68% mortality on DDT. Insecticide susceptibility tests on F_1 *An. arabiensis* families showed an average mortality of 85.9% (n = 567) after exposure to 4% DDT and 69.8% (n=372) after exposure to 0.75% permethrin. Six families showed resistance to both DDT and permethrin. Biochemical assays of F_1 *An. arabiensis* families revealed comparatively high levels of monooxygenase (48%, n = 33, $p<0.05$), glutathione S-transferase (26%, n = 31, $p<0.05$) and general esterase activity compared to the reference colony. The *kdr* analysis by PCR revealed the presence of the East and West African mutations, but sequencing did not confirm these results.

Conclusions: The detection of permethrin and DDT resistances in *An. arabiensis* populations from Gwave has serious implications for malaria vector control in this area, particularly since Zimbabwe has reverted back to DDT for indoor house spraying. Use of mosaic insecticide application or rotational use of insecticides is recommended.

Signals and cues in the recruitment behavior of stingless bees: An introduction

Friedrich G. Barth

University of Vienna, Wien, Austria

Stingless bees are a large group of eusocial hymenopterans with several hundreds of species. In the tropics they play a role in pollination similar to that of honey bees in temperate regions. Stingless bees show a remarkable diversity of life styles and form colonies which depend on the cooperative activities of many individuals. Much of these activities focus on the acquisition and storage of food.

Since the pioneering work of Lindauer and Kerr (1958) numerous species of stingless bees have been known to effectively recruit nestmates to profitable food sources. In recent years behavioral experiments and research using modern instrumentation succeeded in identifying the properties and the origin of a number of signals and cues used by stingless bees either extra- or intranidally when exploiting food sources. Introducing the Symposium, our present knowledge of chemical (scent trail, food marks), mechanical (jostling, thoracic vibrations) and visual signals and cues, and their actual or potential communicatory significance will be reviewed and discussed. There is abundant evidence for a correlation between signals communicated during recruitment and the quality of the food offered at the food source. So far, however, there is no evidence for a "dance" or a similar behavior indicating that stingless bees can communicate the location of a food source using a "symbolic language".

Synaptic circuits in the medulla neuropile of the *Drosophila* visual system

Ian Meinertzhagen, Lu Zhiyuan, Takemura Shin-ya

Dalhousie University, Halifax, Nova Scotia, Canada

Tracing the pathways for vision beneath the fly's compound eye has stalled for decades at the second neuropile, the medulla, the largest neuropile in the fly's brain. Exploiting its modular composition and previous reports of synaptic circuits in the first neuropile, the lamina, we have used 3D reconstruction methods from serial-section EM to identify cells morphologically with reference to previous reports from Golgi impregnation, or more recent genetic reporters using the Gal4/UAS system.

First, we reconstructed input terminals to the distal medulla from: lamina cells L1-L5, photoreceptors R7 and R8, medulla cell T1, and centrifugal cells C2 and C3. The morphology of these conforms to previous Golgi profiles, offering assurance that our reconstructions are complete.

Next, we identified the medulla cell targets of these input terminals. Three medulla synaptic targets of R7 and R8 probably signal colour information: Dm5 receives input from multiple UV-sensitive R7s; Tm5 and Tm9 receives input from R7 and R8, respectively, with both also receiving input from L3. Inputs to five different medulla cell targets from L1 and L2 segregate these two pathways, which play a crucial role in motion detection. L1 is reciprocally connected to L5 and presynaptic to at least two medulla neurons, while L2 is presynaptic to at least three medulla neurons that are not postsynaptic to L1, two of which form synaptic contacts in turn with L4. The L1 and L2 terminals are connected only by C2 and C3, which are possibly required to switch activity between these two motion-sensitive L-cell pathways.

Effects of mycorrhizal fungi on insect herbivores: a meta-analysis

Julia Koricheva, Alan Gange

Royal Holloway University of London, Egham, Surrey, United Kingdom

Insect herbivores and mycorrhizlal fungi are indirectly linked through their common host plant. Moreover, mycorrhizal presence has a wide range of morphological and physiological effects on plants that may change their quality as a food for herbivores. One might therefore hypothesize that insects may be affected by the plant mycorrhizal status. To test this hypothesis, we conducted a meta-analysis of 34 published and unpublished experiments that have examined effects of mycorrhizal colonization of the host plant on performance and density of insect herbivores as well as on the degree of plant damage. Density and consumption of chewing insects were higher on mycorrhizal plants, but this did not lead to higher plant damage presumably because herbivore survival tended to be lower on mycorrhizal plants. Mono- and oligophagous chewers benefited from mycorrhizal colonization of their host plants whereas performance of polyphagous herbivores tended to be reduced on mycorrhizal plants. Among sucking insects, phloem feeders benefited from mycorrhizal infection whereas performance of mesophyll and meristem feeders was lower on mycorrhizal plants. Type of mycorrhizae had no effect on chewing insects, but performance of sucking insects was increased more by arbuscular mycorrhiza (AM) than by ectomycorrhiza. We have concluded therefore that plant mycorrhizal colonization has a significant effect on herbivore performance, but the direction and magnitude of this effect depends on the type of herbivore and type of fungi. Plant mycorrhizal status, therefore, have to be taken into account in studies examining variation in herbivores performance between plants in the field.

Fungus pathogenicity, establishment of bark beetle populations and tree death

Francois Lieutier

Universite d'Orleans, Orleans, France

Since tree death seems necessary for their population establishment, tree killing bark beetles should be associated with highly phytopathogenic fungi. However, when compared to classical fungal pests, bark beetle associated fungi need a high density of inoculations to kill trees, and are thus moderately phytopathogenic. The explanation may be that a highly pathogenic fungus would kill and invade the tree very rapidly, making its tissues unsuitable for beetle brood development. With that strategy, a relationship between fungus pathogenicity and beetle aggressiveness should exist among bark beetle fungi. But it does not. Rather than fungus ability to kill trees, what is important for bark beetle populations in their fungal associations is fungi ability to stimulate tree reactions to aggressions, resulting in lowering the critical threshold of attack density above which beetle attacks succeed. Fungus ability to induce extensive tree reactions appears a better parameter of the efficiency of the association than the critical threshold of inoculation density. However, during natural attacks, beetles do not all vector fungi, and the number of fungal spores in each beetle certainly plays a role, making hazardous the evaluation of reaction stimulation through artificial inoculations. It can be accepted that the above strategy is really operating, and that it works through the ability of the fungus to stimulate tree reactions to aggressions. It is suggested however that the efficiency of the association for beetle population establishment results from three components: the fungus intrinsic ability to stimulate tree defenses, the percentage of contaminated beetles, and the inoculum level on each beetle.

Directed aerial descent in tropical canopy arthropods

Steve Yanoviak

University of Arkansas at Little Rock, Little Rock, Arkansas, United States

Worker ants in seven tropical genera use directed aerial descent to return to their home tree trunk during a fall. Field experiments focusing on the common Neotropical species *Cephalotes atratus* showed that the behavior is not accidental or location-specific, and that performance is partly a function of body size. Falling ants use visual cues to locate tree trunks, and the behavior is strongly influenced by reflectance properties of potential landing substrates. Ablation experiments and high-speed video recordings of falling ants suggest that the hind legs have the greatest influence on aerodynamic stability and control. Ongoing surveys show that the behavior occurs in a broad range of wingless arboreal arthropods, including basal hexapods.

Close-range host searching behaviour of the stemborer parasitoid *Dentichasmias busseolae*: Role of a non-host plant *Melinis minutiflora*

Linnet S. Gohole, William A. Overholt, Louise E.M. Vet, Zeyaur R. Khan

[1]Moi University, Eldoret, Kenya, [2]University of Florida, Florida, United States, [3]Netherlands Institute of Ecology (NIOO-KNAW), Maarsen, Netherlands, [4]International Centre of Insect Physiology & Ecology (ICIPE), Nairobi, Kenya

Introduction: Studies were conducted on the host searching behaviour of the pupal parasitoid *Dentichasmias busseolae* Heinrich (Hymenoptera: Ichneumonidae), which attacks the cereal stemborer *Chilo partellus* (Swinhoe) (Lepidoptera: Crambidae). The aim of the present study was to investigate how molasses grass influences parasitoid close-range foraging behaviour in a diversified habitat.

Methods: The behaviour of individual gravid parasitoids was observed in a semi-field environment of a diversified habitat that consisted of stemborer host plants (maize, *Zea mays* L. and sorghum, *Sorghum bicolour* (L). Moench (Poaceae)) and a non-host plant (molasses grass, *Melinis minutiflora* Beauv. (Poaceae)). Observations of its behaviour and location were recorded for 30 minutes using the computer software package, The Observer.

Results: *Dentichasmias busseolae* strongly discriminated between host and non-host plants with female wasps spending most time on infested host plants and least time on molasses grass. On the infested plant, the wasps spent more time foraging on the stem, the site of damage than other areas of the plant.

Conclusion: The results indicate that presence of the non-host plant does not hinder close range foraging activities of the parasitoid species.

Univoltinity in the winter aggregator *Encosternum delegorguei* (Hemiptera: Tessaratomidae) in relation to abdominal fat, food plants and predation

Cathy Dzerefos[1], Rob Toms[2], Edward Witkowski[1]

[1]University of the Witwatersrand, Johannesburg, South Africa, [2]Transvaal Museum, Pretoria, South Africa

Introduction: *Encosternum delegorguei* is an edible stinkbug eaten with delight each year by people in north-eastern South Africa and southern Zimbabwe. To ensure long-term sustainable harvesting of this insect, a better understanding of its life history and other aspects pertaining to survival are necessary.

Method: Outdoor insectaries were built to observe daily activity, commencement of copulation, oviposition behaviour and egg incubation from May 2006 to February 2007. Field observations under natural conditions were also undertaken. Abdominal dissections on six adults per month were done and fat content categorised from May to December.

Results: Dissections showed that abdominal fat content is highest in June at the onset of diapause. From September *E. delegorguei* commenced feeding on *Combretum imberbe, Combretum molle, Peltophorum africanum, Pennisetum clandestinum, Phaseolus vulgaris* and to a lesser degree *Dodonaea viscosa.* From late October to end of December 1 752 eggs were laid by 103 females. The mean number of eggs in 64 egg clutches was 27.38±13.91 (range of 2 to 56 eggs). The incubation time averaged 18.65±8.95 days (range of 7 to 37 days). Shade cloth (68.8%) was the most commonly used substrate for depositing eggs followed by *P. clandestinum* (12.5%), *C. imberbe* (7.8%), *P. africanum* (6.3%), *D. viscosa* (1.6%), *C. molle* (1.6%) and *Combretum erythrophyllum* (1.6%). The parasitoid wasp, *Anastatus* sp. (Family: Eupelimidae) infected 68.8% of the egg clutches deposited by captive females.

Conclusions: During winter *E. delegorguei* is in diapause in misty mountainous areas where it is secluded from cold winds but is able to imbibe condensed water. This first record of an egg parasitoid, *Anastatus* sp. suggests break up of winter aggregation at the landscape level may be essential to minimise infection and could be a factor causing sporadic harvests. Controlled laboratory conditions where humidity in particular can be controlled and parasitoids excluded are recommended for domestication.

Physiological mechanisms underpinning the rapid cold-hardening response

Richard Lee, Shu-Xia Yi

Miami University, Oxford, Ohio, United States

The rapid cold-hardening (RCH) response refers to a swift acclimatory process by which insects enhance their cold tolerance following brief exposure to moderate chilling. Recently, we obtained strong evidence that RCH occurs under ecologically relevant cooling rates and diurnal thermoperiods. Not only does this widespread response protect against chilling injury but it also preserves locomotor, courtship and mating performance during environmental cooling. During the past few years we have begun to unravel clues to the physiological mechanisms underpinning this response. The cell membrane is generally believed to be the primary site of chilling injury caused, in part, by thermotropic phase changes. During RCH levels of unsaturated phospholipid fatty acids increase in the cell membrane as does membrane fluidity, which should function to decrease thermotrophic membrane damage. In vitro studies revealed that isolated cells of several tissues can respond directly to cold (i.e. cold sensing) and undergo RCH, indicating that neuroendocrine mediation is not required. Further studies indicate that calcium is required in the signaling pathway leading to the RCH response; removal of calcium or blocking with an intracellular chelator diminishes cryoprotection by RCH. Cold shock induces apoptosis or programmed cell death. Presumably cold causes mitochondrial release of cytochrome *c* into the cytoplasm that triggers the apoptotic pathway. RCH blocks cold-induced apoptosis by up-regulating the anti-apoptotic protein Bcl-2 and inhibiting the activation of caspases. Supported by NSF grant IOB-0416720.

Bridging theory and practice: the role of service-learning in bringing entomology to the public

Marianne Robinette, Ray Noblet

University of Georgia, Athens, Georgia, United States

Introduction: Service-learning and study abroad opportunities are critical components of undergraduate education that create an environment of active academic engagement while bringing entomology to the public. Mutually beneficial and sustainable projects with community partners allow students to solve real-world problems through first-hand experience.

Methods: Integrating service-learning into the entomology curriculum at UGA provides students the opportunity to participate in developing and implementing entomological programs for the community both domestically and internationally.

Results: *Entomology Outreach & Service-Learning* is a course where students participate in developing entomological educational outreach programs. Examples of current service-learning projects include building an Apiary as well as an Outdoor Classroom at Classic City High School in Athens, GA. The apiary is used as a concept learning tool for biology, environmental stewardship, sustainable agriculture, entrepreneurship, economics and business classes. Honey is collected and sold to the community for school fundraisers and for sustaining the bee colonies. The Outdoor Classroom is an interdisciplinary service-learning project addressing the need for an innovative space for teaching and learning in all subject areas at the high school. *Insect Natural History in Costa Rica* is a course designed for students to enhance their global awareness of environmental and cultural issues through the use of insects as teaching tools, coupled with structured entomological public outreach experiences. While abroad, students build insect collections, conduct research-based field studies, and participate in entomological outreach activities at Costa Rican elementary schools.

Conclusions: Collectively these service-learning and study abroad opportunities have enabled our students to connect insect science with the public.

Insect resistant transgenic crops: An opportunity for biological control?

Franz Bigler[1], Joerg Romeis[2], Roy G. van Driesche[3], Barbara I.P. Barratt[4]

[1]Agrsocope Reckenholz-Taenikon Research Station ART, Zurich, Switzerland, [2]Agroscope Reckenholz-Taenikon Research Station ART, Zurich, Switzerland, [3]University of Massachusetts, Amherst, United States, [4]AgResearch Invermay, Mosgiel, New Zealand

Plant resistance to insects has played a major role in integrated pest management (IPM) since long, and its compatibility with biological control is principally not questioned. Natural enemies such as parasitic wasps and predators fulfil an important ecological and economic function by reducing herbivore populations and thus, they contribute to sustainable IPM systems. It is well established that plant resistance factors that affect herbivores also interact with natural enemies and consequently with the biological control function they provide. Similarly, host plant resistance derived from genetic engineering will have an impact on biological control. There is evidence today that the currently available transgenic crops that express Cry proteins derived from *Bacillus thuringiensis* (*Bt*) have no direct effects on natural enemies due to their narrow spectrum of activity. However, the fact that the target pests are efficiently controlled by the deployed *Bt* crops has inevitable consequences for natural enemies that specialize on these species as hosts or prey. Landscape level effects may occur for specialists if adoption of *Bt* crops provide area-wide reductions of target pest populations. On the other hand, it has become clear that in crop systems where the deployment of *Bt* varieties has lead to a decline in insecticide use, biological control organisms have benefited significantly. Consequently, in systems where *Bt* crops replace insecticides, this technology can contribute to natural enemy conservation and thus be a useful tool in IPM.

Understanding distribution patterns of invertebrates within inland drift sand areas using life-history tactics and feeding guilds

Marijn Nijssen[2], Hans Esselink[1], Marten Geertsma[2], Toos Van Noordwijk[2], Henk Siepel[3]

[1]Radboud University Nijmegen, Nijmegen, Netherlands, [2]Bargerveen Foundation, Nijmegen, Netherlands, [3]Centre for Ecosystem Studies Alterra, Wageningen, Netherlands

Introduction: European inland drift sands and their characteristic flora and fauna species are highly endangered. Understanding of mechanisms shaping species distribution patterns within these systems is necessary to develop restoration and conservation measures. To unravel the relative importance of different environmental variables life-history tactics and feeding guilds are used.

Methods: Invertebrates were sampled in 8 inland drift sand areas in The Netherlands using extraction of soil samples and pitfall traps. Sampling took place in 5 successive vegetation types which differ in aeolian dynamics, microclimate and food resources. Species specific traits on development, reproduction, synchronisation and dispersal were used to define life-history tactics for mites (Acari), springtails (Collembola), ants (Formicidae) and carabid beetles (Carabidae). Distribution patterns were analysed using multivariate methods.

Results: Within all study areas, similar distribution patterns of species and life history tactics were found. Life-history traits explaining most variance in distribution patterns for all studied invertebrate groups were timing of reproduction and diapause, high dispersal capability and speed of larval development. These traits were highly correlated with differences in aeolian dynamics. Herbivorous browsers dominated in early succession stages, while in older succession stages feeding guilds were equally distributed, implicating an increasing bottom-up regulation from food resources.

Conclusions: Use of life-history tactics and feeding guilds proofs to be a strong tool in analysing mechanisms of species distribution, facilitating comparison of different areas and different invertebrate taxonomic groups. Management should focus on aeolian dynamics in a gradient to stable vegetation for restoration and conservation of complete fauna communities.

Using EPG to compare acceptance by the spittle bug *Carystoterpa fingens* of four plant species

Manoharie Sandanayaka

The Horticulture and Food Research Institute of New Zealand Limited (HortResearch), Auckland, New Zealand

New Zealand is currently free of both *Xylella fastidiosa* (a bacterium that causes several diseases of agricultural, horticultural and ornamental plants) and its vector, glassy-winged sharpshooter (GWSS). Nevertheless, it remains vulnerable to invasion by both organisms. *Citrus sinensis*, *Coprosma repens, Hydrangea peniculata* and *Vitis vinifera* (grape), are four of many species in New Zealand known to be hosts of both GWSS and *X. fastidiosa*. The electrical penetration graph (EPG-DC) technique was used to compare their acceptance as food by the endemic spittle bug *Carystoterpa fingens*; one of the several xylem feeders may potentially act as a conduit for *X. fastidiosa* into native host plants. EPG waveforms representing main stylet penetration activities [pathway, xylem ingestion, resting, and non-probing phases] of 54 adults were recorded for 12 hours per insect. The durations and the number of events were analysed to compare host acceptance. The total probing times on grape were not significantly different from citrus but were longer than on hydrangea and coprosma. Non-probing times were longest on coprosma. The longest periods of xylem ingestion (total duration and the longest event) were recorded on grape and the shortest on coprosma. The shortest durations of pathway were recorded on grape. Citrus and hydrangea were intermediate and not significantly different from one another. The number of xylem ingestion events on citrus was significantly higher than grape, coprosma and hydrangea. It was concluded that grape was the best host, citrus and hydrangea were accepted and coprosma was the least accepted.

Controlling larval chironomids (Diptera: Chironomidae) in Australian rice crops using a commercial formulation of *Bacillus thuringiensis* var. *israelensis*

Mark Stevens, Glen Warren

E H Graham Centre for Agricultural Innovation (NSW Department of Primary Industries and Charles Sturt University), Yanco Agricultural Institute, Yanco NSW, Australia

Introduction: Some larval Chironomidae attack the roots of rice seedlings, and in Australia populations dominated by *Chironomus tepperi* Skuse can cause over 80% seedling loss if not controlled. We evaluated spray applications of Vectobac® WDG, a commercial formulation of *Bacillus thuringiensis* var. *israelensis*, as a potential control option.

Methods: Vectobac® WDG was evaluated in 2 replicated small-plot field trials at rates between 0.5 and 6 kg/ha. Larvae were sampled and extracted using soil coring and magnesium sulphate flotation. Samples were taken at 5 day intervals from 4 to 19 days after treatment. Larvae were divided into target (Chironominae / Orthocladiinae) and non-target (Tanypodinae) groups. Target group larvae recovered from selected treatments at 4, 9 and 14 days after Vectobac® WDG application were identified to species level. Seedling density was also assessed.

Results: Target group suppression was significant ($P < 0.05$) at all rates 4 days after application, and ranged from 39 to 92% over the full 19 days. Complete control of *C.tepperi* was achieved at rates over 1.25 kg/ha. Vectobac® WDG had no noticeable effect on non-target Tanypodinae. In the first trial plant establishment was significantly ($P < 0.05$) enhanced at all rates, however in the second trial no significant differences were found, presumably due to lower pretreatment larval densities.

Conclusions: Vectobac® WDG has the potential to provide highly selective control of pestiferous chironomids in rice. The optimal rate for Australian rice crops is approximately 1.5 kg/ha.

The effect of the entomopathogenic fungi *Beauveria bassiana* and *Metarhizium anisopliae* against the major malaria vector *Anopheles funestus* Giles

Joel C. Mouatcho[1,2], Basil D. Brooke[1,3], Bart Knols[4], Maureen Coetzee[1,3]

[1]National Institute for Communicable Diseases, Sandringham/Johannesburg, South Africa, [2]School of Animal Plan and Environmental Sciences, University of the Witwatersrand, Johannesburg, South Africa, [3]Division of Virology and Communicable Disease Surveillance, School of Pathology of the National Health Laboratory Service and the University of the Witwatersrand, Johannesburg, South Africa, [4]University of Wageningen, Wageningen, Netherlands

Introduction: The increase of malaria cases due to insecticide resistance in some malaria vectors as well as the impact of pesticides on the environment and non-target insects and animals has provided an impetus for the development of alternative forms of vector control using entomopathogenic fungi. We investigated the potential of *Beauveria bassiana* and *Metarhizium anisopliae* against laboratory strains of the major malaria vector *An. funestus.* We also determined the level of infectivity between a pyrethroid resistant (FUMOZ-R) and susceptible strain (FANG) of colonised *An. funestus.*

Methods: Mosquitoes were exposed to dry fungal conidia for 24 hours using World Health Organization exposure tubes. Mortality was recorded daily after exposure. Sporulation was checked on cadavers 2 days post mortality. Data were analysed using *Statistix7 Software.*

Results: *Beauveria bassiana* was found to be effective in killing *An. funestus* with mortalities ranging from 90%-100% after 15 days. A comparison of FUMOZ-R and FANG treated with conidia showed the pyrethroid resistant FUMOZ-R to be more susceptible to fungal exposure than the susceptible strain FANG. Conidia of *B. bassiana* produced 100% mortality in FUMOR-R and FANG within 15 and 22 days respectively while, less than 10% mortality occurred in corresponding unexposed controls. For *M. anisopliae* treatment, mortality rates were higher in FANG than in FUMOZ-R with 100% mortality obtained within 14-17 days for FANG as compared to >20 days for FUMOZ-R. An average of 90% fungal infected mosquitoes sporulated between 2-4 days after death.

Conclusions: *Beauveria bassiana* and *Metarhizium anisopliae* can be used as an alternative mode of vector control. The presence or absence of insecticide resistance is not likely to affect susceptibility to fungal infection in *An. funestus.*

The behavioural ecology of *Ciulfina* praying mantids

James O'Hanlon, Greg I. Holwell, Mariella E. Herberstein

Department of Biological Sciences, Macquarie University, North Ryde, NSW, Australia

Previous research into the ecology of praying mantids has investigated in great detail the population characteristics of particular species and their role as generalist predators that can have significant effects on arthropod community structure. The great majority of this research however has concentrated on a small number of temperate, northern hemisphere mantids occupying similar habitats with similar life history strategies. Understandably this is not representative of the diversity exhibited in the 2300 or so species of mantids found world wide. Tree running mantids of the genus *Ciulfina* differ from those previously studied in many ways including their population structure, habitat type, geographical distribution and evolutionary history. This presentation investigates the behavioural ecology of *Ciulfina* mantids and addresses their population characteristics, intraspecific interactions and mating behaviour.

Natural refugia using alternate hosts of the Asian corn borer (*Ostrinia furnacalis*) for insect resistance management of Bt corn in the Philippines: Possible strategies in tropical setting

Merdelyn Lit

UP Los Baños, College, Laguna, Philippines

Insect resistance management (IRM) is one of the basic requirements for a successful Bt corn production in a country. This is based on the premise that insect pests generally become resistant to high selection pressure such as the use of Bt corn. It is even more complicated if the premise considers the geographical location and corn production systems of the area.

IRM, however, in the tropical sense is governed by two important undelying factors: 1) the tropical corn growing conditions and 2) the tropical feature of the Asian corn borer, *Ostrinia furnacalis* (Guenee). How these two important components interrelate with each other is the basic framework for a sound and ecological insect resistance management in the tropics. Furthermore, for an effective IRM, basic studies on the Asian corn borer must be in place.

This paper will present the basic requirements for IRM to work in a tropical setting highlighting the important role of alternate hosts as natural refuge for susceptible ACB. Some previous and on-going studies will also be presented. It will review the important role of the different alternate weed and crop hosts of ACB in three cropping systems of the country and discuss possible strategies of unstructured or natural refugia in Bt corn IRM in our tropical setting.

These strategies are founded on the above basic requirements and will eventually gain a total advantage if we put nature and biodiversity in the over-all framework.

Wolbachia, bacteriophage WO superinfection and genetic diversity in the uzifly *Exorista sorbillans* (Diptera: Tachinidae)

Puttaraju Hosagavi Puttegowda, Guruprasad Nadipinayakanahalli Munikrishnappa

Department of Sericulture and Lifesciences, Bangalore University, Bangalore, Karnataka, India

Wolbachia pipientis is a maternally transmitted bacterium that often alters the life history of its hosts to maximize transmission to subsequent generations. The various alterations induced by *Wolbachia* are cytoplasmic incompatibility, parthenogenesis, sex ratio distortion, male killing, and feminization. Earlier studies have established that the Uzifly *Exorista sorbillans* a tachinid endoparasite of silkworm *Bombyx mori* harbour A and B *Wolbachia* supergroup. In the present study we detected infection frequency of *Wolbachia* and bacteriophage WO superinfection and their effects on the diversity of Uzifly collected from different geo climatic regions of India. The molecular profiling of infected populations was done by using the Randomly Amplified Polymorphic DNA (RAPD). The dendrogram constructed from un-weighted pair grouped method with arithmetic mean (UPGMA) and distance computed using Euclidean distance clearly estimated the genetic diversity between different populations of *E. sorbillans.* The genetic divergence observed could be the result of the geographic isolation among populations, but it could also be explained by the infection with the rickettsial bacteria *Wolbachia* pipientis and bacteriophage WO It is suggested that the interaction between cytoplasmic incompatibility (CI) inducing *Wolbachia* and its bacteriophage WO of Uzifly perhaps promoting the genetic diversity and speciation in the Uzifly, *E. sorbillans*

Are nitrogen driven changes in host plant quality responsible for the decline of butterfly species in NW-Europe?

Marijn Nijssen[2], Frits Bink[3], Arnold van den Burg[2], Gert-Jan van Duinen[2], Hans Esselink[1], Chris Van Swaay[4], Michiel Wallis de Vries[4], Henk Siepel[3]

[1]Radboud University Nijmegen, Nijmegen, Netherlands, [2]Bargerveen Foundation, Nijmegen, Netherlands, [3]Centre for Ecosystem Studies Alterra, Wageningen, Netherlands, [4]Dutch Butterfly Conservation, Wageningen, Netherlands

Introduction: Many butterfly species in NW-Europe show a strong decline while their host plants are still abundant. This is especially true for species of nutrient poor habitat types such as bog and heathland. There are several indications that changes in quality of host plants due to increased nitrogen deposition might be an important reason for this decline. Changes in host plant quality can be caused directly by increased availability of nitrogen or indirectly by decreased availability of minerals as a result of acidification. This causes imbalances between nitrogen content of the host plant in relationship to levels of minerals, essential vitamins and amino acids. These imbalances can have significant effects on development, survival and reproduction success of butterflies.

Methods: Pilot field studies were carried out for 7 butterfly species. Host plant quality and soil chemistry were analysed from field sites differing in nitrogen deposition level.

Results: Studies showed several nutritional imbalances for micronutrients correlated with soil nitrogen content, including lack of Ni which may cause ureum toxification in caterpillars. Imbalances were found in different host plant types, such as grasses, heather and oak. Feeding experiments for *Hiparchia* species (Lepidoptera: Satyrinae) on grass species *Corynephorus canescens* are now running to analyse the effects of nutritional imbalances on larval development, pupation and adult reproduction.

Conclusions: Host plant quality can change significantly due to nitrogen enrichment, though mechanisms behind these changes are yet unclear. Feeding experiments will be necessary to elucidate actual risks of nutritional imbalances to endangered butterflies.

Learning to escape robotic spiders: predator avoidance learning in bumblebees

Thomas Ings, Lars Chittka

Queen Mary, University of London, London, United Kingdom

Introduction: Learning is expected to be potentially more important in predator avoidance than foraging because a single mistake can be fatal. However, few, if any, attempts have been made to measure the dynamics of predator avoidance learning in a natural context. We therefore quantify predator avoidance learning of nectar foraging bumblebees using a novel, semi-natural, foraging paradigm.

Methods: We presented bees with an artificial meadow containing 16 remotely controlled flowers that could simulate a predation attempt by a crab spider by capturing bees as they fed. Avoidance learning and memory dynamics were measured for bees encountering dangerous flowers with either visible or camouflaged spider models. In addition, flight behaviour was quantified using 3D tracking software.

Results: All bees learnt to avoid dangerous flowers well, irrespective of the visibility of the crab spider models. Bees learnt to avoid visible spiders slightly better than camouflaged spiders, although the speed of learning did not differ. For both spider visibility treatments bees continued to avoid dangerous flowers without significant loss in performance over both middle (minutes) and long time scales (24 hours). The presence of camouflaged spiders on dangerous flowers led to subtle changes in flight behaviour: when rejecting flowers, bees flew slower and spent longer inspecting dangerous flowers than safe flowers.

Conclusions: Bumblebees are readily able to learn to avoid simulated predation attempts at flowers. When predators are difficult to detect they appear to compensate by slowing down inspection flights enabling them to maintain high levels of accuracy.

Phylogenetic relationships among Alysiini (Hymenoptera: Braconidae: Alysiinae); utilizing 28S, 16S, COI and ND1 markers.

Salmah Yaakop[1], Cornelis van Achterberg[1], Bin Abd. Ghani Idris[2]

[1]National Museum of Natural History, NATURALIS, Leiden, Netherlands, [2]Universiti Kebangsaan Malaysia, Bangi, Selangor, Malaysia

Introduction: Information on generic relationships among Alysiinae: Alysiini based on morphological and molecular data is very poor. It is important to answer several related questions, i.e the relationships among genera, genus groups and phylogenetic status in Opiinae in relation to Alysiinae is supposed to be the sister-group of Alysiinae (both are endoparasitoids of cyclorraphous Diptera). The monophyly or paraphyly of Alysiinae/Opiinae is still under debate.

Methods: Sequences of Dacnusini and Opiinae are included in the phylogenetic analysis as well as Exothecinae (*Colastes* sp.) and Gnamptodontinae (*Gnamptodon* sp.) the latter to do grouping the outgroups. Samples of Alysiinae have been taken from fresh and dried museum specimens for PCR and sequencing. For the phylogenetic analysis PAUP 4.0 and MRBAYES 3.0B4 have been used.

Results: According to the preliminary results from the combined trees (28S + 16S) five well defined groups in Alysiini (*Phaenocarpa*, *Asobara*, *Alysia, Cratospila* and *Aspilota*-group) are found and the results agree with the morphology and biology. *Alysia*-group (mining Diptera and rotting organic material) + tribe Dacnusini (mining larvae) are found to be the basal groups, followed by *Heterolexis* sp. (*Dapsilarthra* group, mining larvae) - *Neurolarthra* sp. (aberrant group, biology: unknown) - *Aspilota*-group (parasitoids of Phoridae), while *Cratospila*-group (biology: unknown), *Asobara*-group (fruits-infesting larvae and rotting organic material) and *Phaenocarpa*-group (attacking larvae in galls, fruits, rotting organic material and less also mining larvae) as the more derived groups in Alysiinae. Both protein-coding genes (COI and ND1) are found not to be very useful to resolve genus relationships in Alysiinae, but good for species groups in Alysiini.

Conclusions: Relationships in Alysiini has been largely resolved, but some nodes with moderate support. The results of the molecular analyses are more or less comparable with morphology and biology.

New challenges facing regulatory agencies and advances in technology, communication, and research to support these challenges

Terrence Walters

USDA-APHIS-PPQ-CPHST, Fort Collins, Colorado, United States

As globalization increases, the biodiversity of potential pests arriving at our borders are and will continue to increase. Today, regulatory personnel struggle to have the taxonomic knowledge, background, and just basic information on potential pests to support their required decision-making. The magnitude, the required breadth of taxonomic knowledge, and reference collections of specimens and images required for the biodiversity of potential pests that might enter our country can be rather overwhelming for our agencies. As trade products continue to diversify and as the number of trading partners continue to increase, regulatory agencies have to depend more and more on outside sources for up-to-date pest taxonomic, identification, and diagnostic information.

Regulatory agencies are now depending more and more on their trading partners and global databases for taxonomic and identification resources and information on potential pests arriving at ports. The world-wide-web is now allowing us an amazing opportunity to share our knowledge with our trading partners, as well as to access pest information from our trading partners and others from throughout the globe.

Our decision process on whether a pest is actionable or non-actionable depends heavily on the biology and taxonomic research communities, both nationally and internationally, and our collaboration with and support for them. Regulatory agencies are and will continue to require reporting from these communities to support the ever changing and evolving plant protection and quarantine environment. We are fortunate in that these communities are now re-inventing themselves to share their findings and results with the public using the latest in technologies and methods of communication.

Aboveground-belowground interactions: state of the art and current and future challenges

Martijn Bezemer[1], Jeff Harvey[2]

[1]Laboratory of Nematology, Wageningen University, Wageningen, Netherlands, [2]Department of Multitrophic Interactions, Netherlands Institute of Ecology, Wageningen, Netherlands

Studies exploring interactions between insects and plants over several trophic levels have traditionally focused on aboveground communities. However, ecologists are becoming increasingly aware that plants and insects are part of a complex multitrophic aboveground and belowground environment in which they closely interact.

We will provide an overview of recent developments in the field of above-belowground interactions and will highlight challenges that are currently being addressed. Using examples from a range of studies we will summarize (i) evidence for linkages between aboveground and belowground herbivorous insects and other soil dwelling organisms via a shared host plant, (ii) mechanisms that have been proposed to explain these interactions, (iii) how interactions between above- and belowground organisms can influence parasitoids and predators, and (iv) whether there is evidence for linkages between above- belowground multitrophic communities under natural conditions in the field.

A population perspective on plant-pollinator interactions

Steven Johnson

University of KwaZulu-Natal, Pietermaritzburg, South Africa

The Allee effect (reduced reproductive success in small populations) has been reported for several plant species. One possible explanation for this phenomenon is reduced attractiveness of small populations to pollinators. This is supported by evidence showing a greater degree of pollen limitation in small plant populations. Ecological Allee effects caused by pollen/pollinator limitation are an issue of concern for management of rare and endangered plant populations. On the other end of the scale are invasive plants that appear to be highly resistant to Allee effects. Surveys also show that invasive plants are often capable of self-fertilization. This is consistent with Baker's Law, but it is not yet known whether self-fertilization in colonizing plant species is important because obviates the need for pollinators or because of the shortage of mating partners during early stages of population establishment. In general, there is increasing evidence that pollination processes can impact on plant population dynamics.

The present and future role of insect-resistant genetically modified maize in IPM

Richard L. Hellmich[1], Ramon Albajes[2], David Bergvinson[3], Jarrad R. Prasifka[1], Zhen-Ying Wang[4], Michael J. Weiss[1]

[1]USDA-Agricultural Research Service, Corn Insects & Crop Genetics Research Unit and Department of Entomology, Iowa State University, Ames, Iowa, United States, [2]University of Lleida, Lleida, Catalonia, Spain, [3]Bill & Melinda Gates Foundation, Seattle, Washington, United States, [4]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, Beijing, China, [5]Golden Harvest Seeds, Pine River, Wisconsin, United States

Commercial, genetically-modified (GM) maize was first planted in the United States (USA, 1996) and Canada (1997) but now is grown in 13 countries on a total of over 25 million hectares (>17% of area worldwide). The first GM maize plants produced a Cry protein derived from the soil bacterium *Bacillus thuringiensis* (*Bt*), which made them resistant to European corn borer and other lepidopteran maize pests. New GM maize hybrids not only have resistance to lepidopteran pests but some have resistance to coleopteran pests and tolerance to specific herbicides. Growers are attracted to the *Bt* maize hybrids for their convenience and because of yield protection, reduced need for chemical insecticides, and improved grain quality. Yet, most growers worldwide still rely on traditional integrated pest management (IPM) methods to control maize pests. They must weigh the appeal of buying insect protection "in the bag" against questions regarding economics, environmental safety, and insect resistance management (IRM). Traditional management of maize insects and the opportunities and challenges presented by GM maize are considered as they relate to current and future insect-resistant products. Four countries, two that currently have commercialize *Bt* maize (USA and Spain) and two that do not (China and Kenya), are highlighted. As with other insect management tactics (e.g., insecticide use or tillage), GM maize should not be considered inherently compatible or incompatible with IPM. Rather, the effect of GM insect-resistance on maize IPM likely depends on how the technology is developed and used.

Successes and challenges for the rearing of predatory heteropterans

Patrick De Clercq

Ghent University, Ghent, Belgium

Several predatory mirids and anthocorids are currently being marketed for augmentative releases, mainly in greenhouse crops. Augmentative biological control should be based on a cost effective and reliable production of high-quality natural enemies. In order to reduce costs related to tritrophic rearing systems, factitious foods and artificial diets have been proposed for the production of predatory bugs and some of these have found their way into practice.

Frozen eggs of *Ephestia kuehniella* are routinely used for the production of predatory anthocorids (*Orius* and *Anthocoris* spp.) and mirids (e.g., *Macrolophus* spp., *Dicyphus hesperus*, *Nesidiocoris tenuis*). These lepidopteran eggs constitute a factitious food that is often nutritionally superior to the natural prey. However, the cost of *E. kuehniella* eggs is still high (currently around 500 EUR per kg) and market availability has been under pressure from a continually increasing demand. Cysts of the brine shrimp *Artemia* spp. have been used to replace lepidopteran eggs in part of the production process of certain predatory heteropterans.

In addition, artificial diets have been developed, with a varying degree of success, for several species of predatory anthocorids, mirids and pentatomids, but the practical use of these diets is still in its infancy.

Besides animal foods, many predatory bugs require plant materials for moisture, supplementary nutrients or growth factors, or as an oviposition substrate. The development of artificial oviposition substrates constitutes a further challenge for the rationalisation of rearing procedures for mirid and anthocorid bugs that deposit their eggs into plant tissues.

Quality assurance of mass produced predatory bugs often requires time consuming assessments of developmental and particularly reproductive traits. In this respect increasing attention is given to the development of rapid tools to assess reproductive potential, including dissection tests and ELISA-based detection of yolk proteins.

Multi-trophic maintenance of herbivore populations: how plant secondary chemistry indirectly benefits parasitoid natural enemies.

Angela Smilanich[1], Lee Dyer[1], Deane Bowers[2], Jeff Chambers[1]

[1]Tulane University, New Orleans, LA, United States, [2]University of Colorado, Boulder, CO, United States

Introduction: In the ongoing investigation into the relative importance of various biotic forces maintaining herbivore populations, two main hypotheses have guided research: (1) herbivore abundance is maintained by natural enemies (predator regulation), and (2) herbivore abundance is maintained by host-plant resources, nutritional quality, and plant secondary chemistry (resource regulation). Although there is evidence in support of each hypothesis, no consensus has been reached as to which hypothesis is best supported or most general in application. Herbivore populations are most likely maintained by a combination of both predator-regulated and resource-regulated mechanisms. Currently, many questions remain regarding specific mechanisms by which predators and resources interact, and how these interactions function to maintain herbivore populations.

Methods: In this study, we addressed these questions by investigating how plant secondary metabolites disrupt an important herbivore defense against natural enemies, the immune response. Caterpillars with varying diet breadths were fed diets with high and low plant secondary metabolites.

Results: We found that increased concentrations of plant secondary chemistry negatively affected the caterpillar immune response. Effects were highest on sequestering specialist caterpillars. Similarly, metabolic output was greatest for caterpillars feeding on high concentrations of secondary metabolites.

Conclusions: Together, these results show that plant secondary chemistry can have a positive effect on parasitoids by disrupting the caterpillar immune response, indicating a multi-trophic level function for the maintenance of herbivore populations.

The effect of temperature and climate change on the distribution of bark beetle-associated fungi

Six Diana, Bentz Barbara

[1]Department of Ecosystem and Conservation Sciences, University of Montana, Missoula, Montana, United States, [2]USDA Forest Service, Rocky Mountain Research Station, Logan, Utah, United States

Introduction: The mountain pine beetle (MPB) is a serious forest pest in western North America. This beetle is associated with symbiotic fungi including two mycangial species, *Grosmannia clavigera* and *Ophiostoma montium*, which are important for host beetle development and reproduction. Due to above-average temperatures in the last decade, the beetle and its fungi have expanded their range northward and eastward in Canada. In this study, we looked at genetic diversity of *G. clavigera* collected from five sites in Canada and two sites in the US including sites within the newly expanded geographic range.

Methods: AFLP profiles from 170 fungal isolates were used to assess genetic variability within and among the populations sampled.

Results: Genetic variation was low in *G. clavigera*. There was higher heterozygosity and higher percentage of polymorphic loci in the Rocky Mountain (RM) populations than in the British Columbian (BC) populations. AFLP data indicated the presence of two genetically distinct groups (Group 1 and Group 2).

Conclusions: We found both Group 1 and 2 in the RM populations sampled, but only Group 1 in the BC populations. The presence of Group 1 in the newly expanded range of the beetle is likely due to expansions of beetles from BC northward as well as eastward into the RM region.

Tracing the origins of the praying mantises (Dictyoptera: Mantodea): Is their rapid diversification and the repeated occurrence of ecomorphic convergences linked to the Gondwanan breakup?

Gavin Svenson[1], Michael Whiting[2]

[1]New York State Museum, Albany, NY, United States, [2]Brigham Young University, Provo, UT, United States

A comprehensive taxonomic and distributional sampling of Mantodea (praying mantises), covering virtually all higher-level groups, was assembled to reconstruct the phylogeny for the order. Sequence data were generated from five mitochondrial and four nuclear loci (12S rDNA, 16S rDNA, 18S rDNA, 28S rDNA, Histone III, Cytochrome Oxidase I & II, NADH dehydrogenase subunit 4, and Wingless) for 331 mantis species along with ten cockroach and termite species as outgroups. Phylogenetic reconstruction using multiple methods recovered nearly congruent topologies. Only 7 of 14 families, 14 of 33 subfamilies, and 7 of 14 tribes were recovered as monophyletic indicating that phylogeny is largely incongruent with current mantis classification. Mapping biogeographic regions on the phylogeny demonstrated that our results adhere closer to geographic distribution than to the current classification. Specific patterns in distribution suggest that major morphological convergences have confounded taxonomist's ability to construct natural groups. Rather, we found that major mantis lineages diverged prior to the isolation of geographic regions and subsequent ecomorphic specializations within these regions led to convergences in morphology. Divergence time estimations place the origins of Mantodea at the beginning of the Jurassic with modern mantises originating on Gondwana during the Early Cretaceous. The first major divergences among modern mantises occurred with the splitting of South America and Africa. The subsequent breakup of other Gondwanan continents spurred numerous divergences within the order and led to the contemporary paraphyletic assemblages of taxa within each biogeographic region.

SimBeetle: Agent-based model for simulating red flour beetle in two-dimensional flour landscapes

Paul Flinn, James Campbell

USDA-ARS, Manhattan, Kansas, United States

Red flour beetle (*Tribolium castaneum*) is a common insect pest that infests flour mills. Over the last 80 years, dozens of mathematical models have been developed to simulate its population dynamics. Although these deterministic and analytical models predict general population trends, they are not able to simulate individual behavior and movement, and most don't include a spatial dimension. We developed a spatially explicit, agent-based model to better understand and predict beetle population dynamics in fragmented landscapes. Because an agent-based model allows for differences in agent behavior and interactions between agents, these models can be more realistic than deterministic models, and facilitates the testing of hypotheses about the consequences of stochastic factors and behavioral interactions. An object-oriented language was used to simulate the behavior of beetles. The model allows movement and distribution of individual beetles to be recorded. The model is a useful tool for predicting the effects of landscape structure on the stability of red flour beetle population dynamics.

Biological control of the Indianmeal moth on finished stored products using egg and larval parasitoids

Matthew Grieshop[1], Paul Flinn[2], James Nechols[3]

[1]Michigan State University, Lansing, Michigan, United States, [2]USDA-ARS, Manhattan, Kansas, United States, [3]Kansas State University, Manhattan, Kansas, United States

Biological control using hymenopteran parasitoids presents an attractive alternative to insecticides for reducing infestations and damage from the Indianmeal moth (*Plodia interpunctella*) in retail and warehouse environments. We examined the potential for using combinations of the egg parasitoid *Trichogramma deion* Riley, and the larval parasitoid *Habrobracon hebetor* (Say), for preventing infestations of *P. interpunctella* in coarse ground cornmeal, as well as the influence of packaging on parasitoid effectiveness. Treatments included one or both parasitoids, and either cornmeal infested with *P. interpunctella* eggs or eggs deposited on the surface of plastic bags containing cornmeal. *Habrobracon hebetor* had a significant impact on *P. interpunctella*, lowering populations by about the same magnitude in both open and bagged cornmeal. In contrast, *T. deion* did not suppress *P. interpunctella* in open cornmeal. However, when released on bagged cornmeal, *T. deion* significantly increased the level of pest suppression over bagging alone. When *H. hebetor* was added to bagged cornmeal, there was a significant reduction of live *P. interpunctella* compared to the control (70.6%) with a further reduction observed when *T. deion* was added (96.7%). These findings suggest that, in most cases, a combined release of both *T. deion* and *H. hebetor* would have the greatest impact because, even though packaging may protect most of the stored products, there are usually areas in the storage landscape where poor sanitation is present.

Decision support systems for prevention and control of vector-borne diseases

Lars Eisen[1], Michael Coleman[2]

[1]Colorado State University, Fort Collins, Colorado, United States, [2]Medical Research Council, Durban, South Africa

Introduction: Recent decades have seen both emergence of vector-borne diseases (VBDs) in new areas (e.g., Lyme disease and West Nile virus disease in North America) and resurgence of VBDs following relaxation of vector and/or disease control campaigns (e.g., dengue in the Americas, malaria in parts of Asia). Public health capacity to meet the threat of emerging VBDs has been found lacking even in developed countries capable of rapidly allocating significant resources to combat these diseases. Novel approaches are urgently needed for improved prevention of emerging and resurging VBDs as well as maintenance of a disease-free environment following successful eradication campaigns. The importance of the latter is highlighted by the recent commitment of major funding and public health agencies to eradicate malaria.

Methods and Results: We will explore the topic of using decision support systems to facilitate prevention and control of VBDs. This will include a discussion of the importance of clearly defining end-users responsible for prevention and control of VBDs and examples of decision support systems for dengue and malaria under development. Four VBDs representing tick-borne bacterial diseases (Lyme disease), mosquito-borne viral diseases (dengue, West Nile virus disease) and mosquito-borne parasitic diseases (malaria) will be used to illustrate problems and possibilities related to use of decision support systems to combat VBDs.

Conclusion: Decision support systems have tremendous potential to counter VBDs through improved capacity for data collection, entry, storage, retrieval, analysis, and display; and through evidence-based decision making and use of locally appropriate vector/disease control program strategies and methodologies.

Respiratory physiology as a tool for understanding ecological patterns in fleas

Boris Krasnov[1], Irina Khokhlova[1], Laura Fielden[2]

[1]Ben-Gurion University of the Negev, Beer-Sheva, Israel, [2]Truman State University, Kirksville, United States

Introduction: We present two case studies demonstrating how measurements of respiratory gas exchanges can be used to understand ecological phenomena in ectoparasites using fleas and their rodent hosts as a model system. The first study asked whether sexual and interspecific differences in jumping performance of fleas that appeared to be not related to differences in the morphometric of locomotory system are instead correlated with differences in metabolic rate (MR). The second study considered energy cost of blood digestion of the host-specific flea that fed on preferred and non-preferred hosts.

Methods: In the first study, we related metabolic rate to jump performance of fleas, where as in the second study we calculated energy expenditure of a flea during digestion of a single bloodmeal taken from preferred or non-preferred host. A flow-through respirometry system was used to measure CO_2 emission.

Results: (1) Differences in jumping ability between males and females were found to be correlated with sexual differences in mass-specific or mass-independent MR. Interspecific comparison showed that the length of jump in both male and female fleas was strongly affected by their mass-specific and mass-independent MR. (2) Fleas expended significantly more energy digesting blood of non-preferred host than blood of preferred host.

Conclusions: Respiratory measurements appeared to be a useful tool when studying ecological patterns.

Comparative acute toxicity of two herbicides, Paraquat and Glyphosate to the larvae of two caddisflies, *Aethaloptera dispar* and *Cheumatopsyche digitata*

Sylvester Ogbogu, Efere Obuotor

Obafemi Awolowo University, Ile-Ife, Osun State, Nigeria

Introduction: Glyphosate- and Paraquat-based herbicides are among the most widely used pesticides in the world. In this study, we compared the susceptibility of the larvae of two caddisflies, *Aethaloptera dispar* Brauer and *Cheumatopsyche digitata* Mosely (Trichoptera: Hydropsychidae) to the acute toxicity of two herbicides Glyphosate (Roundup®) and Paraquat (Gramoxone®) under static bioassay conditions.

Methods: The larvae were collected from the stream below a tropical rainforest reservoir outflow and acclimatized to laboratory conditions. They were then exposed to 500 ppm, 100 ppm and 10 ppm test concentrations prepared from 1000 ppm stock solutions of both herbicides in short-term static bioassay experiments.

Results: There was a dose- and time-dependent mortality with Paraquat, giving an LC_{50} of 60.40 ppm and 112.78 ppm for *A. dispar* and *C. digitata* respectively, at 24-h exposure. For glyphosate however, there was mortality at 15.35 ppm at 96-h exposure.

Conclusions: The results suggest that both herbicides are lethal to the caddisflies at the test concentrations although Paraquat was more toxic to larvae than Glyphosate. Therefore, their concentration before application must be considered to mitigate their harmful effects on non-target aquatic organisms such as caddisflies.

Biogeography of the mutillid wasps (Hymenoptera: Mutillidae)

Arkady S. Lelej

Institute of Biology and Soil Science, Russian Academy of Sciences, Far Eastern Branch, Vladivostok, Russian Federation

Introduction: The Mutillidae is a large family of solitary wasps which currently numbers 213 genera and about 4200 described (c. 6000 estimated) species. Their greatest diversity occurs in the tropical and subtropical regions of the world.

Methods: The distributions of 213 genera and 16 tribes, as well as the distribution and dispersal patterns of subfamilies, were analysed. Faunal similarities between six biogeographical regions were evaluated by using Sorensen's coefficient of similarity. The similarity matrix resulting from pair-wise calculations was then presented by Terent'ev pleiades. The higher classification of Mutillidae follows Lelej & Nemkov (1997).

Results: The current distribution of four basal mutillid subfamilies (Myrmosinae, Kudakrumiinae, Pseudophotopsidinae, and Ticoplinae) and the subfamily Myrmillinae supports the hypothesis that the primary differentiation of the family took place on the Laurasian continents. These five subfamilies had a Palaearctic origin, while Rhopalomutillinae, Mutillinae, Dasylabrinae, Ephutinae, and Sphaeropthalminae originated in the Afrotropical region. Myrmosinae and Pseudophotopsidinae are distributed mainly in the Palaearctic region, while Kudakrumiinae is Holarctic. The greatest diversity of the subfamilies Myrmillinae, Mutillinae, Rhopalomutillinae, Dasylabrinae, and tribe Odontomutillini (in Ephutinae) occurs in the Afrotropical, Palaearctic, and Oriental regions. Sphaeropthalminae dominates in the New World and Australian regions, while the tribe Ephutini occurs only in the New World.

Conclusion: The mutillid faunas of the Palaearctic, Oriental and Afrotropical regions are the most similar on the tribal and generic levels and represent the nucleus of the world fauna. The evolution of Mutillidae in the Palaeogene-Neogene was related to the formation of hemixerophytic (tropical, subtropical) and later hyperxerophytic (desert) biota.

Altruism in insect societies and beyond: voluntary or enforced?

Tom Wenseleers

Katholieke Universiteit Leuven, Leuven, Belgium

The extreme altruism of the social insect worker caste has puzzled researchers for decades. Inclusive fitness theory suggests that close relatedness has been key in promoting such altruism. Recent theory, however, shows that the intermediate levels of relatedness found within insect societies are too low to directly cause the extreme altruism observed in many species. Instead, recent results show that workers are frequently “coerced” into acting altruistically. For example, workers are deterred from laying eggs by egg killing, and female larvae are prevented from developing into queens by food control. This shows that the altruism seen in many modern-day insect societies may not be voluntary but enforced. In this talk I will argue that enforced cooperation in fact is a widespread phenomenon that occurs not just in insect societies, but also in social vertebrates, humans and interspecific mutualisms.

Pheromone guided recruitment to food sources by stingless bees

Stefan Jarau

University of Ulm, Ulm, Germany

Introduction: Stingless bees have developed a variety of signals that are used by foragers to inform their nestmates about the existence and/or the location of a food source. The most effective and accurate recruitment mechanism is the guidance of nestmates along a trail of pheromone spots deposited by foragers on a certain stretch from the food towards the nest.

Methods: In order to identify both the glandular source of these pheromones and their compositions in several species of stingless bees, artificial scent trail bioassays with both natural extracts and synthetic compounds were carried out along with chemical analyses of gland secretions.

Results: Extracts prepared from the bees' labial glands induced trail following behaviour, whereas mandibular gland extracts did not. The chemical analyses of labial gland secretions as well as the bioassays with synthetic compounds showed that the respective pheromone components are various carboxylic acid alkyl esters and terpene esters. Furthermore, for *Trigona corvina* and *Scaptotrigona pectoralis* it could be demonstrated that both the pheromone composition (relative abundance of single compounds) and its effect to elicit trail following behaviour are nest specific.

Conclusions: The trail pheromones of all stingless bee species studied so far by means of chemical analyses and artificial scent trail bioassays (*Trigona recursa*, *T. spinipes*, *T. corvina*, *Scaptotrigona pectoralis*) clearly are secreted from their labial glands. The nest specificity now demonstrated for two species probably helps to avoid competition for resources and, at least in the aggressive *T. corvina*, costly combats between foragers of different nests.

Ecology of cereal aphid – fungal pathogen interactions: A South African perspective with potential for inoculative-augmentation

Justin Louis Hatting

ARC-Small Grain Institute, Bethlehem, South Africa

Introduction: In South Africa, wheat (*Triticum aestivum*) is produced in winter and summer rainfall climates and is prone to attack by any of six cereal aphid species. Of these, the Russian wheat aphid, *Diuraphis noxia*, is considered the most destructive. Entomopathogenic fungi often cause natural epizootics among aphid populations, including those of *D. noxia*. Elevation-driven migration of aphids between South Africa and Lesotho as well as aphid behavioral traits were considered in formulating a hypothetical control strategy based on inoculative-augmentation of the entomophthoralean, *Conidiobolus thromboides*.

Methods: Fungal surveys were conducted employing direct (collection of mycosed cadavers) and indirect (collection and rearing of live aphids) sampling techniques over a four-year period. In-field pitfall trap data were used to qualify the spatial dynamics of aphid mobility leading to potential pick-up of fungal inoculum from soil surfaces.

Results: Eight fungal species known to infect and kill aphids were recorded, *i.e.,* the entomophthoraleans *Pandora neoaphidis*, *Conidiobolus thromboides*, *C. coronatus*, *C. obscurus*, *Neozygites fresenii*, and *Entomophthora planchoniana*. Two Sordariomycetes, *Beauveria bassiana* and *Lecanicillium lecanii* were also isolated. As host, *D. noxia* seemed highly suitable with six fungal species recorded. Compared to other cereal aphid species, observations revealed early-season activity for *D. noxia* and active aphid movement over soil surfaces within the crop.

Conclusion: Hypothetically, early-season migration of *D. noxia* from Lesotho into South Africa could be exploited through interventions increasing the level of latent and/or active infection in the crop environment. The novel use of a millet-based medium for inoculative-augmentation of *C. thromboides* is proposed.

Eukaryotic translation initiation factor 4A (eIF4A) of the diamondback moth, *Plutella xylostella*: a putative molecular target of CpBV15β, a polydnaviral protein derived from an endoparasitoid, *Cotesia plutellae*

Yonggyun Kim[1], Madanagopal Nalini[1], Seungbaeck Song[1], Jai-Hoon Eum[2], Sungsik Han[2]

[1]Andong National University, Andong, Korea, Republic of, [2]Korea University, Seoul, Republic of Korea

Initiation of translation is the most efficient step for regulation of protein synthesis, in which viruses are targeting the recruitment of mRNA to the 43S complex to form the 48S preinitiation complex. This process is accomplished by eukaryotic translation initiation factor 4F (eIF4F), which mainly consists of eIF4A (ATP-dependent RNA helicase), eIF4E (cap-binding protein), and eIF4G (adapter protein). Diamondback moth, *Plutella xylostella*, parasitized by an endoparasitoid, *Cotesia plutellae* (Hymenoptera: Braconidae), exhibits physiological alterations including immunosuppression, antimetamorphosis, and diversion of host nutrients. CpBV15β, a viral protein derived from *C. plutellae* bracovius, has been speculated to act as host translation inhibitory factor because of its homology with circumsporozoite, a malarian toxin protein to inhibit host protein synthesis. CpBV15β also exhibits amino acid sequence similarity to eIF4G at the interacting site with eIF4A, suggesting that its inhibitory action may bind eIF4A of *P. xylostella*. A positive clone corresponding to eIF4A was isolated from a cDNA library of *P. xylostella*. Using both RACEs, a complete eIF4A cDNA (1,700 bp) was cloned. It encodes 422 amino acid sequence with 47961.83 daltons and share high homologies with other eIF4As of *Bombyx mori*, *Drosophila melanogaster*, and *Apis mellifera*. The protein was expressed using a bacterial expression vector and purified by Ni-NTA affinity column. The purified eIF4A protein was injected into rabbit to raise polyclonal antibody. The antiserum reacted the purified protein and *P. xylostella* protein extracts. Immunoprecipitation assay showed that CpBV15β interacts with eIF4A in the parasitized *P. xylostella*.

Influence of potato plant preinfestation on its colonization by aphids

Philippe Giordanengo[1], Laurence Brunissen[1], Vincent Charles[2]

[1]Université de Picardie Jules Verne, Amiens, France, [2]Agriculture and Agri-Food Canada, Saint-Jean-sur-Richelieu, QC, Canada

Introduction: The aphids *Macrosiphum euphorbiae* (Thomas) and *Myzus persicae* (Sulzer) (Homoptera: Aphididae) are serious pests of potato (*Solanum tuberosum* L.), notably in transmitting numerous plant viruses. Heterospecific interactions may occur between these two species as they are often observed at the same time on the same potato plant in the field. As aphid infestation is known to induce systemic changes in the plant, we investigated the effect of a previous infestation of a plant on its colonization by following aphids.

Methods: Behavioral (olfactometry and electrical penetration graph) and physiological studies were performed to evaluate the influence of plant conspecific (i.e. *M. euphorbiae*) or heterospecific (i.e. *M. persicae*) preinfestation on *M. euphorbiae*.

Results: We found that conspecific preinfestation altered olfactory and trophic parameters involved in behavioral steps of plant acceptance by aphids. In contrast, heterospecific preinfestation enhanced plant attractivity and aphid survival.

Conclusions: A previous infestation of potato plants by aphids, either conspecific or heterospecific, led to modified plant acceptance and life history traits for aphids colonizing the plant afterwards. Surprisingly, heterospecific preinfestation altered plant acceptance processes, probably inducing plant defense response. Conversely, heterospecific preinfestation favoured *M. euphorbiae* settlement and population development. Such effects of intraguild interactions and their ecological meanings are discussed.

Differential effects of the induction of direct plant defences on the development of a generalist herbivore and its solitary endoparasitoid

Rieta Gols[1], Jeffrey A. Harvey[2]

[1]Wageningen University, Wageningen, Netherlands, [2]Netherlands Institute of Ecology, Heteren, Netherlands

Introduction: Plants have evolved several defence mechanisms to prevent or reduce feeding by insect herbivores. Among these defences, plant allelochemicals have been shown to play an important role against insect herbivory. Levels of plant defences often increase in response to insect feeding and affect the performance of consecutive herbivore generations. Few studies have investigated the effect of induced plant defence on performance of parasitoids that develop inside insect herbivores. In this study, we investigated the effect of induced plant defence on a generalist herbivore and its larval endoparasitoid.

Methods: We examined the effect induced and non-induced food plants on the performance (survival, body mass development time) of a generalist herbivore (*Mamestra brassicae*) and its larval endoparasitoid (*Microplitis mediator*). Different wild populations and cultivars of *Brassica oleracea* were used as food plant for the herbivore and plants were induced by larval feeding of *Pieris rapae*.

Conclusions: The occurrence of sexual size dimorphism in *M. mediator* depends on the quality of the food plant on which the host has been feeding.

Interactions between generalist and specialist herbivores and their endoparasitoids on the invasive weed, *Bunias orientalis*

Jeffrey A. Harvey[1], Rieta Gols[2], Michael Reichelt[3], Roel Wagenaar[1]

[1]Netherlands Institute of Ecology, Heteren, Netherlands, [2]Wageningen University, Wageningen, Netherlands, [3]Max Planck Institute for Chemical Ecology, Jena, Germany

Introduction: Warty cabbage, *Bunias orientalis*, originates in western Asia but since the 1980s has become a highly invasive weed in parts of central and western Europe. However, it is still comparatively rare in some other parts of north- and south-western Europe, although it is on the 'black list' of plants to watch out for. Thus far, little is known about the factors underlying the success of *B. orientalis*. For instance, the insect fauna that feed on *B. orientalis* is poorly described, and the suitability of the plant to higher trophic levels, such as parasitoid wasps, is also unknown.

Methods: We conducted experiments with different populations of *B. orientalis* originating from two countries where it is an exotic, invasive pest (Germany, Sweden) and one where it is exotic but still rare (Holland). The growth, development and survival of specialist and generalist herbivores are described on German and/or Dutch populations. We then compared the development of a generalist herbivore, *Mamestra brassicae*, and its solitary endoparasitoid, *Microplitis mediator* on field-grown Dutch *B. orientalis* and a lab-grown cultivar (cv. Cyrus) of cabbage, *Brassica oleracea*. Finally, we compared the development of *M. brassicae* and *M. mediator* on plants originating in the 2 exotic invasive and 1 exotic non-invasive populations of *B. orientalis*. Larval preference for herbivore-induced and uninduced plants was also examined.

Conclusions: The results reveal significant variation in secondary chemistry and plant quality amongst the different populations as well as insect performance. We suggest that the various exotic populations may have different geographic origins.

Importance and distribution of the Mediterranean black fig fly, *Silba adipata*, McAlpine in South Africa.

Martin Wohlfarter[1], Elrita Venter[1], Jan Giliomee[2]

[1]Alternafruit SA (Pty) Ltd, Paarl, Western Cape, South Africa, [2]University of Stellenbosch, Stellenbosch, Western Cape, South Africa

Introduction: The Mediterranean black fig fly, *Silba adipata*, McAlpine (Diptera: Lonchaeidae) was recorded in South Africa for the first time from commercially grown figs (*Ficus carica*) late 2006. During 2007 various fig production areas in South Africa were monitored for this fly as part of a greater insect pest and disease survey on figs. The figures presented give an indication of the distribution of this fly as determined by the survey.

Methods: Commercial fig orchards and private backyard gardens were inspected for fruit damage for two consecutive seasons. *Silba adipata* attacks unripe to ripe figs, by ovipositing near or in the fruit ostiole. Larvae feed predominantly below the skin, causing a characteristic premature fruit ripening and internal decay. Twenty such infected fruit where randomly collected per orchard and larvae where reared in the laboratory. In addition to collections McPhail traps baited with Hexanol ($C_6H_{13}OH$) were used in the second season to attract flies and determine population densities.

Results: The occurrence of the fig fly is widespread in South Africa and in one particular orchard caused serious economic damage. Larvae emerged in mid November, suggesting first oviposition around end of October. Fruit damage was observed until late February. The reduction in infection can, however be attributed to targeted insecticidal application against Mediterranean fruit fly (*Ceratitis capitata*). Hexanol which was shown to be a potent attractant to *Silba adipata* in Greece (Katsoyannos & Guerin, 1984), only obtained limited success under commercial production in South Africa.

Conclusions: The Mediterranean black fig fly, *Silba adipata*, is an important new fig pest in South Africa, seriously affecting fruit quality. Its presence was established in the south western part of the country, but it is probably widely distributed all over South Africa. Unkempt orchards show the highest infestation, thus stressing the importance of sanitation practises.

Diversity and relationships of gall-inducing scale insects in South Africa

Penny Gullan[1], Lyn Cook[2]

[1]University of California, Davis, Davis, California, United States, [2]University of Queensland, Brisbane, Queensland, Australia

Introduction: More than 500 species of scale insects (Hemiptera: Coccoidea) are known from South Africa, but very few are reported to induce galls on their host plants. This contrasts with Australia and New Zealand, which have rich faunas of galling Coccoidea, especially in the family Eriococcidae. We use morphological and molecular information to estimate the taxonomic diversity and phylogenetic relationships of gall-inducing scale insects native to South Africa.

Methods: The number of gall-inducing scale insect taxa in South Africa was assessed based on a survey of literature plus recent collections made in the Eastern, Northern and Western Cape provinces. Nucleotide sequence data were obtained for gall-inducing species of soft scale (Coccidae), felt scale (Eriococcidae) and mealybug (Pseudococcidae) and added to a larger DNA dataset for each family to estimate potential relatives of the gallers. Undescribed species were recognized based on insect and gall morphology and DNA data.

Results: Only 13 species of native South African scale insects belonging to five families are known to induce galls, and those of the Asterolecaniidae are mostly nondescript stem pits. The gall-inducing *Calycicoccus merwei* is the only member of the Eriococcidae native to South Africa, and represents an isolated lineage. Two species (one undescribed) of *Cissococcus* are the only gall-inducing soft scales (Coccidae) in South Africa and are related to African non-galling coccids. The only two gall-inducing mealybug genera, *Diversicrus* and *Grewiacoccus* (Pseudococcidae), are not closely related. An undescribed leaf-galling species of armoured scale is reported from *Rhus* species in the Cape region.

Switch in the pest status and range of some true bugs (Heteroptera) due to landscape change and global warming in the neotropics

Antonio Panizzi, Daniel Sosa Gomez

National Soybean Research Center - Embrapa, Londrina, PR, Brazil

Introduction: During the last 40 years, a dramatic change in landscape along with increase in certain parameters indicating global warming has occurred in the neotropics, particularly in Brazil. As a result of this, changes in the species composition and abundance of true bugs (Heteroptera) associated with crops has been observed.

Methods: To demonstrate this, three species of heteropterans, the pentatomids, *Euschistus heros* (F.) and *Dichelops melacanthus* (Dallas), and the alydid, *Neomegalotomus parvus* (Westwood) associated with two major crops, i.e., soybean, *Glycine max* (L.) Merrill and/or corn, *Zea mays* L., were selected and analyzed. Data analyses were based on published records during this time accomplished with field observations.

Results: Results indicated that for all three species a tremendous increase in abundance and distribution has occurred in this time frame (last 40 years). This can be explained due to the expansion of these crops providing abundance of food, and to the massive adoption by growers of the no-tillage cultivation system that favor these species which spend part of their life on the soil surface feeding on seeds and/or using crop residues as shelter. In addition, the increase of minimum mean temperatures (over 1ºC during the last 40 years) and the less frequency of occurrence of frosts are probably favoring these neotropical species to colonize cooler areas of southern Brazil below the Tropic of Capricorn (latitude 23º 27'S).

Conclusions: The change in landscape and global warming are favoring the abundance of the true bugs analyzed.

Effects of short-term laboratory infestation of dried cassava variety TME – 7 by *Prostephanus truncatus* (Horn) (Bostrichidae: Coleoptera)

Popoola Kehinde

University of Ibadan, Department of Zoology, Ibadan, Oyo state, Nigeria

Introduction: Researches have shown that dried cassava varieties are relatively susceptible to *Prostephanus truncatus* (Horn) infestation, which results to about 70% lost in 4 months. This consequently affects a large percentage of the population from developing countries that depends of cassava as sources of food for high energy and income.

Methods: Laboratory studies were conducted to determine weight loss and nutritional status of the infested dried cassava chips (TME-7) and emergence rate of *P. truncatus* over an infestation period of 8 weeks.

Results: Cassava variety TME -7 mean weight loss (±SD) rose to 11.30% ± 4.01 (22.67%) with *P.truncatus* mean emergence rate (± SD) values were 9.93 ± 7.34, 18.53 ± 8.12 and 16.33 ± 6.75 for larvae, pupae and adults respectively. Nutrient proximate analysis conducted on infested TME-7 revealed the dried cassava nutritional status as follows: protein content was 1.30%; fat content recorded was 0.99%, while moisture content was put at 5.50%. Other parameters analyzed were ash content, which was 1.81%, and lastly, crude fiber and carbohydrate was 29.03%.

Conclusion: Dried cassava variety supports *P. truncatus* breeding, with appreciable damage to the crop. Breeding and damage have been implicated in the reduction of nutritional and market values of the dried cassava.

Variation and flexibility of egg discrimination in *Formica* ants

Heikki Helanterä

University of Helsinki, Helsinki, Finland

Social insects face the need to discriminate among different classes of brood in order to maximise their inclusive fitness. In the context of nestmate recognition of eggs workers potentially increase their inclusive fitness by discriminating against eggs laid by unrelated conspecific queens and unrelated social parasite queens. Workers of *Formica fusca*, an ant with highly variable queen number and a frequent target for temporary social parasite *Formica* queens, are able to discriminate against eggs laid by both conspecific and heterospecific alien queens. Our previous results also show that the diversity of eggs the workers experience in the spring affects their future acceptance of eggs from unrelated conspecifics. If this switch in discrimination also applies to eggs of social parasites, this suggests two ways how social parasites may increase the acceptance of their eggs by hosts. First, social parasites may get their eggs reared if they are laid early in the spring, during the period when exposure of workers to diverse eggs affects future acceptance. Second, workers in genetically diverse multiple queen colonies may be more likely to accept parasite eggs. We studied these scenarios using laboratory colonies of *F. fusca* and its sympatric social parasite *F. truncorum*. The results will shed light on the interplay of sociogenetic variation and the behavioural rules underlying recognition in moulding the accuracy of adaptation against social parasites.

Predation by larval *Agabus* (Coleoptera: Dytiscidae) on primary consumers in constructed freshwater wetlands

Lauren Culler, William Lamp

University of Maryland, College Park, Maryland, United States

After decades of wetland destruction for development and agricultural purposes, growing awareness by the public is providing support for their restoration. This support is often met with fear of mosquito annoyance and potential disease transmission since people associate areas of standing water with large mosquito populations. However, studies of macroinvertebrates in restored wetlands show that native wetland predators can suppress mosquito populations. At the Jackson Lane wetland restoration site on the Eastern Shore of Maryland, post-restoration monitoring data show a diverse community of macroinvertebrates with a high percentage of predator species. Predaceous diving beetles (Coleoptera: Dytiscidae) make up 16.9% of the taxa found, though account for only 5.1% of individuals. Adults and larvae of these beetles are known predators of mosquito larvae and we wanted to test if they are contributing to natural suppression of mosquito populations. We focused on *Agabus punctatus*, since these larvae are abundant when mosquitoes may be ovipositing as the wetlands thaw in late winter. A series of laboratory experiments are underway to test the feeding preference of this predator, and to specifically determine if mosquito larvae are an important component of its diet. Experiments address: (1) the performance of *A. punctatus* when fed on three different prey types (mosquito larvae, cladocerans, or copepods), (2) how the behaviour of *A. punctatus* and its prey influences prey selection, and (3) how intraspecific interactions among *A. punctatus* affect rate of prey consumption. Future experiments will address prey selection and the effect of predator density on the prey population.

The influence of maize phenologies and transgenic Bt maize on oviposition and injury to maize by European corn borer

Motshwari Obopile[1], Ronald B. Hammond[1], Peter R. Thomison[2]

[1]The Ohio State University, Wooster, Ohio, United States, [2]The Ohio State University, Columbus, Ohio, United States

Introduction: The European corn borer, *Ostrinia nubilalis* (Hubner), is a damaging pest of maize (*Zea mays* L.) throughout North America. Yield losses associated with *O. nubilalis* are estimated at more than $1 billion annually. A study was conducted to determine the influence of planting date and transgenic maize on oviposition by *O. nubilalis* and subsequent larval injury on maize.

Methods: Transgenic and non transgenic maize hybrids of different relative maturities were planted at three planting dates (early, mid, and late) each year. The study was carried out at the Northwest Agricultural Research Station near Hoytville and at Wooster, Ohio during the 2006 and 2007 cropping seasons. Egg masses, growth stages, and injury levels on stalks, foliar, and ears were recorded on 10 randomly selected plants.

Results: The egg density did not differ significantly between transgenic and non-transgenic maize. However significant differences were observed among planting dates and sampling dates, and with the sampling date by planting date and hybrid by sampling date interactions. Fewer eggs masses were laid on second planting than early and late plantings. Injuries on stalks, foliar and ears were significantly higher on non-transgenic maize. Significant differences were also observed between planting dates, and the planting date by hybrid interactions. The use of transgenic maize did not significantly improve yields in 2006, but did in 2007. Early planted maize yielded significantly more in 2006 but in 2007, yield did not differ significantly among planting dates.

Conclusions: The variability in the benefit from transgenic plants and planting dates makes recommendations difficult at this time.

Comparative aspects of life history regulation in honeybee and fruit fly

Thomas Flatt

Department of Ecology and Evolutionary Biology, Brown University, Providence, Rhode Island, United States

Hormones ensure the systemic coordination of physiological processes in response to environmental cues, from the cellular to the organismal level, and variation in endocrine pathways might thus play a major role in life history evolution. In the solitary fruit fly (*Drosophila melanogaster*), the neuroendocrine system (homologous to the mammalian hypothalamic-pituitary-gonad axis) integrates insulin-like signals, juvenile hormone (JH), and ecdysone signaling. This pleiotropic system coordinates major aspects of life history, including reproduction, stress resistance, immune function, behavior, and lifespan. Remarkably, a similar regulatory principle is found in the honeybee (*Apis mellifera*), a social insect distantly related to the fly. Like the fly, the bee uses a pleiotropic hormonal network to regulate a complex suite of social behavioral and life history traits, including behavioral ontogeny, foraging, pollen versus nectar preference, ovarian development, oxidative stress response, immunity, and longevity. Components of this complex network comprise JH, the JH suppressor vitellogenin, and possibly the insulin, target of rapamycin (TOR), and ecdysone signaling pathways. Together, the comparison of fly and bee suggests that a regulatory system of solitary origin has been co-opted by social insects and might have contributed to the evolution of social life histories. Here I review the endocrine regulation of *Drosophila* life history and draw parallels between this regulation in the fly and the bee. Well-established genetics and genomics in *Drosophila*, combined with the recent advent of RNAi, proteomics, and ease of physiological manipulation in the bee, promise to make such a comparative approach exceptionally powerful.

Different effects of three paracoprid dung beetles baased on their niche

Heason Bang[1], Joon-Ho Lee[2], Young-Eun Na[1], Min-Su Han[1], Ki-Ahn Noh[1]

[1]NIAST, Suwon, Korea, Republic of, [2]Seoul National University, Seoul, Republic of Korea

Introduction: Dung beetle act as removes dung on the ground from the soil surface. They bury the dung in the soil wherever they find it. This helps to accelerate the rate of the circulation of nutrients and to increase the productivity of grassland ecosystem. They use dung as their food and as their offspring. As the result of these activities there were noticeable changes in the soil. Different species of dung beetle were found in different soil layers.

Methods: In this experiment, three paracoprid dung beetles (*C. ochus, C. tripartitus and O. lenzii),* chemical properties, and microbial interactions were studied during the first and second month of dung decomposition. There were two kinds of pot these were the pot with beetles and the pot without beetle. The effects of three dung beetles in organic matter, total N contents, Ammonium N as well as on microbial population were assayed.

Results: After 3 weeks, each dung beetle accelerated nitrification. By dung beetle activity in each soil layer, microbial numbers were highly correlated to the organic matter and total N concentration of the soil. In 0-5 cm soil layer, *O. lenzii* treatment had the highest content of organic matter, total N and ammonium N, Otherwise in 10-30 cm soil layer, *C. ochus* treatment was higher than the other treatments.

Conclusions: Each three dung beetles contributed the changes in the chemical composition and microbiological activity of each soil layer as the result of using by their different ecological niche. Each dung beetle contributed the changes in the chemical composition and microbiological activity of each soil layer. This was the result of using their different ecological niche.

Regulation of cell migration by the gaseous messenger molecules CO and NO during formation of neural circuits

Gerd Bicker, Sabine Knipp

University of Veterinary Medicine, Hannover, Germany

Introduction: The formation of the insect enteric nervous system (ENS) provides a useful model to study the cell biology of neuronal migration. Neuronal precursors emerge from proliferative zones in the foregut epithelium and perform quite extensive cell migrations before they assemble into the neural circuits of discrete ganglia and nerve plexus.

Methods: Using small molecule compounds to activate or inactivate biosynthetic enzymes, we demonstrate that the gaseous messenger molecules carbon monoxide (CO) and nitric oxide (NO) regulate neuron migration in the locust ENS.

Results: CO is produced by heme oxygenase (HO) enzymes and has the potential to signal via the sGC/cGMP pathway. Here we show that inhibition of HO by metalloporphyrins promotes enteric neuron migration in intact locust embryos. This gain of function experiment in conjunction with the suppression of migratory behavior by chemical activation of HO strongly implicates the release of CO as inhibitory signal for neuron migration. Conversely, inhibition of nitric oxide synthase and application of the extracellular NO scavenger hemoglobin reduce cell migration. While migrating on the midgut, the enteric neurons express a transient immunoreactivity for HO.

Conclusions: The cellular distribution of NO and CO biosynthetic enzymes, together with the results of the chemical manipulations in whole embryo culture suggest CO as an intracellular messenger molecule that modulates transcellular NO signalling during neuronal migration. Thus we provide the first evidence that CO regulates neural development in a rather simple model insect.

Alternative foods for *Harmonia axyridis*

Nick Berkvens[1], Jochem Bonte[1], Dirk Berkvens[2], Koen Deforce[3], Luc Tirry[1], Patrick De Clercq[1]

[1]Laboratory of Agrozoology, Department of Crop Protection, Faculty of Bioscience Engineering, Ghent University, Ghent, Belgium, [2]Department of Animal Health, Prince Leopold Institute of Tropical Medicine, Antwerp, Belgium, [3]Flemish Heritage Institute, Brussels, Belgium

Introduction: The exploitation of available resources is an important factor determining the invasion success of an exotic species. An extensive range of arthropod species has been reported to be exploited by the polyphagous coccinellid *Harmonia axyridis*. However, little is known concerning the potential role of plant foods for the establishment potential of this invasive species. Our research investigated the developmental and reproductive success of *H. axyridis* on pollen.

Methods: A long-term laboratory population of *H. axyridis* and a melanic and non-melanic population of the species originating from field collected individuals in Belgium were used in this study. The insects were allowed to develop and reproduce on three diets: frozen eggs of *Ephestia kuehniella*, frozen moist bee pollen or an even mixture of the two.

Results: When fed a diet of pollen alone, 35-48% of the larvae of the field populations of *H. axyridis* successfully reached adulthood, albeit with a prolonged developmental time (31-49%) and a reduced adult body weight (37-68%) compared to individuals offered either diet containing *E. kuehniella* eggs. When fed exclusively on pollen in their larval and adult life, about 40% of the adult females of either field population were able to produce a small number of viable eggs.

Conclusions: The exploitation of pollen and other plant foods at times when insect prey is scarce, may offer a further competitive advantage to the non-indigenous coccinellid *H. axyridis* over native European predatory lady beetles that share the same niche and are less capable of using pollen as an alternative food.

Drosophila-Wolbachia symbiotic interactions: exploring the role of ankyrins

Panagiotis Sapountzis[1], Stefanos Siozios[1], Panagiotis Ioannidis[1], Aggeliki Saridaki[1], Haralabia Boleti[2], Kostas Bourtzis[1]

[1]Department of Environmental and Natural Resources Management, University of Ioannina, Agrinio, Greece, [2]Molecular Parasitology Unit & Light Microscopy Unit, Hellenic Pasteur Institute, Athens, Greece

Wolbachia are obligatory intracellular and maternally inherited bacteria that infect numerous arthropod as well as filarial nematode species. *Wolbachia* is considered as the most ubiquitous symbiotic creature on Earth and has major effects on host biology that are expressed through the establishment of symbiotic interactions and range from reproductive parasitism to mutualistic symbioses. The molecular mechanisms that mediate *Wolbachia*-host symbiotic interactions are currently unknown. However, the sequencing of the genomes of different *Wolbachia* strains (*w*Mel, *w*Ri) that infect insect hosts revealed an unusually large number of genes encoding proteins with ankyrin repeat domains. The role of these proteins is currently under investigation in different laboratories.

The present study investigated the distribution of ankyrin genes in different Wolbachia strains by PCR and Southern analysis. Semi-quantitative RT-PCR analysis was also performed on RNA extracts from different developmental stages and tissues (males, females, testes, ovaries, early and late embryos) of different Drosophila-Wolbachia expressing different reproductive phenotypes. Selected ank-proteins were expressed transiently in insect cells as GFP chimeras and their subcellular localization was analyzed by confocal microscopy.

Our results clearly indicate that most ankyrins present patchy distribution and expression patterns. In addition, the variation in the subcellular localization of the ank-proteins analyzed may reflect different roles of ankyrin proteins on the establishment of host-*Wolbachia* symbiosis and the induction of reproductive abnormalities such as parthenogenesis, feminization, male killing and cytoplasmic incompatibility.

Aspects of non-chemical control of pestiferous termites in agriculture and agroforestry: recent experiences from eastern and southern Africa

Philip Nyeko[1], Gudeta Sileshi[2], Ben Sekamatte[3], Philip Nkunika[2]

[1]Makerere University, Kampala, Uganda, [2]World Agroforestry Centre (ICRAF), Lilongwe, Malawi, [3]DFID, Kampala, Uganda, [4]University of Zambia, Lusaka, Zimbabwe

Introduction: A number of termite species are a major constraint in agriculture and forestry in the tropics. Losses of up to 100% have been reported on some crops and tree species in eastern and southern Africa. This paper summarizes studies recently conducted in the region to evaluate the efficacy of some non-chemical termite control methods in smallholder agriculture and agroforestry.

Methods: The potential of legume intercrops, legume improved fallows, protein and sugar-based baits, and the fungus *Metarhizium anisopliae* in the management of termites on maize and *Grevillea robusta* were assessed. Termite damage to maize and *G. robusta*, maize yields and the activity of termite predating ants were recorded.

Results: Intercropping maize with soybean, groundnut and common beans reduced termite attack on maize and loss of maize yield, and increased ant nesting in maize fields in Uganda. Maize grown in improved fallows suffered less termite damage and produced maize yields comparable with conventionally tilled and fully fertilized monoculture maize in eastern Zambia. Similarly, *M. anisopliae* reduced termite damage to maize and increased maize yield in Uganda. However, the fungus did not reduce termite attack on *Grevillea robusta* seedlings. Fishmeal bait increased ant nesting near maize plants and reduced termite attack on maize with consequent increase in maize yields.

Conclusions: There is a clear scope for non-chemical control of termites in smallholder cropping systems in eastern and southern Africa. However, more efforts are necessary to test such methods rigorously, develop specific recommendations relevant to smallholder farming conditions and appraise potential for commercialization.

Potential impact of *Cameraria ohridella* on maple: Is a host shift likely?

Sylvie Augustin[1], Christelle Péré[2], Carlos Lopez-Vaamonde[1], Romain Valade[1], Marc Kenis[2]

[1]INRA-UR633 Zoologie Forestière, Olivet, France, [2]Cabi Europe-Switzerland, Delémont, Switzerland

Introduction: The horse chestnut leafminer *Cameraria ohridella* is an invasive pest in Europe. This microlepidoptera, first discovered in Macedonia, almost exclusively develops on leaves of horse chestnut, *Aesculus hippocastanum*, but infestations have also been recorded on maples: *Acer pseudoplatanus* and *A. platanoides*. The fact that *C. ohridella* attacks and develops on *Acer* species might suggest that maple may be the ancestral host plant. As a consequence, we have studied the potential impact of this pest on maples, and we used a molecular phylogeny of the genus to reconstruct the ancestral host use and patterns of host shifts of *Cameraria.*

Methods: We sampled leaves on *A. pseudoplatanus* in Austria, Switzerland and France to investigate the impact of *C. ohridella* in relation to the distance to infested horse chestnut and to the arrival of the insect. In addition, a molecular phylogeny of 20 species of *Cameraria* was reconstructed using 2 genes.

Results: Our results showed that *C. ohridella* is mainly found on *Acer* at the vicinity of heavily infested horse chestnut. Females oviposit large numbers of eggs on maple, in contrast to other broadleaved species, but more than 80% of the larvae die in the first two instars. Attack rate and host tree resistance strongly vary between localities and individual maple. Attacks seem to increase slowly with time. Optimization analyses suggest that *Acer* is likely to be the ancestral host plant of *C. ohridella*.

Conclusions: These results suggest that *C. ohridella* could adapt to *Acer* species in the near future.

A phylogenomic odyssey within Hymenoptera: the utility of ESTs for resolving key Apocritan relationships

Barbara J. Sharanowski, John A. Walker, S. Randal Voss, Michael J. Sharkey

University of Kentucky, Lexington, Kentucky, United States

Introduction: Superfamily relationships within Hymenoptera have been exceedingly difficult to resolve using conventional morphological and molecular markers. Genomic scale methods offer an alternative approach to phylogenetic reconstruction, typically overcoming incongruence between single-gene trees and providing increased nodal support.

Methods: We sampled over 2000 clones from cDNA libraries from 7 disparate Hymenopteran taxa. Expressed sequence tags (ESTs) were edited, cleaned of vector sequence, and clustered into contigs under rigorous parameters. To discover orthologous genes in other taxa, we compared these sequences with Hymenopteran and other insect ESTs in public databases using stringent criteria. These EST-derived markers were used to build a large concatenated multi-gene data matrix for a subset of taxa across the Hymenoptera. The concatenated dataset and individual gene matrices were analyzed using both Bayesian and parsimony techniques.

Results and Conclusion: We present a robust and well-supported hypothesis of Hymenopteran evolution at the level of superfamily and clarify several long-contested relationships among putative infraorders within Apocrita. Our results demonstrate the power of a phylogenomic approach for resolving deep evolutionary divergences within the Hymenoptera. Additionally, we show how EST-derived markers analyzed in a phylogenomic perspective offer a complimentary technique to more traditional phylogenetic methods that utilize denser taxon sampling.

Concentration and mixture interactions change the nitric oxide production patterns in the antennal lobe of *Manduca sexta*

Alan Nighorn

University of Arizona, Tucson, AZ, United States

Nitric oxide synthase, the enzyme that produces nitric oxide in response to a calcium signal, is present in the olfactory systems of almost every animal examined to date. We are using the moth, *Manduca sexta*, as a model system in which to investigate the function of nitric oxide in the processing of olfactory information. Using electrophysiological and optical recording methods we have found that NO is present at low levels at basal states and is actively produced in a glomerular pattern in response to odor stimulation. The odor-induced nitric oxide is apparently confined within glomerular borders and its pattern of production is dependent on the concentration and context of the odor stimulus. We find that increasing the concentration of some odorants results in a loss of activity in some glomeruli rather than the simple addition that is expected. We also find that the overall levels of odor-induced NO production may be context dependent. The responses of male moths to general plant odorants may be enhanced in the presence of female pheromone. These results suggest that nitric oxide functions as an important and highly dynamic modulator of antennal lobe neurons.

The present and future role of insect-resistant GM cotton in IPM

Steven Naranjo[1], John Ruberson[2], Hari Sharma[3], Lewis Wilson[4], Kongming Wu[5]

[1]USDA-ARS, Arid-Land Agricultural Research Center, Maricopa, Arizona, United States, [2]Department of Entomology, University of Georgia, Tifton, Georgia, United States, [3]ICRISAT, Patancheru, Andhra Pradesh, India, [4]CSIRO Plant Industry, Narrabri, New South Wales, Australia, [5]IPP, Chinese Academy of Agricultural Sciences, Beijing, China

Transgenic cottons producing Cry toxins from *Bacillus thuringiensis* (*Bt*) control lepidopteran pests and were first commercially grown in Australia, Mexico and the USA in 1996. As of 2007, six additional countries (Argentina, Brazil, China, Colombia, India, and South Africa) now grow *Bt* cotton on a total production area of over 12.2 million hectares. The technology primarily provides highly selective and effective control of bollworms, the most damaging pests of cotton worldwide. Between 1996 and 2005 the deployment of *Bt* cotton reduced the volume of insecticide active ingredient used for pest control by 94.5 million kg and increased farm income through reduced costs and improved yields by US$7.5 billion, with most of the benefit accrued by farmers in developing nations. Reductions in insecticide use have broadened opportunities for biological control and recent meta-analysis has demonstrated that Bt cotton has little or no effect on abundance and interactions among functional guilds of non-target arthropods. Most other pest management tactics in Bt cotton have remained largely unchanged. Several non-target pests have become more problematic in *Bt* cotton fields in some countries largely due to reductions in insecticide use for target pests. Pre-emptive resistance management has helped to preserve the efficacy of the technology. New products are in the pipeline to improve the effectiveness of genetically modified cotton cultivars for resistance to lepidopteran and other pests. Debate over food and environmental safety, regulatory oversight, and farming community welfare are likely to continue as the technology moves forward with new crops and new adopting countries.

Phylogeography of post-Plesitocene population expansion in a fungus-gardening ant and its microbial mutualists

Alexander Mikheyev, Tanya Vo, Ulrich Mueller

University of Texas, Austin, Texas, United States

Although biogeographic forces, such as historical climate-driven range shifts, greatly influence the present day population genetic structure of animals and plants, the extent to they affect microbial communities remains largely unknown. We examined the effect of post-glacial expansion on the population structure of the northern fungus gardening ant Trachymyrmex septentrionalis and compared it with that of its two microbial mutualists: the lepiotaceous fungal cultivars and antibiotic-producing Pseudonocardia bacteria. The ant population genetic structure showed a pattern of population expansion and, similar to many other North American taxa, was sub-structured into eastern and western phylogroups, separated by the Mississippi river drainage, and which likely originated in the Pleistocene. Although dispersal limitation, as evidenced by isolation by distance was present in all three symbionts, east-west subdivision structure was absent from the microbial mutualist populations. While neither the cultivar nor the Pseudonocardia genetic structure was correlated with that of the ants, they were significantly correlated with each other. These results show that biogeographic forces act differently on macro- and microscopic organisms, even in the extreme case when mutualists are vertically transmitted from generation to generation and share the same joint ecological niche. The population structure of the ants appears to be significantly influenced by historical climate change, biotic forces such as pathogen pressure and the structure of microbial populations.

Effects of tropical forest overstory diversity on biodiversity of ground dwelling ants in West Africa.

S. Sky Stephens[1], Mike Wagner[1], Paul Bosu[2]

[1]Northern Arizona University School of Forestry, Flagstaff, AZ, United States, [2]Forestry Research Institution of Ghana, Ghana, West Africa, Ghana

Introduction: Interactions between forest type or complexity and organism biodiversity and other environmental services are poorly understood for most forest types. Forest plantations are typically viewed as biological deserts, having reduced biodiversity. However, the current literature base on biodiversity in forest plantations is based largely on inappropriate comparisons. Most biodiversity and forest type assessments have been of exotic tree species monocultures to native forest conditions. To better assess biodiversity and forest type we compare a gradient of forest plantations including an exotic species monoculture, a native species monoculture, a six native species polyculture and an eleven native species polyculture.

Methods: We assessed ground foraging ants (Hymenoptera: Formicidae) as biological indicators of overstory tree species diversity in four experimental plantations in Ghana, West Africa using pitfall traps. Collections were made over a 48 hour trapping period during the wet and dry seasons.

Results: Traditional diversity indices show increases in diversity in native versus exotic species monocultures. However, a ten fold increase in overstory species diversity, native species monoculture to eleven native species polyculture, ant species diversity only increased by nineteen percent. Functional group assessment was performed and shows more distinct trends in ant response to overstory species diversity.

Conclusion: Biodiversity may be impacted through the manipulation of overstory tree diversity and species composition in forest plantations. Biodiversity is influenced more by overstory tree species composition than diversity and can be maintained, manipulated and managed as a forest plantation management objective.

Trait-mediated effects of termites and vertebrate herbivores in East-African savannas.

Alison K Brody[1], Todd M Palmer[2], Dan F Doak[3]

[1]University of Vermont, Burlington, VT, United States, [2]University of Florida, Gainesville, FL, United States, [3]University of Wyoming, Laramie, WY, United States

Introduction: Understanding what governs the distribution, diversity and abundance of species has been a central theme of ecology for decades. In semi-arid landscapes, termites are one of the most conspicuous and ubiquitous modifiers of habitats. Through their foraging and mound-building activities, termites directly modify the basal components of the ecosystems and indirectly change the foraging patterns of vertebrate herbivores. In so doing, they exert strong direct and indirect effects on entire communities. Although the importance of termites to the structure and function of African savanna communities is almost cliché, few hard data exist on the magnitude and mechanisms of direct and indirect effects of termites in these unique and threatened ecosystems.

Methods: I quantitatively demonstrate the importance of termites (*Odontotermes* sp.) to the invertebrate community, and dissect their direct effects in enhancing soils important to the diversity of host plants from indirect effects mediated through vertebrate herbivores.

Results: Invertebrate density is significantly higher on termite mounds than off mounds. Invertebrate diversity, however, is often lower on mounds than off-mounds. Host plant density and diversity follow these same patterns as well. The interactive effects among vertebrates and termites on invertebrate communities remain to be fully explored.

Conclusions: Termites directly affect plants by enhancing soil quality and indirectly affect entire communities through altering the density and foraging patterns of herbivores and predators. Teasing apart these direct and indirect effects is critical to our understanding of East African savannahs in particular, and to our understanding of food web dynamics in general.

Sexual selection, species isolation and genital evolution in *Ciulfina* praying mantids

Gregory Holwell

Macquarie University, NSW, Australia

The rapid and divergent evolution of male genitalia in animal species with internal fertilization is a commonly observed evolutionary trend. Three hypotheses have been suggested to explain this pattern: pleiotropy, species isolation (lock-and-key) and sexual selection. Whilst pleiotropy and species isolation lack strong support, there is growing evidence for sexual selection as the driving force behind genital evolution. Here I present the results of experiments that explicitly test both the sexual selection and species isolation hypotheses in the praying mantid genus *Ciulfina*. I will discuss the influence of both the shape and size of male genitalia on copulation duration, sperm transfer and fertilization success, and suggest that genital morphology is under sexual selection in these praying mantids. I also present data relating to the role of male genitalia in reproductive isolation between *Ciufina* species.

Small scale dispersal models and habitat selection of the Argentine ant, *Linepithema humile*

Paul Krushelnycky[1], Stephen Hartley[2]

[1]U.S. Geological Survey, Pacific Island Ecosystems Research Center, Haleakala Field Station, Hawaii, United States, [2]School of Biological Sciences, Victoria University of Wellington, Wellington, New Zealand

Local dispersal of insects is mediated by fine-scale variation in the physical environment. Quantifying this influence is difficult in many cases, due to complex dispersal patterns, gentle climatic gradients, and the confounding effects of strong biotic interactions. However, invasive ants often spread through budding, greatly simplifying dispersal patterns and in some cases clarifying the role of physical factors in shaping these patterns. At Haleakala National Park, Hawaii, two disjunct unicolonial populations of the invasive Argentine ant (*Linepithema humile*) have been dispersing in this fashion for over 40 years, producing patterns consistent with the diffusion model of spread. At the same time, an absence of strong predators or competitors, combined with steep climatic gradients at this locale, permit an analysis of the influence of abiotic variables such as temperature and rainfall on the rate and direction of this spread. We discuss how quantification of abiotic factors, as well as biotic factors that affect the physical environment, and the use of tools such as degree-day models can help in understanding both local behavior (e.g. nest site selection) and supercolony-level invasion dynamics. The ultimate goal of this small scale modelling effort is to develop better capacity for regional predictions of invasion patterns.

Insect biodiversity of the North Pacific area

Arkady S. Lelej, Sergey Yu. Storozhenko

Institute of Biology and Soil Science, Russian Academy of Sciences, Far Eastern Branch, Vladivostok, Russian Federation

Introduction: The problem of the biodiversity of the World and its regions is widely discussed. Among about 1.6 million described living organisms in the World, the insects are the most numerous (950,000 species).

Methods: The insect database of the Russian Far East (RFE) which is based on "Key to the insects of Russian Far East" (19 books, 1986-2007) was analysed by common statistical methods.

Results: Three regions in the North Pacific Area have almost the same number of species: RFE (c. 31000), Canada (c. 30000), and Japan (c. 29000). The southernmost boundaries of RFE and Canada have the same latitude (42^{o} N), resulting in similar climates and vegetation belts, which in turn strongly influence the distributions and diversity of organisms. The similar number of insect species for Japan, in spite of a much smaller area, results from the more southerly position of Japan (up to 23^{o} N). The insect fauna of RFE is represented by 631 families of 31 orders. The largest orders are Hymenoptera (72 families, 9000 species), Diptera (120 families, 8000 species), Coleoptera (114 families, 5500 species), Lepidoptera (81 families, 5000 species). The number of families and species strongly increases from north to south: in the tundra of Chukotka 200 families and 1100 species of insects occur, while in the nemoral landscapes of Sikhote-Alin Mts there are 600 and 22500 respectively.

Conclusion: The insect diversity of the large continental regions in the temperate zone generally depends on latitude rather than area.

A supercolony of Argentine ants spans southern Australia

Elissa Suhr[1], Dennis O'Dowd[1], Stephen McKechnie[2], Duncan Mackay[3]

[1]Australian Centre of Biodiversity, School of Biological Sciences, Monash University, Melbourne, VIC, Australia, [2]Centre of Environmental and Stress Adaptation Research, School of Biological Sciences, Monash University, Melbourne, VIC, Australia, [3]School of Biological Sciences. Flinders University, Adelaide, SA, Australia

Argentine ants can form expansive supercolonies that may contribute to their ecological success in introduced ranges. We investigated the colony structure of Argentine ants across southern Australia using microsatellite analyses and intraspecific aggression assays. Eight nests in each of three cities (Adelaide, Melbourne and Perth) spanning 2,800 km were sampled. Two nests from the native range and nine nests from other introduced ranges worldwide were also genotyped. Intraspecific aggression was completely absent between nest pairs within or between cities across Australia. Australian populations of Argentine ants were characterised by widespread genetic homogeneity and little genetic structuring within and between cities relative to source populations. Analysis of molecular variance (AMOVA) revealed that most variance was explained within nests (84.9%). Some continent-wide population structure was indicated by genetic differentiation between cities (10.7%), whereas little variation within cities (4.5%) was detected. A model-based clustering analysis of Australian samples identified three genetic clusters. Individuals had partial membership in multiple clusters and nearly always shared similar membership coefficients within cities. However, one nest in Perth clustered with Adelaide and an admixture between Adelaide and Perth was suggested at another Perth nest. When Australian and potential source genotypes were compared, Melbourne and New Zealand clustered together but marked differences occurred with other samples. Overall, Argentine ants in Australia form an expansive supercolony characterised by absence of aggression and effective local gene flow but limited gene flow across the continent.

Preference and performance of the six toothed bark beetle *Pityogenes chalcographus* L. (Coleoptera : Scolytinae) on native and exotic Pinaceae species in France

Coralie Bertheau, Geraldine Roux-Morabito, François Lieutier

Universite, Orleans, France

Introduction: *Pityogenes chalcographus* L. (Coleoptera : Scolytinae) is one of the important bark beetle species in European forests where it causes damage mainly on *P. abies*. It is considered as an oligophagous insect recorded on indigenous and exotic Pinaceae. This work was carried out on different host trees species belonging to *P. chalcographus* host range. It aimed at firstly estimating the preferences and the performances of the insect on different host species, and secondly testing the role of the between tree taxonomic relatedness in the possibilities of beetle adaptation to various hosts.

Methods: Choice and no-choice assays were set up under laboratory conditions, using logs of five Pinaceae species belonging to *P. chalcographus* host range: two indigenous species (*Pinus sylvestris* L. and *P. abies*) and three exotic north American species (*Pinus contorta* Dougl., *Picea sitchensis* (Bong.) Carr. and *Pseudotsuga menziesii* Mirbel (Franco)). Attack densities, fecundity, survival rate and brood productivity were analyzed, and a morphometric analysis of the emerged adults was performed.

Main Results: *P. abies* was the most attacked host species and *Pinus* species the least ones. In all assays, fecundity and survival rates were significantly higher in *Picea* species than in other species. Brood productivity was the highest in *P. abies*. No difference in beetle size was observed between host species but males were significantly wider and shorter than females.

Conclusions: *P. abies* was both the preferred and the most suitable host species. The closest relative *P. sitchensis* appeared the best substitution host.

Spatial processes in predator-prey dynamics and their importance for biological control of phytophagous pests.

Gösta Nachman

University of Copenhagen, Copenhagen, Denmark

Introduction: Modelling is a popular tool to assess the role of natural enemies in biological control. However, many models assume that herbivorous prey and their natural enemies are homogeneously distributed within a crop, whereas most field studies actually show that both prey and enemies are patchily distributed. This means that predators locally may be confronted with densities of prey that differ significantly from average densities. Many predator species therefore tend to concentrate their searching efforts to areas where encounters with prey are most likely, although this also leads to more intensive intraspecific competition among predators.

Methods: In order to understand the consequences of spatial interactions on predator-prey dynamics, a spatially explicit model (called *DynaMite*) has been developed. It simulates biological control of an arthropod phytophagous pest (two-spotted spider mites) by means of a specialist predator (a predacious mite). The model incorporates prey and predator aggregation at two different spatial scales (within and between plants).

Results: Simulations show that aggregation of predators has a profound effect on their capacity to suppress the prey within individual plants, but increases the risk of local extinctions of both species, which in turn may destabilize the system at the larger (regional) scale. The rate of movement of predators between plants plays a key role in achieving optimal control.

Role of antennae in termite grooming behaviour

Aya Yanagawa[1], Fumio Yokohari[3], Kazuhiro Iiyama[2], Chisa Yasunaga-Aoki[2], Susumu Shimizu[2]

[1]Institute of Biological Control, Graduate school of Bioenvironmental Science, Kyushu University and Research Fellowship of the Japan Society for the promotion of Science for Young Scientist, Fukuoka, Japan, [2]Institute of Biological Control, Graduate school of Bioenvironmental Science, Kyushu University, Fukuoka, Japan, [3]Division of Biology, Department of Earth Science, Faculty of Science, Fukuoka University, Fukuoka, Japan

It is well known that social insects have been developed the social strategy, which provide them great benefits. Likewise, in disease resistance, there are some reports about the advantage of sociality, however it has not been identified enough.

We have studied disease resistance based on the social strategy using termite, *Coptotermes formosanus* Shiraki and entomopathogenic fungi. Since termites live in high density population and a high humidity habitat which has suitable properties for fungal infection, fungal diseases can be quite lethal. However, even though the soils contain resident populations of entomopathogenic fungi, it is difficult to find fungal epizootics in termite populations. Previously, we have suggested the termite protect themselves from entomopathogenic fungus by mutual grooming behaviour. Nest mates remove of foreign bodies, such as fungal conidia, from the cuticle and throw them away through licking the surface of cuticle by glossa. Then, we wondered what elicit them to this behaviour.

To make clear this, the role of antennae in grooming behaviour was examined since antennal contact is important as introduction of other social behaviours. Behavioural experiments were applied to examine whether termite antennae were actually involved in the function of grooming behaviour, and electrophysiological methods were applied to examine whether antennae can detect the entomopathogenic fungal odour. The result of our study indicates that termite antennae have a role to find foreign organisms on their body surface by odour, however it seems that it is not the only method to detect foreign organisms. (238)

Replacement cost estimates of insect pollination services

Mike Allsopp[1], Ruan Veldtman[2], Willem De Lange[3]

[1]Plant Protection Research Institute, Agricultural Research Council, Stellenbosch, South Africa, [2]South African National Biodiversity Institute, Cape Town, South Africa, [3]Council for Scientific and Industrial Research, Stellenbosch, South Africa

Introduction: The importance of insect crop pollination to commercial agriculture is unequivocal. However, whether this service is largely provided by wild pollinators (as genuine ecosystem service) or managed pollinators (as commercial service), and which of these requires immediate action amidst reports of pollinator decline, remains contested.

Methods: Traditionally the value of these services is expressed as the proportional dependence of a crop's total production value, with a portion assigned to managed pollination. These methods either under-estimate (by equating pollination service values to the direct cost of the service) or over-estimate (by equating pollination services values to a proportion of total production value) the service value. In addition, the use of general insect dependence factors and the proportional allocation to managed pollinators have been criticised as being neither based on published data sources nor being regionally specific. We propose and apply the notion of ascribing a more accurate value to the service by calculating the cost to replace it. We employed adjusted insect and managed pollinator dependence factors to estimate the value of replacing insect pollination services for the Western Cape deciduous fruit industry of South Africa.

Results: Using pollen dusting and hand pollination as suitable replacements, we show that current market prices under-value the service, while traditional proportional value estimates is seen to be inflated.

Conclusion: Market prices for pollination service do not reflect the true value of pollination service. This market failure could promote unsustainable landscape use as both managed and wild pollinators are dependent on natural and semi-natural landscapes for forage. Credible valuation of pollination services will aid in justifying investment in their conservation.

Attraction of nectar-seeking mosquitoes to inflorescence odours of *Silene otites* (Caryophyllaceae)

Umma Salma Jhumur[2], Katrin Silke Jahreiß[2], Stefan Dötterl[2], Andreas Jürgens[1]

[1]University of KwaZulu-Natal, Pietermaritzburg, South Africa; [2]University of Bayreuth, Bayreuth, Germany

Introduction: Although mosquitoes are known to visit diverse flowers for nectaring, little is known about the specific cues used by mosquitoes for finding nectar plants. In several investigations flower odours were described as effective attractants for mosquitoes, however, in none of the studies the compounds responsible for attraction were identified. An interesting system to study the role of floral volatiles for attracting nectar-seeking mosquitoes is *Silene otites* (L.) Wibel (Caryophyllaceae), one of only two plant species world-wide in which mosquitoes have been described as effective pollinators.

Results and Discussion: When offering naïve mosquitoes inflorescences of *S. otites* they immediately fly towards them, land on them, and suck nectar. Most of the odour compounds of *S. otites* are electrophysiologically active to both night-active *Culex pipiens molestus* and day-active *Aedes aegypti*. In electroantennographic studies with the 13 most common and abundant odour compounds *C.p. molestus* males and females responded similarly to dilution series but the strength of the responses differed among compounds. Linalool oxide and linalool evoked the strongest responses in male and female mosquitoes, and (Z)-3-hexenyl acetate was strongly active in females. Wind tunnel bioassays with antennal sensitive compounds and *C.p. molestus* revealed that mosquitoes responded to 14 compounds in different magnitudes (65-20%). Furthermore, the significantly higher attraction of conditioned mosquitoes compared to unconditioned ones in wind tunnel bioassays shows that mosquitoes can learn floral volatiles to find their nectar host plants.

Multiple predators sharing prey: Consequences of microhabitat specialization

Maurice W. Sabelis[1], Arne Janssen[1], Izabela Lesna[1], Nayanie S. Aratchige[1], Sara Magalhaes[1], Alexis Onzo[2], Rachid Hanna[2]

[1]University of Amsterdam, Amsterdam, Netherlands, [2]International Institute of Tropical Agriculture, Cotonou, Benin

Introduction: Most species of herbivorous arthropods incur the risk of being eaten by more than one species of predator. Despite sharing the same prey, these predator species may coexist by occupying otherwise separate micro-habitats. While intraguild predation may drive niche specialization (and avoidance of intraguild competitors), its occurrence decreases in frequency with progress in specialization. We therefore predict intraguild predation to play a less important role and multiple predator species to affect the density of their shared prey in a near-additive way.

Methods: To test this prediction we analyze various two-predator-one-prey (=herbivore) systems on plants. The predators are two species of phytoseiid mites frequenting different parts of the same plants (e.g. flower *vs* leaf of a sweet pepper plant; apex *vs* leaf of a cassava plant ; external *vs* internal part of a bulb; different areas under the perianth of a coconut) and we investigate how these predator species, either together or alone, affect the shared prey (thrips, spider mites, rust mites). Moreover, we analyze how the prey chooses between plant parts harbouring different predator species.

Results and Conclusions: From these studies we conclude that the two predator species together act on prey suppression in an additive way and – when at least one predator species has no access to the microhabitat of the other – they may even act in a synergistic way.

Factors promoting Argentine ant colony expansion

Jules Silverman, Robert John Brightwell

North Carolina State University, Raleigh, North Carolina, United States

The success of Argentine ant, *Linepithema humile*, invasions has been attributed to a combination of genetic, behavioral and ecological factors. We have explored intercolony interactions and the contribution of stable food sources as factors contributing to invasion success.

Unlike reports from most regions within its introduced range, Argentine ant colonies in our study zone, the southeastern United States, are relatively small and discrete and display varying levels of intraspecific aggression. We predicted, however, that if environmental constraints, e.g. low winter temperature, were relaxed and colony boundaries expanded fusion would occur between colonies that ultimately made contact. In laboratory and field experiments, most paired mutually aggressive colonies did fuse as evidenced by queen movement between nests. We found a direct relationship between both genetic and cuticular hydrocarbon similarity and colony fusion success.

We also determined that Argentine ant colony expansion is, in part, mediated by available food. When sucrose-containing stations were positioned along a transect into uninfested deciduous forest adjacent to infested urban landscape ants moved at least 50 meters into the forest and thereafter retreated when the food was removed. Also, *L. humile* moved nests towards or away from the base of trees containing honeydew-excreting scale insects, depending on whether access to scales was permitted.

Using terrestrial arthropods to refine and define forest management and conservation in Eastern Canadian Boreal forests

Timothy Work, Christopher O'Connor, Annie Hibbert, Simon Paradis

[1]Université du Québec à Montréal, Montréal, Québec, Canada, [2]CRSNG-UQAM-UQAT Chaire d'aménagement forestier, Rouyn-Noranda, Montréal, Québec, Canada

Introduction: The preservation of biodiversity and ecosystem functions within managed forests has been widely advocated by proponents of sustainable forest management. However, how best to implement and integrate silviculture and conservation objectives remains largely dependent on forest type, natural disturbance regime and species-level differences among arthropod communities. Within Eastern Canadian boreal forests, variations of both clear cutting and partial cut harvesting have been proposed as a means to reflect the variability of stand structures that remain following natural wildfires or large-scale insect outbreaks.

Methods: Here we present a synthesis of recent studies aimed at understanding how these newly proposed silvicultural strategies affect arthropod communities with an emphasis on the responses of soil microarthropods (Collembola), saproxylic organisms within both coarse woody material (CWM) (Diptera and Coleoptera) and recently burned stands (Coleoptera) and higher order consumers (Coleoptera: Carabidae and Staphylinidae, Araneae) to changes in overall stand structure and specific within-stand 'legacy' elements.

Results: These studies indicate that arthropods associated with detrital inputs (i.e (litterfall, snags and CWM), decomposition or detrital-based food webs are sensitive to changes in forest structure. These changes range from species-specific responses to factors relating directly to detrital input or microbial activity to overall community level differences based on interactions between harvesting and time since fire.

Conclusions: We believe these responses can be actively included in forest and conservation planning to define a subset of 'detrital-based' forest management that integrates long-term temporal impacts of silviculture with the functional roles of arthropod biodiversity.

Enemy-induced responses and their indirect effects on arthropod communities on plants

Maurice W. Sabelis, Arne Janssen, Izabela Lesna, Merijn Kant

University of Amsterdam, Amsterdam, Netherlands

Introduction: Interactions between plants, herbivorous and predatory arthropods depend on the direct effects of enemies on their victims, but also on the indirect effects induced by the enemy in its potential victim and thereby on the tritrophic system as a whole. For example, herbivorous arthropods may not only kill plants, but they may also alter the plant's antiherbivore responses and the extent to which plants facilitate the foraging of the herbivore's enemies (so called indirect plant defense). Another example is that predatory arthropods may not only kill herbivorous arthropods, but they may also alter the herbivore's antipredator responses and the degree to which the herbivore alerts the plant's direct and indirect defenses.

Methods: To analyse these effects and their consequences for arthropod communities we made good use of plant hormones that trigger direct and/or indirect plant defense responses and of plants in which genes underlying these defense responses are silenced or overexpressed.

Results and Conclusions: We review recent results of experiments with various tritrophic systems involving predatory mites, herbivorous mites or thrips, and plants (tulip bulbs, cucumber, sweet pepper, tomato) and show that induced responses can have dramatic effects on the structure of arthropod communities.

Remote Diagnostics – research and identifications from afar?

Michael Schauff

Plant Sciences Institute, USDA, ARS, Beltsville, MD, United States

With continuing globalization and increase availability of high speed internet access several groups have begun to develop technology to remotely view, manipulate, and photograph specimens. This technology offers several advantages over current practices In particular, these devices may cut shipping costs, allow for rapid examination of specimens during times of crisis, and make available archives of images that will help reduce the need to repeatedly examine valuable and fragile types and other specimens. It may also make it feasible for regulatory personnel to remotely sort and identify some specimens without the need for an on-site investigator present. One recently developed instrument is highlighted as an example of where this technology is headed. While still limited in some aspects this instrument is able to provide many of the functionalities required of a remotely operable platform. Many challenges remain. Among these are staffing issues, information technology security concerns, access rights of users, storage and archiving of images, and hardware costs.

Conclusion: Remote diagnostics has the capability to mitigate many of the traditional and most difficult obstacles to specimen-based research and identification of insects. While many challenges remain current work has shown the viability of the concept.

Predator-predator interactions: Impact on biological control of a shared prey pest in Africa

Alexis Onzo, Rachid Hanna, Maurice W. Sabelis

[1]International Institute of Tropical Agriculture, Cotonou, Benin, [2]University of Amsterdam (IBED), Amsterdam, Netherlands

Introduction: The issue of introducing single or multiple natural enemy species for classical biological control has been an area of intense inquiry in biological control of cassava green mite *Mononychellus tanajoa* in Africa. This is because this herbivorous mite is preyed on by several predatory mites including *Typhlodromalus aripo, Amblydromalus manihoti* and *Euseius fustis.*

Methods: In series of screenhouse and field experiments where predator species composition was manipulated at plant level, we determined the effects of single and two predator species on suppression of *M. tanajoa* populations and on population dynamics of predators. These trials were supplemented with field surveys.

Results: In screenhouse, either *T. aripo* or *A. manihoti* was sufficient for suppressing *M. tanajoa* populations, with *A. manihoti* being more efficient at high initial prey densities and *T. aripo* more efficient at low initial prey densities. Field surveys showed that presence of other predators, in addition to *T. aripo*, was associated with lower *M. tanajoa* densities. *T. aripo* densities were generally positively affected by the presence of other predators. In manipulative field trials, *M. tanajoa* densities were also relatively lower on plants harboring the key predator *T. aripo* and either of *A. manihoti* or *E. fustis* than on plants with one predator alone. Moreover, no predator species was negatively affected by the co-occurrence of the others.

Conclusion: Suppression of *M. tanajoa* populations was enhanced by the co-occurrence of *T. aripo* and other predators. Two predator species are therefore better than one for biological control of *M. tanajoa* in Africa.

Recognition cues for cooperation and conflict in ants: Interplay between uniformity and variability of cuticular hydrocarbons

Jelle van Zweden

University of Copenhagen, Copenhagen, Denmark

Social insects are the prime evolutionary examples of cooperation and therefore a central model system to test predictions of kin selection theory. Kin recognition is required for kin selection to occur. However, when multiple genetic lineages are present within the colony, accurate information on kinship may lead to internal conflict. The relative influence of genetic background on the variation in recognition cues has remained largely unresolved so far. I used a cross-fostering design to disentangle the different sources of variation in the hydrocarbon profiles of ants, and to obtain relative heritability measures for the different compounds. The results show that the relative abundance of linear alkanes can be highly variable within colonies and that these are the least heritable compounds on a colony level. In contrast, branched hydrocarbons are more heritable components and these are the compounds that are homogenized among nestmates. Hence, only parts of the hydrocarbon profile are uniform among nestmates and can be used for cooperation, whereas other parts remain variable, so that potentially these can be used for within-colony discrimination.

Is there a gradient of predation pressure on specialist caterpillars at different elevations in the North Eastern Andes of Ecuador?

Genoveva Rodriguez-Castañeda, Lee A. Dyer

Tulane University, New Orleans, United States

Introduction: Predation is thought to change as assemblages of predators and abiotic conditions change. We compared survival rates of *Eois olivacea* (Geometridae: Laarentinae) and the associated changes in predator assemblages across a complete gradient of elevation (400-3200m), on both native and experimentally introduced plants.

Methods: In two separate experiments, *E. olivacea* were exposed to natural predator assemblages for 24 hours at different elevations and in forests that varied in ant abundance. In the first experiment, the caterpillars were placed on their natural host plants, which were transplanted one hour prior to the experiment. In the second experiment, caterpillars were placed on a leaf from their natural host plant species, then this leaf was attached to *Piper* plant species that occurred on the understory of the different elevations.

Results: We did not find a significant linear elevational gradient in predation rates for *E. olivacea* when the caterpillars were placed on their native host (predation rate =52.059-0.0062*(elevation), r^2=0.043, P=0.15). However, for the second experiment, predation first decreased with elevation (400-1500m) (predation rate =110.355-0.0275*(elevation), r^2=2.94, P=0.0001) and then increased from 1600-2600m. Predation pressure was not significantly associated with ant presence/absence.

Conclusions: Predation gradients in this study were determined by the native community of mostly specialized predators associated with the local *Piper* species and not by the presence/absence of ants at the different sites.

The role of ecological stoichiometry in outbreaks of forest Lepidoptera

Eric Lind, Pedro Barbosa

University of Maryland, College Park, MD, United States

Ecologists have explained outbreaks of caterpillars in temperate forests using a variety of models to capture the temporal and spatial dynamics of pest populations. Dispersal patterns, natural enemy response, and disease are known to regulate these outbreaks at various scales. Yet a comprehensive understanding of how and where outbreaks begin still eludes researchers. Ecological stoichiometry, an emerging area of ecological theory, may aid in understanding outbreaks by examining the intersection between insect growth rates and elemental nutrient requirements, and plant elemental nutrient content. Growth rates of herbivorous insects are known to be constrained by the nutrient levels in their food, specifically by the high C:N or C:P ratios in plants, but maximum growth rates and elemental ratios both vary between insect species. Under the growth rate hypothesis of ecological stoichiometry, phosphorus may be especially important for maximizing individual growth rate, yet it has not been as well studied as nitrogen in forest insect systems. We measured elemental ratios of outbreak and non-outbreak Lepidoptera in eastern North American temperate forests to determine whether they differed in constitutive elemental ratios. We also examined the spatial pattern in foliar C:N:P in a riparian forest tree, sampling leaves during a localized outbreak of a forest pest (the fall cankerworm *Alsophila pometaria*). Both sets of data suggest the inherent nutritional mismatch between caterpillars and their host plants is more dynamic than has previously been recognized, and that the spatial variability of the availability of nutrients, especially phosphorus, may add to an understanding of where, and with which herbivores, outbreaks occur.

Breeding systems, dispersal and mate choice in the Formosan subterranean termite

Claudia Husseneder[1], Edward Vargo[2]

[1]Louisiana State University, Baton Rouge, Louisiana, United States, [2]North Carolina State University, Raleigh, North Carolina, United States

Introduction: A subterranean termite colony is initiated by a monogamous pair. The pair's fat reserves sustain the incipient colony. Partner relatedness determines the degree of inbreeding within the colony. Therefore, body size and relatedness of reproductives are expected to play important roles in determining colony founding success. We tested whether swarming individuals select partners according to size and whether they avoid pairing with relatives during tandem running.

Methods: From five swarm aggregations in New Orleans, Louisiana, both tandem pairs and single individuals were collected and their weights and head widths were recorded. Degrees of relatedness were determined by microsatellite genotyping.

Results: Males running in tandem with females had larger heads than single males. Weights of tandem running partners were positively correlated as were head widths. Pairing was random with respect to relatedness, showing no evidence of kin avoidance. Interestingly, females forming tandems with males had a higher degree of heterozygosity than females that remained single. Although there was no kin discrimination during partner selection, there was little inbreeding due to long dispersal distances and due to genetic differentiation between the sexes. The dispersal distance of alates was sufficient to provide mixing of an average of 13 colonies within swarm aggregations. Genotypic frequencies differed significantly between males and females. This could not be explained by sex-biased dispersal but by sex-biased investment depending on colony breeding structure. Inbred colonies produced predominantly males, while outbred colonies produced predominantly females. This discrepancy could be caused by the pairing advantage of heterozygous females.

Where being green, profitable, and efficacious meet structural IPM: California, USA

Vernard Lewis

UC Berkeley, Berkeley, California, United States

The term pest control has evolved over the decades. Beginning in the early 1900's, replacement terms like pest eradication, integrated control, and systems control filled the academic and applied literature. More recently, the most widely accepted term is integrated pest management (IPM). Traditionally, the activities surrounding IPM where dominated by researchers, entomologists, agriculturists, and providers of natural enemies of pest populations. Today, stakeholder groups have grown and include urban homeowners, environmental groups, water quality, alternative and non-chemical suppliers, and well as traditional pest management service provides and manufacturers. Definitions that include urban stakeholders, assumed simple to define, have been proven demanding to achieve. California has a powerful economy, rated as high as seventh in the world and demands for protection for pests is great. However, additional responsibilities include being "green" imply being safe to the environment and non-target organisms. Additional regulatory oversight for new policies has placed a considerable demand on commercial service providers to be in compliance, yet all the while joggling budgets and profits. For today's presentation, using my entomological/research perspective, I will give specific examples on how the mandates of being green, efficacious, and profitable interplay with the IPM practices being offered to consumers in California. My hope is to help along the dialog among the world's urban and other stakeholder groups as we move towards pest management strategies that are effective, affordable, locally relevant, and take into consideration the many sensitive environments that occur globally.

Evolution and co-evolution of *Eurosta solidaginis* gall morphology with its host plant and natural enemies

Timothy Craig, Joanne Itami

University of Minnesota Duluth, Duluth, Minnesota, United States

Introduction: *Eurosta solidaginis* varies geographically with galls being more spherical, and having larger diameters in the prairie than in the forest biomes. In addition there is complex variation within biomes. *Eurosta* gall morphology is the result of the interaction of the insect genotype, its host plant, and the environment. The host plant, *Solidago altissima*, has diverged into different subspecies in the two biomes, and the fly populations into two host races.

Methods: Using common garden and reciprocal transplant experiments we measured the impact of host plant subspecies, and the geographic race of the fly on gall size and shape. We also determined whether populations of the parasitoid wasp, *Eurytoma gigantea*, and the inquiline beetle, *Mordellestina convicta*, were locally adapted.

Results: Gall diameter was strongly influenced by the host race of the fly and the environment, but not the plant subspecies. Gall shape was influenced by both the fly host race and the host subspecies but not the environment. *Eurytoma gigantea* showed evidence being locally adapted to the prairie galls each host race had a preference for their local host, and the prairie host race had longer ovipositors that are adaptive for reaching larvae in bigger galls. The inquiline did not show evidence of local adaptation, as both populations performed better on prairie galls.

Conclusion: The gall-maker, the host plant, and the parasitoid show evidence of having a strongly coevolved relationship.

Insect repellents and personal protection as components of integrated disease management

Daniel Strickman[1], Mustapha Debboun[2]

[1]US Department of Agriculture, Beltsville, Maryland, United States, [2]Academy of Health Sciences, US AMEDD Center & School, Houston, Texas, United States

Topical insect repellents seem like a logical choice for protection from arthropod-borne pathogens: they are safe, they are effective, and they target the objective precisely. Despite these apparent advantages, repellents have rarely been used as an important part of programs to protect the public from malaria, dengue, or other important diseases associated with arthropods. The challenges for efficient use of repellents include the difficulties of distribution, individual behavior, cosmetic qualities, and quality assurance of performance. These problems must be addressed in order to truly integrate the use of repellents into an efficient disease management system. At their best, repellents could make a major contribution toward efforts to break the chain of transmission at its weakest links. For non-zoonotic pathogens, the most effective strategy might be targeted application of repellents to those individuals either most susceptible to infection or most likely to serve as reservoirs of infection. For zoonotic pathogens, the thoroughness with which repellents are used should be in proportion to the number of bites experienced by the individual.

The PRONTI species selection method: Can this tool be used for risk assessments with biological control agents?

Jacqui Todd, Louise Malone, Padmaja Ramankutty, Emma Barraclough

HortResearch, Auckland, New Zealand

Introduction: The PRONTI (priority ranking of non-target invertebrates) species selection method has been developed for use in the problem formulation stage of environmental risk assessments of new environmental stimuli. The selection method is a computer-based tool that produces prioritised lists of species, ranked according to five commonly used selection criteria: (1) potential hazard; (2) potential exposure; (3) environmental impact of the species being affected by the new stimuli; (4) anthropocentric value; and (5) testability.

Methods: The selection method is driven by a basic hypothesis of the risk posed by the new stimuli to each invertebrate in the receiving ecosystem. Information on the biology of each species found in the receiving ecosystem is entered into a specially designed database and combined with information on the potential impacts of the new stimuli on each species. A "score" is then appointed to each piece of information, based on its usefulness for meeting each of the five selection criteria under the influence of the base hypothesis. The scores are then combined, using the model, to produce a final PRONTI score for each species. The flexibility of this system should allow it to be used for any stimuli in any agro-ecosystem. Can the benefits of biological control agents be included in the model?

Results: The PRONTI scores have been used to list the species from highest to lowest priority for biosafety testing with hazardous new stimuli.

Conclusions: Modifications that will allow the method to be used for biological control agents will be discussed.

Insects and technology

Arnold van Huis

Laboratory of Entomology, Wageningen University, Wageningen, Netherlands

Biomimicry uses designs and processes in nature to solve human problems. The iridescent blue *Morpho rhetenor* butterfly is visible over a distance of more than half a km, and is attributed to photonic structures formed by discrete multilayers of cuticle and air. The striking optical effect of such nanometre-scale architectures can be used in the paint and coating industry. The elastic properties of resilin, a protein in wings and legs of e.g. fleas, could be used to repair damaged arteries. Dragline silk from spiders is stronger than nylon and steel fibres and can be used to manufacture bulletproof vests, surgical thread, micro-conductors, and optical fibres. Termite mounds captures and manages wind so that it supports nest homeostasis. The complex network of tunnels keeps the heat, humidity and air quality at an optimum. This architecture can be used to design the eco-houses of the future. Google's PageRank algorithm follows the principle of ant trails. Swarm intelligence of social insects is the collective behaviour of independent agents, each responding to local stimuli without supervision. This feature of social insects is being used in robotics and nanotechnology, molecular biology and medicine, traffic and crowd control, and military tactics. The olfactory sensitivity of wasps or bees is at the level of parts per trillion. Wasps can be trained to detect certain compounds. This ability can be used to design cheap ultra-sensitive, flexible and portable odour detectors with wasps to find explosives, drugs, plant diseases, cancer, and tuberculosis.

Reflections and evidences on the present status of biological control of arthropod pests

Gennaro Viggiani

Dipartimento di Entomologia e Zoologia agraria; Filippo Silvestri - Università degli Studi di Napoli, Federico II, Portici, Italy

During the last two decades new tools and methodologies currently available, such as a few entomopathogenic agents and some natural products, suggested several changes in the original concept of biological control.

In the same period, several “chair-authors” started, first, to analyze the literature data on biological control projects concluding that most of them were unsuccessful, and then fearing biological and ecological risks. In particular, matters of concern were the conservation of biological diversity and consequently the accidental introduction of entomophagous species causes environmental risks. Matters of debate are also the methods used for evaluating the potential of biological control agents and their efficiency. In this context of general criticism, rarely based on precise facts, the increase of rigorous procedures and regulations for the importation of exotic entomophagous species do not favour the accomplishment of classical biological control projects against arthropod pests. Even the host specificity of an entomophagous species can avoid any ecological effect. But this “risk”, that is in the balance of nature, should not prevent the benefit derived from the introduction in new areas of predators and/or parasitoids. A classical project of biological control can not be evaluated in the same manner of inoculative and inundative releases for several reasons (long term and expanding area effect, heterogeneous environmental conditions, etc.). The most recent cases study of biological control carried out in Italy are discussed.

Leafhopper host plant associations for egg parasitoids (Hymenoptera: Mymaridae and Trichogrammatidae) in the vineyard agroecosystem of Italy

Gennaro Viggiani

Dipartimento di Entomologia e Zoologia Agraria, Università degli Studi di Napoli, Portici, Italy

During last five years a study was carried out in order to improve the knowledge on the functional biodiversity that can help the natural control of the grape vine leafhoppers. Using yellow sticky traps and samplings on *Vitis* spp., *Rubus ulmifolius*, *Salix* spp., *Ficus carica, Lonicera* spp. and *Ulmus minor* with parasitized eggs, several thousands of parasitoids were obtained and identified. The complex of parasitoids obtained from leaves and twigs was represented by *Anagrus atomus* (Linnaeus), *A. ustulatus* Haliday, *Stethynium triclavatum* Enock (Mymaridae), and *Pseudoligosita pallida* (Kryger) (Trichogrammatidae). The ratio between the *Anagrus* species changes in relation to the leafhopper host plant associations. The dominant species of *Anagrus* obtained from *Vitis* and *Rubus* in Northern, Central and Southern Italy was *A. ustulatus*. From *Ulmus* leafhoppers both species of *Anagrus* were identified, yet in this case the dominant egg parasitoid was the trichogrammatid *P. pallida.* Only *Anagrus*, mostly represented by *A. atomus,* have been obtained from *Ficocyba ficaria* (Horváth) which develops from late autumn to spring on *Lonicera* spp. and then on *Ficus carica*. An important source of *S. triclavatum*, egg parasitoid of *Empoasca* spp., has been found in *Salix* spp. On these plants the mymarid reproduces from spring to autumn on *Empoasca decedens* Paoli. Several phenological observations carried out in Southern Italy on *A. atomus* and *A. ustulatus* confirm that in this area both species can overwinter also as adults and continue to reproduce on developing hosts. In this habitat a wide complex of leafhopper host plant associations can provide in spring the antagonist biodiversity of potential pests that can spread in the vineyards.

Linking habitat use to range expansion rates in fragmented landscapes: a metapopulation approach

Robert Wilson[1], Zoe Davies[2], Chris Thomas[3]

[1]University of Exeter, Penryn, United Kingdom, [2]University of Sheffield, Sheffield, United Kingdom, [3]University of York, York, United Kingdom

Introduction: Insect geographic ranges are limited by temperature at high latitudes, where climate change is expected to lead to range expansions. However, documented expansions are largely restricted to habitat generalist and dispersive species. Therefore, techniques are required to identify the factors that limit range expansions by specialist species breeding in fragmented landscapes.

Methods: A metapopulation model (Incidence Function Model, IFM) was used to test effects of habitat use and landscape-scale habitat availability on patterns and rates of range expansion in the butterfly *Hesperia comma*. The model was applied to the species distribution between 1982 and 2002 in five habitat networks at its high latitude margin in the UK.

Results: Range expansion rates depended on the area and connectivity of suitable habitat, and were well-predicted by IFM modelling. Habitat availability for *H. comma* has increased associated with conservation management and climate change, but despite increased local population sizes the regional distribution of the species lags behind the distribution of suitable habitat. Landscapes lacking in habitat act as barriers to colonization, but long-distance dispersal events may lead to metapopulation state changes when formerly vacant networks are colonized.

Conclusions: Metapopulation models represent a promising approach for predicting rates of range expansion and for identifying landscapes where environmental change or conservation interventions could have the most significant effects on species distributions or persistence.

Passive ventilation in large termite mounds, and implications for human construction methods

Rupert Soar, Henk Versteeg, Weratunga Malalasekera, Haitham Abou-Houley

Loughborough University, Loughborough, Leicestershire, United Kingdom

The TERMES project [www.sandkings.co.uk] is in its final stage and brings together researchers in Entomology, Physiology, Construction and Mechanical Engineering. The project has sought to understand termite architecture (specifically in *Macrotermes michaelseni*) and the underlying function of mound ventilation and internal environmental regulation through structural homeostasis. The project has used 3D imaging and reconstruction techniques to capture both internal and external topology at millimetre scale resolution. Computational fluid dynamics modelling techniques have been applied to the model to explore mound skin permeability, the effects of highly localised perturbations, local and global convective flow within the structure and a simplified model of the internal reticulum to identify the functional components which make up the ventilation system. These will be described and their implication discussed.

Our ultimate objective is to seek novel passive methods which can inform modern construction practice in the face of energy concerns and recycle/re-use demands.

Individual variation in queen pheromone response is correlated with ovariole number in worker honey bees

Sarah Kocher, Christina Grozinger

North Carolina State University, Raleigh, NC, United States

Introduction: In honey bees (*Apis mellifera*), the reproductive queen produces a pheromonal signal that maintains worker sterility and is critical for colony social organization. A subset of this pheromone, a 5-component blend known as queen mandibular pheromone (QMP), produces many of the same effects as a live queen. QMP attracts workers from a short distance (retinue response), inhibits the rearing of new queens, inhibits worker ovary development, modulates age-related division of labor, and alters learning and memory. Despite the fact that queen pheromone plays such a critical role in honey bee social behavior, there is significant variation in QMP sensitivity both within and between colonies and subspecies.

Methods: This study examines the link between variation in pheromone response and ovariole number – a predictor of reproductive potential. The retinue response of individual bees from multiple colonies was scored over several days. Worker ovaries were then dissected and counted.

Results: We identified significant variation in QMP responsiveness among colonies, but also among individual workers within each colony. Individuals with a low pheromone response score had significantly more ovarioles than individuals with a high pheromone response score.

Conclusions: These results suggest that individuals with greater reproductive potential are less responsive to QMP, thus providing a link between pheromone response and reproductive potential in worker honey bees. Future studies will attempt to identify the molecular basis of this genetic variation and examine the evolutionary history of selection on this ecologically-relevant trait.

The impact of diet on immune function and disease resistance in *Spodoptera* caterpillars

Kenneth Wilson[1], Sonia Povey[1], Sheena Cotter[2], Kwang Pum Lee[3], Stephen J. Simpson[4]

[1]Lancaster University, Lancaster, United Kingdom, [2]Cambridge University, Cambridge, United Kingdom, [3]Seoul National University, Seoul, Republic of Korea, [4]University of Sydney, Sydney, Australia

Resisting pathogens is costly and can deplete resources that could otherwise be allocated to other functions, such as maintenance activities. Here, we examine the impact of dietary macronutrients (protein and carbohydrate) on immune function and resistance to bacterial and viral infections in *Spodoptera* caterpillars, and assess the capacity of the insects to alter their diets to offset the costs of mounting an immune response and resisting infection. We show that even in a species whose optimal diet is normally carbohydrate-biased, caterpillars that feed on protein-biased diets not only have elevated immune function (phenoloxidase activity, antibacterial activity, etc) but also exhibit enhanced resistance to both bacterial and baculovirus infections. Moreover, sub-lethally infected caterpillars exhibit an adaptive shift in their feeding behaviour, relative to uninfected individuals, so as to consume more of the dietary protein required for disease resistance.

Using *Tribolium castaneum* as a model to evaluate influence of landscape structure on behavior

Susan Romero[1], James Campbell[2], James Nechols[3]

[1]University of Kentucky, Department of Entomology, Lexington, KY 40546, United States, [2]USDA/ARS Grain Marketing and Production Research Center, Manhattan, KS 66502, United States, [3]Kansas State University, Department of Entomology, Manhattan, KS 66506, United States

Introduction: Landscape structure can influence the fine-scale movement behavior of dispersing animals that ultimately may influence ecological patterns and processes at broader scales. Theoretical and empirical ecological research has emphasized the need for understanding how animals perceive and respond to landscape structure and the importance of integrating both behavioral and landscape approaches when studying movement behavior.

Methods: Our research addresses questions concerning how insects respond to landscape structure by examining movement and oviposition behavior of a model insect, an important stored-product pest, red flour beetle (*Tribolium castaneum*), in experimental landscapes.

Results: Our data show that beetles modify movement behavior depending on landscape structure. Edge effects and inter-patch distances influenced landscape viscosity, or the degree to which landscape structure facilitates or impedes movement, resulting in significant differences in velocity and tortuosity (amount of turning) of movement pathways, as well as retention time in landscapes with different levels of habitat abundance and aggregation. Beetles responded to landscape structure differently depending on the activity in which they were engaged. Distribution of movement pathways was similar to that of the habitat, but distribution of oviposition sites were significantly more aggregated than pathways and habitat.

Conclusions: Our research demonstrates how detailed examination of patterns of movement and oviposition, coupled with measures of lacunarity (variation in gap sizes of a pattern on a landscape) can be useful in determining how an organism responds to various scales of heterogeneity and how this response may change according to the functional use of the landscape.

Tracking the field dispersal of the Colorado potato beetle using a portable harmonic radar

Gilles Boiteau[1], Charles Vincent[2], Bruce Colpitts[3]

[1]Agriculture and Agri-Food Canada, Fredericton, N.B., Canada, [2]Agriculture and Agri-Food Canada, Saint-Jean-sur-Richelieu, Qc, Canada, [3]University of New Brunswick, Fredericton, N.B., Canada

Introduction: The dispersal ecology of this primary pest of potato, walking within and between host plants, remains poorly known because of the cryptic appearance of the adult with the soil and the time spent in the canopy. Harmonic radar technology should make it possible to locate the position of the pest in the field but must also be shown to have no effect on the movement itself.

Methods: In the field, a portable harmonic radar prototype was used to test its ability to detect walking CPB carrying electronic tags In the laboratory, the horizontal and vertical movement of individual CPB with and without electronic tags was compared using motion monitoring equipment and visual observations, respectively.

Results: Tagged adult CPB were tracked successfully on bare ground and within the crop canopy of potato fields. In the laboratory, the addition of a tag on the pronotum of adult Colorado potato beetles had no significant impact on the mean distance traveled by the beetles or on the mean speed of travel horizontally or vertically. However, tagged beetles tended to hesitate more than untagged beetles before a bout of walking activity.

Conclusions: Except for a possible underestimation of the frequency of dispersal over short time periods, small weight electronic tags provided representative tracks of CPB dispersal.

Spatial dynamics of omnivore-prey systems: predatory bugs as a model

Moshe Coll

Hebrew University, Rehovot, Israel

Theoretical studies suggest that feeding on plant materials should destabilize omnivore-prey systems, thus make omnivory rare in nature. This is predicted because the omnivore also competes with its prey for shared resources. These predictions do not, however, consider the spatial properties of omnivore-prey systems, particularly the disjunction often found in the distribution of prey and plant food sources. I will discuss the significance of spatial omnivore-prey dynamics in the light of several studies of anthocorid bugs. Work in Mediterranean forests suggests that *Anthocoris nemoralis* moves among tree species, tracking plant and prey foods. Likewise, *Orius* bugs congregate near pollen sources, often forcing their prey to inhabit sub-optimal sites on the plants. In strawberry system, the move out of preferred feeding sites may provide the prey with spatial refuge from its omnivorous predator, but may also lead to an increase in crop damage. Finally, field data indicate that *Orius* bugs respond to prey and pollen availability at different spatial scales. Taken together, results suggest that omnivore-prey interactions are weakened by changes in the spatial arrangement of plant-provided foods, the omnivore and its prey. This may enable omnivore-prey systems to persist in nature.

Incorporation of mitochondrial fragments in the nuclear genome (*Numts*) of the longhorned beetle *Monochamus galloprovincialis* (Coleoptera: Cerambycidae).

Fotini Koutroumpa[1], François Lieutier[1], Emmanuelle Magnoux[2], Géraldine Roux-Morabito[2]

[1]*University, Orleans, France,* [2]*INRA, Orleans, France*

Introduction: The longhorned beetle, *Monochamus galloprovincialis*, vector of the pinewood nematode in Portugal, presents a large distribution in Europe. In order to evaluate the genetic diversity within this xylophagous insect, a mitochondrial DNA study was conducted on European populations. Numerous ambiguous nucleotide sites were detected, requiring further investigations on their nature. Hypothesis of heteroplasmy and pseudogenes (*Numts*) were examined.

Material and methods: MtDNA was sequenced for part of the Cytochrome Oydase I gene (COI) and COII gene on 43 *M. galloprovincialis* populations. Separation of mtDNA and nuclear DNA was performed using alkaline lysis method and cloning. Populations of a sister species, *M. sutor*, was also sequenced for comparison.

Results: Final alignment of 792bp of the COI and 521bp of the COII genes revealed a high polymorphism within and between *M. galloprovincialis* populations. Half of the studied individuals (44.8%) showed ambiguities on multiple nucleotide sites. MtDNA isolation by alkaline lysis supports the hypothesis that the ambiguous sequences amplified were not of mtDNA nature and validates the presence of *Numts* in the nuclear genome of *M. galloprovincialis*.

Discussion: This is the first time that *Numts* are proved for a longhorned beetle. The incorporation mechanism of *Numts* in unknown for *M. galloprovincialis*, however, excess of ambiguous sites corresponding to synonymous mutations placed on third codon position as well as the absence of *Numts* in its sister species *M. sutor*, conducted to the hypothesis of a recent apparition of *Numts* in the nuclear genome of *M. galloprovincialis*.

Use of molecular markers to identify cryptic species or complexes of sibling species in invasive or potentially invasive conifer pest insects

Géraldine Roux-Morabito, Alain Roques, Marie-Anne Auger-Rozenberg

INRA, Orleans, France

Introduction: Molecular genetic approaches are powerful tools for studying evolutionary aspects of biological invasions, especially for the identification of cryptic species or divergent lineages which can hinder a clear biological characterization of invasive species. Phytophagous insects show several examples of complexes of sibling species as well as successful invasion histories. We will present two case studies of phytophagous invaders. The first case will consider species which have been extensively transported globally for decades along with the seed trade (*Megastigmus* spp. seed chalcids), and the second pine pitch weevil of unknown origin, *Hylobitelus xiaoi,* which is presently in outbreak and is expanding in southern China. We will present data showing tests of the efficiency of molecular techniques for assessing whether the insect species correspond to cryptic native species or invasive species.

Material and methods: We use a phylogeographic approach by sequencing mitochondrial DNA genes (COI and/or COII). Individuals from different localities and from different host species were sampled in both the invaded and the presumed native range of the species.

Results and discussion: The study revealed misidentifications in *Megastigmus* species which have been previously recorded either as invasive or native species. It validated the use of molecular tools to detect cryptic species in this genus. These results also highlighted the importance of studying genetics in native populations to confirm or invalidate species identification only based on morphological traits. It should allow both a clear identification of native lineages and the tracking of the source population for expansion in *Hylobitelus*.

Phylogeny of the Ichneumonidae

Andrew M. Bennett, David B. Wahl, Ian D. Gauld, Ashley P. Dowling, Michael J. Sharkey

[1]Canadian National Collection of Insects, Ottawa, Ontario, Canada, [2]American Entomological Institute, Gainesville, Florida, United States, [3]The Natural History Museum, London, United Kingdom, [4]University of Arkansas, Fayetteville, Arkansas, United States, [5]University of Kentucky, Lexington, Kentucky, United States

Introduction: The Ichneumonidae is the largest family in the Hymenoptera with over 23000 described species classified into 40 subfamilies. Among these subfamilies, several informal groupings have been proposed based on adult and larval morphological characters (e.g., the ophioniformes, pimpliformes and ichneumoniformes). Previous studies have addressed the monophyly of particular groupings, but no comprehensive analysis of all 40 subfamilies has been made.

Methods: Adult and larval morphological characters as well as life history traits and molecular sequence data were scored for exemplars from all subfamilies. The data were analyzed separately and in combined analyses. Different sequence alignment methods were also used.

Results: We present the most comprehensive analysis of the subfamilies of ichneumonids to date. Whereas some hypothesized relationships were upheld, other groupings did not have support in our analysis. Sequence alignment methods had a great effect on overall topology.

Conclusions: Additional sequence data and novel morphological character systems will help greatly to resolve areas of the ichneumonid phylogeny with ambiguous topologies.

A novel methodology for testing for niche partitioning in insect predator communities

Tobin Northfield, Gretchen Snyder, William Snyder

Washington State University, Pullman, WA, United States

Niche partitioning often leads to increased prey suppression with increased predator biodiversity by increasing the proportion of prey available to the predator community. However, it can be difficult to convincingly document that niche partitioning occurs, so we have developed a new methodology to test for niche partitioning by quantifying the niche breadth of predators. We used a hyperbolic decay model to estimate the number of aphids remaining on collard plants after 31 days, in a large scale field experiment wherein predator density was manipulated in cages with high or low predator diversity. The model was fit separately for each species assemblage and reaches a horizontal asymptote that predicts the number of prey remaining after being exposed to an infinite number of predators (the number of prey occupying predator-free niches). Comparing the asymptotes allowed us to test for an increase in functional niche space occupied by predators with increased predator diversity. In our study the functional niche space occupied by the diverse group of predators was significantly greater than the single species treatments, indicating that niche partitioning occurred. This methodology can be used in a wide range of insect communities to gain insight into the role that predator niche partitioning plays in driving biodiversity-biocontrol relationships.

Current and future prospects of microbial insecticides in agriculture

Ramon Georgis

Valent Biosciences Corp, Libertyville, IL, United States

Developing cost-effective programs that combine microbial insecticides with beneficial insects, reduced-risk insecticides, selective insecticides and semiochemicals will be critical for creating opportunities for profitable and sustainable IPM systems.

Advancements in formulation stability, production efficiency, quality control, field efficacy and application strategies of *Bacillus thuringiensis* (Bt) have allowed Bt products to become the most widely used microbial insecticides globally in the cultivation of vegetables, tree fruits and vines. Concerning the other microbial insecticides, although there are successes in certain markets, a substantial effort in basic and applied research, as well as in market positioning strategies, is needed to develop reliable products and ultimately, sustain profitable business.

Although the market for microbial insecticides is approximately US$268 million, its only represents approximately 1.5% of the total crop protection insecticide market and most of this is due to sales of Bt products (US$160 million). However, the market potential for the microbial insecticides will likely increase in the next few years due to the following:

1. The demand of the regulatory agencies and the general public for safer produce and for products with no detrimental effect to the environment.
2. High probabilities of insect resistance developing against reduced-risk insecticides.
3. An increase in the awareness of the growers, distributors and farm advisors about the benefits and the flexibility of including microbial insecticides in insect management programs.
4. The producers of microbial insecticides are positioning their products as partners and not as alternatives to chemical insecticides.

The annual growth rate of microbial insecticides from 1980 to 2004 has been ranging from 8.0% to 10.0% and is projected to be 10.0% in 2009. For the same period, the annual growth of chemical pesticides has been ranging from – 2.3% to 2.2% and is projected to be 0.75% in 2009.

MorphBank: A look into the state of the art of morphology-based systematics

Matthew Buffington

Systematic Entomology Lab, USDA/ARS, Washington DC, United States

The digital revolution has substantially changed the practice of systematic entomology. High-resolution digital images of both taxa and characters are commonplace on a scale never achieved before. How can this enormous amount of image data be store, organized, and easily retrieved? This presentation will focus on experience and methods using Morphbank, an open web repository of biological images available to the research community. The system not only allows for effective management of these images, but is also a powerful collaborative platform supporting research by scientists on opposite sides of the planet.

Expansion of the geographic range of the mountain pine beetle and one fungal symbiont genotype in Canada in response to increasing temperatures

Sangwon Lee[1], Richard Hamelin[2], Diana L. Six[3], Colette Breuil[1]

[1]University of British Columbia, Vancouver, Canada, [2]Laurentian Forestry Centre, Quebec, Canada, [3]University of Montana, Missoula, MT, United States

Introduction: The mountain pine beetle (MPB) is a serious forest pest in western North America. This beetle is associated with symbiotic fungi including two mycangial species, *Grosmannia clavigera* and *Ophiostoma montium*, which are important for host beetle development and reproduction. Due to above-average temperatures in the last decade, the beetle and its fungi have expanded their range northward and eastward in Canada. In this study, we looked at genetic diversity of *G. clavigera* collected from five sites in Canada and two sites in the US including sites within the newly expanded geographic range.

Methods: AFLP profiles from 170 fungal isolates were used to assess genetic variability within and among the populations sampled.

Results: Genetic variation was low in *G. clavigera*. There was higher heterozygosity and higher percentage of polymorphic loci in the Rocky Mountain (RM) populations than in the British Columbian (BC) populations. AFLP data indicated the presence of two genetically distinct groups (Group 1 and Group 2).

Conclusions: We found both Group 1 and 2 in the RM populations sampled, but only Group 1 in the BC populations. The presence of Group 1 in the newly expanded range of the beetle is likely due to expansions of beetles from BC northward as well as eastward into the RM region.

Host specificity, speciation, and coevolution in *Fergusonina* (Diptera: Fergusoninidae) - *Fergusobia* (Nematoda: Neotylenchidae) galling mutualists on Myrtaceae

Gary Taylor[1], Sonja Scheffer[2], Weimin Ye[3], Kerrie Davies[1], Robin Giblin-Davis[4]

[1]Australian Centre for Evolutionary Biology & Biodiversity, The University of Adelaide, Adelaide, South Australia 5005, Australia, [2]USDA Agricultural Research Service, Systematic Entomology Lab., 10300 Baltimore Ave, BARC-West, Beltsville, MD, 20705-0000, United States, [3]Nematode Assay Section, Agronomic Division, North Carolina Department of Agriculture & Consumer Services, 4300 Reedy Creek Road, Raleigh, NC 27607, United States, [4]Fort Lauderdale Research & Education Center, University of Florida, 3205 College Ave, Davie, FL 33314-7799, United States

Introduction: A unique tritrophic association between Fergusonina flies and Fergusobia nematodes forms galls on various myrtaceous hosts. Flies deposit juvenile nematodes into meristematic tissue at oviposition. Nematodes appear to induce gall development; both nematodes and developing flies coexist in the galls. Fertilised pre-parasitic nematodes invade mature female fly larvae and deposit eggs in the haemolymph. These hatch and move to the flies' ovarioles and are again deposited into fresh plant tissue when the adult flies emerge from the gall, disperse and oviposit. Transmission of nematodes between flies is vertical (mother to offspring), suggesting cospeciation between flies and nematodes.

Methods: Galls, flies and nematodes were collected from myrtaceaous plants from Australia and New Zealand. Molecular phylogenies for Fergusonina flies and Fergusobia nematodes were generated using multiple genes and standard techniques. These phylogenies were compared with each other, then with myrtaceous host phylogeny, gall form and fly morphology.

Results: Fly/nematode associations were collected from Angophora, Corymbia, Eucalyptus, Leptospermum, Melaleuca and Syzygium in Australia and Metrosideros in New Zealand. The associations are highly host-plant specific, and each species of fly is associated with a single species of nematode. There is good phylogenetic congruence of the terminal, but not the deeper nodes of the compared fly/nematode phylogenies. Deep nodes had low bootstrap support, and tree topology changed at these levels depending upon which taxa or genes were included in the dataset.

Conclusions: These results are consistent with a general model of cospeciation of flies and nematodes. Speciation by fly/nematode associates appears to be accompanied by periodic host plant shifts; there is strong evidence of evolutionary conservation of plant host genus.

Possible factors possibly acting as triggers for speciation of gall midges (Diptera: Cecidomyiidae)

Junichi Yukawa[1], Tomoko Ganaha[2], Nami Uechi[2], Misako Mishima[3], Shinsuke Sato[1], Makoto Tokuda[4]

[1]Kyushu University, Fukuoka, Japan, [2]Okinawa Prefectural Agricultural Research Center, Okinawa, Japan, [3]Kyushu University Museum, Fukuoka, Japan, [4]National Institute of Agrobiological Sciences, Tsukuba, Japan

Introduction: Most gall-inducing species of Cecidomyiidae (Diptera) are mono- or oligophagous and many examples of association of a gall-midge genus with a particular host-plant genus are known. Many gall midges may have diversified as a result of host-range expansion and host plant-shift within congeneric plant species. We tried to identify factors acting as triggers for speciation of gall midges.

Methods: Oviposition behavior of some gall midges was observed in the field and the development of galls on non-host plants was monitored. We also compared chromosomal numbers between galled and ungalled host plant individuals. In addition, we examined part of the mitochondrial DNA COI gene to determine host ranges of gall midges.

Results: Oviposition mistakes on congeneric non-host plants were occasionally observed in the field. Oviposition mistakes occurred under various ecological conditions when host and non-host plant organs were available for oviposition in the same season. Maturating of galls on non-host plants was rarely observed. We also found that some gall midges could not discriminate among ploidy levels of their host plant individuals, indicating that they cannot recognize slight genetic differences in host plants in the early stage of plant speciation. Host range expansion and host shift may provide gall midges with opportunities to become geographically or chronologically isolated in the course of plant speciation.

Conclusions: Oviposition mistakes and genetic changes in host plants leading to host range expansions and host shift are considered to be possible factors acting as triggers for speciation in gall midges.

Hot plants: heat reward for insect visitors to thermogenic flowers

Roger Seymour, Craig White

University of Adelaide, Adelaide, SA, Australia

Introduction: Over a thousand species of heat-producing flowers in the Neotropical forests are pollinated by large dynastine scarab beetles. Floral thermogenesis enhances scent production in all species, but temperature regulation often continues past the attractive phase and is always associated with insect residence.

Methods: Patterns of activity of beetles (*Cyclocephala colasi*) and thermogenesis of inflorescences of a large arum lily (*Philodendron solimoescence*) were observed in the field in French Guiana. These were related to laboratory measurements of metabolic rate (respirometry) and body temperatures (needle thermocouples and IR camera).

Results: Beetles were active during the night inside the floral chambers, where they mated and fed, and they rested the following day. The 24-hour cycle of respiration mirrored this, with bouts of endothermy at night (particularly in the early evening), and low rates during the day. Flying beetles had thoracic temperatures up to 9 ºC above ambient, but the temperature excess was less than 2 ºC inside the floral chamber. Floral chamber temperature during the night averaged 26.6 ºC while ambient air was 22.8 ºC. Beetles exposed to less than 27 ºC showed bouts of intense endothermy during which respiration could increase over 80-fold. Endothermy was rare at floral chamber temperature and above.

Conclusions: The energy costs of insect activity is so high that as little as 4 ºC elevation in floral chamber temperature can reduce the costs of activity 4-fold. Thus thermogenic flowers can provide a direct energy reward to insect visitors, and floral temperature regulation may be associated with it.

Habitat manipulation and supplementary food spray for enhanced pest management in organic cotton: implications to cotton IPM

Simplice Davo Vodouhe[1], Robert Kofi Mensah[2], Damien Sanfilippo[3]

[1]Organisation Béninoise pour la Promotion de l'Agriculture Biologique (OBEPAB, Cotonou, Benin, [2]Australian Cotton Research Institute, Narrabri, NSW, Australia, [3]Pesticide Action Network-UK (PAN-UK),, London, United Kingdom

Introduction: Many generalist predators have been recorded in cotton cropping systems in Benin in West Africa. Despite their abundance, the potential of these predators has not been fully exploited in cotton pest management due to lack of techniques to maximize their abundance and effectiveness. The study determined provision of supplementary food supplements in commercial cotton crops (surrounded by beneficial insect refuges on the predator to pest ratio conservation and utilization to and biological control cotton of pests. on cotton crops).

Method: The study was conducted ion a 2 ha commercial cotton field interplanted with sorghum at Kandi in the Republic of Benin during the 2006 cotton season. The food sprayFood spray was applied at 2.0 kg per hectare on these crops. The number of Ppests and predators were sampled and comparison made between food sprayed and unsprayed cotton crops. per metre on the cotton plots treated with the food spray was compared with crops that did not receive food sprays. In terms of seed cotton yield and gross margins, the food sprayed plot cotton crops that received food sprays were compared to with cotton cropsplots treated with neem solution and conventional insecticides. - treated plots located 400 metres away from the study site.

Results: The results showed that the food sprayed plot cotton plots interplanted with sorghum and treated with food spray recorded had significantly higher number of predatory insects (ladybirds, spiders, ants, bees, brown earwigs, glossy shield bugs etc) and lower number of pests such as *Helicoverpa armigera*, *Earias huegeli*, *Pectinophora scutigera*, *Crocidosema plebeiana*, *Anomis flava*, *Nezara viridula*, *Dysdercus sidae* per metre than the non-food sprayed treated plots. In terms of yield and gross margins, the average seed cotton yields harvested from plots treated with the food sprayed plot food spray was 805 kg/ha compared with 562 kg/ha in the neem and 1,145 kg/ha in the conventional insecticide treated cotton cropsplots. The gross margin was highest in the food sprayed plots (125,340FCFA/ha) followed by the conventional (89,450 FCFA/ha) and neem treated plots (80,248FCFA/ha).

Conclusion: The use of food sprays in cotton/sorghum interplant system can provide resources such as food and shelter, thereby conserve and increasing the abundance and effectiveness of natural enemies to manage pests profitably on commercial cotton fields.

Foraging patterns in fern-feeding arthropods occurring the Western ghats of Southern India

Alexander Jesudasan, Mini M. K.

Madras Christian College, Chennai, Tamil Nadu, India

Introduction: Though fern associated arthropods have been recorded in many parts of the world, their occurrence has been poorly documented from India. Hence, a study was initiated in the Western ghats of Southern India, which is one of the biodiverse hot spots of the world.

Methods: Surveys were conducted in fifteen places in the above cited ecological zone for diverse arthropods during September, 2006 – August, 2007. While the deformity to the foliage of pteridophytes by the herbivores was observed, the feeding damage by them was assessed using a portable leaf area meter.

Results: The study revealed the occurrence of thysanopterans [*Selenothrips rubrocinctus* (Giard)), *Heliothrips haemorrhoidalis* (Bouche), *Astrothrips* sp.], lepidopterans [*Callopistria* sp., *Herpetogramma* sp.], hemipterans [*Labioproctus polei* (Green), *Lepidosaphes* sp., *Coccus* sp., *Anchon ulniforme* Buckton, *Parayasa maculosa* Distant, *Telingana consobrina* (Distant)], coleopterans [*Chilochorus* sp.], orthopterans [*Orthacris maindronii* L., *Oxya fuscovittata* (Marsch) and *Chitura* sp.], a phasmid [*Carausius morosus*] and a mite [*Floracarus perrepae*], on sixteen ferns in the study area. The type and intensity of damage inflicted by the fern-feeding arthropods are discussed.

Conclusion: A comprehensive understanding of the herbivorous arthropods on some pteridophytes and their damage to the hosts existing in the western ghats of Southern India is reported.

Understanding insect biodiversity through insect faecology

Alexander Jesudasan, Vidhya S. A.

Madras Christian College, Chennai, Tamil Nadu, India

Introduction: A study on the biodiversity of four coleopteran stored product pests viz., *Oryzaephilus surinamensis* L. (Silvanidae), *Lasioderma serricorne* F. (Anobiidae), *Tribolium castaneum* Herbst (Tenebrionidae) and *Sitophilus oryzae* L. (Curculionidae) with reference to frass morphology and morphometry has been undertaken and reported.

Methods: Cultures of *Oryzaephilus surinamensis* on dates, rice and apricots(dry); *Lasioderma serricorne* on turmeric and fenugreek powder; *Tribolium castaneum* on Bengal gram flour, wheat flour, fenugreek powder and dates; and *Sitophilus oryzae* on rice were maintained in the laboratory. The frass deposited by each of them was collected and observed under a compound microscope and details of form, texture, colour, shape and size were recorded.

Results: Observations on the morphological characteristics of the frass of the insects revealed that differences existed in the frass egested by them and also in the frass deposited by individuals belonging to the same species depending on the developmental stage, sex and diet. Striking differences in the colour of the frass were noticed not only among the four insects, but also in the frass of the individuals of the same species reared on different stored products.

Conclusion: A study on the diversity of insect frass of the four coleopteran stored product pests based on the morphological characteristics has been presented.

First record of a *Conidiobolus* species (Ancylistaceae: Entomophthorales) infecting house fly, *Musca domestica* L. (Muscidae: Diptera) from India

C. M. Senthil Kumar

North East Institute of Science and Technology (CSIR), Substation, Lamphelpat, Manipur, India

Introduction: A new fungal pathogen infecting *Musca domestica* was discovered in an epizootic during 2006 – 2007 near cattle shed located inside the campus of NEIST substation, Manipur, India.

Methods: Morphological identification was based on the length and width of conidia, number of nuclei, presence/absence of special structures etc. Conidia and nuclei were stained in lactophenol cotton blue/lactophenol aceto-orcein and observed under phase contrast microscope.

Results: Infected flies were attached to the substrate especially on plant leaves by means of numerous rhizoids emerging out from the thorax. Unlike the symptoms of *Entomophthora muscae* (complex), the proboscis was not attached to the substrate but was extended. Wings and legs were also spread over the substrate. Mating of dead females by males (necrophilous) was observed. The conidia appeared larger than the *E. muscae* (complex) and the nuclei failed to stain in aceto-orcein. Primary conidia not surrounded by halo drop of cytoplasm and the papillae emerged from the spore outline and varied in shape. The size of the primary conidia ranged from 26-43µ × 213-35µ and that of the secondary conidia was in the range of 18-36µ × 14-30µ. Numerous smooth resting spores were observed. Based on these preliminary observations, the fungus appears to be an undescribed species of *Conidiobolus*.

Conclusions: This is the first record of *Conidiobolus* causing disease in house fly populations in India and further studies are underway to develop into a commercial biocontrol agent.

One hundred years of occupation: The Argentine ant in South Africa

Melodie McGeoch, Ndivhuwo Luruli

Centre for Invasion Biology, Dept. Conservation Ecology and Entomology, University of Stellenbosch, Stellenbosch, South Africa

Introduction: As is now generally appreciated for species range structures, the globally invasive Argentine ant is not evenly distributed within its range and its distribution and abundance is strongly associated with abiotic conditions. Here we examine in detail the range expansion and distribution of the Argentine ant in South Africa, one hundred years after its introduction.

Methods: Locality data were collated from literature, museum records and supplementary country-wide surveys. We examine trends in the temporal and spatial distribution of occupancy, and compare the distribution of the species with those predicted by bioclimatic models.

Results: Following the first records of the Argentine ant in South Africa in 1901, there was a sharp increase in the number of presence records in the mid 1950's and again in the mid 1980's. The extent of the range was reached fairly early and subsequent records have been largely space-filling. Minimum estimates of the rate of radial spread of the Argentine ant in South Africa are within the range of jump-dispersal spread rates recorded for the species globally. The extent of occurrence at present is estimated at 58 % of the countries surface area.

Conclusion: The agreement between observed and predicted distribution records of the species in South Africa was poor, a likely consequence of widespread human-mediated microclimate modification and the comparative paucity and narrow range of presence records for the species in natural areas.

Re-distribution of ex-South African strain of *Cotesia plutellae* Kurdjumov (Hymenoptera: Braconidae) in Africa for control of diamondback moth: Lessons from East Africa

Brigitte Nyambo[1], Gatama Gichini[1], John John Obiero[2], Bernhard Lohr[1], Glady Njumwa[1]

[1]icipe, Nairobi, East Africa, Kenya, [2]KARI, Muguga, Kenya

The ex-South African strain of *Cotesia plutellae* was field released in warm and semi-arid areas of Uganda and Kenya between 2003 and 2006, respectively, for control of diamondback moth (DBM) (*Plutella xylostella*).

In Central Uganda releases were done in November 2003. Post-release surveys 21 months later indicated that *Cotesia plutellae* was established and co-existed with *Oomyzus sokolowskii* and *Diadegma mollipla,* the indigenous DBM parasitoids. The level of parasitism due to *C. plutellae* was as high as 100% in some fields. In February 2006, the parasitoid was recorded for the first time in Western Kenya where parasitism rate increased from 5.9 to 36.6% by October 2007. During the October 2007 field survey, the parasitoid was also recovered further south close to the Tanzania border, an indication that it was still spreading and colonizing new areas.

In Kenya, first field release of *C. plutellae* ex-South African strain was done in June 2005 in semi-arid areas of Eastern Province. However, despite repeated releases on similar sites, establishment and its impact remains unsatisfactory. Contrary to expectations, *Diadegma semiclausum*, an efficient parasitoid for cool highlands, released earlier in Kenya highlands, colonized the areas and became the most frequently found parasitoid of DBM. Despite additional releases of *C. plutellae* done in other areas of Eastern Province in June 2006, its establishment and spread remains unsatisfactory. Lessons learned and implications to wider use of the *C. plutellae* ex-South African strain are discussed.

Plant mediated multitrophic interactions between aboveground and belowground herbivores

Roxina Soler

Netherlands Institute of Ecology (NIOO-KNAW), Heteren, Netherlands

Introduction: The study of interactions between spatially separated organisms is scaling up from simple interactions between organisms directly associated to the plant roots and shoot to a more complex approach involving higher trophic levels. The multitrophic approach linking food webs from the soil and the aboveground domains aims to address the complexity of populations of plants, herbivores and carnivores more realistically, to identify and further understand the forces that regulate populations of plants and insects in terrestrial communities.

Results and Conclusions: I will present a number of case studies that explored interactions between root herbivores, foliar herbivores and their parasitoids. Remarkably, the results of these studies show evidence that the presence of herbivores feeding on a plant in one (sub) domain can have negative effects on the herbivores in the opposite domain by reducing herbivore's performance, and simultaneously can provide advantages for the herbivore by interfering with the plant mediated attraction of parasitoids. Soil organisms, whose presence passes habitually unnoticed, can interfere in the interactions of plants, herbivores and their parasitoids, generating complex processes that still are far to be unravel.

Neural circuits controlling feeding behavior and metabolism in *Drosophila*

Michael Pankratz

University of Bonn, Bonn, Germany

Feeding behavior is regulated by external sensory inputs and internal metabolic status. We are interested in studying the genes and neural circuits that coordinate this universal behavior in *Drosophila*. The current focus is on a small assembly of neurons in the subesophageal ganglion that expresses the neuropeptide gene hugin, which has homology to mammalian neuromedian U and insect PBAN (pheromone biosynthesis activiting neuropeptide). We have begun a genetic and anatomical dissection of the hugin neurons with respect to their possible function in gustation and metabolism, and with their connection to other central and neuroendocrine circuits.

The status of the genus *Hylaeus* F., supposed ancestral bees of the old authors

Holger H. Dathe

Deutsches Entomologisches Institut, ZALF, Müncheberg, Germany, Germany

The Colletidae is considered to be a basal group of bees. The species are easily distinguishable from all other Apidae by a short, broad glossa, which was interpreted as a spheciform character. Whilst many Colletidae are densely hairy and actually look like bees, the small, black, practically hairless *Hylaeus* species resemble some Crabronidae; they possess no scopa and transport larval food in the oesophagus. They nest like *Pemphredon* in narrow cavities in plant stems. For this reason they were long regarded as the most ancient taxon of extant bees („Urbienen").

Phylogenetic analyses have supported the monophyly of the Hylaeinae, but no support could be found for its basal position. The supposedly basal characters are apparently the result of convergence driven by functional pressure. The broad tongue is a tool used to cover the interior of the brood cells with a silk secretion, whilst pubescence and external apparatus for food collection were probably lost secondarily. Unfortunately there are few exact studies on habits at species level, and cladistic studies are nearly completely lacking.

The genus *Hylaeus*, the largest in the family with worldwide distribution, is considered difficult, but when examined closely it is highly differentiated. Conspicuous characters such as scent gland fields on the 6th sternite of the male, that emit a characteristic lemon scent, have so far not been evaluated. The contribution provides an overview on the state of our knowledge and the diversity in significant characters, as well as providing hints on phylogenetic character evaluation preferably in Palaearctic species.

The spread and distribution in Europe of *Harmonia axyridis*, a non-native coccinellid.

Peter M.J. Brown[1], Michael E.N. Majerus[3], Helen E. Roy[2], David B. Roy[2]

[1]Anglia Ruskin University, Cambridge, United Kingdom, [2]NERC Centre for Ecology and Hydrology, Monks Wood, United Kingdom, [3]University of Cambridge, Cambridge, United Kingdom

Native to Asia, *Harmonia axyridis* (Pallas) (Coleoptera: Coccinellidae) is considered an invasive alien coccinellid in Europe and North America, where it was widely introduced as a biological control agent of aphids and coccids. There is strong evidence that *H. axyridis* will have a negative impact on the native insect fauna of Europe. The species was sold by various biological control companies from 1995 in France, Belgium and the Netherlands, and was also intentionally released in at least nine other European countries. It has spread very rapidly, particularly since 2002, and is now regarded as established in thirteen European countries. The established range extends from Denmark in the north to southern France in the south, and from Czech Republic in the east to Great Britain in the west. In this paper we map the spread and distribution of *H. axyridis* in Europe. We report first records of the species in seven countries; Spain, Sweden, Scotland, N. Ireland, Denmark, Czech Republic and Italy; and first evidence of *H. axyridis* establishment in the latter three countries. Despite releases of *H. axyridis* in Portugal, Spain and Greece, there is little evidence of establishment in southern Europe. It is predicted that the spread and increase within Europe will continue and that *H. axyridis* will become one of the most widely distributed coccinellids in the continent. We report on vectors for the spread of the species, particularly transportation via human activity. We also briefly examine the occurrence of the species in Africa and North and South America.

Multitrophic level interactions in changing landscapes

Teja Tscharntke

Agroecology, University, Goettingen, Germany

Understanding multitrophic level interactions and their relation to ecosystem services, needs a perspective from human-dominated landscapes, because most species experience their surroundings at spatial scales beyond the plot level, and spillover across natural and managed ecosystems is common. Management is often focused on few species and local processes, but in the dynamic, agricultural landscapes, only a diversity of insurance species may guarantee resilience, i.e. the capacity to reorganize after disturbance. Structurally complex landscapes enhance local diversity in land-use systems, which may compensate for local high-intensity management. Organisms with high dispersal abilities and little habitat specialisation appear to drive these patterns and processes, because of their recolonisation ability and larger resources experienced. In simple landscapes, local allocation of habitat, i.e. changes in landscape configuration, is more important than in complex landscapes, which are in total at risk. Examples from plant-insect, predator-prey and host-parasitoid interactions will illustrate how interacting species experience their surrounding landscape at different spatial scales, which influences food web structure and multitrophic interactions.

Complementary resource use in species-rich predator and parasitoid assemblages

Teja Tscharntke

Agroecology, University, Goettingen, Germany

Suppression of prey and host species may be more effective in species-rich enemy assemblages, but empirical evidence is mixed. Experimental manipulation of rich enemy complexes is often difficult or even impossible, so understanding patterns and processes relies on well-designed field studies in most cases. Here, I present the outcome form our case studies of the natural enemies of gallmakers, cereal aphids, bees and wasps, testing the idea of complementarity via resource partitioning and discussing its relative importance. The findings will be also discussed in the context of the insurance hypothesis, i.e. whether only a wealth of enemy (insurance) species provides the capacity to reorganize after spatio-temporal disturbance at small and large scales.

Coffee pollination on a landscape scale

Teja Tscharntke

Agroecology, University, Goettingen, Germany

The destruction and fragmentation of tropical forest negatively affects pollinators, causing a decline in successful pollination in fragmented sites. Rainforest serve as a source habitat for pollinators foraging in the agricultural landscape, so the distance of non-forest areas like coffee agroecosystems to forest fragments or continuous forest influences pollinator diversity and ecosystem services such as enhanced coffee pollination and yield. Coffee intensification changed traditional shade coffee to open sun coffee and reduced the area of neighbouring forests, which resulted in dramatic losses of biodiversity and associated ecological functions. Increased diversity of bees may enhance magnitude and stability of fruit set, yield and net revenues of farmers. When coffee shrubs flower synchronously, the landscape-wide density of coffee bees may be limited, resulting in a dilution effect and reduced yields. Local and landscape management for coffee bees require a more detailed understanding of landscape composition and configuration allowing spillover of bees across the noncrop-crop interface.

Landscape perspectives on land-use change and insect outbreaks

Teja Tscharntke

Agroecology, University, Goettingen, Germany

Spatiotemporal changes in insect densities require a landscape management perspective, because the species pool in the surrounding landscape and the distance of crop from natural habitat is important for the conservation of enemy diversity and, in particular, the conservation of poorly-dispersing and specialized enemies. Hence, structurally complex landscapes with high habitat connectivity may enhance the probability of pest regulation. In contrast, generalist and highly vagile enemies may even profit from the high primary productivity of crops at a landscape scale and their abundance may partly compensate for losses in enemy diversity. Enemy distribution in agricultural landscapes is determined by beta diversity among patches, while enemy communities in managed systems are more similar across space and time than those in natural systems, emphasizing the importance of natural habitat for a spillover of diverse enemies. Complex landscapes characterized by highly connected crop-noncrop mosaics may be best for long-term conservation biological control and sustainable crop production, but experimental evidence for detailed recommendations is still needed.

Integrated pest management Pest Information Platform for Extension and Education (*ipm*PIPE)

Dennis Kopp, Kitty Cardwell

USDA/CSREES, Washington, DC, United States

Introduction: The *ipm*PIPE is a web-based information system platform which provides the capability for real time early-warning, tracking and monitoring of invasive or migrating pests. This system also provides decision making tools and IPM options for pest and disease risk reduction and crop protection.

Methods: This information system was first developed and implemented for soybean rust in 2004. Developed by private and public sector agricultural scientists, supported by grower organizations and private industry, the *ipm*PIPE charted the movement of soybean rust, informed soybean producers regarding the disease spread and identified best management options. The *ipm*PIPE has expanded beyond soybean rust reducing crop loss risk and improving pest and disease management in numerous other crops across Mexico, the US and Canada.

Results: Since 2005, *ipm*PIPE provided soybean growers with maps and information about the spread of soybean rust, describing effective management options reducing many unnecessary fungicide treatments. In `05 and `06, PIPE saved soybean producers an estimated $299 million. By 2007, 73% of soybean grower decisions to spray for rust were based on *ipm*PIPE data. At $18 per acre for a fungicide application, it is estimated that US soybean producers using PIPE saved **$836.63 million** in saved crops and production expenses.

Conclusions: The *ipm*PIPE is a coordinated effort involving agricultural scientists in the private and public sector and representatives from grower organizations. These scientists reduce the risk of crop loss by monitoring, tracking, and delivering expert advice to growers, providing real time decision-making support for management of invasive or migrating pests.

A phylogeny of the leafhopper genus *Flexamia* (Hemiptera: Cicadellidae) constructed with morphological and molecular characters

Therese Catanach[1], Chris Dietrich[2], Robert Whitcomb[3], Jim Woolley[1]

[1]Texas A&M University, Department of Entomology, College Station, TX, United States, [2]Illinois Natural History Survey, Center for Biodiversity, Champaign, IL, United States, [3]Deceased, n/a, United States

Flexamia (Hemiptera: Cicadellidae) is a broadly distributed North America leafhopper found mainly in grasslands. While various phylogenies have been published, no single study has included both morphological and molecular data. Data were analyzed using parsimony in both PAUP and TNT. Based on morphological data and two mitochondrial genes, 16S and NADH dehydrogenase 1, the monophyly of *Flexamia* was supported. Some species groups proposed by Whitcomb and Hicks were found to be polyphyletic while others are well supported. Overall, constructed phylogenies partially agree with previous phylogenies although there are some major differences.

The evolution of lady beetles (Coleoptera: Coccinellidae): Reconstructing phylogeny based on molecular data

Jose Giorgi, Joseph McHugh, Adam Slipinski, Kelly Miller, Lori Shapiro, Michael Whiting

University of Georgia, Athens, GA, United States; CSIRO Entomology, Canberra, ACT, Australia; University of New Mexico, Albuquerque, New Mexico, United States; Pennsylvania State University, University Park, Pennsylvania, United States; Brigham Young University, Provo, Utah, United States

Introduction: Lady beetles are conspicuous and charismatic elements of most insectan faunas. With nearly 6,000 described species, Coccinellidae represents one the most diverse families within Cucujoidea. Coccinellid evolution has produced a spectacular variety of forms and adaptations, some of which are beneficial to humans; however, the phylogeny of the group has never been investigated in a rigorous manner. This study examines the phylogenetic relationships of the main coccinellid lineages in order to provide the first robust evolutionary framework for the family and to form the basis for a meaningful and stable classification.

Methods: This dataset, with 96 ingroup species and 6 genes (12S, 16S, 18S, 28S, COI, COII), is the largest ever utilized in a phylogenetic study of Coccinellidae. Species of Erotylidae, Discolomatidae, Latridiidae, and Endomychidae were used as outgroups. Sequences were aligned using Muscle. Parsimony analysis was accomplished using NONA as implemented by WinClada.

Results: Coccinellidae was supported as monophyletic. Four of the six currently recognized subfamilies, Sticholotidinae, Chilocorinae, Coccidulinae, and Scymninae were recovered as paraphyletic.

Conclusion: Coccinellidae appears to be a natural group, however, the current subfamilial classification is unsatisfactory and requires major modification in order to reflect the evolution of the group.

The role of a maternal gift in the larval development of a dung beetle

Marcus Byrne[1], Bronwen Watkins[1], Megan Yates[2], Gus Bowyers[1], Marlien Maritz[1], Jeremy Midgely[2]

[1]University of Witwatersrand, Johannesburg, South Africa, [2]University of Capetown, Capetown, South Africa

One aspect of brood ball construction in scarabaeine dung beetles has been either overlooked or mentioned only in passing; the production a faecal "gift" by the mother. Once she has constructed a ball inside the nest, the female lays a large egg into a cavity within the dung, and in many species cements the egg into place by what appears to be her own faeces. The attachment of the egg varies from a simple faecal smear in *Euoniticellus intermedius*, to an elaborate faecal pillar in other species. The role of the maternal gift has never been investigated, but is assumed to be a microbial inoculation of the larval food store with symbionts which will assist in breakdown of the dung creating an "external rumen" for the larva. Brood balls of *E. intermedius* were manipulated by removal of the maternal gift and sterilisation by heat or antimicrobials, to determine if the gift was simply a provision of small food particles for the newly hatched larva or microbial injection of symbionts essential for larval development. Results from sterility trials were supported by stable isotope analysis to estimate how many trophic levels separate larval and adult dung beetles from their food source and considered together, suggest a new role for the maternal gift as a "packed lunch" for the newly hatched larva.

Simultaneous disruption of a leafroller complex using a common pheromone dispenser

Ashraf El-Sayed, Jill Mclaren, Vanessa Mitchell, Lee-Anne Manning, Max Suckling

HortResearch, Lincoln, New Zealand

Introduction: Three leafrollers, *Epiphyas postvittana*, *Ctenopseustis obliquana* and *Planotortrix octo* are widespread in New Zealand, and economic pests of NZ's export horticulture industries. Mating disruption has been successfully used in the past against these pests. However, two pheromone dispensers are needed to provide control of the complex. This research was undertaken to develop a common pheromone dispenser for mating disruption of these three species simultaneously, thus reducing the labour required for application of the separate pheromone dispensers and enable widespread adoption of the technology.

Methods: Several laboratory and field experiments were conducted to investigate the interaction in the pheromonal communication systems among the three leafrollers. Accordingly, several blends were formulated and tested for mating disruption of these leafrollers in the lab and in a small field plot experiment. Based on the results obtained in these previous experiments, a pheromone blend was chosen and formulated in a twist-tie dispenser and tested in area-wide mating disruption trials.

Results: Cross-talk experiments indicated that the three leafrollers can detect the pheromone of each other and there were various degrees of antagonism between the pheromone of the three species when combined in a single lure. The combination of carefully selected blends showed various degrees of mating disruption, with blends that contained all pheromone components of the three species showing the optimum mating disruption effect on the three species.

Conclusions: A common pheromone dispenser has been developed that provides simultaneous and efficient mating disruption of the three leafrollers. Because this generic pheromone dispenser was not attractive to any of these leafrollers, this indicates that mating disruption was achieved via habituation or adaptation of olfactory system.

What is special about the Argentine ant, and what is not? – A comparison with other invasive ants

Jes S. Pedersen

Department of Biology, University of Copenhagen, Copenhagen, Denmark

Introduction: Some ants have realised the old truth that in union there is strength. They have abandoned boundaries between colonies so that a free exchange of individuals within a network of nests makes the entire population function as single social unit. Such unicolonial organisation is probably responsible for the invasiveness of these ants as they form extensive and ecologically dominating supercolonies when introduced outside their native range. In recent years the Argentine ant *Linepithema humile* has been studied intensively and stands currently as a model species for such invasive ants. Here I ask the question to what extent the various characteristics of this species can be generalised to other invasive ants.

Methods: Data from genetic, behavioural, and chemical analyses were used to compare the Argentine ant to two species that represent different histories of invasion and time associated with man: the pharaoh ant *Monomorium pharaonis* and the invasive garden ant *Lasius neglectus*. Closely related non-invasive species were also included.

Results: The comparative studies revealed that the three invasive species share a number of traits likely to increase their ecological success when introduced, and differences may be attributed to their specific history. Paradoxically, the most important preadaptation to become invasive seems to be local mating and a very limited dispersal of new queens. Furthermore, ecological release may be important for the success of introductions.

Conclusions: These findings confirm the Argentine ant as a good model for invasive ants and potentially makes it possible to predict new invasive ant species.

The history of sleeping sickness control in Africa

Ian Maudlin, Susan Welburn

[1]Centre for Infectious Diseases, Royal (Dick) School of Veterinary Studies, College of Medicine and Veterinary Medicine, The University of Edinburgh, United Kingdom, [2]Centre for Infectious Diseases, Royal (Dick) School of Veterinary Studies, College of Medicine and Veterinary Medicine, The University of Edinburgh, United Kingdom

Attitudes towards sleeping sickness have changed from the colonial view - *the* disease that must be controlled at all costs - to its present position as one of the 'neglected' diseases. This change in perception does not truly reflect a change in the threat posed by sleeping sickness to the peoples of the endemic area but rather reflects changes in economic drivers of African development. Agriculture, particularly rubber and cotton, was the backbone of colonial African economies and huge resources were put into the control of sleeping sickness that threatened rural labour. Africa, in common with other developing parts of the world, is now subject to very different economic drivers, reflected in rapid urbanization. Control of endemic diseases in Africa is no longer a matter left to sovereign states, but is subject to external economic forces. Sleeping sickness, because of the habit of its vector – the tsetse fly - exclusively affects the rural poor and no longer attracts the sort of resources now devoted to diseases of urban/peri-urban Africa (e.g. HIV, malaria, TB). Sleeping sickness nonetheless remains a disease that is fatal if left untreated and, as we have seen recently, is undiminished in its ability to cause serious epidemics of disease. In response to these shifts in economic priorities, tsetse researchers have provided cheap and safe tools that enable the poor livestock keeper in sub-Saharan Africa to deal with both human and animal trypanosomiasis within the community.

Exocrine glands of leaf beetle larvae: Protective structures against attacking predators and pathogens

Juergen Gross[1], Henrike Schmidtberg[1], Kerstin Schumacher[2], Andreas Vilcinskas[1]

[1]Justus-Liebig-University, Giessen, Germany, [2]Julius Kuehn Institute – Federal Research Centre for Cultivated Plants, Kleinmachnow, Germany

Introduction: The exocrine glandular secretions of leaf beetle larvae of the taxon Chrysomelinae are well-known defensive devices used against generalistic predators. Recently it was shown that larvae of some species produce fluid exocrine secretions containing deterrent and antimicrobial compounds. As leaf beetles share with other eukaryotes an innate immune system mediating endogenous defense against pathogens, the ecological role of antimicrobial compounds from secretions was investigated.

Methods: Morphological structures of larval glands were studied by scanning electron microscopy. The chemical composition of glandular volatiles collected from the larval headspace was analysed by GC-MS. Antimicrobial properties were investigated by inhibition zone tests and *in vivo* experiments using several entomopathogenic microorganisms (bacteria and fungi)

Results: We identified different volatiles as major components of enveloping perfume clouds. They are emitted by specialized openings of larval glandular reservoirs and inhibit *in vitro* the growth of bacteria as well as the germination of fungi. The suggested role of these components as fumigants in exogenous antimicrobial defense was confirmed *in vivo* by their removal from glandular reservoirs. This resulted in an enhanced susceptibility of the larvae to infections with the fungal entomopathogens *Beauveria bassiana* and *Metarhizium anisopliae.*

Conclusions: We conclude that exocrine glands of leaf beetle larvae are defensive devices which act not only against predators but also against pathogens. Hence, antimicrobial defense in leaf beetles can be expanded beyond innate immunity to including external disinfection of their microenvironment. For the first time we report the contribution of fumigants to antimicrobial defense in animals.

Multitrophic interactions between the apple proliferation phytoplasma, its psyllid vectors, and their host plants

Juergen Gross[1], Christoph Mayer[2], Andreas Vilcinskas[1]

[1]Justus-Liebig-University, Giessen, Germany, [2]Julius Kuehn Institute – Federal Research Centre for Cultivated Plants, Dossenheim, Germany

Introduction: In recent years it was discovered that the univoltine psyllid species *Cacopsylla melanoneura* (Foerster) and *C. picta* (Foerster) (Hemiptera: Psyllidae) are the vectors for *Candidatus* Phytoplasma mali, a small bacterium which causes major economic yield losses in apple orchards by inducing shoot proliferation and tasteless dwarf fruits (apple proliferation disease). In the presented study we investigated the interactions between the psyllids, their different host plants for reproduction and overwintering, as well as the influence of the transmitted phytoplasma on both plant chemistry and vector behaviour.

Methods: Behavioural responses on olfactory cues were tested using dynamic Y-shaped olfactometers. Plant volatiles were collected from their headspace and analysed by GC-MS. Infection of plants and insects by the phytoplasma were detected by PCR using apple proliferation phytoplasma specific primer pairs.

Results: The overwintering and reproduction host plants of both psyllids species were determined and the distribution of the apple proliferation phytoplasma in the phloem of these plants was investigated. Only in apple trees the phytoplasma could be detected. Further, we show that phytoplasma altered the odour of infected apple trees as well as the attractiveness of emitted plant volatiles to their vector *C. picta*.

Conclusions: The psyllid vectors use several plants for reproduction and overwintering, but only the apple plants could act as reservoir for the uptake of the apple proliferation phytoplasma. Finally, we conclude that the apple proliferation phytoplasma manipulates the odor of infected apple as well as the behaviour of vector insects to promote its propagation.

Lethal and sublethal effects of methoxyfenozide on Colorado potato beetle *Leptinotarsa decemlineata* (Say) (Coleoptera: Chrysomelidae)

Roghaiyeh Karimzadeh, Mir Jalil Hejazi

University of Tabriz, Tabriz, Islamic Republic of Iran

Introduction: One of the major management challenges posed by CPB is its ability to develop resistance against insecticides; and new insecticides are needed to aid in CPB management programs. Methoxyfenozide is a biorational insecticide and has been shown to have sublethal effects on some insects. In this study the lethal and sublethal effects of this insecticide was assessed on the CPB.

Methods: To assess the lethal effects on 1st instars, the range of concentrations tested was 48-120 mg ai/L. Potato leaves used for feeding the larvae were dipped in the insecticide solutions. The treatments were kept at 25±1°C, 60±5 RH and a photoperiod of 16:8 (L: D) h. Mortalities were recorded 72 h after treatment. To evaluate the sublethal effects of methoxyfenozide, two concentrations equivalent to LC_7 and LC_1 were used. First instars were fed on treated leaves for 48 or 96h and later on, untreated leaves; and were monitored until adult stage. Fecundity of the adults was then evaluated.

Results: LC_{50} for the 1st instars was 80.6 mg ai/L. Sublethal doses of methoxyfenozide prolonged the larval developmental time and caused mortality in later instars. The number of larvae developing into pupae and adults was significantly lower in methoxyfenozide treatments compared with control. The number of eggs per female was also significantly decreased.

Conclusion: It was concluded that the combination of lethal and sublethal effects of methoxyfenozide is considerable; and if this insecticide performs equally well in the field, it might be a suitable candidate for integrated management of the CPB.

Insect community structure and invasive insect species: Potential impacts of a rapidly changing climate

Nigel Andrew

University of New England, Armidale, NSW, Australia

The relative importance of climate, host plant evolutionary history (phylogeny), and host plant traits on structuring insect herbivore assemblages is fundamental to understanding how insects will respond to a rapidly changing climate. The use of Climate Change Response Groups, may also deliver powerful predictive tools for understanding the impacts of climate change on herbivore-plant interactions worldwide. However, what happens when an invasive species enters the community and begins to significantly change the interactions among species and trophic levels? This presentation will assess the current status of our understanding of insect communities in relation to the potential impacts of climate change and assess the influence that invasive specie may have on community structure.

The impact of *Bombus terrestris* invasions on natural ecosystems

Amots Dafni, Peter G. Kevan, Caroline C. Gross

[1]Haifa University, Institute of Evolution, Department of Evolutionary and Environmental Biology, Haifa, Israel, [2]Guelph University, Department of Environmental Biology, Guelph, Canada, [3]University of New England, Ecosystem Management, Armidale, Australia

Bombus terrestris has been reared artificially and supplied commercially from the 1980s especially for pollination of tomatoes in greenhouses. Very early after its introduction, it was recognized that this species is invasive (especially in Tasmania, Japan, and Israel) and may disturb local ecosystems. *B. terrestris* has various characteristics that suggest its capacity to be a successful pollinator: high adaptability to artificial conditions, the ability to produce large colonies, high pollination efficiency in various crops, better quality of seed/fruit production as a result of pollination by this bee, year-round availability and activity under greenhouse conditions and a high pollination efficiency in open air crops.

The invasive characteristics of *B. terrestris* are: high migration ability, early seasonal emergence, high adaptability under adverse climatic conditions in various habitats, generalist or polylectic foraging using a wide variety of flowers for resources, wide foraging, a thermoregulatory metabolism that enables it to withstand low temperatures, no natural enemies to check population growth in areas outside its natural range, and it may develop two reproductive cycles in a year (bivoltine) in a newly colonized area. In addition, commercial bees produce more gynes and are better competitors than the local conspecific populations and may replace them in the likely event of an escape.

The documented evidence on invasion impact of *B. terrestris* on natural ecosystems includes: negative interactions with local bee fauna, competition for nest sites with, and genetic contamination of, local *Bombus* spp, spread of parasites and pathogens and negative interactions with plant reproductive capacity.

We will discuss the possible measures that must be taken to minimize the *B. terrestris* invasion on local as well as on global levels.

When pollination syndromes break down: Principles and a case study of *Cyclamen persicum*

Amots Dafni

Institute of Evolution, Department of Evolutionary and Environmntal Biology,Haifa University, Haifa, Israel

Introduction: Pollination syndrome breakdown – an abrupt case in which the flowers show clear suit of adaptations to a certain pollinator but are actually pollinated by an agent of another "pollination guild", e.g. a typical bird flower which is pollinated by a bee. The plants don't show any adaptive changes towards the promotion of new pollinator. That to differ from "pollination shift" in which a flower adapted to a certain pollinator is replaced by (or share) another pollinator as a result of local selective forces on floral traits.

Theoretically one may consider several cases in which pollination syndromes could break down:

1. Extinction of the original pollinator and a replacement by a" surrogate" pollinator which is not includes at the original "pollination guild".
2. Invasion of a new pollinator to a new territory and an exclusion of the local original pollinator.
3. Invasion of a plant to a new territory and an adoption of local pollinator which can operate the flower and to cause pollination.
4. A genetic change of floral trait which cause a switch from one pollination guild to another one.

Literature survey reveals very rare events of such cases.

Results: *Cyclamen persicum* is, morphologically, a typical buzz pollination flower (pendulous flowers, radially symmetrical, reflexed petals and introrsely poricidal anthers). Buzz pollination in *C. persicum* is extremely rare and the most frequent pollinators are various unspecialized species of thrips and syrphids and also a primitive moth *Micropterix elegans.*

Conclusions: Based on the lack of buzz pollination in *Cyclamen* spp. along the Mediterranean and our results, we assume that the original pollinator what extinct and the other assemblage of unrelated and unspecialized pollinators invade into this vacant pollination niche. This low efficiency situation is compensate, long stigma receptivity and prolonged pollen viability and the actual result is a high seed production. Pollination syndromes break down, from its own definition, could be found in specialized flowers which are relative rare while most of the flowers are generalistic. So this phenomenon may be a priori rare.

Isolation and characterization of *Bacillus thuringiensis* and their toxicity against different ISSR- PCR based biotypes of *Helicoverpa armigera*

Senthilkumar Nachimuthu

Department of Biotechnology, Mizoram University, Aizawl - 796 009, Mizoram, India

Introduction: The search for new virulent strain of *Bacillus thuringiensis* (Berliner) has gained much significance for biological control purposes. Biotypes are distinct lineages of an organism that differ in some aspect of their biology and have implications for the design and implementation of pest control strategies. Inter Simple Sequence Repeats (ISSR) amplification utilizes anchored SSR primers that are complementary to genomic micro satellites and have been used for genetic characterization of insects.

Methods: In the present study, eight geographical isolates of *Bt* were isolated and their protein concentrations were determined. We characterized the biotype status of *Helicoverpa armigera* (Hubner) from S. India and tested the efficacy of *Bt* against different biotypes of *H. armigera*. ISSR-PCR was utilized for revealing polymorphisms between the biotypes of *H. armigera.*

Results: The genetic variation resulted in identification of two biotypes. The Coimbatore and Bangalore larvae were found to be genetically related, whereas the Hyderabad larva was very distantly related. *Bt* samples were tested for their toxicity against *H. armigera* and was found to vary significantly between the different biotypes of *H. armigera*. *Bt* samples numbered 5 and 8 produced higher mortality and the mean mortality was 70% in *H. armigera* larva and both had high protein concentration. The susceptibility of the biotypes varied and the Hyderabad biotype was found to be less susceptible than the other biotypes.

Conclusions: The results disclosed the usefulness of ISSR in differentiating the biotype variation among the genotypes and the differential toxicity of *Bt* against different *Helicoverpa* biotypes.

Scratchpads: getting biodiversity online, redefining publication

Vincent Smith, David Roberts, Simon Rycroft

Natural History Museum, London, United Kingdom

Introduction: Taxonomists have been slow to adopt the web as a medium for building research communities. Yet, web-based communities hold great potential for accelerating the pace of taxonomic research.

Implementation: We have developed an intuitive web application (Scratchpads) that collaboratively enables researchers to build, share, manage and publish their data online. Our architecture is based on the Drupal content management system and provides a scalable, flexible resource that allows distributed communities of taxonomists to collaborate. Sites are hosted at the Natural History Museum London, and offered free to any scientist that completes an online registration form. Information supported by the Scratchpads includes bibliographies, image galleries, specimen records, documents, custom data sets and maps. Data are classified and aggregated around a taxonomy supplied by the user. This is supplemented with information from high quality web accessible databases (currently Genbank, GBIF, Biodiversity Heritage Library, Yahoo! Images and Google Scholar) to automatically construct rich web pages about any taxon documented within a site.

Results: In the first year of operation, the Scratchpads have attracted 466 registered users from more than 30 countries, across 53 separate sites. Collectively these users have produced more than 110,000 web pages, and attract an average of 6,000 visits with 50,000 page views per month.

Conclusion: Ongoing work is linking the Scratchpads to the Encyclopedia of Life project, and the EDIT Cybertaxonomy platform. The template of our architecture may serve as a model to other research communities developing knowledge bases outside biological taxonomic research. Further details from http://scratchpads.eu.

EGF signaling and the origin of dorsal-ventral polarity in insects

Jeremy Lynch, Axel Drechsler, Siegfried Roth

University of Cologne, Cologne, Germany

The establishment of the anterior-posterior (AP) and dorsal-ventral (DV) axes is a critical step in the development of bilaterally symmetric animals, and often depends on maternal cues. Among the insects, this process is only well understood in *Drosophila*, where both axes depend on signaling provided by the tgf-alfa like ligand Gurken, whose mRNA is localized around the oocyte nucleus, and whose protein activates the EGF-receptor in the overlying somatic follicle cells. We have sought to test whether this system operates in insects with different modes of oogenesis and embryonic development by cloning and testing the function of tgf-alfa like ligands and EGF receptors from a variety of insects: the beetle *Tribolium,* wasp *Nasonia*, bug *Oncopeltus*, and the cricket *Gryllus*. In *Tribolium* pRNAi against the ligand and receptor leads to defects in oocyte nucleus migration and major disruptions of DV axis patterning, including apparent duplication of the DV axis, and in other cases the expression of DV markers perpendicular to the DV axis of the egg. In all insects tested, tgf-alfa RNAi leads to defects in oocyte encapsultion by the follicle cells. We have also found a conserved association of high EGF signal and the position of the oocyte nucleus in late oogenesis. In summary, EGF signaling from the germline to the soma appears a mechanism of providing spatial cues for proper oocyte and egg patterning broadly conserved among the insects, but whose deployment and downstream output is variable due to different modes of oo- and embryogenesis.

Morphological description of the last instar larva of *Solenopsis saevissima* Forel (Hymenoptera: Formicidae)

Eduardo Fox, Daniel Solis, Carlos Jesus, Odair Bueno

CEIS / UNESP, Rio Claro, SP, Brazil

Introduction: Larval descriptions are suposed to aid in taxonomy and systematics of hymenopterans, but are generally neglected by specialists in the field. Herein we present the description of the last larval instar of *Solenopsis saevissima*, a poorly studied species.

Methods: Whole nests were obtained from Estiva, Minas Gerais, Brazil, from which immatures were fixed in Dietrich's and conserved in 80% alcohol. The last instar larvae were sorted based on morphological differences as in *Solenopsis invicta*. All samples were slide-mounted and observed under an optical microscope or under a scanning electronic microscope.

Results: Body dolichoderoid about 300-um long with evenly-distributed deeply bifid, bifid and simple setae; ten spiracles. Head setae: 6-8 occipital bifid; five simple frontal on the frons; five simple genal, and one bifid and one simple above antennae; antenna a row of three setaceous sensilla, with a setacious sensila under it. Two sensilla near base of each mandible. Clypeus rectangular with four setae lining the roughly rectangular depressed mesad labrum, which is heavily scuptured at lower surface with rounded and spike-like papillae. Peg-like galeae with two setaceous sensilla; maxillary palpus with three basiconic sensilla and a setacious sensilum. Mandibules robust with two prominent apical teeth and one or two subapical short teeth followed by a blade. Labium elliptical; labial palpus an elevation with three basiconic and one setacious sensillum.

Conclusions: We hope the provided description adds to the knowledge of this species and facilitate species diagnosys in this complicated ant group. We are currently describing the other immature stages.

Different identification protocols yield incongruous species identification to Brazilian Fire Ants (Hymenoptera: Formicidae: *Solenopsis*)

Eduardo Fox[1], Cintia Martins[1], Adriana Pianaro[2], Daniel Solis[1], Anita Marsaioli[2], Odair Bueno[1]

[1]CEIS / UNESP, Rio Claro, SP, Brazil, [2]IQ / UNICAMP, Campinas, SP, Brazil

Introduction: Fire ants are of particularly difficult systematics, and to assess taxonomically. Many species are polymorphic and prone to considerable morphological variation, rendering most characters used for their identification poorly reliable. Also, some of them have been demonstrated to hybridize and there are cryptical species. Some identification methods have been proposed by different authors in order to facilitate species diagnosis in the group, and should provide similar results. Herein, we demonstrate some of these methods yielding clearly conflicting species identification with Brazilian specimens.

Methodology: Entire nests and samples were collected from the field. Some ants and ant larvae of each sample were morphologically analysed for classical characters, while others were surveyed through the mitochondrial DNA technique proposed by Shoemaker et al. Moreover, the alkaloid composition of their venom was determined through GC-MS, being compared to species records in the literature.

Results: One nest was morphologically identified as *Solenopsis invicta*, and was confirmed by the other techniques. However, one sample from other nest was identified as *Solenopsis saevissima* through adult and larval morphology, while being appointed as *S. invicta* through DNA and presenting venom alkaloid composition equal to *Solenopsis aurea*. Another sample was morphologically identified as *Solenopsis richteri*, while being appointed as *S. invicta* through DNA analysis and of unprecedented alkaloid composition.

Conclusions: We think our results clearly demonstrate the techniques do not fit. We suspect South American species have been poorly sampled in past studies, and also that identification by non-specialists might have misguided the design of the molecular approaches.

Community and ecosystem consequences of plant genetic differentiation along an elevational gradient

Joe Bailey, Jennifer Schweitzer

University of Tennessee, Knoxville, TN, United States

While many physical environmental factors vary along gradients of elevation and latitude, variation in temperature is commonly implicated as a mechanism driving variability in biodiversity and ecosystem function. However, many of the patterns of biodiversity and ecosystem function we find along elevational or latitudinal gradients may be an indirect consequence of natural selection acting on a focal species rather than a direct consequence of the physical environmental factors varying with elevation or latitude, however this hypothesis remains untested. In support of this hypothesis, in a common garden of clones taken from a variety of localities along an elevational gradient, we found significant genetic variance for plant performance and fitness, morphology, phytochemistry, arthropod community composition, species richness, total abundance, trophic interactions, soil nitrate, and total soil nitrogen at the genotype and locality level. Generally, locality averages for the phenotypes measured were correlated with the elevation of the site from which the trees were initially collected, suggesting that phenotypic differentiation was related to underlying physical factors related to elevation. Average leaf area appeared to be an important trait affecting biodiversity and ecosystem function along this elevational gradient. We believe this represents a critical new hypothesis describing patterns of biodiversity and ecosystem function across the landscape, particularly in relation to elevational and latitudinal gradients. These results provide evidence that there were cascading coevolutionary and ecosystem level consequences of population level genetic differentiation in *Populus* and are important for understanding the whole system consequences of climate change.

Revegetation for pest management - designing the 'right' biodiversity for sustainable production in Southern Australia

Glenys M. Wood, Helen E. Degraaf, Richard V. Glatz

Entomology Unit, South Australian Research and Development Institute, Box 397 GPO Adelaide, Australia

Introduction: The utility of endemic vegetation as a refuge for beneficial insects in agricultural systems has been the focus of much investigation over the preceding decade. Here we present work aiming to refine the approach to assessing and predicting the effect of endemic plants. We have developed an *in vitro* screening assay to predict plants that will reduce pest pressure and identified key parasitoids for manipulation using native vegetation.

Methods: The Northern Adelaide Plains provides a model where exotic weeds host *Frankliniella occidentalis* (Western flower thrips; WFT) a vector of Tomato Spotted Wilt Virus, the major cause of vegetable crop loss in the region. We utilised mechanical vacuum, sticky traps and flower funnels for field sampling of various plants. Petri-dish arenas were used to develop a screening system to identify vegetation not supporting WFT development. Key parasitoid species were identified by field sampling and subsequent culturing with potential hosts.

Results: Sampling showed endemic plants supported diverse parasitoids. Among these were a small number of potential biological control agents including parasitoids of WFT, an Agromyzid leaf-miner and the Rutherglen Bug (Lygaeidae). In vitro leaf assays showed a range of endemic plant species supported less WFT reproduction than control capsicum plants.

Conclusions: We developed a reproducible system to identify plants not supporting WFT, for recommendation as low-risk revegetation plants. Analysis of beneficial insects should focus on key parasitoid species rather than total parasitoid diversity. Results suggest integrated plant refuges can create a buffer to rapidly support colonisation of useful insects.

Mass trapping of the male moths (*Metisa plana* Wlk, Lepidoptera: Psychidae) for control of bagworms on mature oil palms in a smallholder plantation in Malaysia

Norman Kamarudin, Siti Nurulhidayah Ahmad, Othman Arshad, Mohd Basri Wahid

Malaysian Palm Oil Board, Bangi, Selangor, Malaysia

Introduction: The bagworm, *Metisa plana* Wlk (Lepidoptera: Psychidae) is an important pest for oil palms in Malaysia. A serious infestation will cause yield decline of around 30-40% over two years after attack. Pheromone trapping is an easy method for smallholders. Success of mass trapping depend on the efficient removal of male adults, hence preventing its copulation with females which can result in a decline in the population.

Methods: Sticky vane traps were baited with four receptive females of *M. plana*. The traps were hung on wooden poles (6' and 12'). Three trapping transects were set in the trapping plot. Ten traps (alternate for different heights) were placed in each transect. Captures were recorded up to 14 days. Percentage of hatchings were recorded to determine the effects of trapping on mating and reproduction success. Yield of the palms were compared between the trapping and control plots.

Results: The population of live larvae (30/frond) and percentage of egg hatching (14-28%) in the trapping plot was always lower compared to the control plot (respectively, at 48/frond and 30-49%). Trapping plot has significantly higher yield (14 kg/bunch) compared to control (10 kg/bunch). Hence, mass trapping reduced the chances of mating and egg hatching, frond damage and subsequently improving yields

Conclusions: The use of the female pheromone of *M. plana* for mass trapping the male moths to reduce the next generation of bagworm larvae has shown potential. The damage in the trapping plot remained lower than the control plot, contributing to higher yield.

Comparative effectiveness of two release rates of the egg parasitoid *Trichogramma chilonis* Ishii (Hymenoptera: Trichogrammatidae) to control a sugarcane borer in Reunion.

Marlène Marquier[1], Clarisse Clain[1], Elisabeth Tabone[2], Régis Goebel[3], Estelle Roux[1]

[1]Département de Mise au Point des Méthodes de Lutte, FDGDON-Réunion, 97460 Saint-Paul, Reunion, [2]Unité de lutte biologique, INRA – Centre de Sophia Antipolis, 06560 Valbonne, France, [3]Unité de Recherche Systèmes cultures annuelles, CIRAD, 34398 Montpellier, France

Introduction: *Trichogramma chilonis* Ishii (Hymenoptera: Trichogrammatidae) is an egg parasitoid of *Chilo sacchariphagus* Bojer (Lepidoptera: Crambidae), a stem borer attacking sugarcane stalks during the growth period. This research aimed at improving the cost / benefit ratio of a release method established in 2002 and 2004 trials. We evaluated two strategies with either reduced a) release points or b) release rate.

Methods: *T. chilonis* was released at two rates in nine sugarcane plots in Reunion. Response to release rate was measured by the percentage of stem attacked 2, 4 and 6 month after the first release. Releases were made with a density of 100 release points in six plots, three plots with a release rate of 16/ 7d and three with 10 /10d. Three more plots were tested with 50 release point at 16/7d release rate.

Results: All nine release sites had significantly lower level of damage, on average half that of the control plots. The damage reduction was not significantly different in fields with 50 and 100 release points. Likewise the release rate did not affect damage reduction.

Conclusion: These results help define augmentative release parameters for successful and cost effective use of *T. chilonis* as a biological control agent of sugarcane stem borer in field conditions. Combining both optimizations will bring a sustainable control strategy to Reunion sugarcane growers.

Chemical ecology of parasitic honeybee workers

Vincent Dietemann[1], Peter Neumann[2], Stephan Härtel[3], Jochen Pflugfelder[4], Robin Crewe[1]

[1]Zoology and Entomology Department, University of Pretoria, Pretoria, South Africa, [2]Swiss Bee Research Centre, Agroscope Liebefeld-Posieux, Bern, Switzerland, [3]Institut für Biologie, Molekulare Ökologie, Martin-Luther-Universität Halle-Wittenberg, Halle (Saale), Germany, [4]Institut für Bienenkunde, (Polytechnische Gesellschaf), J. W. Goethe-Universität Frankfurt a. Main, Oberursel, Germany

Introduction: Workers of the Cape honeybee, *Apis mellifera capensis*, were brought into contact with and invaded colonies of the neighbouring subspecies *A. m. scutellata*. Once they enter a host colony, *A. m. capensis* workers produce female offspring thelytokously, thus replicating themselves while using the colony's resources, eventually destroying their host. We used the unique clonal lineage that constitutes the parasitic population to determine the pheromonal mechanisms that mediate social parasitism between the two honeybee subspecies. Since the mandibular gland pheromone is tightly linked with reproductive dominance in workers, we tested the hypothesis that the parasitic lineage has been selected on the basis of pheromonal dominance.

Methods: We performed pheromonal contest bioassays by exposing individual workers to workers or queens of different origins (hosts and parasites). After four to seven days, we extracted their mandibular gland pheromones and analysed their composition by gas-chromatography.

Results: The parasitic lineage of *A. m. capensis* won the pheromonal contests against workers in all cases and the onset of their reproductive activity was not hindered by the presence of host queens.

Conclusions: The difference in composition of mandibular pheromones of queens between the two subspecies of honeybees is likely to be the key that gives one of them the ability to parasitise the other. We suggest that the parasitic lineage was selected for the speed with which it is able to produce inhibitory mandibular signals, a trait associated with its ability to take over reproduction in host colonies and to out compete other parasitic strains.

Low tide is high time! Timing of adult eclosion in *Clunio marinus*

Tobias Kaiser[1], Dietrich Neumann[2], David G. Heckel[1]

[1]Max-Planck-Institute for Chemical Ecology, Jena, Germany, [2]University of Cologne, Cologne, Germany

Introduction: In adaptation to its intertidal environment the chironomid *Clunio marinus* ecloses only on the days of spring tide (lunar rhythm) and only during the time of low tide (circadian rhythm). For each population the circadian eclosion time is adapted to the local time of low tide. Crossing experiments show that these adaptive differences are genetically determined. The differences might lie in the circadian clock itself, in the eclosion hormonal cascade – or in the still unknown coupling mechanism between these two. The molecular basis of lunar entrainment is also unknown. cOpsins, light receptive proteins discovered in insects only recently, are promising candidates to be moonlight receptors.

Methods: Microsatellites, AFLP fingerprints and intron length variation are being used to map the loci that control circadian eclosion time. Additionally, possible points of circadian regulation and thus candidate genes are examined by (1) testing clock genes for differential expression and (2) testing for differential release of eclosion triggering neuropeptides through antibody staining. Two cOpsins have been cloned. Their expression patterns across artificial daily and lunar cycles have been measured using qRT-PCR.

Results: A preliminary genetic map shows that QTL mapping is feasible and crosses between populations with different rhythms for QTL mapping are in progress. In a moonlight-receptive population, one cOpsin shows a striking expression pattern that appears to anticipate full moon.

Conclusions: Mapping of these and other clock-related genes will enable testing of specific hypotheses on the genetic variation that underlies the physiological and behavioural adaptations by which different populations of *Clunio marinus* respond appropriately to their local environments.

Morphometry of the salivary glands in pollen-feeding butterflies of the genus *Heliconius*

Stefan Eberhard, Harald Krenn

Department of Evolutionary Biology, University of Vienna, Vienna, Austria

Introduction: *Heliconius*-butterflies actively collect pollen-grains with their proboscides. The pollen is admixed with saliva forming a pollen-lump outside on the proboscis. During pollen-treatment amino acids are extracted. The utilization of pollen was a key-innovation in the evolution of these neotropical butterflies. In this study two pollen-feeding species, two related non-pollen-feeders, and one outgroup-species were used for a biometrical comparison of the salivary glands. Since high quantities of saliva are expected to be necessary for pollen-feeding it is hypothesised that the salivary glands of pollen-feeding butterflies differ from those of related non-pollen-feeding species.

Methods: Several paramters of dissected salivary glands were measured using a drawing tablet connected with a computer. Additionally, the individual body lengths were measured and the volume of the secretory part of the salivary glands was calculated. A multivariate data analysis was performed using log-transformed data for allometric reasons to reveal differences of the salivary gland morphology between pollen-feeders, non-pollen-feeders, and the outgroup-species.

Results: The salivary glands of pollen-feeders are larger than those of the non pollen-feeding groups. The multivariate data analysis of the salivary glands and body lengths indicated differences between pollen-feeders, non-pollen-feeders, and the outgroup species especially concerning the salivary gland volumes.

Conclusions: The salivary glands are larger in pollen feeding *Heliconius*-butterflies. Despite their similar anatomy the greater secretory region enables *Heliconius*-butterflies to release bigger amounts of saliva. Salivary gland morphology is regarded to be an adaptation to pollen-feeding and might be a crucial innovation for the evolution of this unique feeding-behaviour.

The effects of anthropogenic activities on the termite-fungus mutualism in fungus-growing termites

Paul Eggleton

Natural History Museum, London, United Kingdom

Introduction: Fungus-growing termites (Termtidae: Macrotermitinae) have a unique mutualism with the white-rot fungus, *Termitomyces.* This mututalism has allowed the termite:fungus symbiont complex to become one of the most effective decomposer systems in the world. Here, I describe what is known about the effect of human disturbance on that system.

Methods: Data from standardised transect surveys from all tropical regions are presented and analysed.

Results:.Tropical rain forests have the highest species-level and phylogenetic diversities of Macrotermitinae. Human disturbance results in a general decline in diversity of the Macrotermitinae but not necessarily in their ecological or economic impact. In Africa and Asia, areas cleared from forest for intensive sylviculture and agriculture often have major problems from macrotermitine crop pests that feed on roots and leaves, particularly of saplings. The major leaf litter removing and decomposing invertebrates in such systems are often Macrotermitinae, particularly of the genus *Macrotermes*.

Conclusions: The ability of many fungus-growing termites to control their internal nest environment very precisely may contribute to their survival in heavily disturbed environments.

Termites – the sophisticated cockroaches

Paul Eggleton

The Natural History Museum, London, United Kingdom

Introduction: The position of termites among the Dictyoptera has long been disputed. I present molecular evidence to show conclusively that termites are cockroaches. However, termites have diverged from cockroach traits in many ways, particularly through the greater phenotypic plasticity that eusociality has provided.

Methods: I will present two phylogenetic datasets, one for Dictyoptera (five genes) and a larger one for termites (three genes) as well as data on gut structure and function.

Results:.Termites are eusocial cockroaches. However, termite eusociality has allowed for an extraordinary range of behavioural, anatomical and physiological traits to evolve. One good example is trophic ecology - a wider variety of feeding substrates can be consumed by termites than by other closely related cockroaches. This has been made possible through the development of specialised castes that have freed workers to evolve gut structures not possible, for intrinsic design-cost reasons, in other cockroaches. These changes are not just observed between *Cryptocercus* and other termites, but also found in other parts of the tree: the general trend being from mid-gut detritivory to hind-gut fermenting. I will discuss the evolutionary and ecological consequences of these changes.

Conclusions: Eusociality has allowed termites to become a very sophisticated sort of cockroach.

Phylogenetic evidence for steps in the early social evolution of termites

Paul Eggleton

The Natural History Museum, London, United Kingdom

Introduction: all termites are fully social: all have a sterile caste within a colony led by a king and a queen. Even the earliest branching termites (*Mastotermes*, *Stolotermes*, *Archotermopsis*) have true soldiers, even though some may not have true workers. We therefore have to look to the closest relatives of termites to find phylogenetically well-supported hypotheses of early termite evolution particularly for the origin of eusociality. A well corroborated phylogenetic tree now exists for the Dictyoptera (mantids, cockroaches and termites) and that tree will be used as a basis for discussing how eusociality evolved in termites.

Methods: A robust phylogenetic tree was constructed using a Bayesian method and five gene markers. The tree was used to examine the plausibility of existing hypotheses concerning the early social evolution of termites.

Results: The tree clearly corroborates a hypothesis relating termites to wood-feeding cockroaches, particularly to *Cryptocercus*, the sister group of termites. This hypothesis emphasises parental care in cockroaches that have highly-specialised gut biotas and therefore need extended offspring:parent contact to allow inter-generational passage of that biota.

Conclusions: The finding that termites are derived cockroaches has greatly helped to clarify the steps to eusociality in termites.

Evolution of neotenic lineages in Lycidae (Coleoptera: Elateroidea): from body softness to larviform females.

Ladislav Bocak[1], Milada Bocakova[2], Alfried P. Vogler[3]

[1]Palacky University, Fac. Sci., Olomouc, Czech Republic, [2]Palacky University, Fac. Educ., Olomouc, Czech Republic, [3]Imperial College, Dept. Biol., London, United Kingdom

Introduction: Neoteny is a radical way of generating evolutionary novelty. Often controlled by the environment in facultative neotenics, retention of larval features is obligatory in many species of Lycidae (net-winged beetles). They are studied here as an example of how developmental shifts and ecology interact to produce macroevolutionary impacts.

Method: We conducted an evolutionary analysis of Lycidae based on DNA sequences from nuclear (18S and 28S rRNA) and mitochondrial (*rrnL*, *cox1*, *cob* and *nad5*) genes from a representative set of lineages (73 species), including 17 neotenic taxa. Almost all higher taxa of Lycidae were included in analyses.

Results: Phylogenetic analyses universally supported three independent origins of neotenics in Lycidae without reversals to fully metamorphosed forms. The south-east Asian Lyropaeinae and Ateliinae were in basal positions indicating evolutionary antiquity, unlike the Neotropical leptolycines nested within Calopterini and presumably much younger. Neotenics exhibit typical K-selected traits including slow development, large body size, high investment in offspring and low dispersal. Although neotenic lineages are ancient, their representatives are rare and all affected lineages are species poor.

Conclusions: Our findings are contradicting earlier suggestions of recent evolution from dispersive non-neotenics or reversal from neotenic to winged forms. We propose the series of morphological modifications from body softness to winglessness and to the evolution of lineages with completely larviform females.

Outcome of enemy-enemy interactions: Role of behavior, life-history and scale

Christer Bjorkman

Department of Ecology, Swedish University of Agricultural Sciences, Uppsala, Sweden

Introduction: It has lately become evident that it is important to consider the combined, total effect of sets of natural enemies when evaluating the role of top-down forces in ecological systems.

Methods: Field and laboratory studies were used to explore the outcome of enemy-enemy interactions on willows (*Salix* spp.). Two species of mirid bugs (Miridae) and an anthocorid bug (Anthocoridae) were studied. The two mirids are characterized by their habit of staying at a site and eat all prey before moving ('find-and-stay') whereas the anthocorid typically feeds on one or a few prey and then moves along ('run-and-eat'). The bugs are all predators of leaf beetles (Chrysomelidae), an important pest in willow plantations used for producing biofuel.

Results: At the scale of individual plantations, we found (1) a negative relationship between the density of two mirid bug species and (2) a tendency for a positive relationship between the density of the most common mirid bug and the anthocorid bug. At the scale of willow saplings, we found (a) an additive effect when combining two mirid bug individuals or when combining one mirid and one anthocorid bug, but (b) a negative, synergistic effect when combining two anthocorid bugs.

Conclusions: Enemy-enemy interactions are likely to be negative when (a) enemies with active and similar behavior compete over prey or (b) enemies compete over a strongly limited resource. The interactions are neutral when (a) enemies with less active, but similar behavior compete over prey or (b) enemies with different behaviors compete over prey.

Locusts versus grasshoppers: presence of adipokinetic peptides and functional aspects

Gerd Gade

University of Cape Town, Rondebosch, South Africa

Introduction: The corpora cardiaca of insects synthesise the adipokinetic peptides which are involved in regulating the level of circulating metabolites (lipids, carbohydrates, proline) by activating phosphorylases or lipases in fat body cells.

Aim and Results: Here the isolation and primary structure elucidation of such octa- or decapeptides of the adipokinetic hormone family of peptides in various members of the caeliferan Orthoptera are presented. Moreover, the physiological actions of such AKH peptides are contrasted in true locusts where lipid-mobilisation is controlled by them during long-distance flight and in those grasshoppers which are unable to fly or fly relatively poorly. The South African pest species *Locustana pardalina* serves as a test case for the group of locusts. Whereas all investigated species of locusts and grasshoppers contain AKH peptides (between 2 and 3 per species), pronounced overt changes of haemolymph lipids are only measured in locusts and not grasshopper species investigated. Flight in *L. pardalina* results in a decrease in the haemolymph carbohydrate concentration first and subsequently in an increase in the concentration of lipids during longer flight periods.

On the relationships between biodiversity and habitat fragmentation across spatial scales

Joan Ll. Pretus[1], Guillem Chust[2,] Nuria Roura-Pascual

[1]Universitat de Barcelona, Barcelona, Catalonia, Spain, [2]AZTI Tecnalia, Sukarrieta, Basque Country, Spain

Introduction: We synthesize our recent results and current research on the effects of habitat fragmentation on several insect assemblages at different spatial scales. In all cases sampling effort was designed to capture a gradient of natural habitat loss, and samples were taken on remaining fragments of climax vegetation. Studied biomes comprise two Mediterranean zones (Menorca Island and Mediterranean Pyrenees, Spain), one Euro-Siberian (Central Pyrenees, France) and one Tropical locality (Seasonally dry tropical forest in Guerrero, Mexico). Sampling design comprised small (250 cm^3) soil cores (Collembola), 10x10 m quadrats at constant effort (Diptera, Homoptera), transects for gall wasps (Cynipidae, Hymenoptera), and light traps (Lepidoptera).

Methods: Landscape parameters were extracted at increasing scales from land cover types produced through supervised classification from satellite images. Local microhabitat factors and spatial coordinates were taken into account as covariates. Insect data were regressed to landscape parameters to model its composition, species diversity (total richness, endemic richness, extrapolated richness through Collector's curves, alfa- and beta-diversity), and life history. Variance partitioning at different scales unveiled the mixture of spatial influences affecting insect assemblage parameters.

Results: Scales of response ranged from 60 m in Homoptera to a few kilometers in several other groups. When trophic level is considered, predators and parasites respond with more precision and to a lower scale than saprophagous and phytophagous. The number of endemics in Collembola respond to two spatial scales, 150 m and 1710 m, with 71,6% of the richness variance incorporated into a linear model.These findings allow for high resolution maps of potential richness distribution for target groups, at useful but yet unsolved scales. Ongoing research is centered in defining intrapatch quality of remaining natural fragments and its effects on moth diversity.

Metabolic strategies and adipokinetic hormones of two stinkbug taxa

Heather G. Marco, Gerd Gade

University of Cape Town, Rondebosch, South Africa

Introduction: In insects studied to date, metabolism is regulated by small neuropeptide hormones belonging to the adipokinetic hormone (AKH)/red pigment-concentrating hormone (RPCH) peptide family. In the sister group, crustaceans, AKH/RPCH affects the movement of epithelial and retinal pigment. In decapod crustaceans, RPCH is conserved, whereas insects contain a variety of AKH structures. Recently, we discovered RPCH in the corpora cardiaca (CC) of the stinkbug *Nezara viridula* (Superfamily: Pentatomoidae; Family: Pentatomidae), where it acts as an AKH. In the current study, we perform comparative investigations on metabolic regulation in *N. viridula* and the related inflated stinkbug *Encosternum delegorguei* (Family: Tessaratomidae); the latter occurs in the Limpopo Province of RSA where it is a sought-after food item for local tribes.

Methods: CCs were dissected from stinkbug heads; peptides were extracted and purified via RP-HPLC, structurally characterised by mass spectrometry and used in *in vivo* bioassays to monitor their effect on circulating levels of lipids and carbohydrates in stinkbugs. Additionally, metabolites were monitored before and after flight episodes, and the activation of glycogen phosphorylase in the fatbody of bugs in response to CC extract or RPCH were determined.

Results: *E. delegorguei* produces two AKH peptides, viz. RPCH and Schgr-AKH-II. Homologous bioassays reveal that both stinkbugs react to injection of CC extracts and conspecific peptides by increasing lipid levels in the haemolymph; carbohydrates are not affected. Flight of two min (*N. viridula*) and 3 min (*E. delegorguei*) resulted in small increases in lipids and a small decrease in carbohydrates.

Conclusion: Two related stinkbugs show a similar metabolic strategy and both contain RPCH as an active AKH. A second AKH occurs in the tessaratomid.

Evolution of cleptoparasitism, eusocial behavior and shifts in diversification rates in apid bees (Hymenoptera: Apidae).

Sophie Cardinal[1], Jakub Straka[2], Bryan Danforth[1]

[1]Cornell University, Ithaca, NY, United States, [2]Charles University in Prague, Faculty of Science, Prague, Prague, Czech Republic

Apidae is the most speciose family of bees with over 5600 species. Its monophyly has been well established, but relationships among the tribes within Apidae are unclear. Among the most challenging phylogenetic questions within the apid bees are the phylogenetic affinities of the cleptoparasitic groups. To address this problem, we performed a phylogenetic study of the family Apidae based on molecular (DNA sequence) data and morphology from both adults and larvae. The study includes representatives from all apid tribes and every presumed independent origin of cleptoparasitism. Five nuclear protein-coding genes and two nuclear ribosomal genes were sequenced for 190 taxa and 220 morphological characters were coded. We then used the phylogeny to investigate origins of cleptoparasitism and patterns of host-parasite relationships within the family. Results indicate that there have been fewer independent origins of cleptoparasitism in the Apidae than was previously hypothesized based on morphological data alone. We used a relaxed fossil calibrated molecular clock model to investigate the antiquity of eusocial and cleptoparasitic behavior within apid bees as well as major shifts in diversification rates. This study represents the first comprehensive tribal level phylogeny of the family Apidae based on molecular and combined molecular plus morphological data.

Rynaxypyr® (Chlorantraniliprole): A novel DuPont insecticide with low toxicity for beneficial arthropods providing excellent tools (DuPont™ Coragen® and Altacor®) for uses in integrated pest management (IPM)

Axel Dinter

DuPont de Nemours (Deutschland) GmbH, Bad Homburg v.d.H., Germany

DuPont™ Rynaxypyr® insecticide (chlorantraniliprole) is a new anthranilic diamide insecticide with a novel and very specific mode of action activating insect ryanodine receptors causing impaired regulation, paralysis and ultimately death of sensitive species at rates of 10 to 60 g per ha. Anthranilic diamide insecticides exhibit > 500-hold differential selectivity toward sensitive insect, over mammalian, receptors. In worst-case Tier 1 glass plate tests the two indicator species, *Aphidius rhopalosiphi* (DeStephani-Perez) (Hymenoptera: Braconidae) and *Typhlodromus pyri* Scheuten (Acari: Phytoseiidae), were not sensitive to either formulated product, DuPont™ Coragen® or Altacor® insecticides, at up to 750 g Rynaxypyr® per ha, the maximum rates tested indicating low toxicity for non-target arthropods. Low risk for non-target arthropods was confirmed in a wide range of tests with several other beneficial arthropods (e.g. predatory mites, chrysopids, anthocorids, coccinellids and syrphids) under worst-case laboratory and field conditions. Overall, Rynaxypyr® and the formulations, Coragen® and Altacor®, were demonstrated to be safe to numerous beneficial non-target arthropod species including honeybees or to have rather low and transient short-term impact. The DuPont™ Rynaxypyr® insecticide formulations will be excellent tools in integrated pest management (IPM) programmes to conserve naturally occurring beneficial arthropods in the field as well as protect predators and parasitic wasps released for greenhouse pest control.

Attraction and repellence of grubs in soil systems as part of pest control strategies: the cockchafer *Melolontha melolontha* example

Rob van Tol, Gerrie Wiegers, Willem Jan de Kogel

Plant Research International, Wageningen-UR, Wageningen, Netherlands

Introduction: Despite the presence/availability of several natural enemies to control pests in soil systems (entomopathogenic nematodes, fungi and predators) the overall control results are still variable and poor for most soil pests. Lack of knowledge about the existing interactions in soil may explain this poor and variable control. Understanding these interactions may provide us with new tools for growers how and when to apply natural enemies in a more efficient way leading to higher and more reliable control of soil pests. For the white grub - plant roots - natural enemies interaction it is our goal to select for attractive plant species to lure the grubs and study the efficacy of these plants with natural enemies in a lure-and-kill system. The involvement and identification of semiochemicals in attracting or repelling white grubs and/or natural enemies to host-plant roots and pest in the soil is part of this study as well. Integrating aboveground attraction/repellence of the adult beetle to pheromone and plants as part of a system approach to control this pest insect is a further goal in this project.

Methods: A specific olfactometer for studying these grubs has been developed and different plant species were tested on attraction or repellence for the grubs in single and dual plant choice experiments.

Results: We demonstrate that for the white grub *M. melolontha* several plant species are highly attractive in an olfactometer where the grubs are unable to contact the roots. Two plant species were clearly preferred over several other plant species tested. Further we found two plant species that repelled 100% of the responding grubs from a distance.

Conclusions: White grubs appear to use sensory receptors for detection and selection of plant species from a distance. The grubs can detect several plant species without contacting the roots and are strongly attracted or repelled by some of the tested plant species. The strong preference and repellence may be used in a push-pull or attract-and-kill system with effective natural enemies.

Generalization and odor learning by honeybees

Geraldine Wright

Biology, Newcastle University, Newcastle upon Tyne, United Kingdom

Sensory biases in the responses of signal receivers to novel stimuli can be produced when an animal learns to associate two different outcomes, such as reward and punishment, with perceptually similar stimuli in the same modality. While such biases are well-described from experiments using visual and auditory stimuli, we know little about the development of learned sensory biases towards odors. Here, I describe a series of experiments showing that honeybees can acquire sensory biases towards both simple and complex odors as a result of differential learning of two perceptually similar olfactory stimuli. These experiments also demonstrate that the strength of a sensory bias depends upon the relative value of the positive and negative reinforcers. The implications for the use of odor signals by bees during foraging and nestmate recognition, and their significance with respect to our understanding of bee “cognition” will be explored.

How do long-range insect migrants influence their flight direction?

Jason Chapman

Rothamsted Research, Harpenden, United Kingdom

Behavioural adaptations of long-range insect migrants are often disregarded by many researchers, as migrant windborne insects are generally considered to be “passive” or “accidental” dispersers at the mercy of the wind. This simplistic approach has come about because of the difficulty associated with studying insects actively engaged in migration, which often utilise fast winds by flying hundreds of metres above the ground. In this talk I describe how two new research tools, vertical-looking entomological radar (VLR) and computerised flight simulators, are providing evidence that a wide range of insect taxa have evolved specialised behaviours to influence their direction of movement. Data from our VLR studies demonstrate that these behaviours include simple path straightening mechanisms in green lacewings *Chrysoperla carnea*, and selection of favourable airstreams in noctuid moths. Flight simulator studies of the Painted Lady butterfly *Vanessa cardui* indicate that this species uses a sun compass without time-compensation to direct its migratory flights in seasonally-advantageous directions. Finally, VLR data from migrant Silver Y moths *Autographa gamma* demonstrate that the high-flying moths use a compass to select favourable winds for their southerly return migrations, and also to compensate for lateral wind-drift away from their preferred migratory direction. Our data demonstrate that a wide range of species have evolved complex behavioural adaptations that significantly increase their chances of successfully exploiting seasonal resources.

Pestilence arising from cooperation: symbiotic associations among plant enemies

Matthew Ayres

Dartmouth College, Hanover, NH, United States

We propose that mutualisms among plant enemies have the general ecological effect of promoting plant pestilence. The theory, which we have dubbed "*Pestis symbiotica*", is comprised of six postulates: (1) symbioses are common among plant enemies; (2) symbioses tend to be mutualisms and commensalisms; (3) plant pestilence is typically the result of extreme population fluctuations in plant enemies; (4) population fluctuations are wrought by complex endogenous dynamics and/or variable exogenous effects; (5) commensalisms, and especially mutualisms, tend to destabilize population dynamics by contributing to complex endogenous dynamics and amplifying exogenous effects; (6) symbioses among plant enemies promote pestilence in evolutionary time by favoring the retention of virulence in microsymbionts and selecting for increased aggressiveness in macrosymbionts. If these postulates hold, it follows that many cases of plant pestilence are an emergent property of symbiotic associations among plant enemies, and that understanding this class of plant pestilence involves understanding community interactions among plant enemies. In support of *Pestis symbiotica*, 37-42% of the taxa that appear on plant pest quarantine lists for Europe (EPPO) and the United States (APHIS) have symbiotic associations with other plant enemies. *Pestis symbiotica* may also be relevant to animal pestilence and human disease. A general implications is that food web theory requires expansion to accommodate positive interactions, which are generally not trophic interactions. Finally, *Pestis symbiotica* runs counter to a prevailing theme of symbiology: the emergence of cooperation among previously independent biological entities. Ironically, the theory predicts that symbionts as ecological units tend to become "red in tooth and claw".

Bee diversity in coffee agroecosystems in Costa Rica

Hien Ngo, Laurence Packer

York University, Toronto, Ontario, Canada

Introduction: The intensification of coffee agroecosystems affects animal groups in different ways. The effect of shade trees on bee diversity in coffee agroecosystems was examined.

Methods: Bees were collected with Malaise traps in: i) shaded coffee farms, ii) unshaded coffee farms and iii) non-agricultural sites during 2005 and 2006 in Costa Rica. Bee diversity, evenness, species richness and abundance were compared among three site types. In addition, similarity indices were used to compare community complementarity.

Results: The diversity of bees across all site types did not differ from each other ($F_{2, 14} = 1.72$, $p=0.224$). Unshaded coffee farms had greater species richness and abundance but lower evenness than the other two site types. Results of the same analyses for different bee guilds will be presented. Similarity indices based on presence/absence (Jaccard) and abundance (Morisita-Horn) both show that non-agricultural sites are different in composition than agricultural sites types. *Lasioglossum* subgenus *Dialictus* made up 49% of the bee individuals collected. *Dialictus* has never been reported to be commonly found in coffee agroecosystems and this may be due to biases of different sampling methods. These findings have important implications for pollinator conservation and coffee agriculture.

Conclusions: Shade trees do affect the patterns of bee diversity in coffee agroecosystems. Sampling methods exhibit strong biases which can affect conservation strategies by misrepresenting biodiversity. The possible role of *Dialictus* and other often ignored bees in coffee pollination requires further investigation.

Integrated pest eradication: technologies for incursion response against invasive species

David M. Suckling

HortResearch, Lincoln, Canterbury, New Zealand

Introduction: Eradication of any insect from an area is normally only undertaken after justification from an economic and/or environmental impact analysis. Further key considerations include the ability to fully delimit and characterise the target population, as well as the availability of suitable technologies that can be used in the landscape where the pest has been detected. While standard IPM tools such as insecticides may be available, their suitability for use in an eradication programme may be constrained in urban or natural ecosystems. The types of tools available depend on the pest biology, and certain orders of insects have a wider arsenal available than others. For example, there are attractants identified for many Lepidoptera, while the same applies for certain Coleoptera, Diptera and Hymenoptera, and to a lesser extent for Hemiptera and other groups. In many cases pest management programmes have provided the basis for "Integrated Pest Eradication" when pests are detected in new regions.

Conclusions: More socially-acceptable tactics are urgently needed to reduce the almost inevitable establishment and range expansion of invasive species. Research challenges include the discovery of new and more powerful attractants and their development into mass trapping, lure and kill, mating disruption or other tactics which are broadly more acceptable than broadcast insecticides. In addition, the sterile insect technique, biopesticides, and other methods will be used increasingly, but need research along with key aspects of pest biology and ecology. Recent experience with successful and unsuccessful eradications of various species will be used to illustrate progress in this area.

Obscure mealybug pheromone is the kairomone of an introduced parasitoid in New Zealand

Vaughn A. Bell, David M. Suckling, James T.S. Walker, J.G. Millar, Lee-Anne Manning, Ashraf El-Sayed

HortResearch, Lincoln, Canterbury, New Zealand

Introduction: The obscure mealybug (*Pseudococcus viburni*) is a serious cosmopolitan pest of apples and many other crops. New options for managing this species in New Zealand include the release in 2001 of the host-specific parasitoid, *Pseudaphycus maculipennis* and the recent identification of a synthetic sex pheromone.

Methods: Pheromone-baited sticky traps with a range of loadings of *Pseudococcus viburni* pheromone were tested in orchards to determine optimal doses for monitoring mealybugs as part of anIPM program.

Results: This study evaluated the efficacy of the mealybug pheromone in the field and serendipidously discovered that the parasitoid was also attracted to traps baited with the pheromone of its host. The presence of female *P. maculipennis* in baited (but not control) traps suggests recognition of the host female sex pheromone as a kairomone. Male *P. viburni* were trapped in 11 Hawke's Bay orchards. Traps also recovered the parasitoid *P. maculipennis* from eight Hawke's Bay orchards where releases had been made.

Conclusions: The finding of kairomonal activity in the parasitoid has readily enabled monitoring the fate post-introduction of a biological control agent. The phenology of the two species as revealed by the trap data showed a mealybug generation without evident parasitoid catch in the middle of winter. Future applications of mealybug sex pheromones for managing the pest and parasitoid will be discussed.

Soil invertebrate-plant feedbacks and community change in a California coastal prairie

Daniel Gruner[1], Donald Strong[2]

[1]University of Maryland, College Park, MD, United States, [2]University of California, Davis, CA, United States

The yellow bush lupine (Fabaceae: *Lupinus arboreus*) is a dominant, nitrogen-fixing woody shrub in California coastal prairie. It is attacked by a suite of aboveground foliar- and seed-feeding herbivores which can defoliate plants and strongly reduce seedset. Belowground, the primary herbivore is a stem- and root-boring lepidopteran (Hepialidae: *Hepialus californicus*). By severing vascular cambia, these ghost moth caterpillars also can reduce reproduction, but often girdle and kill mature bushes, releasing limited space, light and available nitrogen to native and invasive plant colonists and facilitating change in plant community structure. In field and laboratory experiments, soil-dwelling entomopathogenic nematodes ('EPN', *Heterorhabditis marelatus*) can control *Hepialus* and provide protection to lupines via a trophic cascade. However, longer duration, spatially explicit studies demonstrate that the strength of these interactions varies temporally and spatially, and caterpillar outbreaks and lupine devastation can occur even within a background of robust EPN populations. Limited locomotion – both by nematodes and insect hosts in soil – impair EPN recruitment to high local host densities and reinforce the inherent patchiness of naturally-occurring EPN populations. Spatial autocorrelation functions showed that characteristic patch sizes of EPN were larger than the scale of individual lupine rhizospheres, but that these dynamic 'clouds' swelled into grasslands during the wet season and retreated to lupine rhizospheres following dry Mediterranean summers. Summer desiccation risk drove EPN into moisture refugia, both within lupine rhizospheres and into deep (>80 cm) soils lacking host insects. Monthly samples of soil columns from grassland and lupine rhizospheres over one year confirm that lupine canopies facilitate EPN populations with higher soil moisture and by harboring greater diversity and abundance of arthropod larvae in the soil. These features create greater opportunity under lupine canopies for individual movement, host-finding behavior, and survival of IJs, and promote recycling of additional EPN generations through alternative arthropod hosts. Research from the *Heterorhabditis – Hepialus – Lupinus* system provides clear examples of how subterranean interactions can instigate potent ramifications for the structure and diversity of aboveground plant and animal communities.

Interactions among invasive ants, herbivores, and plants

Lori Lach[1], Andrew V. Suarez[2]

[1]Murdoch University, Murdoch, WA, Australia, [2]University of Illinois, Urbana, IL, United States

Because ants play so many roles in ecological communities, invasion by non-native ants can have many direct and indirect consequences. For example, invasive ants can positively or negatively affect herbivore populations, which can then have cascading effects on the plant community. Outside of agricultural settings, however, few experiments have examined interactions among invasive ants, herbivores, and plants. We studied the effects of invasive ants via ant exclusion experiments on two plants on a small Mauritian islet. The native shrub, *Scaevola taccada,* hosts sap-sucking scale insects, and the invasive tree, *Leucaena leucocephala*, also hosts scale insects, but offers extrafloral nectaries as well. *Technomyrmex albipes* was the most common ant visitor to both plants. Honeydew-producing hemipterans declined rapidly on branches of *S. taccada* to which ants had been excluded, and these branches had 22-30% and 32-45% greater growth and fruit production, respectively, compared to ant-allowed branches on the same plants. On *L. leucocephala*, ant exclusion resulted in 22% and 35% lower vegetative growth and seed production, respectively, most likely because ant presence lowered the prevalence of psyllids. However, the beneficial effect of the ants was diminished when scale insects were present on the tree. Stable isotope analysis confirmed that the ants behaved more as herbivores on the native *S. taccada*, and as predators on the invasive *L. leucocephala* tree. Our findings illustrate the context-dependency of invasive ant effects on plants. Negative effects on native plants and positive effects on invasive plants are means through which ants may be especially insidious invaders.

Social parasitism in the allodapines: new insights from a unique tribe of bees

Jaclyn Smith[1], Theresa Wossler[2]

[1]Flinders University, Adelaide, South Australia, Australia, [2]University of Stellenbosch, Matieland, South Africa

Introduction: Allodapine bees are unique among bees, with most species rearing their highly dependent brood progressively in an undivided communal tunnel without the presence of cell partitions. Social parasitism within these bees has received little attention in the past, but recent research on allodapine social parasites indicates that these bees have much to contribute to our general understanding of social parasitism. Behavioural work on allodapine social parasites has shown that they are able to invade host colonies with surprising ease. These results are largely unexpected since the costs associated with parasitism should result in the selection of nest defence with it expected that the host colonies should be able to refuse entry to a parasite.

Methods: We investigated whether allodapine social parasites are manipulating their cuticular hydrocarbon profiles to avoid detection and gain entry into host colonies. Two species of allodapine bees, *Exoneura robusta* (host) and *Inquilina schwarzi* (social parasite) were collected in Australia and their hydrocarbons were extracted. The cuticular hydrocarbon profiles of both species were analysed in South Africa, using gas-chromatography mass-spectroscopy (GC-MS).

Results: Multivariate statistical analyses have indicated some interesting differences between the hydrocarbon profile of the host and parasite species within the parasitised nests, but also differences between parasitised and unparasitised nests.

Conclusions: The results from the GC-MS analyses, together with previous behavioural observations on these two species have provided a unique insight into the fascinating phenomena of social parasitism.

Understanding the evolution of social parasitism: Implications from phylogenetic analyses of allodapine bees.

Jaclyn Smith, Michael Schwarz

Flinders University, Adelaide, South Australia, Australia

Introduction: Much research has focused on the social parasites of ants, wasps and honeybees, however, very little research has focused on social parasitism within allodapine bees. This group of bees have much to contribute to understanding the evolution of social parasitism, as social parasitism has evolved many times in the allodapines, resulting in this tribe having a higher proportion of socially parasitic species than any other social insect group. The allodapines can therefore provide a unique insight into the processes that were involved in the evolution of a parasitic strategy.

Methods: Allodapine social parasites, from Australia, Madagascar, Africa and Asia (19 species in total), were analysed with molecular tools to explore the host-parasite relationships. Bayesian analyses were used to determine phylogenetic relationships and divergence dates were estimated with Sanderson's Penalised Likelihood Method (R8s).

Results: Eight independent origins of social parasitism were found. These origins have varying divergence ages, ranging from relatively recent, to very ancient, and each of these origins demonstrated variable phylogenetic relationships between the parasites and their hosts. In most cases, social parasites were phylogenetically allied to their hosts. However, where taxonomic sampling was dense, there was no evidence for a sister-group relationship between hosts and parasites and therefore no evidence for sympatric speciation origins for social parasites.

Conclusions: No firm evidence for sympatric origins of social parasitism are apparent, though host and parasite lineages were usually phylogenetically allied. There is good evidence for cospeciation between hosts and parasites suggesting that the two become very closely linked.

The impact of phosphate fertilizer as a pest management tactic in four cowpea varieties

Joseph Asiwe, Frank Kola Ewete, Sagary K Nokoe, Louis E.N. Jackai

[1]ARC-Grain Crops Institute, Potchefstroom, South Africa, [2]Department of Crop Protection and Environmental Biology, University of Ibadan, Ibadan, Nigeria, [3]University for Development Studies, Ghana., Accra, Ghana, [4]2 GWC-Agricultural Experiment Station, College of Agricultural, Environmental and Natural Sciences, Tuskegee University, Tuskegee, Alabama 36088, USA, Alabama, United States Minor Outlying Islands

Introduction: Insect pests constitute serious threat to cowpea production in sub-Saharan Africa. In some severe situations, total yield loss results. Chemical control is the most effective and quick method. However, it is not a sustainable method for cowpea insect management. Investigation of other control options such as cultural practices that are environment friendly is critically important.

Methods: This paper reports the effects of four levels of phosphorus fertilizer application (0, 15, 30 and 45 kg P_2O_5 ha^{-1}) on insect population, damage and grain yield of four cowpea varieties (IT91K-180, IT95M-118, TVu 1890 and Vita 7) planted at research farm of International Institute of Tropical Agriculture (IITA), Nigeria. Data collected included insect counts, pod evaluation index, and damage by insects (*Aphis craccivora, Megaluro sjostedti*, *Maruca vitrata* and pod-sucking bugs).

Results: Results indicated that infestation by *A. craccivora* in cowpea plots fertilized at 30 kg P_2O_5 ha^{-1} was significantly ($P < 0.05$) lower in the first than second season. Damage by *M. sjostedti* was significantly ($P < 0.05$) lower at 30 and 45 kg P_2O_5 ha^{-1} during second season. Pod evaluation index (*Ipe*) was significantly higher in cowpea plots treated with 30 and 45 kg P_2O_5 ha^{-1}. Counts of pod-sucking bugs were not significantly different among P-levels and test varieties.

Conclusions: Insect damage was minimal at 30 and 45 kg P_2O_5 ha^{-1} and consequently higher grain yields were obtained. These P-levels are recommended, and can be used in conjunction with other cultural interventions for integrated insect pests management in cowpea.

The phylogeographic population structure of Argentine ants in South Africa: genetic evidence for multiple introductions

Bettine van Vuuren, Thomas Lado, Steven Chown

DST-NRF Centre of Excellence for Invasion Biology, University of Stellenbosch, Stellenbosch, South Africa

Introduction: Much is known about the genetic structure of the Argentine ant across its native and introduced ranges. However, very little is known about the genetic composition of the species across South Africa.

Methods: Segments from two mitochondrial DNA genes (COI and cytb) as well as six microsatellite loci were used to investigate the phylogeographic population structure of ants sampled across South Africa.

Results: Alignment of COI sequences indicated four variable sites resulting in five haplotypes, two of which are identical to those from other parts of the world. COI haplotypes are separated by (at most) only 0.4% uncorrected sequence divergence or 3 mutational changes. As is documented for introduced Argentine ants across the world, the majority of South African specimens (93%) are characterized by a single haplotype. In contrast to the COI results, genotyping of Argentine ants revealed moderate levels of genetic diversity (H_e = 0.51 ± 0.22). Microsatellite analyses further indicated significant sub-structure across South Africa (R_{ST} = 0.14; $p<0.05$). This result was confirmed by non-metric multidimensional scaling of pairwise genetic distances. A comparison of Argentine ant cytb haplotypes from South Africa and across the world indicated multiple source populations for introduction into South Africa.

Conclusions: Limited mitochondrial genetic variability characterizes Argentine ants from South Africa. In contrast, moderate levels of variation were found for microsatellite loci. Significant substructure further characterized nuclear loci with evidence for introductions from multiple source populations

Western corn rootworm and European corn borer important pests of maize in Croatia

Marija Ivezic[1], Emilija Raspudic[1], Mirjana Brmez[1], Ivana Majic[1], Andrija Brkic[2]

[1]*Josip Juraj Strossmayer University of Osijek, Faculty of Agriculture in Osijek, Osijek, Croatia,* [2]*Agricultural Insitute Osijek, Osijek, Croatia*

Introduction: Western corn rootworm (WCR) (*Diabrotica virgifer virgifera* LeConte) and European corn borer (ECB) (*Ostrinia nubilalis* Hübner) are considered to be the most harmful pests of maize in Croatia. Research was done with the aim to evaluate combined attack of both pests in Croatia.

Methods: The research was carried out at the Agricultural Insitute Osijek, in years from 2003 to 2007 on 7 Croatian commercial maize hybrids. WCR population was monitored by pheromone traps. Root injury was assessed during July according to the Iowa Node Injury Scale (0-3). In order to determine ECB larvae and total damages per plant were dissected in September.

Results: Node-injury ratings ranged from 0.58 to 1.61. From 2003 to 2006, rating of all hybrids except one, planted in monoculture for 7 years, were assessed over 1. Hybrid OSSK 617 showed greater tolerance to the WCR larvae. Since the maize was grown in monoculture only for two years, considerably less damage was determined in 2007 when node-injury ratings ranged from 0.38 to 0.73. ECB attack in 2003 and 2004, was more than 81%, in 2005 and 2006 damage was more then 41% and it was considerably lower. In 2007, nearly 100% maize stalks were infested with ECB larvae. Stalk damage was positively correlated with the intensity of ECB attack.

Conclusions: The obtained results indicate that Western corn rootworm and European corn borer are severe pests of maize in Croatia and in order to avoid economic damages integrated pest management is recommended.

The characteristics of ant subfamilies (Hymenoptera: Formicidae) wing venation and their significance for paleontological investigations

Ksenia Perfilieva

Lomonosov Moscow State University, Biologycal Faculty, Moscow, Russian Federation

Introduction: Ants are among the most common and dominant groups of insect in various Cenozoic. While, winged ants or only the wings form a large part of preserved fragments, which are very difficult in identifying, since the venation of wings is not used as taxonomic characteristics for recent ants. Differences in wing venation of recent ant subfamilies have not practically been investigated yet.

Methods: Investigations has been made on the 17 recent ant subfamilies of Formicidae. Differences in wing venation of subfamilies were analyzed by geometric morphometrics methods.

Results: We present the principals of wings description for recent and fossil ants, which will permit more precisely to describe a forewing venation of ants. For that we proposed scheme of forewing venation types, which consist of 16 types. The different subfamilies may have the same types of forewing venation. Nevertheless, recent subfamilies have different composition and ratio of venation types. Differences in features of venation of the same type that in turn indicate the differences between various subfamilies are very important for paleontological research. Usually the features of venation (relative length, slope of veins) are conditioned by various ways of wing evolution in different subfamilies. With the help of geometric morphometrics methods, we show that subfamilies (Pseudomyrmecinae, Dolichoderinae, Myrmicinae, Myrmeciinae, Poneromorpha, etc.) has peculiar venation traits, such as the shape of cells, location, slope of definite veins and other.

Conclusions: Subfamilies of Formicidae (Pseudomyrmecinae, Dolichoderinae, Myrmicinae, Myrmeciinae, Poneromorpha, etc.) has peculiar venation traits, which allows identifying recent and fossil ants wings.

Yield losses due to natural infestation of tomato by *Liriomyza* spp., Central Sudan

[1]Faiza. E. Salah, [2]E. M. Elamin, [1]E. M. A. Eltoum, [3]D. Bordat

[1]Dept. Crop Protection, Gezira University, Medani, Sudan. P.O. Box 20; [2]Agricultural Research Corporation, Medani; [3]CIRAD, Montpellier, France

The leafminer (LM), *Liriomyza* spp. (Diptera: Agromyzidae) is known to attack tomato crops in the Gezira all year around. The effect of such infestation was not tackled researches in the Sudan. This study was done at the Experimental Farm of the Faculty of Agricultural Sciences, University of Gezira on the tomato variety Peto 86 (season 1996/97) and the breeding line Wad El-Obaid (season 1997/98). One experiment was conducted for each. Two treatments (i.e. insecticide-treated and untreated) were laid out in a RCB design with six replicates. The untreated plots were left to the LMs natural infestation, while the treated plots were protected by the IGR Trigard 75% WP. Highly significant differences ($P<0.01$) in percentage of leaf infestation were correlated with the highly significant differences in yield between treated and untreated plots. Differences in leaf infestation of *ca*. 48% in plots of the tomato variety Peto 86 resulted in a yield loss of approximately 44%, compared to 43% loss in yield of Wad El-Obaid, where the percentage of leaf infestation was *ca*. 56%. Therefore, it is recommended that tomato crop should be treated with insecticides to reduce the effect of the LMs.

Monitoring the operational impact of insecticide usage for malaria control on *Anopheles funestus* from Mozambique

Michael Coleman[1], Sonia Casimiro[2], Janet Hemingway[3], Brian Sharp[1]

[1]Medical Research Council, South Africa, Durban, South Africa, [2]National Institute of Health, Maputo, Mozambique, [3]Liverpool School of Tropical Medicine, Liverool, United Kingdom

Introduction: Indoor residual spraying (IRS) has again increased for malaria control in Africa. DDT was re-introduced into Mozambique's IRS programme in 2005 and has become the main insecticide used for malaria vector control. Use of DDT in Mozambique is evidence-based, taking account of the susceptibility of Anopheles funestus and Anopheles arabiensis to all available insecticide choices and operational costs of spraying. To maintain integrity of control operations, monitoring the susceptibility status of both major vectors needs to be embedded within routine operations of the control programme.

Method: Sentinel sites were monitored for insecticide resistance using WHO bioassays and biochemical assays. Assays were conducted on 1-3 day old F1 offspring of field collected adult females to determine levels of insecticide resistance and gene resistance frequency in vector population.

Results: Lambda cyhalothrin replaced DDT for malaria control in Mozambique in 1993. However, resistance appeared quickly to this insecticide and, in 2000, the pyrethroid was phased out and the carbamate, bendiocarb, introduced. Low level resistance was detected by biochemical assay to bendiocarb in 1999 in both *An. funestus* and *An. arabiensis*.

Surveys conducted between 2002-2006, detected bendiocarb resistance in *An. funestus,* populations using WHO bioassays and resistance levels increased over this period. The pyrethroid resistance is linked to elevated levels of monooxygenase activity and the carbamate resistance is predominantly due to an altered acetylcholinesterase. Pyrethroid resistance declined after lambda cyhalothrin was withdrawn. This process of monitoring resistance is incorporated into an integrated malaria decision support system, improving the malaria control programme's ability to make informed decisions and policy.

Monitoring the operational impact of insecticide usage for malaria control on *Anopheles funestus* from Mozambique

Michael Coleman[1], Sonia Casimiro[2], Janet Hemingway[3], Brian Sharp[1]

Pyrethroid resistance declined after lambda cyhalothrin was withdrawn. This process of monitoring resistance is incorporated into an integrated malaria decision support system, improving the malaria control programme's ability to make informed decisions and policy.

Effects of soil type on incidence of *Agrotis ipsilon* (Hfn.) on potato, in Sudan

[1]Faiza E. Salah, [2]A. M. Zein Elabdien, [2]S. El –Tom, [2]A. Azrag

[1]Dept. Crop Protection, Gezira University, Medani, Sudan. P.O. Box 20; [2]Dept. Crop Protection, University of Khartoum, Sudan

The potato in the Sudan is growth in different soil types. The black cutworm (BCW), *Agrotis ipsilon* (Hfn), is one of the major pests of this crop. The present work objective was to study the effect of light soil (Karari site, Northwest of Omdurman) and heavy vertisol (Shambat site, Khartoum North) on the incidence of this pest.

The results revealed that potato grown in light soil exhibited higher BCW damage (29.7) than that grown in the heavy vertisol (16.13). The mean (%) BCW damage in the marketable tubers of the three tested potato varieties Alpha, Ajax and Formosa was 20.4, 32.6 and 36.1% for the light soils and 12.3, 14.2 and 21.9% for the heavy soils, respectively. Differences in BCW damage were highly significant between varieties and the soil types. Thus, it is advisable to grow potato in heavy soils.

From DDT to integrated pest management of Colorado potato beetle (*Leptinotarsa decemlineata* Say.) in Poland

Stefan Pruszynski, Danuta Sosnowska

Institute of Plant Protection, Poznan, Poland

Colorado potato beetle (CPB) (*Leptinotarsa decemlineata*) is an insect of high importance for Polish agriculture and Polish plant protection, as a result of intensive potato production and the role of this crop in the Polish economy. The area under potato in Poland amounted until quite lately to 2.7 mln ha, and presently amounts to about 0.7 mln ha. The pest is controlled by repeated insecticide applications to a yearly total of 1.0 mln ha, which is the greatest amount of insecticide used in Poland.

The first CPB was found in Poland in 1945 and a great invasion of this pest took place in 1950. The first compounds recommended were arsenates and in the following years the main pesticides were from chlorinated hydrocarbon group withdrawn from the use in beginning of the seventies. Those pesticides were replaced by organophoshorous insecticides, carbamates, synthetic pyrethroids and recently chitin synthesis inhibitors, neonicotinoid insecticides and phenylpyrazole.

The programme of scientific work started after CPB appearance and consisted the following subjects: biology and ecology of CPB, influence of appearance and control of CPB on the biocenosis of fields, methods of control, biochemical factors influencing the life cycle of these pest and forecasts and prognosis of appearance of pest. The possibility of using biological methods was also started.

Pioneering studies carried out at the beginning on the entomopatogenic fungi, mainly of the genus *Beauveria.* In 1959 trials of introduction in to Poland of natural enemies of CPB were undertaken and predatory bugs: *Perillus bioculatus* and *Podisus maculiventris*, (Pentatomidae, Heteroptera) were introduced. In 1967, an unsuccessful trial introduction of *Doryphorophaga doryphorae* (Tahinidae, Diptera) was undertaken. Research conducted on parasitic nematodes, protozoans, entomopathogenic fungi and registration of bioproduct Novodor contining a new strain of *Bacillus thuringiensis* should also be mentioned here.

During 1996/1997 joint Polish, Czech and USA research project on evaluation of the possibility of elaboration of biological and integrated CPB control was carried out. From that research we conclude that three treatments with either of the biopesticides Mycotrol (*Beauveria bassiana*) and Novodor prove level of control of *L. decemlineata* similar to two treatments with chemical pyrethroid. Economical aspects of CPB recommendation should be also discussed.

A forensic conflict: What happened to *Sarcophaga cruentata*?

Jacobus Hendrik Kolver, Theunis Christiaan Van der Linde

University of the Free State, Bloemfontein, South Africa

Introduction: Recent casework raised the question whether burning has an influence on the decomposition of and insect succession on bodies. Prof. T. C. van der Linde conducted a trial and found that *Sarcophaga cruentata* (Diptera: Sarcophagidae) was the most dominant decomposer due to the fact that burning resulted in sufficient desiccation of the carcasses to completely skip the initial phases of decomposition. The current study was undertaken to provide a more complete database of the influence of burning on insect succession and the decomposition process.

Methods: Three pig carcasses were doused with different volumes of petrol and burnt to different degrees (Slight = 1.5L. Medium =5L, Heavily = 10L). The decomposition of and insect succession onto these carcasses was compared to a control carcass.

Results: In the current study it was found that *Chrysomya albiceps, Chrysomya marginalis* and *Chrysomya chloropyga* (Diptera: Calliphoridae) were the dominant decomposers. Representative samples of larvae collected during decomposition revealed that *C. albiceps* larvae preferred to feed underneath the carcasses, with *C. marginalis* larvae feeding mostly inside and on top of the carcasses. *Sarcophaga cruentata* was only present in very low numbers and only a small number of larvae were found feeding on the carcasses. This conflictive finding raised the question: What happened to *S. cruentata*?

Conclusions: The correct question is: What happened to the other decomposers during Van der Linde's trial? Baseline research is vital, because the accuracy of determining the PMI is based on the knowledge base of the research scientist.

A forensic anomaly: Decomposition in the fast lane

Jacobus Hendrik Kolver, Theunis Christiaan Van der Linde

University of the Free State, Bloemfontein, South Africa

Introduction: Recent casework raised the question whether burning has an influence on the decomposition of and insect succession onto bodies. During a criminal investigation, the major contribution made by a forensic entomologist is an estimate of the postmortem interval (PMI), requiring the entomologist to analyse the species of insects present and the weather conditions that allow these species to be active. The accuracy of determining the PMI is therefore based on the knowledge base of the research scientist.

Methods: Three pig carcasses were doused with different volumes of petrol and burnt to different degrees (Slight = 1.5L. Medium =5L, Heavily = 10L). The decomposition of and insect succession onto these carcasses was compared to a control carcass.

Results: Burnt carcasses decomposed faster than a control carcass during summer conditions in previous trials, with a control carcass reaching the skeletonised stage within 11 to 14 days. During one trial peculiar results were obtained, with all four carcasses reaching the skeletonised stage within 3½ days. During January and February 2006 the average relative humidity was 68.7% and 75.8%, respectively. Average total rainfall during January was 147.6mm and for February 147.2mm. Average temperatures for January and February were 22.8°C and 21.5°C, respectively.

Conclusions: The anomaly was attributed to environmental conditions, since the decomposers remained the same as in other trials.

The ecology of insect-pathogen interactions and the implications for microbial control of locusts and grasshoppers

Matthew Thomas, Simon Blanford, Justine Klass

Penn State, University Park, PA, United States

Recent years have seen an upsurge in locust and grasshopper populations in many parts of the world. Environmentally sustainable approaches to locust and grasshopper control may be possible through the use of biopesticides based on entomopathogenic fungi. Unfortunately, the performance of these biopesticides is highly variable. Here we demonstrate that environmental temperature and host thermoregulatory behavior critically determine host resistance and pathogen virulence and hence, the pattern and extent of locust mortality after biopesticide applications. We quantify these effects through a combination of lab and field studies and use the information to develop a temperature-dependent model that enables us to predict the field performance of *Metarhizium anisopliae* var. *acridum*, the key fungal pathogen used in locust biopesticides. We demonstrate how the model can assist in the development of improved application strategies to optimize the performance of the biopesticide. More generally, we show how quantifying the effects of local environmental factors can enhance our understanding of the ecology and evolution of host-pathogen interactions.

Costly butterfly anti-aphrodisiac: direct and indirect arrestment of egg parasitoids

Nina Fatouros[1], Martinus Huigens[1], Joop van Loon[1], Marcel Dicke[1], Monika Hilker[2]

[1]Wageningen University, Department of Entomology, Wageningen, Netherlands, [2]Free University of Berlin, Berlin, Germany

Introduction: To locate tiny eggs of herbivorous host insects, egg parasitoids employ chemical cues either from the plant induced by host egg deposition or from the adult host stage[1]. The large cabbage white *Pieris brassicae* and its egg parasitoid *Trichogramma brassicae* were used to investigate, which chemical cues the wasps use to locate the butterfly eggs.

Methods: Bioassays were conducted in an olfactometer, an arena and a small Petri-dish. Female butterfly accessory gland secretion was analyzed by GC-MS.

Results: (1) Mated female butterflies were the most attractive to the wasps. During mating, *P. brassicae* females receive with the male ejaculate the anti-aphrodisiac benzyl cyanide (BC) that reduces the females' attractiveness for males[2]. Female wasps responded only to virgin female butterflies when they were treated with the anti-aphrodisiac showing that they spy on the pheromone. Once the wasps located mated host females, they mount them and hitch-hike to oviposition sites to parasitize freshly laid host eggs[3]. (2) *P. brassicae* egg depositions were shown to induce phytochemical changes in Brussels sprout plants arresting *T. brassicae* wasps[4]. The elicitor inducing this plant defence response was identified as BC present in butterfly gland secretion associated with eggs. When applied onto leaves, BC alone induced phytochemical changes that arrested the egg parasitoid. Thus, the male-transferred butterfly anti-aphrodisiac in egg secretions elicits oviposition-induced plant cues luring egg parasitoids[5].

Conclusions: Our results suggest that the anti-aphrodisiac pheromone incurs fitness costs for the butterfly both by mediating phoretic behaviour and plant defence traits.

The potential for novel malaria control interventions using fungal entomopathogen sprays

Matthew Thomas[1], Penny Hancock[2], Charles Godfray[3], Andrew Read[1]

[1]Penn State, University Park, PA, United States, [2]Imperial College, Silwood Park, United Kingdom, [3]Oxford University, Oxford, United Kingdom

Biopesticide sprays containing spores of infectious fungi are being evaluated as a novel method of controlling mosquito vectors of human diseases. Unlike chemical insecticides, fungal entomopathogens do not kill mosquitoes instantly. They can nonetheless be very effective at reducing disease transmission because malaria and other pathogens require time to mature in the vector, and thus mosquitoes do not transmit the disease until relatively late in their life. Different strains of fungi vary in virulence (the mean time to death) as well as the temporal pattern of mortality they induce. To compare the epidemiological impact of these different strains and to aid in the design of vector control programmes, we developed a model of a malaria-transmitting mosquito population that explicitly includes mosquito age and the duration of both fungal and malaria infections. The model shows how the density of infectious mosquitoes is influenced by the choice of fungal strain, and how the optimum choice may depend on parasite maturation time, a variable that is strongly affected by local environmental conditions. The effect of biopesticide coverage and the reduction in biopesticide efficacy with time after spraying is also explored. Overall, the results indicate that fungal biopesticides have the potential to cause considerable reductions in the density of malaria-transmitting mosquitoes while potentially imposing minimal selection pressure for evolution of resistance.

Identification and field evaluation of host plant volatiles attractive to sorghum chafer, *Pachnoda interrupta*

Wolde-Hawariat Yitbarek[1], Bengtsson Jonas[2], Seyoum Emiru[1], Jembere Bekele[1], Negash Merid[1], Hansson Bill.S[3], Hillbur Ylva[2]

[1]Addis ababa University, Addis Ababa, Ethiopia, [2]Swedish University of Agricultural Sciences, Alnarp, Sweden, [3]Max Planck Institute for Chemical Ecology, Jena, Germany

Introduction: Sorghum chafer is an economically important pest of sorghum in Ethiopia. The aim of the study is to develop host derived kairomones.

Methods: Headspace volatiles were collected from sorghum, *Sorghum bicolor* (Poaceae) and *Abutilon figarianum* (Malvaceae). The response of *Pachnoda interrupta* antennae, to these volatile compounds were recorded by coupled gas chromatography electroantennographic-detection (GC-EAD). Compounds were identified using coupled gas chromatography-mass spectrometry (GC-MS) and comparison with authentic samples. The attractivity of the identified compounds was tested under field condition.

Results: Antennally active compounds includes (*Z*)-3-hexen-1-ol, tridecane, 1-octen-3-ol and 1-octanol from sorghum and (*Z*)-3-hexen-1-ol, tetradecane, methyl salicylate and methyl anthranilate from abutilon. The identified compounds performed well in the field when they are tested as a blend than when they are applied individually. Moreover, the addition of compound(s) such as eugenol and methyl salicylate to sorghum blend and the addition of eugenol to abutilon blend have increased the trap catch more significantly indicating that these compounds could be part of the host components used by the insect in locating its hosts.

Conclusions: This study suggests that synthetic sorghum or *Abutilon* blends with the addition of eugenol /and methyl salicylate, can be used as a tool for monitoring or control by themselves or can be incorporated in IPM package of sorghum chafer control.

Changes on the species diversity of craneflies (Diptera: Limoniidae) by improvement cutting of Yambaru, a subtropical forest of Japan

Masahiro Sueyoshi, Hideaki Goto, Hiroki Sato

Kyushu Research Center, Forestry and Forest Products Research Institute, Kumamoto, Japan

Species richness and abundance of limoniid craneflies captured by emergence traps for logs were compared among forest stands of different ages after improvement cutting of natural forests (ICNF) and among different quantity and quality of decaying woods in Japanese subtropical forests. The objective of this study is to investigate the effects of ICNF on species diversity of saprophagous forest insects in the Yambaru, which is northern mountain area of the Okinawa Island, Ryukyus, Japan. Limoniids are one of major forest insects in species richness and abundance, inhabiting rotten woods at their immature stages.

From February 2006 to February 2007, we set 12 plots (10m*10m) in the eight stands aged 1-23 years after ICNF, one stand of 50 year-old ater clear-cutting, and one stand without cutting records. All decaying woods (fallen trees and branches) (> 3cm in diameter and > 50cm in length) in the plots were measured and their volumes were calculated. These decaying woods were classified into six categories by diameter and stages of decay, and then packed separately by a category in the emergence traps. Number of species and individuals of limoniids emerged from the decaying woods were counted. Humidity of each plot was recorded at summer and winter seasons.

Species richness and abundance of limoniids increase by ICNF and they decline along with succession of forests after ICNF. Supplement of rotten woods in middle size and the late stage of decay and high humidity at the stands conserve species diversity of limoniids in the Yambaru.

Genes and pheromones: The molecular basis of social parasitism in insect societies

Robin Moritz[2], Theresa Wossler[1]

[1]Stellenbosch University, Stellenbosch, South Africa, [2]Martin-Luther-Universitat, Halle-Wittenberg, Germany

Social parasitism is a fascinating phenomenon within the social insects where one species exploits the social resources of another species or conspecific. Many of these social parasites are unable to survive without their hosts. This relationship is obviously beneficial to the parasite, but is often detrimental to the host colony. The goal of the session will be to close the gap between organismal approaches dealing with parasitism and the molecular mechanisms driving the transition from sociality to parasitism. Social parasites are found throughout the social insect taxa and have been studied with various ant, bee and wasp species, with the intriguing host-parasite relationships in these species being used to explore many areas such as, behavioural interactions between species, colony recognition processes.

Sitotroga cerealella (Olivier) interactions with *Rhyzopertha dominica* F. and *Sitophilus* spp. on threshed and unthreshed sorghum columns

Brighton M. Mvumi[1], Tanya E. Stathers[2], Pete Golob[2], Denash P. Giga[1]

[1]University of Zimbabwe, Harare, Zimbabwe, [2]Natural Resources Institute, Chatham Maritime, Kent, United Kingdom, [3]formerly with University of Zimbabwe, Harare, Zimbabwe

Sitotroga cerealella is an important pest of stored grains in the tropics. While its biology has been well-researched in small laboratory experiments, comparatively little is known about its interactions with other key storage pests which share a similar ecological niche.

This study examined the spatial and temporal interactions of *S. cerealella* with *Rhyzopertha dominica* and *Sitophilus* spp. in columns of sorghum. Investigations were conducted, under controlled temperature and relative humidity, to determine the interactions between *S. cerealella* and *S. oryzae* on threshed grain and between *S. cerealella* and *R. dominica* on unthreshed grain over a 21-week storage period. A sampling procedure was developed to provide information on the comparative vertical dispersal pattern and populations changes of the insects in the grain after being introduced at the top of the grain columns.

In threshed sorghum, both *S. cerealella* and *S. oryzae* were concentrated in the top 30-35cm in single populations but the *S. cerealella* population was generally lower. In mixed populations, *S. oryzae* was the dominant species. In unthreshed sorghum, *S. cerealella* was more prolific than *R. dominica* at all depths as single species but was adversely affected by *R. dominica* in mixed populations although it still remained more abundant. The density of threshed grain prevented *S. cerealella* from performing its normal biological functions which require inter-granular space as was available in the unthreshed grain. The results are discussed in relation to the ecology of these storage pests and the implications for pest management strategies.

Social regulation of plasticity in the circadian clock of the honeybee (*Apis mellifera*)

Yair Shemesh, Mira Cohen, Guy Bloch

The Hebrew University of Jerusalem, Jerusalem, Israel

In honeybees (*Apis mellifera*) natural plasticity in circadian rhythms is associated with the division of labor that organizes their colonies. “Nurse” bees (typically < 2 weeks old) care for brood around-the-clock whereas bees older than 3 weeks of age typically forage for flowers with strong circadian rhythms. We found that nurses care for brood around-the-clock even under a light/dark illumination regime. Brain oscillations in the abundance of the putative clock genes *Period* and *Cryptochrom-m* were attenuated or totally suppressed in nurses as compared to foragers, irrespective of the illumination regime. However, nurses showed circadian rhythms in locomotor activity and molecular oscillations in brain clock gene expression shortly after transfer from the hive to constant laboratory conditions. The onset of their activity occurred at the subjective morning, suggesting that some clock components were entrained even while in the hive and active around-the-clock. These results suggest that the hive environment induces reorganization of the molecular clockwork. To test this hypothesis, we studied activity and brain clock gene expression in young bees that were confined to a broodless area on the honeycomb in a light/ dark illuminated observation hive. These bees experienced the hive environment and could interact with other bees, but not with the brood. By contrast to same-age nurses from these colonies, the confined bees showed molecular oscillations in clock gene expression and were more active during the day. These findings are consistent with the hypothesis that interactions with the brood modulate plasticity in the molecular clockwork of the honeybee.

Assessing the risk of introduction of *Bactrocera invadens* (Diptera: Tephritidae) into sub-Saharan Africa

Abraham Addo-Bediako

University of Limpopo, Polokwane, South Africa

Introduction: Trade is increasing significantly in Africa, and as trade increases, the risk of introduction of exotic pests would also increase. The entry of exotic species into a country can have devastating effect on Agriculture and export programmes. The fruit fly, *Bactrocera invadens* was recently recorded for the first time in Kenya, and has subsequently been reported in many countries in Africa.

Methods: The risk associated with the likelihood of introduction and establishment of *Bactrocera invadens* from infested areas to non infested areas within sub-Saharan Africa was assessed using both qualitative and quantitative risk assessment. The pathways considered for the analysis included movement of infested fruits from infested to non infested areas including hitchhikers, natural spread and vendors. The likelihood for establishment in various areas in the region was examined and patterns of spread described, in relation to the prevailing climatic conditions and host availability.

Results: The preliminary results using qualitative assessment indicated a high risk of introduction and establishment of the fruit fly due to the absence of effective mitigation measures to control illegal movement of fruits in certain parts of the region, the high reproductive potential of the pest, availability of suitable hosts, and favourable climatic conditions in most parts of the region.

Conclusion: It is important for countries to implement acceptable quarantine measures to reduce the risk of introduction.

The functional organization of size-related division of labor in bumblebees – from circadian rhythms and phototaxis to gene expression

Guy Bloch

The Hebrew University of Jerusalem, Jerusalem, Israel

Size, division of labor, and diurnal activity rhythms are correlated in colonies of the bumblebee *Bombus terrestris*. Large workers typically forage outside the nest with strong diurnal rhythms and low activity at night, whereas small bees typically care for (nurse) brood around the clock with weak or no diurnal rhythms. In laboratory conditions under constant darkness or a light: dark illumination regime, we found that activity rhythms were weaker, less stable, and developed at a later age in small (nurse-size) bees compared to their larger (forager-size) sisters. The brain expression of the "clock genes" *Period* and *Cryptochrome* appeared to oscillate with a stronger amplitude in foragers compared to nurses collected from free-flying colonies. More cells immunostained with antiserum against the clock neuropeptide Pigment Dispersing Factor in the brain of large, forager-size bees as compared to small nestmates. Taken together these findings reveal naturally-occurring attenuation or suppression in the circadian clock of small bees that is determined during pre-adult development. We also found stronger positive phototaxis in foragers relative to nurses. In one of two colonies, foragers had higher brain mRNA levels of *PKG*, a gene previously implicated in phototaxis in honeybees. This deficiency in clock function and phototaxis in small bees, however, does not result in pathology but rather appears to be functionally significant because it facilitates around-the-clock brood care activity in the nest, and therefore apparently improves divisions of labor and colony efficiency. These findings suggest that the social biology of bees influences traits of the circadian clock and phototaxis.

Assessing the risk posed by the invasion of *Harmonia axyridis* on European ladybirds. 1. Likelihood of encounter

Marc Kenis[1], Renate Zindel[1], Rene Eschen[1], Michael Majerus[2], Remy Ware[2]

[1]CABI Europe-Switzerland, 2800 Delemont, Switzerland, [2]Department of Genetics, University of Cambridge, Cambridge, CB2 3EH, United Kingdom

Introduction: The risk posed by the invasion of the harlequin ladybird, *Harmonia axyridis*, on native ladybirds in Europe can be considered as the product of the likelihood that a given ladybird species encounters *H. axyridis* in the field, and the consequence of this encounter, through direct predation, or competition for food. In this presentation we will focus on the likelihood of encounter, whereas the consequences of encounter will be the topic of the following presentation.

Methods: Ladybird larvae and adults were collected in various habitats and ecosystems recently invaded by *H. axyridis* in Switzerland. Niche overlap indices, cluster analyses and canonical component analyses were used to assess which species most often encounter *H. axyridis* in the field. Data were compared to published data found in the literature.

Results: *Harmonia axyridis* was found in nearly all habitats surveyed. However, niche overlap was greater with arboreal aphidophagous species found on broadleaved trees than with ladybirds found mainly or exclusively in grasslands or on conifer. The European species that will most likely encounter *H. axyridis* during their lifetime are *Calvia quatuordecimguttata*, *Adalia bipunctata*, *Adalia decempunctata* and *Oenopia conglobata*.

Conclusion: These results, once combined with data on the consequence of encounter, will allow us to list the species that will most likely suffer from the invasion of *H. axyridis* and to develop adequate management and conservation strategies.

HYMAToL: Assembling the Hymenoptera tree of life

HYMAToL Team, Michael Sharkey

Department of Entomology, University of Kentucky, Lexington, Kentucky 40546-0091, United States

Introduction: For almost five years a large international team of systematists have been working towards developing a robust phylogenetic hypothesis for the Hymenoptera at the superfamilial level. This talk will summarize the results obtained.

Methods: A number of separate analyses were conducted by various labs. These include standard morphological data and sequence information from 28S (domains 1-10), 18S, EF1α, and CO1, as well as data from numerous protein coding genes for a restricted number of exemplar taxa. Here we include all data in a total evidence analysis. Some of the later talks in this symposium will investigate and summarize results of analyses of the component datasets.

Results: Preliminary results corroborate many of the groupings that have recently been proposed by various authors based on single genes or intuitive analyses of diverse morphological data.

Conclusions: Although our concatenated analysis is not complete at the time of writing this abstract we expect that the data will support a monophyletic Proctotrupomorpha, and the classical symphytan position as a basal hymenopteran grade is also expected to be substantiated. The most interesting conclusions will center on the relationships among the remaining non-proctotrupomorpha Apocrita, especially the Evaniomorpha. Monophyly of this group and relationships among the included superfamilies remain problematic. It is hoped that further progress will be made with the concatenation of the component datasets.

Herbivory-boosted primary metabolism: A mechanism to alleviate fitness costs of plant vaccination

Andre Kessler[1], Rayko Halitschke[1], Jason Hamilton[2]

[1]Cornell University, Ithaca, NY, United States, [2]Ithaca College, Ithaca, NY, United States

Introduction: Herbivory is thought to be detrimental to plant fitness and the paradigm of an herbivore-induced metabolic shift in plants is emerging: photosynthetic processes are typically down-regulated, while resource allocation to defenses is increased in herbivore-attacked plants. This metabolic shift contributes to the fitness costs of induced plant responses. However, herbivore attack does not always decrease host plant fitness. In the native tobacco plant *Nicotiana attenuata* damage by leaf-chewing tobacco hornworms (*Manduca sexta*) but not cell content-feeding mirid bugs (*Tupiocoris notatus*) reduces plant fitness although both herbivores induce a similar plant defense response.

Methods: We used CO_2 gas exchange and chlorophyll fluorescence measurements to analyze herbivore-induced changes in photosynthetic activity of tobacco plants in response to both herbivore species—a hypothesized plant mechanism to alleviate the fitness costs of herbivore attack.

Results: We report a mirid-induced increase in photosynthetic activity as a compensatory plant response, which likely provides the resources to alleviate fitness costs of induced defenses and tissue loss. By applying isolated salivary secretions we demonstrate that component(s) of the mirid salivary secretions specifically elicit an increase in photosynthetic activity.

Conclusion: In contrast to earlier studies we suggest that the photosynthetic activity in herbivore-damaged leaves is not solely regulated by a simple feedback loop sensing the source/sink status of the leaf changed by tissue loss. It rather represents an herbivore elicitor-specifically induced mechanism of the plant to compensate for tissue loss and resources allocation to defense production.

The effects of six novel insecticides and an acaricide on *Galendromus occidentalis* Nesbitt, Acarina, Phytoseiidae

Noubar J. Bostanian[1], Howard Thistlewood[2], John M. Hardman[3], Gaetan Racette[1]

[1]Hortic. Dev.Res.Centre, St. Jean-sur-Richelieu, Qc., Canada, [2]Pacific Agri_food Res. Centre, Summerland,BC, Canada, [3]Atlantic Food and Hortic. Centre, Kentville, NS, Canada

Introduction: Biological control of phytophagous mites in orchards requires that pesticides used to manage other arthropod pests or diseases in orchards are innocuous to predacious mites as these are essential to keep phytophagous mites at non-injurious population levels. This study evaluates seven new pesticides currently used in western Canadian orchards.

Materials and Methods: *Galendromus occidentalis* collected from the Okanagan valley BC was reared in growth chambers in Quebec and used for toxicological tests in the laboratory. Leaf discs were treated with formulated pesticides at different concentrations and the pesticides were evaluated for toxicity to adults, fecundity, egg viability and repellency. Probit analyses were done to establish LC_{50} values and compare them with label rates.

Results: Acetamiprid and imidacloprid were toxic to the adults. Spinosad, thiamethoxam, thiacloprid, methoxyfenoxide and spirodiclofen were harmless. Significantly fewer eggs were laid by females exposed to acetamiprid and imidacloprid residues. The effect on fecundity was intermediate for thiamethoxam and spirodiclofen. None of the compounds were ovicidal. However, imidacloprid was toxicity to the larvae, as was spirodiclofen. Intrepid acetamiprid and thiacoprid were repellent to *G. occidentalis*.

Coclusion: The safest of the seven compounds evaluated were, in order, thiamethoxam, spinosad, and thiacloprid. Imidacloprid and acetamiprid showed adverse effects in at least three of the four parameters measured. The label rate for acetamiprid is 0.1 167g/ Land is 5.6 fold the LC_{50} (0.02 g/ L). The field rate for imidacloprid is 0.1600g/L and it is 10.2 fold the LC_{50} value of 0.0156g/L.

Present and future of GM corn in Romania

Ioan Rosca, Rada Istrate, Constantin Popov

[1]*University of Agricultural Sciences and Veterinary Medicine; Bucharest, Bucharest, Romania,*
[2]*Agricultural Research and Development Institute Fundulea, Fundulea, Romania*

Introduction: The maize, cultivated on three million ha in Romania, is one of the most important crops, and the crop technology involves complex protection measures versus pests.

Methods: The main problems for corn in Romania are weeds and pests, after corn weevil (*Tanymecus dilaticollis*) and Western Corn Rootworm (*Diabrotica virgifera*) the most important lepidopterous pests are *Ostrinia nubilalis* and *Helicoverpa armigera* which affected more than 0.3 million of ha.. Possible impact of Roundup Ready® or Bt corn on the trophic chains in agrocenosis is of concern to farmers who cannot any longer afford expensive mechanical or chemical control of weeds and pests, to policy makers who recommend expansion of maize fields, and to organisations and societies interested in environment conservation. Our objective was to evaluate potential impact of Roundup maize on the epigeic fauna and on the useful fauna on the corn plants.

Results: Data obtained regarding resemblance of whole insect fauna from the corn variants investigated represented by value of Sörensen index (71.43, 79.25, 86.66 in 2000 and 91,3 in 2004), confirmed the hypothesis that genetically modified corn (Bt or RR), has no impact on the insect fauna in corn field. In conclusion it is possible to affirm that the cultivation of genetically modified corn (Bt or RR), has no influence on the epigeic fauna or plant-dwelling predators. Structure of predatory Heteroptera species seems to be an indicator for biodiversity in corn fields, because being predaceous, their number and species composition could reflect changes in whole corn agro ecosystem.

Landscape effects of insect resistant GM crops

Nicholas Storer[1], Galen Dively[2], Rod Herman[1]

[1]Dow AgroSciences LLC, Indianapolis, IN, United States, [2]University of Maryland, College Park, MD, United States

Putative effects of incorporating GM crops into agricultural landscapes have long been proposed. Here we examine the evidence for such effects within dynamic and heterogeneous agroecosystems, based on widespread commercial deployment insect resistant *Bt* crops for over 10 years. While there is good evidence for changes in the population sizes of several target pest populations and for the increasing importance of some secondary pests, there is no evidence of landscape-level effects on non-target species. These findings were anticipated by laboratory and field characterization of the high specificity of action of the *Bacillus thuringiensis* proteins currently deployed, and the equivalence of the GM crops to their non-transformed conventional counterparts. Indirect effects of the insect resistant GM crops on the agricultural ecosystems due to multitrophic exposure, loss of prey, or reduction of prey quality, are generally negligible compared with the direct effects of other more dramatic environmental manipulations that are standard agricultural practices.

Insulin-signaling regulates static allometry in *Drosophila*

Alexander Shingleton

Michigan State University, East Lansing, United States

The regulation of static allometry, the relationship between final body size and organ size, is a fundamental developmental process that determines the shape of an animal. Nevertheless, the mechanisms that underlie this regulation remain virtually unknown. Here we elucidate the developmental regulation of static allometry in *Drosophila.*

Most organs scale isometrically with body size in *Drosophila*. However, the male genitals scale hypoallometrically with body size, and are approximately the same absolute size irrespective of body size. Variation in developmental nutrition is a major regulator of body and organ size in *Drosophila*, and we show that the hypoallometry of the genitals reflects their relative insensitivity to reduced developmental nutrition compared to other organs. The insulin-signaling pathway regulates growth with respect to nutrition in all animals, and suppression of the pathway's activity has a less of an effect on the size of the genitals than on other organs. Thus, variation among organs in their sensitivity to changes in insulin-signaling, and hence developmental nutrition, appears to underlie variation in their scaling relationships with each other and with body size. We present data indicating that it is the organ-specific expression or activity of insulin-signaling genes that regulates insulin sensitivity, and show that altering the expression of these genes in a single organ is sufficient to alter that organ's allometric relationships. These data implicate the insulin-signaling pathway – which plays major roles in longevity, diabetes and the regulation of cell, organ, and body size – as a key regulator of allometry and organismal shape.

Soil-applied imidacloprid is translocated to nectar and kills nectar-feeding beneficial insects in landscapes

Vera Krischik

University of Minnesota, St. Paul, MN, United States

Currently, few published studies quantify the concentration of imidacloprid in nectar and its affects on behavior and survival of nectar feeding beneficial insects. Since imidacloprid is widely used in greenhouse on plants later installed in landscapes and on ornamentals and crops, the potential non-target effects of imidacloprid on beneficial insects, such as lady beetles, lacewings, parasitoids, and bees is important. Soil-applied imidaclopird (Marathon 1%G) was imidacloprid translocated to nectar and altered behavior and survival of beneficial insects, such as pink lady beetle, *Coleomegilla maculata* (DeGeer), (Smith and Krischik 1999), green lacewing, *Chrysoperla carnea* (Stephens), (Rogers et al. 2007), and *Anagyrus pseudococci* (Girault) parasitoid (Krischik et al. 2007). Residue analysis of nectar from *Asclepias curassavica* (L.) treated with 1X or 2X label rate of soil -applied imidacloprid (Marathon 1%G) showed imidacloprid levels in flower nectar as 2 ppb in controls, 15 ppb in 1X, and 27 ppb in 2X treated plants, which is similar to levels found in another species, *Fagopyrum esculentum* (Moench) (0 control, 16 ppb 1X, and 29 ppb 2X) (Krischik et al. 2007). Residue analysis detected imidaclopird in nectar at the last sample date 63 d after application. A second application 7 mo later resulted in 0 ppb in controls, 53 ppb in 1X, and 110 ppb in 2X treated plants. The hydroxy and olefin metabolites were also found in nectar. Higher levels of residue may be due to imidacloprid persistence in nectar, since it can persist in tree leaves 1 to 2 years after application.

Segmentation in the honeybee (*Apis mellifera*)

Peter Dearden, Megan Wilson

University of Otago, Dunedin, New Zealand

Insect segmentation is a well-studied developmental pathway in flies and segmentation genes have been studied in a few other insects. We employ a systems-biology approach to understand how this complex developmental cascade evolves. Using the Honeybee, with its recently sequenced genome, as our model, we have investigated long-term evolution of this pathway. In this talk I will present our recent studies of *giant* and *even-skipped* function and regulation, using RNA interference and transgenic *Drosophila* to identify differences in the control of segmentation from the fly paradigm, and to discover how those differences may have evolved.

Microbial control of rhinoceros beetle, *Oryctes rhinoceros* (Coleoptera: Scarabeidae) on oil palm in Malaysia

Ramle Mslim[1], Norman Kamarudin[1], Mohd Basri Wahid[1], Trevor A. Jackson[2], Idris A. Ghani[3]

[1]Malaysian Palm Oil Board, PO Box 10620, 50720 Kuala Lumpur, Malaysia, [2]AgResearch, Gerald Street, PO Box 60, Lincoln, New Zealand, [3]National University of Malasysia, Faculty of Science and Technology, UKM 43600 Bangi Selangor, Malaysia

Introduction: *Oryctes rhinoceros* is a major pest of oil palm causing significant yield losses to the plantations. Two types of microbes, the fungus *Metarhizium anisopliae* (Ma) and the *O. rhinoceros* virus (OrV) were used to control the beetle in several plantations in Malaysia.

Methods: The Ma was applied by (i) direct spraying of spore solutions, (ii) broadcasting of granule made from mycelium and (iii) by inoculation trap to disseminate the spores into the beetle breeding sites. The OrV was introduced by releasing the inoculated young adults into the field.

Results: Application of fungal spore solutions reduced the beetle population, especially the immature stages. This technique, when applied onto the breeding sites significantly reduced the third instars larvae, pre-pupa and pupae of the beetle. Application of the granule of the Ma was much easier than the spore solution. The granule was supplemented with the nutrient for fungal growth, which gave longer effect in the field. The use of inoculation trap for dissemination of fungal spores is simple. The attracted adults get infected in the trap and carry the spores and contaminating their habitat. High trap density was required to ensure the effectiveness of this technique in controlling the beetle. The release of OrV gradually reduced the adult population, followed by the reduction of the palm damage. The released virus spread all over the field after a year of introduction.

Conclusions: The Ma is targeted for reducing the immature stage and the OrV is for the adult stage of the rhinoceros beetle. Application of both microbes reduced the population of the beetle.

The role of haemoglobin in diving insects

Philip Matthews

The University of Adelaide, Adelaide, South Australia, Australia

Introduction: Aquatic backswimmers (Hemiptera: Notonectidae) use haemoglobin and a small bubble of air held on the abdomen to supply them with oxygen while underwater. Unusually for an aquatic insect, they have a pelagic habit, entering a protracted phase of near-neutral buoyancy during every dive. To determine haemoglobin's role in buoyancy regulation and supplying oxygen for respiration, the oxygen partial pressure (PO_2) and volume of the backswimmer's air bubble, as well as the insect's buoyancy, were measured.

Methods: Fibre optic oxygen probes were placed in the air bubbles of submerged backswimmers (*Anisops deanei*) to measure changes in PO_2 during a dive. These data were analysed to determine the haemoglobin's oxygen-binding properties. Changes in buoyancy were measured by securing backswimmers to a submerged rod suspended from an electronic balance. Air-bubble volume was determined indirectly from buoyancy measurements and by collecting air bubbles from free-diving insects.

Results: Following an initial linear decline, the PO_2 of the backswimmer's bubble temporarily plateaus as oxygen is released from the haemoglobin. This serves to stabilise the volume and buoyancy of the air bubble while supplying the insect's respiration. The oxygen-binding properties of backswimmer haemoglobin in critical in establishing this plateau by unloading over 50 % its oxygen across a very narrow (4.14 – 3.30 kPa) range of oxygen partial pressures.

Conclusions: Haemoglobin is fundamental to the backswimmer's ability to occupy its pelagic niche. The haemoglobin's oxygen-binding properties ensure that the PO_2 and volume of the air bubble are stabilised at a level where the insect is neutrally buoyant.

The biological control of codling moth using entomopathogenic nematodes

Jeanne de Waal, Antoinette Malan, Matthew Addison

University of Stellenbosch, Western Cape, Stellenbosch, South Africa

Introduction: Previous control measures of codling moth, *Cydia pomonella* (L.) Lepidoptera: Tortricidae), an established key pest of apple and pear fruit in South Africa, was grounded predominantly on the use of broad spectrum insecticides. Concerns such as resistance of codling moth to certain insecticides and the negative environmental effect of continuous pesticide use have forced the industry to consider alternative methods which are environmentally friendly and serve as an alternative to pesticides, such as entomopathogenic nematodes (EPNs). Using EPNs as inundatively applied microbial biopesticides for the control of codling moth in South African apple and pear orchards was therefore investigated.

Methods: A survey was conducted to isolate endemic EPN strains from soils. Strains obtained were molecularly identified to species level. Strain efficacy was examined in the laboratory. Overall field-performance of the most promising strain was investigated, whereby the optimum concentration nematodes required per tree was determined and the addition of adjuvants to increase efficacy was investigated in a quantitative spray-deposition assessment.

Results: Several endemic strains were isolated from 202 soil samples collected, with *Heterorhabditis zealandica* being the predominant species. All isolates were effective against codling moth larvae and morphologically suitability. The most promising isolate selected (SF41, *H. zealandica*) performed best at 25℃, 90% RH and at an appropriate concentration in laboratory experiments. Field trials indicate that EPNs are promising candidates to be used for the control of codling moth.

Conclusion: Entomopathogenic nematodes have great potential for the control of codling moth as part of an integrated pest management strategy under local conditions.

The biological control of codling moth using entomopathogenic nematodes

Jeanne de Waal, Antoinette Malan, Matthew Addison

University of Stellenbosch, Western Cape, Stellenbosch, South Africa

Introduction: Previous control measures of codling moth, *Cydia pomonella* (L.) Lepidoptera: Tortricidae), an established key pest of apple and pear fruit in South Africa, was grounded predominantly on the use of broad spectrum insecticides. Concerns such as resistance of codling moth to certain insecticides and the negative environmental effect of continuous pesticide use have forced the industry to consider alternative methods which are environmentally friendly and serve as an alternative to pesticides, such as entomopathogenic nematodes (EPNs). Field trials indicate that EPNs are promising candidates to be used for the control of codling moth.

Conclusion: Entomopathogenic nematodes have great potential for the control of coding moth as part of an integrated pest management strategy under local conditions.

IRM policies and compliance: A stakeholder's perspective from India

Dattatray Shirale, Shivraj Devkar, Prasanna Padmasali, Chandrashekhar Chaporkar, Srinivas Parimi

Maharashtra Hybrid Seeds Co. Ltd., Jalna, Maharashtra, India

Bollgard® (Bt) cotton in India is commercialized and cultivated on approximately 60% of the cotton growing area. Bt cotton in India is grown since 2002 and recently Bollgard II® was commercialized in 2006. Since Bollgard® was commercialized there are around 25 companies marketing more than 150 Bollgard® and Bollgard II® hybrids in different parts of the country. The production of cotton in India doubled in the past six year period of Bt cotton commercialization. One of the regulatory requirements for the sustainability of the Bt crops in India is to plant a refuge besides resistance monitoring in populations as a part of Insect resistance management (IRM) plan. Current IRM plan for the Bt cotton necessitates the growers to plant 5 rows or 20% crop as refuge planted around the Bt crop. Increase in yield and monetary benefits from growing Bt cotton encouraged growers to plant more acreage each year. However, planting the crop following the regulatory requirements has been a challenge for the stakeholders. We conducted a survey among 400 cotton growers from different part of the country with an objective to better understand these challenges and refuge compliance among them. In this presentation we discuss various issues related to IRM plan(s), awareness among growers through various stakeholders specifically the technology providers, refuge compliance, and/or any reasons for non-compliance of IRM plans.

Insects, plants, diversity and spatial scale in the Cape

Serban Proches[1], Richard Cowling[2]

[1]University of KwaZulu-Natal, Durban, South Africa, [2]Nelson Mandela Metropolitan University, Port Elizabeth, South Africa

It has been argued that the remarkable plant diversity of the Cape Floristic Region is not paralleled by an equally diverse insect fauna. Here we present the results of extensive plant surveys and insect collections in various vegetation types in the Cape. We show that fynbos vegetation (a mediterranean-type shrubland characteristic to the Cape) is not particularly insect-poor, and that its insect fauna is largely vegetation-specific, although sharing species with both arid vegetation ("karoo") and summer-rainfall grasslands. Subtropical thickets in the Eastern Cape have a distinctive insect fauna of rainforest affinities. This latter vegetation type is composed of distantly related plants (high phylogenetic diversity), thus accommodating a high diversity of insect herbivores at the local scale; however, insect species turnover between thicket patches is limited. On the other hand, fynbos, similar to karoo and grassland vegetation, has lower plant phylogenetic diversity, a consequence of most component lineages having radiated recently. Nevertheless, numerous insect species from fynbos, grassland and karoo, in particular those belonging to flightless lineages, have localized distributions, given the highly dissected geography of the region.

Insect versus wind pollination in the South African cycad *Stangeria*

Serban Proches[1], Steven Johnson[2]

[1]University of KwaZulu-Natal, Durban, South Africa, [2]University of KwaZulu-Natal, Pietermaritzburg, South Africa

Stangeria eriopus represents an isolated South African cycad lineage previously thought to be wind pollinated. We found the scent of *Stangeria* to mimic that of rotten fruit, the main volatiles being esters (ethyl and propyl acetate, 1-butanol, 2-methyl-acetate), ketones and aldehydes. Unlike in most cycads, there was no evidence of thermogenesis. The main insect visitors were sap and rove beetles (Coleoptera: Nitidulidae, Staphilinidae), and fruit flies (Diptera: Drosophilidae), but only sap beetles were able to effect pollination under experimental conditions. Since sap beetles are also pollinators of *Cycas* and of several ancient angiosperm families, their role in the pollination of *Stangeria* adds interesting details to the role this group has played in the history of plant-pollinator interactions.

Evolution of fungal enzymes in the attine ant symbiosis

Henrik H. De Fine Licht, Morten Schiøtt, Jacobus J. Boomsma

Centre for Social Evolution, University of Copenhagen, DK-2100 Copenhagen, Denmark

The attine ant symbiosis is characterized by ancient but varying degrees of diffuse co-evolution between the ants and their fungal cultivars. Domesticated fungi became dependent on vertical transmission by queens and the ant colonies came to rely on their symbiotic fungus for food and thus, indirectly, on fungal enzymes to break down the plant material brought in by the ants as fungal substrate. The more than 210 extant fungus-growing ant species differ considerably in colony size, social complexity and substrate-use. Only the derived leaf-cutting ants are specialized on using fresh leaves as garden substrate, whereas the more basal genera use leaf litter, insect feces and insect carcasses. We hypothesized that enzyme activity of fungal symbionts has co-evolved with substrate use and we measured enzyme activities of fungus gardens in the field to test this, focusing particularly on plant decomposing enzymes. We further obtained gene sequences coding for specific enzymes and used them to reconstruct the fungal symbiont phylogeny and to compare the trees obtained with those known from sequence information of genes that have no specific link to enzyme function. Differences in fungus garden enzyme activity across ant genera could indeed be partially explained by substrate differences. This implies that fungal enzyme activity has likely coevolved with the genus- or species-specific substrates that the ants use to manure their fungus garden. Plant decomposing enzymes are thus not only essential for the symbiosis in general, but have contributed specifically to the evolution of the symbiosis.

The value of changing phenotypes: Herbivore population consequences of induced plant responses

Andre Kessler[1], Katja Poveda[2]

[1]Cornell University, Ithaca, NY, United States, [2]Georg August University, Göttingen, Germany

Introduction: Plants respond to insect herbivore damage with an array of changes in primary and secondary metabolism. Some of these metabolic changes can cause increased resistance of the plant to current and subsequent herbivore attack and may function as direct and indirect defenses. Such induced resistance effects have been extensively studied but very little is known about their role in structuring arthropod communities, influencing insect herbivore population dynamics, and conversely the distribution of herbivory within plant populations.

Methods: We used field and laboratory choice and preference bioassays and analyzed the herbivore-induced secondary metabolite production of the plants to study the effect of herbivore-induced responses of *Solidago altissima* plants on the population dynamics of the larvae of the specialist Chrysomelid beetle *Trirhabda virgata*.

Results: *T. virgata* damage results in an increased production of secondary metabolites that is correlated with a higher resistance of the plants to beetle attack. Moreover, *Trirhabda* larvae move actively away from the damage site and choose undamaged over damaged plants on their way through the plant population. This plant response-mediated alteration in larval behavior causes a change of beetle and damage distribution within the plant population over the season, from a clumped distribution early in the season to an equal distribution later in the season.

Conclusion: The data demonstrate that herbivore-induced plant responses can have dramatic effects on herbivore population dynamics, which likely has significant effects on community composition and productivity.

The ecology and acoustic biology of the duetting bushcricket *Leptophyes punctatissima*.

Patricia Ash, Marion Hall, David Robinson

The Open University, Milton Keynes, United Kingdom

Introduction: The flightless bushcricket *Leptophyes punctatissima* communicates using ultrasound. We report the habitat and food plants exploited, the distribution of instars in the habitat and the sites from which males call, part of a long-term study of acoustic biology and mate choice.

Methods: Three sites were studied. They were surveyed using belt transects and the percentage cover of all the species of plant in each square meter, were recorded. The position of each immature *Leptophyes* instar and the plant that it was on when first spotted was noted. Observations on adult mating behaviour were made at night adults being located using directional ultrasound detectors. Food choice experiments were conducted with immature instars.

Results: Although *Leptophyes* is present at all sites, the vegetation is different. Wood sage is only present at one site and early instars were found almost exclusively on that plant, usually clumped and close to the ground. Food choice experiments in the laboratory showed that the immature instars preferred wood sage, even if they had been collected from a habitat where it was absent. Mating is rapid and difficult to observe and some adult males have been located singing 14m above the ground implying a long journey down for the female to lay her eggs.

Conclusions: The results suggest that there are food preferences and, given the small size of the hatchlings, the site at which eggs are laid the previous year would be expected to be close to an acceptable food plant.

Towards agro-ecological management of sugarcane stalk borers in South Africa and Reunion: a synthesis of results and perspectives

François-Régis Goebel, Mike Way

CIRAD, Montpellier, France

Introduction: In the last 10 years surveying and formal experiments have concentrated on elucidating the main factors that impact on the major sugarcane borers *Eldana saccharina* Walker and *Chilo sacchariphagus* Bojer on commercial and small-scale farms in South Africa and Réunion.

Results: Synergies appear in the research findings for these species. The following factors had a significant impact on damage levels : cultivar type, age of cane, soil nitrogen and soil silicon level, and biodiversity richness. As such, an Integrated Pest Management (IPM) approach is proposed for control of these particular pest species. The IPM strategy would ideally encompass a combination of recognised control tactics, principles and complementary management practices. In this instance these would likely include implementation of biological control programmes, use of breeding resistant varieties, adoption and monitoring of correct applications of fertilizer in terms of quantities and promoting farming practices among grower communities that conserve habitat diversity on sugarcane farms. Levels of complexity of the landscape structure, coupled with the existence of a fragmented habitat, also impact on the population dynamics of pest species. Accordingly cognisance of these factors is also important in our endeavour to develop a holistic management strategy within sugarcane fields.

Conclusions: Following on from past findings this paper discusses future research work that take into account all the ecological processes influencing the abundance, richness, and diversity of insects in these specific sugarcane agrosystems.

Sensory Map Formation in the Drosophila Olfactory System

Marc Lattemann, Oezkan Adymir, Britta Kuhlmann, Thomas Hummel

WWU Muenster, Muenster, Germany

Introduction: A striking feature of olfactory system organization is the evolutionarily conserved arrangement of olfactory receptor neuron (ORN) terminals into an odortopic map. In mouse and Drosophila, ORNs expressing the same odorant receptor, distributed over the surface of the sense organ, form connections to a common set of CNS dendrites spatially segregated into distinct synaptic glomeruli. In the mouse, odorant receptors play an instructive role in ORN targeting but, despite the anatomical and physiological similarities, targeting of fly ORNs seems to be independent of odorant receptor function.

Methods: To uncover the molecular basis of wiring specificity in the Drosophila olfactory system, we have performed a large-scale genetic mosaic screen and identified mutations that lead to ORN class specific changes in axon targeting or odorant gene expression.

Results: Here we present the functional characterization of two signaling molecules, Dscam and Semaphorin-1a. We demonstrate that *Dscam* mutant antennal ORNs frequently converge onto ectopic glomeruli throughout the AL but that these ectopic glomeruli still contain single ORN class innervation, indicating that ORN axons of the same sensory class recognize each other and induce glomerular convergence independent of their target area. In contrast, removal of Sema1a in ORN-specific somatic mosaics does not interfere with the axonal projection towards the AL target area but disrupt local axon sorting between neighboring glomeruli.

Conclusions: From these data we propose a model in which connection specificity in the olfactory system is achieved through a series of inter-axonal signaling events leading to a progressive refinement into distinct synaptic units.

Phylogeny of Cleroidea (Coleoptera) inferred from 18S ribosomal DNA

Milada Bocakova, Ladislav Bocak

[1]*Department of Biology, Faculty of Education, Palacky University, Olomouc, Czech Republic,*
[2]*Department of Zoology, Faculty of Science, Palacky University, Olomouc, Czech Republic*

The Cleroidea is one of important beetle superfamilies housing almost 10,000 species of worldwide distribution, and belong to a very diverse Cucujiformia series. The modern concept of Cleroidea proposed inclusion of melyrids, while other groups as dermestids, passandrids, bothriderids, and ciids were excluded. Currently the Cleroidea consists of 7 families. Distinctive coloration of some checkered beetles and other groups as well as extensible glands of Malachiinae appear to be aposematic signal. While basal cleroid groups are fungivorous (Trogossitidae: Peltinae), many cleroids are predaceous or polyphagous, and a lot of Melyridae feed preferentially on pollen. The monophyly of this group was challenged by latest molecular analyses. In this study we performed molecular phylogenetic analyses of small ribosomal subunit sequences (18S) of 38 outgroup and 115 cleroid taxa representing 5 families. In contrast to previous published molecular analyses, the results show cleroids including Phloiophilidae as monophyletic group although the low support values are very low. The internal relationships show several features never revealed before. The Trogossitidae were shown to be a paraphyletic assemblage. Results of our analyses further placed the subfamily Trogossitinae as a sister group of checkered beetles, which is in agreement with predatory feeding habits of these groups. Further, the Melyridae were shown to include Prionoceridae, while lately proposed family Mauroniscidae was supported as one of early cleroid splits.

Reasons for successes and failures of microbial control products and businesses in Europe

Juerg Huber

Julius Kühn-Institute, Institute for Biological Control, Darmstadt, Germany

In Europe (EU) about 8 microbial strains are approved as active ingredients of pesticides and more than 20 are in the pipeline, waiting for registration (most of them “old” a.i.).

Success or failure of a product depends on two key elements: the product itself and the market situation (the real market, not the potential one). The market has to be shared with competitors and is further reduced by the fact that in most cases only a small proportion of the potential buyers are inclined to actually buy the product. Therefore, apart from an optimal selection of the target pest, the other factor a company can try to manipulate in order to increase the sales of its products, is the behaviour of the buyer.

What reasons a farmer could have to choose a specific microbial control agent ? (1)The most convincing argument is always low costs. This can be achieved either by a low price of the product, or by financial support (through subsidies from the government - as they are foreseen in the framework of the EU modulation procedures – or directly from consumers, willing to pay better prices for agricultural produce grown without chemical pesticides). (2)The product has to be effective and reliable. (3)A farmer might be forced to use a biocontrol agent if no conventional alternatives are available (either because the pest is resistant against most other means of control or because legislation bans the use of chemical pesticides for reason of environmental or consumer protection). (4) Finally, the decision of a farmer can also be influenced by pressure from the public (to use environmentally more friendly or safer methods) and by good marketing and farmer’s support from the side of the company.

Some of the point listed above can hardly be influenced by the producer; they are the realms of legislators (pesticide ban; registration costs) or even the individual consumer. But several traits which can decide about success or failure of a product are under the control of the producer: A successful biopesticide has to be (1) effective and reliable (right choice of microbial; formulation), (2) cheap to produce (production method), and (3) in demand (market analysis; promotion; support). Producers are well advised to concentrate on these features rather than complain about issues beyond their control as, e.g. high registration cost or hurdles built up by regulators against their products.

The biotic and abiotic controls on ant community structure

Sarah Wittman[1], Nathan Sanders[2], Aaron Ellison[3], Erik Jules[4], Nicholas Gotelli[1]

[1]University of Vermont, Burlington, VT, United States, [2]University of Tennessee, Knoxville, TN, United States, [3]Harvard Forest, Harvard University, Petersham, MA, United States, [4]Humboldt State University, Arcata, CA, United States

Introduction: In ant communities the interaction of competition and temperature has been used to describe diversity patterns on local and continental scales, how communities are affected by disturbance, and how non-native species are able to invade and dominate assemblages. We pair null model analyses with field and laboratory experiments to disentangle the role of interspecific competition and temperature in controlling the structure of ground-foraging ant communities in forests of the Siskiyou Mountains of southern Oregon.

Methods: To assess the potential role of competition as a structuring agent, we used null model analyses to ask whether species partition either space or time. To understand the role of thermal tolerance as a structuring agent, we conducted thermal tolerance experiments in the laboratory. Finally, we conducted a field experiment in which we manipulated temperature and competition by a dominant species (*Formica moki*) to investigate which factor had the greater impact on the ant community.

Results: Although the foraging activity of species broadly overlapped across a range of times and temperatures, the peaks of activity for each species were spaced at regular intervals of soil surface temperature. Species decreased abundance in shaded plots was a direct effect of shading and was not an indirect effect of competitive interactions. Most strikingly, the response of species to shade additions was successfully predicted by the results of the thermal tolerance experiment.

Conclusions: Collectively, our results suggest that ant thermal tolerance may mediate competitive effects in habitats that experience strong diurnal and seasonal fluctuations in temperature.

Evidence for the evolutionary nascence of a novel sex determination pathway in honey bees

Martin Beye, Martin Hasselmann, Tanja Gempe, Morten Schiøtt, Carlos Gustavo Nunes-Silva, Marianne Otte

Genetics, Duesseldorf, Germany

Sex determination in honey bees (*Apis mellifera*) is governed by heterozygosity at a single locus harbouring the *complementary sex determiner* (*csd*) gene, in contrast to the well-studied sex chromosome system of *Drosophila melanogaster.* Bees heterozygous at *csd* are females, whereas homozygotes and hemizygotes (haploid individuals) are males. Although at least fifteen different *csd* alleles are known among natural bee populations, the mechanisms linking allelic interactions to the development program are still obscure. Here we report a new component of the sex-determining pathway in honey bees, encoded 12 kb upstream of *csd*. The gene, *feminizer* (*fem*), is the ancestrally conserved progenitor gene from which *csd* arose. FEM shares the same arrangement of SR-/proline-rich-domain with the *Drosophila* key sex-determining gene *transformer* (*tra*). Like *tra*, the *fem* transcript is alternatively spliced and encodes a functional product only in females. We show that RNAi-induced knockdown of *fem* results in male bees, indicating that the *fem* product is required for entire female development. Furthermore, RNAi-induced knockdown of *csd* results in the male-specific *fem* splice variant suggesting that the *fem* gene implements the switch of developmental pathways controlled by heterozygosity at *csd*. Comparative analysis of *fem* and *csd* coding sequences from five bee species indicates a recent origin of *csd* in the honey bee lineage from the *fem* progenitor and provides evidence for positive selection at *csd* accompanied by purifying selection at *fem*. The *fem* locus in bees uncovers gene duplication and positive selection as evolutionary mechanisms underlying the origin of a novel sex determination pathway.

Love thy neighbour: Argentine ants do not attack non-nestmates

Natasha Palesa Mothapo, Theresa Wossler

University of Stellenbosch, Stellenbosch, South Africa

Introduction: The Argentine ant, *Linepithema humile*, is a widespread invasive species. In the introduced range it is characterized by a social structure known as Unicoloniality, where intraspecific aggression between nests is reduced or absent. This results in the formation of large and spatially expansive 'supercolonies' which lack defined colony boundaries and territoriality. Ants within these 'supercolonies' show very low levels of aggression towards more distant colony members, probably due to the erosion of some important nestmate recognition cues. In line with this observation, we set out to determine the colony boundaries of this ant within the Western Cape Region, South Africa, using behavioural aggression bioassays.

Methods: We collected ants from Elim in the south (30°3'0S, 22°4'60E) to Porterville in the north (33°0'19''S, 18°59'3''E). Pairwise aggression bioassays, with ants, were conducted within and between sites. We extracted and identified cuticular hydrocarbons from individuals for each nest, to relate these signals to worker aggression.

Results: There were very low levels of aggression between individuals within sites, as well as between sites. Except ants from Elim nests where individuals showed very high levels of aggression towards all other ants in this study. The role of cuticular hydrocarbons in nestmate recognition of this ant will be discussed.

Conclusion: Our results suggest a unicolony boundary exists between Elim in the south and all other nests to the north. This suggests that at least two 'supercolonies' exist within this study area, indicating at least two introductions into South Africa.

Desert ants Cataglyphis use olfactory topographical cues to pinpoint their nest entrance

Markus Knaden, Kathrin Steck, Bill Hansson

Max-Planck Institut for Chemical Ecology, Jena, Germany

Cataglyphis fortis forages for dead arthropods that are killed by heat stress in the inhospitable saltpans of Tunisia. Both high surface temperatures and a non-patched food source distribution result in the absence of any trail-laying behaviour in these individually foraging ants. Instead of odour trails, path integration is the fundamental system of long-distance navigation in *Cataglyphis*. This system constantly informs an ant about its position relative to the nest. In order to compensate for errors accumulated during path integration the ants also rely on visual landmarks as geocentric navigational aids. Here we show that, in addition to its visual orientation system, *Cataglyphis* can learn environmental odours and use them to pinpoint the nest entrance. Ants that were trained to a nest entrance being situated within a squared array of four different odours, concentrated their nest search within this array in a test situation. The search accuracy degraded when the odour array was rotated or when the positions of the odours within the array were swapped. Hence, the ants are able to learn not only the association of the nest entrance and the odours but also the spatial distribution of different odours surrounding the nest entrance. A topochemical representation has already been predicted by Forel and v. Frisch. However this is the first time that the use of topochemical cues in the context of landmark orientation could be proven.

Insects, nematodes and fungi: A hodgepodge of multispecies interactions in natural and agricultural systems

S. Patricia Stock

Dept. Entomology, University of Arizona, Tucson, Arizona, United States

In biological control, direct interactions between pairs of species are fairly well known, whereas indirect interactions (involving more than two species) are only beginning to be comprehended. Most studies of indirect interactions have mostly focused on the life history and ecology of these associations, from a bilateral perspective: plant- insect or insect-pathogen interactions. Entomopathogens have a diverse and widespread role in plant–herbivore interactions and both direct effects and indirect effects have been reported. In this respect, insect-parasitic nematodes are significant component of below ground systems and play a major role controlling insect pests and other noxious arthropod populations. Nontheless, very little is known on the impact that other organisms may have in the success of entomopathogens to control herbivore populations in the soil. In this presentation, I will discuss interactions among entomopathogenic nematodes and and other organisms in food webs in natural and agricultural settings. A recent study on multispecies interactions between insect-pathogenic nematodes, plant-pathogenic fungi, herbivores and plants in a Sonoran desert agricultural ecosystem will be considered. The influence of plant-pathogenic fungi on the dynamics of entomopathogenic nematodes, insect herbivores, and plants will be discusse

Optophysiological approaches to dissect neuronal circuits underlying learning and memory in *Drosophila*

Andre Fiala

University of Wuerzburg, Wuerzburg, Germany

Introduction: For many years *Drosophila* has been the geneticist's dream but the physiologist's nightmare, mainly due to the small size of central neurons that makes them almost inaccessible for extensive electrophysiological studies. However, novel genetic tool might help to combine the advantages of *Drosophila* - most notably the possibility to target defined neurons - with physiological techniques. We are using on the one hand DNA-encoded fluorescence sensors to monitor neuronal activity, on the other hand light-sensitive ion channels to depolarize neurons by illumination.

Methods: Using these optical imaging and optical activation techniques we investigate how behaviour is influenced by modulatory neurons. In particular we follow up the hypothesis that two bidirectional modulatory systems might mediate the evaluation of external stimuli as indicative for positive or for negative outcomes, respectively.

Results: Using optical calcium imaging of dopaminergic neurons innervating the mushroom body we show that these neurons are responsive to electric shocks, which are commonly used as punishing stimuli during olfactory associative training procedures. Light-activation of dopaminergic neurons in the larval *Drosophila* brain using channelrhodopsin-2 can substitute for the reinforcing effect of a punitive salt stimulus in an olfactory associative learning paradigm. Activating octopaminergic and/or tyraminergic neurons substitutes for a rewarding stimulus in appetitive learning.

Conclusions: Our experiments indicate that the biogenic amines octopamine or tyramine might act as positive reinforcer in associative learning tasks in insects. Conversely, dopamine is hypothesized to mediate the reinforcing effects of aversive stimuli in associative learning. Arguments for and against this model will be discussed.

Exciting body structures of apterous flat bugs (Heteroptera: Aradidae) of Madagascar - what for?

Ernst Heiss

Tiroler Landesmuseum, Innsbruck, Austria

Introduction: For 180 years after the description of the first Aradid by Linnaeus 1758 (*Aradus corticalis*), apterous forms were regarded as mere larval stages. Only in 1938 N.C.E. Miller recognized wingless Malaysian samples as adults and described on them the first apterous genus Chelonocoris.

After discovering and describing apterous Aradidae from Madagascar by Drake and independantly by Hoberlandt, both in 1957 followed by Usinger & Matsuda and Kiritshenko in 1959 respectively, several new genera and species were recognized since by the author.

Results: While in macropterous species the thorax is dorsally divided into three distinct separated sclerites (pro-, meso- and metanotum), these structures are indistinct in apterous taxa and variously fused to each other and even to the first two abdominal tergites.

Discussion: What for is the question? As all known apterous Aradidae are associated with rainforest habitats where they are found in leaf litter or on wooden parts infested by fungi, no obvious function can be correlated to these curious structures. But even a possible reason for the complete loss of wings is not yet clear. Is it an adaptation and evolutionary process due to rather stable conditions in rainforests or the contrary – that lack of sufficient nutrition in such environments induces the observed development of thoracal structures instead of wings for a better energy balance?

Samples of such dorsal body structures are given and an update of the presently known Aradid fauna of Madagascar and adjacent islands is presented and discussed.

Fossil Neanastatinae (Chalcidoidea: Eupelmidae) — implications for inferences of evolution and relationships of the subfamily

Dr. Gary Gibson

Canadian National Collection of Insects and Arachnids, Agriculture and Agri-Food Canada

Introduction: Neanastatinae is one of three subfamilies comprising Eupelmidae. Putative apomorphies support monophyly of all three subfamilies, but morphological evidence for the monophyly of Eupelmidae is lacking and it has been hypothesized as possibly a paraphyletic grade-level taxon linking Cleonyminae (Pteromalidae) with Encyrtidae and/or Tanaostigmatidae. Hypotheses of relationships derived from molecular data are currently unstable but also do not support a monophyletic Eupelmidae. Phylogenetic analyses combining morphological and molecular evidence of extant taxa are needed to help resolve questions of monophyly and relationships, but the discovery and description of fossil taxa is equally important as a third source of information and test of hypotheses.

Methods: The morphological attributes of five females representing four distinct species of Eupelmidae in Eocene Baltic amber were compared with those of the four extant genera classified in Neanastatinae to test hypotheses of groundplan states, character evolution and relationships.

Results: Two of the species resemble species classified in extant genera of Neanastatinae, though they lack some of the differentiating features hypothesized as groundplan states of the respective genera. The other two species are much less similar to extant Neanastatinae. One exhibits none of the putative apomorphies postulated to support monophyly of the subfamily and has features that suggest some Pteromalidae-like ancestor as well as a possible relationship with the common ancestor of Encyrtidae + Tanaostigmatidae. The fourth species shares a combination of features linking the previous species with the other, more typical, members of the subfamily. As a result, three new genera are recognized in Neanastatinae and hypotheses of groundplan states and character evolution are modified to reflect the new discoveries.

Conclusions: The morphological diversity of extinct and extant Neanastatinae suggests many other fossil taxa remain to be discovered. Baltic amber is comparatively rich in Chalcidoidea and the study of fossils belonging to other families, particularly Pteromalidae, is essential prior to rigorous, stable hypotheses of higher-level relationships among Chalcidoidea.

CATE – Creating a Taxonomic E-Science

Malcolm Scoble

Natural History Museum, London, United Kingdom

Fixed-publication (whether paper, CD-ROM or PDF files) as the medium for descriptive taxonomy is being challenged almost by default and is unlikely to survive in the long-term - at least as the sole means of publication. The future is already apparent in a number of online approaches to revisionary (descriptive, monographic) taxonomy that involve continuous addition and correction of data. Such information comes from single source web pages to databases linked in distributed networks. The ubiquity of the Internet for promoting particular views is likely to be too strong to resist, however persuasive the arguments for control by the codes of nomenclature. This prediction is strengthened by the diminishing workforce of professional taxonomists (who are largely responsible for shaping the Codes) involved in describing life on the planet. While taxonomists may be unable to control taxonomic content in the new and more anarchic medium (other than within their own diminishing community), they do have the opportunity to shape the field to the benefit of their own close community and the much wider (yet undefined) user base.

An Internet-based approach to revisionary taxonomy is being taken in the CATE project (www.cate-project.org). The system allows new taxonomic proposals to be made in an open peer-review process forming part of the workflow. It also provides the opportunity for high quality products to be maintained through the incorporation of well-tested taxonomic standards. There seems much merit in treating taxonomy overtly as an information science, while still regarding it as an intellectual endeavour in its own right. This shift in emphasis is explored by examining the growing influence of e-projects in the changing taxonomy landscape.

Gall midges (Diptera: Cecidomyiidae) in the forest-tree fauna of Turkey

Sabri Ünal, Cihan Cilbircioglu

Kastamonu University, Kastamonu, Turkey

The family Cecidomyiidae is one of the largest of the Diptera. Gall midges are small, inconspicuous flies, but they may be very important both in forest ecosystems and in agroecosystems. The present fauna of gall midges of Turkey includes 71 species belonging to 38 genera. In this study, forest gall midges (Diptera: Cecidomyiidae) fauna of Turkey was examined and deduced this fauna that consists 33 species in 24 genera on 34 host trees species in 15 genera. Of them, 30 species are phytophagous, 1 species is zoophagous, 1 species is phytophagous-inquilines and one species phytosaprophagous.

Plant genotype and herbivory alter ecosystem processes: Extended, evolutionary implications for species genetic interactions.

Jen Schweitzer[1], Joe Bailey[1], Steve Hart[2], Tom Whitham[2]

[1]University of Tennessee, Knoxville, TN, United States, [2]Northern Arizona University, Flagstaff, AZ, United States

Insect herbivory may influence terrestrial ecosystem-level processes in many ways. The indirect impacts of insect-induced alterations of leaf litter, however, may have a consistent impact on ecosystem-level processes as chronic herbivory is more common than outbreaks and leaf litter represents a regular and important source for internal nutrient cycling in forest ecosystems. Furthermore, the effects of genetic variation in plants on ecosystem-level processes are now beginning to be recognized and the effects of individual plant genotypes have been shown to repeatably modify associated arthropod and microbial communities, as well as nutrient cycles of carbon and nitrogen. Utilizing several model plant systems (including *Populus* spp. and *Hammemalis* spp.), here we address how interactions between plant genotype and herbivory by specialist arthropods can modify the impacts of plant genetic variation on ecosystem-level processes. Overall, the data to date suggest that "afterlife" effects of herbivory (by insect species from multiple feeding styles – i.e., gallers and leaf chewers) on leaf litter quality can have extended effects on rates of decomposition and nutrient release and in many cases mediate the effects of plant genetic variation by reducing the overall variation in litter quality and subsequent decay by 22-33% within a population. These results suggest that the interactions between herbivores and genotypes may have predictable effects on variation in ecosystem responses such that herbivores may homogenize the effects of plant genetic variation to stabilize plant-soil feedback interactions.

Revision of *Dilyta* Förster (Hymenoptera: Figitidae: Charipinae) with the description of eight new species

Jordi Paretas-Martínez[1], George Melika[2], Juli Pujade-Villar[1]

[1]Universitat de Barcelona, Barcelona, Spain, [2]Pest Diagnostic Laboratory, Tanakajd, Hungary

Introduction: The genus *Dilyta* includes very small wasps that are hyperparasitoids of Psyllidae (Homoptera) via Encyrtidae (Hymenoptera: Chalcidoidea). *Dilyta* is now represented by three species: *D. subclavata* Förster from Europe, *D. rathmanae* Menke & Evenhuis from Washington state (USA), and *D. africana* (Benoit) from Zaire.

Methods: The type material of all the described species of *Dilyta* has been examined, along with long series of undetermined material loaned from several institutions. The specimens have been studied under stereomicroscopy and with the help of low-vacuum SEM images taken on a Quanta 200 Environmental Scanning Electron Microscope.

Results: Eight new species of *Dilyta* are here described: four from Africa, two from Europe and two from Asia. Morphologically, the four new African species clearly differ from the rest by having the scutellum with only two small apical carinae, instead of the typical inverted U-shaped apical carina of *Dilyta*. Besides this, the differences betwen species can only be found in the proportion of the antennal segments. Moreover, *Apocharips talitzkii* (Belizin) from Moldova is transferred to *Dilyta talitzkii* (Belizin) n. comb. Lastly, the diagnosthic characters of the genus *Dilyta* are discussed and defined.

Conclusions: The genus *Dilyta* is a widespread genus that includes twelve species. The first records of this genus in Asia are presented here, and its distribution in Africa, Europe and North America is widened considerably. There are no records of *Dilyta* in South America and Australia.

Basal phylogenetic relationships in Dictyoptera and Mantodea

Klaus-Dieter Klass

Museum of Zoology, Dresden, Saxony, Germany

Monophyly and placement of Dictyoptera: The Dictyoptera include the Mantodea, Blattaria, and Isoptera, altogether comprising some 9.300 species. Dictyopteran monophyly is unambiguously supported by molecular data and morphological characters (e.g. anterior transverse bridge in tentorium, formation of ootheca with functional differentiations in accessory glands, female subgenital plate coxosternum VII). Dictyoptera are one of 11 principal lineages of Neoptera, whose relationships are altogether not clearly resolved.

Principal dictyopteran lineages and their relationships: Monophyly has been convincingly demonstrated for several lineages inside Dictyoptera: 1) Mantodea. 2) Isoptera + Cryptocercidae (resulting from molecular analyses, association with specific flagellates, and a few morphological characters). 3) Blattellidae + Blaberidae (resulting from the structure of male genitalia and molecular data). 4) Blattidae (male genitalia and molecular data). 5) Polyphagidae (molecular data). 6) Nocticolidae (molecular data). Two further lineages are 7) Lamproblattidae (1 genus) and 8) Tryonicidae (2 genera). The relationships among these 8 lineages vary strongly among the various recent molecular- and morphology-based phylogenetic analyses. Most analyses yield Mantodea and Blattaria (incl. Isoptera) as sister taxa, but one finds a clade Mantodea + Nocticolidae subordinate in Blattaria. (Molecular data for Tryonicidae and Lamproblattidae have not yet been used in large analyses.)

Basal relationships in Mantodea: The structure of the male genitalia strongly supports *Mantoida* + (*Chaeteessa* + (*Metallyticus* and remaing Mantodea). For *Mantoida* and *Metallyticus* this placement has been confirmed by molecular data, which are not yet available for *Chaeteessa*. Characters of wings and forelegs are incongruent with this hypothesis, but are also incongruent with each other.

Plant-insect interactions are controlled by the underworld

Wim Van der Putten

Netherlands Institute of Ecology, Heteren, Netherlands

Interactions between plants and aboveground insects are usually studied without considering interactions between plants and soil biota. However, soil organisms influence plant community composition, plant quality, plant defense and the survival of insects. I will present results of a long-term addition experiment where we exposed species-rich grassland communities to grasshoppers, wireworms and nematodes in a full factorial outdoor experiment. The effects of the grasshoppers on plant community composition depended on the community composition in the soil. Interaction effects were non-linear. I will discuss how interactions in the 'underworld' influence plant community composition and plant-insect interactions.

Above-belowground interactions, global warming, and biological invasions

Wim Van der Putten

Netherlands Institute of Ecology, Heteren, Netherlands

Above- and belowground multitrophic communities play an important role in the control of plant abundance. Global warming may disrupt these interactions, when the individual components respond differently to warming. I will discuss effects of plant range shifts on above and belowground interactions in new habitats. These effects were determined in the field, as well as in controlled greenhouse experiments

Environmental influence on tri-trophic interactions: Plant phenotypic diversity and multiple herbivory

Cesar Rodriguez-Saona[1], Jennifer Thaler[2]

[1]Rutgers University, New Brunswick, NJ, United States, [2]Cornell University, Ithaca, NY, United States

Introduction: Herbivore-induced plant responses can affect the preference and performance of herbivores and their natural enemies. We hypothesize that when herbivores from different guilds feed on plants these interactions are disrupted, and that the abundance of arthropods on plants is influenced by heterogeneity in plant neighbourhood.

Methods: We damaged tomato plants either by caterpillars, aphids, both, or none. Then, we investigated plant-herbivore-natural enemy interactions from the molecular to the organismal levels, including the effects of induced responses on the abundance of herbivores and predators on individual plants and their neighbors in patches of plants.

Results: *At the molecular level*, aphids attenuated several plant defense genes induced by caterpillars. *At the chemical level*, caterpillars increased proteinase inhibitor activity regardless of the presence of aphids. Aphids reduced the C:N ratio but not when caterpillars also fed on the plants. *At the organismal level*, caterpillars reduced oviposition by moths but not when aphids also fed on plants. Caterpillars reduced growth, consumption, and survival of parasitized and unparasitized caterpillars regardless of the presence of aphids. *At the patch level*, plants in homogeneously induced patches contained fewer flea beetles and more lady beetles compared to homogeneously non-induced patches. *At the neighborhood level*, induced plants in heterogeneous patches contained more flea beetles compared to induced plants in homogeneous patches.

Conclusions: Damage by multiple herbivores influenced the plants' inducible responses differently when using molecular, chemical, and organismal measures, and variation in plant neighborhood generated by induced plant responses affected the abundance of herbivores and predators on plants.

Tri-trophic interactions in native and introduced habitats: furanocoumarins, webworms, and *Copidosoma sosares*

Paul Ode[1], Evan Lampert[1], Arthur Zangerl[2], May Berenbaum[2]

[1]North Dakota State University, Fargo, ND, United States, [2]University of Illinois, Urbana, IL, United States

Comparisons of tritrophic interactions in native and introduced habitats are very rare. Yet, they can provide information regarding the selective forces maintaining multitrophic interactions. Likewise, such studies provide insight into how trophic relationships change as a consequence of being introduced into novel environments. *Copidosoma sosares* is a specialist parasitoid of the parsnip webworm (*Depressaria pastinacella*), itself a specialist on furanocoumarin-containing apiaceous host plants. This system is native to Europe, where the predominant host plants are *Pastinaca sativa* and *Heracleum sphondylium*. The webworm is introduced throughout much of the US where it attacks the introduced *P. sativa* and the native *Heracleum lanatum*. *C. sosares* attacks up to 90% of webworms in European and western US populations, but it is absent in eastern US. *C. sosares* clutch size and survivorship is negatively affected by the furanocoumarin, xanthotoxin. We predicted that in populations where *C. sosares* is present (Europe and western US) plants should produce lower levels of xanthotoxin than populations where *C. sosares* is absent (eastern US). While European plants invest less in xanthotoxin than eastern US populations, western US plants produced xanthotoxin in levels as high or higher than eastern US plants. Consequently, *C. sosares* fitness is lower in introduced (western US) populations than in its native European populations. One possible explanation is the recent reestablishment of *C. sosares* to webworms in the western US. Study of this system across three geographic regions with different trophic compositions and histories can give insight into the underlying dynamics involved in biological invasions.

Utilization of attractants/repellents for pest management of *Culicoides* biting midges

Daniel Kline

USDA, ARS, CMAVE, Gainesville/Florida, United States

Introduction: *Culicoides* biting midges are pests of man and livestock worldwide. They cause annoyance due their attacks in high numbers. They can also transmit diseases to man and livestock. An example is the recent outbreak of bluetongue in Europe. Despite their medical and veterinary importance very little information exists concerning their basic biology, ecology or any strategy to control them. This presentation will review current knowledge and recent efforts to develop a pest management strategy based largely on recent knowledge obtained on the chemical ecology of adult biting midges. Emphasis will be placed on their host seeking behavior, but results from recent studies on the association of adult midges and flowering plants will also be presented.

Methods: Various types of traps were operated to determine their efficacy in capturing adult biting midges. Different experimental and commercial attractant lures were also tested.

Results: Propane powered traps were very efficient in capturing large numbers of most species of *Culicoides*. Different species preferred different attractant combinations. The combination of octenol and carbon dioxide was found to be very efficient at collecting large numbers of most species. The addition of lactic acid often reduced collection size.

Conclusions and Future Work: Properly baited and placed propane powered traps seem to be a promising population management technique for some species of biting midges.

Area-wide management of the Asian tiger mosquito

Daniel Kline[1], Gary Clark[1], Dina Fonseca[2], Randy Gaugler[2], Daniel Strickman[3]

[1]USDA-ARS, Gainesville,Florida, United States, [2]NJ Agricultural Experiment Station, Rutgers University, New Brunswick, New Jersey, United States, [3]USDA-ARS, Beltsville, Maryland, United States

Introduction: The Asian tiger mosquito, *Aedes albopictus*, is often responsible for most complaints to urban mosquito control programs, yet there is no clearly defined protocol for controlling this species. We are developing an area wide, multidisciplinary approach, grounded by an economic analysis, which incorporates extensive public education and involvement, with focused application of established biological and chemical control interventions. Our methodology will be developed in two New Jersey counties. In Phase I, we will perform an initial assessment of *Ae. albopictus* abundance, dispersal, population structure, and insecticide resistance status, as well as of its social and economic impact. In Phase II, we will compare *Ae. albopictus* abundance and associated human behavior in two pairs of experimental and control plots of 1,000 homes (up to 640 acres) each. In Phase III, we will expand our control efforts county-wide (>140,000 acres) initially targeting source populations. Throughout the project, the costs of all control procedures will be documented and an economic analysis will be conducted. If we succeed in controlling the Asian tiger mosquito and our strategy is economically sound, we will proceed to Phase IV and expand the initiative nationally by recruiting 12 geographically diverse mosquito control agencies to implement our methodology.

Methods: A 5 year Area Wide collaborative research project was established among federal government, universities and mosquito abatement districts in 2008.

Results: Project has just been initiated. This talk will present overview of objectives and preliminary results.

Conclusions and future work: No conclusions yet.

The threat of insect resistance to phosphine in bulk grain storages in Australia

Manoj Nayak[2], Joanne Holloway[3], Matthew Head[4], Robin Reid[5], Hervoika Pavic[2], Patrick Collins[2]

[1]Cooperative Research Centre for National Plant Biosecurity, Deakin, ACT, Canberra, Australia, [2]Department of Primary Industries and Fisheries, Indooroopilly, Brisbane, Queensland 4068, Australia, [3]NSW Department of Primary Industries, Wagga Wagga Agricultural Institute, Wagga Wagga, New South Wales 2650, Australia, [4]GrainCorp Operations Ltd, North Geelong, Victoria 3215, Australia, [5]GrainCorp Operations Ltd, Toowoomba, Queensland 4350, Australia

Introduction: Australia's $7billion grain industry relies heavily on phosphine fumigant to disinfest stored grain of insect pests. Recently however, development of high resistance to phosphine in four major pest species has become a serious biosecurity threat in the central bulk handling storage system; which adheres to a 'nil tolerance' principle for live insects for marketing grain. As there are no practical alternatives to phosphine, management of resistance is a priority. The development of phosphine fumigation protocols effective against resistant insects is essential to the successful management of resistance.

Methods: Laboratory strains of purified resistant genotypes were exposed as mixed-age cultures (including all life-stages) to a range of phosphine concentrations and exposure periods. The 'time to population extinction' data obtained were used to develop new fumigation protocols and these were verified under commercial conditions at bulk handling storage sites. Cages of mixed-age cultures of resistant strains were placed at different parts of the bulk grain prior to fumigation. Phosphine concentration, temperature and moisture of the grain mass were monitored during fumigation and insect survival was assessed after the fumigation.

Results: Results from this research show that manipulation of concentration and exposure periods is the key to the successful control of strongly phosphine resistant populations of storage pests.

Conclusions: A protocol incorporating a range of phosphine concentration options and exposure periods for use in large central storages was successfully developed. Correct use of this protocol should ensure that the practical life of phosphine is extended in Australia.

Optimizing cotton pollination period by using high stocking rate of honeybee colonies

Marwan Keshlaf[1], Robert Spooner-Hart[1], Robert Mensah[2], Oleg Nicetic[1]

[1]University of Western Sydney, Sydney NSW, Australia, [2]NSW Department of Primary Industries, Narrabri NSW, Australia

Introduction: Cotton is an important world crop and one of the most insecticide-intense cropping systems. Pesticide use in cotton is regarded as a major cause of honeybee losses but with the release of transgenic (Bt) cotton, it was anticipated that pesticide use would be substantially reduced. Reduction of pesticides offers opportunities for increased use of honeybees in cotton, providing benefits to both cotton producers and beekeepers.

Methodology: A study to evaluate the potential of optimizing honeybee, *Apis mellifera*, pollination in the shortest period possible during cotton flowering was carried out in a 2 ha transgenic cotton (Bollgard II) Sicot 71BR crop at Narrabri, Australia in 2007. Thirty honeybee colonies were placed adjacent to the cotton field. The number of honeybee flower visits were recorded over a four week period from two rows of cotton located 60 and 80 m away from the apiary. In addition, the effect of the time of exposure to honeybee pollination on cotton yield and quality was determined by (1) caging five plots for the ten days in peak flowering, (2) caging five plots for four weeks and (3) leaving five un-caged.

Results: Bee visitation to cotton flowers averaged 3.24 bees/ 100 flowers. Cotton yield and lint micronaire were both significantly higher in un-caged plots and plots caged for ten days, compared with control plots.

Conclusions: Honeybees are efficient cotton pollinators, increasing cotton yield and improving lint quality. A period of ten days during peak cotton flowering may be sufficient for honeybee pollination, and could be practicable in IPM programs.

Role of pollen beetles in cotton pollination, and their effect on the foraging behaviour of honeybees

Marwan Keshlaf[1], Robert Spooner-Hart[1], Robert Mensah[2], Oleg Nicetic[1]

[1]UNiversity of Western Sydney, NSW, Australia, [2]New South Wales Department of Primary Industries, NSW, Australia

Introduction: Pollen and nectar of *Gossypium* spp. attract beneficial as well as harmful insects. Pollen beetles, *Carpophilus aterrimus*, were observed in cotton flowers in the field, but there was no published information about whether they pollinated flowers, damaged them or deterred pollinators.

Methodology: A study to investigate the direct and indirect effects of pollen beetles on cotton pollination was carried out in a 2 ha flowering crop of transgenic (Bt) cotton (Bollgard II) at Narrabri, Australia in 2007. Cotton plants were (1) caged to prevent pollinator entry, (2) caged with beetles, and (3) uncaged and exposed to beetles and managed honeybees, *Apis mellifera*, for a period of one week. A further study was conducted whereby (1) single flowers were bagged to prevent insects (2) flowers were bagged with varying numbers of pollen beetles, and (3) flowers were unbagged. The effects of beetles on boll set, yield and lint quality were determined. In addition, their effect on honeybee foraging behaviour was assessed by recording the number of bees visiting cotton flowers containing or not containing beetles.

Results: Plants exposed to honeybees had significantly higher yield and improved lint quality than those not exposed to pollinators or exposed to pollen beetles only. No bolls were produced from flowers infested with ≥10 pollen beetles. Honeybees rarely visited beetle-infested flowers when there was a choice but did visit them when there was no choice.

Conclusion: Pollen beetles do not contribute to cotton yield. Heavy beetle infestations can reduce cotton yield, by direct damage, or indirectly by deterring honeybees from visiting and pollinating cotton flowers.

Improved monitoring of early-season emergence of males, virgin and mated females of oriental fruit moth and codling moth in Australian orchards

Alexandre Il'ichev, David Williams

Department of Primary Industries Victoria, Biosciences Research Division, Tatura, Victoria, Australia

Pheromone mediated mating disruption (MD) is widely used in Australia to protect stone and pome fruit orchards without chemical sprays and produce “clean and green” fruit for domestic and overseas markets. Unfortunately, conventional sex pheromone traps are not reliable for monitoring of pest males under MD. Attracting females of orchard pests to synthetic host-plant volatiles could allow growers to control females and their unlaid eggs and to monitor pest life cycles precisely in orchards treated with MD.

Sex pheromones, food traps and new female attractants were used for detailed daily monitoring of codling moth (CM) in apples and pears, and oriental fruit moth (OFM) in peaches, pears and apples conducted at the beginning of three growing seasons to identify the first catches of males, virgin and mated females. The results demonstrated that OFM males and females emerged in pear blocks earlier than in their preferred host peach. First catches of OFM males and females in food traps in apples were recorded approximately 1 month later than in pears. Also, OFM males were caught in sex pheromone and food traps 2-3 weeks earlier than females in food traps. First mated OFM females were caught in food traps 4-10 days later than the first virgin OFM females. Virgin and mated CM females were caught in traps with new female attractants in pears at similar dates, but about a week later than first males in sex pheromone traps. The results of the daily monitoring of OFM and CM males and females helped to estimate Biofix dates for different fruit varieties more correctly and were used in Day-Degree Models.

The possibility of invasion by the coconut hispine beetle Brontispa longissima into mainland Japan

Ai Yamashita[1], Yukinari Taninoki[2], Keiji Takasu[2]

Ranking of the potential host plants for the invasive Siberian moth in Europe

Natalia Kirichenko[1], Yuri Baranchikov[2], Jean-Claude Gregoire[3], Julie Flament[3], Marc Kenis[3]

[1]VN Sukachev Institute of Forest, Krasnoyarsk, Russian Federation, [2]University Libre de Bruxelles, Brussels, Belgium, [3]CABI Bioscience Switzerland Center, Delemont, Switzerland

Introduction: The Siberian moth *Dendrolimus superans sibiricus* Tschtv. (Lep.: Lasiocampidae) has recently been suggested for regulation as a quarantine pest for EPPO member countries. However, no specific report on European hosts for the pest has been published so far.

Methods: Relative growth rate and mortality of the pest larvae were evaluated on coniferous species widely planted in Europe and having high economical significance. The work was done in the quarantine facilities of the Laboratory of Biological Control and Spatial Ecology, Université Libre de Bruxelles (Belgium) in 2007.

Results: Suitability of the possible host plants for the defoliator decreased from European larch *Larix decidua* P. Mill., Eastern white 5-needle pine *Pinus strobus* L., European silver fir *Abies alba* Miller*.,* Norway spruce *Picea abies* (L.), Scots pine *Pinus silvestris* L. to European black pine *P. nigra austriaca* Arnold (all from Pinaceae). Larvae could also develop on the species from exotic genera *Pseudotsuga, Tsuga* and *Cedrus* (also Pinaceae) what appeared to be highly valuable for larval performance. Conifers from other families: Taxaceae and Cupressaceae were inedible for the pest.

Conclusions: Given the laboratory results, the pest is able to survive and develop on the main European coniferous species, including non-native conifers. Taking into account that more than two thirds of the European forest area consists of pine, spruce, fir and larch the introduction and establishment of the moth in Europe may result in devastations of large areas of forest stands.

Laboratory and field evaluation of formulated *Bacillus thuringiensis* var. *israelensis* as a feed additive for controlling house fly (*Musca domestica* L.) larvae in caged-poultry manure

Lizzy Mwamburi[1], Mark Laing[1], Mike Morris[2], Ray Miller[3]

[1]Department of Plant Pathology, School of Biochemistry, Genetics, Microbiology and Plant Pathology,University of KwaZulu-Natal, Scottsville 3201, Pietermaritzburg, South Africa, [2]Plant Health Products (Pty) Ltd, Nottingham Rd, South Africa, [3]Department of Entomology, School of Biological and Conservation Sciences, University of KwaZulu-Natal,Scottsville 3201, Pietermaritzburg, South Africa

Introduction: Infestations of house flies, *Musca domestica* L., are a continual problem around poultry establishments. The high levels of resistance developed by flies toward organochlorine and organophosphorous compounds have made the efforts to control flies using biological control agents (BCAs) increasingly important.

Methods: Prior to conducting field evaluations, laboratory baseline bioassay data were established on a dose-time response relationship closely simulating poultry house conditions in the laboratory. Acute toxicity of two *Bacillus thuringiensis var. israelensis* (*Bti)* formulations was evaluated against larvae in the laboratory, and against natural populations of *M. domestica* larvae in the field applied in oral feed to chickens and as topical application in the poultry houses.

Results: Baseline bioassay data demonstrated that susceptibility of *M. domestica* larvae increased to a given concentration of *Bti* as the duration of exposure increased. In the laboratory studies, the LC_{50} and LC_{90}values of *Bti* for the larvae ranged between 65 - 77.4 and 185.1 - 225.9µg ml^{-1} respectively. LT_{50} and LT_{90} values were 5.5 and 10.3d respectively. In the field, a concentration of 10g *Bti* kg^{-1} of feed resulted in 90% reduction of larvae for 4wk post-treatment. Furthermore, as the exposure duration increased, the level of *Bti* required to cause a significant mortality decreased. A higher concentration (2g L^{-1}) of *Bti* in spray applications was not significantly more effective than the lower concentration of 1g L^{-1}.

Conclusion: Adding *Bti* to chicken feed is a good potential measure for the management and control of house flies in caged-poultry facilities.

Placement of Isoptera inside the Blattaria seen from the morphological perspective: the key role of the cockroach *Cryptocercus* and the termite *Mastotermes*

Klaus-Dieter Klass, Ariane Barton, Gerda Buder, Ute Eulitz

Museum of Zoology Dresden, Dresden, Saxony, Germany

Phylogenetic evidence: All recent molecular- and morphology-based phylogenetic analyses have confirmed Isoptera to be placed inside Blattaria as the sister group of *Cryptocercus*. Most analyses have obtained *Mastotermes* as sister group to all other termites. This emphasizes the key role of both *Cryptocercus* and *Mastotermes* for evolutionary studies on Isoptera.

Key role of *Cryptocercus*: *Cryptocercus*, like all basal Isoptera, harbours a species-rich community of oxymonadid and hypermastigid flagellates in its hindgut and transfers these to the next generation by anal trophallaxis (unique among insects). *Cryptocercus* shows biparental brood care like incipient termite colonies (and a few blaberid cockroaches). However, there are only few, mostly vague morphological apomorphies common to *Cryptocercus* and termites: somewhat moniliform antennae with low number of flagellomeres; strong similarity between primary and secondary sclerites and large size of primary pulvilli in the proventricle. Recent studies of the head capsule, tentorium, hypopharynx, and leg spination in Dictyoptera have not yielded any further discrete similarities.

Key role of *Mastotermes*: *Mastotermes* is in many morphological aspects more plesiomorphic than all other termites, and more similar to cockroaches than those. The female genitalia include a complete ovipositor, with all elements differentiated to the same extent as in typical cockroaches. Malpighian tubules are numerous, spermatozoa are flagellate (though with many flagella instead of only one). There are bacteriocytes in the fat body, harbouring *Blattabacterium*. There is a distinct anal fan in the hindwing. An ootheca is formed using accessory glands with a peculiar, asymmetrical functional differentiation.

Morphological diversity and species distinction in Mantophasmatodea

Klaus-Dieter Klass, Kai Drilling, Anna Hell

Museum of Zoology Dresden, Dresden, Saxony, Germany

Introduction: Since the initial description of Mantophasmatodea in 2002, 16 extant species have been described, further ones are known but yet undescribed, and four fossil species have become assigned to the taxon. The presentation surveys the distinctive characters in the group.

Methods: Male and female postabdomina were studied under the stereomicroscope; the antennal sculpture and tarsal processes were observed by SEM.

Results: Most differences are found in the male postabdomen. This concerns the shape of the (clasping) cerci (especially their tips); the shape of the vomeroid projection and details of the ridge crossing it; extensions of the left arm of the vomeroid sclerite; the shape of the projection of the subgenital plate; and the presence and shape of several genitalic sclerites. In the females the spermathecal bulb and structural details of the subgenital plate (median division, posterior lobes, shape of anterior apodemes) provide important characters. The antennal basiflagellomeres have a sculpture of ridges forming polygons; their details and distinctness vary among species. The dorsal process in the membrane distal to tarsomere 3 (an autapomorphy of Mantophasmatodea) shows differences in its size and shape, and in the pattern of sawteeth along its margins. The colouration of the compound eyes either includes scattered dark spots (mottled type) or a stripe along the lower margin (striped type). No clearcut interspecific differences were found in the left and right mandibles, the cuticular sculpture of the hindgut (where differentiations are entirely absent), and the glands of distiflagellomeres 1 and 6.

Soil macrofauna effect on plant succession in post mining sites

Jan Frouz[1], Ondrej Mudrak[1], Alena Roubickova[2], Karel Prach[3]

[1]Institute of Soil biology, Ceske budejovice, Czech Republic, [2]Charles University, Prague, Czech Republic, [3]South Bohemian University, Ceske Budejovice, Czech Republic

Introduction: Vegetation, survey in chronosequence of unreclaimed post mining sites distinguished (TWINSPAN) two distinct clusters. The first, young sites cluster was dominated by euritopic and ruderal plants. The second cluster covered sites 24-41 years old; with forest and meadow plants in the primary forest. The earthworm colonisation and consequent humus layer development, was selected by a discriminant analysis as the strongest predictor for the second cluster. Earthworm activity, namely the mixing of organic and mineral layers, is expected to cause vegetation changes.

Methods: To test this set of manipulation experiment was started looking on effect of earthworm on plant growth and establishment in presence or absence of earthworms.

Results: In laboratory, earthworms increased biomass of plants including grass, forbs and leguminous. In plants planted on soil in succession age 10-40year plant performance increased with succession age, however if earthworms were added to youngest soil plant performance was the same as on 40 year soil. In field the worm effect was more pronounced on forbs and grasses then leguminous.

Conclusion: The result indicated that changes in the topsoil mediated by soil fauna played an important role for vegetation succession.

The effect of wood ants on nutrient flow and tree growth in spruce forest

Jan Frouz

Institute of Soil Biology, Ceske Budejovice, Czech Republic

Introduction: Wood ants play important role in forest, we studied their effect on nutrient flow and tree growth in spruce forest.

Methods: Amount of nutrient brought into the nest from various sources was studied by analyzing nest material and food flow and nutrient content. Nutrient distribution and tree growth was studied in four distance from the closest ant hill (0-1m, 5-10 m 50m and more than 200 m) by soil sampling and tree ring analysis.

Results. In one ha of forest amount of P brought to the nests was about the same as amount of P coming to forest soil outside nests. Soil in close vicinity of the nest showed significantly higher content of nutrients than samples in the larger distances from the ant nests. Analysis of the tree rings indicated the fastest growth for trees, that were not attended by ants, located >200m from the ant nest. The second highest growth was observed in the trees that were in close vicinity of the nest.

Conclusion: We expect that depletion for nutrients by honeydew collection from the trees may slow the tree growth. The tree, that grow in close vicinity of the nests may compensate for this nutrient depletion by surplus of available nutrients in immediate surrounding of the nest.

From biological control to invasion: the ladybird *Harmonia axyridis*

Helen Roy[1], Eric Wajnberg[2]

[1]NERC Centre for Ecology and Hydrology, Cambridgeshire, United Kingdom, [2]INRA, Sophia Antipolis Cedex, France

Biotic homogenisation is considered among the greatest threats to global biodiversity. The rapid increase in introduced exotic species worldwide and the potential of these species to become invasive are widely recognised to have ecological and evolutionary consequences. The impact of some invaders is unquestionably negative and they are designated as invasive alien species (IAS). *Harmonia axyridis* Pallas (Coleoptera: Coccinellidae), "the most invasive ladybird on Earth", is undoubtedly one such species. Ladybirds have a long history of use as biological control agents against pest insects and are one of the most loved insects worldwide but *H. axyridis* is extremely unpopular outside of its native range for a number of reasons. First and foremost, *H. axyridis* threatens the diversity of native aphidophagous species through direct competition and as a voracious, polyphagous predator. Second, *H. axyridis* is now considered a pest species because it consumes soft fruit and is adversely affecting the wine and fruit growing industries. Third, *H. axyridis* occurs at high densities in buildings during overwintering and is thus regarded as a human nuisance. In this paper we introduce *H. axyridis* and particularly refer to the collaborative work of scientists across Europe (and USA) that resulted in a special issue of the journal BioControl ("From biological control to invasion: the ladybird *Harmonia axyridis* as a model species"). We conclude that *H. axyridis* should be used as a model to prevent, or mitigate against, subsequent releases of high risk organisms, by contributing to our understanding of the mechanisms involved in biological invasions.

Ecology of learning in insect parasitoids: From gene to behavior

Hans Smid[1], Michaël van den Berg[1], Saartje Hontelez[1], Patrick Verbaarschot[1], Louise Vet[2]

[1]Wageningen University, Wageningen, Netherlands, [2]Netherlands Institute of Ecology, Heteren, Netherlands

Differences in the expression of learning between closely related species create excellent opportunities to study species-typical learning. We find such an opportunity in our model system of two co-existing *Cotesia* parasitoid species that occupy slightly different niches. In the Netherlands, *Cotesia glomerata* mainly attacks the gregariously feeding caterpillars of the Large Cabbage White *Pieris brassicae*, whereas *Cotesia rubecula* is specialized on the solitarily feeding Small Cabbage White *Pieris rapae*. Both species can learn to associate plant odours with the presence of suitable hosts after an oviposition experience, but there are some profound interspecific differences in the functional requirements for the formation of long-term memory (LTM). *C. glomerata* learns fast and already forms LTM after a single learning event, whereas *C. rubecula* is a slow learner that needs three spaced learning events to change its plant preference. We argue that this inter-specific variation in LTM acquisition reflects a difference in the searching behaviour in nature, related to the distribution of their caterpillar hosts. Our current research focuses on the genetic backgrounds of the observed difference in LTM acquisition and consolidation of LTM. We focus on genes known to be involved in LTM formation, especially the transcription factor cyclic AMP-responsive element binding protein (CREB). Our results show that there are several putative memory activating and inhibiting CREB isoforms present in the brains of both *Cotesia* species. The CREB gene may serve as an important substrate involved in the evolution of learning and memory.

Morphological and biochemical characteristics of a cecidomyiid leaf gall of *Machilus bombycina* – a silkworm host plant

Mantu Bhuyan, Jiban J Mahanta, Jeeten Mech, Pranab R Bhattacharyya

North-East Institute of Science & Technology, Jorhat, Assam, India

Introduction: Leaves of *Machilus bombycina,* the primary host plant of silkworm species, *Antheraea assama* are heavily infested by gall midges of the genus *Daphnephila* (Diptera: Cecidomyiidae). Attempts have been initiated to understand the bioecology of the insect and nutritional quality of its leaf galls.

Methods: A survey has been carried out in order to understand the morphology and distribution of the galls which are pest on the leaves of *M. bombycina*. Biochemical analyses of the galls were conducted using standard protocol.

Results: More galls were found on the basal half rather than on the distal half of individual leaves while peripheral sections of plants had greater no of galls than other parts. On average, 10.77 galls were observed per leaf, which were 0.6 mm apart. Mature galls had 11.08 x 3.69 mm diameters, while their larval chamber were 8.22 x 1.31 mm in size. Galls were found to markedly deplete the nutrient contents of adjacent areas of infested leaves and store these nutrients in the galls in addition to the nutritional layer. Higher gall infestations resulted in greater nutritional content of leaves (including the gall tissues), except for carbohydrates, for which a reverse trend was observed.

Conclusion: Galls infesting silkworm host plant, *M. bombycina* were found to bear distinct morphological characters and play marked role on nutritional physiology of the host plant.

Population dynamics of the southern pine beetle in relation to applied silviculture

Robert Coulson[1], Andrew Birt[1], Maria Tchakerian[1], Frederick Stephen[2], James Guldin[3]

[1]Knowledge Engineering Laboratory, Department of Entomology, Texas, United States, [2]Department of Entomology, University of Arkansas, Arkansas, United States, [3]USDA Forest Service, Southern Research Station, Hot Springs, United States

In 2003 the Healthy Forest Restoration Act (HFRA) became US law and thereby provided the statutory means to address the degraded state of public forests in the US. The HFRA is a set guidelines for directed actions that are intended to adjust (and perhaps regulate) the conditions of the forest environment and thereby alter the frequency and amplitude of natural disturbances (fire and insect and disease outbreaks in particular). One of the first efforts to address the HFRA mandate by the USDA Forest Service was to examine the relation of silviculture (the theory and practice of controlling forest establishment, composition, and growth) and outbreaks of the southern pine beetle, Dendroctonus frontalis (Coleoptera: Curculionidae) (SPB). Considerable previous research on this relation has been reported. In essence, susceptible habitat patches for the SPB include stands containing mature loblolly, shortleaf pine, and slash pine with high basal area and stagnated radial growth. Such stands are considered to be high hazard. Simulation models for the SPB have been developed which mimic population growth in susceptible stands. We are using established knowledge of the SPB/forest silviculture relation to develop a computer based system (SPBsilvix) to evaluate (1) the impact of SPB infestation occurring in specific forest stands and the (2) to assess the risk of infestation in stands occurring in proximity to outbreaks. SBPsilvix is an interactive integrative computer-based system that links spatial data, tabular information, and simulation models from a variety of sources. Interpreted results are provided through the INTERNET.

Insect traces in Antarctic fossil forests: a modern day comparison

Claire M. McDonald[1], Jane E. Francis[1], Steve G.A. Compton[1], Alan Haywood[1], Allan Ashworth[2], Luis Felipe Hinojosa[3], John Smellie[4]

[1]University of Leeds, Leeds, United Kingdom, [2]North Dakota State University, North Dakota, United States, [3]Universidad de Chile, Santiago, Chile, [4]British Antarctic Survey, Cambridge, United Kingdom

Insect body fossils from Antarctica are very rare, yet many collections of Eocene Fossil leaves from Antarctica provide insect trace fossils, indicating that insects were an important component of the unique forests that once grew in south polar regions. These insect traces provide an excellent opportunity to examine the palaeoecology of Antarctica. The fossils studied include Eocene leaves from both Seymour Island and King George Island on the Antarctic Peninsula. A database of all insect traces on the Antarctic fossil leaves was compiled and analysed in terms of the diversity of palaeoherbivory. The fossil leaves are diverse with several different plant families present such as Nothofagaceae and Cunoniaceae. The range of traces that were found includes leaf mines, leaf galls and general leaf chewing, of which both marginal and non-marginal examples were present.

To provide a greater understanding of ancient herbivore intensity and diversity in Antarctica, modern insect traces on Nothofagus leaves, and their associated insects, were examined from the temperate forests in Chile, the modern day analogue of the Antarctic forests during the Eocene. Modern traces show a similar diversity of damage types to that seen in the Eocene, but the intensity of damage appears to be greater now.

The conservation and use of entomopathogenic nematodes and fungi in Chile

Steve Edgington[1], Dave Moore[1], Andrés France[2], Loreto Merino[2]

[1]CABI, Ascot, Berkshire, United Kingdom, [2]INIA, Chillán, XIII Region, Chile

Introduction: This is a Darwin Initiative study on the diversity of entomopathogenic nematodes (EPN) and fungi (EPF) in Chile and an assessment of their use as biological controls. The study is a collaboration between CABI and the Instituto de Investigaciones Agropecuarias (INIA).

Methods: EPN and EPF surveys were carried out in six zones in Chile, covering some of the principle habitats, including desert, sub-Antarctic, temperate rainforest and 'Mediterranean' areas within the central valley. Soil samples were live-baited for EPN and EPF and selected isolates were subsequently profiled for a number of ecological, physiological and behavioural traits, including environmental tolerance, growth characteristics and virulence.

Results: Surveys revealed 90+ and 300+ isolates of EPN and EPF respectively (~ 9 % and 30 % 'positive' hit), including isolates of both EPN and EPF from the Atacama Desert and Tierra del Fuego. Virulence assays showed selectivity amongst the isolates towards a number of key agricultural insect pests. Recent profiling of a thrashing, rather long EPN revealed that the isolate will travel at least 17 cm in 120 h to reach a host and is also capable of significant infection at 6 °C in humid soils. Interestingly no stages of this EPN were able to survive 0 °C for 24 h, even if contained within a host.

Conclusions: EPN and EPF isolates have been recovered from all survey sites in Chile, from a range of habitats, including some environmental extremes. Profiling has revealed interesting traits that may assist in using isolates for biological control.

The *Varroa destructor* invasion in South Africa: doing nothing can be the best response.

Mike Allsopp

ARC-Plant Protection Research Institute, Stellenbosch, South Africa

The varroa mite (*Varroa destructor*) has become an near-global pest of Western honeybee (*Apis mellifera*) colonies, both natural and managed, and in many parts of the world a continuous flow of novel pesticides and other control strategies has been required to prevent collapse of the honeybee population. The strategy chosen in South Africa, however, following the detection of the mite in 1997 was to do nothing and to allow susceptible honeybee colonies to die. This live-and-let die approach has resulted in the South African honeybee population becoming essentially tolerant to the varroa mite within ten years, and without a collapse in the honeybee population. It is suggested that the sub-optimal vitality of unmanaged African honeybee colonies, in which the varroa mite is now just one of a battery of pests and diseases in natural equilibrium with their host, is preferable to lengthy and likely futile efforts on the pesticide or biocontrol treadmill. Doing nothing was clearly the correct response to the arrival of varroa mites in South Africa, and the same is true for *Vespula germanica* and other insect invaders. It is suggested that efforts at control might frequently frustrate the development of natural tolerance and are often of questionable long-term value.

Male and female *Culex* mosquitoes match their flight tones at frequencies beyond their auditory range.

Ben Warren[1], Gabriella Gibson[2], Ian Russell[1]

[1]School of LIfe Sciences, University of Sussex, Sussex, United Kingdom, [2]Natural Resources Institute, University of Greenwich at Medway, Kent, United Kingdom

Introduction: Mosquitoes produce sexually dimorphic wing-beat frequencies (*wbfs*), with multiple harmonics. The flight tones produced alter in response to sound stimuli. This study explored the auditory interactions between pairs of *Culex quinquefasciatus* and *Cx pipiens*.

Methods: The *wbf*s of pairs of *Culex* in tethered-flight were recorded with a particle velocity microphone. Mechanical tuning curves were measured with a laser diode interferometer directed at the base of the antennae. The electrical responses of the antennae to sound were measured with an extracellular electrode from the pedicels.

Results: The resonant frequency of the JOs of the females of both species ~300Hz and are broadly tuned, whereas males are tuned to higher frequencies (*Cx quinquefasciatus* ~ 330 Hz and *Cx pipiens* ~ 380 Hz) and are more narrowly tuned. In tethered flight, male-female pairs responded to the sound of the other by altering their respective *wbfs*, converging on their nearest shared harmonic. The fundamental *wbf* of the male is at least 1.5 times higher than that of the female and the closest shared harmonic can be > 1000 Hz, which exceeds the sensitive frequency ranges of the mechanical tuning of their antennae and the neural tuning of their JO. However, the electrical tuning curves shows they also respond to low frequencies (10–80 Hz); during auditory interactions they may detect the *difference* between their respective frequencies, usually < 20 Hz when they are close to synchrony.

Conclusion: *Culex* mosquitoes interact through alterations in flight tone by mechanisms not fully understood.

In vivo visualization of odor propagation along the olfactory pathway of the *Drosophila* brain

Andre Fiala, Thomas Völler

Department of Genetics and Neurobiology, Wuerzburg, Germany

Introduction: Animals are able to differentiate a large variety of odors with respect to their chemical identity and concentration. We ask how different odor identities and intensities are represented in the brain of the fruit fly *Drosophila melanogaster* at various levels of processing, from sensory neurons to mushroom body neurons.

Methods: We presented several odors at different concentrations to the antennae of the fruit fly while monitoring calcium activity in different parts of the olfactory pathway. We have used the genetically encoded, FRET-based calcium sensor Cameleon 2.1 because of the minimization of movement artefacts due to its ratiometric properties, a good signal-to-noise ratio and high fluorescence intensity in the non-activated state. The expression of this calcium sensor in three different neuropils by specific Gal4-driver lines enabled us to trace the processing of the presented odor concentrations along a part of the olfactory pathway: in olfactory sensory neurons terminating in the antennal lobe, in olfactory projection neurons in the antennal lobe, in terminal arborisations of projection neurons in higher brain regions, and in Kenyon cells, the intrinsic neurons of the mushroom body.

Results and Conclusions: The results indicate that odor-evoked calcium responses in all these investigated neuropils show an odor concentration dependent activation. We have found no indication for any concentration-invariant activity at any stage of olfactory processing.

The epicuticular waxes as a plant defence barrier towards grain aphid

Agnieszka Wojcicka[1], Bogumil Leszczynski[1], Roman Warzecha[2]

[1]University of Podlasie, Siedlce, Poland, [2]Institute of Plant Breeding and Acclimatisation, Radzikow, Poland

Introduction: Physical and chemical characters of plants, especially their chemical constitutes are in the first line of their defense towards herbivorous insects. The present paper reports on role of the epicuticular waxes of triticale in its defense towards the grain aphid, *Sitobion avenae* (Fabricius).

Methods: The experiments were carried out on waxy covered (RAH 122) and wax-less (RAH 366) triticale hybrids. Feeding deterrents/stimulants from surface of the waxy triticale RAH 122 were extracted with dichloromethane, chloroform and ethanol. Seedlings of the wax-less hybrid RAH 366 were sprayed with the previously obtained surface extracts from the waxy RAH 122. The grain aphid feeding behavior on wax-removed and on sprayed with wax extract seedlings was studied using the EPG method (electrical penetration graphs) in 10 independent replicates.

Results: Removal of the surface wax compounds shortened non-probing period of the grain aphid on the waxy hybrid. Extracts from RAH 122 hybrid applied on seedlings of wax-less hybrid RAH 366, showed a strong reduction in penetration of peripheral plant tissues and prolonged the non-probing period. Generally, chemicals extracted from heavy-waxy hybrid reduced the aphid feeding on wax-less triticale.

Conclusions: Results presented here suggest that chemicals occur within epicuticular waxes layer of the triticale play an important role in its acceptance by the grain aphid.

Beyond the wasp-waist: Mesosomal anatomy and phylogeny of apocritan Hymenoptera

Lars Vilhelmsen[1], Istvan Miko[2], Lars Krogmann[3]

[1]Natural History Museum of Denmark, Copenhagen, Denmark, [2]Vas County Plant Protection and Soil Conservation Service, Tanakajd, Hungary, [3]Staatliches Museum für Naturkunde, Stuttgart, Germany

Introduction: We present the results of the first comprehensive investigation of the skeleto-musculature of the mesosoma across Hymenoptera, and analyse the resulting data set to elucidate the higher level phylogeny of the order.

Methods: Specimens were dissected and investigated with SEM and light microscopy. More than 270 morphological characters were scored and analyzed in TNT under different weighting conditions.

Results and Discussion: Relationships of basal, non-apocritan Hymenoptera were very similar to results of previously published analyses. At the base of Apocrita, the relationship Xiphydriidae + (Orussidae + (Stephanidae + other Apocrita)) was consistently reproduced. Within Apocrita, most superfamilies were retrieved as monophyletic, with the exception of Proctotrupoidea, Chrysidoidea, and Vespoidea. Aculeata were usually not monophyletic and Ichneumonoidea usually came out as sister to the majority of Aculeata. Cynipoidea were usually placed as the sistergroup of Proctotrupoidea + Platygastroidea, the latter being nested deeply within the former. Chalcidoidea was sometimes placed as sister to the remainder of the Proctotrupomorpha. Mymarommatidae and Maamingidae usually came out as sister groups, but the placement of this clade varied. Evaniomorpha excluding Stephanidae was always retrieved, with Evanoidea being monophyletic and Ceraphronoidea sister to Megalyridae. In general, within Apocrita relationships above the superfamily level were weakly corroborated and subject to substantial change under different analytical conditions. The mesosomal dataset provides substantial useful phylogenetic information and clade support at various taxonomic levels within Hymenoptera. However, the mesosomal dataset is highly homoplasious and additional sources of characters are needed to produce a more robust phylogeny for Apocrita.

Movement towards favourable microhabitats on the apple tree by *Cydia pomonella* caterpillars

Silvia Dorn, Ute Kuehrt, Joerg Samietz, Sibylle Stoeckli, Karsten Mody

ETH Zurich, Applied Entomology, CH 8092 Zurich, Switzerland

Introduction: While many studies focus on external feeders on plant leaves, little is known on cues guiding caterpillars within fruits. Neonate Cydia pomonella caterpillars bore quickly into apple fruit, then feed several weeks within the fruit before leaving it to search a cocooning site.

Methods: To determine temperature selection of feeding larvae, apple trees with newly infested fruits were radiated with infrared lamps under controlled conditions. After 3.5 weeks, thermal response of feeding larvae within apples was quantified by distribution of the feeding tunnels over each the radiated and the shaded hemisphere. Temperature selection of final-instar larvae was assessed in a cylindrical temperature gradient area.

Results: Caterpillars feeding inside fruits select the radiated, warmer hemisphere for building feeding tunnels. The proportion of larval cavities in the warmer hemisphere is positively related to increasing apple temperatures on that side, as well as to the temperature difference between the warm and the cold side. In contrast, final-instar larvae in search of cocooning sites show no temperature preference.

Conclusions: Beyond biotic factors known to influence larval movement, temperature appears to shape spatial microhabitat use even in internal feeders. Codling moth larvae change their behaviour during development from cryptic basking to no thermal preference, according to changing benefits, needs and constraints. Temperature as a driving force for movement in this species is further confirmed by a recent analysis of spatial distribution of fruits with larval damage on trees in two different environments.

Combining top-down with bottom-up forces to control bruchids: larval parasitoid and protein-based host plant resistance

Silvia Dorn[1], Guido Velten[1], Anja S. Rott[1], Ine Schmale[1], Cesar Cardona[2]

[1]ETH Zurich, Applied Entomology, CH 8092 Zurich, Switzerland, [2]Centro Internacional de Agricultura Tropical (CIAT), AA 6713 Cali, Colombia

Introduction: For the control of a coleopteran pest feeding within stored bean grains, we investigated the potential of a larval parasitoid in combination with protein-based plant resistance. This pest, the bruchid Acanthoscelides obtectus, infested the beans in 80% of the observed cases already in the field (Colombia). This infestation, invisible at harvest for the farmer, can lead to a complete yield loss within a few months storage period, rendering on-farm storage difficult.

Material: To evaluate the natural storage protein arcelin as a bottom-up force and the natural antagonist Dinarmus basalis as a top-down force, bioassays were carried out on beans with different relative arcelin content.

Results: All arcelin-containing bean lines consistently prolonged bruchid development and affected fitness of bruchid females, as indicated by their reduced body mass. The parasitoid accepted hosts on all bean lines, and parasitoid fitness was not impeded by arcelin. Even under conditions mimicking temporal complexity of bruchid infestations in the field, bruchid suppression is significantly higher on arcelin-containing bean lines than on arcelin-free cultivars.

Conclusions: Arcelin as a bottom-up force not only suppresses the bruchid Zabrotes subfasciatus as has been previously demonstrated, but also supports the proposed two-component integrated pest management system against the discussed bruchid A. obtectus. It extends the time frame during which parasitoids can attack the host successfully, and directly reduces its population growth rate. The storage protein arcelin appears to be harmless to the ectoparasitoid D. basalis, which therefore holds great promise as a top-down force in this system.

IPM practices on insect populations on stored rice in Portugal

Ines Pires[1], Diogo Lemos[1], Claudia Santos[2], Blaine Timlick[3], Maria Otilia Carvalho[4]

[1]Saludaes, SA, Oliveira de Azemeis, Portugal, [2]SOS Cuétara, Pombal, Portugal, [3]Canadian Grain Commission, Winnipeg, Manitoba, Canada, [4]Tropical Research Institute of Portugal - IICT, I.P., Lisbon, Portugal

Portugal is the biggest consumer of rice in Europe and consequently a large number of farmers and industries are associated with rice production and processing. In Portugal, rice is usually planted in April and harvested after August. Prior to processing, rice is stored as paddy on farm or in co-operatives until the end of winter when the remainder of the rice is transported to the processing facility.

As a tool to assist in rice storage decision making, monitoring programmes for environmental conditions and insect activity were conducted on farms and at rice milling facilities, in several warehouses, bins and granaries, containing paddy and brown rice and distributed through the three main rice production regions: Mondego, Tejo and Sado Valleys.

Monitoring on-farm storages, more insect species were identified than in rice mill. The main insect species were fungus-feeders. At rice mills, the main insect species caught were commodity feeders with the most abundant species being *Sitophilus* spp. (*S. zeamais* and *S. oryzae*) and *Tribolium castaneum*.

The studies conducted on five varieties of rice, Gladio, Fani, Eurosis, Ariete (paddy) and Suriname (brown rice), stored in granary and bin structures belonging to one rice mill, showed that grain temperature of stored rice was different among varieties and among paddy and brown rice and Gladio variety was the most susceptible to *Sitophilus* spp attack.

Chemically-Induced anosmia in mosquitoes: A novel way to prevent host finding

Ulrich Bernier[1], Kamlesh Chauhan[2], Daniel Kline[1], Donald R Barnard[1]

[1]USDA-ARS-CMAVE, Gainesville, FL, United States, [2]USDA-ARS-IICBL, Beltsville, MD, United States

Introduction: Hundreds of volatile to semivolatile chemical compounds on the skin of humans and other animals act as kairomones and allomones to produce host-seeking or host-avoidance by mosquitoes and other haematophagous insects. We have spent a decade examining the effect of these human-produced emanations on the host-seeking behavior of the anthropophilic mosquito species, *Aedes aegypti* L. and *Anopheles albimanus* Weidemann. Single compounds act as weak attractants alone, e.g. L-lactic acid but attract synergistically when combined in blends of two to three compounds. Within blends, the release rate and relative abundance of each compound can have a significant impact on attraction. Furthermore, there are some compounds that when added in trace amounts can inhibit the host-seeking ability of these mosquitoes in laboratory behavioral assays.

Methods: Analysis of human skin emanations was accomplished using gas chromatography-mass spectrometry. Bioassays were performed with a dual-port triple cage olfactometer using approximately 75 females, aged 6-10 days, per assay.

Results: Several compounds identified tentatively in human skin emanations suppress or inhibit host-seeking of mosquitoes when trace amounts of these were single compounds are combined with either synthetic attractant blends or attractant odors from human volunteers. We examined 42 compounds similar in chemical structure to the compounds in human emanations that inhibit host-seeking in mosquitoes. Of these, 24 produce significant inhibition of attraction from host-seeking *Ae. aegypti*. A subset of 12 of these compounds has been tested against *An. albimanus* and also inhibits host-seeking in this species.

Conclusions and Future Work: We believe that these compounds produce anosmia in mosquitoes and hope to characterize the physiological basis for this effect in the near future.

Spinosad 45 SC – the novel pesticide for the management of chilli pests

Monilal Chatterjee

Bidhan Chandra Agril University, Kalyani, West Bengal, India

Introduction: Chilli is an important vegetable as well as spices crop in Indian Agriculture. Though India ranks first in the world with reference to area and production of chilli, however the average productivity is very low in comparison to other countries. A major constraint in chilli production is direct damage to fruit by *Helicoverpa armigera* (H) and *Spodoptera litura* (F) and damage by thrips (*Scirtothrips dorsalis*) at vegetative growth of plants. As chilli is one of the most popular and profitable crop, farmers everywhere feel the need to protect such high value crops from any type of damage caused by insect pests. They often use synthetic insecticides indiscriminately, and insect resistance to insecticides and resurgence are very common in the tropics.

Methods: To control chilli thrips and fruit borers efficiently, a new organic pesticides Spinosad 45 SC with novel mode of action has been developed recently. To determine the effectiveness of this new pesticides at different doses compared with traditional chemicals effect on natural enemies and compatibility to other insecticides, fungicides and urea, two field experiments were done over two seasons. They compared five pesticides (Spinosad 45 Sc @ 45, 56 & 73 g a.i./ha, Imidacloprid 20SL @ 40 g a.i., Chlorpyrifos 20 EC @ 500 g a.i., Endosulfan 35 EC @ 525 g a.i. and Fipronil 5 Sc @ 40 g a.i./ha) with untreated control. All other agronomic practices were standard, and a blanket sprays to control mites was applied when necessary. First spraying was done with the appearance of thrips and thereafter three sprays at fortnightly interval were followed.

Results: The results showed that Spinosad 45 % SC at 56 and 73 gm a.i./ha gave best control of thrips up to 14 days in both seasons. It has also reflected in yield parameter. Similarly the fruit borer infestation was sharply reduced in Spinosad treated plot that was closely followed by Fipronil. In another observations Spinosad showed less hazard to natural enemies viz. *Menochillus* sp., *Syrphus* sp. And *Chrysoperla* sp. at different doses compared to untreated control. The compatibility of Spinosad with Quinalphos, Carbendazim and Urea was well and no phytotoxicity was noted at any stages of the crop growth .

Conclusions: Spinosad is a naturally derived insecticide produced by fermentation of bacterium, *Saccharopolyspora spinosa* and consists of a mixture of related Spinosyn toxins, principally Spinosyn-A and D. It acts as contact and stomach poison (Dow, 1997, Salgado, 1997; Thompson *et al.* 2000). It has novel mode of action, disrupts the functions of GABA receptors of small neurons in the central nervous system. Spinosad is considered to be 'fast-acting' insecticide provides 7 to 14 days of control have practically no odor, moderately strong soil absorption and degrades rapidly in the environment. It offers excellent selectivity to beneficial organisms with low environmental risk to human beings and has potential use in Integrated Pest Management (IPM) systems.

HIPV, HIPPO and IPM: Telling plants to pull in their defenders

David James[1], Vincent Hebert[2], Deborah Brooks[1], Lawrence Wright[1], Tessa Grasswitz[1], Castle del Conte Sandra[1]

[1]Washington State University, Prosser, Washington, United States, [2]Washington State University, Richland, Washington, United States

Deployment of synthetic methyl salicylate (MeSA), a herbivore-induced plant volatile (HIPV), in controlled release dispensers (CRD) in hops and grapes in the Pacific Northwest (PNW) of the United States has been demonstrated to increase populations of beneficial insects, improve conservation biological control (CBC) and suppress pests. Other synthetic HIPV (e.g. hexenyl acetate, methyl jasmonate) have also been shown to attract beneficial insects in the field. Identifying and understanding the chemical-ecological and eco-physiological mechanisms mediating beneficial insect attraction to HIPV, is a current focus of this project. Determining whether beneficial insects are recruited by direct attraction or whether plants are stimulated by synthetic HIPV to produce their own beneficial insect-attracting volatiles, is a key question. Preliminary results from laboratory experiments indicate that hop plants exposed to CRD of MeSA emit a different profile of volatiles compared to unexposed plants. Some of these volatiles from MeSA-exposed plants are known attractants of beneficial insects and/or repellents for pests. Turning on or telling plants to produce their own natural enemy attractants is an appealing idea and strategy, and may be responsible for much of the success seen hitherto in improving natural enemy populations and CBC in PNW grapes and hops. Field experiments using agricultural spray oil formulations with 2% MeSA applied to hop and grape plants, have demonstrated recruitment of some natural enemy species. This might be a more cost-effective and practical way of delivering HIPV to plants. This project is a good example of a crop protection application of chemical ecology: turning HIPV into HIPPO (Herbivore-Induced Plant Protection Odors)

Termite-fungus interactions: Are semiochemicals involved in the defense behaviour of the termite, *Macrotermes michaelseni*?

David . M. Mburu, Lynett Ochola, Nguya .K. Maniania, Peter. G. N. Njagi, Linus. M. Gitonga, Mary.W. Ndung'u, Ahmed Hassanali

[1]Icipe-African Insect Science for food and Health, Nairobi, Kenya, [2]Icipe-African Insect Science for food and Health, Nairobi, Kenya, [3]Icipe-African Insect Science for food and Health, Nairobi, Kenya, [4]Icipe-African Insect Science for food and Health, Nairobi, Kenya, [5]Jomo Kenyatta University of Agriculture and Technology, Nairobi, Kenya, [6]Jomo Kenyatta University of Agriculture and Technology, Nairobi, Kenya, [7]Icipe-African Insect Science for food and Health, Nairobi, Kenya

Introduction: Termites encounter diverse array of infective and symbiotic fungi in their hemiedaphic habitats. How these hemiedaphic insects cope in habitats with infective fungi is not well understood.

Objectives: To explore the relationship, if any, between virulence and repellency of fungus, *Metarhizium anisopliae* against termite, *Macrotermes michaelseni* and identify the mediating signals.

Materials and Methods: 15 isolates of *M. anisopliae* were screened for their virulence against *M. michaelseni* at standard conditions. Of these, virulence of 9 selected isolates was determined at different doses and LC_{50} values obtained. In a preliminary study, the repellency of a highly pathogenic isolate of *M. anisopliae* (ICIPE30) against *M. michaelseni* was tested in a Y-olfactometer. To establish if the repellency of the different isolates correlate with their virulence, the RC_{50} and LC_{50} values, respectively, were determined. Fungal volatiles were collected from the most and the least repellent isolates. GC-MS and GC-EAD profiles were obtained.

Results: The virulence and repellency of the different isolates showed a positive correlation. The GC-MS profiles obtained showed qualitative and quantitative difference in volatiles collected.

Conclusion: Our results suggest that termites have defensive behavioural repertoire to detect infective fungi through olfaction and avoid direct physical contact. The results suggest that the avoidance behaviour is mediated by differential semiochemical signals.

Tribolium spp. as model insects for pesticide efficacy studies

Frank Arthur, Jeff Lord

USDA-ARS-GMPRC, Manhattan, Kansas, United States

Stored-product insects can infest stored raw agricultural commodities, processed and packaged warehouses, and urban distribution and retail centers. There are a variety of important pest species, with varying degrees of susceptibilities to insecticides, and researchers often must make choices as to which species are appropriate for laboratory and field studies.

Tribolium castaneum, the red flour beetle, and *Tribolium confusum*, the confused flour beetle, are often used for pesticide studies, particularly those involving treated surfaces or exposure studies with aerosol insecticides. Adults of these species are often more tolerant to insecticides compared to other stored-product beetles, and therefore are good indicators species. Also, they are important economic pests, particularly in mills and warehouses. They are cosmopolitan and found in a variety of stored-product environments, including bulk grains. Finally the adults of *T. castaneum* rarely fly unless temperatures are above 27°C, and *T. confusum* does not fly at all. Consequently, they can be placed in open Petri dishes and directly exposed to aerosol insecticides in actual field trials. They can also be used in laboratory studies in which adults are exposed on different treated surfaces. Finally, the two species often differ in their susceptibility to insecticides, depending on a variety of factors, including the specific strains being tested, the actual insecticide, and methods of exposure.

Although *Tribolium* species can be found in stored raw commodities, they may not be as useful for pesticide studies on treated grains compared to internal feeders such as *Rhyzopertha dominica* and weevils of the genus *Sitophilus*. In these types of studies, progeny production is often measured in addition to direct mortality of adults. However, depending on the commodity and region of the world, Tribolium spp. can be an important component of the pest complex.

Sexual cannibalism and male risk-taking behavior in the Chinese praying mantid

William Brown

State University of New York at Fredonia, Fredonia, NY, United States

Introduction: Praying mantids are famous for the act of sexual cannibalism. Previous work in my laboratory showed that males actively assess the risk imposed by individual females and alter their mating behavior to avoid cannibalism. Here I examine the level of risk taking by males with varying prior experience with mates. Specifically, I hypothesized that males will alter rate of approach, extent of courtship, and degree of cautiousness with which they approach hungry, rapacious females depending on their perception mate availability.

Methods: We collected adult praying mantids (*Tenodera aridifolia*) from wild populations in Autumn 2006 and 2007 and placed individual males into either (a) high or (b) low female encounter treatments to alter male perception of mate availability. Subsequent to the treatments we tested the behavior of males under 2 conditions of differing risk of sexual cannibalism, either (a) approaching a hungry female head-on (high risk), or (b) approaching a well-fed female from behind (low risk).

Results: Males responded to the differing risk of cannibalism by altering approach to females. As predicted, males with prior exposure to females displayed the greatest difference in behavior, slowing down their approach and mounting from a greater (and probably safer) distance in response to level of risk. In contrast, males without prior exposure to females approached both high- and low-risk females relatively rapidly and closely, indicating greater overall risk taking.

Trees as mediators of pathogen-insect interactions: The role of systemic induced resistance

Pierluigi Bonello[1], Daniel Herms[2], Thomas Gordon[3], David Wood[4], Nadir Erbilgin[5], Donald Cipollini[6]

[1]Dept. of Plant Pathology, The Ohio State University, Columbus, Ohio, United States, [2]Dept. of Entomology, The Ohio State University, Wooster, Ohio, United States, [3]Dept. of Plant Pathology, University of California, Davis, California, United States, [4]Div. of Insect Biology, University of California, Berkeley, California, United States, [5]Dept. of Renewable Resources, University of Alberta, Edmonton, Alberta, Canada, [6]Dept. of Biological Sciences, Wright State University, Dayton, Ohio, United States

Plant defense theory revolves around plant responses to herbivory by animals, especially arthropods, with significantly less reference to what could be called “microbial herbivory”, *i.e.* parasitism of plants by symbiotic microbes, *e.g.* pathogens. The virtual absence of this microbial component has constrained a comprehensive understanding of plant defense, given the increasing evidence that plant-associated microbes can be potentially strong modulators of plant-herbivore interactions.

Coniferous trees are often dominant species in both boreal and temperate forests, wherein they play critical roles in ecosystem function. In natural environments, ecosystem stability appears to be the norm, notwithstanding the co-occurrence of insect and microbial species inherently capable of killing their host trees. Adaptive plasticity of host trees involving inducible mechanisms of resistance against invading organisms is likely to play a crucial role in these interactions. We hypothesize that systemic induced resistance (SIR) elicited by pathogens and mutualists represents a common and important phenomenon in coniferous trees, allowing for a balanced allocation of resources between growth and defence. We also propose that the growth/differentiation balance hypothesis (GDBH) should be integrated with the SIR hypothesis to provide a fuller and more mature extension of existing plant defence theory. Several lines of evidence will be provided in support of these hypotheses along with proposed future lines of investigation.

Products and services of the Armed Forces Pest Management Board, USA

Stanton Cope, Sharon Spradling, Richard Johnson

Armed Forces Pest Management Board, Forest Glen, MD, United States

The Armed Forces Pest Management Board, located in Forest Glen, Maryland, USA, provides a wide variety of products and services that are useful to medical entomologists, public health personnel and preventive medicine professionals. This presentation will review all available products and services and demonstrate a step-by-step methodology of how to access them from our website at afpmp.org.

Temperature-controlled colour change in the chameleon grasshopper (*Kosciuscola tristis*) (Orthoptera: Acrididae).

Kate Umbers, Gregory Ian Holwell, Adam James Stow

Macquarie University, Sydney, NSW, Australia

The chameleon grasshopper can change colour from black to pale turquoise in just 30 minutes. This condition is likely to have a thermoregulatory function and is unique amongst arthropods. This study investigated the environmental factors that influence colour change in the chameleon grasshopper. The only previous work on colour change in the chameleon grasshopper was carried out by Key and Day in 1954. Our aim was to identify any relationship between ambient temperature, light level and time of day and the colour of chameleon grasshoppers. In caged field experiments, we employed spectrophotometry, digital photographs and a laser thermometer to measure the colour and temperature of grasshoppers and their environment. We found that grasshoppers kept at higher temperatures were significantly paler than those kept at lower temperatures. We show that this response is independent of circadian patterns and light intensity.

Evidence for transitions to sociality in the small carpenter bees (Apidae: Ceratinini)

Sandra Rehan[1], Miriam Richards[1], Michael Schwarz[2]

[1]Brock University, St. Catharines, Ontario, Canada, [2]Flinders University, Adelaide, South Australia, Australia

Introduction: Presocial taxa are vital to understanding the origins of sociality and the evolutionary steps from solitary to social life. Many authors have inferred incipient sociality in *Ceratina* and suggested their potential for understanding the origins of sociality. Ceratinini is a primarily subsocial lineage, with mothers known for their longevity, nest loyalty throughout the breeding season, and extended maternal care. Both solitary and social behaviour is reported within the tribe, but these observations lack a phylogenetic context. A phylogenetic framework is imperative in order to reveal evolutionary transitions between solitary and social behaviour.

Methods: Ceratinini comprises a lone genus, *Ceratina*, that represents 23+ subgenera of cosmopolitan distribution. To date, representatives from 13 subgenera have been sampled for phylogenetic analysis based on sequences of one nuclear (EF1α-F2) and two mitochondrial (COI and cyt b) genes. Maximum parsimony and Bayesian analyses were used to infer phylogenetic relationships.

Results: Maximum parsimony and Bayesian analyses produce similar topologies and high support of subgeneric nodes. The continental endemism of most morphologically described subgenera is well supported genetically and geographically. However, a few subgenera appear to be biogeographically disjunct, as well as paraphyletic, suggesting a need for revision of their taxonomic status. Mapping social behaviour onto a consensus tree reveals basal subsociality for the tribe, and at least two evolutionary transitions to sociality.

Conclusions: *Ceratina* offer key insights into the transition from subsocial to social states. With subsocial preadaptations set, a few taxa have achieved sociality under the right combination of ecological and behavioural circumstances.

The utility of molecular diagnostics in biological control: evaluating non-target effects associated with introduced parasitoids

Tara Gariepy, Russell Messing

University of Hawaii at Manoa, Department of Plant and Environmental Protection Sciences, Kapaa, Hawaii, United States

Direct and indirect non-target effects associated with exotic parasitoids can be difficult to predict and measure using conventional rearing and dissection techniques. Host and parasitoid mortality that occur during rearing can limit the accuracy of information obtained from field-collected samples, and dissection does not always provide accurate identification of parasitoids to the species level. However, polymerase chain reaction (PCR)-based techniques provide rapid and accurate identification of parasitoid species, and are not affected by mortality issues associated with host rearing. Furthermore, information regarding multiparasitism and hyperparasitism of individual hosts can be obtained using PCR-based techniques, and may provide additional insight on multitrophic interactions and interspecific competition among parasitoids that share the same host. Here, we provide case studies to demonstrate the utility of PCR-based assays in both pre- and post-release studies on classical biological control agents. Molecular diagnostic tools for detection and identification of parasitoids within host insects provide a unique approach to study host-parasitoid, parasitoid-parasitoid, and parasitoid-hyperparasitoid interactions in field-collected insects. A better understanding of these interactions in the field may improve the success of natural enemy establishment and suppression of pest populations and may be used to predict and measure potential non-target effects.

Long-term sustainable area-wide mating disruption program with improved monitoring tools for oriental fruit moth and codling moth in Australian orchards

Alexandre Il'ichev

Department of Primary Industries Victoria, Biosciences Division, Tatura, Victoria, Australia

Area-wide pheromone mediated mating disruption (MD) has been successfully used for long-term and sustainable Integrated Pest Management (IPM) programs in Australian orchards. Initially, hand-applied MD dispensers were used to treat individual orchard blocks and only known hosts of oriental fruit moth (OFM) and codling moth (CM). An increased incidence of pest damage on the borders of MD treated blocks adjacent to blocks without MD treatment stimulated an area-wide application of MD for better crop protection. An initial area-wide MD program, with more than 1,100 ha of 40 contiguous orchards covered with MD dispensers, applied to all fruit trees in the Cobram region of northern Victoria, Australia, substantially improved protection against OFM damage during 3 years. When the initial program was finished, a number of small growers stopped area-wide MD applications and returned to the conventional insecticide spay program on pome fruit with MD treatment of only stone fruit. This resulted in an increase of OFM damage to the neighbouring properties where area-wide MD treatment continued. Affected local growers took the initiative to continue this area-wide MD program as a self-sufficient community approach and re-established MD across the whole Cobram region.

Later area-wide MD program to control OFM and CM has been successfully established in Greater Shepparton and Invergordon regions of northern Victoria. Both OFM and CM have the ability to infest new hosts and could quickly build up population level in orchards without proper MD treatment. Reliable monitoring of these pest in orchards treated with MD is crucial for sustainable pheromone-based IPM. New host-plant attractants were tested to improve monitoring of these pests, particularly mated females in the orchards treated with MD. Semiochemical-based IPM and selective area-wide MD programs are the key elements in development of cost effective strategies for pest control while protecting the environment by reducing pesticide pressure in orchards.

The butterfly bell curve: linking behavior, brains, and life history in the study of host learning

Emilie Snell-Rood, Wulfila Gronenberg, Goggy Davidowitz, Daniel Papaj

University of Arizona, Tucson, AZ, United States

Introduction: Learning allows animals, including insects, to exploit rare or novel environments. In nature, hostplants of butterflies generally bear green foliage, and many butterflies show innate preferences for green during host search. However, butterflies may encounter hosts of other colors, such as red. This work sought to determine if butterflies can learn uncommon colors in relation to oviposition and if such learning is associated with costs, such as increased neural tissue, that might maintain innate color biases.

Methods/Results: In field cage assays, host search in both the pipevine swallowtail butterfly, *Battus philenor* and the cabbage white butterfly, *Pieris rapae*, is innately biased towards green, yet females readily learn red in association with oviposition on red hosts. In the cabbage white, full-sib families varied in initial green bias and ability to learn red hosts. The capacity to learn red was associated with larger brains and less mature ovaries at emergence, suggesting a 'production cost' of learning. However, regardless of genetic background, the size of certain brain regions increased and fecundity decreased with experience learning red hosts, suggesting an 'operating cost.' Finally, cabbage whites originating from agriculturally-intensive areas had a stronger green bias, suggesting that costs may select against learning in constant or predictable crop settings.

Conclusions: Host learning in butterflies is maintained by benefits of using novel hosts but in less variable environments the costs of learning, in terms of neural tissue and delayed reproduction, may favor innate biases in host cue preference.

Juvenile Hormone as a regulator of plasticity in adulthood: from butterflies to beetles

Emilie Snell-Rood[1], Daniel Papaj[1], Goggy Davidowitz[1], Wulfila Gronenberg[1], Armin Moczek[2]

[1]University of Arizona, Tucson, AZ, United States, [2]Indiana University, Bloomington, IN, United States

Introduction. Many organisms cope with environmental variation through the development of suites of traits appropriate to local conditions. Such phenotypic plasticity is often mediated by endocrine regulators with many downstream effects. While we know much about how hormones, such as juvenile hormone, mediate plasticity during larval and pupal development, we know much less about how it mediates plasticity in adults confronted with changing internal or external environments.

Methods. This study investigated the effects of JH on mediating host learning in adult butterflies. It is known that early in adulthood, JH regulates reproductive development in Lepidoptera; given that learning is costly, we predicted that JH may antagonistically link investment in learning and neural tissue to investment in reproduction.

Results. Adult butterflies (*Pieris rapae*) treated with methoprene (a JH analog) were, relative to controls (treated only with the solvent), less likely to increase their ability to locate novel (red) hosts over two days of learning. Instead, they were more likely to search for innately-preferred green colors. Furthermore, prior to host-learning, hormone-treated butterflies developed relatively smaller mushroom bodies, regions of the insect brain involved in learning.

Conclusions. This research supports the idea that JH has a suite of effects in adult insects. Further insights will depend at least in part on our understanding of the downstream targets of JH action. We end by highlighting several experimental avenues designed to identify and characterize interactions between JH and its targets using recently developed gene function and genomic approaches in polyphenic horned beetles, *Onthophagus*.

Development and application of a genetically engineering strain WG-001 of *Bacillus thuringiensis*

Ziniu Yu, Ming Sun, Ziduo Liu, Jianhong Li

National Engineering Research Center for Microbial Pesticides, Wuhan, China

Eight strains highly toxic to lepidopteran, dipteran, and coleopteran insects isolated from 1800 *Bacillus thuringiensis* strains stored in our lab had been screened, and their insecticidal crystal protein genes *cry1Ab*□*cry1Ac*□*cry1Ea*□*cry1C*□*cry2Ab* and *cry1A* , and assistant protein gene *P19* and *P20* had been cloned. Three plasmids with different functions were constructed with replication vectors of pBMB9741□pBMB 2062 and pBMB 607□ resolution vectors of pBMB 801 and pBMB1808, and integration vectors of pBMB R14, pBMB f7, pBMBr13 and pBMBF13, respectively.

Through gradually increasing culture temperature, nine non-crystallous mutant strains were screened. plasmid-free derivative strain BMB171 had highest transformation efficiency among four vectors transformed. The function of upstream promoters of target gene *cry1A* and *cry1D* of their effects on cry-lacZ fusion gene's transfection and regulation was analyzed, and difference of expression and regulation of target genes *cry1A* and *cry1D* was analyzed in different strains. It indicated that gene expression was related to early-stage carbon resource and cell metabolization.

The engineering strains with various functions were constructed. Fermentation medium and culture condition of highly effect engineering strain WG-001 were optimized, and fermentation dynamics and productive technique of the strain WG-001 was investigated. The safety certificate of the strain WG-001 was acquired in 2005 after Mid-test in laboratory done by China Agriculture Genetic Engineering Safety Assessment, Environment release and commercialized test. Large-scale production of the strain WG-001 was done with potency 60000IU/mg of technical powder and 8000IU/mg of oil emulsion. WG-001 had been applied to control agricultural and forestry pest, such as *Helicoverpa armigera*, *Plutella xylostella*, *Tryporyza incertulas* and *Dendrolimus punctatus*. Some product of WG-001 had been exported in abroad.

Next generation repellents of public health value

Scott P Carroll

University of California, Davis, CA, United States

Insect repellents provide flexible means of personal protection to fill inevitable gaps in other control measures– gaps currently most profound in tropical regions of the developing world. Safe and effective repellents based on deet, picaridin, IR3535 and PMD are available; properly deployed, such products could in theory limit disease outbreaks. However, currently available repellents have not been developed specifically to address public health needs, and thus suffer from several (surmountable) logistic limitations. These include affordability, distribution, duration of efficacy, and user acceptance (particularly important when daily use is critical to disease prevention). Positive developments include formulation improvements that increase the cosmetic appeal of deet and the duration of efficacy of IR3535. In addition, a new, affordable PMD-based repellent is being developed to enter local markets in impoverished regions. Vital to such initiatives is US Environmental Protection Agency approval, which is globally influential, but difficult to attain due to increasingly stringent and costly human research subject oversight.

Evolution in response to climate change and species invasions

Scott P Carroll

University of California, Davis, CA, United States

The biological consequences of climate change and species invasions should be studied from an evolutionary perspective. Affected populations, whether *in situ* or displaced, invading or invaded, may exhibit substantial adaptation within a few generations. Swift adaptation may avert extinction, permit establishment after colonization, or, in invaded communities, act to limit the spread or impact of an invader. I will summarize recent findings on evolution in response to climate change and species invasions, and discuss the potential for *adaptive biological management* of disrupted communities.

The impact of floral resource subsidies and landscape context on biological control in forage brassicas

Mattias Jonsson[1], Steve Wratten[1], Cory Straub[2], Hannah Buckley[1], Brad Case[1], Raphael Didham[3], Roddy Hale[1]

[1]Lincoln University, Lincoln, New Zealand, [2]University of Wisconsin, Madison, United States, [3]University of Canterbury, Christchurch, New Zealand

Introduction: The intensification of agricultural production systems has resulted in a severe decline in biodiversity and this is likely to lead to deteriorating ecosystem services such as biological control. Several studies have shown that complex landscapes with a high proportion of non-crop vegetation have higher densities of natural enemies and tend to have lower pest numbers than do simpler landscapes dominated by agriculture. However, it is not known how best to design landscapes to maximise biological control. Conservation biological control aims at improving the conditions for natural enemies of pests, for example by adding flowering plants that can provide non-prey food as well as shelter. To date, conservation biological control research has usually focused on plots or single fields while ignoring processes at larger spatial scales. However, it is likely that the effect of local measures depend on the composition of the surrounding landscape. In the research project presented here we firstly investigate how vegetation composition at different spatial scales surrounding fields of forage brassicas in New Zealand determines biological control of the key pests diamond back moth, *Plutella xylostella* and cabbage grey aphid, *Brevicoryne brassicae.* Secondly we study if the effect of local conservation biological control measures, in the form of floral resource subsidies is influenced by landscape features. Analysis and field experimentation are still under way. Key results from both these studies will be presented.

The impact of flowers and omnivory on a four trophic level food web – implications for biological control

Mattias Jonsson, Katherine Robinson, Steve Wratten, Shona Sam

Lincoln University, Lincoln, New Zealand

Introduction: Many insect predators feed on nectar and/or pollen and increasing the availability of such resources can improve biological control. If such resources also increased the fitness of predators' enemies, this may affect the likelihood of success of biological control programmes. The lacewing *Micromus tasmaniae* is a true omnivore that as an adult feeds on both flowers and aphids, whereas the parasitoid wasp, *Anacharis zealandica* is a life-history omnivore, feeding on lacewings at the larval stage and flowers as an adult.

Methods: In a series of laboratory bioassays and a field cage experiment we explored how flowering buckwheat affected longevity, oviposition and population dynamics of lacewings and parasitoids at different levels of aphid availability.

Results: The effect of flowering buckwheat on lacewing longevity and oviposition depended on aphid availability, having a positive effect only at low aphid densities. Buckwheat significantly increased parasitoid longevity. In field cages, buckwheat decreased the density of lacewings when the aphid density was high, probably because of increased parasitism rates. Towards the end of the experiment when the aphid populations had declined, the effect of buckwheat on lacewing density became positive, probably because lacewings were starving in the absence of flowers and with low prey availability.

Conclusion: Flowers may benefit species at the fourth trophic level and this may reduce the populations of predators of pests. More effective biological control may be achieved by providing food plants that selectively benefit predators of pests but have a lesser or no effect on their antagonists.

Historical biogeography of selected species of cicada within the tribe Platypleurini (Hemiptera: Cicadidae).

Benjamin Price, Martin Villet, Nigel Barker

Rhodes University, Grahamstown, South Africa

Molecule-based phylogenetics, and in particular comparative phylogeography of phytophagous insects, can prove useful in identifying places and processes central to the origin and maintenance of biological diversity. Cicadas in particular have proven useful as tools for examining the effects of distribution, host plant association and geographic barriers on gene flow in species. The family (Cicadidae) is subdivided into about 20 tribes, of which the tribe Platypleurini is predominantly African. Molecular studies have shown that the platypleurine cicadas are a fairly ancient tribe within the cicadas and have indicated that the group dispersed in a southward and westward radiation from East Africa. The process of biodiversification has apparently involved host plant switching (though altered host-finding cues), modified acoustic signalling, altered habitat preferences, and population genetic effects brought about by climate change and sea-level fluctuations. The high rates of endemism shown by these insects can assist in generating insight into the radiation and diversification of the platypleurines, which is crucial to a mechanistic understanding of biodiversity.

Modelling the responses of tsetse to climate change: from mechanisms to macroecology

John Terblanche[1], Steven Chown[2], John Hargrove[3]

[1]Dept Conservation Ecology & Entomology, Stellenbosch, South Africa, [2]Centre for Invasion Biology, Stellenbosch, South Africa, [3]SACEMA, Stellenbosch, South Africa

As the vectors of trypanosomiasis, what some have called a neglected tropical disease, tsetse are of considerable medical and veterinary significance in sub-Saharan Africa. In consequence, understanding the factors determining their population dynamics, spatial variation in abundance and geographic distributions has long been of interest. For several species, large-scale, largely bioclimatic modelling work has identified temperature and saturation deficit as significant factors influencing spatial variation in abundance. Small scale work on population dynamics has identified temperature as a major direct and indirect contributor to mortality in the adults, and saturation deficit a source of mortality in the pupae. However, the mechanisms by which physiological tolerances translate to population dynamic effects and to large scale distributions have yet to be fully explored. Here we do so for *G. pallidipes* and *G. morsitans* from southern Africa, using laboratory and field-based physiological data, field collected population data, and a model combining the two. Using the model we also make predictions for changes to populations of these species using a gradual temperature increase model typically applied to climate change effects and models incorporating extreme thermal events that are also predicted to increase. In so doing we also provide information on a much-debated topic in evolutionary biology: the contribution of rare, extreme events, and more common sub-lethal events to population dynamics and evolutionary change.

Development and demonstration of Earth Observation technology for identifying potential mosquito larval habitats in Kilifi, Kenya.

Charles Mbogo[1], Jiangui Liu[2], Janet Midega[1], Joseph Nzovu[1], John Bennett[1], Mark Kampfer[1], Tom Hirose[1]

[1]Kenya Medical Research Institute, Kilifi, Kenya, [2]Noetix Research Inc, Ottawa, Ontario, Canada

Introduction: Malaria is a serious health problem in the Sub-Saharan region of Africa, Latin America and tropical areas in Asia, affecting approximately 300 million people and causing over 1 million deaths each year. Solutions are needed by governments and health organizations to combat with this disease. Remote sensing and GIS techniques are useful for generating thematic map layers that identify the spatial and temporal variability of malaria risk. This information can be invaluable for allocating limited resources in an effective way. Under the TIGER initiative and the support from Canadian Space Agency, Noetix Research in collaboration with the Kenya Medical Research Institute are working on a project to develop technologies based on earth observation data for malaria risk mapping. This paper reports our results using remote sensing data and digital elevation model (DEM) to map potential mosquito larva habitats in Kilifi district, Kenya.

Methods: Shuttle Radar Topographic Mission (SRTM) DEM was used to map topographic features, such as slope, depressions, streams and topographic wetness index. SPOT image was used for vegetation and soil wetness mapping. Multi-temporal synthetic aperture radar (SAR) images were obtained for 2006 and were used for mapping wetland features, such as permanent and ephemeral water bodies, areas that are potential to cumulate water during precipitation. Field surveys were carried out to deploy sample sites, record larval status, and characterize the physical environmental conditions of the sites. The ability for mapping mosquito larvae habitat using remote sensing data generated thematic layers was evaluated using statistical analysis. Our data shows that the thematic layers can correctly identify over 60% of the sites, representing a fair agreement with the observations.

Conclusions: Multi-temporal Radarsat SAR images are useful in developing thematic layers which are useful in mapping potential mosquito larval habitats or environmental factors that regulate vector-borne disease transmission.

RNA interference (RNAi) with allatoregulating neuropeptide genes from *Gryllus bimaculatus* (Ensifera: Gryllidae) and *Spodoptera frugiperda* (Lepidoptera: Noctuidae) and its effects on reproduction

Klaus H. Hoffmann, Manuela Klim, Sandra Merz, Mehriye Sertkol, Stephanie A. Westerlund, Martina Meyering-Vos

Animal Ecology I, University of Bayreuth, Bayreuth, Germany

Double-stranded (ds) RNA gene interference is an efficient method to silencing gene expression in a sequence-specific manner. Here, we show that dsRNA targeting genes for allatoregulating neuro-peptides in the Mediterranean field cricket, *Gryllus bimaculatus* (type-A allatostatins; FGLamide allatostatins), and the fall armyworm, *Spodoptera frugiperda* (type-C allatostatin or Manse-AST, Spofr allatotropin-2), injected into freshly moulted last instar larvae or adults produced a rapid and long lasting reduction in the mRNA levels in various tissues. The effects lasted for up to 7 days. Following dsRNA injections, the juvenile hormone titers in the haemolymph (as measured by HPLC-mass spectrometry) were clearly affected in a peptide- and stage-dependent manner resulting in significant changes in adult development and reproduction:

(1) Type-A allatostatin dsRNA injection induced a reduced body weight gain in larval and adult crickets and the imaginal moult was incomplete.
(2) Silencing the allatostatin type-A expression also reduced the egg and testes development in crickets, and the oviposition rate was drastically reduced in both species.
(3) Following injection of either type-C allatostatin or allatotropin-2 dsRNA into last instar larvae of *S. frugiperda*, the last larval stage was prolonged. In prepupae, the juvenile hormone titer was decreased, but the animals pupated and moulted normally.
(4) In adult moths, gene silencing for both peptides clearly reduced the oviposition rate.

The present study confirms the effectiveness and specificity of gene silencing of allatoregulating neuropeptides by RNAi. Thus, RNAi can be used in order to prove putative functions of the various types of allatoregulating neuropeptides in different insect orders.

Supported by the Deutsche Forschungsgemeinschaft (ME-2034/1-3 and GRK 678/2)

Cloning and characterization of the genes responsible for larval body color mutants in the silkworm, *Bombyx mori*

Yan Meng[1], Susumu Katsuma[1], Takaaki Daimon[1], Kazuei Mita[2], Yutaka Banno[3], Toru Shimada[1]

[1]Department of Agricultural and Environmental Biology, Graduate School of Agricultural and Life Sciences, The University of Tokyo, Yayoi 1-1-1, Bunkyo-ku, Tokyo 113-8657, Japan, [2]Insect Genome Research Unit, National Institute of Agrobiological Sciences, Owashi 1-2, Tsukuba, Ibaraki 305-8634, Japan, [3]Institute of Genetic Resources, Graduate School of Bioresource and Bioenvironmental Sciences, Kyushu University, Hakozaki 6-10-1, Higashi-ku, Fukuoka 812-8581, Japan

Hundreds of mutant strains of the silkworm *Bombyx mori* are valuable genetic bioresources, quite a few of which are related to body color pigment formation. *red blood* (*rb*, 21-0.0) is a recessive mutant with larval skin reddish, whose hemolymph turns red in the air although hemolymph from normal strains turns black in melanization. *lemon* (*lem*, 3-0.0) is another recessive mutant, which grows normally but body color is deep yellow. *lem^{l}*, a *lem* allele, is homozygous lethal immediately after the first ecdysis with bright yellow skin. Previous studies showed that the red body color was caused by abnormal accumulation of 3-hydroxykynurenine in *rb* strain, and that a large amount of 7,8-dihydropteridin was accumulated in the integument of *lem* larvae. Recently, we successfully identified the candidate genes, i.e. *kynureninase* (*BmKyn*) for *rb* and *sepiapterin reductase* (*BmSpr*) for *lem* and *lem^{l}* using *B. mori* EST databases. Kynureninase is an important enzyme in the kynurenine pathway of tryptophan metabolism. *BmKyn* encodes a 406-aa protein. A single nucleotide mutation, which substitutes isoleucine for threonine at residue 102, was found in the *BmKyn* ORF of *rb* strains. This mutation resulted in a marked reduction of BmKYN activity as compared to that of normal type. Sepiapterin reductase catalyzes the biosynthesis of tetrahydrobiopterin in the metabolic processes of guanosine triphosphate. An abnormal forward stop codon in the *BmSpr* ORF caused 5-aa deletion in the *lem* strains. We also found that 27 nts were tandemly inserted into *BmSpr* ORF of *lem^{l}* mutant resulting in an addition of 9-aa residues. Our data suggest that BmSPR activity deficiency leads to *lem* larvae body color deep yellow, and that BmSPR activity loss is responsible for *lem^{l}* larvae lethality.

The impacts of alien plants on native pollinators

Caroline Nienhuis, Jane Stout

Trinity College Dublin, Dublin, Ireland

Introduction: Invasive alien plants can impact native plant communities directly and indirectly but little is known about their effects on native pollinators. The invasive alien *Impatiens glandulifera* (Balsaminaceae) was used to investigate the effects of alien plant removal and density on native pollinator assemblages and native co-flowering plants.

Methods: Pollinator assemblages in sites where *I. glandulifera* was absent, present and had been experimentally removed were assessed by measuring insect visitation to *I. glandulifera* and artificial potted native plant communities. Mark-recapture experiments were conducted to estimate bumblebee utilisation of all sites.

In addition, bumblebee foraging behaviour on *I. glandulifera* and native co-flowering plants was examined. The effect of *I. glandulifera* plant density on bumblebee visitation to native plants, deposition of alien pollen on native plant stigmas and subsequent seed set was assessed.

Results: Although the presence and/or removal of *I. glandulifera* did not affect insect abundance, bees, especially bumblebees showed high visitation levels to the alien. Invaded sites did not attract a greater abundance or diversity of bumblebees.

Bumblebee species differed in foraging behaviour with low levels of flower constancy potentially causing improper pollen transfer. Although high *I. glandulifera* densities seemed to facilitate visitation to native plants, high alien density significantly decreased seed set of some native plants.

Conclusions: Its high nectar secretion rate and sugar concentration make *I. glandulifera* an extremely attractive nectar source for bumblebees. Self-incompatible perennial plants, in particular those relying on cross-pollination and growing at low densities may be greatly affected by *I. glandulifera*.

Monitoring fruit flies (Diptera: Tephritidae) in Africa

Mervyn Mansell, Jeffrey Austin, Kenneth Nagata

Animal and Plant Health Inspection Services (APHIS), United States of America Department of Agriculture (USDA), Pretoria, South Africa

Fruit flies are among the world's worst pests of cultivated fruits and vegetables. They endanger food security globally, especially in Africa and are a serious impediment to trade. Africa is home to a number of economically important flies, including Mediterranean fruit fly, generally regarded as the world's most dangerous fruit pest. Besides the indigenous taxa, four additional species have recently invaded Africa, further compromising Africa's trade potential and food security. Millions of dollars are spent annually on phytosanitary measures to control Tephritidae and to prevent the establishment of invasive populations in pest free countries.

At least 12 species of indigenous Tephritidae are of economic significance in Africa: *Ceratitis capitata* - Mediterranean fruit fly, *C. rosa* – Natal fruit fly, *C. fasciventris*, *C. anonae*, *C. cosyra* – Marula fruit fly, *C. silvestrii*, *Dacus bivittatus*– Pumpkin fly, *D. ciliatus* – Lesser pumpkin fly, *D. vertebratus* – Jointed pumpkin fly, *D. frontalis*, *Trirhithrum coffeae* – Coffee fly, *T. nigerrimum*, *Bactrocera oleae* – Olive fly, as well as several in Madagascar (*Ceratitis malgassa* – Madagascan fruit fly, *C. catoirii* – Mascarene fruit fly, *Dacus demezzeri*). In addition, four species of *Bactrocera* have recently invaded Africa: *B. zonata* – Peach fly, *B. invadens* – Invader fly, *B. cucurbitae* - Cucurbit fly, *B. latifrons* – Solanum fly.

A number of countries in Africa have established surveillance programmes and one has a sterile male facility to enhance phytosanitary capacity. An overview is provided of the pest species and phytosanitary measures to counter them.

Novel application of pollen to augment predatory mite populations

Phyllis Weintraub[1], Carmit Tal[1], Eric Palevsky[2], Yonattan Maoz[2], Moshe Coll[3], Samuel Gan-Mor[4]

[1]Agricultural Research Institute (ARO), Gilat Research Center, Israel, [2]ARO, Newe-Ya'ar Research Center, Ramat Yishay, Israel, [3]Faculty of Agricultural, Food and Environmental Quality Sciences, Hebrew University, Rehovot, Israel, [4]ARO, Volcani Center, Bet Dagan, Israel

Introduction: Pollen supplements have been demonstrated to improve the efficacy of biological control agents. However, supplements have not been used beyond small trials because of the arduous application. We have developed an efficient application unit for orchards, greenhouse and field crops and report preliminary results.

Methods: A patented pollen application unit, which places an electrostatic charge on pollen, was used to deliver corn pollen to seedling peppers (affected by *Polyphagotarsonemus latus*) and avocado trees (affected by *Oligonychus perseae*). Plants were treated with pollen then predatory mites (*Amblyseius swirskii* and *Euseius scutalis*, respectively) were released. Pest and predator populations were monitored by rinsing leaves in 80% EtOH or by direct observation.

Results: On greenhouse peppers we obtained significantly more *A. swirskii* for a period of 26 days after 1 pollen application as compared to non-pollen treated plants, in field trials there were fewer *P. latus* on plants in which the predators were supplemented with pollen. At the end of a 6-week potted avocado trial, there were significantly more predators and fewer pests as compared to non-pollen-treated plants. Pollen supplements of natural occurring *E. scutalis* in avocado orchards showed similar trends.

Conclusions: The goal of this work is to improve the biological control provided by generalist predators by allowing their early establishment. These initial trials demonstrate the beneficial effects of pollen supplements on *A. swirskii* and *E. scutalis* in greenhouse and field trials. Optimum pollen density and application rates, effect of pollen on pests and IGP have yet to be determined.

Relating ichneumonoid phylogeny to global diversity patterns

Donald Quicke, Owen Jones, Andy Purvis

Imperial College London, Silwood Park Campus, Ascot, United Kingdom

Species-richness varies in complex ways across the globe and among phylogenetic lineages. Clade diversification is shaped by both organism traits and features of their environments, but most data sets are too small to allow these two kinds of influence to be separated. High-diversity cosmopolitan clades showing many independent geographic and biological transitions are needed in order to distinguish the two effects.

The results of new phylogenetic analyses of a cosmopolitan insect group, the Ichneumonoidea, are used to investigate this further. A 1001 taxon molecular (28S rDNA) and a combined molecular-morphological data set is used to generate Ichneumonidae phylogeny estimates using a range of alignment algorithms. The data set comprises representatives of all subfamilies, all except three tribes and all but one of the genera highlighted as placed uncertainly. These trees were used to construct lineage through time plots to which models of diversification rate such as Yule process, or birth-death models, etc. were fitted. The slopes of these models provide estimates of 'birth' and/or 'birth-death' rates for the included lineages.

Diversification rates are estimated for the whole tree and for subsets of lineages from different regions (tropical or temperate) and with different functional traits (idiobiont or koinobiont). The effect of geography and life-history on our diversification rate estimates was then examined. By repeating analyses under a range of diversification models we the statistical support for each. These results will help to explain current ichneumonoid diversity patterns and go some way to addressing hypotheses of distribution patterns in other taxonomic groups.

Potential of entomopathogenic nematodes for the control of false codling moth, *Thaumatotibia leucotreta*, (Lepidoptera: Tortricidae) in laboratory bioassays

Antoinette Malan[1], Sean Moore[2]

[1]*Department of Conservation Ecology and Entomology, University of Stellenbosch, Stellenbosch, Western Cape Province, South Africa,* [2]*Citrus Research International, Humewood, South Africa*

Introduction: False codling moth (FCM), *Thaumatotibia leucotreta* (Meyrick), is an endemic key pest of citrus in South Africa. None of the current control measures target the soil stages of FCM. The inundative use of entomopathogenic nematodes (EPNs) against the soil stages of FCM offers a window period for the control of FCM.

Methods: A survey for EPN in citrus orchards from three provinces of South Africa was conducted. The nematodes were identified to species level using molecular techniques. Specific strains effective against FCM larvae and pupae were selected by means of laboratory bioassays, which included 24-well plates, sand and soil assays.

Results: A total of 164 samples were collected and trapped with wax moth or mealworm for the presence of EPNs. Nematodes were isolated from 33 samples with a 20% recovery rate. The species identified during the survey were *S. khoisanae*, *Steinernema* sp., *Heterorhabditis bacteriophora* and *H. zealandica*. Mortality was found to be high for late instar FCM larvae, while mortality for pupae were much lower. All three of the selected EPN species performed well in different soil types and infectivity was high. *Heterorhabditis bacteriophora* gave 100% control in all soil types tested, followed by *H. zealandica* (99%) and *S. khoisanae* (81%). Time of persistence for the three species and minimum concentration of infective juveniles for field trails were obtained using soil bioassays.

Conclusions: Results in the laboratory indicate EPNs to be of great potential as biological control agents against the soil stages of FCM as part of an IPM system.

Early experience with alternative prey affects adult performance in predatory mites

Peter Schausberger, Daniela Hoffmann, Andreas Walzer, Hasan Rahmani

University of Natural Resources and Applied Life Sciences, Department of Applied Plant Sciences and Plant Biotechnology, Institute of Plant Protection, Vienna, Austria

Learning in the context of foraging is a widespread phenomenon in both vertebrate and invertebrate animals. Among arthropods, learning has been mainly studied in insects and within insects in eusocial and parasitoid hymenopterans. In contrast, learning is far less well documented for predatory arthropods, in particular mites. Studies on mites dealt with herbivorous spider mites and long-distance olfactory learning by predatory mites. There exist no reports about the effects of learning in early life on adult performance. However, experience with a given prey in the early stages of life may have profound impacts on feeding performance of adults. Moreover, although learning is generally assumed to be adaptive, the adaptive significance of learning has been rarely documented. I here give two examples of how learning in the juvenile phase may affect predation performance and fitness of adult predatory mites. The first example deals with adaptive learning in the specialist predatory mite *P. persimilis*. Adults emerging from juveniles experienced with alternative prey attacked this prey sooner than those emerging from inexperienced juveniles. Learning was adaptive because it increased the survival prospects of adults. The second example shows that adult generalist predatory mite females, *Neoseiulus californicus*, have an improved predation performance on the alternative prey western flower thrips, *Frankliniella occidentalis*, after having had contact with this prey in the early stages of development. I argue that the putative learning mechanisms are priming/sensitization and/or food imprinting.

The role of advertisement, rewards, and defense against insect herbivores in the pollination biology of African cycads (*Encephalartos*)

John Donaldson[1], Terence Suinyuy[2], Steven Johnson[3]

[1]South African National Biodiversity Institute, Cape Town, South Africa, [2]University of Cape Town, Cape Town, South Africa, [3]University of KwaZulu Natal, Pietermaritzburg, South Africa

Early models of insect pollination in cycads were based on angiosperm examples in which pollinators are attracted to reproductive structures by floral rewards and advertising. Subsequent studies have shown that cycad pollination may involve more complex push-pull systems in which insects are both attracted to and dispersed from cones by attractant and repellant compounds, and cyclical patterns of cone thermogenesis. We present data from studies on the African cycad genus, *Encephalartos,* to test hypotheses based on the push-pull model. We also examine how pollination involving insect herbivores may be especially complex in *Encephalartos* because it has a higher diversity of insect herbivores than any other cycad genus, including the only known cycad seed predators. As a result, there is a tradeoff between attracting pollinators and defense against herbivory. Preliminary data from olfactometer experiments, analysis of cone volatiles, and insect responses to plant defensive compounds indicate significant differences in pollination systems between *Encephalartos* and other relatively well studied systems such as Australian *Macrozamia* species. Data from *E. villosus* indicates that volatile compounds vary at different times of day, over the lifespan of the cone, and between male and female cones, and these differences are coupled to changes in insect behaviour. Our studies of responses to apparent defensive compounds (macrozamin, BMAA) show that they can act as both deterrents and feeding stimulants for different herbivores, although their role in determining pollinator specificity is still not clear.

Who goes first? Arrival order influences reproductive success in two species of group-living beetles *Ips grandicollis* and *Dendroctonus ponderosae* (Coleoptera: Curculionidae)

Tanya Latty[1], Mary Reid[3], Matthew Symonds[2]

[1]University of Sydney, Sydney, New South Wales, Australia, [2]University of Melbourne, Parksville, Victoria, Australia, [3]University of Calgary, Calgary, Alberta, Canada

In group-living animals, individuals can choose to either join established groups or to start new groups. Individuals who found new colonies are called pioneers. By arriving first, pioneers may benefit from lower competition. However, if a resource is dangerous, pioneers may suffer high injury/mortality rates. Here we examine pioneering in two group-living bark beetles: the mountain pine beetle (*Dendroctonus ponderosae,* herein MPB**)** which colonises living trees, and the eastern fivespined bark beetle (*Ips grandicollis),* herein *Ips*) which colonises dead trees. By attacking living trees, MPB pioneers may face an increased risk of mortality due to tree defences. We predicted that successful pioneers would produce more offspring than joiners because of lower competition (the primary cause of larval mortality). As expected, MPB pioneers were found to have high mortality rates (12%). Surprisingly, successful pioneers produced fewer offspring than joiners, suggesting there is no reproductive benefit associated with pioneering. Given the costs, why do individuals pioneer? We tested the hypothesis that pioneering in MPB is condition-dependent such that individuals become pioneers only when they have run out of energy. We found that individuals in poor condition were indeed more likely to pioneer than individuals in good condition.

In contrast to MPB, *Ips* colonises dead trees which lack active defence mechanisms. Pioneer mortality is therefore negligible. We predicted that *Ips* pioneers would benefit from lower competition. Contrary to our expectations, *Ips* pioneers had lower reproductive success than joiners, suggesting that tree defences do not fully explain why pioneers suffer poor reproductive success.

The potential for biocontrol in stored products in general, with specific attention to application of parasitoids against *Sitophilus granarius* in grain stores at low temperatures

Lise Stengaard Hansen

Aarhus University, Department of IPM, Danish Pest Infest. Laboratory, Kgs. Lyngby, Denmark

Introduction: This presentation will give an overview of the current state of biocontrol in stored products. An EU-funded COST Action Working Group, active during 2000-2006. evaluated the possibilities in different sectors: grain stores, mills and bakeries, pasta factories, stored nuts and dried fruit, etc. Three situations were identified with the greatest potential for widespread application: (1) empty room treatment against mites, beetles and moths, (2) treatment of bulk commodities against *Sitophilus* spp. and mites, and (3) application of egg-parasitoids against moths in packaged products. As an example, results of research concerning the larval ectoparasitoid *Lariophagus distinguendus* (Hym.: Pteromalidae) for biological control of the granary weevil *Sitophilus granarius* (Col.: Curculionidae) will be presented. This weevil is an important pest in grain stores in cool temperate climates, e.g. Northern Europe. Here, aeration of stores is carried out in order to bring grain temperatures down to about 5°C in the first months after harvest. Investigations were conducted on the effect of low temperatures on *L. distinguendus*: a) life table parameters and parasitoid induced mortality (PIM) and b) survival during exposure to a simulated winter.

Results: *L. distinguendus* can develop and reproduce at temperatures as low as 16°C. In addition, the parasitoid population did not seem to be affected by the low temperatures, as opposed to its host. Some mortality was observed in *S. granarius* after exposure to 6°C for >4 weeks. This indicates that *L. distinguendus* will be able to survive winter conditions and resume its activity when grain temperature increases in spring.

Effects of spruce budworm (*Choristoneura fumiferana*) outbreaks on fire hazard in central Canada's boreal forest landscapes

Richard Fleming[1], Jean-Noel Candau[2]

[1]Canadian Forest Service, Natural Resources Canada, Sault Ste. Marie, Canada, [2]Unite de Recherches Forestieres Mediterraneennes Institut National de la Recherche Agronomique (INRA), Domaine St Paul, Canada

Introduction: During its periodic outbreaks, the spruce budworm (SBW) defoliates extensive forest areas and has occasionally been blamed for subsequent wildfire.

Methods: To better understand the SBW-wildfire interaction at landscape scales, we studied the spatiotemporal relationships between these two major disturbance types as reflected in historical survey records.

Results: Within the vast region defoliated at least once by SBW since 1941: fires tended to occur 3-9 years after an outbreak; the strength of this interaction and the start and duration of this 'window of opportunity' for wildfire varied geographically; fires occurring within the 'window of opportunity' accounted for over half of the 2,710, 000 ha burnt.

Conclusions: SBW outbreaks have a discernible effect on wildfire at landscape scales. These results can be partly explained by the interaction of two opposing processes operating on different time scales. Fuel production and restructuring during SBW outbreaks increases fire hazard and opens the 'window of opportunity' for wildfire. Fuel decomposition later closes this 'window'.

Clinical evaluation of plant-based insect repellents against malaria in the Bolivian Amazon and coils in China

Nigel Hill

London School of Hygiene & Tropical Medicine, London, United Kingdom

Background: Insecticide treated nets (ITN's) are highly effective in Africa where the main malaria vectors bite indoors late at night. However, outside Africa mosquitoes often feed before local inhabitants retire to bed or prefer to feed outdoors where ITN's are less likely to be as effective. We have been investigating methods of personal protection which may prove beneficial as an alternative or in combination with ITN's. Anti-mosquito products such as repellents and mosquito coils are widely used yet there is very little robust evidence of clinical reduction of insect-borne disease from their use.

Repellents: A randomised, placebo-controlled clinical study of over 4,000 individuals conducted in the Bolivian Amazon found a significant 80% reduction in clinical malaria cases in the group using plant-based insect repellent plus ITN's compared to a placebo plus ITN. The study proves that in areas where the local vector bites in the early evening the effectiveness of ITN's can be dramatically enhanced by using repellents.

Mosquito coils: A new clinical study has just been completed in the border area of China / Myanmar where over 7,000 individuals were randomised into 4 arms; mosquito coils, LLIN, coils+LLIN or a no-treatment control. Each individual was screened for *P. falciparum* / *P. vivax* each month by rapid diagnostic test over an entire high risk season. Findings from the study will be presented.

Future Studies: A range of traditional mosquito control measures used by inhabitants of remote / isolated regions will be summarised and candidates for further investigation will be suggested.

Communities of ants and carabid beatles after clear cut of spruce forest: the effect of site age and landscape position.

Adam Vele[1], Jaroslav Holusa[1], Jan Frouz[2]

[1]Forestry and game management research institute, Prague, Czech Republic, [2]Institute of soil Biology, Ceske Budejovice, Czech Republic

Introduction: What affects insect community site conditions or clearcutting history in surrounding areas?

Methods: The communities of ants and carabid beetles were studied in spruce forest clear-cuts using pitfall traps on five chronoseuences 500-2000m apart, each containing five neighboring plots different age.

Results: In total 13 and 64 species of ant and carabids were found. Shading was principal factor that directly or indirectly affect ant and carabid community along succession. However for both, the difference between chronosequences was more important than differences between succession stages. The influence of succession stages near the pitfall trap, in 50m and 300m diameter from the trap was compared using CCA and variation partitioning. Proportion of individual succession stages in 300m around the sampling point was more important for community composition condition in sampling site itself.

Conclusion: Shading was the most important succession driver. Beside conditions in the site itself the community was strongly affected by availability of a optimal habitat in surrounding landscape, more suitable habitat is in surrounding more likely higher density will be in both optimal and suboptimal habitat.

Metabolic resistance to insecticides in the dengue vector *Aedes aegypti*

Shavanthi Rajatileka[1], William C. Black IV[2], Chamnarn Apiwathnasorn[3], Yuwadee Trongtokit[3], Pradhya Somboon[4], Mark J.I. Paine[1], Philip McCall[1], Hilary Ranson[1]

[1]Liverpool School of Tropical Medicine, Liverpool, United Kingdom, [2]Colorado State University, Fort Collins, Colorado, United States, [3]University of Mahidol, Bangkok, Thailand, [4]Chiang Mai University, Chiang Mai, Thailand

Dengue fever and dengue haemorrhagic fever are major causes of mortality and morbidity and present a substantial public health and socioeconomic problem throughout the Tropics. Currently, control of the vector mosquito *Aedes aegypti* is the only method of controlling disease transmission. However resistance to the limited number of insecticides available for vector control in *Ae. aegypti* populations is impeding control programmes. Determining the molecular basis of insecticide resistance will facilitate vector control programmes by enabling the development of 'early warning systems' for emerging resistance. Metabolic resistance, whereby the rate of insecticide detoxification is enhanced, is a very common but poorly understood resistance mechanism. The over-expression of GSTe2 an Epsilon class GST has already been shown to cause resistance to DDT in the malaria vector *Anopheles gambiae* and in *Ae aegypti* from Thailand. In this study we have determined the level of insecticide resistance in six field populations of *Ae. aegypti* from Thailand. High levels of DDT resistance and low to moderate levels of pyrethroid resistance are present throughout Thailand. Using Quantitative PCR analysis we have investigated the expression levels of selected candidate detoxification genes in adult females and identified genes whose expression correlates with the resistance profile. In addition to the preliminary analysis of the qPCR data, western blot analysis and immunolocalisation experiments implicate several Epsilon class glutathione-S-transferases as being involved in insecticide resistance. We report progress on the development of diagnostic assays to detect these metabolic resistance mechanisms in field populations of *Ae. aegypti*.

Viability of *Beauveria bassiana* formulations for the control of stored product pests

Bryony Taylor, Belinda Luke

CABI-Europe UK, Egham, United Kingdom

Introduction: This study investigated the viability of several formulations of two isolates of *Beauveria bassiana* currently being trialled as biopesticides in the stored product pest environment.

Methods: 0.1g of *B. bassiana* conidia from isolates IMI 386243 and IMI 389521 were formulated in: mineral oils, powder (conidia +/- electrostatic powders, +/- lumogen tracers, +/- bulking agents), emulsifier, 0.05% Tween 80 or as conidia only. Formulations were sonicated for 3min to break up aggregations of conidia, stored at 5℃ and 25℃ and assessed regularly for viability.

Results: After 365 days all IMI 389521 formulations stored at 5℃ displayed excellent germination (>90%), apart from Tween 80 where viability dropped below 50% after 150 days storage. Formulations stored at 25℃ showed good viability (except Tween 80 formulation with <5% germination after 28 days) with germination generally above 80% up to 243 days and dropping below after 300 days. All IMI 386243 formulations showed good germination (>80%) after 183 days at 5℃, except the emulsifier and Tween 80 formulations in which viability dropped below 10% within 15 days. Good germination was observed at 25℃ for the 28 days, before a drop in viability after 77 days, and after 183 days viability dropped below 60% in general. Emulsifier and Tween formulations displayed a rapid loss in viability.

Conclusions: IMI 389521 retained viability better than IMI 386243 under storage when formulated. Tween is a poor formulating agent for both isolates and the emulsifier is not suitable for isolate IMI 386243.

Genomic signature of reproductive success among competing fire ant queens

Yannick Wurm[1], John Wang[1], Kenneth G Ross[2], Laurent Keller[1]

[1]Université de Lausanne, Lausanne, Switzerland, [2]University of Georgia, Athens, United States

Division of labor between reproductive and non-reproductive individuals is a key characteristic of social insects societies. During an ant colony's life cycle, both the number and reproductive status of queens can vary greatly. Little is known about the factors controlling which queens are reproductive, nor about their genetic basis. Examining gene expression, this study aims to identify what determines reproductive success among candidate replacement queens in an orphaned fire ant colony.

A mature monogyne fire ant colony comprises a single mother queen, territory, thousands of workers and up to several hundred virgin queens. Upon the mother queen's death, many virgin queens shed their wings and begin reproductive development. They thus forgo a mating flight in hope of becoming the replacement queen. Over the following weeks, workers execute almost all reproductive queens. The surviving queen is thus "elected" to replace her mother.

The workers base their collective decision on cues provided by the virgin queens as reproductive development begins. In our artificial orphaning setup, we examined whether virgin queens that shed their wings faster are more likely to become replacement queens than queens that shed their wings slower. This was not the case. Instead, our data indicate the importance of another, genetic component. Using microarrays, we identified major molecular-physiological changes in orphaned queens: more than 2,000 genes are differentially expressed after orphaning, including several involved in Juvenile Hormone degradation. Interestingly, one of these degradation genes was among 100 genes differently expressed between likely replacement queens and queens likely to be executed.

Thermal imaging establishes behavioural fever in the desert locust, *Schistocerca gregaria* during mycosis

Victoria Hunt, Gary Lock, Keith Charnley

University of Bath, Bath, United Kingdom

Introduction: The desert locust *Schistocerca gregaria* is a major agricultural pest which periodically is responsible for considerable economic damage. A bio-pesticide based on the fungus *Metarhizium anisoplia* var. *acridum* has been developed as an alternative to chemical pesticides. However, field trials have reported varied success. This is thought to be in part due to the locusts' ability to thermoregulate. During infection with a pathogen, locusts seek out higher environmental temperatures. This 'behavioural fever' has been associated with both an improved immune response and a direct detrimental effect on the pathogen. For the first time we have shown in detail how fever develops during the early stages of mycosis.

Method: An Indigo Systems Omega Infrared camera was used to measure locust body temperature. The development of behavioural fever was recorded in the desert locust, *Schistocerca gregaria* during mycosis. Characteristic green spores were observed to grow from surface sterilized cadavers confirming *M.a.*var *acridum* as the causative infective agent.

Results: The onset of fever in infected locusts occurred before the fungus was present in the haemolymph. Fever was sustained throughout day light hours reaching temperatures *ca.* 8 ° C above that of controls. Consistent with previous work, fever delayed the development of disease.

Conclusion: Behavioural fever is an adaptive response. Locusts are able to detect a fungal infection before it has reached the haemolymph and respond by selecting higher environmental temperatures in anticipation. Infrared imaging provides a non-invasive, more accurate alternative to previously used thermocouple-based measurements of temperature.

The underpinning science and practice of intercropping, mixed cropping and undersowing for control of insect pests of crop plants

John Pickett

Rothamsted Research, Harpenden, United Kingdom

It is essential that there is a sound scientific base for any habitat management strategy to be sustainable. Furthermore, this type of management strategy, as with all others, must represent a robust and effective intervention. Undoubtedly, the most potent and manageable intervention, which at the same time allows acceptable yield and economy of labour or inputs, exploits semiochemicals for manipulating pests and their biological or biochemical antagonists. Intercrops provide a means of disrupting pest and pathogen development in the main harvestable stand, but this can also be achieved by mixed cropping. Trap cropping can provide an opportunity to use strategies more expensive to apply for population control and where special considerations need to be maintained, for example for use of beneficial pathogens. Besides the need to identify appropriate semiochemicals and plants for habitat management strategies, there are also opportunities for plant breeding and heterologous gene expression to create new companion crops. Not only are these approaches required to satisfy new demands on world agricultural production, but this situation requires that all companion crops have their own value, for example as animal feed or industrial crops, for fine chemicals through to bioenergy.

Non-host repellents for arthropod vectors of pathogens: evolutionary aspects and practical exploitation

John Pickett[1], Michael Birkett[1], Ahmed Hassanali[2], James Logan[1], A Jennifer Mordue[3], Lester Wadhams[1]

[1]Rothamsted Research, Harpenden, United Kingdom, [2]ICIPE, Nairobi, Kenya, [3]University of Aberdeen, Aberdeen, United Kingdom

Botanicals: By conveying a strong plant cue, these materials interfere with the normal host location of carnivorous and haematophagous biting flies and other arthropods. Where plant essential oils are involved, these are highly volatile and can be readily lost. These agents also often cause dermatitic problems. The nepetalactones under current development by us may avoid some of these problems. However, as with synthetic repellents derived from structure-activity relationship studies, hosts can easily be detected through the botanical cues.

Non-host species: Although the response to compounds from, related but, non-host species is more deeply embedded in the behavioural ecology of arthropod vectors than for botanically derived repellents, it is still possible for hosts to be detected in the presence of non-host species. For example, human beings are easily located by highly anthropophilic mosquitoes, such as *Anopheles gambiae* s.s., even when surrounded by numerous cattle. However, compounds derived from waterbuck, a non-host for tsetse fly, repel tsetse flies and there are compounds derived from the African hunting dog, a non-host for ticks, potentially useful against ticks.

Host derived repellents: Individuals within an animal population, e.g. bovine or human, can be extremely unattractive to even the most anthropophilic arthropods. We have proved this to be due to the presence of additional compounds which can themselves be used as repellents on normally attractive human beings and will be dealt with in detail by James Logan in this Symposium 9.9.

Genes, networks, and the evolution of phenotypic plasticity: first insights from genomic approaches in horned beetles

Emilie Snell-Rood, Amy Cash, Teiya Kijimoto, Justen Andrews, Armin Moczek

Indiana University, Bloomington, IN, United States

Introduction: Complex, integrated phenotypes emerge during ontogeny through interactions between genotype, environmental conditions, and developmental processes. However, little is known about how such interactions evolve to give rise to novel traits, and which genetic and developmental mechanisms distinguish the ontogenies of canalized and plastic traits.

Methods: We studied gene expression underlying a phenotypic novelty - horns - in the beetle *Onthophagus nigriventris*, using spotted cDNA microarrays. Specifically, we compared genes whose expression is associated with canalized, sex-specific differences in horn expression to those associated with environment- (nutrient) dependent expression of horns in alternative male morphs.

Results: Our results suggest large scale cooption of pre-existing genes and pathways in the origin of beetle horns. A subset of these genes are non-intuitive candidates given their known functions in other organisms. In addition, our microarrays suggest that a number of genes found only in *Onthophagus* may play a role in the integration and diversification of horns. Finally, genes vary in the degree to which their expression is relatively specific to alternative phenotypes.

Conclusions: Genomic approaches provide powerful tools to begin characterizing genetic networks underlying the evolution, integration, and diversification of novel traits. These analyses of co-expressed genes lay the foundation for exploring how the gene network architecture underlying phenotypic plasticity may constrain or foster diversification within and between species. For instance, sets of genes expressed in a highly modular and specific manner may be far less constrained than those expressed as an integrated unit.

Climatic effects on pestilence: parsing the processes and predicting the patterns

Matthew Ayres

Dartmouth College, Hanover, NH, United States

Since the early 1990s, it has been hypothesized that the projected trajectory of climate change would have rapid consequential impacts on biotic disturbance in forests. The argument was mainly based on two points: (1) even in the absence of directional changes in climate, forests throughout the world are strongly influenced by episodic events of pestilence, and (2) insects are very responsive to climatic variation because of their short generation time, high reproductive potential, and physiological sensitivity to temperature and food quality. The most likely potential pathways of ecological change include: direct effects of temperature on insects; effects of temperature, soil moisture, or cloud cover on plant defenses, nutritional suitability, and compensatory growth; and effects of temperature on community interactions between herbivores and their predators, competitors, and mutualists. There are now numerous examples of insect populations whose distribution and abundance have changed in ways that are consistent with the expected effects of climate change. Some globally noteworthy examples of recent pestilence may be attributable to climate change during the last two decades. Presumably there have been some other impacts that are positive from the perspective of traditional forest management. Biological responses have been uneven across insect species and forest systems, and have not usually been predictable in their details. There is a need for well validated models for any forest system that can predict changes in biotic disturbance given specific scenarios of climate change. I offer the following suggestions to facilitate progress: (1) develop, test, and refine general qualitative hypotheses that can predict when and where impacts will be large vs. small, and positive vs. negative; (2) develop programs of focused studies in systems with high importance and a high probability of consequential impacts; and (3) conduct multi-faceted tests (including meteorology, physiology, and population ecology at least) of explicit mechanisms by which climatic variation is theoretically transduced into biotic disturbance.

How to select a limited number of non-target species for host specificity testing?

Peter Mason[1], Ulrich Kuhlmann[2]

[1]Agriculture and Agri-Food Canada, Ottawa, Ontario, Canada, [2]CABI Europe-Switzerland, Delemont, Jura, Switzerland

Selection of appropriate species for host specificity testing of candidate biological control agents is the first critical step in the process to determine potential impacts once the need for pest suppression is justified and one or more potential agents have been identified. The centrifugal phylogenetic method has been suggested as the primary method for use in selecting non-target species for testing candidate entomophagous biological control agents. However, this approach may not always be feasible because of taxonomic uncertainties and the greater number of taxa that could be required in testing compared to weeds. Furthermore, other parameters such as the phenology, feeding niche or the common habitat of target and non-target species may be more meaningful, at least for some biological control agents.

We proposed methods for setting up test species lists for arthropod biological control programmes that are scientifically based and ensures that all aspects of potential direct impacts are considered. Moreover, the methods take into consideration possible practical constraints associated with arthropod host specificity screening to ensure that the number of non-target host species selected for testing is manageable.

New insights in venation pattern morphology of Paleozoic insects

Jakub Prokop[1], André Nel[2], Dong Ren[3]

[1]Charles University in Prague, Faculty of Science, Department of Zoology, Praha, Czech Republic, [2]Muséum National d'Histoire Naturelle, Laboratoire d'Entomologie, Paris, France, [3]College of Life Sciences, Capital Normal University, Beijing, China

Introduction: Paleozoic insect fauna greatly differs from Mesozoic and Cenozoic ones. Insects are entirely known as compression fossils or 3-D from siderite nodules. Wing venation is the most common structure preserved on Paleozoic insect fossils. Besides the venation pattern morphological limitations due to various adaptations and pattern stability within the certain groups it remains crucial structure for systematic of Paleozoic insects. Unfortunately many fossil taxa described by some authors are based on fragmentary material of different body structures those are usually misguided. Such enthusiasm caused noise in systematic and generates further difficulties to make any serious comparison with other taxa. The aim is finding of significant venation characters on newly discovered material and revision of selected Paleozoic fossils.

Results: Current research in several institutional and private collections enabled study and of a new Upper Carboniferous material of palaeopterous and neopterous insects from several localities in Euro-America and China. The first results of comparative studies mainly based on wing venation pattern morphology revealed new significant characters for taxonomy and phylogeny of different insect groups (e.g., Ephemeroptera: Syntonopteridae, Palaeodictyopterida: Homoipteridae, Namuroningxiidae, Odonatoptera: Meganeuridae and others). Contemporary studies extend our knowledge on past insect diversity and display variability of venation pattern in evolution. Moreover, those results provide support for palaeogeography, such as evidence for a Euro-American connection during the Late Carboniferous.

Effects of milkweed modularity on foraging by monarch larvae at different scales

Stephen Malcolm, Tammi Roberts, Barbara Cockrell

Western Michigan University, Kalamazoo, Michigan, United States

Introduction: Mobile, holometabolous insect herbivores are confronted with diet qualities that are influenced at small scales by plant and larval interactions and at large scales by adult responses to a variable hostplant landscape. Monarch butterflies in eastern North America migrate between overwintering resources in Mexico and larval milkweed resources distributed across much of the continent, east of the Rocky Mountains. At a continental scale adult monarchs can choose to oviposit among an array of approximately 115 species of milkweed in the genus *Asclepias.* These plants vary considerably according to defense investment and modularity. Once the adult choice has been made in space and time, their larvae then choose where to forage according to plant modularity and the plant's response to larval feeding.

Methods: Here we examine the implications of these foraging scales with larval feeding experiments, in both the laboratory and field, that manipulate defense expression in different *Asclepias* species and examine feeding behavior, growth and sequestration by larvae.

Results and conclusions: Our results show that both adults and larvae make foraging decisions in response to both small and large-scale variation in plant quality and may help to explain the nature of selection for long-distance migration in this mobile insect herbivore.

Does the southern monarch butterfly, *Danaus erippus,* migrate?

Stephen Malcolm, Allister Malcolm, Barbara Cockrell

Western Michigan University, Kalamazoo, Michigan, United States

Introduction: Anecdotal evidence from Argentina suggests that the southern monarch butterfly, *Danaus erippus,* migrates in southern South America much like its northern congener, *D. plexippus.* Other than these seasonal observations nothing is known about the distribution and abundance of *D. erippus* in South America, south of the equator. In contrast to the northern monarch, which has an array of approximately 115 species of *Asclepias* to exploit as a larval host plant, *D. erippus* has only 10 *Asclepias* species available throughout South America. Here we examine the seasonal movements of *D. erippus* in Bolivia using hostplant sequestered cardenolides as fingerprints of host origin.

Methods: We collected *D. erippus* adults at 3 different times of the year in various locations in Bolivia and analysed their steroidal cardenolides by HPLC. We also measured fat content, wing size, wing wear and reproductive status of adults. The bursa copulatrix was dissected from all females and analysed separately for possible male contributions to cardenolide profiles. In the field we also searched for milkweeds at a range of altitudes and searched for immatures of *D. erippus.*

Results and conclusions: Adult *D. erippus* in Bolivia are some of the best defended butterflies known, with extremely high cardenolide concentrations. The plants most commonly exploited as larval host plants in Bolivia were *Asclepias curassavica* at lower altitudes*, A. boliviensis* at mid altitudes and *A. barjoniifolia* at altitudes up to 4,000m. We conclude that *D. erippus* is both a seasonal latitudinal migrant as well as a seasonal altitudinal migrant, but that there is no evidence for the dense overwintering aggregations that characterize *D, plexippus.*

Dynamics and impact of chemical defence expression in a plant-aphid-coccinellid interaction

Stephen Malcolm[1], John Couture[2], Brett Blaauw[1]

[1]Western Michigan University, Kalamazoo, Michigan, United States, [2]University of Wisconsin, Madison, Wisconsin, United States

Introduction: Specialist insect herbivores that sequester plant chemical defenses pose a problem for plants; should they induce defenses to try and remove herbivores, or should they reduce defenses to make the herbivores more vulnerable to natural enemies in the third trophic level. We examine these bottom-up and top-down hypotheses in a milkweed, aphid, coccinellid system with laboratory experiments that manipulate the dynamics of source-sink interactions among three trophic levels.

Methods: We manipulated the density of the aposematic aphid, *Aphis nerii* on the neotropical milkweed, *Asclepias curassavica,* to determine the cardenolide response of the plants to aphid phloem-feeding and the consequent sequestration of these steroidal defences by the aphids at these densities. We then took aphids at different densities and fed them to newly emerged, 4th instar larvae of the coccinellid *Coccinella sepempunctata* and measured their functional response to aphid density.

Results and conclusions: Milkweeds show a U-shaped reduction-induction cardenolide response to aphid density, with reduction of cardenolides at low aphid density in comparison to aphid-free controls and induction above constitutive levels at high aphid densities. This plant response resulted poorly defended aphids at low density and well-defended aphids at high density. The plant response generated a domed, or type 4 functional response in coccinellid larvae to *A. nerii* density. This response destabilizes tritrophic interactions characterized by sequestered chemical defences when examined with Rosenzweig-MacArthur models of tritrophic dynamics.

Modular Ecological Design: A fruit and vegetable polyculture system

Joseph Kovach

Ohio State University, Wooster, OH, United States

Introduction: The layout of crops (alternating high and low crops) could improve pest management while limiting pesticide use and increasing yields. The goal of this project is to determine the optimal layout (in terms of economics, pest density and efficiency) of an intensive polyculture system that can be used by the small urban farmer.

Methods: This experiment began in 2005 with 4 treatments (18.2 m x 13.3 m) replicated 4 times on 0.54 hectares. The treatments are a solid row planting, a checkerboard, a mixed row and a mixed row on raised bed. Each treatment is a mixture of 8 crops (4 woody fruit commodities and 4 herbaceous commodities) arranged in different patterns and heights. To increase temporal diversity each crop has an early, mid and late harvest. For the perennial crops (apple, peach, blueberry, raspberry, strawberries), different cultivars were selected for different harvest times, for the annual crops (tomatoes, soybeans, snap peas) three planning dates were used. Insect and disease pests were monitored regularly throughout the growing season and harvest evaluations were conducted on each commodity. In 2007, Haygrove high tunnels were placed over 1 replicate of each treatment.

Results: Aphids, mites and powdery mildew densities were much higher on crops grown in the high tunnels. The raised bed treatment had the most insect biodiverstiy. Of the crops grown, peaches and strawberries had the most insect biodiverstiy and tomatoes the least.

Conclusions: This agroecosystem is stabilizing and is on track to meet the project goals.

Age specific fecundity and temperature dependent population growth rate of *Eurygaster integriceps* Put. (Heteroptera: Scutelleridae) at four constant temperatures

Shahzad Iranipour[1], Aziz Kharrazi Pakdel[2], Gholamreza Radjabi[3]

[1]University of Tabriz, Tabriz [2]University of Tehran, Karaj, [3]Plant Pests and Diseases Institute, Tehran, Islamic Republic of Iran

Introduction: Sunn-pest, *Eurygaster integriceps* Put. is the most important insect pest of wheat and barley in Iran. A demographic study was carried out in order to determine effect of temperature on fitness of the pest.

Methods: Fertility life tables of the pest were constructed in four constant temperatures 22, 25, 27, and 30 ± 1℃ on MAHDAVI wheat kernels. Both finite and intrinsic rates of population increase, gross and net reproductive rates, intrinsic rates of birth and death, cohort generation time, doubling time, total fecundity per female and adult life time components were compared among temperatures.

Results: Significant differences were observed in all statistics. Intrinsic rate of natural increase, r_m increased linearly by temperature ($r^2 = 0.89$, $P < 0.01$). It was estimated as 0.0126, 0.0381, 0.0541, and 0.0789 females/ female/day in above mentioned temperatures respectively. An opposite trend was observed in generation time ($r^2 = 0.93$, $P < 0.01$), as the longest and the shortest generation times were measured 121 and 40 days at 22 and 30 ℃ respectively. Net replacement rate was significantly lower at 22 ℃ than other temperatures. It was about one fifth of them (4.57 vs. 22.17 to 25.83 females/ female/ generation). Total fecundity per female was ranged from 123.07 at 22 ℃ to 209.36 at 30 ℃. Adult life time as well as its components was affected by temperature. Oviposition period was the longest course among life time periods. Thermal threshold and effective temperature required for pre-oviposition development were estimated as 20 ℃ and 68 degree-days respectively.

Discussion: The best fitness and the most reproductive output of sunn-pest *Eurygaster integriceps* was occurred at 30℃ among studied temperatures.

An international cooperative effort to protect *Opuntia* cactus resources in the American Southwest and Mexico from the South American cactus moth, *Cactoblastis cactorum*

Joel Floyd[1], Kenneth Bloem[2], Stephanie Bloem[2], James Carpenter[3], Stephen Hight[4], Arturo Bello[5], Walther Enkerlin[6]

[1]USDA, APHIS, PPQ, Riverdale, Maryland, United States, [2]USDA, APHIS, PPQ, Raleigh, North Carolina, United States, [3]USDA, Agriculture Research Service, Tifton, Georgia, United States, [4]USDA, Agriculture Research Service, Tallahassee, Florida, United States, [5]Dirección General de Sanidad Vegetal, Mexico City, D.F., Mexico, [6]North American Plant Protection Organization, Ottawa, Ontario, Canada

The South American Cactus moth, *Cactoblastis cactorum*, was intentionally introduced to an island in the Caribbean in the 1950's and eventually made its way to the Florida peninsula by 1989. In 2004, the United States Department of Agriculture's (USDA) Animal and Plant Health Inspection Service (APHIS) and Agriculture Research Service (ARS) began a joint effort to establish a barrier to its spread along the US Gulf Coast before reaching areas of significant *Opuntia* diversity. Since 2006, the Mexican government's Secretería de Agricultura, Ganadería, Desarrollo-Rural, Pesca y Alimentación (SAGARPA), through the North American Plant Protection Organization (NAPPO), has been cooperating to help fund the monitoring and prevention of the spread of this pest in on the continent. There has been technology transfer with survey methods and sterile insect release in Mexico. Other cooperation has occurred with state departments of agriculture, agencies, and environmental groups that manage lands in trapping and setting up sentinel sites for visual monitoring of plant populations for early stages of infestation. The program has been successful in slowing the spread and raising awareness with other cooperators such as national parks, wildlife refuges, ranchers, nursery operators, and home owners.

Can extra-floral nectaries facilitate predation by cursorial spiders in row crop agroecosystems?

Robert Pfannenstiel, Joseph Patt, Felix Wäckers

[1]USDA-ARS Subtropical Agricultural Research Center, Weslaco, TX, United States, [2]Centre for Sustainable Agriculture, Lancaster Environment Centre, Lancaster University, Lancaster, United Kingdom

Introduction: Extrafloral nectaries are a significant resource for many natural enemies. However, the importance of extrafloral nectar to cursorial spiders (Anyphaenidae, Miturgidae, and Clubionidae), which are common foliage inhabitants, is not understood. Our laboratory and field studies are examining the relationship between nectar availability and these spiders' potential to act as biological control agents in row crops.

Methods: Sentinel eggs of pest moths (*Helicoverpa zea* and *Spodoptera exigua*) were used to measure levels of spider predation in cotton, corn, and soybean fields. Estimates of the level extrafloral nectar consumption by spiders were made in cotton fields. Laboratory studies evaluated the impact of nectar consumption on growth and survivorship; acceptance and assimilation of sugars from nectar and honeydew; and, the influence of contact and olfactory cues on searching behavior for nectar and prey.

Results: Cursorial spiders were the dominant predator of lepidopteran eggs in cotton but were less important in crops that lacked extrafloral nectaries. Spiders in cotton were commonly detected as positive for fructose, indicating that they had fed on nectar within the previous three days. Laboratory diet studies demonstrated that nectar consumption could significantly improve their survival, growth, and development. Behavioral studies showed that they were stimulated by nectar aromas and could learn to recognize and remember novel aroma cues. In combination, these data suggests that cursorial spiders are adapted for finding and utilizing extrafloral nectar and that nectar availability significantly increases their role as biological control agents in cotton vs. other crops.

Predator biodiversity strengthens herbivore suppression

William Snyder, Gretchen Snyder, Deborah Finke, Cory Straub

Washington State University, Pullman, WA, United States

Concern over biodiversity loss, especially at higher trophic levels, has led to a surge in studies investigating how changes in natural enemy diversity affect community and ecosystem functioning. These studies have found that increasing enemy diversity can strengthen, weaken, and not affect prey suppression, suggesting that multi-enemy effects on prey are context-dependent. In a series of field experiments we have examined the relationship between natural enemy species diversity and the suppression of aphids on pea, potato, and collard plants. We have found that, across a range of predator, aphid, and plant species, aphid biological control consistently strengthens with higher predator biodiversity. However, we have found that plant traits, such as surface chemistry, can dramatically alter the strength of predator biodiversity effects. Field and laboratory experiments indicate that members of our aphid predator community differ in where they forage on plants, perhaps contributing to complementary resource partitioning among species. Thus, plant traits that accentuate or diminish interspecific differences in foraging behavior may likewise strengthen or weaken predator-predator complementarity, and thus the relationship between predator biodiversity and herbivore suppression.

Evolutionary riddles and phylogenetic twiddles: the sternum V gland in Trichoptera

Marie Djernaes, Felix Sperling

University of Alberta, Edmonton, Alberta, Canada

Introduction: The sternum V gland is found throughout Trichoptera and the most basal Lepidoptera and generally produces sex pheromones. The present study focused on morphology and microstructure of this gland in an evolutionary context.

Results and Discussion: All Trichoptera and Lepidoptera studied had a gland opening muscle that inserts on the gland duct just inside the gland orifice. In most Trichoptera the gland opening muscle originates mesad on the cuticle of sternum V while in Lepidoptera this muscle originates on the anterior edge of sternum VI. Four trichopteran families (Glossosomatidae, Hydroptilidae, Rhyacophilidae and Philopotamidae) have a gland opening muscle of the lepidopteran type. Glossosomatidae, Hydroptilidae and Rhyacophilidae belong in the problematic suborder Spicipalpia which may be basal within Trichoptera. However, the fourth spicipalpian family, Hydrobiosidae, has a typical Trichopteran gland opening muscle. Philopotamidae is considered basal within the suborder Annulipalpia. However, philopotamid females have fenestra on sternum IV, otherwise found on females in the lepidopteran families Eriocraniidae, Neopseustidae and Nepticulidae.

Gland opening muscles originating on the anterior edge of sternum VI are found both in Lepidoptera and some Trichoptera. Thus it might be assumed that this type is ancestral and that the trichopteran type is a later development. However, this raises the question of one or several origins of the trichopteran type. A single origin would place Glossosomatidae, Hydroptilidae, Rhyacophilidae and Philopotamidae as basal within the Trichoptera, a placement that disagrees with recent phylogenetic studies. Multiple origins posit that morphologically indistinguishable muscles can arise independently as apparent neoformations.

Reduction of respiration by aggregate formation in *Parastrachia japonensis*

Sumio Tojo[1], Lisa Filippi[2]

[1]Department of Applied Biological Sciences, Saga University, Saga-Shi, Saga Prefecture, Japan, [2]New College of Hofstra University, Hempstead, N.Y, United States

Nymphs of the univoltine shield bug, *Parastrachia japonensis* grow by feeding on the drupes of their sole food plant, which are provisioned by their female adult and available for only two weeks a year in late June. New adults which emerge in late July soon enter diapause until reproductive stage in next May, live mostly in aggregated conditions and can survive more than one year on only water. Diapausing adults have a high tendency to form clusters with no sexual bias. When three to 40 insects were enclosed in chambers of equal volume used to measure respiration, oxygen consumption was reduced to nearly half that when a single individual was enclosed. However, this reduction in metabolic rate was lost when the bugs were prevented from having physical contact with other individuals, partly lost by being enclosed with dead individuals, totally lost with the ones being washed with dietylether, and not influenced by humidity. No such effect of aggregation on respiration was found in adults in the reproductive stage, nor in two other diapausing bugs, *Erthesina fullo* and *Plautia crossata*, which hibernate in groups. These results indicate that the reduction in oxygen consumption in *P. japonensis* is due mostly to physical contact with other individuals and partly to chemical cue that functioned to settle them down and resulted in a greatly reduced respiration rate. This trait is an effective strategy that allows diapausing adults to conserve energy and prolong survival until reproductive stage.

Insecticidal formulation with African nutmeg *Monodora myristica* (Gaertn) dunal seed extracts for the control of cowpea seed beetle, *Callosobruchus maculatus* (Fabricius) (Coleoptera: Bruchidae}

Chris.O. Adedire, Olabinmpe.O Okosun

Federal University of Technology, P.M.B. 704, Akure, Nigeria, Akure,Ondo state, Nigeria

Introduction: Plant-derived biopesticide such as plant powder and oils exert various physiological and behavioral activities on stored product insect .These are relatively cheaper and ecologically more tolerable than convectional chemical pesticides.

Method: Insecticidal bioassays involving *Monodora myristica* (Gaertn) Dunal seed extracts using: methanol, ethanol, acetone, Pet-ether, n-hexane and water as solvents were accomplished at ambient tropical conditions of temperature and relative humidity. The extracts at 0.5**%** (v/w) were evaluated for insecticidal activity on *Callosobruchus maculatus* using mortality, oviposition and progeny development as *indices.*

Results: Steam distillate and non-polar extracts of hexane and pet ether significantly ($p<0.05$) reduced oviposition and evoked high mortality of *C. maculatus* compared with other solvent extracts. When the bruchids had the choice of oviposition media, the mean number of eggs laid on cowpea seeds treated with steam distillate was significantly lower than those laid in other treatments. The adult that emerged from the seeds with different African nutmeg treatments was significantly lower (0-22%) than that of the untreated seeds (55%).

Conclusion: Steam distillate of *M.myristica* could serve as a potent protectant of cowpea seeds against *C. maculatus* infestation and damage.

Ecological risk assessments for the invasion of *Bombus terrestris* in Japan

Yoko Kawate Kunitake, Koichi Goka

Josai International Univeristy, Chiba, Japan

The large earth bumblebee, *Bombus terrestris*, has been recognized as an invasive alien species and greatly expanding its distribution over the native range. In Japan, since the first introduction in 1991, a lot of individuals of this species including queens and males have escaped from the commercial colonies into the field. As a result, *B. terrestris* have naturalized in Japan, especially on the northern island, Hokkaido.

In this talk, I will review the progress of studies for ecological risk assessment of *B. terrestris* in Japan, based on the following ecological aspects; 1) competition with native bumblebee species 2) hybridization with native species 3) transmission of alien parasites into the field 4) disturbance against the reproduction of native flora through changing interaction among pollinators.

I will also introduce the invasion status and the process of *B. terrestris* in Japan. This study demonstrates how selected key factors affect the distribution of naturalized population. We have found that the landscape components (forest coverage rate), not the local propagule pressure (the number of commercial colonies), is the critical factor. However, the effect of landscape components on the distribution of *B. terrestris* varied among regions. This is possibly because of large difference in the propagule pressure among regions. Understanding such state dependent process in the invasion ecology is considered to be important for the future study and for the practical control of invasive bumblebees.

Consequences of temperature fluctuations on tritrophic systems plants-aphids-parasitoids: adaptation to climate change and biocontrol

Thierry Hance, Alexis Descampe, Herve Colinet

Université Catholique de Louvain, Louvain-la-Neuve, Belgium

Introduction: Global warming predictions mask regional situations where likely outcomes will be more frequent heat or cold waves, droughts and extreme precipitation events. For tritrophic systems, the increase in temperature fluctuation and the occurrence of more frequent extreme will be a greater challenge than the gradual increase in average temperature. Temperature changes may influence differently the biology of each component species of a system, provoking a destabilisation in their population dynamics that may lead to the extinction of part of the system. The impact of climatic changes is likely to be more important in higher trophic levels that depend on the capacity of the lower trophic levels to adapt to these changes.

Methods: We analyzed the effects of low and fluctuating temperature on the life-history traits of parasitoids and interactions with their aphid hosts and possible consequence on biological control.

Results: Four trends can be identify: 1) Differential modification of the development time or diapause pattern (timing or rate) of one of the partners of the trophic systems may change the temporal synchronisation between host and parasitoid and may result in aphid outbreaks. 2) The temperature-induced size variation produces also changes in parasitoid fecundity and survival. 3) Parasitoid searching behaviour is affected after exposition to low temperature. 4) In the opposite, if during cold exposure temperature raises during several hours, survival, fecundity and some behavioural traits are clearly improved. Such fluctuating temperatures correspond to changes in some proteins expression as shown by the proteomic profiles obtained under different conditions. In consequence, fluctuating temperature may perhaps compensate at least partially more frequent exposure to extreme temperature.

Conclusions: It appears that impact of climate changes on trophic systems should be studied under systemic and multidisciplinary approaches.

Exocrine glands in the legs of ants

Johan Billen

University of Leuven, Leuven, Belgium

Ants no doubt can be considered walking glandular batteries, as their tiny bodies contain a plethora of exocrine glands, the secretions of which play crucial functions in the social organization and the communication system of their colonies. Although the head, thorax and abdomen appear the most obvious sites where such glands can be found, also the appendages like antennae and legs contain a number of glands. This talk reviews the various glands that are known from the ants' legs.

The first leg gland to be reported in literature (by Reinhard Leuthold in 1968) was the tibial gland in the hindlegs of *Crematogaster* ants, with a function in the elaboration of trail pheromones. This pioneer report was later supplemented with several additional descriptions, with especially Bert Hölldobler and our own work extending the knowledge of the variety of exocrine glands in the legs of ants. At present, this variety comprises 20 different glands that can be found among the various ant species that have been studied, with glands occurring in all leg segments (coxa, trochanter, femur, tibia, and tarsal segments). Some glands are found in all species (such as the pretarsal arolium gland), although most are more restricted, and occur in a single genus or species. Several of these glands, especially these in the hindlegs, produce trail pheromones. Other functions reported for leg glands include functions like antenna cleaning, lubricant production, and elaboration of sex pheromones.

Potential for host plant-mediated genetic differentiation in a tritrophic system

Betty Benrey

University of Neuchatel, Neuchatel, Switzerland

Many insect species are distributed over populations that live in different habitats where they experience different environmental conditions. If gene flow among these populations is limited and natural selection operates differently in different habitats, this can lead to genetic divergence and local adaptation.

We study a tritrophic system comprised of several species of beans (wild and cultivated), bruchid beetles that feed on these beans, and the parasitoids that attack the bruchids. Insects that emerged from beans collected throughout Mexico were used for microsatellites and mitochondrial DNA analyses. For bruchids, most of the between-population genetic differentiation was explained by geographic distance and not by variation in their host plant. Interestingly, isolation by distance was only evident for populations that originated from wild beans and not from cultivated beans. This can be explained by long-distance migrations of beetles on domesticated plants resulting from human exchanges of bean seeds.

Three parasitoid species of the genus *Horismenus* showed some degree of isolation by distance. For one of the species it was found that individuals collected from one bean species were genetically distinguishable from individuals from another bean species, even within populations. Behavioural assays confirmed that these genetic groups were closely associated to the plant of origin: female wasps were more attracted to the odour of the bean species from which they were collected than to the odour of an alternative bean species. These results imply that plants can contribute to the genetic structuring of the parasitoid populations, possibly leading to host race formation.

Current pest status, life-cycle and ecology of *Hieroglyphus perpolita* (Uvarov, 1932) (Acrididae: Orthoperta) of Pakistan

Riffat Sultana, M.Saeed Wagan

Department of Zoology, University of Sindh, Jamshoro, Pakistan, Hyderabad, Palestinian Territory, Occupied

Introduction: The species of genus *Hieroglyphus* are very important from economic point of view they are major pest of paddy, sugarcane, wheat, and maize in Pakistan Among the all species of *Hieroglyphus H.perpolita* (Uvarov) goes to totally oppose extreme regarding their habits and habitat .Its habits and habitat are mostly associated with the presence of *Saccharum bengalense* locally called Sarkanda.

Material and Methods: The stock culture consisted of nymphs & adults were collected mostly from the *S. bengalense* having thick and coarse (thorny) leaves, near the cultivated field of *Z*ea *mays* and *Arachis hypogaea* with the help of traditional insect hand-net as well as by hand picking. In the field the collected material was transferred into polythene bags for transfer to the laboratory where collected material was killed and preserved by standard entomological method.

Results: Incidence of *H.perpolita* reported significantly highest during the months of July and August than the other months. They go through six nymphal stages becoming adult. They live an aggregation except few adults found on cultivated field. They seem to prefer thorny bushes rather than other plants, which do not provide protection from enemies. The eggs were also laid in the root of same plants, which remain undisturbed when nearby land is ploughed for cultivation. *S. bengalense* was report as new host plant of *H.perpolita* from Pakistan for the first time.

Conclusions: The results of such type of study will be instrumental in understanding and devising population management strategies, which could help to avoid or prevent any possible future outbreak.

Specific adaptations to plant chemical defences in a generalist herbivore: Detoxification of isothiocyanates by glutathione-S-transferases in midguts of *Spodoptera littoralis*

Katharina Schramm[1], Jonathan Gershenzon[1], Ute Wittstock[2]

[1]MPI for Chemical Ecology, Jena, Germany, [2]IPB, TU Braunschweig, Braunschweig, Germany

Introduction: Generalist insect herbivores feed on numerous plant species, yet how do they cope with the many different chemical defences they encounter? Possible strategies include avoidance, insensitivity to toxins or detoxification and excretion. Brassicaceae (e.g. cabbages, rapeseed or Arabidopsis) use glucosinolates for their defence, which are the precursors of toxic isothiocyanates and other compounds that are released upon tissue damage, for example, after herbivore attack. Some specialist Brassicaceae feeders have developed biochemical mechanisms to avoid the toxicity of isothiocyanates. We employed *Spodoptera littoralis* (Lepidoptera), whose larvae feed, amongst others, on Brassicaceae, to study the metabolism of the glucosinolates in a generalist herbivore.

Methods and Results: Analysis of the faeces of larvae which had fed on different Brassicaceae, including Arabidopsis transgenics, revealed that glutathione conjugates of isothiocyanates occur whenever isothiocyanates are formed in the food plant. *S. littoralis* was able to form glutathione conjugates from a large variety of isothiocyanate structures. The conjugation was shown to be catalysed by glutathione-S-transferases in the larval gut, inducible by feeding on isothiocyanate-containing diets. The identification of the specific enzymes responsible for isothiocyanate detoxification by two-dimensional protein separation is in progress, as is a molecular approach for identifying the corresponding genes. Future investigations will explore the costs of this detoxification ability and determine whether glutathione-*S*-transferase activity can cope with the range of isothiocyanates present in potential hosts.

Conclusion: In *S. littoralis*, one pathway of detoxification of isothiocyanates derived from glucosinolates with variable side chains is the enzymatic conjugation with glutathione.

Resistance management for Bt crops: from theory to reality

Anthony Shelton

Department of Entomology, Cornell University/NYSAES, Geneva, New York, United States

In the decade leading up to the first commercial release of transgenic-insecticidal crops expressing proteins from *Bacillus thuringiensis* (*Bt*), several deployment strategies designed to delay resistance were proposed. These strategies were built on a considerable body of theoretical and empirical work on resistance to conventional insecticides. However, *Bt* crops were considered a special case since target insects were exposed to toxins over the entire season. Thus, *Bt* plants were more akin to conventionally bred, insect-resistant plants than most conventional, short-lived insecticides. For various political, social, ecological and economic reasons, in many countries *Bt* crops have been introduced with requirements for managing the evolution of resistance. However, the scope and adoption of such requirements is variable within and between countries. Despite this variation, since their introduction in 1996, *Bt* cotton and *Bt* maize have been grown on more than 162 million ha worldwide with minimal evidence of resistance evolution. This situation is in stark contrast to most conventional insecticides and has been credited to proactive insect resistance management (IRM) strategies, as well as characteristics of the insects themselves and the ecology into which *Bt* crops have been introduced. Present and future challenges remain for IRM and it is important that the agricultural sectors (scientific, grower, regulatory and producers) that work with *Bt* crops remain vigilant to ensure the long-term successful performance of this first wave of transgenic-insecticidal crops.

IPM and insect-protected transgenic plants: Thoughts for the future

Anthony Shelton[1], Jörg Romeis[2], George Kennedy[3]

[1]Department of Entomology, Cornell University/NYSAES, Geneva, New York, United States, [2]Agroscope Reckenholz-Tänikon Research Station ART, Zurich, Switzerland, [3]Department of Entomology, North Carolina State University, Raleigh, North Carolina, United States

Transgenic maize and cotton varieties expressing insecticidal proteins from the bacterium, *Bacillus thuringiensis* (*Bt*), have become important components in integrated pest management (IPM) programs globally. In 2006, *Bt* maize and *Bt* cotton were grown in 13 and 9 countries, respectively. *Bt* plants have provided opportunities and challenges to managing insect pest complexes, but overall their use has resulted in strong economic and environmental benefits. Their adoption rate has been dramatic. Only 11 years after their introduction, they were grown on 32.1 million ha in 2006. In some parts of the world, *Bt*-transgenic varieties dominate the crop area. For example, *Bt* cotton makes up 65% of the total cotton acreage in China, 59% in Australia, 56% in the USA and 42% in India. Adoption of *Bt maize* has reached 75% in the USA. Thus, *Bt* plants have turned what was once a minor foliar insecticide (*Bt*) into a major control strategy. Other *Bt* commodities are expected to be registered in the near future. Additionally, new insecticide molecules are being developed for expression in plants and plant genes are being altered to affect biochemical pathways that elicit insect resistance. Adoption of *Bt* plants should be viewed within the larger context of food systems, cultures, human values, politics and the roles and responsibilities of science in the modern world. Such a context helps explain the variable adoption rates of *Bt* plants on a global basis and helps provide insights for the future deployment of insect-resistant plants.

Trap cropping in pest management strategies

Anthony Shelton, Francisco Badenes-Perez

[1]*Department of Entomology, Cornell/NYSAES, Geneva, New York, United States,* [2]*Department of Entomology, Max Planck Institute for Chemical Ecology, Jena, Germany*

The concept of trap cropping fits into the ecological framework of habitat manipulation of an agroecosystem for the purpose of pest management. Interest in trap cropping, a traditional tool of pest management, has increased considerably in recent years as a result of concerns about potential negative effects of pesticides on human health and the environment, pesticide resistance, and general economic considerations of agricultural production. Recently, we proposed a broader definition of trap cropping that encompasses the inherent characteristics of the trap crop plants themselves as well as the strategies associated with their deployment. Inherent characteristics of a trap crop may include not only natural differential attractiveness for oviposition and feeding, but other attributes that enable the trap crop plants to serve as a sink for insects or the pathogens they vector. Successful deployment of trap crops within a landscape depends on the inherent characteristics of the trap crop and the higher value crop, the spatial and temporal characteristics of each, the behavior and movement patterns of insect pests, and the agronomic and economic requirements of the production system. Thus, trap cropping is more knowledge-intensive than many other forms of pest management. From a commercial standpoint, we consider that currently there are only 10 cases of successful applications of trap cropping in agricultural and forest systems. Ultimately, the combination of insect and trap crop characteristics and practical considerations determines the success of a trap cropping system.

The roles of floral colour and scent in a shift from wind to insect pollination in the sedges (Cyperaceae)

Peter D. Wragg, Steven D. Johnson

University of KwaZulu-Natal, Pietermaritzburg, KwaZulu-Natal, South Africa

The shift from wind to insect pollination was a key transition in the early evolution of flowering plants. Several lineages have subsequently reverted to wind pollination, in association with loss of floral attractants (bright colour, floral scent) and rewards (nectar). Here we present the first experimental evidence for a switch back to insect pollination in one of these wind-pollinated lineages, the family Cyperaceae. We focused on *Cyperus obtusiflorus* var. *obtusiflorus* in the KwaZulu-Natal coastal grasslands. Flowers from which insects, but not wind, were excluded showed a significant 98 % reduction in seed set compared to open pollinated controls, indicating that insect pollination was more important than wind pollination. Bees, beetles and flies visited the white, scented inflorescences of *C. o.* var. *obtusiflorus* more often than the brown, unscented inflorescences of the co-flowering, wind-pollinated *Pycreus oakfortensis* (nested within *Cyperus*). We explored the cues responsible for attractiveness to insect pollinators. Colour was more important than scent in attracting insects to artificial inflorescences: white artificial inflorescences attracted more insects than brown ones, but those mimicking the scent of *C. o.* var. *obtusiflorus* with a blend of ocimene, linalool, benzyl alcohol and phenylethyl alcohol were no more attractive than unscented controls. In a wind tunnel, wind transported pollen of *P. oakfortensis* more effectively than pollen of *C. o.* var. *obtusiflorus*. Thus, there appears to be a tradeoff between effectiveness of insect pollination and effectiveness of wind pollination in these sedges.

An instructional DVD on collecting entomological evidence from crimes scenes

Richard W. Merritt[1], Ryan K. Kimbirauskas[1], Mark E. Benbow[1], John R. Wallace[2], Jeffery K. Tomberlin[3]

[1]Michigan State University, East Lansing, MI 48824, United States, [2]Millersville University, Millersville, PA 17551, United States, [3]Texas A&M University, College Station, TX 77843, United States

This DVD was created by forensic entomologists to fulfill the immediate need to standardize practices for collecting entomological evidence. The material is intended to instruct forensic crime scene investigators, detectives, and associated personnel on how to collect specimen samples and field data in a way that will be scientifically valuable and credible in court. The DVD includes an overview of forensic entomology and the decomposition of an animal model has been time-lapsed to demonstrate the association of insects with various stages of decay. Insects commonly found with human remains are shown and factors that influence insect activity and development are described. Crime scene photographs and video are used to aid in the recognition of what information should be collected during death investigations. A list of equipment needed to process entomological evidence is given, and the collection and preservation of insect specimens has been clearly demonstrated in a step-by-step procedure. The main purpose of this DVD is to standardize the practices which are critical to the development of postmortem intervals and the utilization of insects as evidence during criminal investigations. The entire training video is 22 minutes; however, the multi-media format provides self-paced instruction and allows the viewer to select specific modules for quick referencing.

Shed leaves revitalized by a galling insect

Makoto Tokuda[2], Shigeru Takahashi[3], Masashi Suzuki[4], Naoki Mizusawa[5], Seiichi Nishimura[6], Junichi Yukawa[7], Takema Fukatsu[4]

[1]National Institute of Agrobiological Sciences, Tsukuba, Japan, [2]RIKEN Plant Science Center, Yokohama, Japan, [3]National Agricultural Research Center, Tsukuba, Japan, [4]National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan, [5]The University of Tokyo, Tokyo, Japan, [6]National Institute for Agro-Environmental Sciences, Tsukuba, Japan, [7]Kyushu University, Fukuoka, Japan

Introduction: Galling insects have remarkable abilities to manipulate plant tissues physiologically and morphologically for their own benefit. Here we report that *Contarinia* sp. (Diptera: Cecidomyiidae), which induces leaf galls on *Styrax japonica* (Styracaceae), shows a striking ability to regulate the survival, growth, and proliferation of host-plant cells even after shedding of the gall-bearing leaves

Methods: We examined the number and size of plant cells in galled tissues, and analyzed chlorophyll fluorescence, carbon fixation, C:N ratio, and water content of the galls on intact and shed leaves in autumn, when the first instars of *Contarinia* sp. started molting into second and then third instars.

Results: Concurrently with the larval development, flat galls started to grow into a globular shape even on shed leaves. The number and size of gall-tissue cells increased significantly on the shed leaves during the larval developmental period. Even when the ungalled portion of shed leaves had already died, the galled portion was fresh until the larvae left the galls. Galls on the shed leaves exhibited only weak photosynthesis activity. The nitrogen concentration of galls was higher than that of ungalled tissues, and the water content of galls increased during the gall growth. Tracer experiments using tritium water demonstrated that galls were able to actively absorb water from the environment.

Conclusions: We demonstrated that *Contarinia* sp. is able to regulate the survival, growth, and proliferation of galls on shed leaves. The growth of the galls on such leaves is probably sustained by utilizing residue nutrients in the galled leaves and by absorbing water from the environment.

The *ipm*PIPE: Focus on the Other I in IPM

James VanKirk[1], Julie Golod[2], Scott Isard[2]

[1]Southern Region IPM Center, Raleigh, NC, United States, [2]Pennsylvania State University, State College, PA, United States

The *ipm*PIPE , a coordinated framework initiated to address the arrival of Asian soybean rust (ASR) in the United States, offers utility in management of many pests that migrate seasonally. It already has evolved to address several other pests and for use across international borders.

Information management, integration, and model development has been led to date by Dr. Scott Isard of Penn State University. Crop and pest information collected in the field is correlated with diagnostic information from a separate data system. Modeling integrates weather and climate data from a variety of sources with all other pertinent information to provide predictions of pest movement, population development and crop risk.

An unrestricted website provides timely information including reports of pest presence and development; crop development; and expert advice on risk and management options. A map-based interface enables users to focus on a particular region, state, or county. The calendar-based function provides access to all information from inception in 2005 to the present. A restricted site provides models outputs and other in-depth information for qualified experts.

Success derives in part from the extensive communication, coordination, and education efforts integral to this approach. Another critical contributor is the strong collaborative approach to all aspects of the framework of diverse stakeholder groups including producers and grower organizations, government agencies of several nations, agribusiness, and others.

Visual learning of a landmark sequence in wood ants, *Formica rufa*

Natalie Hempel de Ibarra[1], Olena Riabinina[2], Thomas S. Collett[2]

[1]University of Exeter, Exeter, United Kingdom, [2]University of Sussex, Brighton, United Kingdom

Introduction: Ants are known to travel long distances to a food source and back home. Field experiments performed on desert ants Cataglyphis and Melophorus suggest that ants are able to memorise and retrieve certain features of their idiosyncratic routes. However, it is not entirely clear if the animals are able to prime one memory of a visual stimulus by another visual stimulus, i.e. if they are able to learn a sequence of patterns.

Methods: We have designed a set of experiments with wood ants *Formica rufa* to investigate their ability to learn a visual sequence. First we selected four stimuli discriminated by the ants (horizontally or vertically oriented stripes (H and V) or green and UV colours (G and UV).

Results: We presented the ants with either stimulus H or V on the surrounding background walls while offering a choice between G and U in a Y-maze. In this paradigm G was rewarded if the context was set by H, and the same for U and V. Ants were able to learn this task quickly. Also the ants learned to perform right or left turns in the context of H and V, respectively. Finally, the ants encountered H or V first in a Y-maze, and later had to choose between G and U. The ants found this last task difficult.

Conclusions: We conclude that whereas these ants are very good at linking stimuli together when they are presented simultaneously, they are not adept at sequential binding i.e. linking stimuli that are separated in time.

Developing novel pesticide applications for vector control with US military funding

Graham White

University of Florida, Gainesville, Florida, United States

Since 2004, the US Armed Forces Pest Management Board supports research efforts to find and develop new pesticides and better application methods against mosquitoes and other biting flies. Primarily designed for protection of military personnel against vector-borne diseases, these products have wider potential for controlling pests and vectors of public health and veterinary importance. With $5m/year budget, this initiative called “Deployed WarFighter Protection (DWFP) against disease-carrying arthropods” already yielded >100 refereed publications, posters and presentations, from USDA Agricultural Research Service units dealing with medical and veterinary entomology, plus 30 competitive awards to academics, industry, CDC, and military entomologists. Leading product developments will be highlighted, with explanation of arrangements (via USDA project IR-4 for minor use registrations) to expedite EPA regulatory approvals.

New vector control tools from the US armed forces pest management board

Graham White

University of Florida, Gainesville, Florida, United States

Faced with dwindling availability of effective public health pesticides, in 2004 the US Armed Forces Pest Management Board launched an initiative to boost the discovery, development and registration of new insecticides and application methods for vector control and personal protection against arthropods of medical importance. Known as the R&D program for Deployed WarFighter Protection (DWFP) against disease-carrying arthropods, with $5m annual budget, efforts focus on new adulticide formulations and application methods to combat mosquitoes, phlebotomine sand flies and muscoid flies. Projects include screening chemical libraries from commercial partners, finding compounds with new modes of action, computational chemistry, synthesis and assays (QSAR) for optimization of candidate compounds, reformulating agricultural insecticides suitable for vector control, design and improvement of spraying systems, field demonstrations of vector control tools and strategies. Based on reviving collaboration with USDA-ARS National Program for Veterinary, Urban and Medical Entomology, the DWFP program also awards grants of up to $250K for 3 years to competitive proposals from academics, industry, military entomologists and other government agencies, not restricted to the USA. Some of the most productive DWFP projects will be showcased.

Phylogeny and biology of the Tineoidea: a review of current research on the 'basal' families of Ditrysia

Donald Davis

Smithsonian Institution, Washington, DC, United States

The superfamily Tineoidea is recognized generally to be the most plesiomorphic group of ditrysian Lepidoptera; until 1988 the superfamily included the groups now assigned to the Gracillarioidea or even Gelechioidea. Molecular work in progress reconfirms the basal position for the Tineoidea, as well as the closer association of the Gracillarioidea with Yponomeutoidea. Currently five families are included within Tineoidea, with their interrelationships appearing as Tineidae + (Eriocottidae + (Psychidae + Arrhenophanidae) + Acrolophidae))). The principal autapomorphy of the Tineoidea is the presence within A10 of most females of a slender pair of ventral pseudapophyses, whose development is associated typically with an unusually elongated, telescopic oviscapt. Other characteristics useful in distinguishing Tineoidea from Gracillarioidea and most ditrysian Lepidoptera are the presence of erect scales on the frons, labial palpi with lateral bristles, and haustellum with short, disassociated galeae. Tympanal organs are absent except on S2 of Harmacloninae (Tineidae). Possible synapomorphies of the non-tineid families are the strong tendency of the antennae to bipectination, reduction of the maxillary palpi, forewing with Rs4 terminating on the termen rather than on the costa, and female frenulum with more than 4 bristles. A general overview of the biology, subfamily diversity, and morphology of each family will be presented, emphasizing major discoveries over the last decade as well as of work now in progress.

Buruli ulcer disease in Africa: The potential role of aquatic insects in transmission

Richard W. Merritt[1], Mark E. Benbow[1], Heather Williamson[2], Ryan K. Kimbirauskas[1], Mollie D. McIntosh[1], Rebecca Kolar[1], Pamela Small[2], Daniel Boakye[3]

[1]Michigan State Univesity, East Lansing, MI 48824, United States, [2]University of Tennessee, Knoxville, TN 37996, United States, [3]Noguchi Memorial Institute for Medical Research, Univ. of Ghana, East Legon, Ghana

Buruli ulcer is the third most frequent mycobacterial disease in humans, next to tuberculosis and leprosy, often causing serious skin ulcerations, bone deformities, and disability. Buruli ulcer has emerged dramatically since the 1980's, with increasing numbers of cases being reported from at least 31 countries, mostly in tropical and subtropical areas, including Africa. Although poorly understood, the epidemiology of Buruli ulcer associates the resurgence with people who live and/or work close to wetlands, especially slow flowing (riverine) or stagnant water bodies (marshes, swamps), often created as a result of some human environmental disturbance. The disease is not known to be contagious between humans, and epidemiological studies have not yet established natural reservoirs or modes of transmission. Laboratory studies suggest possible transmission via aquatic biting insects; however, no field studies have tested this hypothesis. Our study represented the first field examination of biting water bugs (Hemiptera: Naucoridae, Belostomatidae, Nepidae) in disease endemic and non-endemic areas of Ghana, Africa. From collections of 22,832 invertebrates we compared composition, abundance and associated *M. ulcerans* positivity between 15 endemic and 12 non-endemic sites. Biting hemipterans were rare and represented a small percentage (usually < 2%) of invertebrate communities. There were no significant differences in hemipteran abundance or pathogen positivity between endemic and non-endemic sites, and there were no correlations between biting hemipteran abundance and *M. ulcerans* positivity. Therefore, while it is possible for infection through insect bites, there is little field evidence to support biting hemipterans as primary vectors of *M. ulcerans*.

Phylogeny of the heelwalkers (Insecta: Mantophasmatodea) based on mtDNA sequences, with evidence for additional taxa in South Africa

Jakob Damgaard, Klaus-Dieter Klass, Mike D. Picker, Gerda Buder

Natural History Museum of Denmark, Copenhagen, Denmark

Introduction: Less than a decade after the description of Mantophasmatodea, a considerable amount of material has been collected from various places in southern Africa. The material shows a striking diversity, not only in overall morphology, but also in reproductive organs, as far as such information is available. Since the sister group to Mantophasmatodea is uncertain, few such characters are directly comparable among insect orders, and a molecular phylogeny is established in order to make the taxonomy reflect the evolutionary relationships within the order.

Methods: A parsimony analysis on app. 1300 bp of mitochondrial DNA sequence data (COI + 16S) was performed on a selection of mantophasmatodeans including multiple specimens from eight described and four undescribed species of Austrophasmatidae; three specimens of *Sclerophasma paresisense* (Mantophasmatidae); and two specimens of *Praedatophasma maraisi* and one of *Tyrannophasma gladiator* (not yet convincingly assigned to any family). For outgroup comparison a broad selection of taxa from hemi-metabolous insect orders was included.

Results: Equally weighted parsimony analyses of the combined data sets supported Austrophasmatidae and all species and genera of Mantophasmatodea as being monophyletic. Most species were highly supported, but *Karoophasma biedouwense* had only moderate support and *Austrophasma caledonense* low support. Mantophasmatodea, Austrophasmatidae, and a *Tyrannophasma gladiator* + *Praedatophasma maraisi* were all strongly supported, while relationships among the two latter clades and Mantophasmatidae remain ambiguous. Concerning the relationships among genera of Austrophasmatidae, support values are moderately high for some nodes, but not significant for others.

Conclusions: COI and 16S are highly congruent at the species level as well as at the base of Mantophasmatodea, but congruence is poor for most intergeneric relationships. In forthcoming studies, deeper relationships in the order will be additionally explored by nuclear genes for a reduced sample of specimens.

Entomological experiences for rural youth in Oregon through university partnerships

Sujaya Rao

Oregon State University, Corvallis, Oregon, United States

Children have an innate curiosity about insects but, as they grow older, the 'entomologist' in children is lost due to perceptions that bugs are 'yucky', scary, and not 'cool', or due to lack of encouragement from parents and teachers who may themselves be intimidated by insects. The innate curiosity about insects can be fostered if children are provided rewarding entomological experiences, as it is well recognized that 'experience' is the greatest teacher. At Oregon State University, through partnerships with K-12 schools, students in rural Oregon schools have been engaged in entomological activities formally in the classrooms and informally during public events. One formal and one informal example will be presented: 1) A new innovative 'Bees and Pollination' unit that was implemented through which university researchers engaged students in four rural communities in an ongoing research project while providing them with a typical scientist's experience. Students developed hypotheses, conducted experiments, collected data and made inferences. They presented their results through oral and poster presentations during a 'Discovering Partners in Nature' conference organized at the university. 2) Family Bug Nights that were organized in rural schools to increase awareness about insects in children, their parents and community members. These evening events, organized by Oregon State University's undergraduate club, BugZoo, in collaboration with teachers in the schools, drew over 250 rural community members per night. Both programs and their impacts will be discussed.

Understanding the invasive potential of the khapra beetle, *Trogoderma granarium* Everts, in the Australian grain storage system using the established warehouse beetle, *T. variabile* Ballion as a model

Katarina Mikac

University of Canberra, Canberra, ACT, Australia

Introduction: The invasive warehouse beetle *Trogoderma variabile* (Coleoptera: Dermestidae) is an international pest of grain storage structures, packed goods and stored grain. Individuals were first documented in eastern Australia in 1977 and later Western Australia in 1979. Recent *T. variabile* distribution surveys indicate that its abundance has doubled in Australia during the period 1990-2000. The increased abundance of *T. variabile* is of serious concern as it is often confused with the destructive khapra beetle *T. granarium*, a visually indistinguishable sister species of *T. variabile*, currently not found in Australia. In this study the genetic structure, gene flow and dispersal patterns among *T. variabile* populations in eastern and Western Australia were investigated and the findings used as a model to understand the invasive potential of *T. granarium*.

Methods: The mitochondrial gene *Cytochrome Oxidase I* (COI) was used to estimate the genetic structure, gene flow and dispersal of eight *T. variabile* individuals from 20 populations in eastern and Western Australia.

Results: Moderate to low levels of genetic structure was found among populations. No pattern of isolation by distance was found. There is evidence to suggest that individual *T. variabile* from eastern Australia founded populations in Western Australia, indicating dispersal over large distances.

Conclusions: Preliminary results indicate that a single introduction of *T. variabile* in eastern Australia was possibly responsible for the subsequent spread and introduction of *T. variabile* to Western Australia. It is assumed that like *T. variabile*, *T. granarium* has the potential to disperse over large distances should it accidently be introduced to Australia.

Ejaculation strategies of *Ephestia kuehniella* Zeller (Lepidoptera: Pyralidae) males in relation to potential remating and female age

Jin Xu, Qiao Wang, Xiong Zhao He

Institute of Natural Resources, Massey University, Palmerston North, New Zealand

Introduction: Sperm and other material associated with ejaculates are limited resources. Thus in the polygamous mating system males are expected to allocate ejaculates strategically depending on the quality of their mates and their opportunity to remate. The Mediterranean flour moth, *Ephestia kuehniella*, is a polygamous species. During copulation *E. kuehniella* males transfer gelatinous secretions and a spermatophore containing accessory gland secretions and dimorphic sperm, eupyrene and apyrene sperm, to females. Here we investigated whether and how *E. kuehniella* males adjusted their ejaculation size in the presence/absence of rival males or other potential partners, and in response to the age of their partners.

Methods: Mating trials were performed in different sex ratio, density and female age. Spermatophore and associated ejaculated material were dissected and weighed immediately after mating. The number of eupyrene and apyrene sperm was counted.

Results: In the presence of other potential partners a male transferred significantly smaller spermatophore size with fewer number of eupyrene and apyrene sperm to his partner than in the absence of other potential partners. The presence of rival males had no effect on spermatophore size and number of sperm. The male ejaculated a significantly smaller spermatophore with fewer number of sperm to the old than to the young female.

Conclusions: Males allocate smaller ejaculates when they mate with older partners or when they have immediate opportunity to inseminate other mates. The presence of rival males does not appear to affect the amount of ejaculates males transfer.

Induction of self-superparasitism by the presence of a conspecific in the infanticidal parasitoid *Echthrodelphax fairchildii* (Hymenoptera: Dryinidae)

Emi Ito, Yoshihiro Yamada

Graduate School of Bioresources, Mie University, Tsu, Mie, Japan

Introduction: Van Alphen and Visser (1990) suggested that self-superparasitism is likely to be adaptive when conspecifics are present. Ito and Yamada (2005, 2007) disclosed the adaptiveness of self-superparasitism in the parasitoid *Echthrodelphax fairchildii* when conspecifics are present. They indicated that the total fitness performance of the first and second progenies on triple-parasitized hosts is larger than the fitness performance of the first progeny on double-parasitized hosts when the first-to-second oviposition interval is short. Moreover, they suggested that the probing for infanticide of earlier-coming progenies is less profitable when conspecifics are present than when they are not. In the present study we examined whether the presence of a conspecific induces self-superparasitism and hesitation in infanticidal probing. Results on self- and conspecific superparasitism when a conspecific was present were compared with those on self- and conspecific superparasitism when conspecifics are not present

Methods: After placing two parasitoids of *E. fairchildii* in a small vial for one hour one of the two was allowed to perform self- or conspecific superparasitism with different oviposition intervals. By observing superparasitism bouts we recorded the occurrence of superparasitism and infanticidal probing, and the sex of eggs laid based on the movement of the genitalia (Yamada & Imai, 2000).

Results: The self-superparasitism rate was higher when a conspecific was present than when it was not, when the oviposition interval was 8 h or shorter, in particular, less than 0.5 h. However, the presence of a conspecific did not change the superparasitism rate when the oviposition interval was 24 h or longer, and when superparasitism was conspecific. The presence of a conspecific did not change either the probing rate or the sex ratio of eggs laid irrespective of whether superparasitism was self- or conspecific. The probing rate was mostly less than 20% when the oviposition interval was 8 h or shorter under both self- and conspecific superparasitism, while it was mostly more than 40% when the oviposition interval was 24 h or longer. The eggs laid were almost always female.

Conclusion: The presence of a conspecific induced self-superparasitism when the oviposition interval was short.

Do queenless colonies of *Apis mellifera* and *A. florea* attract more drifted workers than colonies with a queen?

Nadine Chapman[1], Piyamas Nanork[2], Julianne Lim[3], Wandee Wattanachaiyingcharoen[4], Madeleine Beekman[1], Benjamin Oldroyd[1]

[1]University of Sydney, Sydney, NSW 2006, Australia, [2]Mahasarakham University, Mahasarakham 44150, Thailand, [3]University of Queensland, St Lucia, QLD 4072, Australia, [4]Naresuan University, Phitsanulok 65000, Thailand

When a honey bee (*Apis*) colony becomes queenless and broodless its only reproductive option is for some of its workers to produce sons before the colony perishes. However, for this to be possible the policing of worker-laid eggs must be curtailed and this provides the opportunity for queenless colonies to be reproductively parasitized by workers from other nests. Queenless colonies of the open nesting *A. florea* are heavily parasitized by non-natal workers, whereas the cavity nesting species *A. mellifera* and *A. cerana* are less heavily parasitised. Genetic analysis of worker populations has demonstrated that the proportion of non-natal workers present in *A. mellifera* colonies declines after a colony is made queenless, where as the proportion of non-natal workers increases in queenless *A. florea* colonies. We compared the rate of drift between queenless and queenright colonies of *A. florea* and *A. mellifera.* Here we show that workers from queenless *A. florea* colonies are more likely to leave their nest and join another colony compared with workers from queenright colonies and these drifted workers are much more likely to join another unrelated queenless colony than a colony with a queen. In contrast, no pattern was detected during drift of workers between queenless and queeright *A. mellifera* colonies.

RATS! *Rattus rattus* and *Rattus exulans* are eating rare Hawaiian arthropods

Francis Howarth

Bishop Museum, Honolulu, Hawaii, United States

Introduction: Although circumstantial evidence implicates rat predation as threatening native arthropods, few data demonstrating their impacts are available. To begin filling this lacuna, rats were collected during a multidisciplinary study of the ecology of Kipahulu Valley, a wilderness area on Maui Island managed by the US National Park Service.

Methods: Stomach contents from 160 *Rattus rattus* and 174 *Rattus exulans* were analyzed. The sexes were about equally represented. Arthropod remains were separated, mounted on slides and identified. Arthropod surface micro-sculpture proved valuable for associating individual macerated fragments into identifiable composites.

Results: Highly sclerotized exoskeletons (beetles, true bugs, legs and claws) were over represented compared to softer tissues, but even soft chitin fragments, such as moth larval skins, could be recognized and associated with other pieces by their micro-sculpturing. Arthropod remains were found in all but one *R. exulans* stomach, and all but five *R. rattus* stomachs. *R. exulans* stomachs contained 9.2 morpho-species/rat, whereas *R. rattus* stomachs contained significantly fewer (5.0 morpho-species/rat). Lepidoptera larvae were the most abundant food item occurring in 91% of *R. exulans* stomachs and 82% of *R. rattus*. Beetles were next in frequency, 77% of *R. exulans* and 40% of *R. rattus*, followed by spiders, true bugs and crickets. Several rare insects were eaten including some that remain only known from rat stomachs, such as remarkable new species of crickets, beetles, and lacewings.

Conclusion: These data corroborate the conjecture that rat predation is a major factor in the rarity of many native arthropod species.

Development of host range testing for a potential *Uraba lugens* biological control agent

Lisa Berndt, Toni Withers

Scion (New Zealand Forest Research Institute Ltd), Rotorua, New Zealand

Uraba lugens (Lepidoptera: Nolidae) is an invasive pest of *Eucalyptus* from Australia, recently established in New Zealand. Although it is currently causing damage mainly in urban amenity trees, it continues to spread, and is predicted to establish throughout eucalypt growing regions of the country. Development of biological control is currently underway for this pest. Host range testing has begun on *Cotesia urabae* (Hymenoptera: Braconidae), a solitary larval endoparasitoid presumably specific to *U. lugens* in Australia.

Sequential no-choice small arena tests were used initially to determine physiological host range, followed by choice tests at a larger scale to examine host finding abilities. Initial results have shown that this parasitoid is willing to attack a number of non-target species, one of which may be a suitable physiological host. Here we discuss options for further experimentation to best clarify the status of this parasitoid as suitable candidate for *U. lugens* biological control.

Management strategy of *Helicoverpa armigera* resistance to Bt cotton in China

Kongming Wu

Institute of Plant Protection, Chinese Academy of Agricultural Sciences, Beijing, China

Transgenic cotton expressing the Cry1Ac toxin from *Bacillus thuringiensis* has been widely planted in China since 1998. Susceptibility of *H. armigera* field populations to the Bt insecticidal protein Cry1Ac was monitored from 1997 to 2007. The results indicated that the field populations sampled were still susceptible to Cry1Ac protein and that a shift toward resistance among *H. armigera* populations was not apparent. The evaluations on natural refuges showed that a planting system consisting of wheat, soybean (peanut), corn, and Bt cotton could supply refuges for cotton bollworm throughout the year. Adequate provision of refuges on an area-wide basis, and successful production of susceptible insects could increase the probability that a rare resistant homozygote mated with a susceptible individual to produce heterozygous progeny susceptible to Cry1Ac. This strategy has been recommended for areas where farmers exclusively grow cotton without natural refugia from other crops.

Cellular level examination of a bark beetle-fungus interaction

Cetin Yuceer[1], Olga Pechanova[1], Kier Klepzig[2]

[1]Mississippi State University, Department of Forestry, Mississippi State, MS, United States, [2]USDA Forest Service, Southern Research Station, Pineville, LA, United States

Introduction: The southern pine beetle, *Dendroctonus frontalis* Zimmermann (Coleoptera: Scolytidae), harbors fungal symbionts in its mycangium. These fungi grown within the host tree provide necessary nutrition to developing beetles and compete with a pathogenic bluestain fungus. Secretions from the mycangial gland cells appear to regulate the species composition of and provide nourishment for these symbiotic fungi. However, the mechanisms (e.g., secreted antibiotic chemicals or nutrients, proteins or pathways) by which this relationship is maintained are not known.

Methods: We conducted qualitative and quantitative proteomics experiments to identify proteins using pronotal tissues from both sexes of SPB.

Results: We identified a number of proteins that are involved in metabolism, cell structure, contractile apparati, and defense, using information from the red flour beetle (*Tribolium castaneum*) genome sequence.

Conclusions: Although we currently don't have direct evidence that the more abundant proteins in the female SPB pronotum are involved in the synthesis/secretion of chemicals/nutrients, their possible roles should not be dismissed. These proteins could be parts of pathways regulating fungal growth and/or reproduction or be involved in selection against non-symbiotic fungi. They may also be expressed as a part of mycangial self-maintenance.

Developing an integrated pest management (IPM) strategy for the legume pod borer (*Maruca vitrata*)

R. Srinivasan[1], Song-Tay Lee[2], Mei-Ying Lin[1], Ching-Yi Lee[2], Chun-Chu Huang[1], Yun-Che Hsu[1], Fu-Cheng Su[1]

[1]AVRDC-The World Vegetable Center, Shanhua, Tainan, Taiwan, [2]Southern Taiwan University of Technology, Yung-Kang City, Tainan, Taiwan

Introduction: The legume pod-borer (LPB), *Maruca vitrata* is most serious on legumes in Asia and Africa. Alternative pest management strategies are warranted based on economic, social and environmental issues due to pesticide abuse.

Methods: Field explorations were made to identify potential natural enemies. Mass-culturing techniques were established for two promising parasitoids. A nucleopolyhedrovirus (NPV) was isolated, characterized, formulated as a potential bio-pesticide and field evaluated.

Results: *Nemorilla maculosa* (Tachinidae) and *Apanteles taragamae* (Braconidae) were the two most promising parasitoids on LPB in Taiwan. *N. maculosa* preferred the fifth instar larvae, and one female parasitized about five larvae. The maximum parasitism occurred at 20-35℃. *A. taragamae* preferred the first instar larvae. A single female parasitized about 30 larvae. The maximum parasitism occurred at 30℃. A NPV infecting LPB (MaviMNPV) was characterized based on ultra-structural morphology, REN patterns and sequences of the coding region of the *Polh* gene. The effectiveness of MaviMNPV was tested alone and in combination with neem and *Bacillus thuringiensis*. The efficiency of the MaviMNPV formulation containing lignin as a UV protectant was significantly higher (84.44%). However, the other formulation that contained optical brightener performed better in reducing LPB damage (14.77%) in yard-long bean. The pod damage in hyacinth bean was significantly reduced by both formulations (8.38 and 9.79% as against 18.29% in control).

Conclusions: An IPM strategy based on parasitoids and bio-pesticides is being validated. Additional parasitoids will be explored from the Southeast Asian region, which is supposed to be the origin of LPB, to broaden the sustainability of this IPM strategy.

Functionally-linked ultrastructural changes in the water vapour absorptive epithelium of the firebrat, *Thermobia domestica* (Packard), during development and the moulting cycle

John Noble-Nesbitt

School of Biological Sciences,, Norwich, United Kingdom

Sustained active water vapour absorption (WVA) from relative humidities down to as low as 43% is essential for the growth, development and survival of the firebrat in hot, dry environments where liquid drinking water is lacking. WVA starts falteringly during the second nymphal instar and reaches its mass-specific peak in the late-third and fourth instars.

The water vapour absorptive epithelium, in the posterior rectal (anal) sacs, boasts the highest known concentration of elongated mitochondria densely packed in hexagonal array alongside deep pleated infolds of the enormously hypertrophied, portasome-studded apical plasma membrane (apm). This apical complex comprises some 80% of the cell volume. It arises post-embryonically and reaches fully functional maturity just as WVA peaks in the third instar.

Early in the short-lived first instar, rapid mitochondrial biogenesis occurs in 'mitochondrial factory cells'. These cells become densely packed with mitochondria which are shared out amongst the daughter cells during mitoses. The mitochondria subsequently elongate alongside apm infolds, creating the apical complex.

During each moult WVA temporarily ceases. Despite the considerable investment represented by the apical complex, it regresses fully as a new cuticle overlying the epithelium is secreted. Portasome-studded apm rafts form and remain sequestered within the cells. Mitochondria round off and multiply. Cells divide. Mitochondria and rafts pass to the daughter cells. At the end of the moult, the rafts rapidly re-coalesce into deep-pleated infolds alongside elongating mitochondria, re-forming the apical complex. WVA resumes immediately after ecdysis.

Investigations on biology and host range of *Urentius* spp. (Hemiptera: Tingidae) in Sudan

Abdalla A. Satti

Environment and Natural Resources Research Institute, National Centre for Research, Khartoum, Khartoum State, Sudan

Introduction: *Urentius hystricellus* and *U. euonymus* are major pests of eggplant and pigeon pea, respectively. Several alternative hosts were also reported for each pest species, but some hosts were believed to be infested by the two pests. Actually, a lot of confusion has been found between these pests and their host plants. Accordingly, this work aimed to differentiate between such species and to verify their biology and host range in Sudan.

Methods: Host plants for both *Urentius* spp. were thoroughly surveyed throughout the year concentrating mainly at Khartoum State, but some areas in central and northern Sudan were also observed. The surveys also included other wild and cultivated plants in search for new hosts. Morph metrical studies were done for insects collected from each host. The life cycles were performed during autumn and winter seasons for the two pests, each on two (cultivated and wild) of its major hosts. Moreover, *U. euonymus* collected from pigeon pea and a wild host (*Abutilon* sp.) were reared on caged eggplant to confirm the differentiation between the two pests.

Results: The results showed clear morphological and biological differences between *U. hystricellus* and *U. euonymus*. The durations of pre-imaginal stages of the latter pest were longer than those of the former, but each exhibited similar durations on their respective hosts. Each pest has its own host range, and no single host was found infested by the two pests together, as believed. Some mistaken hosts for each pest were corrected and new hosts were added. However, among three hosts indicated for *U. hystricellus*, *Solanum incanum* was a new record. On the other hand, five hosts were indicated for *U. euonymus*, two of which (viz. *Chrozophora plicata and Rhynchosia memnonia*) were new records. Insects collected from the two hosts of *U. euonymus* didn't breed and died within 3-5 days when confined to eggplant in cages, thus ensured their difference from eggplant tingid bug.

Conclusions: This study verify the presence of both *U. hystricellus* and *U. euonymus* as different pest species infesting different host plants in Sudan, with mistaken hosts being corrected and new hosts added.

Quantitative food webs in space: herbivore-parasitoid communities on pedunculate oak *Quercus robur*

Riikka Kaartinen, Tomas Roslin

University of Helsinki, Helsinki, Finland

Introduction: While quantitative food webs provide accurate information about community structure and relationships between species, they have rarely been used to compare multiple local communities. In this study, we construct quantitative food webs of insects for tens of host trees, and thereby examine the impact of landscape context on the relative frequency and strength of interspecific interactions.

Methods: In 2006 and 2007, we sampled 30 oak trees in south-western Finland. 22 of these trees were located within a 5 km^2 island, where the spatial location of all oak individuals has been mapped. Eight additional trees were sampled elsewhere, within particularly dense oak stands or especially far from all other oak individuals. We sampled each tree twice both years by cutting down 30 c. half metre branches. All leaf mines and galls were collected for rearing.

Results: In 2006 we collected 33 800 leaf mines and galls of which 13 300 were reared, and in 2007 we collected a further 28 800 individuals of which 15 900 were reared. Preliminary analyses suggest that both the species composition of local communities and the type and frequency of host-parasitoid interactions within them may vary with the spatial context and the local abundance of host plants.

Conclusions: Once completed, we expect this study to offer the first quantitative insight into he effect of habitat fragmentation on herbivore-parasitoid food web structure.

Bioecology of the invasive B biotype compared to the indigenous Ms biotype of *Bemisia tabaci* on tomato

Bernard Reynaud[1], Helene Delatte[1], Pierre- François Duyck[4], Aurélie Triboire[1], Nathalie Becker[3], Patrice David[2]

[1]CIRAD UMR PVBMT, Saint Pierre, La Réunion, France, [2]CEFE CNRS UMR 5175, Montpellier, France, [3]MNHN CNRS UMR 5202, Paris, France, [4]University of California, Davis, CA, United States

Studies on success or failures of biological invasions by different insect biotypes are scarce and could provide interesting insights into the traits that determine greater or lower ability to invade. Life history traits of invasive whiteflies *Bemisia tabaci* of the B biotype (known as a worldwide invasive biotype) and of the indigenous biotype Ms (not known as an invader anywhere in the world), both from the island of La Réunion (Indian Ocean), were compared for this purpose. In our study we demonstrated that within a cultivated host plant (tomato), the B biotype differs from the Ms by a combination of several life-history traits. This combination gives the invasive biotype an advantage over the resident both in terms of rapid demographic growth (increased intrinsic rate of increase and associated traits such as short developmental times and high fecundity) and in terms of competition (large adult and offspring sizes), without any recorded trade off. However, in the field the resident biotype remains dominant on non-cultivated hosts (weeds) and in a particular climate (high humidity). This suggests that invasive biotypes are characterized by physiological, morphological and biological adaptations to a relatively uniform environment created by anthropic activities at different places in the world, while resident biotypes may persist in less altered habitats.

The aquatic and semi-aquatic Heteroptera of Madagascar: faunal affinities and patterns of intra-island endemism

John T. Polhemus[1], Dan A. Polhemus[2]

[1]Colorado Entomological Instititute, Englewood, Colorado 80113, United States, [2]Bishop Museum, Honolulu, Hawaii 96817, United States

Madagascar represents a significant area of endemism for the infraorders Leptopodomorpha, Gerromorpha, and Nepomorpha.On a world basis these infraorders contain a documented 23 families, 343 genera and 4799 species . Of these, 18 families, 57 genera and 161 species are currently recorded from Madagascar. Although this biota represents only 3% of the described world fauna, it exhibits extreme species level endemism (80%), and contains 12 specialized endemic genera. All the remaining non-endemic genera are shared with Africa. Despite its predominantly African affinities, certain elements that occur elsewhere only in tropical Asia, such as the gerrid subfamily Ptilomerinae and certain Microveliinae, provide evidence of a former connection between Madagascar and India prior to Cretaceous rifting. At the species level, at least 35 new species remain to be described, all of them Madagascar endemics These new species are concentrated in the families Veliidae (Microveliinae, Rhagovelia), Aphelocheiridae (Aphelocheirus) and Naucoridae (Temnocoris). The intraisland distributions of Malagasy water bugs define four major internal biogeographic regions: the eastern wet forest, the central plateau, the western dry forests, and the northern volcanic massifs, with many genera exhibiting localized endemic speciation among these regions. Collections of Madagascar water bugs have been sporadic, with the last major survey in the mid-1980s. Certain key areas remain to be collected, notably Mt. Tsaratanana, the Masoala Peninsula, the Isalo Massif, the Mt. Andringitra massif, and the mountains west of Ft. Dauphin.

Pupal parasitoids of grape berry moth *Lobesia botrana* (Denis & Schiff.) (Lepidoptera:Tortricidae) and their role in an IPM program in vineyards

Gholamali Akbarzadeh Shoukat, Klaus Horstmann, Ebrahim Ebrahimi

[1]1Agricultural and Natural Resources Research Center, Orumieh, Islamic Republic of Iran, [2]Lehrstuhl Zoologie 3 Biozentrum, Am Hubland, Wuerzburg, Germany, [3]Plant Protection Research Institute, Tehran, Islamic Republic of Iran

Introduction: In order to alleviate growing public concerns regarding the effects of pesticides on human health and environment impact much attention has been given to biological control using parasitoids in recent decades. Since grape berry moth *Lobesia botrana* (Denis & Schiff.) was known as the key pest of grapes in Orumieh, Iran therefore this study was conducted to determine pupal parasitoids of the pest and to assess their potential for natural control during 2005-2007.

Methods: Pupae of GBM were collected under loosen barks of unsprayed vineyards form early December until mid April and were reared in containers at room condition with 15-20 days interval. Emerged parasitoid adults were counted and classified to different families then each group were studied and identified by related specialists. Average of parasitism and its trend was discussed according two years data.

Results: Seven parasitoid species were reared from grape berry moth pupae including: *Itoplectis tunetana* (Schmiedeknecht), *Pimpla aracadica* Kasparian, *Pimpla ?confinis* Kasparyan, *Dicaelotus inflexus* Thomson, *Labiinae* sp. belonging to Ichneumonidae family as well *Pteromalus puparum*(L.) and *Homoporus* sp. belonging to Pteromalidae. The occurrence of these parasitoids on grape berry moth pupa are reported for the first time. Pupal parasitism ranged from 12 to 48% with an average of 21%. Parasitism rates were increased toward initiation of the growth season.

Conclusions: Parasitism was medium and it is likely that additional surveys in this area will yield new parasitoids for introduction into Iran.

Population ecology of *Scotinophara lurida* in rice fields in Korea: its spatial distribution and phenology model

Hunsung Kim, Joon-Ho Lee

Seoul National University, Seoul, Republic of Korea

Introduction: The spatio-temporal pattern of the rice black bug, *Scotinophara lurida* was studied in rice fields, and its phenology simulation model was developed for development of its management program.

Methods: Visual counts of *S. lurida* were conducted in rice fields, and its spatial patterns for egg, nymph and adult were examined with SADIE (Spatial analysis by Distance IndicEs). The components for the phenology simulation model were a degree-day immigration flight model of overwintered adults, temperature-dependent developmental model of each stage, survival rate of each stage and an adult oviposition model. To develop an immigration flight model of over-wintered adults, the cumulative percentage light trap capture data were fit to a Weibull function as a function of degree-days. Laboratory and greenhouse experiments were conducted to determine the effect of temperature on the development and survival of each stage and fecundity of female adults. A linear function was used to model the developmental rate of each stage. Distribution of developmental time for each stage was modelled against physiological age by a Weibull function. The oviposition model was developed incorporating the three components of average total fecundity, cumulative oviposition rate function, and survival rate function which were modelled using extreme value function, two-parameter Weibull function and sigmoid function, respectively. The phenology model was validated with the data collected over 2 years in a rice field.

Results: The distribution pattern of overwintered *S. lurida* and egg were random ($I_a = 1$) or uniform ($I_a < 1$) in rice field, while aggregated distribution pattern ($I_a > 1$) appeared to be common for nymphs and newly emerged adults. Overall, the simulation model predictions agreed with the observed pattern of each developmental stage of *S. lurida* in the field.

Conclusions: The spatial distribution pattern of *S. lurida* is temporally very stable and the distribution of immigrated overwintered adults strongly affected the spatial distribution of later developmental stages. The phenology simulation model predicted the time of peak occurrences of life stages of *S. lurida* well.

Phoretic mites on *Pityokteines curvidens* (Coleoptera: Curculionidae: Scolytinae) caught in pheromone traps

Milan Pernek[1], Stacy Blomquist[2], John Moser[2]

[1]Forest Research Institute, Jastrebarsko, Croatia, Croatia, [2]USDA Forest Service, Southern Research Station, Pineville, Louisiana, United States

Introduction: The species composition and abundance of phoretic mites of the bark beetles *Pityokteines curvidens*, caught in pheromone traps were investigated in Croatia. Mites, phoretic on bark beetles are involved in complex symbiotic interactions with bark beetles, fungi, including ophiostomatoid species and their host trees. This research may form the basis for further studies on the hitherto unknown interactions between *P. curvidens*, their phoretic mites and fungal associates.

Methods: Beetles were sampled by using "Curviwit" pheromones (composed of metilbutenol and ipsenol) in Theysohn traps placed at two localities in Croatia. *P. curvidens* beetles caught in the pheromone traps were weekly collected in 2006, placed into plastic cups with 70% ethanol. For mite inspection beetles were transferred to lactophenol for clearing and their accompanying mites were counted and plucked from their bodies.

Results: A total of 10 mite species were documented which included *Dendrolaelaps quadrisetus*, *Histiostoma piceae*, *Paraleius leontonychus*, *Pleuronectocelaeno barbara*, *Tarsonemus minimax*, *Trichouropoda lamellosa, Uroobovella ipidis, Schwiebia* sp., *Histiostoma* sp. and an unidentified species from the family Orimbatidae. *U. ipidis, P. leontonychus,* and *D. quadrisetus* were the most frequent mites. While *Pleuronectocelaeno japonica* and *Schizostethus simulatrix* were not found in this study as on beetles collected from logs in previous studies, four new mite species including *Schwiebia* sp., *Histiostoma* sp. *Pleuronectocelaeno barbara* and an unidentified mite from the family Oribatidae, were found as new mite associates of *P. curvidens*.

Conclusions: The records of mite species in this study increase the number of known mite associate of *P. curvidens* from 10 previously documented species to 14 species.

The genus *Carminator* (Hymenoptera: Megalyridae): geographic distribution and phylogeny

Toshiharu Mita[1], Kazuhiko Konishi[2]

[1]Kyushu University, Fukuoka-shi, Fukuoka-ken, Japan, [2]National Agricultural Research Center for Hokkaido Region, Sapporo-shi, Hokkaido, Japan

The family Megalyridae is a relatively rare group of parasitic wasps. They parasitize larvae of wood-boring beetles (Cerambycidae, Buprestidae, Bostrichidae) and mud-nesting wasps (Sphecidae) rarely (Shaw, 1990). Almost all other megalyrids are distributed in Southern Hemisphere, but a genus *Carminator* Shaw is the representative in Asia. This genus comprises the Cryptalyrini Shaw together with South American *Cryptalyra* Shaw (Shaw, 1990). Unlikely *Clyptalyra* or other genera, the *Carminator* has bizarre appearance by many unique characters like the shallow subantennal groove; the five-toothed and stout mandible; the prognathous head; and the strongly arching ovipositor (Shaw, 1988, 1990). Six species have been recorded from Japan, Southeast Asia, and Bismarck Archipelago (Shaw, 1988, Mita *et al*., 2007). All of them except for *C. ater* are monotypic, and no male has been reported. In the course of our study on the *Carminator*, two female specimens, which exhibited two additional undescribed species, and a male specimen, which could not be placed in any species yet, were found from Southeast Asia. In this presentation, we discuss the morphology of the species, analyze their phylogenetic relationships, and attempt to demonstrate the preliminary view of the dispersion pattern of the *Carminator*.

The role of immune defence in avian predation risk on a territorial damselfly

Markus Rantala, Johanna Honkavaara, Jukka Suhonen

University of Turku, Turku, Finland

Introduction: It has been commonly thought that predators prey more often on socially subordinate individuals that are in poor physiological condition, although empirical evidence supporting the hypothesis is scarce.

Methods: Here we tested whether the activation of immune system, or individual variation in immunity has any effect on survival and predation risk of the territorial banded demoiselle, *Calopteryx splendens*.

Results: We found that immune challenged males were less frequently territorial than control or sham-manipulated males. This suggests substantial fitness cost of the activation of immune system as territorial males had higher mating success than non-territorial males in damselflies. We also found that immune challenged males were more often predated by a small passerine bird (*Motacilla alba*), than control or sham-manipulated males. The overall survival of immune challenged males was reduced, supporting the prediction that the activation of immune system is costly. Interestingly, we also found that territorial males had lower predation risk than non-territorial males, suggesting that predation risk is condition dependent. Furthermore, males with weak immune defence had a higher predation risk than males with strong immune defence, supporting the hypothesis that predators prey upon individuals of inferior phenotypic quality.

Conclusion: In the light of these experiments it appears that predation risk is strongly associated with the immune system in the wild, may cause substantial selective pressure on immunity and may shape trade-offs between immunity and life history traits.

The maintenance of high ant diversity in tropical rain forest canopies: Empirical evidence for a lottery model with taxonomically limited competition.

Tom Fayle[1], William Foster[1], Paul Eggleton[2]

[1]University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, [2]Natural History Museum, London, United Kingdom

One of the major questions facing ecologists today is that of how high diversity is maintained in tropical ecosystems. We investigate this question using the ant communities in epiphytic bird's nest ferns as a microcosm. Bird's nest ferns are widespread and abundant tropical epiphytes, which collect leaf litter and acquire nutrients from the ensuing decomposition. The resulting mass of decomposing material is an ideal habitat for arthropods in the canopy, being buffered against changes in microclimate. We surveyed 87 ferns and found 71 species of ant with colony centres within these ferns. Three factors were important in structuring these ant communities:

1. Species richness increased with fern size.

2. Species composition changed with fern size and with fern height in the canopy, although together these two variables explained only 8.1% of the total variation in species composition.

3. Conspecific colonies never co-occurred, and congeneric colonies did so less frequently than expected by chance.

We also carried out experimental invasions of ferns using a model invader (*Diacamma* sp.). Ferns contained either a conspecific colony, a congeneric colony, or a colony of a species from a different genus. We found that *Diacamma* could successfully invade only when there was no conspecific or congeneric colony present. We conclude that while fern size limits the number of species in the ant community, and fern size and height weakly affect community composition, the nature of that community is mainly controlled by interactions between congeneric species, which presumably have similar niches. Ants colonise the ferns more or less at random until the ferns are full, with the proviso that colonisation will be unsuccessful if there is a congeneric colony already present. This means that stochasticity will play a large role in determining the species composition of the ferns, allowing the high diversity in this canopy ecosystem to be maintained.

Beetles at our service

Olga Ameixa, Pavel Kindlmann

Department of Theoretical Ecology, Institute of Systems Biology and Ecology AS CR and Faculty of Natural Sciences of the University of South Bohemia, Ceske Budejovice, Czech Republic

Introduction: Simplification of local landscape mosaics and of landscape composition result in a decreased ability of agricultural landscapes to support natural ecosystem components and processes. With the dismantling of collective farms, agriculture in the Czech Republic is being restructured. Some conservative policies are being applied, like building new natural corridors. These structures help to maintain biological diversity, protect water resources, conserve soil and help to maintain functional habitats, which includes travel corridors for native wildlife, when they move from nests or burrows to areas where they hunt, feed, or breed. After joining the European Union, the pressure for yield has forced farmers in the Czech Republic to increase the amount of agrochemicals used and the expectation is for a further increase of these inputs to face of these new challenges. It is known that intensive production methods severely deplete the ability of the agricultural landscape to provide services, but the effects of these actions on the local biodiversity are still unknown.

Methods: Coleoptera individuals were collected (beating/sweep netting and pitfall traps) from natural and semi-natural habitats; individuals were identified to the species level.

Results: Here we characterize the Coleoptera (Coccinellidae and Carabidae) diversity in several types of habitats (natural and semi-natural). We discuss how agricultural practices and the use of natural corridors influence the “goods and services” supplied by Coleoptera. Differences between the species assemblages in the different habitats were observed.

Conclusions: The species assemblages in natural communities are influenced by agricultural intensification, the impact of corridors is unclear.

Forenseek: a simulation program of carrion-feeding insect's development dedicated to forensic entomology.

Damien Charabidze[1], Gildas Morvan[3], Didier Gosset[1], Benoit Bourel[2]

[1]Université Lille 2, Lille, France, [2]Faculté Libre des Sciences et Technologies, Lille, France, [3]Laboratoire de Génie Informatique et d'Automatique de l'Artois, Bethune, France

Introduction: Post-Mortem Interval (PMI) estimation and understanding of circumstances of death in forensic entomology are only based on the expert analysis. The expert exploits insect samples and many other important data, such as environment description, meteorological data, police investigation data or bibliography. The quality of diagnosis and information analysis depends on a rigorous scientific method as well as a strong experience and intuition of the expert. However, all the factors cannot obviously be taken into account. Nevertheless, in a forensic context, the conclusion must be absolutely explained and justified, and not any hypothesis can be disregarded.

Methods: ForenSeek is a computer based Decision Support System (DSS) dedicated to forensic entomology. The core part of the software program is a multiagent model of behaviour and development of necrophagous diptera larvae. This concept allows to model complex group behaviours from simple individual data, and thus is particularly well adapted to study insect populations. Moreover, results provided by this model are intended to be automatically computed to extract relevant information and then estimate PMI.

The aim of this project is 1: the PMI estimation after retrieving available parameters and field data, including their reliability degree; 2: the simulation of various situations and processes of colonisation from initial data and parameters.

Results: In fact, complexity of the matter brings us to divide the whole project in two sub-projects: a simulation system of the behaviour and development of insect larvae;
A DSS that analyses these simulations and estimate PMI

Conclusion: Together, these tools form a comprehensive software program, which should allow a clear increase of speed and accuracy of entomological forensic expertises.

Establishing a protocol for South African agriculture, based on new crop case studies

Vaughn Swart, Maitland Seaman, Schalk Louw

University of the Free State, Bloemfontein, South Africa

Introduction: The greatest threat to biodiversity in the past 50 years has been due to habitat destruction associated with agriculture. The sustainability of an agro-ecosystem depends on the conservation of its biodiversity, whilst, conversely, the agro-ecosystem affects the surrounding environment. The development of a robust methodology is thus necessary by implementing measures of biodiversity as mechanisms to indicate degree of disturbance of the environment.

Methods: Two sites with different crop and natural vegetation types, climate and agricultural practices were chosen as case studies, i.e. Green Valley Nuts, Prieska, Northern Cape, (with a pistachio crop) and Winterton, Kwazulu-Natal, (with a kenaf crop). At each site marked transects were sampled for insects and vegetation. At four different locations on site, three transects in the relevant crop and three in the surrounding environment were set 2, 10 and 50 metres from the crop border. Insects were used as indicator community since they are prevalent, have high species diversity, are easy to sample, are important in ecosystem function, provide early detection of ecological changes and respond to environmental changes faster than vertebrates. Insect morpho-species were categorised into functional feeding groups.

Results: After analysis, patterns of similarity in the biodiversity of each transect can be seen at the different locations, relative to the frequency and diversity of vegetation sampled.

Conclusions: Biodiversity should indicate a relationship between communities and is a sign of the level of ecosystem integrity. An early prototype version of the model design is suggested and further streamlining is planned for the future with the aid of a workshop.

Establishing a protocol for South African agriculture, based on new crop case studies

Vaughn Swart, Maitland Seaman, Schalk Louw

University of the Free State, Bloemfontein, South Africa

Introduction: The greatest threat to biodiversity in the past 50 years has been due to habitat destruction associated with agriculture. The sustainability of an agro-ecosystem depends on the conservation of its biodiversity, whilst, conversely, the agro-ecosystem affects the surrounding environment. The development of a robust methodology is thus necessary by implementing measures of biodiversity as mechanisms to indicate degree of disturbance of the environment.

Methods: Two sites with different crop and natural vegetation types, climate and agricultural practices were chosen as case studies, i.e. Green Valley Nuts, Prieska, Northern Cape, (with a pistachio crop) and Winterton, Kwazulu-Natal, (with a kenaf crop). At each site marked transects were sampled for insects and vegetation. At four different locations on site, three transects in the relevant crop and three in the surrounding environment were set 2, 10 and 50 metres from the crop border. Insects were used as indicator community since they are prevalent, have high species diversity, are easy to sample, are important in ecosystem function, provide early detection of ecological changes and respond to environmental changes faster than vertebrates. Insect morpho-species were categorised into functional feeding groups.

Results: After analysis, patterns of similarity in the biodiversity of each transect can be seen at the different locations, relative to the frequency and diversity of vegetation sampled. **Conclusions:** Biodiversity should indicate a relationship between communities and is a sign of the level of ecosystem integrity. An early prototype version of the model design is suggested and further streamlining is planned for the future with the aid of a workshop.

Tools to improve surveillance for insect plant biosecurity in Australia

James Ridsdill-Smith, Darryl Hardie, Rob Emery

Cooperative Research Centre for National Plant Biosecurity, Perth, Western Australia, Australia

When an invasive insect species becomes established in a new area/region/country populations are very low and hard to detect, however with every month that they remain undetected they will become harder and more expensive to eradicate. Australia with a coastline of 60,000 km requires sentinel trapping to detect key threats like Asian gypsy moth and fruit fly species. We are looking to improve trap design, including remote traps that wirelessly self-report as well as developing software for identification through shape and pattern recognition. Regularly serviced grids of traps are used for fruit flies to acquire measurable evidence of absence. Even when an incursion has occurred, many traps catch no flies. We are researching the use of fewer traps placed in strategic locations predicted from fly behaviour studies using new spatial statistical methods. The development of these new surveillance trends will produce massive amounts of biological and spatial data and the development of software tools on hand-held PDAs (Personal Digital Assistants) is a cost effective way to collect, audit and validate these biological and spatial data in the field. Spatial data from GPS can be used to navigate to traps and data can be ported to third party web applications like Google Earth for desktop validation. The CRCNPB brings together many organisations to develop a new generation of surveillance tools that can be used by regulatory authorities throughout Australia to detect incursions earlier, allowing eradication before they impose a major economic impact on industry and government.

Arbuscular mycorrhizal symbiosis triggers prey-mediated changes in the life history of the predatory mite *Phytoseiulus persimilis*

Daniela Hoffmann[1], Horst Vierheilig[2], Peter Schausberger[1]

[1]Institute of Plant Protection, Department of Applied Plant Sciences and Plant Biotechnology, University of Natural Resources and Applied Life Sciences, Vienna, Austria, [2]Departamento de Microbiología, Estación Experimental de Zaidín, CSIC, Granada, Spain

Soil organisms such as arbuscular mycorrhizal (AM) fungi may influence aboveground herbivores via shared host plants. Only a few studies examined whether these effects are passed on to higher trophic levels. We investigated the effects of AM symbiosis on selected life history parameters of the specialized predatory mite *Phytoseiulus persimilis* feeding on two-spotted spider mites *Tetranychus urticae*. Experiments were performed on plant and artificial substrates to distinguish between effects mediated by prey with and without direct influence of the host plant on the predator. The plant substrate were leaves of broad bean (*Phaseolus vulgaris*) that were either colonized by the AM fungus *Glomus mosseae* (+M) or not (-M). The artificial substrate were closed acrylic cages. On the leaf juvenile survival and development, and oviposition were assessed supplying prey in surplus. In the cage juvenile survival and development were assessed as a function of the predator feeding history (mothers feeding on prey reared on either +M or -M), prey feeding history (+M or –M) and quantity of prey supplied. Oviposition in the cage was also measured at limited prey availability. Juvenile survival in the cage with limited prey supply was significantly increased if prey or predator or both had a +M feeding history. Moreover, developmental time in the cage and on the leaf (for feeding stages) was significantly shorter for individuals feeding on +M prey. Minimum prey needed to oviposit was not affected by AM symbiosis. We discuss possible implications of our results for multi-trophic aboveground - belowground interactions.

Global change and IPM: the emblematic case of *Bemisia tabaci* in Mediterranean Europe

Olivier Bonato, Jacques Fargues, Frédéric Pellegrin

UMR CBGP, Montferrier/Lez, France

The impact of global change on Integrated Management of *Bemisia tabaci* in protected crop is assessed under predictive hypothesis of ambient air temperature increase. The increase of air temperature modifies temperature inside greenhouse. All the components of the agrosystem are affected by this change and particularly the biotic potential of both whitefly and natural enemies. Therefore the efficiency of integrated management strategies usually employed to control *B. tabaci* is questioned in a Mediterranean context of global change.

Ditrophic relationship of *Liriomyza* spp. with its potato host

Sunita Facknath

University of Mauritius, Reduit, Mauritius

The genus *Liriomyza* (Diptera : Agromyzidae), includes several species which are important pests of ornamentals and greenhouse crops. In *L.trifolii* (Burgess) and *L. huidobrensis* (Blanchard), age of potato leaves and trichome density had the strongest influence on host preference and performance.

Adult choice of host species had a pre-imaginal component, which could be reinforced by an imaginal component, while choice of plant variety operated at imaginal level and was not inherited. Intraplant preference was towards larger, older, lower leaves, although the middle leaves were superior for growth and development of young stages, i.e. oviposition preference–offspring performance hypothesis was not supported, but Hopkins' host selection principle operated at the level of host species, and to some extent at level of host variety, but at host age.

L. trifolii and *L. huidobrensis* were more attracted to conspecific- and heterospecific-infested plants and potato odour, than to uninfested plants/ odour. *L. trifolii* showed a lower preference for *L. huidobrensis*-infested plants than to conspecific-infested plants. *L. huidobrensis* attraction to conspecific-infested plants was due to increased amounts of E-4,8-dimethyl-1,3,7-nonatriene, methyl salicylate, germacrene D, germacrene-4-ol, and caryophyllene released by infested plants.

Liriomyza huidobrensis females were found to lay a greater number of eggs in a situation of inter-specific competition than in an intra-specific one. *L. huidobrensis* larvae consumed greater amounts of nutrients compared to *L. trifolii*, and exhibited interference and exploitative competition.

Plants grown under high nutrient levels were more attractive due to higher leaf nutrients and differential levels of phytovolatiles.

Handling of large numbers of names in Braconidae with Taxapad, exemplified by the revision of European Opiinae

Cornelis van Achterberg[1], Dicky Yu[2]

[1]Nationaal Natuurhistorisch Museum (Naturalis), Leiden, Netherlands, [2]University of Kentucky, Lexington, Wyoming, United States

The parasitoid family Braconidae (Hymenoptera) belongs to the Ichneumonoidea, which is one of the largest superfamilies in the animal kingdom. In total about 44,000 taxa (species and genera) are known, of which ca 43 % or 19,000 taxa belong to the Braconidae. These taxa are associated with numerous other spp. (e.g. as hosts) accounting in total for more than 221,000 taxa to be handled. It looks like a Sisyphean task but it can be accomplished with the interactive software "Taxapad" developed by the second author. How this is done, and how it can be used for a large revision, is exemplified by the European Opiinae with more than 300 valid species and many synonyms.

Data on the distribution, life-history and morphology of immature stages of *Eupales ulema* (Coleoptera: Chrysomelidae: Eumolpinae)

Károly Vig

Savaria Museum, Szombathely, Hungary

Introduction: *Eupales* is a monospecific eumolpine genus native to SE Europe, mostly to the Balkan Peninsula and Turkey. The northernmost known populations of *Eupales ulema* breed in southern parts of Hungary on the southern slopes of the Mecsek Hills, which are sub-Mediterranean in climate. The life-history and the morphology of the immatures stages of the species have still not been described, and the purpose was to obtain this information.

Results: Field observations so far find the adults appearing in mid-April. They feed exclusively on the cornelian cherry *(Cornus mas)*. Mating occurs on the food plant in the typical riding mode of leaf beetles. The eggs of the female are placed in the soil, where the larvae presumably feed on the roots of the food plant and pupation is also thought to occur. In Hungary, one generation develops each year. It proved possible to raise L1 larvae in the laboratory. The neonate larvae are yellowish white with developed legs. As with all the typical eumolpine species, the larvae are totally blind with no sign of stemmata on the head capsule. The last abdomen segment of the freshly hatched larvae do not carry a caudal abdominal shield. After hatching, the larvae bore into the ground and do not feed on cornelian cherry leaves offered to them. This presentation details the knowledge of species distribution and life-cycle acquired and sets out and illustrates the typical morphological features of the larva.

Evaluation of termite resistant plant attributes for their bioactivity against *Macrotermes* termites

Bekele Jembere, Gedion Yohannes, Mengistu Gemech, Ermias Dagne

Addis Ababa University, Addis Ababa, Ethiopia

Introduction: The monotypic genus *Hagenia abyssinica* (Rosaceae) commonly known as Kosso is most widely used to expel human tapeworm and the wood is resistant to termite. Attributes of the plant responsible for such effect sought investigation and hence this study was initiated.

Methods: Tests were conducted on toxicity, anti-feedant and repellent effects of the plant on *Macrotermes* termite workers under field and laboratory conditions. Different levels of aqueous extract of the plant's female flower powder was applied on filter papers to test toxicity effect. Repellency effect of polar and non polar extracts of the different parts of the plant was tested using Y tube olfactometer, while anti-feedant effect of the plant was tested by applying the different extracts on *Croton macrostachyus* (susceptible wood) stakes and providing them to the termites in mounds.

Results: The female flower extract killed the entire worker termites at all levels of extraction, while no repellency effect of any part of the plant was observed. However, susceptible wood stakes treated with different polar extracts of *H. abyssinica* saw dust were significantly protected. Phytochemical investigation of the koso plant resulted in the isolation of one compound partially characterized on the basis of spectroscopic data.

Conclusion: Results from the toxicity and anti-feedant tests indicate that the tree is resistant to termites for it ha s toxic and anti-feedant bioactive compounds.

Biological control of *Callosobruchus theobromae* (L.) (Coleoptera: Bruchidae), a seed pest of edible legumes

D.R. Thakur, H.S. Banyal

Department of Biosciences, Himachal Pradesh University, Shimla, Himachal Pradesh, India

Introduction: Class Insecta comprising largest fascinating fauna of the animal kingdom. Beetles, the insect order Coleoptera, are dominant form of life on earth and one of every five living species is a beetle. Insects belonging to the family Bruchidae (Coleoptera) are commonly called “pulse weevils” or bruchids or “Dhoras”. These bruchids are cosmopolitan in distribution and cause serious loss to legumes both in fields and stores worth million of rupees every year. Therefore, an increased attention towards non-chemical methods of stored product protection is the need of modern agriculture system, because chemical control is often not affordable for sustainable farming, whereas the chemicals available are health hazards. Therefore, simpler, environmentally innocuous, self-regulatory, long lasting and relatively inexpensive mode to retain pest population below economic injury level is by inoculating the stores and fields by their natural enemies. Thus main aim of the present study is to catalogue entomophagous diversity and assess their potential in regulating active population of *Callosobruchus theobromae* (L.) (Coleoptera: Bruchidae), a seed pest of different legume commodities.

Materials and Methods: Pods of *Dolichos lab lab* infested with *C. theobromae* were collected from different localities of Punjab and Himachal Pradesh, India and carried to laboratory in wire mess cages. Pods infested with bruchids were also carrying different stages of parasitoid on host insect. Culture was maintained to observe emergence both of host and parasitoid insects. Adults of *U. femoralis* also emerged in the culture from the eggs of host insects, which were already parasitized in the field. Females of *U. femoralis* were allowed to lay eggs by supplying different age host eggs. Numbers of eggs laid by a female parasitoid were observed microscopically. Development of parasitoid egg inside the host egg and their emergence as adult were recorded carefully. Similarly larval parasitoid emerged were also maintained in culture by supplying different old aged larvae of host insect. Behaviour of parasitoids, mating, egg laying and developmental duration etc. were also recorded at ordinary environmental conditions.

Results: Egg endoparasitoid, *Uscana femoralis* (Trichogrammatidae: Hymenoptera), a eupelmid and two pteromalids species have been identified as idiobiont and koinobiont parasitoids of *C. theobromae*. Egg parasitoid deposited its eggs inside the host eggs by puncturing chorion through its ovipositor. Host eggs of 0-84 hours old were accepted for parasitization. Parasitoid eggs hatched inside the host eggs and further development was completed inside at the cost of host egg ooplasm. Adult parasitoids came out after 9.4 ± 0.46 days by making a circular cut in eggshell of host insect.

Gravid females of koinobiont hymenopteran parasitoids felt the presence of host larvae inside the seeds with the help of their antennae and laid eggs on or inside the developing larvae. It has been observed that parasitoids deposited their eggs when larvae were either in 2^{nd} or 3^{rd} instar stages. The parasitized larvae developed at the usual rate up to the last instar or pupal stage but their after development was paralysed by developing parasitoid. An exist hole was excavated in the mid dorsal region of the host body to come out of it. Thus parasitoid larvae while coming out killed the host larvae in the operation and used their remains as a mat for further development. Parasitoid larvae pupate outside the host body but were still inside the seed of *D. lab lab*. Adult parasitoid came out by cutting a small irregular but circular hole in testa of seed and life cycle was completed in 16-24 days.

Conclusion: Parasitoids are fast developing and having inherent capacity to complete their development more quickly at the cost of host organisms. Synchronization of life cycle with developing stages of host insects is an ecological adaptation of parasitoids to ensure continues food supply and developmental mat to sustain their growth and development from sufficiently bigger size and long developmental duration hosts which are available in the vicinity for a brief time period.

High egg laying capacity, destruction of host eggs before they hatch into larvae and low developmental duration place the idiobiont parasitoids in the category of potential biocontrolling agents. However, larval parasitoid killed the host larvae when sufficient damage was done to legume seeds, but their role as bio-controlling agent even at that stage cannot be ignored, because killing of bruchid pest at any stage may check its out break in next generation. Thus induction of these hymenopteran parasitoids in the '**Integrated Pest Management**' strategy of bruchid is advocated through this research.

Bulb mite biocontrol in lilies

Izabela Lesna[1], Maurice Sabelis[1], Cor Conijn[2]

[1]University of Amsterdam, Amsterdam, Netherlands, [2]Applied Plant Research, Lisse, Netherlands

Introduction: Bulb mites (*Rhizoglyphus robini*) are a serious pest of many ornamental bulb crops, in particular cultivated lilies. We investigated possibilities for biological control with the soil-dwelling predatory mite, *Hypoaspis aculeifer*.

Methods and Results: Biocontrol of bulb mites was applied in three phases of lily bulb cultivation:
Bulb propagation phase (storage rooms): Experiments were carried out in closed plastic bags filled with lily bulb scales and vermiculite, as is common practice in lily bulb propagation. The results showed that *H. aculeifer* was able to suppress its prey to very low densities, when released in a ratio of 1 : 20 prey.
Flower production phase (greenhouse): Experiments in the greenhouse soil (peat, sand) showed that in absence of predatory mites populations of the bulb mite, on lily bulbs increased, whereas the release of predatory mites caused the bulb mite populations to decrease, when released in a ratio of 1 : 2 prey.
Bulb growth phase (field): Experiments in lily fields showed suppression of population growth of the bulb mites when the initial predator-to-prey ratio varied between 1 : 1 and 3 : 1 prey.

Conclusions: Our results are among the very few showing the feasibility of biological control of a below-ground plant pest. The method to control bulb mites is now available for lily growers (e.g. under the trade-name ENTOMITE) and recommended especially for application in the lily bulb propagation phase. Implementation in practice has been achieved via successful trials at 6 selected lily farms in the Netherlands.

Potential of repellents in the control of tsetse and other disease vectors

Rajinder Saini, Ahmed Hassanali

icipe-African Insect Science for Food and Health, Nairobi, Kenya

Repellents for the control/management of disease vectors like tsetse are being identified at *icipe* from synthetic sources or from natural blends of un-preferred animals, which are common in tsetse habitats but not fed upon.

The synthetic tsetse repellent 2-methoxy-4-methylphenol can provide substantial protection to cattle either in 'push' mode or when used in conjunction with baited traps in 'push-pull' strategy. Most livestock keepers prefer the repellent technology compared to other tsetse and trypanosomiasis control options due to the technology's simplicity and mobility. Toxicological assessment of the repellent indicates no adverse effect on the health of exposed animals. A major constraint of the technology, however, at the moment is the repellent collar prototype, which breaks easily and needs to be commercially produced.

The repellent blend responsible for making waterbuck refractory to tsetse has been identified as pentanoic acid, geranlyacetone, guiaiacol and δ-octalactone. This blend was as effective as the 15 component waterbuck repellent blend (WRB) that contributes to refractiveness to these animals. The WRB not only reduces number of flies (*G. pallidipes*) coming to an ox (>75%) but also the feeding efficiency by >90% indicating that WRB is a potent repellent. Dispensers for WRB are being developed.

Preference for feeding at specific on-host sites by the vector of East Coast Fever, *Rhipicephalus appendiculatus,* has also opened up the possibility of manipulating the behaviour of this tick by 'push' and 'push-pull' tactics and suggests that investigations of feeding preferences of other vectors may similarly yield useful tools and tactics for their control.

Molecular phylogenetics of the Vespoidea

Erik Pilgrim, James Pitts, Carol von Dohlen

Utah State University, Logan, UT, United States

The 24,000+ described species of Vespoidea include many well-known stinging wasps, such as paper wasps and hornets (Vespidae), velvet ants (Mutillidae), spider wasps (Pompilidae), and ants (Formicidae). Members of this family exhibit compelling behaviors associated with prey capture, nest construction and provisioning, and parental care, including complex social behaviors. Indeed, behaviors in Vespoidea have been instrumental in developing evolutionary theories positing stepwise transitions from simple to complex. Such theories necessarily depend on an understanding of evolutionary relationships among taxa exhibiting the putative transitional states, yet phylogenetic proposals for Vespoidea are conflicting, with no well-supported consensus emerging from morphology. We collected molecular data from four nuclear genes (elongation factor-1 F2 copy, long-wavelength rhodopsin, wingless, and the D2-D3 regions of the 28S ribosomal RNA (~3000 bp in total)). We analyzed molecular data under both maximum-parsimony and Bayesian inference methods. Bayesian inference returned a well-resolved consensus with posterior probabilities of over 95% for most nodes. We used this topology as the best estimate of phylogeny at the family and subfamily levels. Notable departures of our phylogeny from previous estimates include: 1) paraphyly of Vespoidea resulting from the nesting of Apoidea within a lineage comprising Formicidae, Scoliidae, and two subfamilies of Bradynobaenidae; 2) paraphyly of Bradynobaenidae, Mutillidae, and Tiphiidae; 3) a sister relationship between Rhopalosomatidae and Vespidae, 4) Rhopalosomatidae + Vespidae as sister to all other vespoids/apoids.

The Buzz and the Beat(les): insect inspiration for music throughout the ages

Frank Turpin

Purdue University, West Lafayette, Indiana, United States

Ecologically and metaphorically insects seemingly are everywhere. Including music created by humans. Insects and their behavior have not only inspired music lyrics and song titles but also names for musical groups. Insect-inspired songs include children's chants, folksongs, rock and roll and classical music. The first insect-related song to top the popular music charts in the United States was "Glowworm" recorded by the Mills Brothers in 1952. "Glowworm" is an adaptation of a 1908 song from the German operetta "Lysistrata." Butterflies are the most common insects referenced in music but insects from most major orders have also managed occasionally to "strike a chord" with songwriters over the years.

Micro-hotspot determination and buffer-zone value in the core of a global hotspot (Cape Floristic Region)

Paul B.C. Grant, Michael J. Samways

University of Stellenbosch, Stellenbosch, Western Cape, South Africa

Introduction: The Kogelberg Biosphere Reserve (KBR) is a buffered, second-order biodiversity hotspot within a first-order global biodiversity hotspot, the Cape Floristic Region, South Africa. The extraordinarily rich flora is matched by an extremely rich dragonfly (Odonata) fauna, which are excellent indicators of habitat type and environmental quality.

Methods: Number of individuals and species of male dragonflies, in addition to environmental variables, were recorded during 15-min observation periods in quadrats within the core, buffer and transition zones of the (KBR).

Results: Using this micro-distributional data on this special but vagile faunal component, it is shown that the KBR consists of distinct and localized hotspots of many nationally rare, endemic and Red Listed species exclusively within its protected core.

Conclusion: Determination of these local third-order hotspots is of critical importance from a reserve management point of view. They are important in conservation planning, prioritization of areas for alien vegetation removal and environmental monitoring. Presence of buffer zones, as well as transition areas, surrounding the core play a vital role in buffering edge effects and maintaining core patch quality. While these buffer and transition areas do not support high numbers of species, nor any endemic species they never the less provide habitat heterogeneity, which inevitably leads to overall increased species richness. The inclusion of these buffer and transition zones into the biosphere reserve is therefore highly recommended to protect core habitat and to boost species richness through habitat heterogeneity.

Temperature-dependent development of insects simulated with INSIM for MatLab

Lia Hemerik[1], Egbert van Nes[2]

[1]Wageningen University, Biometris, Department of Mathematical and Statistical Methods, Wageningen, Netherlands, [2]Wageningen University, Department of Aquatic Ecology and Water Quality Management, Wageningen, Netherlands

Introduction: For many practical purposes it is useful to be able to predict the development of a pest insect. Insect development is strongly influenced by temperature. Each species ceases to grow below a certain threshold temperature. Duration of the development of egg, larval and pupal stages of insects are mostly reported at constant temperatures. Measures to eradicate pest species in agricultural practice can only be taken at the right time, if the occurrence during the year of stages is known. We introduce a new version of the insect simulation model INSIM, that calculates the development of insects under different temperature regimes.

Methods: In INSIM for MatLab the development of insects is simulated based on daily minimum and maximum temperatures together with tables of relative mortality, development time and its standard deviation at different temperatures. The threshold value of development should be denoted and , if more than one generation is simulated, reproduction of adults should be known at different temperatures.

Results: We present simulation outcomes for one insect species with known temperature dependent developmental rates.

Conclusions: Advantages of INSIM for MatLab are that (1) temperature-dependent development and survival are easily provided to the program, (2) insects with egg to egg development times >1 year can be simulated, (3) different developmental thresholds can be set for different insect stages, (4) INSIM for MatLab is faster, more flexible and more user friendly than the original programme and (5) it is freely available from the internet.

Recent progress in insect telemetry

Wolfram Kutsch

Dept. of Biology, Konstanz, Germany

Recent technical developments enable to accumulate data in freely moving insects, too. Animals can be equipped with telemetric devices that are small enough not to impede normal behaviour. Momentarily there are two major trends: 1) Pursueing of the free-ranging insect, 2) telemetric transmission of physiological data. The latter aspect is of great relevance to understand processes underlying behavioural performances. Initially, the electrical activities of major muscles have been recorded which are involved in free flight of locusts. Recently it became possible also to record the activity of specific sense organs. The approach to record the activity of neuronal elements instantaneously offers the option to describe the participation of selected CNS parts and their interaction with sensory inputs. It is obvious that this approach wil be more fruitful compared to studies analyzing restricted animals.

Odor-mediated parasitoid-host interaction: A model study

Marjolein Lof, Lia Hemerik, Maarten de Gee

Biometris, Department of Mathematical and Statistical Methods, Wageningen University, Wageningen, Netherlands

Introduction: Parasitoids are efficient natural enemies. Once they found a patch parasitism rates can be very high. Moreover, some parasitoids are able to distinguish odors that are associated with their hosts. Our study system is the *Drosophila melanogaster* based food web. Fruit flies of the species *D. melanogaster* feed and breed on ephemeral resources like fermenting fruit. Chemical attraction towards infochemicals like fermentation products and an aggregation pheromone emitted by recently mated females, play a directive role in the localization of these resources. Aggregation of *D. melanogaster* on resources is the result of this process. The fruit fly's natural enemy, the larval parasitoid *Leptopilina heterotoma* is known to use the same odours to find its host. We studied how the ability to use odors affects the interaction between a parasitoid and its host.

Methods: We developed a spatially explicit model that incorporates odours dispersion and population responses in a heterogeneous environment. The interaction between host and parasitoid was modelled by a Holling type II functional response.

Results: We investigate the costs and benefits of the use of infochemicals by studying fruit fly population numbers and larval mortality due to Allee effect, competition and parasitism.

Conclusions: There is a balance between the effects of the three aforementioned processes, where in some cases parasitism just might tip the host population into extinction.

Laurel wilt in the southeastern United States, a new disease caused by a fungal symbiont of *Xyleborus glabratus*

Robert J. Rabaglia[1], Stephen W. Fraedrich[2], Thomas C. Harrington[3], Albert E. Mayfield, III[4]

[1]USDA Forest Service, Forest health Protection, Arlington, Virginia, United States, [2]USDA Forest Service, Southern Research Station, Athens, Georgia, United States, [3]Department of Plant Pathology, Iowas State University, Ames, Iowa, United States, [4]Florida Department of Agriculture and Consumer Service, Division of Forestry, Gainesville, Florida, United States

A non-native ambrosia beetle, *Xyleborus glabratus*, was first found in North America in 2002 near Savannah, Georgia, United States. Extensive mortality of redbay, *Persea borbonia*, has occurred in coastal Georgia and South Carolina since 2003, and northeastern Florida since 2005. The redbay mortality is due to a vascular wilt disease caused by an undescribed *Raffaelea* sp. that is the fungal symbiont of *X. glabratus*. The *Raffaelea* sp. has been isolated consistently from the mycangia of *X. glabratus*, and wilted redbay trees infested with the beetle. Redbay seedlings and trees inoculated with the fungus succumbed to the wilt within 5 to 12 weeks. Field studies have shown greater than 90% redbay mortality in plots in Florida within two years of initial disease detection. Additional lab and field studies have found that other members of the Lauraceae including sassafras, spicebush, pondberry, pondspice, avocado and California bay laurel are susceptible to the wilt caused by the *Raffaelea* sp.

Lessons from IPM successes in managing invasive pest species of horticultural crops in Asia

Peter Aun-Chuan Ooi

AVRDC-The World Vegetable Center, Bangkok, Thailand

As horticulture science advances and international trade in fruits and vegetables increases, so is the risk of inadvertently introducing exotic insect pests into tropical Asia. Two invasive species of interest in Asia are *Plutella xylostella* (L.) from the warm Mediterranean and *Liriomyza huidobrensis* (Blanchard) from South America. The introduction of *Diadegma semiclausum* (Hellen) effectively managed *P. xylostella* but the culture of dependence on chemical control by the growers has fostered the need for an Integrated Pest Management (IPM) approach led to farmer education to understand how an exotic parasitoid works and how to conserve them.

Studies conducted in Thailand showed that *Coenosia exigua* Stein, an indigenous predator, adapted to feed on *L. huidobrensis* and through a programme of breeding this predator in the field, *L. huidobrensis* was brought under control.

A common factor in the successful IPM of both invasive species has been the need to educate farmers about the role of natural enemies. It was important to educate farmers about how *D. semiclausum* attacks and keep populations of *P. xylostella* in check. This was initially challenging as farmers often do not know about parasitoids. However, experiences in Vietnam and Thailand showed that crucifer farmers can learn and appreciate the efficacy of parasitoids and help conserve them thereby reducing dependence on chemical control. In the case of the IPM of *L. huidobrensis*, promoting breeding of *C. exigua* resulted in reduction of pest populations and farmers were educated to adapt this technique to their own field conditions.

A problematic termite genus

Johanna Darlington, Charles Cook, Giselle Walker

University of Cambridge, Cambridge, United Kingdom

The genus *Odontotermes* (Isoptera, Termitidae, Macrotermitinae) is a large genus, with very many nominal species in it. It is characterised by the presence of one large tooth near the middle of the left mandible in the soldier caste. The genus has never been revised for Africa, there are no published keys, and identification of species is often difficult.

W.V. Harris (unpubl.) divided them in two, based on the morphology of the soldier head. Species in his "latericius" group have piriform head capsules (= tapering anteriorly) and either no teeth, or one small weakly defined tooth, near the middle of the right mandible. All others have sub-rectangular heads and one large tooth near the middle of the right mandible, often as large as that on the left mandible

To resolve this dichotomy and define the species present in East Africa, we have produced a partial molecular phylogeny for *Odontotermes* based on mitochondrial DNA. This shows that the residual morphological group is monophyletic (except for one species) while the "latericius" group is not.

The type of fungus comb built by different species fits exactly with the phylogeny. The residual group all build fungus combs of the sponge type (or modifications of it), except for the one species mentioned above. It and all the "latericius" group species build fungus combs of the fragile laminar type. Thus it appears that the architecture of the fungus comb is a more accurate indicator of relatedness than soldier morphology.

A problematic termite genus

Johanna Darlington, Charles Cook, Giselle Walker

University of Cambridge, Cambridge, United Kingdom

The genus Odontotermes (Isoptera, Termitidae, Macrotermitinae) is a large genus, with very many nominal species in it. It is characterised by the presence of one large tooth near the middle of the left mandible in the soldier caste. The genus has never been revised for Africa, there are no published keys, and identification of species is often difficult.

W.V. Harris (unpubl.) divided them in two, based on the morphology of the soldier head. Species in his "latericius" group have piriform head capsules (= tapering anteriorly) and either no teeth, or one small weakly defined tooth, near the middle of the right mandible. All others have sub-rectangular heads and one large tooth near the middle of the right mandible, often as large as that on the left mandible

To resolve this dichotomy and define the species present in East Africa, we have produced a partial molecular phylogeny for Odontotermes based on mitochondrial DNA. This shows that the residual morphological group is monophyletic (except for one species) while the "latericius" group is not.

The type of fungus comb built by different species fits exactly with the phylogeny. The residual group all build fungus combs of the sponge type (or modifications of it), except for the one species mentioned above. It and all the "latericius" group species build fungus combs of the fragile laminar type. Thus it appears that the architecture of the fungus comb is a more accurate indicator of relatedness than soldier morphology.

Local adaptations of life history traits of a *Drosophila* parasitoid, *Leptopilina boulardi*

Joffrey Moiroux, Cécile Le Lann, Jean-Sébastien Pierre, Philippe Vernon, Joan van Baaren, Jacques van Alphen

[1]*University of Rennes 1, Rennes, France,* [2]*Leiden University, Leiden, Netherlands*

Introduction: Local climate is an important source of selection on life history traits. Clinal variation in life history traits on a continental scale has been well documented for a number of insect species, but local adaptation to climate has not often been investigated. We have studied local adaptations to climate of a parasitoid, focusing on early reproduction.

Methods: Four populations of *Leptopilina boulardi,* a pro-ovogenic *Drosophila* parasitoid, originating from contrasting climates were sampled in the North of Iran, and cultured under standard conditions. We compared several life history traits of females (size, early reproduction, lipids content, activity, development time), and associated trade-offs.

Results: Discriminant analysis revealed that the four populations differed in one or more of the measured traits. Under very dry and hot desert conditions, large females with a rapid development are found - in contrast to the trade-off usually observed - whereas in the humid warm climate of the Caspian coast, females are smaller and invest more in early reproduction. We predicted that host distribution, which depends on climate, would explain the observed patterns better than abiotic climate itself. *Drosophila* hosts are more abundant during a longer season in the region with a humid climate allowing the parasitoids there to spend less energy and time in patch finding in comparison to wasps from desert populations. This results in selection for early reproduction traded off against a body size and longevity. In the hot and dry climate, a larger body size and smaller initial egg load allow dispersal and facilitate patch finding, while a short development time allows better tracking of the host populations that go through bust and boom periods. In addition a relatively high water content provides them with some protection against dessiccation.

Conclusions: Climate can exert a strong selection pressure on a local-scale for parasitoids, via spatial or temporal distribution of hosts.

Susceptibility of *Anopheles* mosquito larvae to some selected entomopathogenic fungi in the tropical climate of Nigeria

Funmilola Oluyemi Omoya, F. A. Akinyosoye, Bolanle Boboya

Federal University of Technology, Akure, Nigeria

Introduction: Malaria, a mosquito-borne and a potentially deadly disease in tropical African countries as well as the increasing level of insecticide resistance, has attained a global concern/attention. The ineffectiveness of chemical pesticides so far has lead to an intensive search for new control measures. Three types of entomopathogenic fungi were used in order to determine the larvicidal activity.

Methods: The susceptibility of *Anopheles* mosquito larvae *Varicosporium elodae, Trinacrium substile* and *Articulospora inflata* were isolated from the cricket and grasshopper species and investigated under laboratory conditions. The larvicidal activities on the anopheles mosquito larvae sampled from Akure, Western Nigeria, were analysed and observed for 72 h using different levels of concentrations, ranging from 1.1×10^5 spore/ml to 6.3×10^5 spore/ml on the third instars larvae of *Anopheles arabiensis.*

Results: Different values of mortality rates were observed among the investigated larvae with a range of 50%. *V.elodae* displayed the highest mortality rate of 80%, *T. substile* 50% and *A. inflata* 30% on the larvae of *Anopheles arabiensis.*

Conclusion: Among the fungi used in this study the larvicidal activity of *Varicosporium elodea* was most pronounced. This clearly indicates that it can be used as a bio-control agent for *Anopheles arabiensis,* thereby affording minimum disturbance within the tropical and temperate climate regions as compared to the chemical pesticides.

Modelling the attractivity of colours for aphids

Thomas Döring, Jim Hardie

Imperial College London, Ascot, Berkshire, United Kingdom

Introduction: In aphids and other Hemiptera, colours play an important role in the process of host finding. However, the mechanisms underlying the responses of these insects to colours in the field are still not fully understood.

Methods: Water traps (14 cm diameter) of 140 different colours (hues ranging from blue to green to yellow, with varied brightness) were set out in the field in spring 2007 in a completely randomised design. All caught aphids were identified to species level. Trap colours were measured with a spectrophotometer. Using information from previous electrophysiological work, the 'attractivity' of trap colours was modelled with two input variables, the photon catch G that a given trap spectrum produced in a green receptor (with a peak sensitivity at 530 nm), and B, the respective photon catch for a blue receptor peaking at 470 nm. The model was then applied to spectra of leaf colours to predict their relative attractivity for aphids.

Results: The trap catch, totalling 17383 winged aphids, was dominated by *Brevicoryne brassicae* and *Myzus persicae*. The best model for the attractivity y (ranging from 0 to 1) had the form $y=a*\log(G/B)+b$, for $G>B$, and $y=b$ else, with $a=1.92\pm0.055$ and $b=0.019\pm0.001$ (mean ± s.e., $r^2=0.89$, $n=140$). Red leaves were predicted to be less attractive than green leaves.

Conclusions: The model can accurately predict the response of aphids to coloured surfaces. The selection of appropriate non-attractive leaf colours may be used as a tool for aphid control.

Genomics and post-genomics of parasitoids

John Werren

University of Rochester, Rochester, NY, United States

The three species of *Nasonia* are the first parasitic hymenoptera to have their genomes sequenced. Here I describe the status of the genome project and its applications. The genome information greatly increases utility of *Nasonia* as a model genetic system, but more importantly will greatly enhance advancement of genetic and genomic studies of parasitic hymenoptera. Comparisons with honey bee and other insects reveal possible hymenopteran specific and chalcidoid specific gene sets. RNAi has been developed in *Nasonia*, providing a means to investigate function of these genes. Opportunities now exist to identify parasitoid genes involved in host preference, diapause, mate discrimination, pathogen resistance, sex ratio control, parthenogenesis, and many others of biological importance and implications to biological control. The possibility of directed genetic modification to produce “domesticated” parasitoids is no longer just an abstraction. In the long-term, such developments could reduce human dependence on chemical pesticides, with significant positive implications to human health and the environment. Therefore, research efforts into the genetics and genomics of parasitoids should be expanded and vigorously pursued.

Extinction debt of vascular plants and butterflies in five European countries

Jochen Krauss[1], Riccardo Bommarco[2], Ingolf Steffan-Dewenter[1]

[1]University of Bayreuth, Department of Animal Ecology I, Population Ecology, Bayreuth, Germany, [2]Swedish University of Agricultural Sciences, Department of Ecology, Uppsala, Sweden

Introduction: Time lags in species extinctions (extinction debt) are a rarely recognised threat for long-term species survival in fragmented habitats. Abandonment of extensive management practices and agricultural intensification lead to enormous landcover changes and loss of natural or semi-natural habitats within the last 50 years in Europe. However, especially long living species might be delayed in their extinction. Our project aimed to reveal the impact of historic habitat loss on current species richness and potential future extinction risks of vascular plants and butterflies in five European countries.

Methods: In the EU project COCONUT (Understanding effects of land use changes on ecosystems to halt loss of biodiversity, www.coconut-project.net) we recorded vascular plant and butterfly species richness in 30 fragmented semi-natural grassland sites in Finland, Sweden, Estonia, Germany and Spain. Within a 2km buffer around each study site we quantified actual habitat loss using current and historic aerial photographs. Species were categorized with respect to habitat specialization and dispersal ability to analyse trait-related differences.

Results: We recorded 180 – 370 vascular plant species and 50 – 80 butterfly species in the five countries. Historical habitat loss was 36 ± 4 % (range: 4 – 78 %) for Finland und is currently calculated for the other countries. The data will allow us to calculate expected future species loss due to historical land use change.

Conclusions: Time delayed extinction events might cause a severe reduction in species richness, even if conservation strategies manage to keep remaining habitat fragments at a constant quality.

The Offshore Pest Information System – early pest warning for US borders

Ronald Stinner, Karl Suiter

NSF Center for IPM, NCSU, Raleigh, NC, United States

International trade is rapidly expanding; the relevance of international borders is diminishing. With that expansion comes the risk of the spread of exotic plant pests. The Offshore Pest Information System (OPIS) is a secure, structured, risk-focused process designed to collect, synthesize/analyze, communicate and utilize relevant offshore pest information by USDA/APHIS officials. The system was developed cooperatively by USDA/APHIS and the NSF Center for IPM and is linked to other relevant sources of pest information.

Homeland Security inspectors at ports of entry need to be aware of pest situations abroad on a daily basis in order to focus their inspection activities. State plant regulatory agencies also need similar information for their pest surveys. APHIS risk assessors and trade managers need to know what pest threats exist offshore as they evaluate potential trade opportunities with countries that may harbor pests of concern to the USA. Producers and importers need current pest incidence information before they negotiate sale contracts to ensure that the products they purchase from Offshore will not be infested with plant pests and suffer quality loss or seizure upon arrival due to infestation/infection.

The timely collection, synthesis and communication of offshore pest information provides US safeguarding personnel with the tools necessary to focus their activities based on commodity and origin-based risk posed in a dynamically changing world.

This paper describes the technical aspects of OPIS, including how reporting is handled electronically, data sources, linkages with other database systems, and security issues involved.

Impacts of environmental alterations on the population dynamics and the gregarisation of the red locust in the Sofia basin (Madagascar)

Alex Franc[1], Gérard Duvallet[2], Annelise Tran[3], Valeria Soti[3], Jean-François Duranton[1]

[1]Locust Ecology & Control research unit, Agricultural Research Centre for International Development (CIRAD), Montpellier, France, [2]Centre for functional and evolution ecology, Paul Valery University, Montpellier, France, [3]Epidemiology Research Unit, CIRAD, Montpellier, France

The red locust *Nomadacris septemfasciata* (Serville, 1838) *Orthoptera*: *Acrididae* is found in southern Africa and on islands in the Indian Ocean. Although responsible for plagues in southern Africa, only a few local outbreaks have been reported in Madagascar. Yet, in 2002, locusts became gregarious in the Sofia basin, i.e., swarms and larval bands threatened the two main rice-producing basins of the country. The overall scope of this study is to explain this new gregarisation of the red locust in Madagascar.

Factors controlling the locust population dynamics were determined during a four year field monitoring program (2003 to 2007). The ecological requirements of this locust were assessed during the different periods of its life cycle. The evolution of the locust habitat was mapped using remotely sensed data (Spot satellite).

Our results show a close connection between red locust ecological requirements and environmental modification in the Sofia basin. First, the locust potential of each habitat at the eco-regional and macro-regional scale was quantified. Second, these habitats were mapped in 1986 and 2004. Satellite images revealed extensive deforestation thus providing new favourable breeding habitats for locusts. This environmental alteration also opened migration pathways between complementary ecological areas. The combination of both these factors allowed the red locust gregarisation to be possible. A red locust forecasting system is outlined within the scope of a preventive control strategy.

Arthropod Aloft: The new science of insect flight

Robert Dudley

University of California, Berkeley, CA, United States

Flying insects represent an abundant and diverse set of design solutions to the common biomechanical problem of creating and controlling aerodynamic forces. Hovering insects are stable yet highly maneuverable, long-distance migrants fly and navigate over thousands of kilometers, and major ecological themes of the terrestrial biosphere, such as pollination and tropical biodiversity, derive from adaptive radiations of the pterygote insects. Recent technological advances, ranging from quantitative flow visualization and unsteady force measurements on flapping wings to remote telemetry of free-flying insects, have substantially enhanced our abilities to capture and describe varied features of the flight envelope. Neurophysiological studies of sensory mechanisms and associated locomotor output have increasingly revealed sophisticated, integrated pathways for flight control. Ecological, allometric, and phylogenetic studies of aerodynamic performance, in turn, permit elucidation of the broader significance of particular flight behaviors and capacities. Although the insect analogue of *Archaeopteryx* has yet to be unearthed, recent demonstrations of controlled aerial behavior in the absence of wings have suggested new evolutionary trajectories for the initial origin and functional utility of protowings. Ongoing aerodynamic studies of flight performance in the modern insect fauna are suggesting enviable and perhaps even unattainable design specifications for the emerging technology of microair vehicles. This symposium presents diverse experimental studies within the exciting and technologically infused science of insect flight.

Some determinants of insect species distributions across spatial scales

Jorge Soberon, Joaquin Hortal

University of Kansas, Lawrence, Kansas, United States

There are many factors that affect the distribution of a species, and they act with different strengths at different spatial and temporal scales. At coarse scales (large extent, low resolution), bioclimatic modeling has proven to be very predictive of the broad features of distributions of many species. Physiological tolerance, movement capacities and historical factors are predictors of these broad features, and can be statistically modeled using the suites of techniques known as “Ecological Niche Modeling”. However, the fine grained details of distributions are determined by different processes, related to habitat selection and availability, species interactions, and resource consumption. In this presentation I will discuss one conceptual approach to integrate several processes acting at different scales. I will highlight some theoretical and practical problems to an integrative, multiscale estimation of species distributions. Using the example of *Baronia brevicornis* (Lepidoptera: Papilionidae) I will illustrate the possibilities and limitations of the method.

Role and evolution of viral cystatins in an insect host-parasitoid interaction

Céline Serbielle[1], Shafinaz Chowdhury[2], Jean-Michel Drezen[1], Elisabeth Huguet[1]

[1]Institut de Recherche sur la Biologie de l'Insecte, Université François Rabelais, Tours, France, [2]National Research Council Canada, Biotechnology Research Institute, Montreal, Canada

Introduction: Parasitoid wasps have developed amazing strategies to parasitize their insect hosts. One of the most effective involves the domestication of polydnaviruses which are injected in the host. Expression of viral genes inside the insect host alters its immune response and developmental program resulting in the emergence of adult parasitoid wasps. We are interested in characterizing the role and evolution in the host-parasitoid interaction of a viral gene family encoding cystatins which are inhibitors of cysteine proteases.

Methods: We performed functional studies which consisted in determining expression levels and biochemical activity of viral cystatins. To understand the constraints imposed on polydnavirus evolution, we measured selection pressures acting on cystatin genes. By homology modelling we obtained the 3D structure of a viral cystatin which enabled us to precisely map selected sites.

Results: Viral cystatins are expressed at an early stage and reach very high levels of expression during parasitism. The purification of a recombinant form of one viral cystatin (cystatin1) revealed that this cystatin is functional having potent inhibitory activity towards human and insect cysteine proteases. Furthermore, we demonstrate strong adaptive evolution acting on cystatin genes. The model of the 3D structure of cystatin1 provides a framework to position the positively selected residues and reveals that they are situated in key sites which are important for the interaction with target proteases.

Conclusions: The combination of physiological and evolutionary approaches emphasizes the potential role of cystatins as pathogenic factors and suggests that cystatins coevolve with host cysteine proteases.

CO_2 as a floral scent: When "primary" metabolites have "secondary" functions

Robert Raguso

Cornell University, Ithaca, NY, United States

Introduction: Fragrance plays diverse roles in plant-pollinator interactions, and its information content depends upon the sensory milieu in which it is perceived. Flowers emit CO_2 in different contexts, including thermogenesis. Could CO_2 function as a pollinator attractant? CO_2 was studied in rewarding and deceptive flowers with phylogenetic and allometric controls.

Methods: CO_2 was measured with a LI-COR 840 CO_2/H_2O analyzer and normalized per floral mass from hawkmoth-pollinated *Oenothera, Nicotiana, Ipomoea* and *Mirabilis* species and their bird-, bee- and self-pollinated relatives. Similar data were collected from *Asimina* and *Trillium* species with red, fermented-smelling flowers and their white-flowered, non-sapromyophilous relatives. Flower-naïve hawkmoths were tested in a laminar flow wind tunnel using artificial, scented flowers with or without above-ambient CO_2 emissions.

Results: Hawkmoth pollinated flowers from all lineages opened explosively, emitting a burst of CO_2 that persisted for the first hour after anthesis, when nectar was available. *Manduca sexta* moths utilized CO_2 as a redundant scent for tracking flowers from a distance, but preferred flowers with scent and CO_2 to those with scent alone in choice assays. Red-flowered *Asimina* and *Trillium* species had no nectar but emitted yeasty or carrion odors; high CO_2 emissions from these flowers may complement visual and olfactory signals mimicking microbial decay. White-flowered *Asimina* and *Trillium* species emitted less floral CO_2 than their deceptive relatives.

Conclusions: Floral CO_2 is prevalent in nectar-rich or deceptive flowers and should be sought in those harboring nectar yeasts.

Reliability, quality and cost: The basic challenges of commercial natural enemy production

Karel J.F. Bolckmans

Koppert BV, Berkel en Rodenrijs, Netherlands

The reliability and cost-effectiveness of production techniques for natural enemies and the quality of the end-product are important for both the farmer (customer) as well as for the producer of natural enemies.

Farmers need to have access to sufficient numbers of high quality natural enemies at the right moment and at an acceptable cost. If the natural enemies are of high quality, lower numbers of natural enemies will be needed to achieve good pest control, and the cost to the grower will therefore be lower.

Reliable and cost-effective production systems and supplying high quality products can give a producer a very important competitive advantage in the market. Substantially decreasing the cost of natural enemies allows entering into new crops and other geographic areas. The use of invertebrate biological control agents for augmentative biological control is expanding rapidly. As the opportunities for biological control increase also the challenges and economic risks for producers of natural enemies increase. Different approaches are needed for mass-rearing large quantities of beneficial insects and mites.

Reliability, quality and cost are key challenges of all manufacturers of goods, not only for producers of beneficial insects and mites. Organizing and rethinking current production practices around these 3 key challenges will allow the biological control industry to further professionalize and to prepare for the future.

Ecosocial implications of cattle health improvement based on adaptive management of arthropod transmitted diseases

Gianni Gilioli[1], Getachew Tikubet[2], Andrea Sciarretta[3], Pasquale Trematerra[3], Andrew Paul Gutierrez[4], Johann Baumgärtner[5]

[1]Università Mediterranea di Reggio Calabria, Dipartimento di Gestione dei Sistemi Agrari e Forestali, Reggio Calabria, Italy, [2]ICIPE, Regional Office Addis Ababa, Addis Ababa, Ethiopia, [3]Università degli Studi del Molise, Dipartimento di Scienze Animali, Vegetali e dell'Ambiente, Campobasso, Italy, [4]University of California Berkeley, Department of Environmental Science, Policy and Management, Berkeley, California, United States, [5]Università degli Studi di Milano, Istituto di Entomologia agraria, Milano, Italy

Introduction: Bovine trypanosomiasis is a key constraint in the development of many East African agro-pastoral communities. Suppression of tsetse fly (*Glossina* spp.) and control of trypanosomiasis were carried out in a community-based project at Luke, South-western Ethiopia, from 1995 to 2006.

Methods: The control system relied primarily on drug administration and tsetse vector suppression based on odour baited trap technology. Geostatistical analysis was used in trap deployment and precision-target vector management operations. Impact was assessed by monitoring vector abundance and disease prevalence and by survey based changes in cattle husbandry, land management and community socioeconomics. A bioeconomic model was used to interpret ecological, economic and social changes.

Results: On the positive side, tsetse populations fell to very low levels, disease incidence decreased to about 10% greatly increasing cattle and oxen densities and productivity, oxen availability increased land cultivation, and revenue increased allowing purchases of more cattle and the establishment of a school. Negative effects include: tsetse control will lead to overstocking and intensified agriculture and land degradation that will require land use planning to achieve sustainability. The bioeconomic model predicts the positive and negative outcomes and provides bio-economic decision support to stakeholders in interpretative dimensions.

Conclusions: Trypanosomiasis control is possible by implementing available technology in an adaptive management framework. However, new social structures and responses are required to cope with the eco-social changes on system sustainability and resilience.

Assessing the risk posed by the invasion of *Harmonia axyridis* on European ladybirds. 2. Consequence of encounter

Remy Ware[1], Michael Majerus[1], Renate Zindel[2], Rene Eschen[2], Marc Kenis[2]

[1]Department of Genetics, University of Cambridge, Cambridge, United Kingdom, [2]CABI Europe-Switzerland, Delémont, Switzerland

Introduction: The risk posed to native European coccinellids by *Harmonia axyridis* can be considered in terms of the likelihood of encounter between *H. axyridis* and a given species, and the consequence of this encounter, which could be competition or predation. The likelihood of encounter was reviewed in the previous presentation. Here we assess the impact of competition, based on published information on the dietary requirements of different species, and the impact of predation, based on field observations and empirical laboratory studies.

Methods: The impact of competition between *H. axyridis* and a given European species is assigned to a numerical scale based on the degree of dietary overlap between them, and the ability of a species to revert to specialist habitats following the encroachment of a competitor. The impact of predation by *H. axyridis* is also applied to a quantitative scale, which takes into account any chemical, physical and behavioural defensive strategies. Where possible, we utilise our own experimental data on predatory interactions in this assessment, but for species where such data is lacking, we make informed extrapolations based on field observations and published information. For each species, the product of likelihood of encounter with *H. axyridis*, and the impact of competition is calculated, and added to the product of likelihood of encounter and impact of predation. This gives a total risk index score which can be compared across species.

Results: From this assessment, *Adalia 2-punctata* emerges as the species most at risk from the establishment of *H. axyridis*. This is attributable to its high degree of habitat overlap, its shared diet, its suspected inability to shift to an optimal habitat, and the vulnerability of its immature stages to intraguild predation. In contrast, the host-plant restricted phytophage *Epilachna argus* is considered least at risk due to its unusual dietary and host plant requirements.

Conclusions: This procedure has allowed us to identify species that may be particularly threatened by *H. axyridis*, and thereby provides the impetus for conservation strategies. In addition, it raises issues over the adequacy of previous risk assessment procedures when introducing species outside their native range for the purpose of biological control.

Indirect interactions: Competition among fungal mutualists from sympatric and allopatric bark beetle populations

Thomas Seth Davis[1], Richard Hofstetter[1], Kier Klepzig[2]

[1]Northern Arizona University, Flagstaff, Arizona, United States, [2]USDA Forest Service, Pineville, Louisiana, United States

Introduction: The role of interspecific interactions can have implications for population dynamics, endemic-epidemic transitions and plant-insect interactions. Several *Dendroctonus* species maintain strong relationships with mutualist fungi, which they transport between hosts in mycangia and developing larvae feed upon. Mycangial fungi play an important role in mediating the fitness of emerging adult beetles by providing nutritional supplement to larvae, interactions among mutualist fungi in the gallery environment of host trees may have consequences for beetle population dynamics.

Methods: We isolated 20 strains of mycangial fungi from two bark beetle species (*D. frontalis* and *D. brevicomis*) in Arizona, 9 from *D. frontalis* in Mississippi, and 10 from *D. brevicomis* in California. We performed a total of 1144 pairwise competition assays among sympatric fungi (Arizona) and between allopatric fungi (Arizona, Mississippi, and California). We also determined the rate of growth for all fungal strains at six temperatures. We also report the results of replacement series experiment of beetles in live trees.

Results and Conclusions: We demonstrate that fungal performance varies with respect to evolutionary history, beetle host, and fungal species. Fungal species with an evolutionary history of competition were the strongest competitors overall. We used temperature and competitive performance both independently and in combination. Results in the discriminate function analysis were strongest when both environmental (temperature) and ecological (competitions) interactions were included. Also, our analysis is the first to demonstrate that interactions among fungal species can be used to delineate competitive communities in ordination space.

Indirect interactions: Competition among fungal mutualists from sympatric and allopatric bark beetle populations

Genetic variability of *Ixodes ricinus* ticks and diversity in prevalence and genospecies of *Borrelia burgdorferi s. l.* in Lithuania and Norway

Algimantas Paulauskas[1], Daiva Ambrasiene[1], Jana Radzijevskaja[1], 0lav Rosef[2], Jurga Turcinaviciene[3]

[1]Department of Biology, Vytautas Magnus University, Kaunas, Lithuania, [2]Department of Environmental and Health Studies, Telemark University College, Bø i Telemark, Norway, [3]Department of Zoology, Vilnius University, Vilnius, Lithuania

Introduction: In the last decade northward expansion and density of *I. ricinus* tick in Fennoscandia was increased. Genetic variability of ticks and the prevalence of *B. burgdorferi* s.l and Borrelia genospecies in *I. ricinus* ticks were analyzed in different biotopes of Lithuania and Norway.

Methods: RAPD markers were used to measure the genetic diversity of ticks collected from 6 populations. Ticks collected in different landscapes were tested for the presence of the *Borrelia* using *fla* and *OspA* genes of *B. burgdorferi* s.l. PCR.

Results: The high level of diversity of RAPD markers in *I. ricinus* populations was detected. The number of fragments and the amount of intraspecies polymorphism varied between the primers, the sites and the countries. The overall prevalence of *Borrelia* infection was 14% in Lithuania, and 5.6% in Norway. The highest prevalence of *Borrelia* (20%; 21.2%) was found in deciduous and mixed forests; a lower prevalence (7.4%) in pine forests and in the coastal zone coastal (4.7%), and the least prevalence (2.4%; 0.6% in Lithuania and Norway, accordingly) in grasslands. In Lithuania, *B. afzelii* genotype was found in 76% of infected ticks, *B.garinii* in 10%, and *B. burgdorferi* s.s. in 7%. Double infections were observed in 1% of infected ticks. *B. afzelii* was found in 59.4%, *B.garinii* - in 18.8%, and *B. burgdorferi* s.s. - in 9.4% of Norwegian infected ticks.

Conclusions: The occurring genetic variation in ticks populations might be explained by aggregation of migratory birds in places situated on the main birds migratory rout during the spring and the autumn.

The causes and consequences of multiple mating in the social wasp *Vespula maculifrons*

Michael Goodisman[1], Jennifer Kovacs[1], Eric Hoffman[2]

[1]Georgia Institute of Technology, Atlanta, Georgia, United States, [2]University of Central Florida, Orlando, Florida, United States

Introduction: The evolution of insect societies depended on high relatedness among interacting group members. Thus it is surprising that some social insect queens mate with multiple males (polyandry), because polyandry decreases relatedness among colony members relative to cases where the queen mates singly. The fact that some social insect queens are polyandrous suggests that multiple mating may provide benefits that counteract the perceived relatedness costs. However, few studies have demonstrated benefits to polyandry in social insect species.

Methods: We used molecular genetic markers to dissect the breeding system of the social wasp *V. maculifrons*. We assessed colony fitness by counting the number worker and queen cells that colonies produced. Statistical methods were then used to determine if levels of polyandry were associated with increased production of cells within colonies.

Results: Our results indicated that *V. maculifrons* colonies were always headed by a single, multiply-mated queen. We also found that queen mate number was directly, strongly, and significantly correlated with the number of queen cells produced by colonies. Because *V. maculifrons* queens are necessarily reared in queen cells, our results demonstrated that queens that mated with many males headed colonies capable of producing many new queens.

Conclusions: Our data revealed that multiple mating by *V. maculifrons* queens may be associated with increased reproductive success. Thus this research provides a rare example of an association between multiple mating and fitness in a natural social insect population and helps explain why some social insect queens mate multiply.

Effects of adjacent pasture and forest land uses on leafhoppers vectors of *Xylella fastidiosa*, causal agent of Crespera disease in coffee

Nilsa Bosque-Perez[1], Mariangie Ramos[2]

[1]Department of Plant, Soil and Entomological Sciences, University of Idaho, Moscow, ID, United States, [2]Joint PhD Program, University of Idaho and Tropical Agricultural Research and Higher Education Center (CATIE), Turrialba, Costa Rica

Introduction: Leafhoppers in the subfamily Cicadellinae are potential vectors of *Xylella fastidiosa*, the bacterial causal agent of Crespera disease of coffee in Costa Rica. Cicadellinid leafhoppers (sharpshooters) are generalist xylem-sap feeders, and are known to move between habitat types in the landscape, potentially seeking complementary resources. The effects of adjacent forest and pasture land uses on coffee leafhopper communities and *X. fastidiosa* presence were studied in Turrialba, Costa Rica.

Methods: Leafhoppers were sampled bimonthly in 2006 in three conventional coffee farms. Migration Malaise traps were placed in the center of the farm and along farm edges neighboring forest and pasture. Yellow sticky cards were placed at the same farm locations, in addition to adjacent forest fragments and pasture lands. In each farm, eight coffee plants per site (edge with forest, edge with pasture, and farm center) were collected and tested for *X. fastidiosa* presence.

Results: Sixty-one leafhopper species were collected. Leafhopper communities in coffee farms had greater similarity to pasture than to forest communities. Leafhopper abundance was higher at the farm edge with pasture than with forest. Leafhoppers moved equally to pasture and coffee at the farm edge with pasture, but unidirectionally to coffee from forest. Leafhopper patterns of abundance could not be related to *X. fastidiosa* presence.

Conclusions: Leafhoppers appear to use complementary pasture and coffee resources. Forests appear to be sources of leafhoppers in these landscapes.

Multiple lines of evidence reveal the earliest radiations of true flies (Insecta: Diptera)

Brian Wiegmann

North Carolina State University, Raleigh NC, United States

Introduction: Resolution of the earliest lineages of true flies (Diptera) is a major goal of the US NSF-funded Assembling the Tree of Life project, FLYTREE. This international collaborative project has assembled data from nuclear and mitochondrial genomes, morphology, and the fossil record to reconstruct the history of diversification within this major insect order.

Methods: Fourteen nuclear genes, full mitochondrial genomes, and over 400 morphological characters from all life stages were assembled for a comprehensive sample of dipteran taxa. Parsimony, Bayesian, and maximum likelihood methods are used to estimate relationships. Nucleotide data, together with key fossils, are used to estimate divergence times for dipteran infraorders and superfamilial clades.

Results: Diptera originated in the Permian approximately 270 mya and all of the major extant dipteran infraorders originated before 250 mya. This rapid proliferation of fly clades, morphologies, and life histories has made it difficult to establish a stable classification. Individual data types yield radically different scenarios for the pattern and timing fly diversification. Combining multiple genes, genomic data, and morphology provides the clearest picture to date of this rapid expansion of fly lineages. We compare alternative statistical methods for investigating the strength of support for hypotheses based on individual genes or data partitions.

Conclusions: The earliest lineages of Diptera radiated in parallel in aquatic and semi aquatic habitats followed by impressive later expansions of lineages that use flowering plants as primary or secondary food resources.

The roles of PKC in mediating 20E-induced gene expression in salivary glands of Drosophila melanogaster

Qisheng Song, Yaning Sun, Shiheng An

University of Missouri, Columbia, Missouri, United States

Ecdysone receptor (EcR) and its heterodimeric partner, Ultraspiracle protein (USP), are nuclear receptors that mediate the action of the insect molting hormone, 20-hydroxyecdysone (20E). There is evidence that the activity of both receptors is affected by phosphorylation. Using molecular and proteomic approaches, we have shown that protein kinase C (PKC) activity is necessary for mediating 20E-induced expression of a specific set of genes, including 11 novel ones, and is also responsible for the intracellular localization of EcR and USP in larval salivary glands of *Drosophila melanogaster*. Inhibition of PKC activity resulted in alternation of EcR and USP subcellular localization and reduced 20E-dependent transcriptional activity of some of the newly identified genes rapidly, raising the possibility that these are direct gene targets of EcR and USP. We also investigated the effect of RNAi disruption of PKC isoforms on 20E-induced gene expression in the larval salivary glands. The composite data suggest that PKC plays an important role in mediating 20E-induced gene expression.

Effects of local and landscape context on leafhopper communities in coffee farms of Costa Rica

Mariangie Ramos[1], Nilsa Bosque-Perez[2], Luko Hilje[3], Sanford Eigenbrode[2]

[1]Joint Ph.D. Program, University of Idaho and Tropical Agricultural Research and Higher Education Center, Moscow, ID, United States, [2]Department of Plant, Soil and Entomological Sciences, University of Idaho, Moscow, ID, United States, [3]Department of Agriculture and Agroforestry, Tropical Agricultural Research and Higher Education Center (CATIE), Turrialba, Costa Rica

Introduction: Cicadellinid leafhoppers are potential vectors of *Xylella fastidiosa*, the bacterial causal agent of coffee Crespera disease. Little is known about *X. fastidiosa* vector ecology in Costa Rica. We examined effects of local (shade, management, weed cover) and landscape (surrounding area in coffee, forest, pastures, and fallows) factors on leafhopper abundance and richness in coffee agroecosystems.

Methods: We monitored leafhoppers seven times from 2005 to 2006 using yellow sticky traps in four farm treatments: a) organic two-strata systems with *Erythrina poeppigiana* shade trees, b) organic three-strata with *Cordia alliodora-Musa-E. poeppigiana* shade trees, c) conventional two-strata with *E. poeppigiana* shade trees, and d) conventional three-strata with *C. alliodora-Musa-E. poeppigiana* shade trees. Shade percentage and weed cover data were collected during each sampling. Landscape context was characterized by determining land use (coffee, pasture, forest, and fallow) percentage within two different radii (100 and 500m) around each farm.

Results: Principal Components Analysis demonstrated different leafhopper species assemblages were associated with each farm treatment, but no significant differences in overall leafhopper abundance or species richness were observed among treatments. However, some leafhopper species were significantly more abundant in conventional two-strata systems than in other systems examined. Shade was a key local variable, negatively affecting leafhopper abundance. Proportion of land in fallow was positively correlated with leafhopper species richness at 100m and 500m radii, but other land cover types had no effect.

Conclusions Leafhopper assemblages and some individual species differed among coffee shade systems, but landscape variables had a weak effect on overall leafhopper abundance.

Do the crazy-ants *Paratrechina fulva* Mayr, 1862 (Hymenoptera: Formicidae) control the passage of foods inside their bodies?

Carlos Massuretti de Jesus, Daniel Russ Solis, Odair Correa Bueno

Departamento de Biologia, Centro de Estudos de Insetos Sociais, Universidade Estadual Paulista – UNESP, Rio Claro, São Paulo, Brazil

Introduction: Over evolution ants developed distinct strategies to find, consume and use food resources. Studies about feeding in ants are important as they allow us to identify where storage, digestion and absorption of foods occur in their body. The present investigation aimed at analyzing the passage of food through the digestive system of the crazy-ant *Paratrechina fulva*.

Methods: Water-soluble dye Rodamin B and the lipid-soluble dye Sudan Black were added to 3 different diets as tracers. The solid food was prepared by mixing equal parts of dehydrated bovine liver, Pullman® sponge-cake, peanut oil with Sudan Black (0.1%) and aqueous honey solution (1:1) with Rodamin B (0.2%). Two liquid foods were also used: aqueous honey solution (1:1) with Rodamin B (0.2%), and peanut oil with Sudan Black (0.1%). The foods were then offered to laboratory colonies of crazy-ants. We collected 80 workers which had ingested food, and past set periods of time they were dissected under a stereomicroscope. The ingested quantity of tracers was measured in the infrabucal pocket, postpharingeal glands, crop and ventriculus of each ant.

Results: Solid foods were retained in the infrabucal pockets and were later eliminated as small pellets; only liquid substances were actually ingested. Water-soluble tracers were found in infrabucal pockets, crops and ventriculi, while lipid-soluble tracers were found in infrabucal pockets, postpharingeal glands and crops.

Conclusions: Our results suggest workers can control the passage of foods through their digestive systems. We also think lipids ingested might be stored and metabolized in the postpharingeal glands.

Effects of forest insect invasions on forest succession

Andrew Liebhold

USDA Forest Service Northern Research Station, Morgantown, WV, United States

Given the trend of escalating globalization, increased numbers of alien insects are inevitable and can be expected to be one of the dominant influences in the world's forest ecosystems over the next century. When considering the likely impacts of these invaders, it is necessary to consider more than just effects on forests as they currently exist but to regard forests as dynamic systems and evaluate the role that invaders play in altering long-term forest succession processes. In some cases we can observe that invaders may cause spectacular short-term impacts (e.g., high levels of tree mortality), but if these effects mimic disturbances caused by pre-existing, natural disturbance agents then their effect on long-term patterns of forest dynamics may be minimal. In contrast, other alien species may induce changes to forest ecosystems, unlike any pre-existing disturbance agents and these impacts may destabilize natural cycles of forest dynamics, ultimately leading to drastic changes in ecosystem properties and ecosystem services. We illustrate these varying roles played by alien invaders using examples from eastern N. America.

Interaction rate and task allocation in harvester ants

Deborah M Gordon

Stanford University, Stanford, CA, United States

Introduction: Ant colonies operate without central control. Task allocation is the process that adjusts the numbers of workers performing each task, according to the current situation. A long-term study of a population of about 300 colonies of the red harvester ant *Pogonomyrmex barbatus*, in the southwestern US, shows that the rate of brief antennal contact informs task decisions.

Methods: Small glass beads treated with task-specific cuticular hydrocarbon extract were used as artificial ants to manipulate interaction rate.

Results: Ants respond to contact with beads treated with cuticular hydrocarbon extract, demonstrating that ants use task specific cuticular hydrocarbon extract to assess the task of the ants they meet. Foraging is initiated by interaction with returning patrollers. Interaction must occur at a rate of one per 10 sec to stimulate the onset of foraging. Once foraging begins, the intensity of foraging is regulated by interaction with returning successful foragers. Since the duration of a foraging trip depends mostly on the amount of time spent searching, the rate at which foragers return with food is a measure of current food availability. Foraging intensity responds very quickly to changes in the rate at which foragers return. This may be due to the limited interval over which an ant can remember an interaction.

Conclusions: Task allocation depends on a dynamical network of brief antennal contacts, during which one ant evaluates the task-specific cuticular hydrocarbon profile of the other.

Education in quality assurance for rearing insects

Norman Leppla, Frank Davis

University of Florida, Gainesville, Florida, United States

Introduction: The purpose for education and training in quality assurance for insect rearing is to maintain consistent, reliable production of high quality insects that meet established standards at the lowest possible cost.

Methods: Education in insect rearing and quality assurance can be gained from courses at Mississippi State University, Department of Entomology and Plant Pathology and Insect Diet and Rearing Research, LLC; working in an established insect rearing facility; and by studying available literature (http://www.amrqc.org, proceedings and http://www-naweb.iaea.org/nafa/ipc/index.html, publications). Studies focus on generic procedures, such as measuring and monitoring life history and performance characteristics, and on developing site-specific tests indicative of quality. Quality Assurance tests have been developed for many mass- reared insects, including major pest species and certain predators and parasitoids used in biological control.

Results: Education and training in quality assurance helps to make insect rearing more productive because entire systems are involved. Optimization of each step in the insect rearing processes affects the others in a system, e.g., egg quality and quantity results in a certain density of developing larvae per rearing unit and this affects the size of pupae and performance of adults. Students learn about the additive effects of environmental factors on rates of development and survival of successive insect growth stages. Quality assurance then becomes a matter of managing environments (production control) to satisfy the needs of the insects (product control).

Conclusions: Quality assurance in insect rearing requires knowledge of all aspects of the physical rearing system relative to the biology of the insect.

Global population genetics of the *Wolbachia* pandemic in arthropods and implications of *Wolbachia*-insect lateral gene transfers to arthropod evolution

John Werren

University of Rochester, Rochester, United States

Wolbachia are among the most abundant intracellular parasites on the planet, infecting upwards of 65% of insects, as well as many other arthropods and filarial nematodes. The implications of these bacteria to arthropod cell biology, ecology and evolution are potentially profound, but still remain controversial. In particular, a key question is whether *Wolbachia* accelerate adaptive evolution and speciation in their hosts. Here I present recent data showing that lateral gene transfers from *Wolbachia* to animal genomes are common and widespread. In one case, the nearly entire genome of *Wolbachia* has been incorporated into that of the fly *Drosophila ananassae*. The potential fitness consequences and possibilities for acquisition of novel gene function are discussed. Studies of the global diversity and distribution of Wolbachia among arthropods are also presented. These studies reveal extensive global movement of some strains, taxon associations of others, and genetic exchanges among members of the global *Wolbachia* metapopulation.

Regional effects of exotic forest pests in eastern North America

Andrew Liebhold[1], Randall Morin[2], Kurt Gottschalk[1]

[1]USDA Forest Service Northeastern Research Station, Morgantown, WV, United States, [2]USDA Forest Service Northern Research Station, New Town Square, PA, United States

Given trends of ever-increasing levels of global trade and travel, non-indigenous forest insects and diseases are becoming increasingly common throughout the world. While most of these species remain sparse and their effects on forests remain unnoticed, a few of these species cause wide-spread dieback and mortality of forest tree species. Eastern North America has experienced a particularly large number of invasions by destructive forest pests. While many studies have been conducted to measure the effect of these pests in individual stands, little or no information is available to assess their impacts over large regions. Here, we present analyses of the regional impacts of three alien forest pests, the gypsy moth (*Lymantria dispar*), hemlock woolly adelgid (*Adelges tsugae*) and beech scale, (*Cryptococcus fagisuga*) on a regional scale across the eastern USA. These analyses were conducted by comparing the historical ranges of these species with forest inventory data collected at thousands of points. Results indicate that while impacts on tree mortality may be particularly high in some locations, these impacts tend to be diluted over large areas and more difficult to detect. Based upon these results suggestions are made for how to go about quantifying regional impacts in the future.

Translocation tools for New Zealand weta

Corinne Watts, Ian Stringer, Greg Sherley, George Gibbs, Chris Green

[1]Landcare Research, Hamilton, New Zealand, [2]Department of Conversation, Wellington, New Zealand, [3]Department of Conversation, Auckland, New Zealand, [4]Victoria University, Wellington, New Zealand

Examples of transfers involving three species of New Zealand weta (Orthoptera: Anostostomatidae) are used to illustrate improvements in transferring and monitoring these insects. Weta are large, nocturnal insects that occupy a similar niche to small rodents elsewhere in the world. Some are locally extinct where introduced mammals occur and many transfers were done for species recovery and/or restoration purposes. The initial transfer method, simply collecting and releasing, and their subsequent irregular monitoring is illustrated using Mahoenui weta (*Deinacrida mahoenui*). The first improvements using artificial retreats to both release and monitor tree weta (*Hemideina thoracica*) took advantage of this species' roosting behaviour. In one case, both the donor and released populations were monitored. Transfers of the very rare tusked weta, *Motuweta isolata*, illustrate further improvements including captive rearing, monitoring the released insects and their progeny with artificial objects and exploring other monitoring methods including the use of harmonic radar and transmitters. An example of using a transfer for further research is provided with the Cook Strait giant weta (*D. rugosa*) where transmitters were used to follow their dispersal after release. Future directions and research are briefly discussed followed by a plea to follow release protocols and, in particular, fully document any releases.

The importance of Allee effects in predicting and managing insect pest invasions

Andrew Liebhold, Patrick Tobin

US Forest Service Northern Research Station, Morgantown, WV, United States

The Allee effect refers to decreasing net population growth with decreasing density; under strong Allee effects there exists a threshold below which low-density populations are driven toward extinction. They may arise from a variety of factors such as failure to find mates, failure to saturate predators and inability to utilize hosts through cooperative feeding. Though Allee effects have historically been applied to species conservation, there has been recent recognition of their importance in low-density populations during biological invasions. Given the importance of Allee dynamics during the establishment and spread of invading species, Allee effects create powerful opportunities for managing invasions. Specifically, by strengthening Allee effects, low-density populations of invaders can be driven to extinction without further management intervention, defying the notion that eradication can only be achieved by killing all individuals. Here we briefly review Allee effects with specific attention to their role in biological invasions and outline current management techniques, such as mating disruption and the sterile insect technique, from the context of their manipulation of the Allee threshold to manage invasions. We also suggest new approaches for manipulation of Allee effects that could be used to manage invading species; these approaches include natural enemy augmentation and other methods that affect population growth and consequently alter the Allee threshold. Finally, we discuss how variation in life history traits influence the strength of Allee effects and how this information can be used to predict invasions success among different pest species.

Evolutionary genetics using the *Nasonia* species complex

John Werren

University of Rochester, Rochester, NY, United States

Nasonia is a complex of four closely related species that is rapidly emerging as a model for evolutionary genetics and the genetics of complex traits. It has several features that make it an excellent genetic system. These include ease of handling, short generation time, male haploidy, interfertile species, visible and molecular markers, and a wealth of phenotypes of biological relevance. The form of sex determination, called haplodiploidy, makes *Nasonia* particularly suited for genetic studies. Females are diploid and develop from fertilized eggs, whereas males are haploid and develop parthenogenetically from unfertilized eggs. This allows geneticists to exploit many of the advantages of haploid genetics in an otherwise complex eukaryotic organism. *Nasonia* readily inbreeds, permitting production of isogenic lines, and the four species in the genus are inter-fertile (after removal of the endosymbiont *Wolbachia*), facilitating movement of genes between the species for efficient positional cloning of quantitative trait loci (QTL). Full (6X) genome sequencing of *N. vitripennis* and partial (1X) sequencing of the interfertile species *N. giraulti* and *N. longicornis* is now completed. This genome project provides a wealth of interspecies polymorphisms (SNPs, indels, microsatellites) to facilitate positional cloning of genes involved in species differences in behavior, morphology and development. Here we report the cloning of genes involved in sex specific wing size differences between sibling species of *Nasonia*. These represent the recent micro-evolution of gene networks affecting sex specific development. We also report studies of the genetic basis of interspecies hybrid breakdown, which involves genes encoding nuclear and mitochondrial components of the electron transport chain. The system shows great promise for dissecting the genetic basis of speciation and species differences in development and behavior.

Life history responses to nutritional deprivation in aphidophagous Coccinellidae

Mpho Phoofolo[1], Kris Giles[1], Norm Elliott[2]

[1]Oklahoma State University, Stillwater, Oklahoma, United States, [2]United States Department of Agriculture, Agricultural Research Service, Stillwater, Oklahoma, United States

Introduction: Preference for aphids by coccinellids makes them particularly susceptible to nutritional stress caused by within-season food scarcity because aphid populations are both spatially and temporally ephemeral (exhibit 'boom-and-bust' dynamics over short intervals) in nature. This study examined the ability of coccinellid larvae to cope with unpredictable food resources.

Methods: We studied life history responses of three species, *Coleomegilla maculata*, *Hippodamia convergens*, and *Harmonia axyridis*, when deprived of aphids for different periods of time during the 4th stadium.

Results: For larvae fed only on day 1 of the stadium, *H. convergens* had the highest starvation resistance, followed by *H. axyridis*, then *C. maculata*. Both *C. maculata* and *H. axyridis* lost significantly more weight than *H. convergens* when starved throughout the 4th stadium. Access to aphids for ≥1 day was required for pupation in all three species, with 35.7% pupation success in *H. convergens*, 14.3% in *C. maculata*, and 5.9% in *H. axyridis* when fed for 1 day. The weight of 4th instars and adults declined in an accelerating pattern as food deprivation period increased. However, food deprivation period had no significant effect on pupal development time for any of the three species or on larval development time for *C. maculata* and *H. convergens*. The increase in *H. axyridis* larval development time as a result of an increase in food deprivation period was curvilinear.

Conclusions: Based on this study, it would appear that *H. convergens* is better able to cope with acute nutritional stress than either *C. maculata* or *H. axyridis*.

Odor evoked neural oscillations in Drosophila

Nobuaki Tanaka[1], Kei Ito[2], Mark Stopfer[1]

[1]NICHD, Bethesda, Maryland, United States, [2]IMCB, The University of Tokyo, Tokyo, Japan, Japan

Odor elicited neural oscillatory synchronization has been observed in a very wide and diverge range of species. In two intensively studied insects, honeybee and locust, such oscillations have been shown to contribute to the encoding and decoding of odor quality. Yet there is no evidence for such oscillations in Drosophila, a preparation that offers many genetic tools for the analysis of olfactory pathways.

To study odor elicited temporal patterns of neural activity in Drosophila, we developed a way to do intracellular recording with sharp electrodes. We succeeded in recording from various antennal lobe neurons under odor stimulation for up to 30 min. After recording, we confirmed which neurons were recorded by injecting a neuronal tracer, neurobiotin. In addition, we also succeeded in recording odor-elicited local field potential (LFP) oscillations from the mushroom body: presentations of common, diluted odorants elicited ~10 Hz oscillations. Paired intracellular and LFP recordings showed spikes and subthreshold membrane potential oscillations in antennal lobe neurons were strongly phase locked to the LFP, suggesting that oscillations arise from antennal lobe circuitry.

Characterizing the mechanism underlying the neural oscillations, we found picrotoxin, antagonist for the GABAA receptor, can reversibly block the oscillatory activity. To isolate circuit elements responsible for the oscillations, we are now using the GAL4-UAS system to express shibire, a temperature sensitive dynamin mutant gene, in specific populations of antennal lobe neurons. This system will allow us to conditionally and transiently block chemical synaptic transmission from targeted neurons, revealing precise mechanisms underlying neural coding.

Reproduction in fire ant (*Solenopsis invicta* Buren) queens: vitellogenin receptor biology

Patricia Pietrantonio, Hsiao-Ling Lu, Mei-Er Chen

Texas A&M University, College Station, TX, United States

Introduction: In social insects, control of reproduction is a complex and poorly understood process. The red imported fire ant, *Solenopsis invicta* Buren (Hymenoptera: Formicidae) is an invasive, aggressive pest with high reproductive ability. To aid in population management, knowledge is needed on the effector proteins and the regulatory pathways involved in reproductive control. The vitellogenin receptor (VgR) is responsible for the receptor-mediated endocytosis of vitellogenin (Vg) for egg formation and embryonic development. Understanding VgR biology may be useful to elucidate mechanisms leading to high reproductive capacity in queens. Other hormone receptors, such as the short neuropeptide F receptor from fire ants, are being investigated as potentially involved in reproductive control.

Methods and results: We cloned the fire ant VgR (*Si*VgR), characterized the transcriptional expression pattern in virgin queens and demonstrated that methoprene increases transcript abundance, suggesting JH is involved in VgR regulation. An antibody specific against *Si*VgR was developed. Caste and tissue specific expression of *Si*VgR was studied through western blot analysis. A *Si*VgR protein of 202 kDa was detected in both virgin (alate) and mated (dealate) queen ovaries. Immunohistochemistry of ovarioles of virgin and mated queens showed differential VgR distribution in early and late stage oocytes. This is the first report on the spatial and temporal expression profile of a hymenopteran VgR.

Conclusion: The specific antibody against fire ant VgR is a powerful tool to test hypothesis of VgR regulatory gene networks. This study may contribute to understand the regulation of VgR in other hymenopteran species.

Ants, scales, and ladybeetles: complex interactions and natural pest control in a coffee agroecosystem in Mexico

Heidi Liere, Ivette Perfecto, John Vandermeer

University of Michigan, Ann Arbor, Mi, United States

We study the mutualism between an important coffee pest, the green scale (*Coccus viridis,* Hemiptera: Coccidae) and an aggressive tree-nesting ant, *Azteca instabilis* (Hymenoptera: Formicidae) in a coffee agroecosystem in Chiapas, Mexico. One part of our research project focuses on the interaction between this mutualism and a voracious scale predator, the ladybeetle *Azya orbigera* (Coleoptera: Coccinellidae). While adult ladybeetles feeding on the scales suffer from constant attack by the ants, the larvae have waxy filaments that render them immune to ant attacks and thus are able to prey freely upon ant-tended scales. Furthermore, the ants indirectly benefit the ladybeetle larvae by providing them enemy-free space. Consequently, we hypothesized that the distribution of the ladybeetles is closely linked to that of the ants. To test this hypothesis we established a 45-ha plot, marked all *A. instabilis* nests, and conducted a two-year long ladybeetle survey. We found significantly more ladybeetle larvae and adults in sites with ant nests. Furthermore, we found a significant relationship between the occupancy and persistence of the ladybeetle populations and the clustering of ant nests. The more ant nests within 20 m of the sampled site, the higher the probability the site was occupied by ladybeetles and the higher the probability that it remained occupied for longer. Our results suggest that the presence of this tree-nesting ant in the coffee plantation plays a key role in the persistence of ladybeetle populations, which in turn may play an important role in maintaining the scale populations below levels that may be damaging to the coffee plantation.

Climate change, forest disturbance and feedbacks: the mountain pine beetle in western North America

Allan Carroll[1], Werner Kurz[1], Caren Dymond[1], Graham Stinson[1], Greg Rampley[1], Eric Neilson[1], Tim Ebata[2]

[1]Natural Resources Canada, Canadian Forest Service, Pacific Forestry Centre, Victoria, BC, Canada, [2]British Columbia Ministry of Forests and Range, Victoria, BC, Canada

The mountain pine beetle is native to the pine forests of western North America where it normally exists at very low densities, infesting only weakened or damaged trees. Under conditions conducive to survival, populations may erupt and spread over landscapes causing the mortality of large numbers of healthy trees. While there have been 4 such eruptions during the past century in western North America, the ongoing epidemic is unprecedented in its size and severity – causing the mortality of mature lodgepole pines over approximately 14 million hectares in Canada alone. In addition to the direct ecological and economic impacts of such widespread tree mortality, the loss of carbon uptake and the increased emissions from decaying trees has converted the forests of western Canada from a small net carbon sink to a large net carbon source. Indeed, during the peak year of beetle impacts, emissions were similar in magnitude to the average annual direct emissions from forest fires for all of Canada. Moreover, through reductions to net primary productivity and increases in heterotrophic respiration, beetle impacts have negated any potential gains in carbon sequestration associated with climate warming, elevated atmospheric CO2 concentrations and nitrogen deposition. Significant warming has already allowed the mountain pine beetle to expand its range into formerly climatically unsuitable habitats. Additional warming could facilitate further range expansion, including invasion of the boreal forest, and lead to significant positive feedback to the global climate system.

Phenology of apple leaf-curling midge (Diptera: Cecidomyiidae) and its parasitoid *Platygaster demades* Walker (Hymenoptera: Platygastridae) in the field

Xiong Zhao He[1], Qiao Wang[1], Jim T. S. Walker[2], Dave J. Rogers[2], Peter L. Lo[2]

[1]*Institute of Natural Resources, Massey University, Palmerston North, New Zealand,* [2]*HortResearch, Havelock North, New Zealand*

Introduction: Apple leaf-curling midge (ALCM), *Dasineura mali* Kieffer, is a pest of apple in many countries in the world, and *Platygaster demades* is an important parasitoid that attacks ALCM eggs and larvae. Here we report our findings on the phenology of both species in Palmerston North (40.3° S, 175.6° E), New Zealand, in 2006-2007.

Methods: Shoots infested by ALCM were sampled every three days, and ALCM mature larvae were buried fortnightly. Emergence of buried insects was monitored daily and their development examined weekly.

Results: Both species had four generations. ALCM populations in the 2nd and 3rd generations were higher than in other two generations. The parasitism rate by *P. demades* was 44.5, 69.4, 78.6 and 86.9% for the 1st, 2nd, 3rd and 4th generations, respectively. All unparasitised 1st and 2nd and some unparasitised 3rd generation ALCM emerged in the same growing season. All unparasitised 4th generation and most unparasitised 3rd generation ALCM overwintered as cocooned larvae. *P. demades* entered aestivation as eggs between mid-November and late February, with mean aestivation rate being 6.3, 65.6 and 18.1% for the 1st, 2nd and 3rd generations, respectively. Aestivated *P. demades* eggs in the 2nd and 3rd generations and non-aestivated eggs in the 3rd and 4th generations hatched by early June and overwintered as larvae.

Conclusions: ALCM overwintered as mature cocooned larvae while *P. emades* aestivated as eggs and overwintered as larvae. Results suggest that vast majority of ALCM cocoons found on apple fruit are parasitized by *P. demades*.

Stoichiometric constraints within and across trophic levels

Residual toxicity of spinosad to predatory mites and their effectiveness against western flower thrips, *Frankliniella occidentalis* Pergande (Thysanoptera: Thripidae) in strawberry, *Fragaria ananassa* (Rosaceae)

Touhidur Rahman[1], Helen Spafford[1], Sonya Broughton[2]

[1]*School of Animal Biology, The University of Western Australia, Crawley, Western Australia, Australia,* [2]*Department of Agriculture & Food Western Australia, South Perth, Western Australia, Australia*

Introduction: Western flower thrips (*Frankliniella occidentalis*) has become a major horticultural pest throughout Australia following its first detection in 1993. Spinosad (trade name Success™) is the only insecticide currently registered in Australia that is both efficacious against *F. occidentalis* and regarded to be compatible with integrated pest management. To determine whether spinosad can be integrated with innudative biological control, we evaluated the interaction between spinosad and three predatory mite species *Typhlodromips montdorensis*, *Neoseiulus cucumeris*, *Hypoaspis miles*, available in Australia for control of *F. occidentalis*.

Methods: In the glasshouse, three strawberry cultivars (Albion, Camarosa and Camino Real) were sprayed once with water (control) or spinosad (120g/L). Adult thrips were released 24 h after spraying and predatory mites released 6 days later. Mites were released as single species, two species or three species combinations.

Results: Spinosad significantly reduced thrips numbers ($p < 0.05$) compared to the control. Interestingly spinosad had no effect on predatory mites as their numbers (*T. montdorensis* and *N. cucumeris*) gradually increased. Mites releases in combination with spinosad applications were generally more effective at reducing *F. occidentalis* numbers than spinosad application alone, with *T. montdorensis* and *H. miles* the most effective two species combination. No significant differences ($p > 0.05$) were found between releases of *T. montdorensis* and *H. miles* or *T. montdorensis*, *N. cucumeris* and *H. miles* in combination.

Conclusion: These results suggest that spinosad applications can be used to initially reduce *F. occidentalis* numbers, followed by combined releases of predatory mites.

Disruption of Argentine ant trail integrity using pheromone

David Suckling, Robert Peck, Lee-Anne Manning, Lloyd Stringer, Justin Cappadonna, Ashraf El-Sayed

HortResearch, Lincoln, New Zealand

Introduction: Argentine ants are considered one of the 100 most invasive species worldwide, because they can significantly reduce biodiversity, affect horticultural production, and cause a nuisance in urban situations, including hospitals. Currently, poison baiting systems are widely used against Argentine ants and many other important invasive ants. More environmentally-friendly control tactics are urgently needed for management and eradication of these invasive ants. This work investigates the possibility of using trail pheromone to disrupt trail following behaviour of the Argentine ants.

Methods: The trail pheromone (Z9-hexadecenal) was formulated for slow release in order to test whether trail following behaviour could be disrupted. Ant walking behaviour was recorded and digitized using video tracking before and after presentation of the trail pheromone.

Results: Disruption of Argentine ant trail following behaviours and reduced foraging success was achieved after presentation of an oversupply of trail pheromone, Z9-hexadecenal. Ants following trails showed a unimodal distribution of walking angles, but after presentation of the trail pheromone, there was no clear peak in the distribution of the walking angles. Ants showed initial high trail integrity, defined as the correlation statistic r^2, on a range of untreated substrates from painted walls to wooden or concrete floors, but this behaviour was significantly reduced by presentation of a point source of pheromone. The number of ants in the pheromone-treated area also increased over time, as recruitment from both directions apparently exceeded departures. Ant counts at bait cards were significantly reduced compared to the controls on the day of treatment, but trails recovered by two days after treatment due to rapid pheromone loss from the first formulation. Disruption effects lasted for several days. In larger plots, significant reductions in ant foraging to bait cards and reductions in trail formation were seen for up to two days from this formulation, and longer for a prototype micro-encapsulated formulation.

Conclusions: These results show that disruption of the trail following behaviour of Argentine ants may be possible using trail pheromone.

Rate of colonisation of *Bemisia tabaci* and its parasitoid *Eretmocerus hayati* : The role of landscape composition

Nancy Schellhorn

CSIRO, Indooroopilly, QLD, Australia

Introduction: Biological control is most effective when the control agent arrives in the crop at the same time or shortly after the pest. We investigated how the landscape composition (number, size and spatial arrangement of source populations) influences the process of colonisation of a pest, silverleaf whitefly, *B. tabaci*, and its parasitoid, *E. hayati*.

Methods: Sentinel melon seedlings (half infested with *B. tabaci* and half un-infested "clean") were placed in six cane trash fields either adjacent ($\leq$ 100 m) or far ($\geq$ 300 m) from host crops in two landscapes. They were arranged in a 100 m x 75 m 20 point grid and left for four days, removed and replaced three times.

Results: We found that the pest and parasitoid colonise seedlings within four days, and repeatedly. In landscapes with many sources of *B. tabaci,* colonisation of the new seedlings can be explained by the number of sources at the scale of kilometres, while in landscapes with limited production colonisation can be explained by the number of sources of *B. tabaci* within 100m. *Eretmocerus hayati* is also highly mobile, and colonisation can be explained by the density of the parasitoid at a scale of 2kms and being adjacent to a host crop of *B. tabaci*.

Conclusions: In landscapes with intensive cropping a combination of an area-wide approach, plus on farm management is necessary to control *B. tabaci*. Refuges of *E. hayati* within 2kms of the target crop allow for fast colonisation and may lead to better *B. tabaci* control.

Potential of entomopathogenic nematodes as biological control agents of stored product insects

James Campbell, Olgaly Ramos-Rodriguez

USDA ARS GMPRC, Manhattan, KS, United States

Entomopathogenic nematodes at first appear poorly adapted for use as biological control agents against insects that infest grain and processed grain-based products. However, the population structure and movement patterns of stored product insects indicate that in many environments pests originating from food material that accumulates in hidden refugia -- such as cracks or crevices in structures, empty grain bins, spillage outside facilities -- and subsequent movement into stored commodities can be important factors in product infestation. Biological control in general, and entomopathogenic nematodes in particular, may be an effective component of an IPM program when targeted at these refugia populations. We evaluated the efficacy of three *Steinernema* spp. against a range of stored product pest species and stages under laboratory conditions and found many pest species were susceptible. Tests of *S. riobrave* pathogenicity as a biopesticide under simulated field conditions, suggested that nematodes applied in a manner similar to some conventional chemical pesticides had a sufficient window of time to find and infect insects. Further research to enhance efficacy, evaluate range of field situations where nematodes might be used, and determine the impact of refugia treatments on overall pest population levels is still needed.

Assessment of structural fumigation efficacy in food processing facilities

James Campbell

USDA ARS GMPRC, Manhattan, KS, United States

Structural treatments such as heat or fumigation are sometimes needed to eliminate pest populations hidden in the buildings and equipment. Historically, methyl bromide has been widely used in food processing facilities such as flour mills for the suppression of stored-product insect pests; primarily the red flour beetle *Tribolium castaneum*. Use of this fumigant is being phased out and development and adoption of alternative control tactics, such as sulfuryl fluoride or heat, has been made more difficult due to the extremely limited published field data on action thresholds, efficacy, and rate of population rebound. Here, we evaluate the impact of multiple fumigations with methyl bromide or sulfuryl fluoride on red flour beetle populations in multiple flour mills. Red flour beetle population levels were assessed using either direct counts of insects from product samples, direct counts of insects sieved from the product stream (i.e., tailings samples), or from pheromone baited trap captures. From this data, average levels at time of treatment, percent decrease in number following treatment, and rate of rebound were determined. Influence of season, pest density and IPM tactics on efficacy and rebound were also evaluated. From the compilation of this type of monitoring data we can begin to develop a better understanding of the impact of fumigation on pest populations and improve the selection, timing and application of pest suppression tactics in flour mills.

Semiochemicals for managing storage pests: monitoring, mating disruption and precision-targeted pest control

Thomas Phillips[1], Manuel Campos[1], Rizana Mahroof[2], Kishan Sambaraju[1]

[1]Kansas State University, Manhattan, KS, United States, [2]South Carolina State University, Orangeburg, SC, United States

Pheromones and other semiochemicals have been identified for over 40 species of stored product insect pests. Monitoring programs are now well-established for key moth and beetle pests. Research on host volatiles has led to increased activity of aggregation and sex pheromones in monitoring programs for tenebrionid flour beetles, anobiid beetle pests, and moths. Mating disruption of pyralid moth pests has been demonstrated in commercial settings and the technology is being registered for commercial use world-wide. Semiochemical-based pest management methods provide reduced input or chemical free methods to suppress populations below action levels.

Documenting biodiversity: No end in sight in Staphyliniformia (Coleoptera)?

Alfred Newton, Margaret Thayer

Zoology Department, Museum of Natural History, 1400 South Lake Shore Drive, Chicago, Illinois 60605, United States

Known diversity of the beetle group Staphyliniformia (11 families placed in 2-3 superfamilies) is reviewed based on a recently completed world catalog in database form of all species-group names in a current classification. Preparation of this catalog (soon to be web-accessible) was greatly facilitated by the recent publication of modern printed catalogs of world species for all or significant parts of the largest families, and for all Palearctic species.

Through 2007, more than 87,700 species-group names have been proposed for 69,246 currently recognized species and 1,676 subspecies worldwide, of which 466 species (0.7%) are known only as fossils and 1,456 (2.1%) are also or only known in the larval stage.

Analysis of the description of new species by decade from Linnaeus 1758 to the present shows that the discovery rate in this group is accelerating dramatically, not tapering off. The numbers of active authors and total publications have roughly doubled in the past four decades and are more geographically dispersed now than ever before. From 1998-2007, a total of 370 authors in 1750 publications described on average more than 850 new species per year, all of these being much higher numbers than in any of the previous 24 decades since Linnaeus. Factors probably contributing to this increased taxonomic activity include dramatically improved sampling methods and access to systematic resources, and increased collaboration among systematists. This accelerated rate hinders estimation of actual species numbers using trend curves and similar historical methods because our species inventory is obviously very incomplete.

Ensuring high mortality of locusts and grasshoppers treated with Green Guard® (*Metarhizium anisopliae* var. *acridum)*

David Hunter

125 William Webb Drive,, McKellar ACT 2617, Australia

A critical part of ensuring that a biological control agent will cause high mortality, and at a reasonable price, is the initial choice of the isolate. Green Guard®, used in the control of locusts and grasshoppers, consists of an oil formulation of spores of the Australian isolate FI-985 of *Metarhizium anisopliae* var. *acridum.* The FI-985 isolate has high yield during production (100-120g spores per Kg of rice substrate), is virulent against target pest locusts and grasshoppers, and survives moderately well under UV light: the resulting combination of high yield, high virulence and good survival after application means that Green Guard® causes high mortality at a minimal dose, substantially reducing costs. Equally important in ensuring high mortality is proper formulation and application of the product. Dry spores can be stored for several years at cool temperatures and can be quickly formulated when required, essential in the highly variable market for locust and grasshopper control. However, for transport, Green Guard® is formulated as a spore concentrate in oil to limit temperature increases in the product during transport in the very hot summer conditions typical of regions infested with locusts and some species of grasshopper. Spores are transported in corn oil, which is thick enough to reduce settling during transport and storage, though settling is not eliminated completely. Just before use, the concentrate is mixed with a locally available light oil and applied using readily available equipment. In Australia, Green Guard® ULV has been applied to over 70 000 ha, mostly at a dose of 25g spores in 500 mL oil/ha. When it is very hot (maximum temperatures 35-42^{o}C), there is >90% mortality in 7-10 days, though mortality takes longer during the milder temperatures of spring. Similar high mortalities have been obtained in China, East Timor and Mexico, but when vegetation was dense and/or the spray equipment was of less consistent quality, alterations in the dose of spores and types and amounts of oil were required to ensure high mortality.

Royal manipulation of G-protein coupled receptors in the brain of the bee: impacts on brain function and behaviour

Alison Mercer, Kyle Beggs

University of Otago, Dunedin, New Zealand

Honey bee queens produce a pheromone that blocks aversive olfactory learning in young workers, but leaves appetitive learning intact (Vergoz et al., 2007, *Science*, 314, 384-386). Evidence suggests that the effects on aversive learning occur a consequence of pheromone-induced changes in dopamine signalling in the brain (Beggs et al., 2007, *PNAS*, 104: 2460-2464). Queen mandibular pheromone (QMP) reduces brain dopamine levels in young worker bees, selectively alters the expression of dopamine receptor genes, and changes the responsiveness of brain tissues to dopamine. We have found in addition that one of the key components of QMP, homovanillyl alcohol, has direct effects on the function of at least one of the GPCRs that mediates dopamine's actions in the brain. The selectivity of QMP's effects provides important clues about dopamine's role in the formation of associative olfactory memories in the bee.

Towards an integrated diversity and pest management (IDPM) of termites in an oil palm agroecosystem

Faszly Rahim[1], Idris Ghani[1], Ahmad Said Sajap[2]

[1]Universiti Kebangsaan Malaysia, Bangi, Selangor, Malaysia, [2]Universiti Putra Malaysia, Serdang, Selangor, Malaysia

Introduction: The emergence of termite as pest in oil palm agroecosystem on peat was alarming, which called for a multivariate ecological community study to identify the contributing factors and point of emergence. The results from the study was formulated towards an integrated management programme.

Methods: Factors contributing to the changes in community structure were extracted using the nonmetric multidimensional scaling (NMDS). A time-series analysis was then performed on the community data across a putative synthetic gradient of oil palm intensification.

Results: The NMDS ordination identified termite communities to be structured by the geographical position, history, and fragmentation of oil palm agroecosystem. Distinct communities were separated by latitudinal and longitudinal gradient. Lower diversity was found to be historical (age dependant), but more strongly influenced by total cover area and distance to forest patches. Changes in termite community structure along oil palm intensification gradient fitted the decreasing trend function, signalling that a decline in diversity resulted in pest emergence through time. The pest was found generally suppressed by high diversity of species interactions within the communities. However, improper control intentions had greatly reduces the strength of competition of spaces and resources, hence, pest infestation aggravated through time.

Conclusion: Termite management in the oil palm agroecosystem must consider also conservation and utilisations of termite as ecosystem engineers and the “do-nothing strategy”, to reduce treatment cost, is the central for pest management towards a new concept of Integrated Diversity and Pest Management (IDPM).

Molecular characterization of phosphine (fumigant) resistance in grain insect pests using the red flour beetle, *Tribolium castaneum* (Herbst.) as a model organism

Rajeswaran Jagadeesan[1], Paul Ebert[1], Patrick J. Collins[2], David Schlipalius[2]

[1]University of Queensland, St.Lucia, Queensland, Australia, [2]2Queensland Department of Primary Industries and Fisheries, Indooroopilly, Queensland, Australia

Introduction: Understanding the evolution of phosphine resistance in an insect genetic model and grain pest, *T. castaneum*, may assist with effective management of the major problem of phosphine resistance.

Methods: Inheritance of phosphine resistance was determined by dose-mortality response bioassays using genetic crosses of resistant (QTC931) and sensitive (QTC4) strains and the results were tested statistically for monogenic or polygenic inheritance. To determine genomic regions linked to resistance, phosphine-resistant F4 progeny were selected from a single-pair intercross (QTC4XQTC931) and bulk-segregant analysis was performed using RAF (Random Amplified DNA Fingerprinting). DNA markers putatively linked to phosphine resistance genes were cloned, sequenced and located within the *Tribolium* genome assembly. Nearby markers of known sequence (micro-satellites) were then used to confirm the genomic regions containing resistance genes.

Results: Backcross experiments revealed that the mode of inheritance of phosphine resistance genes is autosomal and incompletely recessive with two or more genes controlling high-level resistance. These results are corroborated by RAF bioassay which indicated the possibility of two or more loci involved in high-level resistance. Fine scale mapping of the genomic regions associated with phosphine resistance is currently underway.

Future Directions: Candidate genes identified by fine scale mapping will be characterized by gene expression and systematic gene disruption studies using RT-PCR, Micro-array and RNA interference techniques. This study will lead to diagnostic markers for resistance in a new species, enabling us to monitor the effectiveness of resistance management strategies and identify factors that cause phosphine resistance in the field.

The utilization of biomasses and returned benefits of termites in an oil palm agroecosystem

Faszly Rahim[1], Ahmad Said Sajap[2], Idris Ghani[1]

[1]Universiti Kebangsaan Malaysia, Bangi, Selangor, Malaysia, [2]Universiti Putra Malaysia, Serdang, Selangor, Malaysia

Introduction: Termites are important decomposer communities. However, in oil palm agroecosystem, termites functional benefits have yet to be appreciated. The significant contributions of termites utilization of biomasses in oil palm are quantified through niche and resource analysis to highlight their significant contributions.

Methods: Termite encounters on every resources in oil palm agroecosystem with variable management practices were used as the measure of frequency in a standardized transect sampling protocol. Niche-resource analysis was performed on the data to identify community preferences. Spatial pattern analysis was performed using SADIE to identify the correlation between community aggregation and environmental factors.

Results: Termites were found utilizing fragments of forest biomasses (timber stumps, trunks and chunks), predominantly wood chunks, as well as oil palm biomasses (stand and frond heaps) in the fields. The utilization of biomasses in oil palm were for food as well as nesting and breeding sites. No significant overlapping of niches were found indicating the specialization of the termite functional in resource preferences. Aggregation of communities across field blocks were found influenced by the partitioning of resources as well as levels of oil palm intensification. A shift in wood feeder to soil feeders; and from utilization of forest resources to oil palm biomasses, was noted as a successional response of communities through time.

Conclusion: Termites are important decomposer of the biomasses in oil palm agroecosystem that directly reincorporates the nutrients back to oil palm, however, the rates will be influenced by levels of intensification, which determines the availability of resources.

Area-wide spatial and successive mapping of termite infestation in an oil palm agroecosystem

Faszly Rahim[1], Ahmad Said Sajap[2], Idris Ghani[1]

[1]Universiti Kebangsaan Malaysia, Bangi, Selangor, Malaysia, [2]Universiti Putra Malaysia, Bangi, Selangor, Malaysia

Introduction: The termite *Coptotermes curvignathus* infestation is rampant in oil palm agroecosystem on peat. However, a complete mapping of infestation in any plantation had never been attempted that this study was initiated.

Methods: An area-wide mapping project was conducted through census on oil palm stands with cooperation of the management of an oil palm plantation. Spatial analysis using the SADIE method and mapping by Surfer surface mapping software was made on the grided field data. Rubber wood bait plots intensified within an infestation cluster was successively monitored for a period of a year.

Results: Infestation pattern significantly clustered into patches in an area-wide scale, suggesting mirror of the initial colonies distribution in the forest and environmental affinities, most importantly compartmentalization by drainage system. Generally, fields with high infestation showed clusters of very high local index of aggregation (suggested as hotspots) that emerges as isolated small patches as well as contiguous patches from fusion of several small patches. In contrast, fields with low infestation showed distinct hotspots with low intensity. The infestation pattern also showed the possible orientated infestation and dispersions proposed to be geomagnetism. Significant annual rhythm in the pest activity dynamics, suggested the circannual rhythm synchronizations with environmental and competing species.

Conclusion: The area-wide and successive mapping should be a future in pest surveillance and population ecology of the pest, as an improvement for targeted pest management strategy.

Biting patterns of *Anopheles minimus* (Diptera: Culicidae) in experimental huts treated with DDT and deltamethrin

Theeraphap Chareonviriyaphap[1], Pisit Poolprasert[1], Wannapa Suwondkerd[2]

[1]Kasetsart University, Bangkok 10900, Thailand, [2]Ministry of Public Health, Nontaburi 10100, Thailand

Movement patterns of natural population of *Anopheles minimus* females into experimental huts treated with DDT and deltamethrin were carried out at Pu Teuy Village, Sai Yok District, Kanchanaburi Province, west Thailand. Two experimental huts, control and treatment, were constructed in the fashion of local Thai homes. Under unsprayed conditions, peak biting activity of *An. minimus* females occurred at 1900-2200 hr. After one hut was sprayed with DDT, a significant reduction in number of *An. minimus* females biting in the treated hut was observed ($P < 0.05$). In addition, biting activity almost disappeared from the DDT treated hut before sunrise (0300-0600 hr). Apart from DDT, we also observed a significan reduction in biting of *An. minimus* females in the hut treated with deltamethrin ($P < 0.05$). However, *An. minimus* females continued to enter the deltamethrin treated hut and maintained significantly high levels of biting after 2100 hr and through the remainder of the night ($P < 0.05$). Overall comparisons with matched control, huts there was a greater proportion of *An. minimus* females biting in the hut treated with deltamethrin than in the hut treated with DDT. We conclude that DDT exhibited a stronger excito-repellent impact than deltamethrin on natural populations of *An. minimus*, an important vector of malaria in Thailand.

Wasp diversity ‘down under’: systematics and biogeography of Australian Rhopalosomatidae (Hymenoptera: Apocrita)

Lars Krogmann, Andrew D. Austin

[1]Staatliches Museum für Naturkunde Stuttgart, Stuttgart, Germany, [2]Australian Centre for Evolutionary Biology and Biodiversity, School of Earth and Environmental Sciences, The University of Adelaide, Adelaide, Australia

Introduction: The wasp family Rhopalosomatidae is represented in Australia solely by the genus *Olixon* Cameron, comprising 2 of the 11 known world species. *Olixon* species are wing-reduced, solitary, ectoparasitoids of crickets. Based on new material from intensive surveys we here record 17 species from Australia, 15 of which are new, thus more than doubling the number of world species of *Olixon*. We also discuss the distribution of the new species and present the results of cladistic analyses to evaluate the biogeography of the Australian fauna.

Material & Methods: Cladistic analyses of the world species of *Olixon* based on 47 morphological characters and 24 ingroup species were conducted in TNT under equal and implied weighting.

Results and discussion: The Australian rhopalosomatid fauna is much more species-rich than previously thought, but many species are restricted to fragmented forest patches in the south-west of the continent and are likely to be of significant conservation value. The results of the cladistic analyses indicate that 1) the Australian species of *Olixon* are polyphyletic, 2) about three-quarters of the Australian species form a monophyletic group, and 3) a South American *Olixon* is sister to all other species.

Reducing the chemical footprint when managing chrysomelid leaf beetles in eucalypt plantations: lethal trap trees

Jane Elek[1], Geoff Allen[2]

[1]Forestry Tasmania, Hobart, Tasmania, Australia, [2]CRC for Forestry, Hobart, Tasmania, Australia

Defoliation by native chrysomelid leaf beetles, *Paropsisterna bimaculata,* can cause economic losses of wood volume at harvest in *Eucalyptus nitens* plantations in Australia. Defoliation late in the summer is predicted have double the impact of defoliation that occurs earlier. Current populations are controlled using an IPM program where egg and larval populations are monitored and, if over an economic threshold, are aerially spraying with a synthetic pyrethroid. We explored alternative methods of managing defoliation that do not rely on spraying broad-spectrum insecticides using five criteria. Preferred landscape methods of management were: genetic selection of resistance to insects, promote habitats of beneficial insects by increasing plant diversity and silvicultural management. New options for managing outbreaks were: attract and kill traps, lethal trap trees and using softer chemicals. The easiest, short-term option would appear to be replacing a broad-spectrum insecticide with softer chemicals. However, implementation in the field has been disappointing. The softer chemicals are more expensive, more difficult to use logistically because of their shorter window of activity and they do not control the adult beetles that cause the higher impact damage at the end of the summer.

Therefore we are developing the option of lethal trap trees for outbreak management. The native forest species, *E. regnans* and *E. delegatensis*, have been identified as being more attractive to *P. bimaculata* for feeding and oviposition than plantation *E. nitens* and *E. globulus.* However, these trees were ineffective when planted as unprotected trap trees because they grew so poorly, due to repeated defoliation, that they were no longer sufficiently attractive to the beetles. Infusion of the trap trees with systemic insecticide, rendering the foliage lethal to beetles, would not only protect the trees but also reduce the population pressure of leaf beetles. Trials have been established to test the concept of lethal trap trees, and the nicotinoid insecticides, imidacloprid and clothianidin, are being evaluated for the best application method and dose that would provide at least three months of protection for the lethal trap trees.

For the longer term, we are working towards identifying kairomones or pheromones that could be used in attract-and-kill traps.

Spatial distributions and development of sampling methods for *Aphis gossypii* in commercial greenhouse cucumbers

Taek-Jun Kang[1], Heung-Yong Jeon[1], Seung-Ryong Cheong[1], Joon-Ho Lee[2]

[1]National Horticultural Research Institute, RDA, Suwon, Kyunggi-Do; [2]Department of Agricultural Biotechnology, Seoul National University, Seoul, Republic of Korea

Introduction: Cucumber, *Cucumis sativus* L, is major horticultural crop in Korea and cotton aphid, *Aphis gossypii* Glover, is one of the serious insect pests in commercial greenhouse cucumbers. So, spatial distribution and occurrence of *A. gossypii* were investigated in commercial greenhouse cucumbers during 2001 and 2005.

Methods: By investigating densities of *A. gossypii* within and between cucumber plants, we analyzed population dynamics and distributions of *A. gossypii*. Taylor's power law and geostatistical variogram model (SPATIALSTATS module) were used for analyzing spatial distribution patterns of *A. gossypii*, and developed economic sampling methods of *A. gossypii* in commercial greenhouse cucumbers.

Results: Most of *A. gossypii* were distributed in lower parts of leaves within plants (about 70% of total *A. gossypii* were between 1st and 7th leaves) and also highly clumped between plants (TPL b > 1) during all investigating periods. We developed stratified sampling plans within plants and could get a good estimation of *A. gossypii* by counting in lower 3rd and 6th cucumber leaves. By the results of variogram models (spherical, exponential, Gaussian model), distances which represent average degree of similarity between samples were about 18, 22, 17m respectively. Spatial distribution patterns of *A. gossypii* by ordinary kriging were similar with real distributions of *A. gossypii* in commercial greenhouse cucumbers.

Conclusions: Detailed studies of *A. gossypii* in cucumber greenhouses will provide insights into spatial distributions of *A. gossypii* in greenhouse cucumbers, which could lead to the development of economic sampling methods for *A. gossypii*.

The basis for floral specialization in a guild of wasp-pollinated plants

Adam Shuttleworth[1], Florian Schiestl[2], Steven D. Johnson[1]

[1]University of KwaZulu-Natal, Pietermaritzburg, KwaZulu-Natal, South Africa, [2]University of Zürich, Zürich, Switzerland

The basis for specialization in plants with exposed nectar is still poorly understood. Our research has revealed a guild of plants with exposed, concentrated nectar which are specialized for pollination by *Hemipepsis* pompilid wasps. We test the hypothesis that these plants use cryptic colouring, toxic nectar and selectively attractive floral volatiles to filter non-pollinating insects and achieve specialization. Reflectance spectrometry revealed that pompilid-pollinated flowers are typically dull-coloured and have similar spectra to the background vegetation. Choice tests with nectar from two species and sugar solutions showed that the nectars (which are consumed by *Hemipepsis* wasps) are unpalatable to honeybees. Choice experiments in the field and in the laboratory (using a Y-maze) revealed that pompilid wasps are attracted primarily by floral scent. Gas chromatography-mass spectrometry (GC-MS) and Gas Chromatography-Electro Antennagram Detection (GC-EAD) were used to analyze the floral volatiles produced by pompilid-pollinated flowers and to identify physiologically active compounds which function to attract *Hemipepsis* wasps. We conclude that pompilid-pollinated plants achieve specialization through crypsis, toxic nectar and selective pollinator attraction (through specific volatiles).

Circadian clocks regulate insect response to pesticides

Jadwiga Giebultowicz, Shawn Butcher, Louisa Hooven

Oregon State University, Corvallis, Oregon, United States

Introduction: Circadian clocks allow organisms to adapt biochemical and physiological processes to their environment in rhythms entrained by the solar day. There is emerging evidence that the toxicological response varies with time of day in many insect species. We use the model insect, *Drosophila melanogaster*, to investigate the role of genes encoding clock components in modulating susceptibility to pesticides at the physiological and molecular levels.

Methods: *D. melanogaster* used in these studies were either wild type or mutants in specific clock genes. Flies were exposed to several classes of pesticides at different times of day and LD-50 was calculated. Expression of genes involved in pesticide detoxification was investigated by RT-PCR. Enzyme activity of P-450, esterases and GST enzymes was assayed in different fly genotypes.

Results: By monitoring mortality of *D. melanogaster* exposed to selected pesticides at different times of day, we uncovered daily rhythms in susceptibility to several pyrethroids, fipronil, and malathion. A substantial decrease in permethrin resistance was observed in flies deficient in the gene *Clock* (*Clk*) and *cycle* (*cyc*) which encode positive elements of circadian feedback loop. A similar decrease was noted in flies deficient in the gene *Pdp1*, which is under transcriptional control of *Clk*/*cyc* complex.

Conclusions: We began to decipher the pathways that may govern the varying response of insects to pesticides at different times of day. Similar mechanisms may exist in insect pest species and assessment of putative daily rhythms of susceptibility should become an integral part of IPM practices.

Pyrethroid resistance in the redlegged earth mite: current situation and prospects for the future

Paul Umina, Ary Hoffmann

The University of Melbourne, Parkville, Australia

The redlegged earth mite (*Halotydeus destructor* Tucker) is an important pest of field crops and pastures in Australia, New Zealand and South Africa. Control of this pest relies heavily on chemicals, with few genuine alternatives presently available. Pesticide responses of *H. destructor* from the field which had reported chemical control failures were compared with mites from susceptible 'control' populations. Toxicology bioassays were conducted on adult mites across multiple generations. Very high levels of resistance to two synthetic pyrethroids, bifenthrin and alpha-cypermethrin, were detected in this species for the first time. This resistance was shown to be heritable, persisting after several generations of culturing. There was no evidence that resistance to organophosphorous chemicals had evolved, although low levels of tolerance have been detected in a previous study. Resistance to pyrethroids appears to be spreading and has the potential to become a widespread problem in Australia and elsewhere. These results highlight the need for more judicious management decisions in order to control pest species in a sustainable manner. Future research and management of the redlegged earth mite should be shifted away from broad-spectrum chemicals to cultural control, biological control, host plant resistance and the use of more selective pesticides.

The functional organization of a tropical insect society

Raghavendra Gadagkar

[1]Centre for Ecological Sciences, Indian Institute of Science, Bangalore, Karnataka, India, [2]Evolutionary and Organismal Biology Unit, Jawaharlal Nehru Centre for Advanced Scientific Research, Jakkur, Bangalore, Karnataka, India

Insect societies such as those of ants, bees, wasps and termites are characterised by reproductive division of labour and cooperative brood care. Thus these societies consists of one or a small number of reproductives (usually only queens but also kings in the case of termites) and a large number of sterile or nearly sterile workers. While the queens engage in laying eggs, all the tasks required for nest building, acquisition and processing of food, and brood care are performed by the workers. The functional organization of such insect societies that leads to efficient division of labour is a topic of obvious interest. In this lecture I will describe experiments designed to understand the functional organization of one such insect society. I have chosen the primitively eusocial wasp *Ropalidia marginata* for these investigations. *Ropalidia marginata* is abundantly distributed in peninsular India and serves as an excellent model system. An important feature of this species is that queens and workers are morphologically identical and physiologically nearly so. How does an individual become a queen? How does the queen suppress worker reproduction? How does the queen regulate the non-reproductive activities of the workers? What is the function of aggression shown by different individuals? How and when is the queen's heir decided? I will show how such questions can be experimentally investigated and discuss what the answers to these questions tell us about the functional organization of this primitive insect society and what they tell us about the evolution of insect sociality.

Antimicrobial production by fungus-growing ants: phenotype, genotype and an abrupt evolutionary transition in the host-parasite interaction

William Hughes[1], Jacobus Boomsma[2]

[1]University of Leeds, Leeds, United Kingdom, [2]University of Copenhagen, Copenhagen, Denmark

The metapleural gland of ants is an ancestral structure that is a key first-line defence against parasites. The paired glands located at the posterior of the thorax produce a broad spectrum of antimicrobial compounds that spread over the cuticle passively or by active grooming. The glands are fixed in size in adults, making them potentially useful for comparing investment in disease defence within and between taxa because the size of the glands is not confounded by factors such as age or health. The fungus-growing ants are particularly useful group for such comparisons because they are a monophyletic tribe in which taxa differ in several factors likely to affect their relationship with parasites. Furthermore, the two most derived genera, the leaf-cutting ants, have a diversity of phenotypes (castes) that may also differ in their host-parasite interactions. Here I will examine how the size of the metapleural gland differs between leaf-cutting ant castes and whether there is genetic variation for this key fitness-determining trait. I will also compare the size of the metapleural glands of leaf-cutting ants with those of the other fungus-growing ants and discuss the insights this provides into the relative parasite pressure experienced by the different taxa.

Rates of larval parasitism of false codling moth, *Thaumatotibia leucotreta* (Meyrick) (Lepidoptera: Tortricidae), on citrus in South Africa

Kierryn Keeton[1], Nomahlubi Sishuba[1], Sean Moore[2], Martin Villet[1]

[1]Rhodes University, Grahamstown, South Africa, [2]Citrus Research International, Port Elizabeth, South Africa

Thaumatotibia leucotreta is a major pest of citrus in South Africa. Due to problems associated with pesticides, alternative methods, such as the use of parasitoids, are becoming an increasingly attractive means of control of crop pests. However, it has been hypothesised that larvae of *T. leucotreta* are protected from parasitoids by their fruit-tunneling habits, and that because of this they will show low rates of parasitism that militate against using parasitoids against them as biological control agents. A six-month survey at two sites in the summer and winter rainfall regions of South Africa found only one specimen of parasitoid. In the equinoctial rainfall region, *Agathis bishopi* (Nixon) (Hymenoptera: Braconidae) was reared from two sites with rates of parasitism of 2.5%-37%. In the field, rate of parasitism was inversely related to age of the host larva, and in laboratory experiments female wasps showed a preference for ovipositing on second- and third-instar larvae and took 23-50 days to develop from egg to adulthood at 27°C. This suggests that this koinobiont preferentially attacks younger larvae, not because it is poorly adapted to the tunneling behaviour of its host and cannot reach older larvae, but because it requires younger larvae to allow it sufficient time to complete its development. Suggestions are made for incorporating these findings into integrated pest management programmes.

Pollinator food-webs on granite outcrops – diversity, specificity and a fly story

Caroline Gross, Wendy Waters

The University of New England, Armidale, NSW, Australia

Introduction: Granite outcrops often hold unique vegetation communities that function as island-refuges for biodiversity. Richness is high with 16-20 plant species in a 10 m^2 area. We tested a corollary that these communities have highly specialized floral systems and pollination mutualisms with the aim to determine the structure of pollinator food webs.

Methods: In Spring 2007, we studied plants and pollinators for 24 plant species and their insect visitors across three granite outcrop sites in eastern Australia. We resolved plant breeding systems for six key-plant species using bagging and hand–pollinations. We determined diversity and fidelity of visitors through observation periods, videoing and insect swabs (c. 110 hours of observations).

Results: Key plant species were mostly self–compatible. Pollinator specificity was low with most species sharing floral visitors. We detected 30 species of insect that we classified as abundant floral visitors. Flies were dominant followed by bees including the introduced honeybee. Most fly and native-bee species carried pollen and came into contact with anthers and stigmas in the observation flowers. Flies were more active early in the season than bees.

Conclusion: This is the first community level study of plant-pollinator interactions in Australia. High plant-species diversity was matched by high levels of diversity in floral-visitors. No single plant-pollinator partnerships were found. Some plant species were visited predominantly by flies and others by bees. We conclude that the granite habitats provide an oasis for many pollinators as the surrounding landscape has a simplified structure devoid of many understory components.

The conservation ecology of the endangered brackish water damselfly, *Mortonagrion hirosei*: Planning to establish a new habitat for mitigation

Mamoru Watanabe

University of Tsukuba, Tsukuba, Ibaraki, Japan

Introduction: In 1998, a tiny habitat of the brackish water damselfly, *Mortonagrion hirosei*, which is an endangered species in Japan was discovered in Ise, Mie Pref. It was a dense reed community on the brackish water, from which had been going to be reclaimed under the construction of sewage plant. The government of Mie Prefecture decided to preserve the local population.

Mitigation Project: The mitigation project started, because the habitat was too small to maintain the local population, and because surroundings of the habitat would become unavailable vegetation for the damselfly due to the plant development. In those days, however, there were few reports on the biology of the species. Therefore, we had to start to clarify quantitatively the population parameters of larvae and adults, behaviour, flight habit, body colour change for adults, saline tolerance of larvae as well as to measure abiotic environment, such as saline, water depth, water temperature and relative light intensity in the original habitat. Based on the accumulation of such information, the design for a newly established habitat was proposed.

Results: In early spring of 2003, huge number of reed rhizomes were transplanted for establishing the new habitat. Artificial brackish water was continuously supplied throughout the year. The artificial reed community has developed year after year and nearly completed to the dense community, though a lot of problems for the mitigation appeared during 2003-2007. Consequently, the adult population has increased in both the original and the established habitat. The mitigation project has now proved successful.

Dolichopodid species number in the North and South of West Palearctic (Diptera): Explanation of differences and forecast

Igor Grichanov

All-Russian Institute of Plant Protection, St. Petersburg, Pushkin, Russian Federation

West Palearctic as a whole is one of the best studied regions, but being investigated rather spotty regarding dolichopodids. The author has generalized their fauna for North Europe (NE) and East Mediterranean (EM) in form of species lists and keys (Grichanov, 2006, 2007). About 400 species are registered in NE and 520 in EM with many more EM species waiting descriptions.

Ten countries or territories with the biggest species lists (between 60 and 330) have been selected in each part of the Palearctic. The species number has been compared with the total area and ecological features of countries.

Sweden has the longest species list (330) in NE (followed by Finland, Leningrad Region and Norway), while Romania (263) in EM (followed by Krasnodar Territory and Ukraine). Taking into consideration country areas, we see other countries at top. Denmark, Estonia and Latvia have the highest index (12.20 to 5.77 species per 1000 sq.km) in NE, while Israel and Caucasian republics Karachai-Cherkessia and Kabardino-Balkaria are the most diverse EM territories (10.85 to 4.64).

There are subjective and objective reasons for this difference. Number of expeditions and enthusiastic dipterists in a country is the main subjective reason. A gradual decrease of biodiversity per unit area northward and eastward is an objective trend in NE. In EM the greatest biodiversity is observed in montane regions, such as the Caucasus, that is supported by data on Dolichopodidae. If a country has large area of flat lands in addition to mountains, then the species index is low.

Coarse woody debris and saproxylic beetles in a managed forest landscape in boreal Sweden

Barbara Ekbom, Martin Schroeder, Thomas Ranius, Stig Larsson

Dept. of Ecology, Swedish University of Agricultural Sciences, Uppsala, Sweden

Saproxylic beetles constitute a significant proportion of boreal forest biodiversity. However, the long history of timber production in Fennoscandia has significantly reduced the availability of dead wood and is considered a threat to the conservation of saproxylic beetle assemblages. Therefore, since the mid-1990s dead wood retention in harvested stands has formed an integral part of silvicultural practices. However, the contribution of this biodiversity-orientated management approach to conserving saproxylic beetle assemblages in boreal forest landscapes that include production forestry remains largely untested. Few studies have attempted to analyze the occurrence of CWD at the landscape level. We studied the occurrence of CWD in stands of different ages and management background in a boreal forest landscape in central Sweden. We examined differences in resident saproxylic beetle assemblages among stands under different management in the same boreal forest landscape, and in particular stands managed according to new conservation-orientated practices. We also investigated the relationship between beetle diversity and forest stand characteristics. The active creation of coarse woody debris (CWD) has been suggested as a measure to preserve and restore biodiversity in managed forests. A common practice in Sweden is to create high stumps at final cutting. Using the same boreal forest landscape we also evaluated the importance of high stumps for saproxylic (wood-dependent) beetles. The consequences of these results for biodiversity-oriented forest management are discussed

Novel mariner-like elements (MLE), Pmmar1, 2 and 3, isolated from the big-headed ant, *Pheidole megacephala*, inhabiting Okinawa, and their phylogenetic analyses

Yuichi Kawanishi, Hitoshi Ohnishi, Akito Kasahara, Kazuki Tsuji, Hideaki Maekawa, Yumiko Nakajima

University of Ryukyus, Nishihara-cho, Okinawa, Japan

Three types of *mariner*-like elements (MLE), named *Pmmar1*, *Pmmar2* and *Pmmar3*, were isolated. *Pmmar1* and *Pmmar2* are defective type elements in their ORFs encoding the transposase whereas *Pmmar3* inserted into *Pmmar1*, was an intact MLE element with inverted terminal repeats and a complete ORF. Sequence comparative analysis revealed that they show highly conserved homology one another and belong to the *mauritiana* subfamily of MLE. *Pmmar1* and *Pmmar2* are closely related to *Myrmar2* from red ant, *Myrmica ruginodis*, and *Botmar1* from bumble bee, *Bombus terrestris*. *Pmmar3* has the highest identity with *Mboumar* from harvester ant, *Messor bouvieri*. Novel MLEs from this big-headed ant in Okinawa were quite homologous to the ant inhabiting in Reunion island of French territory between Madagascar and Mauritius. This means the same population as in Reunion island but not in Libreville, Gabon, west coast of central area of Africa had been transported into Okinawa few hundreds years ago. Micro-satellite DNA analyses data also supported this situation.

Termite species inventory across an oil palm agroecosystem with variable scales of sampling

Faszly Rahim[1], Idris Ghani[1], Ahmad Said Sajap[2]

[1]Universiti Kebangsaan Malaysia, Bangi, Selangor, Malaysia, [2]Universiti Putra Malaysia, Serdang, Selangor, Malaysia

Introduction: No single sampling method has been found to significantly retrieve the species of termite communities across sites, which calls for an integrated sampling scheme. An inventory across oil palm agroecosystem on peat in Peninsular Malaysia was made to monitor termite diversity using sampling methodologies with variable scales as a proposed integrated sampling scheme.

Methods: The inventory was conducted from 2001 to 2005 using 16 units of 100 m x 2 m belt transects, 44 units of successively monitored 500 m^2 rubber wood bait plots, and various hectares of oil palm stand scouting. Community structure was extracted using hierarchical clustering and variations amongst community composition across sites were analysed using the multi response permutation procedure (MRPP).

Results: A total of 46 species of termites from three families, and 17 genera were collected during the inventory. These were collections of 36 species from the transects, 12 species attracted to rubber wood bait, 20 species from stand scouting, and some additional species from the casual samplings. Species-area curves indicated ample effort in retrieving species. This is the first known extended list of termite in oil palm as well as peat soil ecosystem. Hierarchical clustering extracted distinct communities existing in the oil palm agroecosystem on peat. The variations between communities across sites depended on the management history of fields rather than site and peat type alone.

Conclusion: Integrated sampling scheme is a practical method for inventory in retrieving termite species richness across agroecosystem as well as identifying community structures.

Yellow coloration in gregarious desert locusts: function and regulation

Jurgen Huybrechts, Filip Sas, Marisa Geens, Tim Vandersmissen, Arnold De Loof, Liliane Schoofs

K.U.Leuven, Leuven, Belgium

In adult insects, the colour of the cuticle changes rarely once the hardening has been completed. Even more so when colour changes are gender-specific and coincide with sexual maturation. Adult males of the desert locust *Schistocerca gregaria* turn yellow about 10 days after adult molt, but only if they live in crowded (gregarious) conditions. Isolated-reared (solitarious) males do not turn yellow, neither do females. Upon regrouping, yellowing is quickly induced, but again, only in males. All this suggests the existence of a gender-specific control mechanism, perhaps hormonal in nature. Juvenile hormone is known since long to play a role, but the gender-specificity of its effect on yellowing suggests that other factors are involved as well. The discovery that yellowing is due to the deposition in the already hardened cuticle of a carotene-binding 'yellow protein' has facilitated the analysis of the yellowing process. The results of our behavioral observations favor the view that the yellow color does not act as sexual attractant but rather as a signalling colour to discourage other males from mounting a male instead of a female.

Intraguild predation involving *Harmonia axyridis*: a threat to native biodiversity and ecosystem function?

Judith Pell[1], Jason Baverstock[1], Remy Ware[2], Michael Majerus[2], Helen Roy[3]

[1]Rothamsted Research, Harpenden, Hertfordshire, United Kingdom, [2]University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, [3]NERC Centre for Ecology and Hydrology, Abbots Ripton, Cambridgeshire, United Kingdom

As an effective generalist predator of aphids and other hemipteran pests, *H. axyridis* has been a successful biological control agent. However, the very functional traits that have contributed to its success also implicate it as an intraguild predator that not only threatens the diversity of other natural enemies of Hemiptera (and their associated ecosystem services), but biodiversity more widely. A review of existing data on intraguild predation involving *H. axyridis* concludes that niche complementarity is almost certainly the mechanism by which *H. axyridis* remains in equilibrium with its co-evolved native guild of predators. In its alien range, the guild of predators are co-evolved with each other but not with *H. axyridis* and as such come into direct competition with *H. axyridis*. This has significant implications for predator diversity, biodiversity *per se* and also ecosystem services. Pest management strategies, aimed at maintaining predator diversity through habitat manipulation and the diversification of our agricultural landscapes, could help counter declines in predator diversity associated with the arrival of *H. axyridis*. Although implications for biodiversity in natural habitats are of grave concern, it is perhaps through the manipulation of managed land that we have the greatest chance of optimising the environment to favour our native diversity in the presence of *H. axyridis*, thereby also protecting diversity in natural habitats. To achieve this we need robust research data to fill gaps in knowledge and develop mitigation strategies.

Genetic relationship of *Diadegma semiclausum* populations of Taiwan and Syria by means of mitochondrial and nuclear DNA sequences

Kadirvel Palchamy, Robert de la Pena, Srinivasan Ramasamy

The World Vegetable Center, Shanhua, Tainan, Taiwan

Introduction: *Diadegma semiclausum* (Hellen) (Hymenoptera: Ichneumonidae) is an effective larval parasitoid for diamondback moth, *Plutella xylostella* L. (Lepidoptera: Plutellidae), and has been successfully introduced as a biological control agent in many parts of the world. In Taiwan *D. semiclausum* is adapted to low temperatures; in Syria, it is adapted to high temperatures. To explain the possible bases for this adaptation of *D. semiclausum* populations in Taiwan and Syria, it becomes necessary to examine if there is any species-level difference between the populations.

Methods: Using at least 10 insects each from Taiwan and Syria, the mitochondrial gene *cytochrome oxidase I* (COI) of *D. semiclausum* was amplified using the primer pair (UEA3: TATAGCATTCCCACGAATAAATAA and UEA8: AAAAATGTTGAGGGAAAAATGTTA) and partial sequences were obtained.

Results: Sequence alignments and further editing identified a consensus sequence of 707 bp in all the samples. Alignment of sequences of the Taiwan and Syria samples, based on the consensus sequence, did not reveal any difference between them. A high level of sequence similarity was also observed across the COI sequences of *D. semiclausum* insects from various countries available in the database.

Conclusion: Our initial results suggest that the *D. semiclausum* population in Syria does not differ from the population in Taiwan. However, we are in the process of confirming the species identity of the *D. semiclausum* populations of Taiwan and Syria using additional mitochondrial and nuclear genomic regions.

Discovering potent tsetse repellents from odours of refractory hosts and structure and blend optimization studies

Ahmed Hassanali, Rajinder Saini, Mathew Bett

icipe-African Insect Science for Food and Health, Nairobi, Kenya

Two approaches to discovering potent tsetse repellents will be highlighted. One has involved (i) initial GC-MS identification and wind-tunnel evaluation of EAG-active odour constituents specific to a wild animal (waterbuck) that is refractory to savannah tsetse, followed by (ii) field assays (against wild populations of *Glossina pallidipes*) of each group of candidate compounds, individually and in combinations, and successive subtraction assays that compared the relative repellencies of different blends with one of each of the constituents in different groups missing. The process showed that a blend of 4 constituents belonging to different classes of compounds reproduced the repellent activity of the original blend of 15 electrophysiologically-active repellent candidates identified from the host odours. The second approach has involved hypothesis-led wind-tunnel assays of a series of analogues of a known mild repellent of savannah tsetse (2-methoxyphenol) followed by detailed field evaluation of one of the promising candidates. A small modification of the known mild repellent enhanced significantly the repellency of the resulting compound against wild populations of *Glossina pallidipes* in Kenya. Performance of the two repellents in field experiments and their potential in tsetse management will be highlighted.

Ecological metabolomics of plant-insect interactions

Mirka Macel, Nicole M. van Dam, Wim H. van der Putten

Netherlands Institute of Ecology, Heteren, Netherlands

Traditionally the role of plant defense compounds in plant – insect interaction has been investigated using targeted analysis. By doing so, the effects of specific groups of compounds such as glucosinolates and alkaloids on insect herbivores and higher trophic levels have been extensively assessed. However, plants produce a wealth of different compounds and key compounds in plant – insect interactions could be overlooked by taking a targeted approach. Metabolomics is an emerging field that covers the identification and quantification of the suite of metabolites within an organism, tissue or cell. We apply the comprehensive metabolomics approach to study induced plant responses mediating above and belowground plant - insect interactions associated with *Brassica* spp. and in plant – insect interactions of invasive plant species.

Neuromodulation-induced neural circuit interaction in the desert locust

David Rand, Yael Zilberstein, Amir Ayali

Tel Aviv University, Tel Aviv, Israel

Introduction: Insect feeding and ecdysis-related air swallowing are complex rhythmic behaviours characterized by interactions among functionally related central pattern generator neuronal circuits. They involve rhythmic movements of mouth appendages, governed by the suboesophageal ganglion (SOG), and foregut movements, controlled by the frontal ganglion (FG). In our work we focused on the interaction between the FG and SOG circuits in the desert locust, *Schistocerca gregaria*, and specifically on the role of neuromodulation in this interaction.

Methods: *In vivo* recordings demonstrated coordination and synchronization between the motor outputs of the two neuronal centers. Simultaneous extracellular recordings were made from the FG frontal connectives and the SOG mandibular nerves in three *in vitro* configurations: (1) isolated ganglia, (2) FG-SOG preparation with intact nerve interconnections, and (3) a fully connected brain-FG-SOG preparation.

Results: Bath application of the NO donor SNP or of IBMX, followed by the muscarinic agonist pilocarpine, was found to consistently induce robust SOG rhythmic pattern, which consisted of alternating bursts of activity in the mandibular nerves (opener and closer). This finding suggests that the mandibular motor pattern in Schistocerca is activated via muscarinic acetylcholine receptors in a cGMP-dependent manner. The ongoing FG rhythm was accelerated by SOG modulation. Different extents of synchronization of the modulators-induced rhythmic patterns were observed when the FG and SOG were connected or when brain inputs were kept intact.

Conclusions: Our results imply that neuromodulation-mediated interactions between the different neural centers, in the absence of sensory inputs, is sufficient for generating the complex rhythmic motor patterns of the mandibles and gut muscles during Locust feeding or ecdysis-related air swallowing.

Status of pollination ecosystem services in South Africa

John Donaldson, Ruan Veldtman

South African National Biodiversity Institute, Cape Town, South Africa

Introduction: As part of the Global Pollinator Project funded by GEF, apples, seed onions, and sunflower seed crops were identified in South Africa to assess the importance of wild pollinators for their pollination. However, commercial agriculture dependent on insect pollination frequently makes use of managed honeybees (*Apis mellifera* L.) for crop pollination in South Africa. Consequently the importance of both wild and managed pollination services for each of the selected crops require quantification. Another factor not normally considered in crop pollination is differences in pollination at the crop edge and centre. The effective distance of pollination for wild and managed pollinators will thus also be quantified.

Methods: Contribution of wild and managed pollinators to crop pollination will be determined by pollinator exclusion experiments and simultaneous recording of insect pollinator visits. Fields sampled will vary with respect to the presence or absence of bordering natural areas and use of managed hives. For each crop, seed or fruit set will be recorded at the edge, centre, and between these two positions.

Results: Preliminary findings suggest that both wild and managed pollination is a vital part of crop pollination in South Africa. For example, in large sunflower fields surrounded by other agricultural crops managed pollination is required, while for fields bordered by natural areas resident wild honeybee populations ensure sufficient pollination.

Conclusions: Providing information on wild and managed pollination services will identify landscape management strategies that improve crop pollination and ensure conservation of both these services.

The influence of machinery innovation on *Ephestia kuehniella* population in flour mill in the Czech Republic

Vaclav Stejskal, Radek Aulicky

Crop Research Institute, Prague, Czech Republic

Introduction: In Czech Republic (CZ) *Ephestia kuehniella* is a main pest moth species infesting flour mills. In CZ, control of populations of *E. kuehniella* has been traditionally achieved by regular structural fumigation by methyl bromide (CH3Br) or hydrogen cyanide (HCN).

Methods: However, the use of both fumigants is now restricted. CH3Br, as an ozone depletor, is completely unavailable for mill fumigation in CZ. HCN is frequently not permitted by hygienic officers for mill fumigation in urban environment due to its high toxicity. In such circumstances the pest control relies solely on mechanical cleaning, spot phosphine fumigations and use of aerosol insecticides. This was also a case of the studied mill, located in the center of the town.

Results: This study documented that ususal cleaning and limited use of insecticides was not effective enough to control *E. kuehniella* in mills equipped with traditional machinery based on wood transport technology of flour. This case history provided evidence that the introduction of new automated machinery drastically decreased population of *E. kuehniella* in the year of reconstruction.

Conclusions: Although E. kuehniella population increased in the consequent years, it did not reach the population level recorded before reconstruction. This study was supported by the by MZe Project Vyzkumny zamer 0002700603.

Host regulation by a noncoding RNA of TnBV

Patrizia Falabella[1], Maria Teresa Valente[1], Lea Riviello[1], Silvia Gigliotti[2], Magda De Eguileor[3], Francesco Pennacchio[4]

[1]Università degli Studi della Basilicata, Potenza, Italy, [2]Istituto di Genetica e Biofisica - A.Buzzati Traverso; CNR, Napoli, Italy, [3]Università degli Studi dell'Insubria, Varese, Italy, [4]Università degli Studi di Napoli Federico II, Napoli, Italy

The genome of polydnaviruses shows structural features resembling those of eukaryotes, with many genes interrupted by introns and the occurrence of large noncoding regions. The immunosuppressive properties of specific viral gene products has been unequivocally demonstrated, while the possible role in the host regulation of the noncoding regions of the polydnavirus genome remains elusive.

Here we show that a small noncoding RNA of the bracovirus associated with the parasitic wasp *Toxoneuron nigriceps* (*Tn*BV) regulates the expression in the lepidopteran host, *Heliothis virescens,* of a gene which appears to be involved in the immune response. This noncoding RNA displays sequence complementarity with the regulatory 5' UTR of its target gene that it is able to silence. This host gene encodes a protein localized in membrane-delimited compartments of haemocytes, where it gives rise to amyloid fibrils, which favour melanin formation *in vitro*.

Our results demonstrate for the first time the occurrence in polydnaviruses of a noncoding RNA, which controls gene expression, likely via sequence-specific interactions with a regulatory region of a host transcript. Moreover, the discovery that the silenced gene encodes for a precursor of functional amyloids produced by haemocytes stimulates new interesting investigations on the molecular mechanisms regulating innate immunity in insects.

The observed horizontal transfer of genetic material between the host moth larvae and *Tn*BV has interesting evolutionary implications, as it corroborates the hypothesis that bracoviruses may derive from a baculovirus ancestor.

Molecular analysis of circadian system in male moth reproductive organs

Piotr Bebas[1], Joanna Kotwica[1], Jadwiga M. Giebultowicz[2]

[1]University of Warsaw, Department of Animal Physiology, Warsaw, Poland, [2]Oregon State University, Department of Zoology, Corvallis, OR, United States

Introduction: Circadian oscillator in the reproductive system of Lepidoptera is essential for male fertility. Research on the cotton leafworm, *Spodoptera littoralis*, demonstrated that circadian oscillator controls the rhythm of sperm release from the testis into the vas deferens (VD), and coordinates daily changes in the VD environment, which are necessary for sperm maturation. We report functional molecular studies aimed to understand this circadian system.

Methods: Protein expression was investigated by immunocytochemistry and gene expression by qRT-PCR. To determine functions of the molecular oscillator, we cultured testes-sperm ducts complexes *in vitro* with double-stranded *per* RNA.

Results: The clock protein PERIOD (PER) displayed clear daily rhythm in the testes and VD of *S. littoralis*. Levels of PER oscillated in cyst cells surrounding sperm bundles, in epithelial cells of the barrier separating testicular follicles from the VD, and in the epithelium of the upper VD. RNA-mediated interference (RNAi) targeting the *per* gene disrupted clock mechanism. RNAi lowered *per* transcript and PER protein levels. These changes caused transient inhibition of sperm release and a shift in the phase of the sperm release rhythm, regardless of the light/dark cycle. In addition, we demonstrated that per-based molecular oscillator regulates rhythmic expression of B and c subunits of proton pump, V-ATPase, which controls circadian changes in pH. Surprisingly, we also revealed rhythmic expression of the gene encoding yolk protein YP2, which is expected to be active only in females.

Conclusions: Our data provide new insights into the functional organization of the insect peripheral clock. MNiSZW-N300306831/2338.

Records of Scarabaeidae from Kütahya Province

Yakup Senyüz[1], Yalcin Sahin[2]

[1]Dumlupinar Üniversity, Kutahya, Turkey, [2]Eskisehir Osmangazi Üniversity, Eskisehir, Turkey

Introduction: There is not enough database about Scarabaeidae fauna of Turkey and also surroundings Kütahya Province. The samples were collected from different location in Kütahya Province and its neighborhood. The distribution of them in Turkey and also throughout the world were given by this study.

Methods: This study was done between April 2003 and October 2004 in the Kütahya Province. The samples were collected by hand and light trap from different localities and they were identified according to different identification books.

Results: The species of family Scarabaeidae evaluated and totally 20 species were found in this study.

Conclusions: This type of study was made the first time for Kütahya Province and all identified species were new record for the fauna of Kütahya Province. It is expected that detailed further studies will continue in future on this group of insects in Turkey.

To be at the crime scene with the police investigation team is vital: Two case reports

Theuns Van der Linde, Kobus Kolver, Shaun Hoffman

University of the Free State, Bloemfontein, South Africa

Introduction: In South Africa the S.A. Police Services are very reluctant to allow forensic entomologists to the crime scene. There are many reasons for this situation. In this paper two case studies will be discussed.

Methods: At the crime scene and during the autopsy the standard procedures for collecting of entomological evidence were followed.

Results: Case 1: A young mother disappeared from a New Years Party and was found 13 days later, dumped alongside a highway. At the autopsy the forensic entomologist immediately realised that something was wrong. The remains were almost skeletonized, but the only insects present were third instar *Chrysomya albiceps* larvae, no pupae or beetles. When questioning the investigating officer, he admitted that the body was wrapped in a sheet. The case was simulated, using two pigs, one wrapped and the other one naked. The two decompositions differed significantly.

Case 2: The body of a young African girl was found in the field. It was a very hot day with the surface temperature of the body at 50^0C. The body was still fresh, no skin slippage seen. The PMI was calculated to be less than 18 hours. At the autopsy the body showed severe skin slippage. The pathologist was convinced that the PMI was at least 48 hours, which was contradictory to the insects on the body.

Conclusion: It is of utmost importance to be at the crime scene with the police investigation team. Significant post-mortem changes might occur from finding the body until the autopsy is done.

Edge effects on landing patterns of aphids in commercial potato fields

Kerstin Krüger, Lezel Muller, Marié Warren

Department of Zoology and Entomology, University of Pretoria, Pretoria, South Africa

Introduction: Plant borders have been suggested as a management tool to reduce incidence of non-persistently aphid-transmitted viruses in crops, the rationale being that aphids lose transmission ability when feeding on a non-virus host plant before moving into potato fields. Although it has been shown that aphids tend to land more frequently in field borders, little information is available on the strength of edge effects in large fields. We examined aphid landing patterns within fields and tested the hypothesis that aphid landing rates in large potato fields are higher at the edges compared to the interior.

Methods: Four transects each consisting of 16 green plastic bucket traps were placed in cross-formation in three circular commercial potato fields ranging from 20-40 ha. The traps were positioned in square groups of four traps and placed at increasing distances (2, 12, 117 and 222 m) from the edge. Traps were emptied weekly for 7 weeks.

Results: Aphid landing rates tended to be higher at edges of fields for up to 7m compared to the interior. However, landing rates tended to increase again closer to the centre of a field. The strength of edge effects was not the same at all sites and sampling weeks and depended on factors such as aphid abundance, aphid species and trap position.

Conclusions: Although edge effects were apparent, patterns within and among sites were not always consistent. However, a trap crop in the centre of large fields in addition to crop borders could contribute towards reducing virus incidence.

Records of Scarabaeidae from the Sündiken Mountains

Yakup Senyüz[1], Hakan Caliskan[2], Davut Ümit Sirin[2], Cüneyt Nadir Solak[1]

[1]Dumlupinar Üniversity, Kutahya, Turkey, [2]Eskisehir Osmangazi Üniversity, Eskisehir, Turkey

Introduction: There is no enough database about Scarabaeidae fauna of Turkey and also Sündiken Mountain in Eskişehir Province. The samples were collected from different locations on the mountain. The distribution of them in Turkey and also throughout the world were given by this study.

Methods: This study was done in the Sündiken Mountain in Eskişehir Province between April and October 2005. The samples were collected by hand and light trap from different localities and they were identified according to different identification books.

Results: Scarabaeidae fauna of the mountain was investigated and totally 22 species were found in this study.

Conclusions: This type of study was made the first time for this mountain and all identified species were new record for the fauna of the Sündiken Mountain. It is expected that detailed further studies will continue in future on this group of insects in Turkey.

Does copulation corrupt resistance against real pathogens in *Tenebrio molitor*?

Terhi Valtonen, Heidi Viitaniemi, Markus J. Rantala

University of Turku, Turku, Finland

The activation and the use of the immune system are costly and should therefore be traded off against other fitness components. According to most studies immune function declines as reproduction increases and mating induces down-reculation of immune function. Previous studies with *Tenebrio molitor* have suggested that copulation corrupts immunity. However, previous immunoecological studies made in *Tenebrio molitor* have received conflicting results suggesting substantial population differences in trade-offs between immune deffence and other life history traits. We tested the effect of mating on immunity in our *Tenebrio molitor* stock population by measuring phenoloxidase activity, encapsulation response against a novel antigen and parasite reistance against real pathogens (fungus *Beauveria bassiana*). The results are discussed in the light of the life-history evolution.

Pyrethroid resistance mutations in the whitefly, *Bemisia tabaci*: an evolutionary perspective on a global scale

Christopher Jones, Kevin Gorman, Martin Williamson, Ian Denholm

Rothamsted Research, Harpenden, United Kingdom

Introduction: Delaying the selection and fixation of mutations that cause target-site resistance is one of the many challenges confronting insecticide resistance management. In this sense, the whitefly *Bemisia tabaci* is highly problematic due to its haplodiploid breeding system, migratory ability and polyphagous nature that all promote the spread of resistance genes. Moreover, *B. tabaci* exists as a complex of morphologically indistinguishable populations termed 'biotypes' that are often reproductively isolated.

Method: A high-throughput real-time PCR assay targeting a single nucleotide polymorphism (SNP) in the mitochondrial cytochrome oxidase I (mtCOI) gene was developed to distinguish between two of the most invasive and widespread biotypes (B- and Q-types). Furthermore, the occurrence of two pyrethroid resistance mutations (L925I and T929V) within the voltage-gated sodium channel gene was investigated across different biotypes along with an adjacent intron sequence to compare variation between resistant and susceptible alleles.

Results: The real-time PCR assay was highly successful at screening field collections of *B. tabaci* from around the world. The technique requires little optimisation, is designed to run on a 96-well plate and can be performed on homogenised individual insects, removing the need for DNA extraction. The pyrethroid resistance mutation, L925I, was present in resistant individuals of all biotypes examined. The reproductive incompatibility between biotypes suggests that this mutation has arisen independently several times. Interestingly, T929V was found solely in Q-type individuals.

Conclusions: Understanding how resistant mutations evolve and spread among and between biotypes will provide valuable information for resistance management tactics employed against *B. tabaci*.

Nectar amino acids and insect responses

Sue Nicolson

University of Pretoria, Pretoria, South Africa

Nectar amino acids have received less attention than the more abundant sugars. The Bakers showed in the early 1980s that amino acids occur widely in floral nectars and suggested possible adaptive significance. Nectar amino acid concentrations are surprisingly high (sometimes exceeding 100 mM) in bird-pollinated *Aloe marlothii* and some *Erythrina* species, largely due to abundant non-essential amino acids e.g. asparagine and glutamine. Other *Aloe* species have much lower concentrations. Nectar of *A. greatheadii* var *davyana*, a major South African bee plant, contains only 2.8 mM amino acids, mainly proline. Amino acids affect the taste of nectar, and chemosensory responses of flies show that the common amino acids may stimulate sugar or salt receptors, be inhibitory, or have no effect. Preference experiments with honeybees show negative responses to most single amino acids at high concentration. We have measured the proboscis extension response of honeybees to dilute sucrose solutions containing amino acids, and found significant positive responses to 2 mM proline, glycine and phenylalanine. Insect responses will depend on concentrations of both amino acids and sugars, and effects of amino acid mixtures are not easily predicted.

Scarabaeidae fauna of the Felent River Basin

Yakup Senyuz, Cüneyt Nadir Solak

Dumlupinar Üniversity, Kutahya, Turkey

Introduction: There is not enough database about Scarabaeidae fauna of Turkey and also Felent Rİver Basin in Kütahya Province. The samples were collected from different locations on the basin. The distribution of them in Turkey and also throughout the world were given by this study.

Methods: This study was done monthly on the Felent River Basin, one of tributaries of Porsuk River, between April 2005 and 2006. The samples were collected by hand and light trap from different localities and they were identified according to different identification books.

Results: Scarabaeidae fauna of the basin was investigated and totally 17 species were found in this study.

Conclusions: This type of study was made the first time for this basin and all identified species were new record for the fauna of the Felent River Basin. It is expected that detailed further studies will continue in future on this group of insects in Turkey.

An evolutionary perspective on biological invasions: insights from the harlequin ladybird, *Harmonia axyridis.*

Lori Lawson Handley[1], Cathleen Thomas[1], Remy Ware[2], Michael Majerus[2]

[1]University of Hull, Hull, United Kingdom, [2]University of Cambridge, Cambridge, United Kingdom

Biological invasions are one of the greatest threats to global biodiversity, agriculture and the economy, but we are a long way from understanding why certain species become invasive, what factors determine their success, and the impacts on the native species with which they interact. An understanding of evolutionary genetics is critical to establish the causes and consequences of invasions, since the genetic make-up of the founding population determines how it will adapt to new conditions and expand its range. Genetic data has revealed that the evolutionary history of invasive species is often complex, for example with multiple introductions or rapid population growth despite genetic bottlenecks in the founding population. Invasive species with well-documented colonisation and expansion histories provide us with excellent models to examine the evolutionary genetics of invasions. One such species is the harlequin ladybird, *Harmonia axyridis,* which is native to central and eastern Asia, and invading other regions including the USA, Europe and South Africa. Since its first recording in Kent in 2004, the UK invasion of *H. axyridis* has advanced at an incredible pace. We are currently investigating the factors contributing to the invasion success of *H. axyridis* in the UK, including the genetic make-up of the founding population, presence of suitable habitat and climatic conditions, and escape from natural enemies. This talk will focus on the theory and justification for an evolutionary perspective on biological invasions, but will also present preliminary data from our study on the evolutionary genetics of *H. axyridis*.

A global indicator for insect invasions: possibilities and challenges

Melodie McGeoch

Centre for Invasion Biology, Department of Conservation Ecology & Entomology, University of Stellenbosch, Stellenbosch, South Africa

Trends in invasive alien species is one of only two headline indicators of threat to biodiversity that forms part of the Convention on Biological Diversity's framework for monitoring progress towards the 2010 target. However, to date there is no fully developed indicator for invasive alien species that combines trends, derived from a standard set of methods, across species groups, ecosystems and regions. McGeoch et al. (2006) proposed such an indicator to meet the 2010 framework goal and targets. Based on broadly accepted principles for biodiversity indicators, single and composite indicators of the status of, and trends in, invasive alien species are used at national and global scales. The indicator includes problem-status and management-status measures, and is designed to be scalable, flexible, readily disaggregated and as far as possible draw on existing data. However, the indicator remains to be tested, in particular to assess its suitability for including poorly known taxa, such as invertebrates. Here I examine the application of the indicator to a sub-Antarctic database of alien species, including invertebrates, and in conjunction with other insect examples assess the options for a global indicator of insect invasions.

Anaerobic respiration by the mangrove ant, *Camponotus anderseni*

Mogens Gissel Nielsen

University of Aarhus, Aarhus, Denmark

Introduction: The small tree-living mangrove ant *Camponotus anderseni* McArthur & Shattuck is remarkably adapted for surviving tidal inundation. By blocking the nest entrance with a soldier's head, water intrusion into the nest cavity can be effectively prevented, but lack of gas-exchange caused extremely high concentrations of CO_2 (>30%) and very low O_2 concentrations (< 1%).

Results: The O_2 uptake in experiments with CO_2 absorption showed a linear decrease until about 4%, whereas the O_2 uptake in chambers without absorbent showed a decrease with a different pattern, consisting of three parts. The first component of this decrease is a linear decrease to about 18%, which is the normal O_2 concentration in open natural nests. The second phase is an exponential decrease continuing to about 4% O_2, showing that the CO_2 concentrations have influence on the O_2 uptake. The final component is also exponential, but with a much smaller slope.

The Respiratory Quotient (RQ) was 0.92 until CO_2 concentration increased to about 15-17%, and after that it showed a strong increase, which is due to the initiation of anaerobic respiration.

Chemical analyses of ants which have experienced anoxic conditions showed no sign of L-lactose, whereas NMR spectroscopy on very few samples shoved a complex changes in concentrations of several metabolites. RNM spectroscopy is currently carried out on a large material, and the results of these findings will be presented.

Conclusions: Anaerobic respiration has not been demonstrated for social insects before, but it is not surprising that it is found in this ant species, which lives in the extreme conditions of a hollow twig in an inundated mangrove.

The importance of stem groups and the need for an integrated approach to insect systematics

Sam Heads

Palaeobiology Research Group, University of Portsmouth, Portsmouth, United Kingdom

The importance of stem groups has been well documented by palaeontologists, who regularly find themselves faced with their novel combinations of plesiomorphic and derived character states. Within entomology, there are two camps: (1) neoentomologists, working exclusively on living taxa; and (2) palaeoentomologists, working exclusively on fossil taxa. Palaeoentomologists engaged in systematic work on fossil insects often disregard the living representatives of the groups they study. In the same token, neoentomologists regularly embark on large phylogenetic revisions of living taxa without considering the wealth of data available from fossils. It is becoming increasingly apparent that stem groups have much to offer in terms of morphological data and are invaluable in establishing character polarities for cladistic analyses. In this respect, fossil taxa are as important as living representatives in phylogenetic studies, where their novel combinations of character states can radically alter tree topology. Here I will illustrate this with examples from my own research on stem-group Orthoptera from the Early Cretaceous of Brazil, and advocate a more integrated approach to the study of fossils. Valuable data is available from both fossil and extant taxa and omitting such data is counterproductive. The future of palaeoentomology requires the study of fossil insects within a more contextualised phylogenetic framework. Similarly, the origins and phylogenetic relationships of modern taxa can never be fully realised without knowledge of their stem groups.

Impacts of the vector-delivered invasive pest, pinewood nematode: process-based modelling of the likelihood of wilt expression.

Hugh Evans, Sam Evans, Makihiko Ikegami

Forest Research, Alice Holt Lodge, Farnham, Surrey, GU10 4LH, United Kingdom

Pinewood nematode (PWN), *Bursaphelenchus xylophilus*, native in North America and normally a saprophytic organism, can induce rapid wilting and tree death given susceptible trees and suitable eco-climatic conditions. Large-scale tree mortality from PWN infestation has taken place in Japan, China, Korea and Portugal where it is an alien invasive. Mortality is driven by the nematode-plant-environment interaction after nematodes enter the host tree during maturation feeding by adult vector beetles (*Monochamus* spp). Although wilt appears to be linked primarily to summer temperature, the mechanisms behind this are unclear. The current study has described this interaction using a process-based model incorporating tree water-carbon relations and the impacts of pinewood nematode on tree physiology. It employs a fully coupled, point scale and daily time step soil-vegetation-atmosphere transfer model incorporating parameters for a forest stand of known structure, with locally determined soil and climate conditions. This 'grows' the trees and produces outputs for key physiological parameters. In the model, PWN is assumed to feed on living tissues, such as parenchyma and cambium, leading to xylem cavitation. The model simulates progression or recovery from xylem cavitation under various environmental conditions. Simulations indicate that high ambient temperatures are the main drivers of irreversible cavitation, but the outcome is tempered by soil moisture availability. In addition, the model predicts that tree mortality can occur either in the year of nematode infestation or in the following year, which has significant implications for managing the PWN problem.

Effect of floral traits and display area on insect visitation rates in lowland vegetation in the Cape Floristic Region

Sven Vrdoljak, Michael Samways

Stellenbosch University, Stellenbosch, South Africa

Introduction: Insects are important pollinators in the Cape Floristic Region, yet interactions between plants and insects, particularly at the community level, are still not fully understood. An important part of these interactions are the mechanisms by which plants attract pollinators. In this study we examine how various floral traits relate to the visitation frequency of species in a plant community during a period of peak flowering.

Methods: Visits by pollinating insects to flowers were observed in 20 standardised plots in the lowlands of the Cape Floristic Region. Each plot was observed for four ten minute intervals, repeated over four days in October 2007. Various floral traits were recorded for all flowering species in the plots and flowers in each plot were counted daily allowing total floral display areas to be calculated per plot.

Results: In total, 1771 visitations were observed in 280 observation periods. Beetles, in particular monkey beetles (Scarabaeidae: Hopliini), were the most frequent flower visitors in this study, accounting for nearly 30% of all visits. Traits such as flower form and colour were found to be significant only in certain cases, whereas visitation frequency showed a strong positive correlation to the size and density of floral displays.

Conclusions: Variation in visitation frequency to plant species is best explained by continuous variables such as the size and density of floral displays rather than other floral traits at the local scale. This concurs with other studies that indicate more non-specific relationships between insects and flowers at the community level.

Immune Responses and Their Potential Role in Insect Outbreaks

Markus Rantala

University of Turku, Turku, Finland

Introduction: Most insect populations do not reach outbreak densities, but some species are known from having populations that never reach outbreak densities as well as populations that display both irregular and regular outbreaks. The long lasting debate about the relative contributions of bottom up and top down factors in population dynamics i.e. in terminating outbreaks, have overshadowed the more important question: why the population densities start to rise in some populations. Parasites and pathogens have been found to regulate insect populations in many theoretical and empirical studies. However, insects are not helpless victims of parasites and pathogens and co-evolutionary processes have favoured the evolution of an effective immune defence system. Thus, the changes in hosts' immune defence may affect the success of parasitoids and pathogens in the host population and potentially may destabilize insect-pathogen dynamics and make control of the insect population by the disease and parasites less likely.

Results: In this talk I present evidence on the autumnal moth (*Epirrita autumnata*) and the gypsy moth (*Lymantria dispar*) that delayed inducible plant defences consequent to grazing by herbivorous insects may be linked to the performance of pathogens through increased immunocompetence of the herbivore feeding on the foliage, in which the defence induction has taken place.

Conclusions: This enhanced immunity of herbivorous insects caused by delayed induced resistance of plant may be the positive feedback effect that enables the increase in the density of moth population.

Effects of pirimicarb, buprofezin and pymetrozine on survival, development and reproduction of *Coccinella undecimpunctata* (Coleoptera: Coccinellidae).

Susana Cabral, Patrícia Garcia, António O. Soares

CIRN, Department of Biology, University of the Azores, Ponta Delgada, Azores, Portugal

Introduction: *Coccinella undecimpunctata* L. (Coleoptera: Coccinellidae) is a euryphagous predator that feeds especially on aphids and can acts as an effective biological control agent against these pests. Although *C. undecimpunctata* has a large geographic range, few studies have assessed the susceptibility of this species to insecticides. To further the development of Integrated Pest Management (IPM) against sucking pests, we evaluated the lethal and sublethal effects on C. undecimpunctata of three insecticides used for control of aphids and/or whiteflies: pirimicab (neurotoxic), buprofezin (insect growth regulator) and pymetrozine (antifeedant).

Methods: The effects of those insecticides on *C. undecimpunctata* were assessed by studying, under laboratory conditions, the survival and development of all preimaginal stages and, the survival and reproductive performance of the adults. For each insecticide treatment, were used the doses recommended by the manufacturer for the control of aphids and/or whiteflies.

Results: None of the three insecticides had significant effect on the survival of *C. undecimpunctata* eggs. When sprayed on larvae, buprofezin significantly reduced survival to adulthood to <33%, compared to > 45% for the control and other insecticide treatments. Rates of adult survival, fecundity, and fertility, and the percentage of egg hatch, were not significantly different between control and insecticide treatments. Thus larval stages were more susceptible to insecticides than were adults.

Conclusions: In general, pirimicarb and pymetrozine had no adverse effects on immature or adult stages of *C. undecimpunctata*, and hence are suitable for IPM of sucking pests.

Native and introduced dung beetles (Scarabaeidae: Aphodidae) using cattle dung in Madagascar

Heidi Viljanen[1], Pierre Rahagalala[2], Ilkka Hanski[1]

[1]University of Helsinki, Helsinki, Finland, [2]University of Antananarivo, Antananarivo, Madagascar

Introduction: Endemic Malagasy dung beetles have radiated with a diverse group of primates (lemurs), the largest native herbivores on the island. Cattle was introduced to Madagascar about 1,500 yrs ago, and thus cattle dung represents a new type of resource for indigenous dung beetles. The most specious dung beetle tribes in Madagascar, endemic Helictopleurini (65 species) and Canthonini (ca 170 species), occur primarily in forests and feed on lemur feces and carrion. In addition, there are three species of Scarabaeini, six species of Onthophagini, and 30 species of Aphodiini and Didactyliini (Aphodiidae) in Madagascar, representing both endemic and introduced species with mostly unknown ecologies.

Methods: We sampled 73 open area localities across Madagascar for dung beetles using cattle dung.

Results: Samples included 28 dung beetle species. Species composition is very homogenous in open areas across the island due to wide ranges of the species, which is in striking contrast to small ranges in forest-inhabiting species. Four endemic Helictopleurini species have been able to switch to cattle dung in open areas and thereby probably expand their ranges in comparison with relatives inhabiting forests. Aphodiini has been able to colonise eastern wet forests, where several endemic species with restricted ranges occur. In contrast, Scarabaeini and Onthophagini occur only in open areas and have not been able to enter wet forests, most likely due to competition with the older Helictopleurini and Canthonini.

Conclusions: Cattle dung is primarily used by introduced dung beetles in Madagascar, but a few endemic species have been able to switch to cattle dung and thereby greatly extend their ranges.

Science on Six Legs: The Insect Connection for Public Outreach

Frank Turpin, Steve Yaninek, Melissa Shepson

Purdue University, West Lafayette, Indiana, United States

Historically one of the goals of some entomologists and entomology departments around the world has been has been to connect with the general public. Today we categorize such programs as outreach and these programs provide an opportunity to engage and teach students and the general public about science using insects as the medium. Current Purdue University programs dedicated to outreach include: “Insectaganza” a program centered on insects which provides 5th grade students with a college-type experience, “Bug Bowl” a festival-type event for the general population which features insects, cockroach racing at the Indiana State Fair, a butterfly count involving people from the local community, and special presentations at schools or for groups that visit campus. These programs engage the audience and connect the public to the science of entomology in a fun way to promote science literacy. The events also provide a training opportunity for Purdue students to develop presentation skills and create programs that are useful for outreach. Our outreach efforts have increased the visibility of the Department of Entomology at Purdue University and enhanced public appreciation for insects and science.

Cognitive processes involved in decision making by honey bees: applications for agriculture

Sharoni Shafir

Hebrew University of Jerusalem, Rehovot, Israel

Introduction: About one-third of our diet is attributed to pollination services provided by insects, predominantly by honey bees. The saying "you can lead a horse to water, but you can't make him drink" applies to the use of honey bees for crop pollination. Bee hives can be placed in the orchard, but ultimately the bees are free to choose which flowers to visit and whether to collect nectar or pollen. Furthermore, bees can be used to efficiently deliver biological agents to control fruit disease. Thus, it is valuable for improving crop quantity and quality to understand, and possibly influence, the bees' decision making processes.

Methods: I will illustrate some techniques used to study bee cognition in studies ranging from basic to applied research. These include the proboscis-extension response paradigm with harnessed bees in the lab, choice of free-flying bees between artificial flowers in enclosures, and assessment of foraging behavior in the field. In addition, hive management techniques and selective breeding can influence the bees' foraging behavior.

Results: Findings from basic research show that bees do not assess absolute values of rewards, but rather that their evaluations are comparative and depend on the other available options. We also have a better understanding of how bees evaluate

variability in rewards. More applied research has concentrated on avocado and various Rosaceae crops (apples, pears, plums). We found that the high mineral content of avocado nectar reduces its attractivity to bees, which is also manifested in their recruitment dances. In Rosaceae crops, naïve bees are better pollinators than experienced bees, which learn to rob the flowers or to forage elsewhere. These findings could guide the management of orchards that will be more attractive to bees. For example, sequential introductions of bee hives into Rosaceae orchards has greatly increased fruit set and yield.

Conclusions: Honey bee perception and decision-making and subsequent behavior determine the quality of services that bees provide to agriculture. The knowledge base from basic research in bee cognition, in addition to applied research, can yield solutions to agricultural problems. Selective breeding can further contribute to developing bee lines with desirable behavioral traits.

Sciapodinae from Baltic amber (Diptera: Dolichopodidae): systematic position and possible palaeoclimatic implications

Igor Grichanov

All-Russian Institute of Plant Protection, St. Petersburg, Pushkin, Russian Federation

The subfamily Sciapodinae was first recorded from Baltic amber (BA) by Meunier (1907), but some other species were misplaced by him at generic level. Bickel (1994) supposed that species described by Meunier in the genus *Nematoproctus* belong to the sciapodine genus *Mesorhaga*. Negrobov and Selivanova (2003) described four BA species of *Amesorhaga*. H. Ulrich (pers.com.) has noted after examination of the type material that *Wheelerenomyia* is a sciapodine genus, as also *Neurigona* sensu Meunier (Grichanov, 2008). The comparison of descriptions and figures provided by Meunier, Negrobov & Selivanova leaves no doubt that all 15 species from BA with strongly sinuate vein M should be transferred into the fossil genus *Wheelerenomyia*. This genus is also known from Ukrainian amber, being recorded previously as *Neurigona* (Grichanov, 2000).

There is practically no true Sciapodini+Chrysosomatini in BA, as fossil specimens have distinct preapicals on mid and hind femora and unbranched M. *Wheelerenomyia* is close to Mesorhagini, differing in many plesiomorphic characters. Tertiary Baltic-Dnieper Subprovince embraces large area of modern Europe. Bickel noted that its fauna has no any Gondwanan palaeotropical elements, and the western Palaearctic appears to have been isolated to recent time. Therefore, it is not surprising that extant Mesorhagini are absent in Europe and adjacent regions. The question is still open: could *Wheelerenomyia* give origin to other sciapodine clades? Anyway, their comparative abundance in amber correlates with mainly tree trunk and tree canopy habitats of almost all Sciapodinae. The subfamily is now basically pantropical that supports opinions about subtropical climate of the Baltic region during the Eocene.

Mass occurrences of *Thaumatomyia notata* (Diptera: Chloropidae) on buildings in Europe

Marion Kotrba[1], Emilia Narchuk[2]

[1]Zoologische Staatssammlung München, München, Germany, [2]Zoological Institute, Russian Academia of Sciences, St. Petersburg, Russian Federation

Introduction: Mass occurrences of *Thaumatomyia notata* on buildings in fall have been known and described in the literature for centuries. They constitute a considerable nuisance for the inhabitants and can even diminish the monetary value of a particular building. The reasons for their appearance at the same location year after year are still not understood and effective control strategies have yet to be developed.

Results: Based on literature records and numerous own observations, the phenomenon of the mass occurrences with tens of millions of flies hibernating in the top region of certain buildings is described. The present state of knowledge on the biology of the species and its hygienic and economic implications for man are summarized. More than 350 historic and new data are evaluated regarding the distribution of the mass occurrences in time and space and their possible correlation with climatic factors. The distribution spans almost all of Europe between 42-61° N. An all time high in southern Bavaria was reached in 2003 after a particularly long and hot summer, with more than 100 cases reported from the region between Munich and the Alps alone.

Conclusions: Mass occurrences of *T. notata* on buildings are not a rare and, therefore, negligible problem. It is expected that with the current global warming the problem will persist or even increase. The need for effective control strategies calls for a sound investigation of the biology of this species and especially the orientation mechanisms on which the formation of the aggregations is based.

Arrival and rapid spread of *Harmonia axyridis* (Coleoptera: Coccinellidae) in South Africa

Riaan Stals

South African National Collection of Insects, Queenswood, Pretoria, South Africa

The Asian lady beetle *Harmonia axyridis* (Pallas) (Coleoptera: Coccinellidae) has emerged as a significant invasive organism in recent years, being eurytopic, broadly polyphagous, very dispersive and phenotypically highly plastic. It can cause complex ecological effects involving changes in invaded communities, besides impacting on agriculture and human health, and potentially being a household nuisance.

Harmonia axyridis established widely in Western Europe since the 1980s. By 1988 it had established in the USA, and subsequently spread rapidly throughout most of the continental USA and southern Canada. In South America, the invader was first recorded in 2002. It reached the UK in 2004 and Scandinavia in 2007. In all of its adopted ranges it spreads rapidly, widely establishing feral populations.

Harmonia axyridis has now also appeared in South Africa, the first known established population discovered in Spring 2004 at Riviersonderend, Western Cape Province. The species' identity was only confirmed in 2006. Subsequently, a South African specimen collected in December 2002 came to light in an European museum.

No structured sampling has been done, yet the rapid spread of *H. axyridis* in South Africa has been noted. It was found in the Eastern Cape Province in Summer 2005/2006, some 600 km from the Riviersonderend locality. Reports of its presence in the eastern Free State Province started in May 2007. In November 2007 it was found in numbers in the KwaZulu-Natal Midlands, and in the Gauteng Province the first specimens were discovered in January 2008. These localities are all widely separated.

There is no reason to seriously doubt that *H. axyridis* will spread rapidly throughout much of South Africa and beyond and bring to bear its negative invasive characteristics here. The early detection of this apparently inadvertent introduction to South Africa presents a rare opportunity to study an anticipated biological invasion virtually from its incipience.

Effects of different routes of exposure to pesticides on the predatory mite *Phytoseiulus persimilis* Athias-Henriot (Acari Phytoseiidae) and its prey

Carlo Duso, Alberto Pozzebon, Paola Tirello, Paulina Bermudez Ortiz

University of Padua, Padova, Italy

Phytoseiulus persimilis Athias-Henriot (Acari Phytoseiidae) is a major predator of spider mites, in particular of *Tetranychus urticae* (Acari Tetranychidae). Predator-prey interactions may be affected by pesticides used to control other pests, and thus knowledge of pesticide side-effects is essential to manage spider mite populations following IPM tactics. Here, we present the results of laboratory studies involving both predator and prey that considered differential routes of exposure. Insecticides with different modes of action and in-plant translocation (e.g. spinosad, thiamethoxam) were used. We evaluated the pesticide effects on *T. urticae* females exposed to pesticide leaf residues, topical applications and systemic applications. Regarding *P. persimilis*, we also considered the effects induced by the contaminated prey. The evaluation of the pesticides impact in relation to differential routes of exposure considered mite survival, fecundity and egg-hatching. The implications of these studies for IPM are discussed.

Ecology of harvesting in stingless bees

Marilda Laurino

University of São Paulo, São Paulo, SP, Brazil

Introduction: Stingless bees are social bees living in tropical and subtropical areas of the world, and today they encompass over 600 species. Considering pollen analysis and collection in flowers, they are polytrophic, which is associated to its perennial nest and social life.

Methods: Most of the bees studied are located in a small experimental station placed in the Amazon forest, specifically Xapuri - Acre. The flight activities, the harvested material, as well as the nests, were observed during dry and rainy seasons. Nectar collected by workers returning to the nest and males in congregations were compared.

Results: The bees harvested all day long, nonetheless the peak of activities occurred in the first hours of the day. Regarding the botanic origin of the pollen, most of them presented Myrtaceae pollen as a dominant component (> 75.8%). Rubbery-gum resin, which was present in small quantities in dry season, has an orange color and oval seeds tagged along with it. Mud appeared only in the rainy season. Meliponini males when leaving their nests may form congregations where they dehydrated nectar with 11-27% of sugar whereas returning workers with 18-36%.

Conclusions: The bees harvest different proportion of resource according to each season, but they still continue to maintain fidelity to temperature and humidity for these activity. Seeds tagged along with the resin make bees another dispersal instrument of some Amazon flowers. Volume and percentage of nectar sugar from males were always lower than those sampled from returning foragers.

Competitive Exclusion Principle and Understanding Parasitoid Success

Robert Luck

University of California, Riverside, Riverside California, United States

Aphytis melinus, an ectoparasitoid of California red scale, *Aonidiella aurantii*, was introduced into southern California citrus groves in 1957. Once established, it rapidly displaced its congener, *Aphytis lingnanensis*. By 1967, it had excluded *A. lingnanensis* from most of the interior groves where it once had been the dominate parasitoid. Although *A. melinus* had also been released in the intermediate inland groves, it took another six or seven years for it to displace *A. lingnanensis* from them. By 1972, *A. lingnanensis* had been relegated to the cooler coastal groves. We also found that both *Aphytis* species allocated male offspring to smaller scales and female offspring to larger scales. Of more interest was the comparison of the scale size from which the female *Aphytis* emerged: *A. lingnanensis* females emerged from larger scales than did *A. melinus* females. Moreover, *A. melinus* offspring emerging from these larger scales where sometimes gregarious, yielding one male and one female or one male and two females. Thus, although these parasitoids utilized the same red scale stages, *A. melinus* produced daughters on a smaller scale and more daughters on larger scales than did *A. lingnanensis.* It was this difference in female progeny production that led to the displacement of *A. lingnanensis* from most of southern California. We then used this information to develop an augmentative release program to suppress California red scale in San Joaquin Valley citrus where third instar scales are small and their age structure is more synchronized than it is in southern California citrus groves.

Community modules and trait-mediated effects: Some theoretical perspectives

Robert Holt

University of Florida, Gainesville, Florida, United States

There is now a large amount of theory on “community modules” – small numbers of species interacting in defined configurations, such as apparent competition, food chains and intraguild predation. Until recently this body of theory assumed organisms had fixed traits, but there is increasing interest in examining the community-level consequences of labile traits. In this paper, I will revisit some classic results for such modules (e.g., involving the potential for trophic cascades, the conditions for prey coexistence, and system stability along productivity gradients), and ask how these conclusions are altered if one incorporates trait-mediated effects. I will touch on commonalities and differences between plastic trait responses, and evolutionary trait responses. Part of my talk will be a review, and part will be new material.

Development of control tactics against the invasive cactus moth, *Cactoblastis cactorum*, in North America

Stephen Hight[1], James Carpenter[2], Stephanie Bloem[3], Kenneth Bloem[3], Joel Floyd[4]

[1]USDA-ARS, Center for Medical, Agricultural, & Veterinary Entomology, Tallahassee, FL 32308, United States, [2]USDA-ARS, Crop Protection Management and Research Unit, Tifton, GA 31794, United States, [3]USDA-APHIS, Center for Plant Health Science Technology, Raleigh, NC 27606, United States, [4]USDA-APHIS, Plant Safeguarding & Pest Identifications, Riverdale, MD 20737, United States

Introduction: The most successful classical biocontrol of weeds program has been the control of invasive prickly-pears (*Opuntia* spp.) by the Argentine cactus moth *Cactoblastis cactorum*. However, the moth has invaded North America and its ability to control its host plant raises concerns for the safety and survival of the many important *Opuntia* spp. in North America.

Methods: A variety of tools and tactics were developed to study and control *C. cactorum*. A survey tool was developed to identify the presence of the moth. Insecticide trials were conducted. In support of a Sterile Insect Technique (SIT), studies were conducted on mass rearing, radiation biology, overflooding ratios, transport - cold storage - release techniques, and sanitation efforts.

Results: Mating of *C. cactorum* takes place within the hour before sunrise. Female sex pheromone components were characterized, and a sticky-bottom wing trap baited with a synthetic female pheromone lure was developed as the survey tool. This trap identified three generations/year in the USA across a large latitudinal gradient. Three insecticides effectively killed eggs and neonate larvae. A radiation dose of 200 Gy is sufficient to fully sterilize females.

Conclusions: Wing traps are a useful survey tool to identify when and where wild insects are present and where to deploy the SIT. Sanitation and SIT are complimentary control tactics. Sanitation is effective in high populations and SIT is effective in low populations. Insecticides may be useful to control *C. cactorum* if restrictions are placed on the movement of Opuntia nursery stock.

Coevolution and the adaptive value of autumn tree colours: colour preference and growth rates of a southern beech aphid

Claudio Ramirez, Blas Lavandero, Marco Archetti

[1]*Universidad de Talca, Talca, Chile,* [2]*University of Oxford, Oxford, United Kingdom*

Introduction: The evolutionary explanation for the change in leaf colour during autumn is still debated. Autumn colours could be a signal of defensive commitment towards insects (coevolution) or an adaptation against physical damage due to light at low temperatures (photoprotection). These two hypotheses have different predictions. Insects should not prefer red leaves in autumn and grow better in spring on trees with green autumn leaves (coevolution) and should prefer and grow better on trees with red leaves because they provide better nutrition (photoprotection).

Methods: In central Chile we studied field abundance of *Neuquenaphis staryi* on trees of *Nothofagus alessandrii* differing in colours in autumn. We also performed a laboratory choice test of colour preference and measured in the field the performance in spring of aphids born on trees that had different leaf colours in the previous autumn.

Results: We found higher abundance of aphids on green rather than red or yellow trees, preference for green leaves in autumn but no differential performance of aphids in spring. No correlation was found between the growth rates of aphids in spring and the autumn colours of the trees.

Conclusions: Preference for green in autumn is consistent with the coevolution theory, but lack difference in growth rate of aphids in spring is not. Autumn colours would confer an advantage to the tree by reducing the impact of parasites but the advantage for aphids seems to be restricted to autumn and not related to growth rates in spring.

Intraspecific variability in the number of larval instars in insects

Toomas Esperk[1], Toomas Tammaru[1], Sören Nylin[2]

[1]University of Tartu, Tartu, Estonia, [2]Stockholm University, Stockholm, Sweden

The number of larval instars varies widely across insect species. However, intraspecific variability in the number of instars is not an exceptional phenomenon either. Nevertheless, the knowledge about the subject has remained fragmentary. In our recent review (J. Econ. Entomol. 100: 627-645), we show that intraspecific variability in the number of larval instars is widespread across insect taxa, occurring in most major orders, in both hemimetabolous and holometabolous insects. Temperature, photoperiod, food quality and quantity, humidity, rearing density, physical condition, inheritance and sex are the most common factors influencing the number of instars. We discuss adaptive scenarios, which may provide ultimate explanations for the plasticity in instar number. The data available largely support the compensation scenario, according to which instar number increases in adverse conditions when larvae fail to reach a species-specific threshold size for metamorphosis. In more specific cases, the adaptive value of the variability in instar number may be in reaching or maintaining the developmental stage adapted to hibernation, producing additional generations in multivoltine species, or increasing the probability of surviving in long-lasting adverse conditions. Finally, we present a life-history perspective of the reaction norms for age and size at maturity for individuals developing through different number of instars.

Activity evaluation of cocoa pod borer sex pheromone in different geographic locations and in cacao fields in Malaysia and Indonesia

Aijun Zhang, Lip Foo Kuang, Navies Maisin, Bhanu Karumuru, David Hall, Ike Virdiana, Smilja Lambert, Hussin Bin Purung, Shifa Wang, Prakash Hebbar

USDA, ARS, PSI, Beltsville/MD, United States

Introduction: The cocoa pod borer, *Conopomorpha cramerella* (Snellen) (Lepidoptera: Gracillariidae), has been reported as the most serious pest of cacao, *Theobroma cacao* L., in Southeast Asia. The sex pheromone of *C. cramerella* were identified in 1986 and field tested in Sabah, Malaysia. However, the use of pheromones against *C. cramerella* was halted in the early 1990s attributed to the possibility of existence of more than one strain of *C. cramerella* in Asia that behaved differently to the pheromone blend.

Methods: Activity of synthetic sex pheromone was re-evaluated using the Delta trap in the cacao fields and release rate of pheromone formulation was tested in the laboratory condition.

Results: It was found that lures containing 100-µg of synthetic sex pheromone blend, (*E,Z,Z*)- and (*E,E,Z*)-4,6,10-hexadecatrienyl acetates and the corresponding alcohols in a ratio of 40:60:4:6 in a polyethylene vial, attracted male *C. cramerella* moths in Sabah and peninsular Malaysia and in Sumatra and Sulawesi, Indonesia, suggesting that the same pheromone strain existed in a wide stretch of the Indo-Malayan archipelago. A release rate study of pheromone formulation demonstrated that a satisfactory “half-life time” of a 100-µg loading is about 6-wk.

Conclusions: Our research results had shown that the presence of a single pheromone strain of *C. cramerella* in a wide geographic region extending throughout the Indo-Malayan archipelago. Development of cost-effective pest management strategies should also include pheromone-based monitoring, mass trapping, and possibly mating disruption at a later date, in addition to regular and complete harvesting, rational use of effective pesticides, biological control, and plastic sleeving.

Activity evaluation of cocoa pod borer sex pheromone in different geographic locations and in cacao fields in Malaysia and Indonesia

Aijun Zhang, Lip Foo Kuang, Navies Maisin, Bhanu Karumuru, David Hall, Ike Virdiana, Smilja Lambert, Hussin Bin Purung, Shifa Wang, Prakash Hebbar

USDA, ARS, PSI, Beltsville/MD, United States

Introduction: The cocoa pod borer, *Conopomorpha cramerella* (Snellen) (Lepidoptera: Gracillariidae), has been reported as the most serious pest of cacao, *Theobroma cacao* L., in Southeast Asia. The sex pheromone of *C. cramerella* were identified in 1986 and field tested in Sabah, Malaysia. However, the use of pheromones against *C. cramerella* was halted in the early 1990s attributed to the possibility of existence of more than one strain of *C. cramerella* in Asia that behaved differently to the pheromone blend.

Methods: Activity of synthetic sex pheromone was re-evaluated using the Delta trap in the cacao fields and release rate of pheromone formulation was tested in the laboratory condition.

Results: It was found that lures containing 100-µg of synthetic sex pheromone blend, (*E,Z,Z*)- and (*E,E,Z*)-4,6,10-hexadecatrienyl acetates and the corresponding alcohols in a ratio of 40:60:4:6 in a polyethylene vial, attracted male *C. cramerella* moths in Sabah and peninsular Malaysia and in Sumatra and Sulawesi, Indonesia, suggesting that the same pheromone strain existed in a wide stretch of the Indo-Malayan archipelago. A release rate study of pheromone formulation demonstrated that a satisfactory “half-life time” of a 100-µg loading is about 6-wk.

Conclusions: Our research results had shown that the presence of a single pheromone strain of *C. cramerella* in a wide geographic region extending throughout the Indo-Malayan archipelago. Development of cost-effective pest management strategies should also include pheromone-based monitoring, mass trapping, and possibly mating disruption at a later date, in addition to regular and complete harvesting, rational use of effective pesticides, biological control, and plastic sleeving.

The spread of viral and parasitic diseases due to climate change

Andrew Githeko

Kenya Medical Research Institute, Kisumu, Kenya

Today's life styles are energy dependent and energy intensive. For example in 2005 the daily global consumption for petroleum was 85 million barrels/day. Human activities produce gases such as carbon dioxide, methane, nitrous oxides and fluro-carbons, known as green house gases and which are deposited in the atmosphere. Evidence of climate change includes an increase in the mean temperature and larger magnitude in departures from the mean temperature.

Insects and micro-organisms cannot regulate their internal temperature and their reproduction and feeding rates is dependent on external temperature. Insects such as mosquitoes, ticks, mites and snails carry human diseases and their populations' sizes are dependent on environmental factors including temperatures. Some of these insects cannot survive in low or very high temperatures and because of this some disease have been absent in regions that experience long periods of low temperatures. However as the earth's climate continues to change the insects are adapting to the new world.

In recent years changes have been observed in the distribution of insect-borne diseases such as malaria, dengue, Lyme disease and West Nile Fever. Evidence of changing disease patterns from Africa, Europe, North and South Americas and Asia indicate that this is a global phenomenon where the common factor is climate change. In Eastern Africa the frequency of malaria epidemics in the highlands and the spread of the disease to new areas have been observed.

Effect of a retardant dose of glyphosate on biocontrol agents of water hyacinth, *Eichhornia crassipes* (Mart.) Solms-Laubach

Ashwini Jadhav[1], Martin Hill[2], Naweji Katembo[1], Marcus Byrne[1]

[1]University of the Witwatersrand, Johannesburg, South Africa, [2]Rhodes University, Grahamstown, South Africa

Introduction: Water hyacinth, *Eichhornia crassipes* (Mart.) Solms-Laubach (Pontederiaceae) has a negative impact on aquatic ecosystems in South Africa despite biocontrol which remains hampered by high nutrient levels and low temperatures. Often, the biocontrol agents are unable to overcome rapid weed growth, necessitating the need for intervention by herbicidal control. However, lethal doses of herbicides have adverse environmental consequences and may kill the biocontrol agents,

Methods: This study tested the effects of a retardant dose of glyphosate on the water hyacinth weevils, *Neochetina eichhorniae* Warner and *N. bruchi* Hustache, and the water hyacinth mirid, *Eccritotarsus catarinensis* (Carvalho). Beetles and mirids were exposed to the herbicide indirectly by spraying plants with glyphosate. Insect numbers were counted and feeding scars were recorded in the laboratory trials and field trials. Survival, feeding and reproduction were recorded.

Results: A retardant dose of 0.8% glyphosate did not influence numbers of adult insects or the immature stages, thereby maintaining population numbers on the weed. However, the retardant dose stunted the growth of the weed in terms of ramet production, but did not kill the plants, thereby preserving the habitat for the biocontrol agents since the mat did not sink. The herbicide may improve the quality of the plant for insect herbivores.

Conclusion: This method offers a low impact, integrated weed management tool for weed affected water systems.

Effect of a retardant dose of glyphosate on biocontrol agents of water hyacinth, Eichhornia crassipes (Mart.) Solms-Laubach

Ashwini Jadhav[1], Martin Hill[2], Naweji Katembo[1], Marcus Byrne[1]

Insects in Asian culture

Kenichi Nonaka

Rikkyo University, Tokyo, Japan

Insects are an important natural resource, both for self-sufficiency and as commercial products in South-east Asia including Korea and Japan. People living there have established various relationships with large amounts of many species of insects such as food, medicine, ornaments, decoration and other miscellaneous uses and adaptations including insect repellents. Insects are also portrayed in songs, tales and beliefs. They also reflect regional preferences and socio-cultural significance, which can be described in terms of regional differences. Activities involved in collecting insects, and also their habitats, are related to subsistence farming, which mainly consists of rice cultivation in the rural areas, where land-use involves a combination of paddy fields and surrounding forests. This study explores and discusses some of the diverse relationships between humans and insects in Asia, where there are various nations and a range of different levels of subsistence as well as diverse environmental conditions, and goes on to discuss the characteristics of insect-use in relation to rice-cultivation and related other subsistence activities and commercialization arising from economic development. Case studies are discussed based on the author's fieldworks focusing the collecting and cooking, marketing and nature-society relationship.

Seasonal distribution and comparison of methods for sampling psocids in stored wheat

James E. Throne, George P. Opit, and Paul W. Flinn

USDA-ARS Grain Marketing and Production Research Center, 1515 College Avenue, Manhattan KS 66502, United States.

Introduction: Psocids are an emerging problem in stored grain and in grain processing facilities in the U.S., yet we know little about which species infest these products or the ecology of these species as related to pest management.

Methods: We compared several methods for sampling psocids in wheat stored in steel bins – cardboard refuges on the surface of the grain and near the bin hatch, grain trier samples, and automated sampling using the StorMax Insector system.

Results: The predominant psocid species found was *Liposcelis entomophila* in 2005 and *L. decolor* in 2006. Numbers of psocids were low immediately after bins were filled in July 2005, peaked in October, dropped to almost zero in December as temperatures decreased during winter, and then remained at low levels until the study was ended in April. In 2006, the number of psocids increased gradually from August to mid- October, and then generally declined until the study was ended in early November. Numbers of psocids in cardboard refuges and the Insectors were indicative of numbers of psocids in grain samples in both years.

Conclusions: The results indicate that cardboard refuges or Insectors may provide an efficient method for sampling psocids in bins of wheat, and that psocid populations can increase quickly to high levels during storage even though they are low early in the storage period.

New genes for new phylogenies: possible candidate genes from termite EST libraries

Srini Kambhampati And Matthew Steller

Department of Entomology, Kansas State University, Manhattan, KS 66506 USA

Introduction: Recent studies on the phylogenetic position of termites in relation to cockroaches have generated controversy. These studies suggest that cockroaches are paraphyletic and/or termites are nested within the cockroaches. Confidence in a phylogeny is generated when several independent genes result in a tree topology that is similar to one another. With the development of genomic resources for termites, there is an opportunity to identify and utilize many different genes for estimating phylogenies for termites, cockroaches, and mantises.

Methods: We have constructed 5 cDNA libraries from *Reticulitermes flavipes*: workers, soldiers, alates, early larvae, and late larvae. We sequenced ~15,000 clones, undertook bioinformatic and gene ontology analyses, and compiled a ~5000 gene EST library. We attempted to identify genes for the resolution of deep (oridinal), medium (family), and terminal (genera) divergences based on percent sequence identity. We constructed preliminary trees from sequences available from public data bases to obtain an indication of the phylogenetic information contained in these genes.

Results: Several genes were identified that are potentially useful for inferring a phylogeny for termites, cockroaches, and mantises. In any phylogeny involving multiple Orders, several independent genes must be used to obtain resolution of different divergences. We hope that our identification of these potential candidate genes will help in generating a robust phylogeny for termites, cockroaches, and mantises.

Conclusions: The genomic resources being developed for termites are likely to be a rich source of genes for inferring robust phylogenies for termites, cockroaches, and mantises.

Across spatial scales dynamics of *Anopheles gambiae* populations and malaria transmission

Gianni Gilioli[1] , Johann Baumgartner[2], Gabriele Cola[3], Andrew P. Gutierrez[4], Hans R. Herren[5], Bernt Lindtjorn[6], Luigi Mariani[3], Sara Pasquqali[7], Wakgari Deressa[8]

Universita Mediterranea di Reggio Calabria, Diparimento di Gestione dei Sistemi Agrari e Forestali, Reggio, Calabria, Italy[1], Università degli Studi di Milano, Istituto di Entomologia agrarian, Milano, Italy[2], Università degli Studi di Milano, Dipartimento di Produzione Vegetale, Milano, Italy[3], University of California Berkeley, Department of Environmental Science, Policy and Management, Berkeley, California, USA[4], Millenium Institute, Arlington, VA, USA[5], Centre of International Health, Bergen, Norway[6], CNR-IMATI, Milan, Italy[7], Department of Community Health, Addis Ababa, Ethiopia[8]

Introduction: In many African regions, *Anophles gambiae* is the main vector of falciparum malaria. The dynamics of vector populations and malaria transmission is modelled at mesoscale (1x1 km resolution) and microscale (0.1x0.1 km resolution).

Methods: The epidemiological system consists of four interacting components: hydrology (water bodies), environment (land use and meteorological driving variables), vector population, and human population. Modeling strategy consisted of: (i) developing and testing a spatially-explicit hydrological model of water bodies in relation to environmental variables; (ii) adding a spatially-explicit model representing the dynamics of stage-structured mosquito populations and malaria transmission. Simulations have been performed at the two spatial scales. Input data for the models are from Kenya and Ethiopia, and parameters are obtained from literature and remote sensing.

Results: At the mesoscale level, the hydrological model, tested with remotely sensed data, yielded a satisfactorily description of the spatial distribution of the potential breeding sites. The addition of vector populations and malaria transmission produced a realistic spatial pattern of malaria prevalence. At the microscale, the models are used in developing adaptive management of vectors and malaria control at the community level.

Conclusions: Mesoscale results suggest strategic planning options at the national level, and the microscale analysis suggests adaptive strategies for ecosocial system management in East Africa. Modeling the epidemiological system at two spatial scales increases the opportunities for parameter estimation in the face of limited data, provides an additional mechanism for model validation and improves model flexibility and use.

Effect of mating on queen quality and consequences for queen-worker interactions in honey bees (*Apis mellifera*).

Freddie-Jeanne Richard, David Tarpy and Christina Grozinger

Department of Entomology and Genetics, W.M. Keck Center for Behavioral Biology, North Carolina State University, Raleigh, NC

Mating profoundly alters honey bee queen behavior and physiology. After mating, queens cease taking flights and remain in the hive to initiate egg laying. There are also dramatic differences in the pheromone profiles of mated versus virgin queens, which lead to different queen-worker interactions. Furthermore, honey bee queens are highly polyandrous. While the effect of mating number on colony fitness have been considered in detail, it is unclear if there are direct effects of mating number on queen physiology or queen-worker interactions. We have used behavioral analyses, analytical chemistry, and functional genomics to determine the effects of mating number on honey bee queen pheromone profiles, physiology, and worker interactions. Furthermore, we have examined the roles of insemination volume and substance (e.g., semen versus saline) on producing these dramatic changes. Singly versus multiply inseminated queens have significantly different pheromone profiles in both the mandibular and Dufour's glands, queen-worker interactions, and gene-expression levels in the brain and fat bodies. Insemination volume appears to be a major factor in producing these changes. These studies elucidate the effects of mating number at the level of queen physiology, gene expression, and behavioral interactions with the workers, lay the groundwork for characterizing the molecular and physiological mechanisms underlying reproduction in honey bee queens.

Protecting a holiday village from termites in a natural park: a challenging experience in Andalusia (Spain)

Elena Pedroni[1], M. Angeles Lopez Martinez[2], Rafael Ocete Rubio[2], Francisco Correa Rodriguez[3], Lara Maistrello[1]

[1]Department of Agricultural & Food Sciences, University of Modena and Reggio Emilia, Reggio Emilia, Italy, [2]Laboratory of Applied Zoology, Department of Physiology and Zoology, Faculty of Biology, University of Seville, Seville, Spain, [3]Integral de Plagas, S.L. Sanidad Ambiental, Santa Ana, 2, 41900, Camas, Seville, Spain

Introduction: Subterranean termites are a serious threat in urban environments and termite management can be difficult in areas with special constraints. This work was carried out in Priego de Cordoba, a place of great historic and naturalistic relevance in South-Eastern Spain, belonging to the Parque Natural de las Sierras Subbeticas, and the intervention was performed in a holiday village (14000 m^2) where an underground spring had been found.

Methods: A preliminary inspection showed the presence of *Reticulitermes grassei* in many buildings of the village so the termite bait system SENTRI^{tm} Tech Dow AgroSciences was chosen as the most appropriate. In March 2007, 135 underground monitoring stations were initially installed in the constructions basement vaults, along the buildings perimeter and in the garden areas, covering all the areas where termite damage could have been most probable. Periodical inspections were performed and when active infestations were found, the monitoring wooden sticks were replaced with Hexaflumuron treated baits.

Results: Monitoring data revealed that termite infestation was rather uniformly distributed all over the village and had a high potential of serious damage. The highest number of active stations (46%) and the highest number of termites was detected in May. After the baiting program, the number of active stations, number of termites and bait consumption gradually decreased and by October only 4% of the stations was still active.

Conclusions: The chosen control method guaranteed protection without negative environmental consequences and additional costs. Early and timely termite management interventions can prevent serious damages and economical losses.

Utilising sex pheromones of raspberry cane midge, Resseliella theobaldi, and apple leaf midge, Dasineura mali, for pest monitoring and control

Jerry Cross[1], David Hall[2], Michelle Fountain[1], Adrian Harris[1], Dudley Farman[2]

East Malling Research, East Malling, Kent, United Kingdom[1], Natural Resources Institute, Chatham Maritime, Kent, United Kingdom[2]

Pheromone identifications: The sex pheromones of the raspberry cane midge and apple leaf midge, have been identified and synthesised and are highly attractive to males. They are acetoxyketones, a new chemical class of midge pheromone.

Pheromone monitoring traps: Standard delta sex pheromone traps with rubber septa lures releasing the sex pheromone racemate have been developed for each species. The height of trap deployment has a large effect on the numbers of midge males caught and standard height of 0.5 m is recommended. Traps for both species have been deployed in fruit plantations in several different countries. 3-5 generations have been recorded, depending on latitude with large variations in numbers captured per season. Linear relationships between the numbers of midges captured for a particular generation and the numbers of galls or larvae that develop subsequently in the crop for that generation have been demonstrated for both species. The traps have proved useful for pest monitoring.

Control attempts: Large scale field experiments investigated the use of the pheromones for control in commercial plantations by mating disruption, attract-and-kill and mass trapping have been conducted in the UK over 2 seasons. A very high degreee of, though not complete, suppression of catches of male midges in traps deployed in the centres of treated plots has been demonstrated. For apple leaf midge, no sustained reduction in galling damage occurred. Good results were obtained in one trial with *R. theoboldi* in an unprotected raspberry crop but not in several other experiments in protected crops. The reasons for the failures will be discussed.

How costly is it to be an intraguild predator?

António O. Soares, Marlene Terra, Rafael Arruda, Patrícia V. Garcia

University of Azores, Ponta Delgada, Azores, Portugal

Introduction: Cages studies were used to evaluate the costs and the benefits for *Harmonia axyridis* (IGpredator) to prey on different preimaginal stages of *Trichogramma cordubensis* (IGprey).

Methods: Eggs, larvae and pupa of *T. cordubensis* were provided *ad libitum* to the fourth larval stage and adults of *H. axyridis*. Voracity, body-weight gain and reproductive performances of *H. axyridis* were evaluated and compared with predators fed on eggs of *Ephestia kuehniella* (EGprey).

Results: The amount of biomass consumed by the adults or larvae of *H. axyridis* on EGprey, eggs and larvae of IGprey was similar, but it significantly decreased when the predator fed on IGprey pupae. The proportion of eggs consumed by the adults or larvae of *H. axyridis* was the same independently of the age of the IGprey. Body-weight of the adults of *H. axyridis* decreased with the age of the IGprey, being more severe in females. After three days feeding on IGprey the number of clutches and eggs laid by *H. axyridis* decreased significantly, being much lower when feeding on IGprey pupae. Development rate and body-weight gain of *H. axyridis* larvae generally decreased after feeding on eggs, larvae and pupa of IGprey.

Conclusions: The results show that long term exploitation of an intraguild prey of low quality is very costly for the biology of the IGpredator. Considering the outcome of the interaction, the results suggest that the IGprey is killed and consumed and, also that the intraguild predation generates sublethal effects on the IG predator.

Development of zero pesticide residue Integrated Pest and Disease Management programmes for UK fruit crops

Jerry Cross, Angela Berrie

East Malling Research, East Malling, Kent, UK

Soft and top fruit crops grown in the UK are subject to attack by a wide range of damaging pests and diseases. Unless these are controlled effectively the crops can not be grown economically. Pest and disease control largely relies on pesticides, though there are a number of biocontrol successes that are widely adopted. Pesticide residues surveillance shows that a high proportion of produce contains residues above reporting limits, though Maximum Residue Levels are rarely exceeded. Several important multiple retailers in the UK are asking their suppliers to strive towards elimination of pesticide residues from fresh produce including fruits to maintain and improve consumer trust. This is providing a strong driver for development and implementation of Integrated Pest Management programmes. General approaches to reducing the occurrence of residues are discussed, including increasing harvest intervals and alternative non-chemical control approaches. Work to develop zero residue programmes was spearheaded by us on apple. A 'zero residue' Integrated Pest and Disease Management (IPDM) programme for apple has been developed at East Malling Research. In the programme conventional pesticides are not used during fruit development. The zero residues IPDM programme has been highly successful even on the most pest and disease prone varieties. Work is in progress to develop zero residue IPDM programmes for raspberry and strawberry. This is particularly challenging because of the short period of flowering and fruit development. Pest control approaches being investigated will be overviewed.

Divergence between populations of the dampwood termite *Schedorhinotermes lamanianus* driven by ancient climate fluctuations

Andreas Marten[1], Manfred Kaib[2], Roland Brandl[1]

[1]Department of Animal Ecology, University of Marburg, Marburg, Germany, [2]Department of Animal Physiology, University of Bayreuth, Bayreuth, Germany

Till the Miocene the tropical forests of Africa formed one single forest block. This block became fragmented by climatic changes as well as the formation of the Great Rift Valley 10 Mya leading to the establishment of an arid corridor that runs from the Horn of Africa to the Cape region. This corridor had a strong impact on the biogeographic history of forest-dwelling species.

We chose the dampwood termite *Schedorhinotermes lamanianus* to estimate the divergence between populations of lowland forest species west and east of the arid corridor. We sequenced a 658bp fragment of the mitochondrial COI gene for individuals of colonies scattered across the range of this termite species.

We found two clusters of sequences: a cluster of sequences from individuals sampled west and a cluster from individuals sampled east of the arid corridor. Mean sequence divergence between these two clusters was 3% with negligible divergence within clusters. These findings corroborate former results using morphometry, AFLP analysis and the occurrence of termitophile tineid moths (*Paraclystis*) in eastern and western populations. The clear separation of a western and an eastern clade in *S. lamanianus* highlights the strong effect of the arid corridor on the biogeographic history of African forest biota. However, assuming a substitution rate of 1-2% per My, the estimated divergence time between the two clades is younger than the fragmentation of the ancient forest block during the Miocene. This result suggests some exchange between western and eastern forests during wetter periods until the early Pleistocene.

Invasive hymenopterans of the Neotropical Region

Paul Hanson[1] and Michael Schauff[2]

[1]*Escuela de Biología, Universidad de Costa Rica, San Pedro, San José, Costa Rica*
[2]*Systematic Entomology Laboratory, c/o National Museum of Natural History, NHB 168, Washington, D.C., U.S.A.*

Introduction: The continental Neotropics harbor numerous invasive hymenopteran species. The list of invasive species is still incomplete but the preliminary results suggest some patterns.

Methods: A recent compilation of the taxonomic and biological literature on the Hymenoptera of the Neotropical Region was used to prepare a preliminary list of invasive species in the region (excluding islands).

Results: Some species have been deliberately introduced while others have arrived unintentionally. The introduction of the African honeybee (*Apis mellifera scutellata*) in 1956 is the best documented hymenopteran invasion in the region although the ecological impact of this species is still debated. In the Galapagos islands and Chile introduced eusocial hymenopterans (e.g. vespids) have had a notable impact on the native biota. Although exotic ants are omnipresent in disturbed habitats, they appear to be relatively insignificant in primary forests in most of the continental Neotropics. Among parasitoids, it is often difficult to distinguish between undocumented introductions for biological control and accidental introductions, but preliminary evidence suggests that there are numerous instances of the latter, especially among parasitoids associated with Sternorrhyncha, stored grain pests, etc. Thelytokous species or races appear to be especially successful invaders. Finally, some introduced species of sawflies, but very few phytophagous Apocrita, have become pests in the region.

Conclusions: It is often difficult to determine the original distribution of widely dispersed species and more taxonomic research is needed to resolve this question. The preliminary evidence suggests that the ecological impact of invasive species has been less severe in the continental Neotropics than in nearby islands.

Current status of termite management in Brazil

Ana Maria Costa-Leonardo[1]

[1]*Department of Biology, São Paulo State University – UNESP, Av. 24A No.1515, 13506-900, Rio Claro, SP, Brazil.*

Brazil is a large tropical country with abundant and varied termite fauna. The most destructive termite genera of structural wood in urban areas are *Cryptotermes*, *Coptotermes* and *Heterotermes*. Considerable damage is also caused by species of *Nasutitermes* in some regions, including Amazonia, and among them, *N. corniger* is the most frequent urban pest. The main agricultural pests of São Paulo State are represented by *Heterotermes*, *Procornitermes* and *Neocapritermes*, which infest sugarcane fields. The introduced species *Coptotermes gestroi* is the most economically serious pest with heavy infestations in the city of São Paulo, where it finds shelter for nesting and sources of humidity in high-rise buildings. This termite causes major damage to buildings, telephone cables, electrical wires and living trees in urban environments. The advance of edifications on natural environments has led to the appearance of native species causing damage to structural timber, case of *Nasutitermes aquilinus, Nasutitermes ehrhardti* and *Microcerotermes* spp., and on the lawns, case of species of *Syntermes.* Preventive measures are not being used in new buildings, and the common practice is to bury wood and cellulosic wastes close to the edifications or fill up the structural voids with this material. The principal management practice is the protection of structures through application of chemical barriers in the soil or local insecticides on the wood. The most common insecticides used in termite management are pyrethroids, nicotinoids and fenilpirazol, however, the use of hexaflumuron bait has increased in the city of São Paulo, for both preventive and curative treatment.

Insecticide resistance and genetic structure of *Cydia pomonella* (L.) (Lepidoptera: Tortricidae) from apple orchards in central Chile

Eduardo Fuentes-Contreras[1], Maritza Reyes[2], Blas Lavandero[3], Wilson Barros[1], Claudio C. Ramírez[3]

[1]Departamento de Producción Agrícola, Facultad de Ciencias Agrarias, Universidad de Talca, Talca, Chile, [2]Instituto de Producción y Sanidad Vegetal, Facultad de Ciencias Agrarias, Universidad Austral de Chile, Valdivia, Chile, [3]Instituto de Biología Vegetal y Biotecnología, Universidad de Talca, Talca, Chile

Introduction: Codling moth, *Cydia pomonella* (L.), is the main pest of pome fruits worldwide. Regular applications of insecticides have been the main management practice against codling moth in Chile. Therefore, we addressed the insecticide resistance and genetic structure of codling moth populations from central Chile.

Methods: We evaluated the mortality of larvae to diagnostic doses of organophosphate, pyrethroid, neonicotinoid and diacylhidrazine insecticides. We also evaluated the activity of detoxifying enzymes, i.e. glutathione s-transferases (GST), cytochrome P-450 monooxygenases (P450) and esterases (EST). An analysis of neutral genetic variability using microsatellites was performed for the same codling moth populations, in order to estimate gene flow and population differentiation.

Results: Post-diapause larval mortality was reduced for organophosphates in several of the analysed orchards. Significantly higher GST activity was associated with insecticide resistance. No relation was found between P450 or EST activity and insecticide resistance. Neonate larval mortality was not significantly reduced in any of the analysed orchards or insecticides. Therefore, insecticide resistance has not yet reached the threshold of field control failure. In spite of the geographical distances between some orchards (approx. 200 km), there was low genetic differentiation and high gene flow between codling moth populations, with only slight isolation by distance.

Conclusions: Low levels of insecticide resistance were found for codling moth in apple orchards from central Chile, mainly based on enhanced GST activity in post-diapause larvae. The maintenance of rather susceptible populations in managed orchards seems to be related with high levels of gene flow between orchards.

Pollinator networks, alien species and the conservation of rare plants: *Trinia glauca* as a case study

Luisa G. Carvalheiro[1*], Eduardo R. M. Barbosa [1] and Jane Memmott[1]

[1]*School of Biological Sciences, Woodland Road, Bristol, BS8 1UG*

Introduction: Despite the essential role of pollination in the maintenance of many rare plant species, conservation management plans rarely consider the service of pollination. *Trinia glauca* (Apiaceae) is a rare English plant species present in natural areas where the removal of alien plants is a part of the conservation management plans.

Methods: We use a community level approach to identify the main flower visitors of *T. glauca* as well as the direct and indirect links between *T. glauca* and other species of the study site plant community. Effectiveness of pollination of the main visitors was tested in a field experiment and the likely consequences of the removal of alien plants on *T. glauca* pollination were simulated.

Results: This study showed that ants were the main pollinators of *T. glauca* and that over the field season 33% of the ants' visits to flowers were to alien plants, with *Cotoneaster horizontalis* making a particularly high contribution (58%) during the *T. glauca* flowering period. Although positive or neutral effects are possible, a negative effect is also possible, whereby the removal of alien plants leads to a crash in ant populations, potentially reducing pollinator visits to *T. glauca* by up to 85.2%.

Conclusion: Management measures involving removal of alien plants should consider possible negative impacts on rare plants through changes in pollinator populations. In this case, a staged removal is likely to prove the best conservation approach, allowing the pollinators' response to be assessed before any serious negative effects occur.

Molecular systematics of braconid wasps (Hymenoptera: Ichneumonoidea)

Ashley Dowling[1], Michael Sharkey[2], Barbara Sharanowski[1]

[1]University of Arkansas, Fayetteville, AR, United States, [2]University of Kentucky, Lexington, KY, United States

Introduction: Braconidae is a megadiverse group of Hymenoptera that exhibits a variety of parasitic lifestyles and host associations. This work is part of the HymAToL project and represents the most taxonomically diverse dataset analyzed to date.

Methods: Genetic information from 28S (domains 1-10) and the variable expansion regions of 18S was obtained for a diverse set of braconid taxa including 137 members from 41 currently recognized subfamilies. Data was aligned using MAFFT and analyzed under parsimony, likelihood, and Bayesian optimality criteria.

Results: Nuclear ribosomal data does an adequate job resolving the majority of the braconid phylogeny. Preliminary results suggest that some traditionally recognized groups are supported by molecular evidence, but new relationships are resolved as well.

Conclusions: Results strongly support some major groupings, but indicate that information from additional gene regions may be necessary to obtain a robust assessment of braconid phylogeny.

Evolution and radiation of stick insects (Phasmatodea) in the Pacific Ocean Region

Thomas Buckley[1], Sven Bradler[2]

[1]Landcare Research, Auckland, New Zealand, [2]Johann-Friedrich-Blumenbach-Institut für Zoologie und Anthropologie, Georg-August-Universität, Göttingen, Germany

Introduction: Stick insects (Phasmatodea) are widespread and diverse throughout the Australasian and the Southwest Pacific. We have used phylogenetic analysis to reveal monophyletic groups and to study the biogeographic history of these clades.

Methods: We have analyzed DNA sequence data from two mitochondrial (cytochrome oxidase subunits I and II) and two nuclear genes (histone subunit 3 and 28S ribosomal RNA) from wide range of stick insects from throughout the Pacific area, with a focus on New Zealand, New Caledonia and Australia. Phylogenetic analyses were performed using maximum likelihood and Bayesian methods.

Results: Our results show the presence of a large monophyletic group of stick insects, corresponding to the Lanceocercata clade (Bradler 2001), distributed from the Mascarene Islands, to New Zealand, including many genera from some Pacific Islands, Australia, New Zealand and New Caledonia. This clade is also supported of a number of morphological synapomorphies. Surprisingly, the Lanceocercata contains taxa previously unsuspected of belonging to this clade. Our analyses also show a close relationship between the stick insect faunas of New Zealand and New Caledonia.

Conclusions:.Our analyses show striking examples of convergent evolution in body form in the Australasian region, where taxa have converged on stick insects from other continental regions. The phylogenetic relationship between the stick insects of New Zealand and New Caledonia exemplifies the importance of the New Caledonian biota in understanding New Zealand biogeography. Several regions of our phylogenetic tree show evidence of bursts of evolution, making the exact branching patterns difficult to resolve.

Constitutive and Inducible Plant Resistance for Rice Pest Management

Michael Stout

Louisiana State University Agricultural Center, Baton Rouge, United States

Introduction: Plant resistance is an important component of the management programs for many key rice insect pests. For some of these pests, resistance is controlled by major genes that confer high levels of resistance. For other key pests, however, high levels of resistance have not been found in screening programs. The rice water weevil (*Lissorhoptrus oryzophilus*), the most important early season pest of rice in the U.S., is an example of the latter type.

Methods: A variety of field and greenhouse experiments were conducted, with the goal of incorporating plant resistance into the management program for the rice water weevil.

Results: A long-standing screening program in Louisiana failed to find accessions or varieties with high levels of resistance to this root-feeding insect. More recent experiments have demonstrated that variation in resistance to the weevil exists among current commercial varieties, and moderate levels of resistance have been found in a few unimproved lines. Experiments were conducted to test the hypothesis that varietal improvement in the southern U.S. has been accompanied by an increase in resistance to the weevil. In addition, a line of research has been initiated to investigate inducible resistance to insects in rice. This research may reveal methods for manipulating plant resistance to the rice water weevil in the field, and will help elucidate the biochemical and morphological bases of resistance to the rice water weevil.

Conclusions: The potential for integrating inducible and constitutive resistance into the management program for the rice water weevil will be discussed.

Coping with asymmetry: Perturbed hovering flight in sphingid moth

Tyson Hedrick

University of North Carolina, Chapel Hill, NC, United States

Insects exhibit a remarkable ability to continue flying despite damage to their wings. These capabilities, both the biomechanical consequences of damage as well as the animal's compensatory response, were investigated in the hovering flight of *Manduca sexta*, L.

As a proxy for natural wing damage, the most distal 18% of the area of a single wing was removed following a baseline flight recording. This asymmetric damage represents a 40% reduction in lift and 50% reduction in torque. As expected, this caused rapid failure in a simulation of moth flight. Actual moths were able to resume flight shortly after wing reduction and exhibited normal flower feeding behaviour. Their response to wing asymmetry was quantified and took the form of 1) a <10% increase in wingbeat frequency, 2) an increase in wing sweep amplitude on the reduced wing, and 3) a decrease in wing sweep amplitude on the intact wing. This response was found to stabilize the simulated moth, although many other kinematic changes would have served the simulated moth equally well.

Furthermore, the addition of a muscle with non-linear force and contractile velocity response to the simulated moth was shown to stabilize it in the face of wing asymmetry and led to wing kinematics similar to those used by actual moths. The benefits of adding the simulated muscle were not dependent on the details of the muscle; all tested muscle parameter improved performance. These results suggest that muscle physiology may play a previously unappreciated role in locomotor stability for animals moving in a fluid environment.

Fine tuning of foraging behaviour to increase control impact of natural enemy

Louise E.M. Vet

[1]Netherlands Institute of Ecology (NIOO-KNAW), Maarssen, Netherlands, [2]Wageningen University, Wageningen, Netherlands

A key component of the success of natural enemies in biological control lies in their ability to efficiently and consistently locate their hosts or prey. Unpredictable foraging behaviour can thus severely hamper the reliability of natural enemies as control agents. There is a clear need to understand the mechanisms that underlie variation in foraging efficiency and to find ways to control them. Empirical and theoretical fundamental research on parasitoids and predators has elucidated important causes of behavioural variation. This relates to both variations in cues and in responses. Considering the cues, a limited availability of key signals can play a crucial role. Over the years, crop plants have been selected for other traits than attracting natural enemies. We now see innovative, also ecogenomic developments to restore this omission. Next there are factors internal to the insects. First there is genotypic variation in responses to important foraging cues, an area of research that has received only limited attention. Second, the insect's physiological state (e.g. its hunger state) can influence its ability and propensity to respond to host or prey cues. A third and well studied cause of behavioural variability is the insect's experience during pre-adult and adult life. Especially for insect parasitoids in multitrophic systems it is almost common knowledge that associative learning can play a steering role in the foraging process. Both genotypic variation and phenotypic plasticity in foraging create the potential to modify behaviour to improve foraging efficiency. It is therefore surprising that it has received such limited attention from practitioners of biological control. I will plea for a strong joint effort to change this situation.

Evolutionary history of Actinote (Heliconiinae, Acraeini) in Southeastern Brazil

Karina Silva-Brandão[1], Ronaldo Francini[2], Niklas Wahlberg[3], Ana Maria Azeredo-Espin[1], André Freitas[1]

[1]Universidade Estadual de Campinas, Campinas, SP, Brazil, [2]Universidade Católica de Santos, Santos, SP, Brazil, [3]University of Turku, Turku, Finland

Introduction: *Actinote* occurs through Central and northern South America to southern Brazil, where 21 species are known – the second largest generic-level radiation of Nymphalidae. A phylogenetic hypothesis for the genus based on molecular data is proposed, and the reasons that led to the present distribution of its species on SE Brazil were investigated.

Methods: The genes COI-COII, EF1alpha and wingless were used to propose a phylogenetic hypothesis to *Actinote*. Three ecological characters were investigated: evolution of host plant use (number of species and genera of Asteraceae), geographical range and altitudinal speciation pattern.

Results: Parsimony searches resulted in one most parsimonious tree. By this hypothesis, *Actinote* is a monophyletic group, and the ancestral state of the genus is the use of a single species of Asteraceae in the genus *Mikania*. During its evolutionary history, there was a tendency to increase both the number of species and of genera of plants used. The geographical distribution of the species of *Actinote* also increased throughout their phylogenetic history, with the spread of species occurring mainly from higher to lower altitudes.

Conclusions: For *Actinote*, and maybe for the entire tribe Acraeini, the tendency in using more species and genera of plants might be related to the amplification of their geographical range. It is believed that the origin of the Neotropical Acraeini has been the Andean region, and we can infer that during the evolution of the group some species had spread to low altitudes together with the expansion of their geographical range.

Evolutionary history of Actinote (Heliconiinae, Acraeini) in Southeastern Brazil

Karina Silva-Brandão[1], Ronaldo Francini[2], Niklas Wahlberg[3], Ana Maria Azeredo-Espin[1], André Freitas[1]

Improvement of *Paecilomyces fumosoroseus* as a biological control agent against Formosan subterranean termites by application of keratin foam

Maureen S. Wright[1], Christopher A. Dunlap[2], Mark A. Jackson[2], Edward D. Freytag[3]

[1]USDA-ARS-SRRC, New Orleans, LA, United States, [2]USDA-ARS-NCAUR, Peoria, IL, United States, [3]NOMTCB, New Orleans, LA, United States

Introduction: Subterranean termites cause several billion dollars in damage in the US annually. Formosan subterranean termites (FST) cause an increasing proportion of this total. In the laboratory *Paecilomyces* sp. have been shown to cause mortality of FST.

Methods: Video observation of the interior of trees confirmed FST infestation. Trees were treated with a liquid formulation of *P. fumosoroseus* (Pfr) blastospores by injection through drill holes. At 12 days post-treatment there was no FST activity in two trees and reduced FST activity in one tree. At 27 and 60 days FST activity was reduced from the pre-treatment level but present in all trees. The reappearance of FST indicated the need for a formulation that allowed expansion of the fungal spores throughout the FST carton nest inside the tree. Biologically-compatible foams were investigated. A formulation of keratin foam and Pfr blastospores was injected into different infested trees. Additional trees were injected with keratin only or left untreated as controls.

Results: On day 9 after the keratin/Pfr treatment the number of observed FST in the trees was significantly reduced. Observations on days 38, 52 and 100 revealed no FST activity in 3 of the treated trees. The remaining treated tree, the largest, in which the carton nest was not filled with foam, had reduced termite activity. FST activity in the foam control and null control trees remained high throughout the observation period.

Conclusion: These studies indicate that the keratin formulation enhanced the effectiveness of Pfr as a treatment against FST in trees.

The influence of fundatrix density and plant module size on gall induction success in adelgids: a test of the dose-dependent gall induction stimulus hypothesis

Dan Quiring, Leah Flaherty

University of New Brunswick, Fredericton, New Brunswick, Canada

Introduction: The dose-dependent gall induction hypothesis states that insects induce galls by injecting a chemical gall induction stimulus into host plants. Gall induction is only successful when the dose injected is large enough to "overcome" normal plant development.

Methods: This hypothesis was evaluated in field studies with two galling adelgids, *Adelges cooleyii* on interior spruce, and *Adelges abietis* on white spruce. The gall induction success of fundatrices on different-sized buds was evaluated for buds with a range of fundatrix densities. Variations in fundatrix densities were assumed to result in similar variations in the dose of gall induction stimulus injected into buds.

Results: As predicted by the dose dependent gall induction hypothesis, gall induction success increased when two or more fundatrices colonized the same bud, especially on larger modules.

Conclusion: These results strongly support the dose-dependent gall induction hypothesis and re-emphasize that the selection of host plant modules is often the result of the trade-off between ease of gall induction on small modules and the increased availability of resources in large modules.

The Hymenoptera Name Server

Norman Johnson

The Ohio State University, Columbus, Ohio, United States

The Hymenoptera Name Server is an on-line database web portal designed with the goal of serving as resolver for the names used for taxa within the order, providing the context in which to understand the meaning of the formal strings used to represent real taxa. The database contains information on over 210,000 names representing nearly 150,000 taxonomic concepts. A taxonomic concept is a class representing the published description or delimitation of a new taxon. Concepts are arranged in a hierarchical structure with parent-child relationships representing either membership in a taxon or a synonymy between concepts. The operating standards used to choose among alternative relationships and to flag names considered to be valid are discussed.

The data associated with names include its position within the taxonomic hierarchy, the status of the name, the citation of its original description, links to an on-line versions of the original description (pdf of the original document and an XML version from plazi.org), and a listing of the synonyms and alternative forms in which the names for that concept have appeared within the literature.

The Hymenoptera Name Server also provides Life Sciences Identifiers for these entities, that is, globally unique identifiers for the names, concepts, publications, and citations. The LSID resolver provides the data in RDF (resource description format) implementing the Taxonomic Concept Schema and is suitable for semantic web applications. The information is also shared with the Integrated Taxonomic Information Service and, thereby, to the Catalogue of Life and the Electronic Catalogue of the Names of Known Organisms. All services are available at the URL purl.oclc.org/NET/hymenoptera/hns.

Metabolite profiling for genotypic discrimination of aspen clones and determination of herbivore resistance

Benedicte R. Albrectsen

Umeå University, Umeå, Sweden

Clone specific measurements of defence compounds and nutrients are often related to damage patterns to the same clones in the field. But how reliable is metabolite profiling as a selection tool for genotype discrimination in a natural population of European Aspen (*Populus tremula* L.)? This is a presentation of a G by E study of twelve wild aspen clones grown in three environments. Clone phenotyping was performed in three ways: metabolomics profiling (GC/MS), phenolic glycoside profiling (HPLC) and profiling of natural herbivore damage under field conditions (general damage score, and presence of specific herbivores). The degree of clone specificity was tested for, and responses were divided into three types: 1. clone consistency, 2. environmental consistency and 3. unpredictable. Damage by two herbivores *Phyllocnistis labyrinthella* (Bjerkander, 1790, Lepidoptera: Gracillariidae) and *Phratora vitellinae* (L. 1758, Coleoptera: Chrysomelidae) was related to clone consistent compounds (from the phenolic pathway, some disaccharides and amino acids) that indicated a canalised and thus potential target candidate for resistance properties; those compounds that mainly varied with environment were considered plastic (for example flavonoids, catechin) or independent of clone or environment (mostly primary metabolites). The results are related to known preferences for phenolic compounds from the literature and genotyping in a trans-omic perspective is discussed.

Characterization of a protein kinase C from Choristoneura fumiferana which may related to Steroid hormone-dependent gene expression

Guo-Xing Quan, Daniel Doucet, Tim ladd, Peter Krell, Basil Arif

[1]Great Lakes Forestry Centre, Sault Ste. marie,ON, Canada, [2]University of Guelph, Guelph, ON, Canada

Steroid hormone 20-hydroxyecdysone (20E) is essential for the development, metamorphosis and reproduction in insects. The hormone signal is transduced by the heterodimer ecdysone receptor (EcR) and USP and binds to specific response elements in the genome and consequently regulates target genes transcription. The phosphorylation of the receptors is a pre-requisite for function. The intracellular signal transduction pathway involved in receptor phosphorylation has not yet been fully elucidated. Previous work in *Drosophila* and *C. fumiferana* indicated that a protein kinase C (PKC) might be involved in the 20E-dependent gene expression. The aim of this study was to identify the PKC involved in this pathway. A *C. fumiferana* PKC (CfPKC) was cloned by RT-PCR and 5' and 3'RACE. The full-length cDNA was 2.3 Kbp with an open reading frame potentially encoding a protein of 669 amino acids. Northern and Western blotting analyses showed that CfPKC was ubiquitously expressed in various tissues at all development stages. Western blot analysis of over expressed CfPKC fused to a GFP tag revealed that it is distributed throughout the cytoplasm, and that activation with phorbol 12-myristate 13-acetate (PMA) resulted in rapid localization of the protein to the cell membrane. Knockdown of CfPKC by double-stand RNA interference (RNAi) in CF-203 cells reduced the 20E-triggered expression of the E75 and CHR3 molting genes. PKC inhibitors also reduced the 20E-induced gene expression, thus supporting the role of CfPKC in 20E signal transduction.

Interspecific competition between parasitoid wasps: sneak vs. guard, who wins?

Tara J. Murray[1], Tara J. Murray[2], Sarah Mansfield[3]

[1]Scion (New Zealand Forest Research Institute Ltd), Rotorua, New Zealand, [2]Lincoln University, BioProtection & Ecology Division, Lincoln, New Zealand, [3]Faculty of Agriculture, Food & Natural Resources, University of Sydney, Sydney, Australia

Paropsis charybdis (Coleoptera: Chrysomelidae) is a pest of Eucalyptus in New Zealand and is attacked by two egg parasitoids (Hymenoptera: Pteromalidae). The first, *Enoggera nassaui*, was introduced as a biological control agent against this pest in 1987, while the second, *Neopolycystus insectifurax*, was self introduced and discovered in 2001. Both species are known to be polyphagous and both achieve almost 100% parasitism of *P. charybdis* in the laboratory. Field observations between 2000 and 2005 indicated that *N. insectifurax* does not parasitise *P. charybdis* as successfully as *E. nassaui.* Laboratory observations showed that the parasitoids have different oviposition behaviours and both will compete with their conspecifics for access to hosts. In this study *The Observer*, a computer software package designed for the collection, management and analysis of observational data, was use to help compare the behavioural characteristics of each of these two species when presented with host eggs in the presence of the other species. Initial results indicate that although *E. nassaui* usually locates and begins ovipositing into host eggs first, it is usually chased away once *N. insectifurax* locates the eggs. *N. insectifurax* then guards the eggs, continuing to chase off *E. nassaui* if it approaches again. Despite this *E. nassaui* frequently manages to oviposit in some host eggs due to its ability to sneak in and assess and oviposit in eggs more quickly than its slow aggressive competitor. The dynamics and results of these interactions are discussed.

Evolution in the New Zealand Subantarctic: Systematics and genetics of *Pseudhelops* Beetles (Tenebrionoidea)

Richard Leschen[1], Eve Butler[2], Thomas Buckley[1], Peter Ritchie[2]

[1]New Zealand Arthropod Collection, Auckland, New Zealand, [2]Victoria University, Wellington, New Zealand

The 8 species of the saprophagous genus *Pseudhelops* is restricted to New Zealand's 5 Subantarctic Island groups, as well as Chatham and Stewart Islands. Here we investigate the phylogenetic relationships among the species and genetics of *P. tuberculatus*. Morphological and mitochondrial DNA data were analyzed using parsimony, Bayesian, ML (trees rooted with mainland *Cerodolus*). Populations of *P. tuberculatus* (Auckland Islands) are geographically structured along a North-South gradient suggests a southern refugia. On Auckland Island's southernmost island (Adams Island) one individual showed a marked genetic divergence from remaining members and study of museum material indicates that this individual corresponds to *P. wenhami*, a species previously synonymised with *P. tuberculatus*. A species-level analysis resulted in the following relationships: (*P. quadricollis* [Snares] + *P. chathamensis* [Chatham]) (*P. capitalis* [Stewart] ((*P. clandestinus* [Antipodes] + *P. liberalis* [Bounty]) (*P. posticalis* [Campbell]*, P. antipodensis* [Antipodes] (*P. tuberculatus* [Auckland] + *P. wenhami* [Auckland]))). These data suggest a widespread *Pseudhelops* + *Cerodolus* ancestor inhabiting the Campbell Plateau and mainland New Zealand, with subsequent divergence in the subantarctic and off-shore islands. The Antipodes Islands may have been colonized twice: once by a *P. clandestinus* + *P. liberalis* ancestor with apomorphic striate elytra, and second by an ancestor of *P. posticalis* and relatives on Auckland and Campbell Islands that lack distinct elytral striations. Meanwhile, the sympatric *P. wenhami* and *P. tuberculatus* diverged from a common Auckland Islands ancestor, and their speciation may have been habitat-mediated by associations with tussocks (*P. wenhami*) and forests (*P. tuberculatus*).

Pheromone mating disruption of codling moth, *Cydia pomonella*, in walnuts and pears using intermediate release rate dispensers

Stephen Welter, Frances Cave

University of California, Berkeley, CA, United States

Introduction: Logistic problems of large tree canopy size and increasing costs of labor associated with hand-applied pheromone dispensers has limited the adoption of pheromone mating disruption in walnuts. New “meso” dispensers were developed with release rates that ranged between 10-30 mg ai codlemone per dispenser per day and evaluated using few point sources per ha.

Methods: Release rates of different combinations of membrane type and size were determined under laboratory and field conditions. Replicated plots were established in pear and walnut orchards using 30-60 dispensers per ha. Using replicated 2 ha plots within a single orchard, the effect of the number of point sources on codling moth suppression was compared for a range of dispenser densities from 30-500 dispensers per ha in a mature walnut orchard.

Results: Effect suppression of codling moth damage was observed using 60 meso-emitters per ha in insecticide treated and organic walnut orchards ($P<0.05$), whereas extreme pressures found in the test pear orchards failed to suppress outbreak situations. Within the point-source trial, all combination programs of pheromone mating disruption plus insecticide treatments outperformed the insecticide treatment alone ($P<0.05$) relative to infestation at harvest. No improvement in control of codling moth was associated with increasing the number of point sources.

Conclusions: Using higher release rates per dispenser, the number of point sources was effectively reduced by >90% without any measurable loss of program performance.

No tri-trophic impacts of transgenic insect-resistant avidin tobacco on predatory carabid beetles fed pure or mixed diets

Elisabeth Burgess[1], Bruce Philip[1], John Christeller[2], Emma Barraclough[1], Richelle Marshall[2]

[1]HortResearch, Auckland, New Zealand, [2]HortResearch, Palmerston North, New Zealand

Adult predatory beetles, *Ctenognathus novaezelandiae,* were fed pure and mixed diets of field-collected prey and/or *Spodoptera litura* laboratory-reared on transgenic avidin tobacco and/or isogenic non-transgenic control tobacco. Female beetles consuming only tobacco-fed prey retained their weight over 140 days regardless of the proportion of avidin vs control tobacco in the diets of their prey, while male beetles fed only tobacco-fed prey lost weight. Females provided with any proportion of field food in addition to avidin tobacco significantly increased in weight over 140 days while males generally retained their starting weight. There were no significant differences among treatments in female survival (mean duration: 209 to 261 days). Males given any amount of field food survived a similar length of time to females (222 to 272 days). However those consuming only tobacco-fed prey, whatever the proportion of avidin and control fed prey, had greatly reduced survival (111 to 126 days). The mean fecundity of all females consuming only tobacco-fed prey was low (0.02 to 0.09 eggs per beetle per fortnight over a year), while those consuming some field food produced 0.5 to 1.4 eggs per fortnight. Egg fertility did not differ among treatments. In a second experiment beetles were fed 33% field food and 67% either avidin or control tobacco-fed prey. There were no treatment effects on beetle mass after 94 or 163 days, although female beetles were larger than males at both time points. Treatment had no impact on food consumption, fertility, fecundity or within-gender survival.

Sex peptide receptor, a G-protein coupled receptor that mediates the post-mating switch in *Drosophila* reproductive behaviours

Young-Joon Kim, Nilay Yapici, Carlos Ribeiro, Barry Dickson

Institute of Molecular Pathology, Vienna, Austria

At various stages in their lifespan, animals undergo marked switches in their innate behavioural patterns. Such behavioural switches provide attractive opportunities to explore the genetic and neural control of the innate behaviours. Mating in many species triggers a dramatic switch in female reproductive behaviour. For example, virgin females are receptive to courting males and retain their eggs, whereas those that have recently mated are unreceptive and lay eggs. In most insects, these changes in female behaviour are induced by factors present in the male's seminal fluid. How these factors exert such profound effects in females is unknown. Here, we identify a receptor for the *Drosophila melanogaster* sex peptide (SP), the primary trigger of post-mating responses in this species. Females that lack the sex peptide receptor (SPR), either entirely or only in the nervous system, fail to respond to SP and continue to show virgin behaviours even after mating. Furthermore, SPR gene encodes a GPCR high sensitive and selective for SP. SPR is expressed in the female's reproductive tract and central nervous system. The behavioural functions of SPR map to the subset of neurons that also express the fruitless gene, a key determinant of sex-specific reproductive behaviour. SPR is highly conserved structurally and functionally across insects, opening up the prospect of new strategies to control the reproductive and host-seeking behaviours of agricultural pests and human disease vectors. Our identification of SPR is the critical step in explaining this behavioural switch at the molecular, cellular and circuit levels.

Eradication and containment of *Cactoblastis cactorum* in Mexico and the United States

James Carpenter[1], Stephen Hight[2], Arturo Bello[3], Rafael Zetina[4]

[1]USDA-ARS, Crop Protection Research Unit, Tifton, GA 31794, United States, [2]USDA-ARS, Center for Medical, Agricultural, & Veterinary Entomology, Tallahassee, FL 32308, United States, [3]SEGARPA, Dirección General de Sanidad Vegetal, México DF, Mexico, [4]Comité Estatal de Sanidad Vegetal de Quintana Roo, Cancún, QR, Mexico

Introduction: To address the advancement of *Cactoblastis cactorum* along the southeastern gulf coast of USA and new incursions in Mexico, control tactics including sanitation and the Sterile Insect Technique (SIT) were validated and implemented.

Methods: Three sites were selected for the SIT validation study: control (no manipulation of infested plants); sanitation only (removal of eggsticks, infested pads/larvae, and pupae); and sanitation plus SIT (removal plus strategic release of sterile moths). Population change and treatment efficacy were monitored with pheromone traps and sentinel plants. Parentage of eggsticks was determined to evaluate sterile/wild moth interaction. Sanitation and host plant removal were part of a multifaceted control program on Isla Mujeres, Mexico, and sanitation and SIT were used on Isla Contoy, Mexico.

Results: In the SIT validation study sanitation alone reduced moth populations but sanitation coupled with SIT lowered the population to immeasurable levels. Effective overflooding ratios (~10:1) (sterile:wild males caught in traps) and collection of eggsticks from wild female and sterile male matings indicated that sterile males were competitive with wild males. Control tactics and other program initiatives used in Mexico greatly reduced or eliminated pest populations on Isla Mujeres and Isla Contoy.

Conclusions: The success of the SIT validation study justified the transfer of this technology to other outbreaks at the western leading edge of *C. cactorum* in Alabama, and to assist Mexico in the removal of *C. cactorum* recently established on two islands off the Yucatan Peninsula.

Advances in semiochemical based management of coleoptera

Cam Oehlschlager

ChemTica Int., San Jose, Costa Rica

Rhynchophorus palm weevils are world-wide pests of oil & coconut palm. In Central & South America *R. palmarum* cause direct larval damage & vectoring of red ring nematode. Our group and collaborators have developed a management system of pheromone trapping & removal of red ring nematode infested palms that is the only economically viable technique used in the Americas used to combat the palm weevil problem. In the Middle East and Southern Europe *R. ferrugineus* is a has become serious pest of date palm. Pheromone / food based trapping is again the method of choice for management. Mass trapping is also used on a wide scale to manage *Cosmopolites sordidus*, the banana corm weevil, as well as *Oryctes rhinoceros*, a pest of newly planted oil palm in South East Asia. Recently, mating disruption has emerged as a strategy applicable to Coleoptera. Pre-commercial application in the United States targets *Exomala orientalis*, Oriental beetle. Repellents are firmly established as management tools for several species of tree infesting Coleoptera in ecologically sensitive areas.

Spatial and temporal dynamics of predators of brassica pests

Heimoana, V.[1], Gurr, G. M.[1], Raman, A.[1], and Pilkington, L.J.[2]

[1]School of Rural Management, Charles Sturt University, P.O.Box 883, Orange, NSW, 2800, [2]NSW, Department of Primary Industries, Gosford Horticultural Institute, Locked Bag 26, Gosford, NSW, 2250

The ladybird beetle, *Hippodamia variegata* (Goeze) (Coleoptera: Coccinellidae), a recent arrival in Australia, and a native brown lacewing, *Micromus tasmaniae* (Walker) (Neuroptera: Hemerobiidae), are being investigated as potential biological control agents for arthropod pests in brassica crops. Monthly surveys of various habitats on vegetable farms in the Central West of New South Wales, Australia have shown that both species are an important numerical component of the natural enemy fauna. Numbers increased during spring but were not uniformly high over summer months possibly reflecting broad-spectrum pesticide use and lack of available prey. Predator densities in non-crop habitats are relatively high in the period leading up to brassica crop planting and may be an important source of natural enemies. Findings from mark/recapture studies of the predators will be presented with results from the use of DNA identification of their gut contents. Results will be integrated to formulate habitat manipulation strategies suitable for maximising the impact of natural enemies in brassica field crops.

Higher level phylogeny of the true Swallowtail Butterflies (Lepidoptera: Papilionidae: Papilioninae) with special reference to the enigmatic and endangered genera Teinopalpus and Meandrusa, and the subgenera within the genus Papilio

Thomas Simonsen*, Evgueni Zakharov**, Felix Sperling*

University of Alberta, Edmonton, Alberta, Canada, University of Guelph, Guelph, Ontario, Canada***

The true Swallowtail butterfly family Papilioninae is comprised of approximately 550 species in 24 genera and three tribes. The two genera *Teinopalpus* and *Meandrusa* are not at the moment definitively associated with any tribe. Though the Swallowtails are among the best known invertebrates, the genus-level phylogeny of Papilioninae is poorly understood. Here we present a "total evidence" phylogenetic analysis of the subfamily based on morphological characters (mainly from literature) and molecular characters from seven genes. The phylogeny is then used to analyze zoogeographical and biological aspects of the Papilioninae.

Morph-specific circadian rhythm for the juvenile hormone titer in wing polymorphic crickets*:* Functional and evolutionary implications for the endocrine basis of morph specialization

Anthony J. Zera

School of Biological Sciences, University of Nebraska, Lincoln, NE 68588-0118

Since the 1960's, juvenile hormone has been proposed to be a major regulator of wing polymorphism, with differences in the JH titer above or below some threshold controlling alternate morph development, reproduction, and dispersal. Although this widely-held hypothesis has nearly attained the status of dogma, experimental support has been surprisingly weak, coming almost exclusively from indirect, hormone manipulation studies, which are often difficult to interpret regarding endocrine mechanisms. Recent direct measurement of the hemolymph JH titer in wing-dimorphic crickets (*Gryllus*) has produced an exciting and unanticipated finding: the blood JH titer exhibits a large-amplitude circadian rhythm (50-fold change in titer within 4-6 hours) in the long-winged (LW) morph, and a nearly temporally-invariant titer in the short-winged (SW, flightless, reproductive) morph. The JH titer in the LW morph cycles above and below the titer in the SW morph. These morph-specific titer differences occur in laboratory as well as in field populations, and represent the first detailed endocrine investigation of insects in natural populations. The morph-associated circadian/temporally-invariant profiles are primarily caused by morph differences in temporal rates of JH biosynthesis. By contrast, the ecdysteroid titer is consistently higher in short-winged vs. long-winged female morphs, in the laboratory and in the field; male morphs do not differ in the ecdysteroid titer. The extent to which the JH circadian profile occurs within or outside of the Orthoptera is unknown. The functional significance and evolutionary implications of these morph-specific differences in the JH titer will be discussed.

Development of an artificial diet rearing system for woolly apple aphid (*Eriosoma lanigerum* H.)

Dario Stefanelli, Kevin S. Powell

Department of Primary Industries, BioScience Research Division, Rutherglen, Victoria, Australia

Introduction: Woolly apple aphid (WAA), *Eriosoma lanigerum* (Hausmann), is one of the economically important pests of apple, *Malus domestica* (Borkh.). Artificial diets are an important tool to study insect development, feeding behaviour, symbiont activity and to screen for novel antimetabolites which may aid in their control. Prior to this study, artificial diets were available for a range of aphids but not WAA. The aim of this study was to develop an *in vitro* rearing system using artificial diets for WAA.

Methods: Two WAA stock populations were reared under greenhouse conditions on susceptible apple seedlings. Two feeding chamber designs ("conventional" and "inverted"), three sucrose concentrations (5%, 10% and 20%), and one diet formulation (Febvay et al, 1988) were tested. In all experiments a no diet control was used. Fifty first instar nymphs were utilised for each treatment and control. The geographical provenience of the aphid populations were tested separately as factors.

Results: The "inverted" chamber design was best suited for WAA feeding and utilised for all subsequent testing. Five and 10% sucrose concentration were statistically different from the control but suboptimal in terms of insect development and survival. Twenty percent sucrose and the Febvay diet more than doubled the survival time, up to 19 days, and evidence of ecdysis was observed. There was a significant difference in the survival curve and duration between the two aphid populations, which is indicative of genetically distinct characteristics.

Conclusions: An *in vitro* feeding system was developed for WAA which could be used to screen antimetabolites.

Occurrence and Control of Psocids in China

Jinjun Wang, Wei Dou

Key Laboratory of Entomology and Pest Control Engineering, College of Plant Protection, Southwest University, Chongqing 400716, P. R. China

Introduction: As small, polyphagous insects generally ignored in most grain storage systems, psocids have recently become a serious problem in food industries and stored products in China. The review is to elucidate the distribution of psocid species in China and may assist in formulating strategies in the control of these rapidly proliferating pests.

Occurrence: *Liposcelis* psocids have gained much prominence as pests in the Chinese grain ecosystem. The specific biological traits (small body size and short generation period) contribute to rapid and substantial psocid population growth. A survey of numerous farms and central storages suggested that four *Liposcelis* spp., *L. bostrychophila* Badonnel, *L. entomophila* (Enderlein), *L. decolor* (Pearman) and *L. paeta* Pearman, are the most commonly detected of these in stored grain.

Control: Routine fumigation of warehouses and storage facilities with methyl bromide or using insecticides has failed to control psocids, which can readily reinfest grain in storage after fumigation or insecticides treatments. As an alternative treatment to the use of methyl bromide for post-harvest insect control, controlled atmospheres (CA) has showed promise for control of stored product pests. Similarly, extensive use of CA in insect control could lead to selection of insect populations resistant to hypercarbia and hypoxia.

Conclusions: Despite numerous reports of resistance to many insecticides, chemical control will continue to play an important role in psocids control programs. Studies on population ecology and resistance development to control treatments are fundamental to the development Integrated Pest Management (IPM) strategies for psocids.

Occurrence and Control of Psocids in China

Jinjun Wang and Wei Dou

Social evolution of the Allodapine bees

Luke Chenoweth, Michael Schwarz

Flinders University, Adelaide, South Australia, Australia

Background: The major lineages of eusocial insects, the ants, termites, stingless bees, honeybees and vespid wasps, all have ancient origins (≥ 65 mya) with no reversions to solitary behaviour. This has prompted the notion of a 'point of no return' whereby the gradual evolutionary elaboration and integration of behavioural, genetic and morphological traits leads to a situation where reversion to solitary living is no longer an evolutionary option.

Methods: We use information on nest composition and dissection data to explore the ubiquity of social behavior in another group of social insects, the allodapine bees, by examining the social behavior of a key species. *Halterapis nigrinervis* is unique in that it is believed to be the only example of a solitary nesting allodapine. We then use molecular phylogenetic techniques to re-estimate the origin of social behavior within the tribe.

Results: We show the allodapine bees have a single origin of sociality > 40 mya. We also show that *H. nigrinervis* is truly social, and our findings therefore indicate there have been no losses of sociality among extant allodapine clades. All females in virtually all allodapine species are capable of nesting and reproducing independently, so the species within this tribe clearly do not fit the 'point of no return' concept.

Conclusions: We argue that allodapine sociality has been maintained by ecological constraints and the benefits of alloparental care, and that similar vulnerabilities may also help explain the lack of reversions to solitary living in other taxa with ancient social origins.

Using artificial neural networks to predict and quantify risk of invasion by insect pests

Dean Paini[1], Sue Worner[2], Matt Thomas[1], David Cook[1]

[1]Cooperative Research Centre for Plant Biosecurity, Canberra, ACT, Australia, [2]Lincoln University, Christchurch, New Zealand, [3]Penn State University, University Park, Pennsylvania, United States

Introduction: Predicting which species are most likely to invade a particular region presents significant challenges to researchers and government agencies. In order to rank the potential list of invasive species, experts and stakeholders are often consulted for their opinion. This method, while valuable, can bring a level of subjectivity to the process. Artificial neural networks, specifically self organising maps (SOM's), present the possibility of objectively identifying and quantifying the risk of invasion by insect pests.

Methods: Using presence/absence data of insect pests from the CABI Crop Pest Compendium we generated SOM's and subsequently a quantitative risk list of invasive insect pests to Australia.

Results: As SOM's are initiated from a randomly assigned starting point, there is the risk of generating significantly different lists each time a new SOM is generated. We examined these variations and the parameters involved in generating a SOM and found that lists were generally very stable, regardless of the various parameters used. We then tested how the presence of errors in the original presence/absence data and their subsequent corrections could affect these lists. We found that the lists were sensitive to these errors and that the size of the SOM's generated and the number of iterative steps influenced the robustness of these lists.

Conclusions: SOM's offer a novel method to identifying and ranking the risk of pest species invading a particular region.

Spider venoms as source of bioinsecticides: a comparison of the insecticidal toxicity of various tarantula venoms

Margaret C. Gentz, Glenn F. King

Institute for Molecular Bioscience, University of Queensland, St. Lucia, Queensland, Australia

Introduction: Spiders are master insect killers that have been optimizing their venoms for over 300 million years. The venoms of modern spiders are a complex chemical cocktail containing hundreds, if not thousands, of discrete components. By comparing the potency of venoms from different species of Australian and American tarantulas we aim to select specific species for isolation of specific compounds that might have application as bioinsecticides.

Methods: Immature domestic crickets (*Acheta domesticus*) and adult houseflies (*Musca domestica*) were injected with dilutions of crude tarantula venom in insect saline. Tarantulas consisted of an unidentified *Phlogiellus* species from north of Cairns, Queensland (Aranea: Theraphosidae), Australia; pooled venom from a cohort of funnel-web spiders *Hadronyche infensa* (Aranea: Hexathelidae) all collected from Fraser Island, Queensland, Australia; pooled venom from Mexican tarantulas *Brachypelma hamorii* and *B. ruhnaui* (Aranea: Theraphosidae).

Results: The Mexican tarantula *B. hamorii* was the most potent, followed by the Australian funnel-web spider, *B. ruhnaui*, and finally *Phlogiellius*. LD_{50} values were in the picogram of crude venom/gram of cricket weight range, which approximates values found previously for peptide toxins from Australian funnel-web spiders.

Discussion: Tarantulas from Australia and Mexico exhibit similar, but subtly different, toxicity in both crickets and flies. However, all crude venoms caused lethality to flies and crickets at roughly $1/100^{th}$ of the concentration delivered during an envenomation.

An integrated approach to management of sweetpotato whitefly and cucurbit yellow stunting disorder

Eric Natwick, William Wintermantel, Robert Gilbertson, Yen-Wen Kuo, Gregory Walker, Jolene Dessert

[1]University of California ANR, Holtville, CA, United States, [2]USDA-ARS, Salinas, CA, United States, [3]University of California Davis, Davis, CA, United States, [4]University of California Davis, Davis, CA, United States, [5]University of California Riverside, Riverside, CA, United States, [6]Imperial County Agricultural Commissioner's Office, El Centro, CA, United States

In 2006 *Cucurbit yellow stunting disorder virus* (CYSDV) was detected in Southern California cucurbit crops. This was verified with RT-PCR and sequence analysis. RT-PCR also verified that *Bemisia tabaci* (Genn.) biotype B was transmitting the virus. Due to the economic impact of CYSDV on melon production it was critical to limit the spread of CYSDV and develop management strategies. Cucurbit germplasm was screened for resistance to both CYSDV and *B. tabaci* in a series for field trials. Trials also were conducted to determine if rowcovers and insecticides could exclude *B. tabaci* and prevent or delay CYSDV infection in melon. The geographic range of CYSDV in the Imperial Valley was determined in the spring and fall of 2007 via surveys of all melon fields. Because the only known (non-experimental) hosts of CYSDV were species in the *Cucurbitaceae* family, cucurbit-free periods were recommended during the summer to prevent severe damage to fall cucurbit crops and to prevent further spread of CYSDV. Common non-Cucurbitaceae weeds and crops in the region were also screened as potential hosts of CYSDV. The spring survey established that the virus had overwintered or been reintroduced (though inefficiently) in spite of an extended freeze the previous winter. Although 2007 fall melon crops were extensively infected with CYSDV, growers produced marketable fruit. Lettuce had been listed as an experimental host of CYSDV; but the virus was detected in Romaine lettuce from the Imperial Valley, indicating that lettuce can be a host of the virus. CYSDV was transmitted from infected lettuce back to melon by *B. tabaci*. Romaine lettuce is potentially an important bridge host for CYSDV between spring and fall melon crops, due to the large acreage of lettuce in the region during the winter months.

Characterising feeding behaviour and nutritional requirements of leafhopper *Orosius orientalis* using *in vitro* and *in planta* systems

Piotr Trebicki[1], Rob M. Harding[1], Brendan C. Rodoni[2], Kevin S. Powell[3]

[1]Queensland University of Technology,, Centre for Tropical Crops and Biocommodities, Brisbane, Queensland, Australia, [2]Department of Primary Industries, Bioscience Research Division, Knoxfield, Victoria, Australia, [3]Department of Primary Industries, Bioscience Research Division, Rutherglen, Victoria, Australia

Introduction: *Orosius orientalis* (Matsumura) (Hemiptera, Cicadellidae) is a leafhopper vector of many plant pathogens. Little is known about *O. orientalis* in relation to its host plant interactions requirements and epidemiology of pathogen transmission/acquisition. To develop alternative management options, we have been investigating *in vitro* and *in planta* systems to study the feeding behaviour and nutritional requirements of this insect.

Methods: Stock colonies of *O. orientalis* (Matsumura) were maintained on celery (*Apium graveolens* L.) and bean (*Phaseolus vulgaris* L.) under glasshouse conditions. Two artificial diet formulations were tested ands enhanced survival was obtained on the PT-07 diet. The antimetabolic activity of three compounds, *Galanthus nivalis* agglutinin (GNA), wheat germ agglutinin (WGA), cowpea trypsin inhibitor (CpTI) towards first instar nymphs was assessed at 0.1% (w/v) concentration in this diet formulation. An electrophysiological technique was used to assess feeding activity on both artificial diet and host plants.

Results: An i*n vitro* diet bioassay system for *O. orientalis* was developed and it could survive for up to 46 days on PT07 diet. GNA and WGA had significant antimetabolic activity and reduced the insects survival duration to 22 and 16 days respectively. CpTI had no significant antimetabolic activity. Preliminary characterisation of feeding waveforms were assessed on first instar nymphs both *in planta* and *in vitro*.

Conclusion: This is the first study to optimise an artificial diet feeding bioassay system for *O. orientalis*, identify potential feeding inhibitors and examine the feeding behaviour by using the EPG system on both host plant and artificial diets.

Can we exploit nature's influence on arthropods and mechanisms of the 'push-pull' technology in resistance management to Bt-maize?

Charles Midega[1], Zeyaur Khan[1], Johnnie van den Berg[2], Ansie Dippenaar[3], John Pickett[4]

[1]International Centre of Insect Physiology and Ecology, Nairobi, Kenya, [2]Northwest University, Potchefstroom Campus, Potchefstroom, South Africa, [3]ARC- Plant Protection Institute, Pretoria, South Africa, [4]Rothamsted Research, Herpenden, United Kingdom

Introduction: A 'push-pull' Technology (PPT) and Bt-maize have been developed to manage cereal stemborers. PPT involves intercropping maize with a moth repellent plant, Desmodium, while an attractant plant, Napier grass, is planted as a trap crop around this intercrop. Studies were conducted to assess (1) numerical response of ground dwelling arthropods to both strategies, using spiders as an indicator group; and (2) potential role of the PPS in stemborer resistance management in Bt-maize through influence on the pests' oviposition and mortality from predation.

Methods: Plots were established in western Kenya and in South Africa. Spiders were sampled using pitfall traps and soil samples. Oviposition preference was evaluated, and predation rates of naturally and artificially infested stemborer eggs and larvae were assessed in natural enemy exclusion studies.

Results: A total of 2175 spiders, 70 species in 18 families, were recovered in Kenya and 658 spiders, 49 species in 12 families, in South Africa. Spider abundance was significantly higher in PP than in control plots. Bt-maize had no direct impact on spider abundance and diversity. Significantly more eggs were oviposited in control than in PP plots. Predation rates of eggs and early-instar larvae were similarly significantly higher in PP than in control plots.

Conclusion: PPS can play a significant role in Bt-resistance management through reduction of pest population getting exposed to Bt-toxin.

Influence of sexual cannibalism on paternity in the Australian praying mantid *Pseudomantis albofimbriata*

Katherine Barry

Macquarie University, Sydney, NSW, Australia

Although the potential benefits of male consumption are well documented for females of many sexually cannibalistic species, the fitness consequences for males are often less obvious, and largely depend on the timing of cannibalism in relation to insemination. If cannibalism occurs during/after mating, a male's loss of future reproductive output may be at least partially outweighed by associated benefits. For example, the male soma may contribute to the fecundity of his mate thereby enabling her to produce more eggs, and/or cannibalised males may fertilise a higher proportion of eggs when mating with a polyandric female. The current study examines the influence of sexual cannibalism on paternity in the Australian praying mantid *Pseudomantis albofimbriata,* a species in which males can initiate copulation and transfer sperm while being consumed. A series of single mating experiments showed that cannibalistic females significantly improved their body condition as a result of male consumption and subsequently produced heavier egg cases than their non-cannibalistic counterparts. Furthermore, female body mass was a significant predictor of egg case mass (positively related to egg number), suggesting females utilize nutrients from the male soma to increase the absolute number of eggs available for fertilization. Since *P.albofimbriata* males are able to mate with several females, we also carried out double mating experiments to compare the paternity allocation of cannibalized and non-cannibalized males under a polyandrous scenario (sterile male technique). We discuss the results of these experiments in the context of male mating strategies, mate choice and sperm competition in praying mantids.

The biology of an emerging mite pest of grains, *Balaustium medicagoense*, in southeastern Australia

Aston Arthur, Andrew Weeks, Ary Hoffmann

Centre for Environmental Stress and Adaptation Research, Department of Genetics, The University of Melbourne, Parkville, Vic, Australia

Balaustium medicagoense have recently been identified as a potential emerging pest mite within the Australian agricultural industry. The damage caused by *B. medicagoense* in Australia has increased in the last decade, with reports indicating that these mites have caused extensive damage to a variety of grain crops and pastures, yet little is known about their biology. Here we address this by gaining insight into the plant host range, pesticide tolerance and population genetics of *B. medicagoense* in Australia. A shade-house experiment showed that *B. medicagoense* causes significant damage and can persist for a generation on five different agriculturally important plant hosts. Pesticide bioassays show that *B. medicagoense* has a much greater level of tolerance than another earth mite species (*Halotydeus destructor*) to several chemicals registered for their control. To determine levels of genetic variation within and between populations, we used the amplified fragment length polymorphism method. The AFLPs showed that *B. medicagoense* reproduces asexually, has limited genetic variation and is made up of a limited number of clones with populations dominated by several common clones. The results suggest that *B. medicagoense* could be a pest of significance to the grains industry within Australia that will be problematic to control.

A simulation model of the greyback canegrub and its pathogens, with special emphasis on *Metarhizium anisopliae*

Frank Drummond[1], Peter Samson[2], Keith Chandler[2], Mohamed Sallam[2]

[1]University of Maine, Orono, Maine, United States, [2]BSES limited, Queensland, Australia

Introduction: A simulation model was developed to explore the dynamics of key factors that influence the long-term population dynamics of the greyback canegrub, *Dermolepida albohirtum* (Waterhouse) (Coleoptera: Scarabaeidae). The model is a stage-specific representation of the canegrub life history.

Methods: A statistical disease sub-model was incorporated in a greyback cane grub computer simulation model. The model is a delay-differentyial equation model that simulates each life stage of the beetle. This model incorporated total disease due to the fungus *Metarhizium anisopliae*, the protozoan *Adelina* sp., and the bacterium *Paenibacillus popillae*. A mechanistic submodel of *M. anisopliae* was developed with relationships developed in laboratory bioassays and field experiments.

Results: Four years of field data from 2003-2006 suggests that *Metarhizium* infections may affect greyback canegrub populations in the following year. However, it appears that disease incidence of 25% or greater is necessary for declines in population levels the following year. Simulation runs suggest that disease mortality (from all sources) can significantly regulate canegrub populations, but only in a stochastic version of the model when intra-specific canegrub larval competition was also incorporated into the model. The design of a probabilistic sub-model of *Metarhizium anisopliae* based upon encounters with infective cadavers will be discussed.

Automated image-analysis arthropod identification

Andrew Moldenke, David Lytle, Tom Dietterich, Eric Mortensen, Robert Paasch

OSU, Corvallis, OR PNW, United States

Introduction: The analysis of ecological samples (aquatic dipnet, Berlese, sweepnet) is often seriously limited by the complexity of the sample (number of individuals/species) and by adequately trained taxonomic personnel. Automated computer-assisted recognition and sorting could significantly decrease time/cost and permit limiting taxonomic expertise to be far more efficiently utilized.

Methods: We are integrating 1) recent advances in computer vision algorithms; 2) novel robotic devices for specimen manipulation; and 3) extensive digital image databasing. We utilize non-specified imaging region detectors so that the protocol can theoretically process images of any type of arthropod. Our initial test samples were non-diverse (1-10 spp) immature aquatic Plecoptera characterized by logarithmic size differences and considerable within-population pattern variability. Currently we are adapting the process for soil mesoarthropods.

Results: We have developed 2 robotic devices for handling, imaging and archiving the specimens. Larger specimens (Plecoptera) are: 1) placed one-at-a-time into a circulating fluid system; 2) sucked through the tubing to a transparent display under the microscope; 3) stopped by an electronic eye and positioned automatically by peripheral fluid jets; 4) photographed with 2 contrasting background colors (so that the stonefly image can be 'segmented' unambiguously from the background); and 5) subsequent to identification, directed to a designated vial. Smaller specimens (mesofauna) are: 1) placed in a Petri plate on a motorized microscope stage; 2) individually recognized from a collage image of the total Petri plate; 5) identified and then removed by a robot arm equipped with a pipette; and 6) placed in an appropriate well plate.

Being prepared: ecological informatics and computational intelligence methods applied to invasive insect risk assessment

Susan P. Worner[1], Michael J. Watts[2], Muriel Gevrey[3], Joel P.W. Pitt[1]

[1]National Centre for Advanced Bio-Protection Technologies, Lincoln University, Canterbury, New Zealand, [2]School of Biological Sciences, University of Sydney, NSW 200, Australia, [3]Laboratoire "Evolution et Diversité Biologique" (EDB) UMR 5174 - Université Paul Sabatier / CNRS, Toulouse Cedex 9, France

As increasing numbers of species are moved around the world and as ranges alter in response to climate change, risk assessment of potential alien invasive species becomes increasingly important. Risk assessment and analysis are required to make decisions concerning which species are likely to cause economic or environmental damage and to allocate resources to prevent or control an incursion. Risk assessments are usually qualitative and reactive and often focused on individual species. Yet, when large numbers of insect species have potential for harmful impact in regions where they are not normally found, conventional risk assessment does little to help prioritise the risk. New approaches based on neural networks, machine learning and spatially explicit models are described that allow pre-emergent species to be identified, potential establishment to be predicted with high accuracy, and spread over a detailed heterogeneous landscape to be simulated. Prioritisation of potential invasive insect species with respect to risk adds a new tool to the risk analysis framework. Additionally, prediction of potential establishment and simulation of spread over topographic, climatic and land-cover features, results in realistic dispersal patterns and identification of potential 'hotspots'. Given appropriate data, a spatially explicit model such as that described here not only allows sampling programs for detection to be tested, eradication strategies to be evaluated, but also bioeconomic models of impact to be refined before an incursion occurs. These quantitative approaches allow uncertainty to be evaluated and utilised for a more informed approach to the threat of non-native insect incursion.

Behaviour of caterpillars on plants at a fine scale: hairs, waxes and chemicals

Bronwen W Cribb[1], Lynda E Perkins[2], Jim Hanan[3], Ezekiel Glaze[2], Myron P Zalucki[2]

[1]Centre for Microscopy & Microanalysis, University of Queensland, Brisbane, Queensland, Australia, [2]School of Intergrative Biology, University of Queensland, Brisbane, Queensland, Australia, [3]ARC Centre of Excellence in Integrative Legume Research, University of Queensland, Brisbane, Queensland, Australia

Introduction: In order to model movement of an herbivorous insect on a plant so that the resultant model becomes predictive, we have divided interactions of the insect with the plant into two scales: the macro and the micro. At the micro scale, insects are exposed to the plant surface structure, local physical properties, and chemistry.

Methods: We have used the polyphagous caterpillar, *Helicoverpa armigera*, along with a range of plants, including the garden pea, cotton, tobacco and cabbage to investigate interactions at the fine scale. Scanning electron microscopy has been used to image plant surfaces (e.g. waxes and trichomes) and document physical interactions between the insect and plant, such as silk attachment points and feeding sites. A range of local and general physical properties have been measured, and insect behaviour has been recorded by direct observation as well as by video.

Results: Only a limited suite of local stimuli appear to be important in effective modeling of the movement behaviour of *H. armigera*. Movement rates and directions are greatly affected by diffuse stimuli perceived in the local environment. Interestingly, the first instar *H. armigera* shows the capacity to modify its local environment for effective feeding behaviour. The relative importance of local versus general sensory input will be discussed

Conclusions: In modeling movement of *H. armigera* effectively, only a limited array of micro-scale data need be included.

Timing and patterns of diversification in beetles (Coleoptera)

Duane McKenna

[1]Harvard University, Cambridge, MA, United States, [2]Museum of Comparative Zoology, Cambridge, MA, United States

Introduction: Modern beetles exhibit extraordinary ecological and taxonomic diversity. However, the absence of a robust phylogeny for beetles has hampered efforts to clarify higher-level relationships, and timing and patterns of beetle diversification.

Methods: Using molecular phylogenetic, fossil, and other data, I will present a brief overview of beetle macroevolution using examples from my research at various taxonomic levels, including (1) the four suborders of living beetles (Adephaga, Archostemata, Myxophaga, Polyphaga), (2) weevils (superfamily Curculionoidea), and (3) herbivorous Neotropical leaf beetles (family Chrysomelidae, genus *Cephaloleia*).

Results: I will present evidence for the rapid radiation of beetle suborders in the late Permian, the codiversification of weevils and angiosperms, and the roles of climate change, geological events, and codiversification in the evolutionary radiation of 'hispine' beetles in the genus *Cephaloleia*.

Conclusions: Taken together, this research show that biological, geological, and climatological events have played important, often synergistic roles in the diversification of beetles.

The 1999–2001 Australian plague locust outbreak in eastern Australia from the perspective of insect monitoring radar

Haikou Wang[1], V Alistair Drake[2], Edward D Deveson[1]

[1]Australian Plague Locust Commission, Australian Government Department of Agriculture, Fisheries and Forestry, GPO Box 858, Canberra, ACT 2601, Australia, [2]School of Physical, Environmental and Mathematical Sciences, UNSW@ADFA, Australian Defence Force Academy, Canberra, ACT 2600, Australia

Introduction: The outbreaks of Australian plague locusts, *Chortoicetes terminifera* (Walker), in the agricultural/horticultural region of south-eastern Australia had long been believed to originate in the arid interior from sudden population developments there after good spring and summer rain, despite northward migrations having been observed with scanning entomological radars over 20 years ago. More recent observations with automated insect monitoring radars (IMRs) with vertical-pointing beams have provided new evidence on how outbreaks of this locust develop.

Methods: Two IMRs have been set up 300 km apart in inland eastern Australia, at Bourke, NSW and Thargomindah, Qld. They run automatically for 11 hours every night starting around sunset. The digitised radar signals are analysed the following morning and estimates of each target's height, speed, displacement direction, body alignment, size, shape, wingbeat frequency, and wingbeat modulation form extracted. Their characteristic echo signature allows overflying plague locusts to be identified with high confidence. Their migration trajectories are calculated from IMR detected flight parameters and related to population distributions and development states obtained from field surveys.

Results: About 140 nights were identified with detectable plague locusts over Bourke during the three seasons 1998–2001 and 31 nights over Thargomindah during 1999–2000. Most plague locusts flew for 6–8 hours after sunset and travelled 200–330 km over the semi-arid region around Bourke, but flew all night covering about 400 km over the arid subtropical region of Thargomindah. These observations revealed that the plague locusts undertake a northward return migration in spring and early summer that helps maintain population persistence. Successful migrations to favourable interior habitats lead to rapid population growth and a risk of an autumn invasion of the south-eastern agricultural belt.

Conclusions: The near real-time data from the IMRs can provide the early warning of significant infestation needed for effective preventive control. Consecutive successful migrations of plague locusts in the variable and heterogenous habitats of eastern Australia contribute significantly to the development of locust outbreaks and their movement into cropping regions.

Dynamic population density of the coconut hispine beetle, *Brontispa longissima* Gestro (Coleoptera: Chrysomelidae)

Sopon Uraichuen[2], Kittiya Suksen[1], Wiwat Suasa-ard[1]

[1]National Biological Control Research Center, Bangkok, Thailand, [2]Kasetsart University, Bangkok, Thailand

Introduction: The coconut hispine beetle, *Brontispa longissima* Gestro was accidentally introduced into continental Southeast Asian countries, presumably in the early 2000's, with ornamental palms. Since then it become one of the most serious insect pest of coconut in Thailand.

Methods: Dynamic population density study of *B. longissima* was taken place by using 3 coconut fields at Kamphaeng Saen, Nakhon Pathom province in the Central Region of Thailand. Data collection was done twice a month. The sampling program was set by using 5 leaves as a sample unit and 16 samples per location. The number of eggs, larvae, pupae and adults of the beetle were recorded from August 2006 to December 2007. All data were subsequently analyzed and considered with density independent (DI) factors.

Results: Analysis results of the combinative DI factors affected to dynamic population of *B. longissima* indicated that rain volume, temperature and relative humidity caused change of the beetle population. The result revealed that the more rain volume and the less relative humidity, the greater number of egg pest. Meanwhile, temperature was a negative additional effect to the survival beetle larvae. Regard to adult population, the DI factors did not directly make a change in its population. Nevertheless, they could substantially give the lower egg laying rate of the female adult as well as the lesser hatch percentage.

Conclusions: The DI factors, rain volume, temperature and relative humidity which seasonal alter through the year round were the combinative effect to the dynamic change of *B. longissima* population.

Status of occurrence and monitoring of ambrosia beetles with alcohol bait traps in Korean apple orchards

Kyung-Hee Choi, Soon-Won Lee, Dong-Hyuk Lee, Dong-Ah Kim

Apple Experiment Station, Gyeongsangbukdo, Republic of Korea

Recently, ambrosia beetles has become very important pest of 2~5years old apple trees with M9 dwarf rootstocks in South Korea. It has killed the branches and stems of the young trees, especially, freeze-damaged trees in winter or drought stressed tree in spring. As the high density apple planting system with M9 dwarf rootstocks reduces the effort of management and enhances the yields, the area of that has been sharply increased since the latter 1990's. But M9 rootstock is weak in frozen damages in winter and then ambrosia beetles has become key pest in Korean apple orchards using M9 rootstock.

According to the survey of damaged apple trees by ambrosia beetles in 1998, *Xylosandrus germanus* Blandford was 62.5%, *Xyleborus apicalis* Blandford was 31.9%, and *Xyleborus minutus* Blandford was 5.5%, while in 2007, *Xylosandrus germanus* Blandford was 75%, *Xyleborus minutus* Blandford was 18%, *Xyleborus apicalis* Blandford was 4%, and *Xylosandrus crasiussculus* Motschulsky was 3%. Although the ambrosia beetles were well trapped in the ethyl alcohol of both 70% and 95%, 70% was considered to be more economical on account of alcohol's volatility. And they got trapped most effectively when traps were equipped at a one-meter height. They began to active and search for a suitable host(apple trees) when the highest temperature of a day exceed 20□ in spring.

From the middle of the 2000's, high density apple planting system has been greatly expanded, and ambrosia beetles which come flying in mountainous area now tend to be the primary hosts as they form density for winter survival themselves in apple orchards.

Morphometrics as applied to medical entomology

Jean-Pierre Dujardin

[1]IRD, Montpellier, France, [2]CVVD, Bangkok, Thailand

Introduction: In medical entomology, one of the main priorities is the set up of low cost but efficient tools for species recognition, especially cryptic species. Morphometrics provides this tool with additional virtues: the one of characterizing local populations, the one of identifying sources of re-infestation after insecticide treatments, and among others not cited here the one of detecting and interpreting population structuring.

Methods: species recognition makes use of PCA and CVA on shape variables, and would benefit from the existence of pictures data bases, re-infestation studies uses the resemblance between offspring and parents, and population structure studies benefits from associated genetic studies when allowing comparisons between Qst and Fst. To improve a strictly morphometric interpretation of population structure, we suggest an original method based on shape similarity between individuals.

Results: A few examples are given about species and re-infestation studies. More detailed presentation is made of the population structure study method, with a few examples combining morphometric and genetic approaches.

Conclusions: The main application of morphometrics to medical entomology, species identification, still needs the set up of relevant images data bases. The perspective of interpreting population structure is suggested.

Parasitoids for biocontrol of coffee berry borer: Past, present and future

Juliana Jaramillo[1], Juliana Jaramillo[2], Fernando E Vega[3]

[1]International Center of Insect Physiology and Ecology, icipe, Nairobi, Kenya, [2]Institute of Plant Diseases and Plant Protection, University of Hannover, Hannover, Germany, [3]Sustainable Perennial Crops Laboratory, United States Department of Agriculture, Agricultural Research Service, Maryland, United States

Introduction: The coffee berry borer (CBB) (*Hypothemenus hampei* (Ferrari); Col.: Curculionidae) is the most important pest of coffee throughout the world. Endemic to Africa, CBB has been accidentally introduced to most coffee producing countries, where it has become a highly damaging pest. In many countries, management of CBB relies on the use of synthetic insecticides, but due to their adverse effects on human health and the environment, other alternatives such as biocontrol are increasingly important. So far, three CBB parasitoids of African origin have been introduce to the Americas, *Prorops nasuta* Waterston, *Cephalonomia stephanoderis* Betrem (Hym.: Bethylidae) and *Phymastichus coffea* LaSalle (Hym.: Eulophidae). However, their impact has been rather limited.

Methods: Detailed surveys for CBB parasitoids were initiated in October 2006 in two coffee growing areas of Kenya (Kisii and Embu). In total, five organic coffee plantations have been sampled every 2-3 weeks. On each sampling date, CBB-infested coffee berries collected from the tree or from the ground were taken to the laboratory and placed in containers. Daily emergence of parasitoids was assessed.

Results: All emerging parasitoids are being identified at the Systematic Entomology Laboratory (USDA, ARS) and their possible role as natural enemies of CBB is being investigated. The most abundant species are *P. nasuta* and *Ceraphron* sp., (Hym.: Ceraphronidae). Our preliminary findings indicate that *Ceraphron* sp. is a hyperparasitoid of *P. nasuta*. Both insects exhibit a distinct phenology linked to the population dynamics of CBB. Emergence data from berries collected from the ground (i.e., in the leaf litter strata), largely exceeds those from the trees, indicating that these berries form an important reservoir for natural enemies.

Conclusions: In Kenya, CBB populations are being controlled mainly by a complex of parasitoids that work synergistically in different periods of the year. Of these parasitoids, the most important species seems to be the bethylid *P. nasuta*. The importance of natural enemies harboured in coffee berries in the leaf litter strata for integrated pest management is discussed.

Brachyceran assemblages (Diptera) as indicators of terrestrial palaeoenvironments in the Late Mesozoic

Mike Mostovski

Natal Museum and School of Biological & Conservation Sciences, UKZN, Pietermaritzburg, South Africa and Paleontological Institute, Moscow, Russia, Pietermaritzburg, Moscow, South Africa

The diversification of brachyceran Diptera started during the Middle or Late Jurassic and continued successfully over Cretaceous and entire Cainozoic. Although there is a number of extinct families, the majority of them is extant. This gives an opportunity to use presumed ecological characteristics of their representatives for reconstructing palaeoenvironments at sites of their burial. Data from the following oryctocoenoses have been examined: Karatau (Kazakhstan; Callovian–Kimmeridgian), 'Tsagaan-Tsav' (several localities in Mongolia; basalmost Cretaceous), Purbeck and Wealden (England; Berriasian–Barremian), Baissa (Transbaikalia; Valanginian–Hauterivian), Bon-Tsagaan (Barremian–Aptian), Obeshchayushchiy (Russian northern Far East; Senomanian), Orapa (Botswana; Senomanian–Turonian). Collecting bed-by-bed at Baissa gives a chance to analyse the environmental history of the deposition basin. The proportion of Empididae *s.l.* seems to be particularly important for establishing humid or mesic *vs.* dry environments. Strong fliers like members of Eremochaetidae, Therevidae, Asilidae, Nemestrinidae, Bombyliidae, and Mydidae indicate the presence of open landscapes. Presumed pollinators like Nemestrinidae and Mydidae suggest the presence of "flowering" plants in the surrounding vegetation.

Revision of some parasitic wasps (Hymenoptera) from Florissant, USA, with certain palaeoenvironmental inferences

Victor Kolyada[1], Mike Mostovski[2]

[1]Zoological Museum of Moscow University and Paleontological Institute, Moscow, Russian Federation, [2]Natal Museum and School of Biological & Conservation Sciences, UKZN, Pietermaritzburg, South Africa

Proctotrupidae is a relatively small and world-wide distributed family of parasitic wasps that prefer temperate and humid habitats. At the beginning of the last century, Brues (1910) and Cockerell (1915) described three species of parasitic wasps from the Florissant locality (Colorado, USA; Upper Eocene/Lower Oliogocene, Florissant Formation) in the families Proctotrupidae, Diapriidae and Scelionidae. Re-examination of types confirms that all this material belongs to Proctotrupidae and represent genera *Oxyserphus*, *Pschornia*, *Mischoserphus*, and *Nothoserphus*. Species of *Oxyserphus* live in temperate and subtropical forests and parasitise on larvae of Curculionidae and Anthribidae (Coleoptera); only recently this genus has been found in the palaeontological record (Lower Oligocene Bembridge Marls and Late Eocene Baltic amber). Species of *Pschornia* are found in temperate and mountain forests and parasitise on larvae of Cleridae (Coleoptera); this is the first record of this genus as fossil. Species of *Mischoserphus* occur in temperate and subtropical forests, preferring mesic habitats, and parasitise on larvae of fungus gnats (Diptera: Mycetophiloidea); only recently this genus has been found in the palaeontological record (Bembridge Marls and Baltic amber). Species of *Nothoserphus* inhabit temperate and subtropical forests and parasitise on larvae of Coccinellidae (Coleoptera); this is the first record of this genus as fossil.

Revision of some parasitic wasps (Hymenoptera) from Florissant, USA, with certain palaeoenvironmental inferences

The impact of herbivorous insects on the photosynthetic characteristics of three cecidomyiid galls and their hosts

Meng-Yuan Huang[1], Yung-Ta Chang[1], Man-Miao Yang[2], Chi-Ming Yang[3]

[1]Department of Life Science, National Taiwan Normal University, Taipei, Taiwan, [2]Department of Entomology, National Chung-Hsing University, Taichung, Taiwan, [3]Research Center for Biodiversity, Academia Sinica, Taipei, Taiwan

Introduction: Multiple changes in response to gall inducers have been found in host plant tissues. While much attention has been focused on the morphology and anatomy of insects or their induced galls, relatively little work has been done on the photosynthesis. Our previous data showed that some photosynthetic apparatus, such as pigment-protein complexes of PSI and PSII, of gall are life time deficient. Based on assumptions of source-sink hypothesis, we predicted that leaf-derived cecidomyiid galls play the role as novel sink in *Machilus thunbergii* and *Litsea acuminata* leaves.

Methods: Gas exchange, chlorophyll fluorescence, scanning electron microscopy were used to investigate the photosynthetic characteristics of leaf-derived cecidomyiid galls and their host leaves.

Results: No gas exchange was found in all galls investigated, whereas the gall-resided and gall-free leaves demonstrated normal gas exchange at equal level. No stoma structure was found on the inside and outside surface of gall. Inside surface of galls was full of fungal hyphae. While chlorophyll fluorescence of gall was at the level of 0.6-0.7, that of gall-resided and gall-free leaves 0.8.

Conclusions: Combination of previous and present result suggested that herbivorous insects may dramatically alter photosynthetic efficiency of leaf-derived gall via changing partial apparatus of PSI and PSII on the thylakoid membrane, but do not alter that of their host leaves. The results further suggest that the leaf-derived cecidomyiid galls are sinks in *Machilus thunbergii* and *Litsea acuminata* leaves.

Comparing mushroom body with surrounding neuropil of insect brains

Friedrich-Wilhelm Schurmann

University of Gottingen, Johann-Friedrich-Blumenbach-Institut fur Zoologie und Anthropologie, Gottingen, Germany

Introduction: Insect brains show two forms of neuropil structure, mainly refered to as so called glomerular, “ordered“ neuropil or “diffuse“ neuropil. A comparison of the two forms of neuropil is presented for the mushroom body and surrounding neuropil.

Methods: Morpological features of brain neuropils of fruit flies, bees and crickets have been analyzed by immuncytochemical, light and and electron microscopic approaches.

Results: Selected similaraties and differences in neuropil design with special reference to mushroom body calycal synaptic microcircuits are considered. Classical and modern light microscopical studies show the obvious geometrical order of repeated arrays of classes of local interneurons in mushroom bodies pointing to redundant nerve cells. In contrast, local and relay neurons in the “diffuse“ neuropil appear as unique neurons identified by structure and forming networks with a “hidden“ order.Transmitters and neuromodulators so far detected are encountered in both forms of neuropil, but their distribution and accumulation underline the ordered neuropil character of mushroom bodies versus surrounding “diffuse“ neuropil stucture. Synapse and vesicle markers appear randomly distributed in the diffuse neuropil, whereas in mushroom bodies synaptic sites are concentrated in subcompartments. A unifying character of both forms of neuropil is their equipment with complex synaptic circuits.

Outlook: The meaning of structural neuropil differences and problems to generalize are considered.

The evolution of psyllids and galls: a review

Daniel Burckhardt

Naturhistorisches Museum, Basel, Switzerland

Introduction: Psyllids (Hemiptera, Psylloidea) often induce galls on the leaves, flowers, woody stems or roots of their host plants. Generally their host plant ranges are very narrow at the species and at higher taxonomic levels. The morphology of psyllid galls is quite diverse ranging from open pits to closed spherical structures. Gall induction is mostly associated with larval stages but eggs and feeding adults can provoke deformations on the host as well.

Result: Gall inducing species are well represented among the Psylloidea but their distribution is taxonomically and geographically uneven. Species of the large genera *Acizzia* (Acizziinae) and *Cacopsylla* (Psyllinae) do not or rarely induce galls, whereas most *Calophya* (Calophyidae) and many *Pseudophacopteron* (Phacopteronidae) species induce conspicuous galls. The gallicolous species are particularly numerous in the tropics. In Java (Indonesia) about 5 % of all galls are induced by Psylloidea. The variation of gall types and distributional patterns is illustrated with examples such as the South American psyllids of the genera *Calophya* and *Tainarys* associated with *Schinus* (Anacardiaceae). Evolutionary aspects are discussed.

Conclusions: Psyllids are specialized with regard to their host species as well as the site on the host where they feed and develop. This specialization probably helps to use food resources more efficiently, and may be an evolutionary strategy to escape predators and parasitoids. A phylogenetic interpretation suggests that the presence and type of galls can be predicted by the psyllid phylogeny in some instances and by the host plant phylogeny in others.

Apterous males in Mutillidae (Hymenoptera: Aculeata): Pattern and process

Denis Brothers

University of KwaZulu-Natal, Scottsville, South Africa

Introduction: In Mutillidae (velvet ants), females are invariably apterous but males are generally fully winged. The differences are thought to relate to the need for females to find suitable hosts, often involving digging, where wings could be impediments or subject to damage, while the males could still disperse widely, thus promoting outcrossing. Some species show phoretic copulation, where males carry females during mating, emphasising the importance of males for dispersal. In several genera, however, males show wing reduction, from brachyptery to complete aptery. The mesosoma (thorax) in females always shows fusion of some or all sutures and most have no ocelli. Winged males have the sutures fully developed and well developed ocelli, but wing reduction or loss is associated with varying degrees of mesosomal modification and even loss of ocelli.

Methods: The form of the mesosoma and ocelli was surveyed in both sexes across the genera of Mutillidae on a worldwide basis.

Results: Males of Pseudophotopsidinae, Myrmosinae (including Kudakrumiini) and Rhopalomutillinae are all fully winged. Brachypterous or apterous males are found in Ticoplinae: Smicromyrmillini (few species, Afrotropical and Oriental); Sphaeropthalminae: Dasylabrini (several species, Afrotropical) and Sphaeropthalmini (few species, New World); Myrmillinae (several species, Palaearctic and Afrotropical) and Mutillinae: Smicromyrmina (few species, Afrotropical). This tendency is apparently most common in southern Africa. The patterns of mesosomal modification in males do not mirror those in females. The paucity of knowledge about the biology of Mutillidae, and the relevant species in particular, prevents any conclusions about the reasons for the distributional or developmental patterns of apterous and brachypterous males.

How does herbivore-induced plant regrowth govern geographic and genetic variation in a feeding preference of a leaf beetle?

Shunsuke Utsumi, Yoshino Ando, Takayuki Ohgushi

Center for Ecological Research, Kyoto University, Otsu, Shiga, Japan

Introduction: We hypothesized that a feeding preference of the specialist leaf beetle *Plagiodera versicolora* adults to new leaves of willows would be favored by natural selection for adaptation to the temporal patterns in food resource recruitment, depending on the extent of induced regrowth response of willows.

Methods: To examine geographic variation in new leaf production of willows and the beetle preference, we conducted field survey and laboratory choice test. Also, to detect a genetic basis for the preference, an half-sib analysis was conducted. Finally, evolutionary change in the preference was examined by directional selection experiment using different leaf age types.

Results: Some allopatric populations displayed strong preference to new leaves of *Salix eriocarpa*, but others showed no preference. There was a positive correlation between new leaf production in early summer and feeding preference to new leaves. Willow regrowth is likely to be responsible for geographic variation in new leaf production in early summer. A genetic basis for the feeding preference was detected; additive genetic variance and heritability were significantly different from zero. Our directional selection experiment resulted in divergence of the feeding preference. A population confined to new leaves produced by regrowth displayed an increased preference to new leaves, and a population confined to mature leaves displayed a decreased preference to new leaves.

Conclusion: Induced willow regrowth would maintain geographic variation in the feeding preference of the leaf beet adult and govern a locally adaptive preference.

Introduction to the biodiversity and heteronomy in Strepsiptera

Jeyaraney Kathirithamby

University of Oxford, Oxford, United Kingdom

Introduction: Since the use of molecular techniques for the study of Strepsiptera we have uncovered several interesting aspects in this group which remained a puzzle before. Aspects such as cryptic speciation are critical for the study of the biodiversity of this bizarre entomophagous parasitoids.

Heteronomy: Heteronomy is less common and often overlooked type of polymorphism and is found only in two lineages of insects: in the hymenopteran subfamily Coccophaginae (Aphelinidae), and in the strepsipteran family Myrmecolacidae. Walter (1983) introduced the term heterotropic heteronomy for the complex and extreme form of behaviour. In the aphelinid the mother (a hymenopteran) selects a totally different host for her male and female eggs. As a consequence the males develop in a different host to the female. The host relationships of the females are conserved and they develop as endoparasites of Sternorrhyncha (whiteflies) (Hemiptera) and males develop as primary endoparasites in eggs of Lepidoptera. The separation of male and female host differs from that in strepsipteran Myrmecolacidae, because in the aphelinid it is the mother which seeks the host to lay the egg of an appropriate sex.

In the strepsipteran family Myrmecolacidae, the males develop as primary parasites in ants (Formicidae: Hymenoptera), and the females as primary parasites in grasshoppers, mantids and crickets (Orthoptera: Tettigoniidae, Grillidae; Mantidae). Yet it is the first instars that encounter/seek the appropriate host. This is a unique form of heterotrophic heteronomous life history, a polymorphism not found in any other insect parasitoid.

Is *Bacillus thuringiensis* better than pesticides in vegetable brassica production systems?

R. Srinivasan[1], B.S. Rekha[2], T.M. Bharpoda[3], Hirak Chatterjee[4], A.R.V. Kumar[2], R.C. Jhala [3], Mei-Ying Lin[1]

[1]AVRDC-The World Vegetable Center, Shanhua, Tainan, Taiwan, [2]University of Agricultural Sciences, Bangalore, Karnataka, India, [3]Anand Agricultural University, Anand, Gujarat, India, [4]Palli Siksha Bhavana, Visva Bharati, Birbhum, West Bengal, India

Introduction: Efforts are underway to develop and introduce *Bacillus thuringiensis* (Bt)-based insect resistant transgenic brassicas, either with a single gene or with two genes. Hence, it becomes imperative to assess the likely impact of Bt on target and non-target organisms.

Methods: Simulated field experiments were undertaken in India and Taiwan to assess the impact of Bt on phytophagous insects, natural enemies and soil arthropods in vegetable brassicas.

Results: The simulated field experiments with *Xentari*, a Bt formulation based on *B. t.* subsp. *aizawai* containing both Cry1A and Cry1C toxins recorded lower infestations of diamondback moth, cabbage head caterpillar and cabbage web worm. However, insects such as aphids, whiteflies and flea beetles were not controlled by Bt. Bt did not have any significant adverse effects on the population of parasitoids like *Cotesia plutellae*, predators such as spiders, and soil arthropods including coleopterans, dermapterans, hymenopterans, lepidopterans and arachnida. However, the populations of ladybird beetles and field crickets were reduced in Bt-treated plots compared to the untreated plots, although the Bt-treated plots recorded higher numbers of these insects when compared to plots receiving synthetic chemical pesticides.

Conclusions: Bt containing two or more Cry toxins kept the population of major lepidopterans on vegetable brassicas under check. However, it was not effective against sucking insects and flea beetles. Comparatively Bt was safer to natural enemies and soil arthropods.

Family-group names in Coleoptera

Patrice Bouchard[1], Yves Bousquet[1], Miguel A. Alonso-Zarazaga[2], John F. Lawrence[3], Chris H. C. Lyal[4], Alfred F. Newton[5], Michael Schmitt[6]

[1]Canadian National Collection of Insects, Arachnids and Nematodes, Agriculture and Agri-Food Canada, Ottawa, Canada, [2]Departamento de Biodiversidad y Biología Evolutiva, Museo Nacional de Ciencias Naturales, Madrid, Spain, [3]Australian National Insect Collection, CSIRO Entomology, Canberra, Australia, [4]Department of Entomology, The Natural History Museum, London, United Kingdom, [5]Zoology Department, Field Museum of Natural History, Chicago, United States, [6]Zoologisches Forschungsmuseum Alexander Koenig, Bonn, Germany

Correct usage of family-group names in zoology has received increased interest in the last 25 years. The motivation behind this recent attention is to standardize and stabilize their usage through time. Sabrosky (1999) reviewed all known Diptera family-group names (based on approximately 2000 type genera) in what could be considered the most comprehensive treatment of such names to date.

In Coleoptera, Lawrence and Newton (1995) presented a landmark review of the higher classification of world beetles as well as a nomenclatural treatment of some family-group names (family and subfamily names only). They estimated that there may be in excess of 10 000 family-group names (including tribes and subtribes) based on distinct type genera in Coleoptera literature. While reviews of Coleoptera family-group names for some of the major clades have been published recently (e.g. Geodephaga, Staphyliniformia, Cucujoidea, Scarabaeoidea, Curculionoidea), an effort to thoroughly review literature associated with names of all groups has not been attempted yet.

The specific goal of our project is to provide a complete catalogue of available family-group names (families, subfamilies, tribes, subtribes) proposed in the order Coleoptera since 1758. This treatment will include recent discoveries on historical entomological literature and will be based on a consistent application the ICZN rules within the entire order. The resulting catalogue will include names of both extant and extinct taxa, will be based on the most recent classification scheme of the order and will be made available freely through an open-access journal.

Conservation of the endemic and endangered Karkloof blue butterfly *Orachrysops ariadne*

Adrian Arnstrong, Sharon Louw

Ezemvelo KZN Wildlife, Pietermaritzburg, KwaZulu-Natal, South Africa

Introduction: This study aims to improve the conservation status of the Karkloof blue butterfly *Orachrysops ariadne*, including through joint community management.

Methods: An egg-monitoring system was developed by comparing a known-area count and an index count. The areas of the host-plant (*Indigofera woodii* var *laxa*) at the known colony sites were delimited. Host-plant seeds were collected from one site and germinated *ex situ*. A host-ant (*Camponotus natalensis*) distribution survey was carried out at that site. Prediction of suitable habitat in which to search for other colonies was carried out by distribution modelling.

Results: The index count was more efficient. A precipitous decline in egg numbers over three consecutive years was recorded at one site, caused by mammalian browsing and uncontrolled fire. After the establishment of a firebreak, an increase in the number of host-plants and hatched eggs was recorded. Host-plant distribution areas at three of the four sites varied from 1.35 ha to almost 10 ha. At one site, the distribution of the host-plant and the host-ant were largely congruent. The number of unrecorded colonies is likely to be few.

Conclusions: Total egg counts will be continued annually at one site and the index method used triennially at each of the other sites. Regular monitoring of eggs allows timeous conservation action to be initiated, and joint community management is important for success. Host-plants germinated *ex situ* and planted where host-ants occur may increase the potential number of oviposition sites. Fencing should help further reverse the decline in egg numbers.

Triphasic screening of cultivated grapevines *Vitis* species for resistance to grapevine phylloxera *Daktulosphaira vitifoliae*

Kevin Powell[1], Ginger Korosi[1], Carolyn Trethowan[1], Ary Hoffmann[2]

[1]Department of Primary Industries, Biosciences Research Division, Rutherglen Centre, Rutherglen, Victoria, Australia, [2]CRC for Viticulture and Centre for Environmental Stress and Adaptation Research, Bio21 Molecular Science and Biotechnology Institute, Building 102, Level 2, 30 Flemington Road, The University of Melbo, Melbourne, Victoria, Australia

Introduction: Screening for resistance or tolerance to grapevine phylloxera *Daktulosphaira vitifoliae* Fitch has generally focused on selecting populations of insects and not the use of genetically distinct clonal lineages. It has also focused on the use of one or more protocols including laboratory, glasshouse and field screening.

Methods: A systematic triphasic approach to screening for phylloxera 'resistance' has been developed using up to six genetically distinct clonal lineages of *D. vitifoliae*. Laboratory studies utilised an excised root bioassay protocol, glasshouse studies utilised a quarantine mesh system, to avoid cross contamination of phylloxera genetic strains and field studies were conducted using trapping techniques to monitor population abundance in commercial vineyards with natural infestations of grapevine phylloxera.

Results: Six genetic strains of phylloxera were tested for resistance under glasshouse and laboratory to a range of commercially available rootstocks and showed different virulence levels on both rootstocks and susceptible *Vitis vinifera* L. Abundance of phylloxera on rootstocks under field conditions was influenced by rootstock and site conditions.

Conclusions: A triphasic screening system has been developed for rootstock 'resistance' to grapevine phylloxera. This will lead to improved rootstock resistance ratings based on genotypic interactions.

Single locus molecular markers can give a misleading trace of the origin and spread of species.

Felix Sperling

University of Alberta, Edmonton, Alberta, Canada

Although mitochondrial DNA and various other molecular markers can be useful for identifying specimens to species when there is good information available on background variation, there have been very few studies that test the efficacy of these markers rigorously. Such markers have been employed to resolve one or more of several distinct problems: 1) identification of a known species, 2) discovery of new species, 3) delimitation of species, and 4) reconstructing phylogenetic relationships. These questions demand different properties from molecular markers. For example, mitochondrial DNA may identify a specimen to species in only part of its geographic range, but this problem is often not be detected because surveys of variation are not geographically comprehensive. Single locus markers may give intriguing hints of cryptic species, but without being integrated into parallel sampling across other character types they can be profoundly misleading about the genomic integrity of species boundaries as well as the origin and spread of species. Since there is much at stake when molecular markers are used to justify holding up shipments or implementing control measures, it is important to have a statistically defensible framework for evaluating the probability of correct identification or source for a sample.

Polytomies and rapid radiations - phylogenetics of the Coenonymphina-Hypocystina group of butterflies (Nymphalidae: Satyrinae)

Ullasa Kodandaramaiah[1], Niklas Wahlberg[2]

[1]Dept of Zoology, Stockholm University, Stockholm, Sweden, [2]Laboratory of Genetics, Department of Biology, University of Turku, Turku, Finland

Rapid radiations have been identified in several groups of organisms and numerous studies have highlighted the problems involved in the reconstruction of their phylogenies. In particular, the combination of short internal and long external branches can lead to near-polytomous nodes, thus misleading tree reconstruction using both Maximum Parsimony (MP) and model-based methods such as Maximum Likelihood (ML) and Bayesian Inference (BI). Based on simulation and empirical studies, several features of rapid radiations with respect to tree reconstruction are identified. In the current study, these features are used to identify nodes that are likely to be near-polytomous, within a group of butterflies - the subtribes Coenonymphina and Hypocystina (Nymphalidae: Satyrinae). We suggest that this approach can be used under certain circumstances to distinguish nodes at which rapid bursts of speciation have occurred from normal nodes. We also argue that in many cases, it is not practically feasible or even impossible to resolve near-polytomous nodes and in such cases the search for a fully bifurcating tree leads to erroneous results. Thus polytomies should be incorporated as a valid hypothesis in phylogenetic reconstruction.

Enhancing sustainability in vegetable farming: Clarification of *Macrolophus* species that colonize tomato and the potential of alternative host plants in conservation biological control

Dionyssios Perdikis[1], Nikolaos Garantonakis[1], Athanassios Giatropoulos[1], Theodoros Gouvitsas[2], Anna Kourti[2], Dionyssios Lykouressis[1], Antonios Peraskevopoulos[3], Efthalia Gkinala[1], Argyro Fantinou[4]

[1]Laboratory of Agricultural Zoology and Entomology, Agricultural University of Athens, Athens, Greece, [2]Department of Agricultural Biotechnology Agricultural University of Athens, Athens, Greece, [3]Directorate of Rural Development, Trifylia, Kyparissia, Greece, [4]Laboratory of Ecology and Environmental Sciences Agricultural University of Athens, Athens, Greece

Introduction: In recent years there is a fast growing interest to increase sustainability in vegetable production by applying less intensive methods for pest control. Under this concept, key functional component of tomato agroecosystems in the Mediterranean region are the widespread, polyphagous predators *Macrolophus melanotoma* (= *M. caliginosus*) and *M. pygmaeus* (Hemiptera: Miridae) originated from two very common non-crop plants *Dittrichia viscosa* L. (Asteraceae) and *Solanum nigrum* (Solanaceae), respectively.

Methods: Open field sampling, greenhouse and laboratory experimentation along with molecular studies were performed to answer: i) which of the two predators colonize tomato and ii) which of non-crop plants could be anticipated to be natural reservoir or banker plant for implementation in conservation biological control schemes in the open field or in the greenhouses.

Results: Field experiments did not detect edge effects on tomato crop colonization. *M. pygmaeus* from *S. nigrum* was proved to be the *Macrolophus* species that can colonize tomato. In contrast, *M. melanotoma* showed, in all scale experiments, a strong preference for its origin host plant, *D. viscosa*.

Conclusions: Our results addressed a main set of uncertainties regarding the conservation of *Macrolophus* predators in vegetable habitats. It was proved that *S. nigrum* could be a main element of cropping systems that aim to take benefit from the conservation of *M. pygmaeus.*

Potential indirect impact of the invasive leaf-miner, *Cameraria ohridella*, on native leaf-miners

Christelle Péré[1], Sylvie Augustin[3], Rumen Tomov[4], Ted Turlings[2], Marc Kenis[1]

[1]CABI Europe-Switzerland, Rue des Grillons 1, 2800 Delémont, Switzerland, [2]University of Neuchâtel, rue Emile Argand 11, CP 158, 2009 Neuchâtel, Switzerland, [3]INRA, 2163 av. de la Pomme de Pin, BP 20619, Ardon, 45166 Olivet Cedex, France, [4]University of Forestry, Bul. Kliment Ohridski 10, 1756 Sofia, Bulgaria

Introduction: The horse-chestnut leaf-miner, *Cameraria ohridella*, is a moth of unknown origin that was first observed in Macedonia in 1984 and has now invaded most of Europe. It is attacked by several native leaf-miners' parasitoids. Despite the low parasitism rates observed in *C. ohridella*, populations are so high that an unusual amount of polyphagous parasitoids are produced in the vicinity of infested horse-chestnut trees two or three times per year. In spring, the bulk of the parasitoids emerge at least six weeks before the first suitable *C. ohridella* larvae or pupae are available. These parasitoids could massively attack the first indigenous leaf-miners developing in spring. We tested the hypothesis that the presence of *C. ohridella* has a negative effect on populations of native leaf-miners through shared natural enemies (apparent competition).

Methods: Species richness and abundance of indigenous leaf-miners were assessed in presence and absence of *C. ohridella*, in Switzerland, France and Bulgaria.

Results: In spring, the species richness of indigenous leaf-miners was significantly lower in the presence of *C. ohridella* than in its absence. Some native leaf-miners, such as the beech and oak leaf-mining weevils, *Orchestes fagi* and *O. quercus*, sharing their parasitoid complex with *C. ohridella,* were significantly less abundant at sites with horse-chestnuts attacked by *C. ohridella* compared to control sites.

Conclusion: Parasitoids, and possibly predators, are the only link between *C. ohridella* and native leaf-miners feeding on other host-plants and are thus probably responsible for the decrease.

The control of *Callosobruchus maculatus* L. (Bruchidae: Coleoptera) in different cereals with Spinosad dust

Adel Khashaveh[1], Nouraddin Shayesteh[2], Farzaneh Attighi[1]

[1]Urmai University, Urmia/west Azarbaijan, [2]Islamic Azad University, Branch of Mahabad, Mahabad/west Azarbaijan, Islamic Republic of Iran

Introduction: Spinosad is a new bacterial-based insecticide. Most available experimental data are for liquid formulations, while very little is know about applying spinosad as a dust.

Methods: The effectiveness of spinosad dust formulation (0.125% a.i.) against *Callosobruchus maculatus* (L) was assessed on four commodities, Cowpea, Chickpea, Lentil and yellow split pea. The experiment was carried out with 4 replication and thirty 0-24 h old adults were used for each replication. Commodities treated with three dose rate; 0.1, 0.2 and 0.3 g/kg at 27℃ and 60± 5% r.h. The mortality of *C. maculatus* adults was measured after 24 h, 48 h, 5 d and 10 d. After the 10-day mortality count, all surviving insects were removed and the samples retained under the same conditions for a further 35 days to assess progeny production.

Results: The increase of dose and exposure interval increased mortality and significant difference was recorded among the four cereal types. After 10 days of exposure, mortality received to 100 % in all commodity at high rate (0.3 g/kg) except of yellow split pea that it was significantly lower than other commodities (79/46% after 10 d exposure). The application of spinosad significantly reduced progeny production in the four commodities tested in comparison with the untreated ones. High reduction in progeny production was recorded when spinosad applied at the rate of 0.3 g/kg on Lentil and Cowpea (94/33 and 94/21, respectively).

Conclusions: This research counseled that spinosad dust formulation could control different life stages of *C. maculatus* in different cereals.

Population dynamics and diversity of leafhopper Cicadellidae vectors of Tobacco Yellow Dwarf Virus (TYDV)

Piotr Trebicki[1], Rob M. Harding[1], Brendan C. Rodoni[2], Gary Baxter[4], Kevin S. Powell[3]

[1]Centre for Tropical Crops and Biocommodities, Queensland University of Technology, Brisbane, Queensland,, Australia, [2]Department of Primary Industries, Bioscience Research Division, Knoxfield, Victoria, Australia, [3]Department of Primary Industries, Bioscience Research Division, Rutherglen, Victoria, Australia, [4]Department of Primary Industries, Ovens, Victoria, Australia

Introduction: To assess geographical distribution, population dynamics and diversity of leafhoppers a variety of different trapping methods are available. Many leafhopper species are important agricultural pests and damage occurs directly through feeding and indirectly through transmission of pathogens. Determining the population dynamics and distribution of potential leafhopper vectors can lead to improve suitable management practices through optimisation of control options. This study compared trapping techniques and assessed the relative abundance of potential leafhopper vectors with the ability to transmit and acquire TYDV.

Methods: During two growing seasons the population dynamics and relative seasonal abundance of Cicadellidae were monitored at four commercial field sites in NE Victoria, Australia. Three different trapping methods; sticky trap, yellow pan water trap and sweep net were assessed on a weekly basis around the borders of cultivated tobacco farms. The presence of TYDV in leafhoppers and host plants was assessed using standard PCR protocols.

Results: During two seasons, the yellow pan trap proved the most effective trapping technique for monitoring diversity and population dynamics of leafhoppers. A greater diversity of leafhoppers were recorded using this technique and a ten-fold increase in some species compared to the sweep net and sticky trap methods. TYDV was detected in *Zygina spp*. and in *O. orientalis* during the summer period.

Conclusion: Trapping techniques were optimised to monitor the seasonal distribution of potential leafhopper vectors and host plants for TYDV. The knowledge gained can improve management practices for this insect-virus complex.

Diabrotica virgifera virgifera LeConte (Coleoptera: Chrysomelidae) appearing in Germany 2007: surprise, disaster, challenges, and consequences for IPM

Hans E. Hummel

Justus-Liebig-University Giessen, Organic Agriculture, Giessen, Germany

In July of 2007 the first leaf beetles of Western corn rootworm (WCR) were detected in maize fields of Southern Germany. Two sites in the States of Baden-Württemberg and Bavaria reported spot infestations with close to six hundred WCR indicating undetected earlier (2005 or 2006) immigration events. Public reactions ranged from surprise to warnings of pending disaster for maize agriculture in north central Europe, while for experts simultaneous detection at 5 sites within two States hardly came as a surprise. The author had predicted this scenario of introduction on numerous occasions. The public, however, decided to adopt a "wait and see" attitude relying both on ecologically questionable, non sustainable insecticide treatments and on EU emergency directives.- While the new findings of WCR in Germany are a blow to quarantine measures, they hardly qualify as an immediate disaster since *Zea mays* can tolerate a modest infestation rate without significant yield loss. Rather, recent WCR infestations may be viewed as a challenge for integrated pest management whose components may consist of 1. mandatory crop rotation as practiced in Switzerland for several years, 2. quarantine, 3. biological and biotechnical control measures, 4. classical selection of resistant maize varieties and 5. a narrow network of monitoring stations. - Further introductions from the US into Europe, including Eastern Europe, by hitchhiking beetles aboard airplanes, ships and trucks cannot be ruled out, nor can transport of WCR to Africa and East Asia be excluded. An even greater challenge may arise from the recent discovery by Hummel et al. (2007a and b) and Hummel (2007) of WCR acquiring additional secondary host plants such as members of the Cucurbitaceae, soybean, sunflower, *Amaranthus, Ambrosia* and *Chenopodium* spp. Given the enormous biotic and genetic potential of WCR, under certain constant selection pressure these plants may, with time, develop into primary hosts and thus diminish their present value for crop rotation. - Sustainable WCR management in Europe is a severe challenge for all entomologists, including the younger members of the profession. Predictions of constant conflicts of *Homo sapiens* with pest insects made by Steven Forbes, State Entomologist of Illinois, close to one hundred years ago, lost nothing of their actuality, and fully apply to WCR in Germany and Europe.

Mosquito species diversity and abundance in relation to land use in a riceland agroecosystem in Mwea, Kenya

Josephat Shililu[1], Ephantus Muturi[2], John Githure[1], Robert Novak[2]

[1]I.C.I.P.E, Nairobi, Kenya, [2]UAB, Birmingham, AL, United States

Introduction: The full scale of mosquito diversity has been scarcely studied in rice agroecosystems despite the strong link between irrigation agriculture and disease transmission. Studies have tended to focus on specific malaria vectors ignoring other mosquito species thriving in rice agroecosystems.

Methods: Adult mosquitoes were sampled bimonthly indoors by PSC and outdoors by CDC light traps for 12 months in 3 villages representing different rice cropping regimen. The mosquitoes collected were identified morphologically to species using taxonomic keys.

Results: Irrigation had a marked effect on the mosquito diversity and abundance with 17 species (n= 66,828) collected in the planned rice growing village, 22 species (n= 21,074) in the unplanned rice growing site and 20 species (n= 10,808) in the non- rice growing village. The density of *Anopheles arabiensis* and other anophelines was higher in the rice field environments than in the non-irrigated sites. The predominant species collected indoors were *An. arabiensis* (80.1%), *Culex quinquefasciatus* (18.2%), and *An. funestus* (1.5%) whereas outdoors common species included *C. quinquefasciatus* (54.7%), *An. arabiensis* (25.9%), *An. pharoensis* (10.3%), *An. coustani* (2.6%), *C. annulioris* (1.8%), *C. poicilipes* (1.2%), *An. maculipalpis* (1.1%) and *An. funestus* (1.1%). *An. arabiensis*, *An. pharoensis* and *C. quinquefasciatus* were mainly associated with rice cultivation occurring in significantly higher densities in the village with the planned rice cultivation than in the unplanned one while *An. funestus* and *An. maculipalpis* were significantly higher in the non-rice village. The mosquito species diversity (H) and evenness (E_H) in the non-rice growing site (Shannon diversity Index, $H = 1.507$, $E_H = 0.503$) was much higher than in the sites with rice cultivation ($H = 0.968$, $E_H = 0.313$, Kiamaciri; and $H = 1.040$, $E_H = 0.367$ Mbuinjeru)

Conclusions: Mosquito diversity is impacted by rice cropping strategies and it is critical to understand mosquito community structure for targeting control strategies in rice agroecosystems.

The southern African lepidopteran fauna in a regional and global context

Martin Krüger

Transvaal Museum, NFI, Pretoria, South Africa

Among the major holometabolous orders, Lepidoptera are thought to have radiated most recently, largely during the Cretaceous and Early Tertiary. Consequently, mesozoic geological events such as the breakup of Gondwana are considered to have had comparatively little influence in shaping biogeographical patterns within the order. After the breakup, Africa underwent a prolonged period of geographical isolation before repeatedly being connected to Eurasia during the Tertiary. The afrotropical Lepidoptera fauna accordingly consists mainly of autochthonous elements resulting from intrinsic post-Gondwanan speciation, with Gondwanan relicts and descendants of Tertiary immigrants being much less numerous.

In keeping with the global pattern, Non-Glossatans and Non-Heteroneuran Glossata are fairly well represented at temperate latitudes in Southern Africa, but are virtually unrecorded further north. Examples include the *Sabatinca*-lineage of Micropterigidae, *Prototheora* (Prototheoridae), *Antihepialus* and *Afrotheora* in the Hepialidae and *Scyrotis* in the Cecidosidae (Incurvarioidea).

Some evidence for a Gondwanan distribution of basal ditrysians notwithstanding, currently accepted chronologies for the fragmentation process are incompatible with the existence of austral disjuncts among higher ditrysians. In addition to the larentiine geometrid tribe Trichopterygini, for which a Gondwanan distribution type of distribution has been tentatively suggested, evidence is presented for the existence in Southern Africa of the ennomine tribe Nacophorini, previously recorded from Australia and temperate South America. The putative Afrotropical members of the tribe are primarily associated with Fynbos, which dates to the Cretaceous; their occurrence in other biomes is considered to be secondary in nature.

Pymetrozine for brown planthopper control overcomes neonicotinoid resistance

Robert Lind, Russell Slater, Domingos Pedroni, Robert Senn

[1]Syngenta, Bracknell, Berkshire, United Kingdom, [2]Syngenta, Basle, Switzerland

Introduction: Resistance to neonicotinoid insecticides has been reported in field populations of the brown planthopper (*Nilaparvata lugens*) in many of the rice growing regions of South East Asia. Resistance factors of 5000 and 500 can be reached for imidacloprid and thiamethoxam respectively. Thus, compounds with novel modes of action such as pymetrozine are needed to combat resistance.

Methods: Neonicotinoid resistant strains were field collected from India and Vietnam and lab bioassays against nymphs and adult egg lay were used to evaluate the potential cross resistance to pymetrozine. To complement this study, the biokinetics of resistance were compared between susceptible and resistant strains by quantifying the rate and levels of metabolites of the archetypal neonicotinoid, imidacloprid using liquid chromatography mass spectrometry (LCMS).

Results: No differences in laboratory pymetrozine dose response in nymph mortality or egg lay was observed between susceptible and resistant strains. In agreement, there was no marked differences in the uptake of pymetrozine or between the rate or amount of the major hydroxy metabolite produced by the susceptible and resistant strains as determined by LCMS. Conversely, there was marked differences in imidacloprid metabolite production in resistant strains of approximately 25-fold compared to susceptibles. The major metabolite was formed by hydroxylation indicating the involvement of cytochrome P450 in the mechanism of resistance.

Conclusions: Laboratory and field studies have proved that pymetrozine can offer effective control of brown planthoppers, with no evidence of cross resistance to neonicotinoids thus providing it utility in resistance management programs providing long term, effective control.

Analysis of Japanese oak wilt spread using aerial photography and GIS

Ryotaro Komura[1], Naoto Kamata[2], Ken-ichiro Muramoto[3], Andrew Liebhold[4], Kojiro Esaki[5]

[1]Ishikawa National College of Technology, Tsubata, Ishikawa 929-0392, Japan, [2]University of Tokyo, Bunkyo, Tokyo 113-8657, Japan, [3]Kanazawa University, Kanazawa, Ishikawa 920-1192, Japan, [4]Northern Research Station, USDA Forest Service, Morgantown, WV 26505, United States, [5]Ishikawa Forest Experiment Station, Hakusan, Ishikawa 920-2114, Japan

In Japan, Japanese oak wilt (JOW) has been known since the 1930s. In the decades directly following its initial discovery, JOW epidemics were only a few years in duration and were confined to only a few areas on the Japan Sea (western) coast of Japan. However, in the last ten years epidemics have intensified and spread to the island's western coastal areas. The symbiotic ambrosia fungus *Raffaelea quercivora* is the causal agent of oak dieback, and is vectored by *Platypus quercivorus* (Murayama). This is the first example of an ambrosia beetle fungus that kills vigorous trees. We provide here an analysis of the historical distribution and spread of JOW previously recorded at the regional scale. Additionally of mortality caused by JOW at the stand scale level was investigated using aerial photographs. In this study, statistical analysis of spread of the oak diebacks was done conducted using a geographical information system (GIS) and rates of JOW spread were among different spatial scales. Results suggest that spread is the result of long, middle and short distance movement by adult beetles.

Evaluation of effect of sunlight on insecticide impregnated fabrics against vector species of mosquitoes under laboratory conditions

Neera Kapoor

IGNOU, New Delhi, India

Introduction: Insecticide treated curtains (ITC) play an important role in controlling vector-borne diseases in urban areas as plain curtains are normally used in majority of urban houses. After impregnating curtains with insecticides they are dried in shade. This implies that sunlight influences the efficacy of impregnated curtains. Since impregnated curtains are expected to be occasionally exposed to sunlight, tests were done under laboratory conditions to determine the residual activity at the interval of 1 week after the treatment.

Methods: Effect of sunlight was studied by exposing impregnated fabric panels to sunlight for 8-10 hours a day till the insecticide activity was observed and bioassay tests were conducted daily by exposing females to treated surface. Bioassay tests were carried out with WHO susceptibility test kits. The experiments were pursued till 0% mortality of the test mosquitoes was observed.

Results: On cotton impregnated with deltamethrin at 40 mg/m^2, there was approximately 50% reduction in *An. stephensi* mortality in 8 weeks and in 10 weeks there was 90% reduction in *An. stephensi*. Similar trend was observed for other two species of test mosquitoes. On nylon and plastic also at 40 mg/m^2, all the insecticides showed drastic reduction in mortality after 4 weeks and complete loss after 8 weeks of exposure to sunlight. At 80 mg/m^2, deltamelthrin showed its residual effect till 12 weeks on cotton and jute against all the three mosquito species tested on nylon. The complete loss of all the insecticides on exposure to sunlight was observed in 8 weeks. At 100 mg/m^2, complete insecticidal loss was observed in 16 weeks against *Cx. quinquefasciatus* on all fabrics and against *Ae. aegypti* on nylon and plastic. The residual effect of insecticide was observed even till 16 weeks against *An. stephensi* on all the fabrics. Lambdacyhalothrin, cyfluthrin and etofenrox impregnated fabrics on exposure to sunlight showed the residual effect for 8-16 weeks with the increase of dosage from 40 to 100 mg/m^2.

Conclusions: Our experiements confirm the earlier findings of Elliot etal, (1978) that sunlight causes rapid degradation of synthetic pyrethroids so it is recommended that curtains should be dried with air driers. Alternatively they can be rolled in daytime and hung at night to escape the effect of sunlight.

Genetic diversity of *Thaumastocoris peregrinus* (Hemiptera: Thaumastocoridae) in South African and South American *Eucalyptus* plantations

Ryan L. Nadel[1], Bernard Slippers[1], Mary C. Scholes[2], Juan Pedro Bouvet[3], Michael J. Wingfield[1]

[1]Department of Genetics, Forestry and Agricultural Biotechnology Institute, University of Pretoria, Pretoria, Gauteng, South Africa, [2]School of Animal, Plant and Environmental Sciences, University of the Witwatersrand, Johannesburg, Gauteng, South Africa, [3]INTA-Estación Experimental Agropecuaria de Concordia, CC34, Sección Entomología, Entre Ríos, Argentina

Thaumastocoris peregrinus (Hemiptera: Thaumastocorisdae) is a *Euclayptus* pest recently introduced into South Africa and South America. It is a short-lived, gregarious, sap-sucking insect that cause leaf discoloration and defoliation of infested *Eucalyptus* trees. Intensive, countrywide surveys for *T. peregrinus* were conducted in South Africa, spanning several *Eucalyptus* species, hybrids and their clones, and various geological and climatic regions. The main species or hybrids found to be infested by the insect were *E. grandis* x *camaldulensis* and *E. grandis* x *urophylla* clones, although *E. camaldulensis, E. macarthurii, E. grandis, E. tereticornis* and *E. smithii* were also heavily infested. The distribution of *T. peregrinus* in South Africa had no obvious climatic or altitudinal limits. Analysis of mitochondrial cytochrome *c* oxidase I (CO I) DNA sequence diversity was used to characterise the population diversity and distribution of the pest in South Africa, Argentina and Uruguay. The results confirmed that it is the same species of the insect that occurs in South African and South American plantations. Three CO I haplotypes were found amongst *T. peregrinus* individuals from South Africa, Argentina and Uruguay. Two of these haplotypes were found in South Africa, one of which is widely distributed in individuals from both summer and winter rainfall areas. The other South African haplotype is dominant in a small area of the sub-tropical summer rainfall zone. The Argentinean and Uruguayan populations displayed a distinct haplotype. The data suggest that there have been two separate introductions of *T. peregrinus* into South Africa and that the insect in South America represents an introduction without any connection to South Africa. This relatively large number of separate introductions emphasises the ease with which the pest is able to move and it also suggests relatively ineffective quarantine measures in areas where it has appeared.

Association of fungus-growing termites (Isoptera: Macrotermitinae) with *Termitomyces* in Kenya

Zipporah B. Osiemo[1], Andreas Marten[1], Manfred Kaib[2], Linus M. Gitonga[3], Hamadi I. Boga[4], Roland Brandl[1]

[1]Department of Animal Ecology, University of Marburg, Marburg, Germany, [2]Department of Animal Physiology, University of Bayreuth, Bayreuth, Germany, [3]Department of Zoology, Jomo Kenyatta University of Agriculture & Technology, Nairobi, Kenya, [4]Department of Botany, Jomo Kenyatta University of Agriculture & Technology, Nairobi, Kenya

Fungus-growing termites of the subfamily Macrotermitinae are abundant in African and Asian tropics where they play a major role in the decomposition of plants. The obligate mutualism between fungi of the genus *Termitomyces* and termite species within the Macrotermitinae seems to be the result of a long co-evolutionary process, with a single phylogenetic origin in African tropical forests during the early Tertiary. However, there are still some uncertainties about the level of the host specifity in fungi (host genera *versus* host species). To address this question we sampled fungi within 40 colonies of termite species from four genera (*Macrotermes*, *Odontotermes, Pseudacanthotermes*) in humid to arid ecosystems across Kenya. We sequenced the nuclear ITS region and used these sequences as well as ITS sequences from African samples from Genbank to construct a phylogeny of the fungi applying parsimony as well as maximum likelihood methods.

ITS sequences formed several clusters with strong sequence divergence between clusters. Each cluster was exclusively associated with one host genus. Sequences of *Termitomyces* samples available in Genbank corroborate this pattern indicating specificity at the level of host genera. On the other hand, within the cluster associated with the host genus *Macrotermes*, strains occurred in several species indicating a low host specificity. Strains may occur across steep environmental gradients e.g. from Magadi to Thika. Therefore, the association of strains with several host species is not the result of an allopatric distribution of strains between climatic regions.

Impact of a formulation of *Beauveria bassiana* conidia on varroa mites and on honeybee colony health

William Meikle[1], Guy Mercadier[1], Vincent Girod[2], Niels Holst[3]

[1]European Biological Control Laboratory, Montferrier sur Lez, France, [2]Association de Développement Apicole pour les Professionnels – Languedoc Roussillon (ADAPRO-LR), Lattes, France, [3]Danish Institute of Agricultural Sciences, Slagelse, Denmark

Introduction: Varroa mites are among the most important bee pests worldwide, and they are usually controlled using chemical miticides or plant-based compounds. In an effort to develop a biological control program against varroa, strains of an entomopathogenic fungus, *Beauveria bassiana*, were isolated from varroa mites found in beehives in France and were tested in lab bioassays.

Methods: *B. bassiana* conidia were formulated with plant-based wax powder and used to treat hives in 4 field experiments. The main response variables measured over time were: 1) mite fall onto sticky boards; 2) infection rate of mites; and 3) number of fungal conidia per bee. Bee colony health was also monitored in terms of total colony weight, brood surface area, adult population weight and food reserves.

Results: Mite fall was significantly affected by fungal application, and repeated applications resulted in significantly lower mite fall among treated hives. All the mites collected immediately after application in treated hives were infected, and the proportion of infected mites declined thereafter, usually faster in the spring than in the fall. The number of conidia per bee declined rapidly from about 10^4 conidia per bee to fewer than 10 per bee in 7-14 days. No adverse effects were observed among the bee colonies

Conclusions: Progress has been made in developing a biopesticide against varroa mites. Issues remain concerning the most economically effective dosage, and the number and timing of applications. The role of *B. bassiana* in hive ecology is largely unknown.

An IGF-like peptide regulates adult development of the silkmoth, *Bombyx mori*

Naoki Okamoto[1], Naoki Yamanaka[2], Hiroshi Kataoka[2], Akira Mizoguchi[1]

[1]Nagoya University, Nagoya, Aichi, Japan, [2]The University of Tokyo, Kashiwa, Chiba, Japan

Introduction: Bombyxin is an insulin family peptide produced by the brain neurosecretory cells of the silkmoth *Bombyx mori*. Our recent analysis of bombyxin-immunoreactive materials in *Bombyx* hemolymph has revealed that a remarkably high amount of 8kDa-bombyxin-like peptide (8K-BLP) with a little larger size than bombyxin is present during pupa-adult development.

Methods: 8K-BLP was purified from the hemolymph of female developing adults by using anti-bombyxin-II antibody affinity chromatography, ion exchange HPLC and reversed phase-HPLC. The structure of the purified peptide was determined using a combination of MALDI-TOF MS, amino-acid sequencing and EST data base analysis. Spatial and temporal expression patterns of 8K-BLP mRNA and peptide were analyzed by quantitative RT-PCR, western blotting and immunocytochemistry. The function of 8K-BLP was investigated *in vitro*.

Results: 8K-BLP was a single-chain polypeptide belonging to the insulin family, indicating that 8K-BLP is structurally similar to insulin-like growth factors (IGFs) rather than insulin. Expression analysis showed that 8K-BLP is produced predominantly by the fat body during pupa-adult development. 8K-BLP secretion by the fat body was strongly stimulated by 20-hydroxyecdysone *in vitro*. When genital disks were cultured in the presence of 8K-BLP, they grew larger and their protein content became higher than the controls. 8K-BLP also promoted BrdU labelling of genital disks and other adult-specific tissues such as sperm ducts, flight-muscle anlagen and wing disks. Overall, these results strongly suggest that 8K-BLP is a *Bombyx* counterpart of vertebrate IGFs and serves as a potent growth factor to regulate adult development in *B. mori*.

Non-target effects of biological control – could there also be implications for agriculture?

Colleen Seymour, Ruan Veldtman

South African National Biodiversity Institute, Cape Town, South Africa

Introduction: Recently, there has been a call for the effectiveness of biological control to be viewed within the context of the ecological consequences of this strategy of controlling alien plants. We investigated whether or not the presence of a biological control agent of *Acacia saligna,* the gall-forming fungus, *Uromycladium tepperianum,* in the citrus-producing area of Citrusdal, South Africa, was providing alternative habitat for the crop pest *Cryptophlebia leucotreta* (False codling moth).

Methods: We established pheromone-baited traplines out into natural vegetation from the centre of 4 patches each of *A. saligna* only, *A. saligna* and orchard, and orchard only. We also collected 2500 cm^3 of gall created by *U. tepperianum* at each site, keeping these in a growing room for two months, to ascertain which invertebrates are using these galls.

Results: Three *C. leucotreta* were trapped in alien only sites, 151 in orchard sites, and 83 in alien and orchard sites. After two months, 90 *C. leucotreta* had emerged from galls collected from alien only sites, and 137 from orchard and alien sites.

Conclusions: Although traps should be able to attract moths over distances of up to 200m, our traps did not capture nearly as many moths as emerged from the relatively small amount of gall collected for the emergence study. That said, it is clear that *C. leucotreta* uses galls on alien plants as nursery sites, and this information could be used to encourage farmers to keep their lands free of *A. saligna,* to minimize refuges for this crop pest.

Effects of *Chilo partellus* Swinhoe (Lepidoptera: Crambidae) and *Sesamia calamistis* Hampson (Lepidoptera: Noctuidae) sublethally fed on Bt maize on the biology of *Cotesia flavipes* and *Cotesia sesamiae* Cameron (Hymenoptera: Braconidae)

Dennis Obonyo[1], Josephine Songa[2], Gabor Lovei[3], Florence Oyieke[1], Gideon Nyamasyo[1], Stephen Mugo[4]

[1]School of Biological Sciences, University of Nairobi, Nairobi, Kenya, [2]Biotechnology Centre, Kenya Agricultural Research Institute, Nairobi, Kenya, [3]Department of Integrated Pest Management, Faculty of Agricultural Sciences, University of Århus, Århus, Denmark, [4]International Maize and Wheat Improvement Centre, Nairobi, Kenya

Introduction: *Chilo partellus* and *Sesamia calamistis* are important maize stem borer species in Kenya. Transgenic maize transformed with delta-endotoxin genes from *Bacillus thuringiensis* (Bt maize) is being developed in Kenya for stem borer control. Two braconid parasitoids, *Cotesia sesamiae* and *Cotesia flavipes* are important natural enemies of lepidopteran larvae in Kenya, and the possible effects of Bt maize on these biological control agents have to be investigated. As a first step in the biosafety evaluation of this Bt maize, laboratory experiments were conducted to assess the potential effect of *C. partellus* and *S. calamistis* sublethally fed on Bt maize on the biology of the two parasitoids.

Methods: Fourth instar *C. partellus* and *S. calamistis* larvae were sublethally fed on Bt (and non Bt as control) maize and subsequently exposed to the parasitoids.

Results: There were no significant differences in host acceptance and host acceptance time by the parasitoids between Bt exposed and control larvae. Pre-cocoon and total development times were significantly longer for *C. flavipes* on Bt exposed *C. partellus*. Proportions of *C. flavipes* female progeny were significantly lower on Bt exposed *C. partellus* while sex ratio for *C. sesamiae* from *C. partellus* varied. The number of *C. sesamiae* cocoons, cocoon mass and progeny numbers were significantly higher on Bt exposed *S. calamistis*.

Conclusions: Response to Bt maize varied between host and parasitoid species and generalisation is not yet possible. Longer term studies are warranted to determine how Bt maize would affect host-parasitoid systems.

Ecophysiology of respiration in dung beetles – a comparative study

Frances Duncan

University of the Witwatersrand, Johannesburg, South Africa

Environmental aridity may be important in explaining the different respiratory strategies used by dung beetles. Previous research on dung beetles has found a general ecological pattern of changing discontinuous gas exchange patterns, from CFO (closed, flutter, open) cycles to CV (closed, ventilation) cycles in species from mesic to arid habitats. Dung beetles inhabiting the arid regions of South Africa are flightless. The fused elytra create a sealed air space called the subelytral cavity. The respiratory function of this cavity into which the posterior pair of metathoracic spiracles and six pairs of abdominal spiracles open is not completely understood. Previous work on the arid adapted flightless beetle, *Circellium bacchus* (Canthonini), showed that CO_2 is stored in the subelytral cavity and later released through the anterior mesothoracic spiracles which open to the exterior (Byrne & Duncan, 2003). The pattern of respiratory gas exchange, as well as the relative contribution of the spiracles to CO_2 release in four arid adapted dung beetles species (Scarabaeinae), was determined using flow-through respirometry for comparison. Carbon dioxide emission was measured from the mesothoracic spiracles and from around the elytral case. The results show that the emission varies from the subelytral cavity and can be altered by the beetles. Pressure changes within the subelytral cavity and tracheal system is specifically described for *C. bacchus* to explain the respiratory patterns observed.

Heteropteran juvenile hormone unveiled: a novel type of juvenile hormone identified in a stink bug, *Plautia crossota stali*

Toyomi Kotaki[1], Kanako Kaihara[2], Tetsuro Shinada[2], Yasufumi Ohfune[2], Hideharu Numata[2]

[1]National Institute of Agrobiological Sciences, Tsukuba, Ibaraki, Japan, [2]Osaka City University, Sumiyoshi, Osaka, Japan

Introduction: Heteropteran insects have been used as model animals for insect endocrinology since the pioneer work by Wigglesworth in 1930's. In a previous study, we reported the evidence for a novel juvenile hormone (JH) in a stink bug, *Plautia crossota stali*. However, the structure of JH of heteropterans has not been identified yet. The purpose of the present study is to elucidate its structure.

Methods: A combination of highly sensitive GC/MS analysis, bioassay-guided analysis, and synthetic methods involving combinatorial and asymmetric synthesis was adopted for structure determination.

Results: Hexane extracts of the incubation medium of the corpora allata (CA) from *P. c. stali* were subjected to GC/MS analysis to estimate the molecular formula. Based on the molecular formula, we constructed a molecular library of the JH candidates by the synthesis of all possible stereoisomers. Preliminary bioassay of the mixture of the library compounds exhibited potent inhibitory effects on the metamorphosis of nymphs. The compounds were then separated into >20 fractions by HPLC to identify the potent compound. NMR analysis of the potent compound provided a proposed structure of the JH that was found to be novel. The relative and absolute stereochemistry of the JH was determined by comparison of the GC/MS and biological profiles of the natural CA product with those of the optically active JHs prepared by the asymmetric synthesis.

Conclusion: The structure of JH in *P. c. stali* was unambiguously determined and found to be novel. Our discovery opens the new door to further progress in JH biochemistry.

The chrysomelid leaf beetle *Diabrotica virgifera virgifera* LeConte as an alien invasive maize pest in the Ticino canton, Southern Switzerland

Hans E. Hummel[1], Mario Bertossa[2]

[1]Justus-Liebig-University Giessen, Organic Agriculture, Giessen, Germany, [2]Swiss Federal Research Station Cadenazzo, Contone, Switzerland

Diabrotica virgifera virgifera (Coleoptera:Chrysomelidae), the western corn rootworm (WCR), is an immigrant from North America and one of the top ten global agricultural pest species. Within the last 15 years, WCR invaded Europe at a minimum of 3 focal points at Belgrade, Milan and Paris and is a severe threat to commercial maize production. The progress of WCR from Italy to North Central Europe via Switzerland has been under scrutiny and of major concern to European quarantine officers. Geographic concentration of transport routes along river valleys of Ticino and Misox necessitated careful observations of these routes by pheromone and kairomone monitoring traps. Experiences with WCR monitoring whose population dynamics are still incompletely understood, may be briefly summarized for 2005 to 2007:

1. WCR moves in south–north direction preferably along major freeways, railroads and associated trading centers for goods and services. 2. WCR densities further remote from these strategic thoroughfares are generally lower than those in their immediate vicinity. 3. WCR likes to hitchhike with *Homo sapiens* using his established traffic technologies, 4. Mandatory crop rotation in the canton Ticino slowed the previous spreading and densities of WCR significantly. After introduction of mandatory crop rotation in the canton Ticino, no further WCR infestations were detectable north of the main Alpine mountain chain during 2005 to 2007. 5.Traps in the side valley of Misox situated in the neighboring canton of Grisons (with delayed obligation for mandatory crop rotation) show a population increase, but WCR counts now stagnate at a higher level than in the canton Ticino. 6. Metcalf sticky traps baited with sex pheromones and kairomones as attractants are highly effective and early indicators of WCR populations. 7. Switzerland with its rigorous crop rotation program may serve as an example and a role model for prudent WCR pest management in the European context.

Movement strategies and plant structure: a modeling system for analyzing foraging insect development

Ezekiel Glaze[2], Jim Hanan[2], Stefan Maetschke[2], Marie-Louise Johnson[1], Bronwen Cribb[3], Lynda Perkins[1]

[1]University of Queensland - School of Integrative Biology, St. Lucia, Australia, [2]University of Queensland - Advanced Computational Modelling Centre, St. Lucia, Australia, [3]University of Queensland - Centre for Microscopy and Microanalysis, St. Lucia, Australia

Introduction: Insect foraging behavior is influenced by many factors. The influence of all factors on foraging, the distribution of damage, and caterpillar survival is difficult to quantify experimentally but can be addressed within a modeling framework. We use an agent-based modeling approach to compare 3 different movement "strategies". We explore the effect of explicit rules for caterpillar movement on caterpillar fitness using realistic 3D "virtual" plant structures with and without induced defenses.

Methods: The three movement strategies implemented in our study are: (1) Implicit - in which movement does not take plant geometry into account, (2) Random - a randomly moving animal constrained to a virtual plant, and (3) Realistic - as in (2) but with more realistic movement rules based on our observations of *Helicoverpa* caterpillars. Each movement strategy is simulated with and without plant induced defenses.

Results: We rank the scenarios (by total development) thus: 1 Implicit movement – no induced defenses 2 Realistic movement - no induced defenses 3 Implicit movement – with induced defenses 4 Random movement – no induced defenses 5 Realistic movement – with induced defenses 6 Random movement – with induced defenses

Conclusions: We show that restricting the insect's movement to plant structures has a marked effect on insect development. Virtual insects develop fastest when their movement simulation does not follow plant topology, as is sometimes done in simplified models. Insects restricted to plant topology develop more slowly but, of these, those with a realistic movement biased toward the top of the plant do better.

Insect pest management with 2-(4-Hydroxybenzyl)cycloalkanol derivatives: A 30-year story

Zdenek Wimmer[1], Martina Wimmerova[1], Ondrej Jurcek[1], Hana Svobodova[1], Blanka Bennettova[2], Ivan Hrdy[3], Jelena Kuldova[3], David Saman[3], Erkki Kolehmainen[4]

[1]Laboratory of Chemistry, Institute of Experimental Botany AS CR, Videnska 1083, 142 20 Prague 4, Czech Republic, [2]Institute of Entomology, Biology Centre AS CR, Branisovska 31, 370 05 Ceske Budejovice, Czech Republic, [3]Institute of Organic Chemistry and Biochemistry AS CR, Flemingovo namesti 2, 166 10 Prague 6, Czech Republic, [4]University of Jyväskylä, Department of Chemistry, Laboratory of Organic Chemistry, Survontie 9, 40500 Jyväskylä, Finland

Derivatives of 2-(4-hydroxybenzyl)cycloalkanols were designed in late 1970's. Since that time, numbers of compounds have been synthesized and tested as insect juvenile hormone bioanalogs (JHAs). Considering a novel way to implement their practical application, we have elaborated the idea of juvenogens (hormonogenic substances) as novel types of insect pest management agents. Juvenogens are biochemically targeted complex substances, which usually display low biological activity upon topical application, and may be activated either through *in vivo* biochemical pathways (enzymatic system of living organisms) or through the environmental conditions (humidity, acidity, UV light *etc.*). They can be synthesized as targeted structures depending on knowledge of the enzymic system of the target insect pests and/or their host plants. These compounds may be more convenient for external application against insects, but not persisting in the environment and displaying as low as possible environmental and/or health risk. In our team, designing and developing new structures has been performed by application of a number of chemoenzymic approaches to get mainly enantiopure compounds available. Subsequent investigation of the structure-activity relationship, and the studies in metabolomics of these compounds followed to get knowledge on potential ecotoxicity of the applied compounds and their metabolites.

However, the future of the insect pest management should be based on the principles of biology-oriented synthesis. An efficient combination of biology-derived compounds with naturally occurring insect pest control agents (mostly plant defense compounds) may result in designing biochemically targeted and species specific substances. Attention will be paid to supramolecular structures based on natural steroid molecules.

The establishment of *Cotesia flavipes* (Hymenoptera: Braconidae) in sugarcane fields of Ethiopia and the origin of the founding population

Yoseph Assefa[1], Andrew Mitchell[2], Desmond Conlong[3], Katherine Muirhead[4]

[1]School of Biological and Conservation Sciences, University of KwaZulu-Natal, Private Bag X01, Pietermaritzburg, Scottsville, 3209, South Africa, [2]Wagga Wagga Agricultural Institute, NSW Department of Primary Industries,, PMB Wagga Wagga, NSW 2650, Australia, [3]South African Sugarcane Research Institute, Private Bag X02, Mount Edgecombe, 4300, South Africa, [4]Centre for Evolutionary Biology & Biodiversity, School of Earth & Environmental Science DP 418, The University of Adelaide, SA 5005, Australia

Introduction: *Cotesia flavipes* Cameron (Hymenoptera: Braconidae) is used as a classical biological control agent against *Chilo partellus* Swinhoe (Lepidoptera: Crambidae). This parasitoid has been introduced into several African countries for the control of *C. partellus* in maize and sorghum, but has never been released in Ethiopia. In recent surveys conducted in Ethiopia, *C. flavipes* was recovered from *C. partellus* in sugarcane at a site more than 2000 km from the nearest known release sites in Kenya and Somalia. These findings question published hypotheses which estimate the dispersal rate of *C. flavipes* to be 60 km per year in Africa, and suggest that since its release in Africa this parasitoid has developed strains adapted to searching particular host plants infested by particular stem borers. The anomalies between our results and previous reports evoked the hypothesis that *C. flavipes* in Ethiopian sugarcane might be a different strain.

Methods: COI gene sequences of *C. flavipes* collected from sugarcane in Ethiopia, from maize in other African countries and different host insect/plants in other continents to determine the origin of the Ethiopian population.

Results: *Cotesia flavipes* population established in Ethiopian sugarcane is most closely related to the populations released against *C. partellus* in maize in other parts of Africa, which were derived from the original population imported from Pakistan.

Conclusions: Maize/sorghum strains of *C. flavipes* can colonize sugarcane fields at least under Ethiopian cropping systems. The dispersal rate of the parasitoid was estimated to be more than 200 km per year.

The importance of floral scent in the evolutionary shift from bird to beetle pollination in *Protea*

Sandy-Lynn Steenhuisen[1], Steven D. Johnson[1], Robert A. Raguso[2]

[1]School of Biological and Conservation Sciences, University of KwaZulu-Natal, Pietermaritzburg, KwaZulu-Natal, South Africa, [2]Department of Neurobiology and Behavior, Cornell University, Ithaca, New York, United States

Introduction: The majority of *Protea* species in South Africa occur in winter rainfall regions, and are pollinated by birds. They produce large, colourful and unscented inflorescences visited by sunbirds and sugarbirds that feed on copious amounts of nectar, accessed by their long bills. Rodent pollination systems have been investigated in a few geoflorous species that produce yeasty scented inflorescences. In contrast, the role of insects as pollinators in this genus has been controversial. In this study, we present evidence that four *Protea* species in the summer rainfall regions of South Africa employ an insect pollination system. These species produce open bowl-shaped, colourful and fruity scented inflorescences, most frequently visited by cetoniine beetles exploiting accessible nectar and pollen rewards.

Methods: We analysed the volatile components of the scent of these species using GC-MS, the source of scent production from dissected inflorescences, ontogeny of scent production in the field, and the change in scent of the inflorescences from microbial fermentation of the nectar. In addition we analysed GC-EAD responses of the most common beetle visitor, *Atrichelaphinis tigrina,* to whole flower scents and selected volatiles.

Results: Choice tests confirmed that *A. tigrina* shows a significant preference for the fruity scent of the flowers. The monoterpene linalool, a known attractant of cetoniine beetles, comprised more than 40% of all scent samples.

Conclusions: We suggest that the evolution of a fruity scent has accompanied the shift from an ancestral bird pollination system to a cetoniine beetle pollination system in this clade.

Invasions by *Bactrocera* spp.: Its implication on horticulture in Africa

Maulid Mwatawala[1], Amon Maerere[1], Marc De Meyer[2]

[1]Sokoine University of Agriculture, Morogoro, United Republic of Tanzania, [2]Royal Museum for Central Africa, Tervuren, Belgium

Two Asian *Bactrocera* species, *Bactrocera latifrons* (Hendel) and *Bactrocera invadens* Drew White and Tsuruta have been reported from Africa in 2004 and 2007 respectively. These two add to the earlier introduced *Bactrocera cucurbitae* (Coquillet) and *Bactrocera zonata* (Saunders). *B. invadens* and *B. cucurbitae* are widely distributed throughout the continent. *B. zonata* has been reported from Indian Ocean islands and Egypt, while the African distribution of *B. latifrons* is still unclear but so far only known from Tanzania and Kenya. The impact of these pests is hereby examined based on the fact that introduced *Bactrocera* species are known to cause heavy losses in the fruits they attack, they are quick to establish themselves and become numerically dominant and in some cases they have been shown to competitively displace the pre-established species from their fundamental niches. Additionally, these pests are of quarantine importance since the presence of larvae in fruit shipments could lead to rejection of consignment and loss of international markets. Most countries will have to design viable management programs in order to meet export standards of importing countries, whereas the countries that have not recorded these pests need to have strong quarantine measures to avoid introduction of these pests and subsequent loss of markets. Experiences, challenges and limitations in achieving these are the main focus of this paper. Specific references will be given on the detection surveys and host range studies of *B. latifrons* in Tanzania.

Ambrosia beetles as affected by environmental factors: Are these phenomena changes or just new findings?

Naoto Kamata[1], Jean-Claude Gregoire[2]

[1]University of Tokyo, Bunkyo, Tokyo 113-8657, Japan, [2]Free University of Brussels, 50 avenue F.D. Roosevelt,B-1050 Brussels, Belgium

Ambrosia beetles are generally recognized as insects that infest weakened, dying, or dead trees, and logs. A few species were known to attack healthy living trees. However, recently reports on ambrosia beetles that infest apparently healthy living trees have been increasing as follows: *Platypus quercivorus* and *P. koryoensis* both accompanied with fungi that kills oak trees in Japan and Korea, respectively. *Platypus mutatus* attacking poplar trees in Argentina and Italy. *Trypodendron domesticum*, *T. signatum*, *Xyleborus dispar* and *Xylosandrus germanus* attacking beech trees in Europe. We would like introduce several examples of ambrosia beetles infesting healthy living trees from all over the world. Ecological and evolutionary aspects of this increase will be discussed in relation to environmental changes and globalization.

Mechanism of multiple functional coupling of a *Bombyx mori* octopamine receptor

Yoshihisa Ozoe, Jia Huang

Shimane University, Matsue, Japan

Introduction: The phenolic biogenic amine octopamine (OA) is derived from tyrosine and is widely distributed in the insect nervous system and peripheral tissues. OA regulates or modulates various physiological processes of insects as a neurotransmitter, neuromodulator, or neurohormone. OA receptors (OARs) belong to the rhodopsin-like family of G protein-coupled receptors. We cloned a cDNA encoding an OAR from the silkworm *Bombyx mori* (BmOAR1) and heterologously expressed it to examine its functional and pharmacological properties.

Methods: The cDNA was prepared using mRNA from the brain and ganglia of *B. mori*, and the wild type and variants of BmOAR1 were stably expressed in HEK-293 cells. Five variants of BmOAR1 with mutation(s) in the putative OA binding site (a crevice formed by transmembrane domain (TM) 3, 5, and 6) were generated by site-directed mutagenesis. The expressed receptors were examined for their ability to change intracellular Ca^{2+} and cAMP levels as well as that to bind [^{3}H]OA.

Results: BmOAR1 was identified as an α-adrenergic-like OAR, which was linked to OA-stimulated elevation of Ca^{2+} and cAMP levels. The S202A (TM5) mutant increased cAMP levels in response to OA as did the wild type, but such a function was abolished in the D103A (TM3), S198A (TM5), and S198A/S202A mutants. Significant [^{3}H]OA binding and OA-induced Ca^{2+} mobilization were also not observed in the case of D103A, S198A, and S198A/S202A mutants, whereas the S202A mutant retained both functions. These findings indicate that D103 and S198 are involved in both G_s- and G_q-protein couplings of BmOAR1 through electrostatic and hydrogen bond interactions with OA, but that S202 does not participate in these processes. In contrast, the Y412F (TM6) mutation eliminated the cAMP response to OA, but was without effect on the Ca^{2+} response and [^{3}H]OA binding. This finding suggests that Y412 is an amino acid residue necessary for G_s-protein coupling, which leads to cAMP production, but not for G_q-protein coupling.

Conclusions: The results lead to the proposal that BmOAR1 exists in three major conformations, and that Y412 plays a key role in transition from a semi-active conformation that favors G_q protein to a fully active one that favors both G_q and G_s proteins.

Can botanical pesticides be used safely and reliably in stored product protection?

Steven Belmain[1], Phillip Stevenson[1], Monique Simmonds[2], Brighton Mvumi[3], Gudeta Sileshi[4], Phosiso Sola[5], Stephen Nyirenda[6], John Kamanula[7], David Hall[1]

[1]Natural Resources Institute, University of Greenwich, Central Avenue, Chatham Maritime, Kent ME4 4TB, United Kingdom, [2]Jodrell Laboratory, Royal Botanic Gardens, Kew, Richmond, Surrey TW9 3AB, United Kingdom, [3]Department of Soil Science & Agricultural Engineering, Faculty of Agriculture, University of Zimbabwe, P. O. Box MP167, Mt Pleasant, Harare, Zimbabwe, [4]World Agroforestry Centre (ICRAF), SADC-ICRAF Agroforestry Program, P.O. Box 30798, Lilongwe, Malawi, [5]Southern Alliance for Indigenous Resources, P.O. Box BE 398 Belvedere, Harare, Zimbabwe, [6]Department of Agricultural Research Services, Lunyangwa Research Station, P.O. Box 59, Mzuzu, Malawi, [7]Mzuzu University, P/Bag 201 Luwinga, Mzuzu, Malawi

Introduction: Poor farmers continue to use pesticidal plants to protect stored grain from insect pests. However, there can be problems associated with their use. Although natural, botanical pesticides are potentially toxic with compounds such as rotenone (classified by the World Health Organisation as a moderately hazardous, Class II) present in many plants currently promoted for stored product protection. Reliability of control is affected through the temporal and spatial variability of bioactive constituents produced by plants as well as poorly understood modes of action such as repellency that may differentially affect different insect species. Despite a growing number of publications on pesticidal plants, key questions on reliability, ecological sustainability and safety remain unanswered. A better understanding on the ecology of pesticidal plants and their interactions with stored product insects will help to optimise their sustainable use by poor farming communities.

Methods: The SAPP[1] research project takes a multi-dimensional approach to optimise the use of pesticidal plants by increasing scientific research on the knowledge gaps and constraints that currently limit their safe and reliable use. Research activities relate to phytochemical characterisation, vertebrate toxicity trials, sustainable harvesting and cultivation, mode of action and bioactivity trials, on-farm trials in poor farming communities and exploration of indigenous knowledge.

Results: Some well known pesticidal plants used commonly in Africa may be inactive against many target insect species. This may be explained by phytochemical analysis which has shown that some of these species, e.g. *Tephrosia vogelii*, do not contain the expected bioactive compounds. Insect behavioural bioassays assessing pesticidal plants for repellent properties indicate that repellency is modulated by the host orientation/finding strategies adopted by different insect species, e.g. *Sitophilus zeamais* is susceptible to repellents whereas *Rhyzopertha dominica* is not.

Conclusions: Promoting pesticidal plants without sufficient knowledge on their efficacy and safety can be dangerous for human health and lead to unpredictable levels of pest control which may diminish confidence in their use.

Biological control-based IPM for citrus in Japan

Masami Takagi

Kyushu University, Fukuoka, Japan

We had no serious citrus pest in Japan before 1900s because the international trade was not very much carried out before 1858. All most of the serious citrus pests were introduced into Japan after that. Classical biological control was very effective against those adventive pests, which are well controlled by introduced natural enemies now. The first attempt of introduction of forging natural enemies into Japan to control citrus pests was that of the vedalia beetle to the cottony cushion scale in 1911. This attempt was very successful like as the cases of many other countries. The second successful case was biological control of the red wax scale, *Ceroplastes rubens* by *Anicetus beneficus*. The last successful classical biological control was that of the arrowhead scale, *Unaspisi yanonensis* by two parasitoids, *Aphytis yanonensis* and *Coccobius fulvus*, introduced from China. The arrowhead scale was the most serious citrus pest in Japan before the introduction of these two parasitoids. All the classical biological control of these pests was very successful and they are no more serious scale pests in Japan. Although we have many native species of scale insects which infest citrus trees, native natural enemies control those pests at noneconomic level. At present several mites such as the citrus red mite and the pink citrus rust mite were the most important pests. Serious outbreak of the citrus red mite is induced usually by pesticide spray for control other pests and diseases which destroy natural enemies of citrus red mite. So conservation of natural enemies is very important for IPM of these pests.

Natural enemies of *Plodia interpunctella* and *Ephestia* spp. in cereal and dried fruit facilities

Consuelo Belda, Maria José Pons, Rosa Gabarra, Jordi Riudavets

IRTA Plant Protection, ctra Cabrils Km2, Cabrils, Barcelona, Spain

Biological control could be an important tool for pest control of Lepidoptera on stored cereals and dried fruits. Population dynamics of Lepidoptera with pheromone traps and their natural enemies with yellow sticky traps and light traps was assessed during one year on six food facilities. Monthly samples of the different products were also taken randomly. Depending on the companies, *Plodia interpunctella*, *Ephestia* spp. or a mix of both species were found. Pest population occurred all year around, but was more abundant from April to September. Regarding natural enemies, Lepidoptera parasitoids *Venturia canescens* and *Habrobracon* spp. were the main species trapped both with yellow sticky traps and light traps. Both parasitoid species were found in all facilities, regardless the pressure of chemical treatments. Mean number of adult parasitoids trapped reached a maximum of 137 individuals per light trap and 64 per yellow sticky trap. Parasitoid individuals were captured in every sampling date, with higher populations in summer till early autumn. The high number of natural enemies seems to indicate that natural biological control can be a complementary tool to be considered for Lepidoptera pest control in stored cereals and dried fruits facilities.

A multi-vector potential for transmitting African horse sickness virus (AHSV) in South Africa

Gert J Venter[1], Isabel M Wright[1], Theuns C Van der Linde[2], Janusz T Paweska[3]

[1]ARC-Onderstepoort Veterinary Institute, Onderstepoort, South Africa, [2]University of the Free State, Bloemfontein, South Africa, [3]National Institute for Communicable Diseases, Sandringham, South Africa

Introduction: During the last decade outbreaks of African horse sickness (AHS), caused by AHS virus (AHSV) (*Orbivirus*, *Reoviridae*), have increased dramatically in South Africa. The virus is transmitted between its equid hosts almost exclusively by the bites of certain species of *Culicoides* (Diptera, Ceratopogonidae). The availability of competent vectors is an important factor determining the occurrence and spread of AHSV. Of the approximately 120 *Culicoides* species in South Africa only *C. imicola* is a confirmed vector. The aim of this study was to determine which of the other *Culicoides* species, found near horses, are susceptible to infection and may therefore be potential vectors.

Methods: Field collected midges from three distinct geographical localities in South Africa were fed on sheep blood spiked with different isolates of one of the nine serotype of AHSV. After 10 days incubation at 23.5°C females were assayed individually on BHK-21 cells following a micro titration procedure.

Results: Oral susceptibility was found to differ significantly between various *Culicoides* species/ populations and different virus isolates. AHSV could replicate in eleven *Culicoides* species belonging to at least six subgenera. These *Culicoides* species are relative widespread in South Africa and in some the infection rate was significantly higher than that found in the confirmed vector *C. imicola.*

Conclusion: Our results indicate that oral susceptibility to infection with AHSV, however it is restricted to certain species, and is widespread in the genus *Culicoides*, thereby implying a multi-vector potential for its transmission in South Africa.

An awkward age for butterflies: when did Nymphalidae (Lepidoptera) diverge and diversify?

Niklas Wahlberg[1], Julien Leneveu[1], Carlos Peña[2], Ullasa Kodandaramaiah[2], Sören Nylin[2], André Freitas[3], Andrew Brower[4]

[1]Department of Biology, University of Turku, Turku, Finland, [2]Department of Zoology, Stockholm University, Stockholm, Sweden, [3]Instituto de Biologia, Universidade Estadual de Campinas, Campinas, São Paulo, Brazil, [4]Dept. of Biology, Middle Tennessee State University, Murfreesboro, TN, United States

Introduction: The phylogenetics of the species-rich butterfly family Nymphalidae has been under close scrutiny for the past 10 years. The major lineages and their relationships are now quite clear and the time has come to infer the basic components of the evolutionary history of the family. Here we investigate the times of divergence of the major lineages.

Methods: A dataset composed of 236 morphological characters and DNA sequences from 10 gene regions (7747 bp) was analysed for 429 taxa (399 genera out of 540, plus outgroups). A relaxed molecular clock was used to infer times of divergences.

Results: Phylogenetic relationships of the major lineages were nearly identical to previous analyses of smaller datasets. Libytheinae was sister to the rest of Nymphalidae, with Danainae being next, then the satyrine clade and finally the heliconiine and nymphaline clades were sister to each other. Nymphalidae began diversifying between 100 and 90 million years ago. Apparently 12 lineages survived the K/T-event 65 million years ago and soon after diversified into the currently accepted subfamilies. The bulk of Satyrinae, the most diverse subfamily with close to 2000 species, diversified around 30 to 25 million years ago, coinciding with a general cooling of the Earth and the spread of grasslands.

Conclusions: Nymphalidae is older than previous speculations about the age of butterflies, in agreement with several recent studies on smaller groups of butterflies. The temporal scale that is now available for Nymphalidae will allow more detailed studies of the evolutionary history of the many model systems being studied, such as *Bicyclus*, *Heliconius* and *Melitaea*.

Population dynamics and within plant distribution of *Megalurothrips sjostedti* and *Frankliniella occidentalis* (Thysanoptera: Thripidae) in a French bean agroecosystem

Linus Gitonga, Bernhard Lohr

Jomo Kenyatta University of Agriculture and Technology, Nairobi, Kenya

Introduction: The temporal, spatial and within plant distribution patterns of *Megalurothrips sjostedti* Trybom and *Frankliniella occidentalis* Pergande on French beans was determined so as to come up with appropriate sampling methods through development of constant precision sequential sampling plans.

Methods: Fieldwork was carried out at three localities. French beans were sown on a monthly basis at each location. Beans parts, namely leaves, flower buds, flowers and bean pods were sampled twice a week and thrips larvae and adults extracted and enumerated. Spatial distribution of larvae and adult thrips was assessed using Taylor's power law, whose constants were used to develop constant-precision level sampling plans.

Results: Both larvae and adult thrips were present in the crop all year round, with population peaks for both species occurring at different times of the year. *Megalurothrips sjostedti* peaked during the period following the rains and in the absence of *F. occidentalis*. The latter peaked during the hot and dry months of the year. There was clear displacement of *M. sjostedti* by *F. occidentalis* in the crop during the hot and dry months of the year and in the hot and drier parts of French bean growing. Both larvae and adults were aggregated, but higher aggregation was observed for larvae than adult thrips in the flowers.

Conclusions: These findings on alternation of occurrence, displacement, habitat partitioning and sampling have implications on thrips control in the context of IPM. *Megaluthrips sjostedti* and *F. occidentalis* have well defined preferred oviposition sites.

Insecticide resistance frequencies in *Bemisia tabaci* in Omani and UAE vegetable farms

Farid Talukder[1], Walid Kaakeh[2], Michael Deadman[1], Jaber Al-Dahmani[2]

[1]Sultan Qaboos University, Al-Khod, Muscat, Oman, [2]UAE University, Al-Ain, Abu Dhabi, United Arab Emirates

The frequency of insecticide resistance in different populations of sweet potato whitefly (*Bemisia tabaci*) were investigated in 40 different vegetables growing farms in the Al-Batinah, Oman and Al -Ain, U.A.E. areas through a joint research program. Field populations of whiteflies were collected, preserved and analyzed through the *in-vitro* insecticide resistance assays. Results showed that enzyme inhibition rates (IR) varied from 35% to 52% in case of different Omani whitefly populations, and from 46% to 74% in case of different UAE populations. When the IR values in different insecticides were compared, the different degrees of insecticide resistance were found in both Omani and UAE insect populations.

A review of the Palaearctic genus *Apodiphus* Spinola (Heteroptera: Pentatomidae: Halyini) and a key to its world known species

Dr. Nasreen Memon, Dr. Imtiaz Ahmed

University of Sindh,, Jamshoro, Pakistan

Introduction: The genus *Apodiphus* Spinola is widely distributed from Eastern Europe – Asia and more than 100 years have been passed, since the 1st description of the genus was made. But only 10 species are described to date. Before Ghauri (1977) most of the literature consists of isolated description, fauna or catalogue. Here we have described and illustrated the new species with allied species and presented a key of 11 world known species and discuss their phylogenetic relationship.

Method: We have examined the external morphology and male and female genitalia of specimen under the dissecting compound microscope. Male and female genitalia were dissected and boiled in Potassium Hydro Oxide (KOH) for 20-30 minutes, examined and the drawings were made on graph paper by using ocular graph.

Results: Our study reveals that our new species *A. iraqiensis* is a new record of the genus from Iraq, although most of its species have been recorded from its neighbouring countries. Within the genus this is the only species that has very indistinct basal angular spots, lateral margins of head much curved upwardly and ventro posterior margin of pygophore with deep v-shaped cavity. This particular combination of character states indicates that these states are autapomorphic.

Conclusion: Here we have described the new species *A. iraqiensis* sp. n. particularly on the basis of male genitalia and discuss its phylogenic relationship within the genus, and presented a key of 11 species.

Action spectrum for the suppression of arylalkylamine *N*-acetyltransferase activity in the two-spotted spider mite *Tetranychus urticae*

Takeshi Suzuki, Makio Takeda

Kobe University, Kobe, Japan

An action spectrum was obtained for the suppression of arylalkylamine *N*-acetyltransferase (NAT) activity in the two-spotted spider mite *Tetranychus urticae* by irradiating the mite with monochromatic lights of various wavelengths using the Okazaki Large Spectrograph at the National Institute for Basic Biology, Okazaki, Japan. Fluence-response curves were obtained for wavelengths between 300 and 650 nm by irradiating the mite for 4 h d^{-1}. The samples were frozen after the third exposure. A negative correlation between the fluence rate and NAT activity was detected in the range of 0.01–1 μmol m^{-2} s^{-1} for wavelengths between 300 and 500 nm and in the range of 0.1–10 μmol m^{-2} s^{-1} for wavelengths between 550 and 650 nm. The constructed action spectrum indicated that the photoreceptors mediating the circadian and/or photoperiodic systems might be ultraviolet (UV)-A- and blue-type photoreceptors with absorption peaks at 350 and 450 nm.

Host location by the braconid paraisitoid *Cotesia flavipes* and suitability of 'wild' and 'cultivated' stemborer species

Meshack Obonyo, Paul-André Calatayud, Johnnie van den Berg

North-West University, Potchefstroom, South Africa

Intoduction: Maize fields in Africa are usually surrounded by land occupied by wild plants many of which harbor lepidopteran stemborer species not found on crops. It is not known if the exotic braconid parasitoid *Cotesia flavipes*, which was released in Kenya in 1993 against the invasive crambid stemborer *Chilo partellus* (the economically most important pest of maize and sorghum in the lowlands of East and Southern Africa) searches for and attacks these borers in their natural habitats and whether they are suitable for parasitoid development.

Methods: The objective of this study was to assess the relationship between acceptance and suitability of six stemborer species attacking cultivated sorghum (*C. partellus, Busseola fusca, Sesamia calamistis, and S. nonagrioides*) or Napier grass (*Busseola phaia* and *Sciomesa piscator*) to *C. flavipes*.

Results: Although all stemborer species were equally accepted for ovipositor probing by *C. flavipes*, only *C. partellus* and *S. calamistis* were suitable and produced parasitoids. In olfactometric bioassays, *C. flavipes* females were more attracted to stemborer-infested than uninfested plants. Analyses of the volatile compounds showed that they produced richer volatile profiles, mainly comprising C5–C6 alcohols, terpenoids, aromatic and aliphatic compounds, than uninfested plants.

Conclusion: It can be concluded that stemborer species, that were accepted for oviposition but were unsuitable for parasitoid development, form a reproductive sink and that the exotic parasitoid would not establish in areas where these are the predominant species.

Climate change and new cultural practices affect incidence and management of sugar cane pests in Mauritius

Seelavarn Ganeshan

Mauritius Sugar Industry Research Institute, Reduit, Mauritius

Management of sugar cane pests in Mauritius relies essentially on biological control and cultural practices, the latter not generally being antagonistic to the former. Insecticides have never been applied on a routine basis or on a large scale for the control of sugar cane pests. To reduce production costs, the Mauritian sugar industry is currently undergoing major changes, such as removal of rock heaps, mechanization and improved irrigation systems. These changes necessitate increasing the size of fields. Also, the scarcity of labour has led to abandoning certain traditional practices like trashing. With mechanization of cane harvest, the dry cane leaves and /or plant residues, which were previously raked and aligned in every alternate interrow, are now being left *in situ* (trash blanketing) in the field. Localised but severe infestations by several pests have as a result occurred recently. For example armyworm *Mythimna* spp. (Lepidoptera: Noctuidae) infestations have been found in machine-harvested fields, while the white borer *Tetramoera schistaceana* Snellen (Lepidoptera: Eucosmidae) and the maize webworm *Angustalius malacellus* (Dup.) (Lepidoptera: Crambidae) have been associated with the presence of weeds, the soft scale *Pulvinaria iceryi* Signoret (Homoptera: Coccidae) is attributed to loss of habitat of natural enemies by removal of natural vegetation in and around sugar cane areas. Prolonged drought periods and lower rainfall have increased the incidence of the armoured scale the *Aulacaspis tegalensis* Zehntner (Homoptera: Diaspididae), thrips *Fulmekiola serrata* (Kobus) (Thysanoptera: Thripidae) and white flies *Neomaskellia bergii* (Homoptera: Aleyrodidae).

The potential of crop borders to reduce incidence of aphid-transmitted *Potato Virus Y*

Michelle L. Fourie, Kerstin Krüger

Department of Zoology and Entomology, University of Pretoria, Pretoria, South Africa

Introduction: Potato Virus Y (PVY), one of the most important viruses of potato, is transmitted to new crops via seed tubers or non-persistently through aphid species. The control of the spread of PVY relies largely on measures that incorporate biological traits of aphid vectors (e.g. flight behaviour) and virus transmission characteristics. PVY incidence can be reduced by aphid vectors' losing the ability to transmit PVY when feeding on a non-virus host before moving into the field proper. Four crops were evaluated as potential border plants by determining host-plant preference of aphids in a semi-field trial.

Methods: Five crops (lucerne, maize, potato, soybean, and wheat,) were planted in a randomized block design. Aphids were sampled using different methods (leaf counts, sweep-netting, and green bucket traps to determine landing rates) in order to avoid sampling bias caused by any specific method.

Results: Based on leaf counts, the highest number of aphids was recorded on maize, whereas lucerne had the highest aphid numbers using sweep net samples. Potato had more species in common with maize and wheat than with lucerne or soybean. Further, the landing patterns of alate aphids in the trial plots were not random but showed a clear preference for specific crops. Although aphid species differentiated between crops when landing, there was no relationship between aphid abundance in the green bucket traps and leaf counts.

Conclusions: Maize and wheat showed the greatest potential as a border crop, based on aphid abundance and species composition

The effect of semiochemicals and aphid resistant cultivars on Russian wheat aphid control.

Goddy Prinsloo[1], Velemir Ninkovic[2], Theuns Van der Linde[3], Amie Van der Westhuisen[4], Robert Glinwood[2]

[1]ARC-Small Grain Institute, Bethlehem, South Africa, [2]Department of Ecology,Swedish University of Agricultural Sciences, Uppsala, Sweden, [3]Department of Zoology and Entomology, University of the Free State, Bloemfontein, South Africa, [4]Department of Plant Sciences, University of the Free State, Bloemfontein, South Africa

Introduction: Behaviour modifying semiochemicals are known to have repellent properties to the grain aphids *Rhopalosiphum padi* and *Sitobion avenae* in Sweden. Possible repellency by these semiochemicals to Russian wheat aphid (*Diuraphis noxia*) was investigated under dryland production conditions in South Africa during a collaborative project between the two countries.

Methods: During the study, olfactometer tests with methyl salicylate and other chemicals from plant essential oils were conducted for *D. noxia* behavioural activity. The semiochemicals were also tested for effects on *D. noxia* population development in field trials in 2004 and 2005 using a *D. noxia* resistant cultivar (Elands) and a susceptible cultivar (Betta). Methyl salicylate was compared with a commercial produced formulation Nocoron which is a slow releasing wax pellet formulation consisting out of three different volatile substances.

Results: Methyl salicylate and Nocoron repelled *D. noxia* significantly during olfactometer tests. *D. noxia* settled less on Elands plants that had been exposed to volatiles, whereas the effect on *D. noxia* settling on Betta was less obvious. In 2004, semiochemicals reduced aphid populations in Elands, but led to increased aphid populations in Betta. Further, the impact of the chemicals on aphid numbers and grain quality varied according to plant variety indicating an interaction between semiochemicals and aphid resistant plant varieties.

Conclusion: The results suggest that differential effects of semiochemicals on insect populations in resistant and susceptible plant varieties can occur, possibly due to complex interactions between the chemical, plant variety and growing environment.

Balancing benefits and risks of biological control

Franz Bigler[1], Dirk Babendreier[2]

[1]Agroscope ART, Zurich, Switzerland, [2]CABI Bioscience, Delémont, Switzerland

Risks of environmental effects from releasing exotic biological control organisms is of increasing concern, and regulatory authorities have taken a more risk-averse attitude for biological control during the last years. Awareness of risks related to biological control has attained a disproportionate attention by governments and sometimes by the public. A more balanced discussion of risks has to take into account the benefits of biological control and the risks of not applying biological control organisms. However, risk-cost-benefit assessment of a biological control agent is a complex task given that it should take into account expected risks, costs and benefits of economic values, human health, and the environment. Environmental impacts can usually not be valued in absolute monetary terms, therefore they are analysed in a qualitative manner. Proposed procedures for environmental risk-benefit assessment consist of identifying, analysing, and evaluating (weighing-up) risks and benefits of monetary and non-monetary values. Procedures that are ranking risks and benefits separately in decreasing order of significance are discussed and examples are given. Even though adverse effects of biological control agents are mostly limited to effects on non-target arthropods, uncertainties about potential long-term and area-wide impacts greatly complicate risk-benefit assessments. Examples demonstrate that the benefits of replacing insecticides by releasing biological control agents outweigh the environmental risks posed by such organisms.

Malaria vector control: Dealing with non-vector species

Richard Hunt[1], Belinda Spillings[2], Lizette Koekemoer[2], Basil Brooke[2], Christophe Kinkanke[2], Maureen Coetzee[3]

[1]School of Animal, Plant & Environmental Sciences, University of the Witwatersrand, Johannesburg, South Africa, [2]Vector Control Reference Unit, National Institute for Communicable Diseases, NHLS; Division of Virology & Communicable Disease Surveillance, School of Pathology of the University of the Witwatersrand, Johannesburg, South Africa, [3]NRF Chair in Medical Entomology & Vector Control, School of Pathology, University of the Witwatersrand, Johannesburg, South Africa

Introduction: There has always been the general assumption that mosquitoes found resting inside houses have fed on the residents and are responsible for any malaria transmission taking place. Before the recognition of the *Anopheles gambiae* complex, there was no reason to doubt this assumption. However, with modern methods for identification of groups or complexes of anophelines, it has become increasingly common for species resting inside houses to be identified as non-vectors. This presentation details recent work carried out in Malawi where modern technology failed to provide an adequate identification of what looked like *Anopheles funestus.*

Methods: Mosquitoes were collected resting inside houses near Karonga, northern Malawi, and returned to the laboratories at the NICD in Johannesburg. Wild females were set up for egg-laying and each egg batch was treated as an individual family. Morphological, cytogenetic, cross-mating and molecular studies were carried out on all samples.

Results: Preliminary morphological studies showed the presence of distinct pale bands at the joints of tarsomeres 1-3, unlike *An. funestus*. All other morphological characteristics were as in the *An. funestus* subgroup. The larvae reared under standard insectary conditions showed a distinct reddish coloration compared with the normally dark grey larvae of *An. funestus*, but with no other morphological differences. None of the 84 wild-caught females were found infected with malaria parasites. Chromosomal banding patterns of the X chromosome were homosequential with *An. funestus*, but a unique polymorphic inversion was seen on autosome arm 2. The population appears to be homozygous for inverted arrangements 3a, 3b and 5a. Cross-mating produced hybrid males from the cross between Malawi females and funestus colony males. The hybrid testes and spermatozoa were apparently normal. The reciprocal cross produced >900 eggs but very few hatched (0.22% - two females). Sequencing of a 740bp fragment of the ITS2 region showed a 4.5% (33/740bp) difference between the field caught samples compared with the laboratory strain of *An. funestus*. Four basepair changes (4/20bp) in the species-specific primer binding site for the *funestus* group PCR identification were seen in the field caught samples which explains why amplification failed.

Conclusions: This population of mosquitoes, while readily utilizing human habitations as a resting habitat, is apparently not involved in malaria transmission. Host preference studies and further molecular analyses are needed but at this stage we tentatively conclude that we are dealing with an undescribed species within the *An. funestus* subgroup.

Platypus quericovrus causing Japanese oak wilt disease in Japan: Why has JOW become epidemic recently?

Masahide Kobayashi[1], Naoto Kamata[2]

[1]Kyoto Prefectural University, Sakyo, Kyoto 606-8522, Japan, [2]University of Tokyo, Bunkyo, Tokyo 113-8657, Japan

In Japan, Japanese oak wilt disease (JOW) caused by a fungus *Raffaelea quercivora* vectored by an ambrosia beetle *Platypus quercivorus* has been spreading rapidly since late 1980s. Fagaceae trees were used as fuels in the past. However, these tree species were left unattended after the fuel revolution since early 1960s in Japan. We speculate that great increase of the number of large-diameter trees suitable for *P. quercivorus* reproduction is one of major causes of JOW epidemics. The number of the insect offspring that emerged from brood trees tends to be greater in trees with larger diameters because these trees provide larger space for the beetle reproduction and maintain necessary moisture for longer period. Other hypotheses on JOW epidemics are related to global warming. Mortality of *Quercus crispula* is approximately 40% but much lower for associated species of Fagaceae (< 5%). It is likely that other tree species resistant to the fungus evolved under a stable relationship between the tree, fungus and beetle during a long evolutionary process. *Q. crispula* was probably not part of this coevolution because *Q. crispula* is distributed in cooler regions than other host tree species. A warmer climate since the late 1980s made possible the fateful encounter of *P. quercivorus* with *Q. cripsula* by allowing the beetle to extend its distribution to more northern and higher altitudes. Tree stress caused by high temperature and by drought is also a likely cause of the epidemics because JOW incidences tend to increase greatly in hot summers.

Aquatic habitat productivity to adult *Anopheles arabiensis* and *Culex quinquefasciatus* in a rice agro-ecosystem, in Mwea, Kenya

Joseph Mwangangi[1], Ephantus Muturi[2], Joseph Shililu[3], Simon Muriu[3], Benjamin Jacob[2], Ephantus Kabiru[4], Charles Mbogo[1], John Githure[3], Robert Novak[2]

[1]Centre for Geographic Medicine Research - Coast, Kenya Medical Research Institute, Kilifi, Kenya, [2]Department of Medicine, William C. Gorgas Center for Geographic Medicine, Alabama, United States, [3]International Centre for Insect Physiology and Ecology, Human Health Division, Nairobi, Kenya, [4]Kenyatta University, Department of Pathology, Nairobi, Kenya

Between April and September 2005, studies were conducted to determine the contribution of diverse larval habitats to adult *Anopheles arabiensis* Patton and *Culex quinquefasciatus* Say production in a rice land agro-ecosystem in Mwea Kenya. Two sets of cages measuring 0.125 m^3 and 1 m^3 were placed in different habitat types to investigate the influence of non-mosquito invertebrates on larval mortalities and the contribution of each habitat type to mosquito productivities, respectively. The cages (emergence trap) were designed having a fine netting material cover to prevent adult mosquitoes from ovipositing in the area covered by the trap and immature mosquitoes from entering into the cage. The emergence for *An. arabiensis* in seeps, tire tracks, temporary pools, and paddies were 10.53%, 17.31%, 12.50%, and 2.14%, respectively while the corresponding values for *Cx. quinquefasciatus* were 16.85% in tire tracks, 8.39% in temporary pools and 5.65% in the paddies from 0.125 m^3 cages during the study. Cages measuring 1 m^3 were placed in different habitat types which included paddy, swamp, marsh, ditch, pools and seep to determine larval habitat productivity. *Anopheles arabiensis* was the most predominant anopheline species (98.0% n = 232) although a few *An. coustani* Laveran (2.0% n = 5) emerged from the habitats. The larval habitat productivity for *An. arabiensis* were 6.0 mosquitoes per m^2 for the temporary pools, 5.5 for paddy, 5.4 for marsh, 2.7 for ditch and 0.6 for seep. The *Cx. quinquefasciatus* larval habitat productivity was 47.8 mosquitoes per m^2 for paddy, 35.7 for ditch, 11.1 for marsh, 4.2 for seep, 2.4 for swamp and 1.0 for temporary pools. Pools, paddy and marsh habitat types were most productive larval habitat for *An. arabiensis* while paddy, ditch and marsh were the most productive larval habitats for *Cx. quinquefasciatus*. The most common non-mosquitoes invertebrates' composition in the cages included dytiscidae, notonectidae, belostomatidae and ephemerellidae, and their presence negatively affected the number of emergent mosquitoes from the cages. In conclusion, freshly formed habitats are most productive aquatic habitats while old and more permanent habitats are least productive due to natural regulation of mosquito immatures.

Using electron microscopy to define species within *Asthenopholis* Brenske, a genus of African leaf chafer beetles (Coleoptera: Scarabaeidae: Melolonthinae)

James Harrison[1, 2]

[1]Transvaal Museum, Northern Flagship Institution, Pretoria, South Africa, [2]Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute, University of Pretoria, Pretoria, South Africa

Introduction: Currently, seven described species comprise the beetle genus *Asthenopholis* Brenske, 1898. A taxonomic revision was initiated for the species placed within *Asthenopholis*, a genus which includes localised African endemics, some of which can become sporadic agricultural pests and consequently require accurate identification. However, although light microscopy could provide intuitive separation of the specimens into morphospecies, scanning electron microscopy (SEM) was used to look for consistent morphological characters to differentiate these into species.

Methods: All type and available specimens (n = 650) were examined. Once morphospecies were obtained via light microscopy and analysis of geographical distribution, representatives of each morphospecies were examined using SEM. Specimens were softened in boiled water, cleaned ultrasonically (50-60 Hz; 80 W), then set and dried. Thereafter, they were mounted on stubs and gold coated using a SEM Auto-coating Unit (E5200) and viewed with a JEOL (JSM-840) SEM. Digital micrographs were captured using Orion 6.60.4.

Results: In total, about 150 hours (or 22 SEM days) produced 1200 micrographs for interspecific comparisons. Diagnostic characters were observed especially in the form and position of setae around the eye and on the pronotum, scutellum, and pygidium.

Conclusions: The SEM morphological analysis provided definable species-specific characters. The analysis recognized seven species of *Asthenopholis* (i.e., five valid existing and two new species; two previous synonymies were confirmed). Specimens from a species complex within the genus require additional material and probably molecular analysis to differentiate them further into definable species, or a cline of a single variable species.

Six years of field trials with transgenic Bt-potato in South Africa - experiences and lessons learnt

Diedrich Visser[1], David Sehlola[1], Walter Pett[2]

[1]ARC-Vegetable and Ornamental Plant Institute, Pretoria, South Africa, [2]Department of Entomology, Michigan State University, East Lansing, MI, United States

Introduction: A Genetically modified potato containing the *Bacillus thuringiensis* gene for the control of the potato tuber moth, *Phthorimaea operculella* (PTM), was evaluated between 2001 and 2007 in South Africa.

Methods: Field trials comprising randomized block designs were conducted in six provinces. Efficacy studies were carried out at all locations, while environmental impact and non-target studies were carried out in three provinces.

Results: Six field trial permits, as well as a permit for the conducting of contained use experiments in laboratories and a greenhouse, were issued by the Registrar of Genetically Modified Organisms Act of South Africa. These permits also included permission to do storage trials in the relevant areas. Seed tubers for all field trials had to be produced in a specially adapted greenhouse modified to multiply mini tubers in a vermiculite substrate open hydroponic system. Movement of all seed tubers, planting, harvesting and storing was strictly monitored by inspectors of the Department of Agriculture. Regular inspections during the season of all field trials were also carried out. In some instances the strict requirements as stipulated in the permit were altered after written objections to the Registrar. At all locations where PTM occurred, the Bt-potato provided excellent control of PTM compared to the non-transformed potato. No PTM were found, nor was any PTM damage observed on the Bt-potato lines tested.

Conclusion: Six years of field trials with Bt-potatoes were conducted successfully in South Africa. However, strict regulations, instructions and inspections always impacted on the normal potato field trial processes.

Advantages, limitations and extrapolation to field situation of different laboratory test methods used to evaluate side-effects of plant protection products to non-target arthropods

Marco Candolfi

BASF SE, Agricultural Center, Limburgerhof, Germany

An overview on laboratory test methods used to access the side-effects of plant protection products on non-target and beneficial arthropods will be presented. Methodology used to access lethal and sub-lethal endpoints will be compared and discussed. Advantages and limitation of different test method approaches will be discussed in view of predictability of effects under field conditions.

Could semiochemicals enhance parasitism of aphids on Russian wheat aphid resistant cultivars?

Goddy Prinsloo[1], Robert Glinwood[2], Theuns Van der Linde[3], Amie Van der Westhuizen[4]

[1]ARC-Small Grain Institute, Bethlehem, South Africa, [2]Department of Ecology, Swedish University of Agricultural Sciences, Uppsala, Sweden, [3]Department of Zoology and Entomology, University of the Free State, Bloemfontein, South Africa, [4]Department of Plant Sciences, University of the Free State, Bloemfontein, South Africa

Introduction: Plants attacked by herbivores, produce herbivore-induced volatiles, which benefit the natural enemies by making the herbivores more vulnerable to the natural enemies. The behavioural response of two Russian wheat aphid parasitoids namely *Aphelinus hordei* and *Diaeretiella rapae* to methyl salicylate was tested in the laboratory. Methyl salicylate is known for its aphid repellent properties

Methods: The response of the parasitoids to an oil formulation of methyl salicylate was tested in a four-arm olfactometer in the laboratory. The resistant cultivar TugelaDN and the near isogenic susceptible cultivar, Tugela were then treated with methyl salicylate. The behavioural response of the parasitoids was then tested against treated and untreated plants.

Results: Both parasitoid species were significantly repelled by the methyl salicylate formulation but *A. hordei* was affected more than *D. rapae*. However, when plants were treated with the formulation the parasitoids were attracted to the plants. This effect was stronger with on resistant TugelaDn than on susceptible Tugela. Being known as a stress signal, methyl salicylate could induce the defence mechanism in the different cultivars, leading to the production of herbivore induced volatiles that were attractive to the parasitoids.

Conclusion: Methyl salicylate may have several beneficial effects when used in the control of Russian wheat aphid. Not only does it contribute to the lower aphid numbers in the wheat crop but could enhance the effect of parasitism in the field and improve the control of the aphids.

Data management and taxonomic applications for the Platygastroidea Global Biodiversity Inventory

Norman Johnson[1], Andrew Austin[2], Luciana Musetti[1]

[1]The Ohio State University, Columbus, Ohio, United States, [2]The University of Adelaide, Adelaide, SA, Australia

The Platygastroidea Global Biodiversity Inventory is an NSF-sponsored international project aimed toward increasing the sampling of these parasitic wasps in collections, development of a robust phylogeny for the group, and the rapid description of a large number of species within the superfamily. Current taxonomic practices are, we believe, insufficient to handle the scale and pace of this taxonomic enterprise, and new tools and paradigms are required to achieve the desired goals.

Data domains associated with taxonomy include nomenclature, literature, characters and their states, collecting data, and imagery. Several informatics tools used to manage these data are described. A complete electronic taxonomic catalog is used to manage names and literature. Access to these data is available through the Hymenoptera Name Server (purl.oclc.org/NET/hymenoptera/hns). A specimen-level database manages information derived from collecting events. This is accessible through Hymenoptera On-Line (purl.oclc.org/NET/hymenoptera/hol). An image management application, Specimage, archives images and provides mechanisms to rapidly compare pictures for diagnosis. A new application, vSysLab (purl.oclc.org/NET/hymenoptera/vsyslab), assists in the development of taxon by character matrices. vSysLab exports data in formats for import into identification software (Lucid interchange files and Structure of Descriptive Data XML format), phylogenetic analyses, and as natural language descriptions. This application links the character data to the specimen and taxonomic portions of the database. As a result, nomenclatural summaries and material examined sections of typical taxonomic descriptions are quickly and accurately produced.

Communication between project collaborators is an essential element of a large-scale taxonomic project. Wiki software provides the mechanism for real-time discussion and documentation of taxonomic research. A weekly newsletter is produced to coordinate activities and to maintain the interest in and momentum of the project. Project results may be viewed at purl.oclc.org/NET/hymenoptera/platygastroidea.

Identification of proteins found in fungus-growing ant fecal material

Morten Schiøtt, Henrik H. de Fine Licht, Jacobus J. Boomsma

University of Copenhagen, Copenhagen, Denmark

Ca. 50 million years ago a single ancestor of today's >210 species of fungus-growing ants committed herself irreversibly to farming fungi for food instead of being a hunter-gatherer as most other ants. However, the Leucocoprini (Agaricales) that were domesticated remained mostly uncommitted to the symbiosis until a single lineage evolved special "ant-feeding" hyphal tips (gongylidia). Recent work has shown that many fungal enzymes pass the ant intestines unharmed to be transferred to the actively growing parts of the fungus garden where the ants deposit their fecal droplets. However, not all of these compounds are benevolent promotors of new fungal growth. Some appear to function primarily as defenses of the resident clonal fungus against alien strains of symbiont that foraging ants might bring in. In order to identify the active compounds in fecal droplets, we have commenced a survey of the proteins present in *Acromyrmex echinatior* fecal droplets. The survey is based on separating proteins with SDS polyacrylamide gel electrophoresis followed by tandem mass spectrometry and PCR to determine the gene sequences encoding the fecal droplet proteins.

Food attraction and reproductive success of the Japanese burying beetle, *Eusilpha japonica*

Wakana Taki, Mamoru Watanabe

University of Tsukuba, Tsukuba city, Ibaraki prefecture, Japan

Introduction: The Japanese burying beetle, *Eusilpha japonica*, seems to search for carrion by walking around the forest floor throughout the day. In order to reveal the food requirement of adults in relation to the reproductive success, food attraction and feeding habits were studied in the field and in the laboratory, respectively.

Methods: Field survey included the consecutive capturing for two days, using pitfall traps with carrion and without carrion. When the adults were collected in the field, they were starved over 72 hrs in the rearing container and then allowed to feed on a meat of chicken to estimate the daily food intake.

Results: Females and males were captured in the pitfall traps with carrion probably due to the attraction of the meat odor, while the traps without carrion tended to have both sexes together. After 2 days starvation, females showed the significantly larger quantity of food intake (0.37±0.02g) than males (0.20±0.02g), and thereafter, their daily food intake decreased. The clutch size of the first brood increased with the cumulative quantity of food intake of the pair until the oviposition. The pairs successively produced 3.2±0.3 clutches for 20 days up to the end of the experiment, though each clutch size after the second brood was not affected by the food intake of the pair.

Conclusions: Because females in the fields required more food than males for egg production especially in their first brood, walking around the forest floor might be a searching behavior for food which appeared temporally and patchily on the ground.

Combining theoretical population ecology and practical biocontrol: Earwigs in fruit orchards

Rob Moerkens[1], Bruno Gobin[2], Gertie Peusens[2], Laurent Crespin[1], Herman Helsen[3], Herwig Leirs[1]

[1]University of Antwerp, Antwerp, Belgium, [2]Zoology Departement, Pcfruit TWO, Sint-Truiden, Belgium, [3]Wageningen UR, Zetten, Netherlands

Earwigs, *Forficula auricularia* (L.) (Dermaptera: Forficulidae) are beneficial predators in apple and pear orchards where they are capable of maintaining several pest species below economic thresholds. Earwigs thus play an important role in integrated fruit orchards and are essential in organic top fruit cultures. Numbers of earwigs show large interannual variations in densities in both organic and IPM orchards, this limits their practical use. All practical attempts for re-establishing earwig populations have failed. These problems indicated that a theoretical approach was necessary. In order to develop strategies for increasing earwig populations we have built a population model. This enables the prediction of earwig phenology throughout the season while a sensitivity analysis allows us to identify key factors and critical periods in the earwigs' life cycle.

It is well know that earwig development is temperature dependent. This allows us to make phenological predictions in a given year using daydegrees, which are the sum of daily temperatures above a certain threshold. Taking into account microclimates and different habitat temperatures we have validated the simulations with existing field data from several European and non- European earwig populations. Predictions of third and fourth instar nymphs produce excellent results, while adults show a considerable bias. First sensitivity analyses reveal that the numbers of nests during winter have a very big impact on the population in relation to spring or summer survival. However more knowledge about limiting and regulating processes is required for developing specific and effective orchard management strategies. Such work is underway.

Preliminary results of laboratory efficacy tests using registered insecticides against the potato tuber moth, *Phthorimaea operculella*, in South Africa

Diedrich Visser, Nolwazi Mkize, Sakhi Sambo

ARC-Vegetable and Ornamental Plant Institute, Pretoria, South Africa

Introduction: Potato tuber moth (PTM) is one of the most destructive potato pests in South Africa. Its larvae feed on foliage and also tunnel into tubers. Yield losses of between 5 and 30% are not uncommon. Poor control is regularly reported when using registered insecticides against the potato tuber moth. Although this could be attributed to many factors, insecticidal resistance is usually assumed. A laboratory study was initiated to elucidate the effectiveness of insecticides against, and possible resistance in, the potato tuber moth.

Methods: In phase one of the study, a diagnostic dose for each of the 15 insecticides tested was used against nine geographically different moth populations, including a susceptible laboratory population. The diagnostic dosages were calculated from the recommended field dosages and applied as a detached leaf dip bioassay. First instar larvae were collected from insectarium reared populations (collected previously in different production regions) and transferred to treated leaves with a fine camel hair brush. The treated leaves with the larvae were incubated in petri dishes for approximately ten days after which mortalities were noted.

Results: Preliminary evaluations showed that all insecticides killed all larvae in all treatments. The next phase of the study will include the use of cumulative half dosages until surviving figures differ from that of the susceptible laboratory population. Dose-response studies using LD50 values will then be instituted on the relevant populations/insecticides.

Conclusion: Thus far no severe insecticidal resistance could be proven using diagnostic dosages in the laboratory against nine geographically different moth populations.

Occurrence of *Wolbachia* in introduced populations of pharaoh ants: A case of enemy release?

Anna M. Schmidt, Jes S. Pedersen

University of Copenhagen, Copenhagen, Denmark

Introduction: Pharaoh ants (*Monomorium pharaonis*) are very successful invaders of human habitation in most parts of the world. Like their fellow tramp ant species pharaoh ants are small, polygynous and unicolonial; traits considered instrumental in their invasion success. Enemy release may likewise be important for their success. This study examines the presence of the intracellular bacterium *Wolbachia* in introduced populations of pharaoh ants from several localities around the world. *Wolbachia* has previously been found to be present in native, but lacking in introduced populations of the highly invasive fire ants (*Solenopsis invicta*) and Argentine ants (*Linepithema humile*); therefore the lack of *Wolbachia* has been implicated as a possible factor increasing the success of the invasive populations.

Methods: Workers from more than 50 populations were screened for the presence of *Wolbachia* using the wsp81F and wsp691R primers. High quality extractions and sequencing will be performed to identify the strains present in the pharaoh ants and to study the occurrence and strains in some of their close invasive and non-invasive relatives.

Results and conclusions: *Wolbachia* was found in about 10% of the populations representing laboratory reared as well as free living colonies. This relatively high frequency raises the question of how harmful *Wolbachia* really is for pharaoh ants, since release from the bacterium does not appear to be a prerequisite for successful invasion. Including more samples will potentially further the understanding of the phylogenetic and geographical relationship of invasive ants and their *Wolbachia* symbionts.

Biology of the egg parasitoid *Trichogrammatoidea lutea* (Hymenoptera: Trichogrammatidae) on three lepidopteran host species

Khethani V. Mawela[1], Kerstin Krüger[2], Rami Kfir[3]

[1]University of Pretoria, ARC-Plant Protection Research Institute, Pretoria, South Africa, [2]Department of Zoology & Entomology, University of Pretoria, Pretoria, South Africa, [3]ARC-Plant Protection Research Institute, Pretoria, South Africa

Introduction: *Trichogrammatoidea lutea* is a parasitoid of Lepidoptera eggs. The effects of ultraviolet (UV) radiated host eggs of three lepidopteran species on life history parameters of *T. lutea* were evaluated as part of developing a mass-rearing programme for this parasitoid. UV-radiation was used to arrest the development of the eggs in order to simplify mass-rearing and to avoid cannibalism by the newly hatched larvae.

Methods: Three lepidopteran host species, *Helicoverpa armigera, Chilo partellus* and *Ephestia cautella,* were used to evaluate the effect of UV radiation (15 min) on the duration of development, parasitism, number of progeny per host egg and sex ratio of *T. lutea*, and to determine the effects of hosts and temperature (18-30℃) on its biology.

Results: *T. lutea* parasitized and completed development on UV-radiated host eggs. Parasitism, number of progeny and sex ratio were not affected by UV-radiation. Developmental time was shorter on un-radiated compared to UV-radiated host eggs. Parasitism increased with temperature on all three hosts. The highest parasitism rate occurred at 27℃ on *H. armigera* and the lowest at 18℃ on *Chilo partellus*. The number of progeny was highest on *H. armigera* at all temperatures. Sex ratio of *T. lutea* was not affected by temperature. Rate of development increased with temperature on all hosts and was fastest on *H. armigera*.

Conclusion: UV-radiation of host eggs had negligible effects on life history parameters of *T. lutea.* Both *H. armigera* and *E. cautella* were found to be suitable hosts for mass rearing of *T. lutea.*

Neuro-endocrinology of reproduction and phase transition in the desert locust, *Schistocerca gregaria*

Jozef Vanden Broeck, Liesbeth Badisco, Elisabeth Marchal, Pieter Van Wielendaele, Heleen Verlinden, Gert Simonet

Animal Physiology and Neurobiology, Leuven, Belgium

The biological process that leads to locust swarm formation is termed 'phase transition'. Locusts can develop into two distinct 'phases', a solitary and a (swarming) gregarious one, which display very prominent differences in behavior, development, coloration, morphology and metabolism. These phases also show important differences in their reproductive physiology. Phase characteristics are likely to be influenced by factors derived from the central nervous system (CNS). Locusts are very suitable experimental models for physiological research. Major advantages are their big size compared to most other insects, their fascinating biology and the vast amount of physiological and endocrinological data that are already available. However, a major disadvantage is the huge size of their genome (several times the human genome). To compensate for this disadvantage, we recently initiated a project to generate an 'Expressed Sequence Tags' (EST) database representing a large number of transcripts expressed in the desert locust (*Schistocerca gregaria*) CNS. This research initiative is performed in collaboration with a specialized high-throughput sequencing center. The aim is to further explore the molecular information gathered in this locust EST database and to study the fundamental physiological mechanisms underlying the complex process of locust phase transition.

Increased habitat complexity to manage natural enemy community of the Colorado potato beetle, *Leptinotarsa decemlineata* (Say) (Coleoptera: Chrysomelidae)

Zsofia Szendrei[1], Matthew Greenstone[2]

[1]Rutgers, The State University of New Jersey, Chatsworth, NJ, United States, [2]Agricultural Research Service, USDA, Beltsville, MD, United States

Introduction: Habitat complexity influences predator efficiency and community structure. Molecular gut analysis is an effective tool to study predator-prey interactions under field conditions. Our goal in this study was to investigate the effects of habitat complexity on predator-prey interactions in potato fields.

Methods: Predators were collected from Maryland potato fields that were either tilled or mulched with winter rye or hairy vetch. Species-specific DNA primers were used to identify Colorado potato beetle (CPB) in predators gut contents. We performed molecular gut content analysis on almost 1700 individual CPB predators during the 2006 and 2007 field seasons. We used CPB-DNA half-lives derived under simulated field conditions to weight these raw proportions, and thereby to rank these predator species in order of their impact on the CPB population.

Results: Seven common and abundant foliar predator species in our experimental fields prey on different CPB life stages. This assemblage includes polyphagous species such as ladybeetles (Coleoptera: Coccinellidae) and *Podisus maculiventris* (Hemiptera: Pentatomidae); and specialists such as *Lebia grandis* (Coleoptera: Carabidae) and *Perillus bioculatus* (Hemiptera: Pentatomidae). Predator species were more evenly distributed in tilled plots than in cover-cropped fields. The most abundant species in all treatments was *Coleomegilla maculata*. The incidence of CPB DNA in the guts of the examined predator species ranged from 0 to 91%.

Conclusion: Our results indicate that habitat management is a potentially viable method of manipulating the CPB predator assemblage. The observed differences in predator species distribution, however, may not translate into better pest suppression.

The phylogeography of sex in the parthenogenic ant, *Platythyrea punctata*

Jon Seal, Katrin Kellner, Juergen Heinze

University of Regensburg, Regensburg, Germany

Parthenogenesis among animals is rather rare, but most animal taxa exhibit at least some members that produce diploid offspring from unfertilized eggs. The relative rarity is explained by some theory that indicates that parthenogenesis is not adaptive over long periods, and will eventually be replaced by sexual populations, owing to the greater variability among sexually produced offspring. The ponerine ant, *Platythyrea punctata*, is one of the six ant species that exhibits parthenogenesis. This species occurs from South Texas to at least Costa Rica on the American mainland and also occurs on nearly all Caribbean islands, south Florida and the Bahamas. Like many members of its genus, its colonies frequently lack queens and a worker (a 'gamergate') assumes queen behavior, but peculiarly, colonies on the islands and Florida can produce diploid eggs from unfertilized eggs by thelytokous parthenogenesis. Whether or not this occurs in mainland populations is unclear. This project documents the range of parthenogenesis in this species. Colonies have been collected from Barbados, the Bahamas, Grenada, Florida, Texas, Puerto Rico, Dominican Republic, Belize and Costa Rica. The data presented here will use a phylogeny constructed from a 1400 bp segment of mitochondrial CO I gene to test whether parthenogenesis is more common in young, rapidly expanding populations, as theory would predict. We will also compare genetic distances among the populations and thus provide their ages, the age of the parthenogenetic populations and perhaps the role of vicariance and dispersal in this population. Supported by DFG (He 1623/20-1).

Management studies against major insect pests of soybean (*Glycine max* (L.) Merrrill)

B. S. Thakur, Sandhya S.R.

Indira Gandhi Krishi Vishvavidhyalay, Raipur (Chhattisgarh), India

Pest succession and management studies against major insect pest of soybean (*Glycine max*) were conducted in Indira Gandhi Krishi Vishwavidyalaya, Raipur (C.G.) India. In pest succession, out of twelve inset species observed *Obereopis brevis* S., *Ophiomyia phaseoli* Coq., *Melanagromyza sojae* and *Spodoptera litura* were the major pests and fourteen bioagent *viz.,* lady bird beetles, lace wing, Cantheconid bug, *Costesia sp.* and *Beauveria bassiana* were regulating the pest population of soybean.

June 25th recorded minimum incidence of girdle beetle, stemfly and *Spodoptera litura* and produced maximum for yield. Avoidable yield losses were higher in 8th and 15th July sown crop. Among the 20 cultivars screened, higher total phenol content varieties showed low incidence of stemfly and girdle beetle and with high level of chlorophyll succumbed to more incidence of *Spodoptera litura.* The carryover of girdle beetle was observed on several alternate hosts. Light trap catches of *Spodoptera litura* indicated its presence almost throughout the year. Pheromone trap population showed negative correlation of *Spodoptera litura* male moth with rainfall.

Combination of Nuclear Ployhedrosis Virus @ 1 lit/ha + Triazophos @ 800 ml /ha gave better result than other combinations against *Spodoptera litura*. The Phorate 10 G @ 1Kg a.i./ha reduced the stemfly infestation. On the basis of LC_{50} insecticides Fenvalerate and Profesophos were highly toxic against *Spodoptera litura* and Lindane & Endosulfan were observed as to least toxic. Integration of all the components studied has given good results in on farm and off farm studies against soybean pests.

Conservation biological control via unharvested enemy refugia: Coppicing willows, leaf beetles and predatory bugs

Christer Björkman

Dept of Ecology, Swedish University of Agricultural Sciences, Uppsala, Sweden

Introduction: Disturbances are common in natural systems and may affect important ecosystem processes (e.g. predation and hence biological control). If the perturbations, e.g. harvesting, are predictable they can be used to test ecological theories in large-scale field experiments.

Methods: Densities of leaf beetles (prey) and mirid bugs (predators) were compared in (i) coppicing willow plantations different years after harvest and (ii) in plantations with and without unharvested parts, expected to function as enemy refugia.

Results: Harvesting disrupts the biological control of leaf beetles in short rotation coppice willow plantations. The reason is that the main natural enemies (mirid bugs) are removed at harvesting, taking place in winter. The reason for this is that the bugs overwinter as eggs oviposited in willow tissue and we show that the density of mirid eggs increase with time after harvesting. The leaf beetles, overwintering outside the plantations, can thereby return to an enemy-free space in spring. We hypothesized that one way to conserve biological control would be to leave unharvested willows, functioning as enemy refugia. The results from a field experiment showed that (1) enemy densities and (2) predation pressure (but to a lower extent) was higher within than outside refugia, and (3) both leaf beetles and mirid bugs were positively affected by refugia on whole stand level.

Conclusions: Leaving unharvested refugia may affect the pest more positively than the predators. Our results illustrate the need to consider scale and basic biological knowledge before launching simple solutions to complex problems.

Insect rearing science opportunities at Mississippi State University

Frank M. Davis[1], Norman C. Leppla[2]

[1]Mississippi State University, Department of Entomology and Plant Pathology, Mississippi State, MS, United States, [2]University of Florida, Department of Entomology and Nematology, Gainesville, FL, United States

Introduction: In 2000 the Department of Entomology and Plant Pathology bought into the concept that insect rearing research and education is vital to the advancement of Entomology and that we would provide it. Fortunately, we had local entomologists who had rearing experience and were interested in developing an insect rearing center and its activities.

Methods: In the following seven years state-of-the-art rearing facilities were designed and constructed, rearing of insects for research was initiated, insect rearing research was begun utilizing staff and graduate students, an insect rearing library based on a gift from Dr. Pritam Singh was established, and a workshop for training insectary managers and rearing specialists was initiated.

Results: Our educational efforts have focused on a 5-day workshop titled “Principles and Procedures for Rearing Quality Insects”. It covers nine areas of rearing which are considered vital to have a successful rearing program. The workshop is team taught using local experts and those from other public and private institutions. Ten workshops have been sponsored. Occasionally two workshops were necessary per year to satisfy the demand for insect rearing education. Two hundred and twenty nine persons from twenty countries have participated in the workshop. A book based on workshop topics is scheduled to be available by the end of 2008.

Conclusions: An insect rearing center has been created with an educational and training component. Plans are being considered to offer an insect rearing course and perhaps the workshop by long distance educational means.

Warning and prognoses of insect pests and diseases in Norway with emphasis on two insect pests in apple orchards

Trond Hofsvang

Bioforsk Plant Health and Plant Protection, Aas, Norway

Introduction: VIPS is a web-based decision support system designed to assist Norwegian growers in the management of pests, diseases and weeds of cereals, vegetables and fruit crops. VIPS was established in 2001 as a collaborative project between Bioforsk and Norwegian Agricultural Extension Service (NAES) under a government-funded action for reducing risk connected to the use of pesticides. The aim of VIPS is to provide information to advisors and farmers to reduce reliance on pesticides.

Methods: Inputs to the forecasting models are weather data from the Bioforsk Agrometeorological Service consisting of a network of 80 automatic weather stations across crop production areas, weather forecasts from the Norwegian Meteorological Institute and biological/field observations collected by NAES.

Results: In 2008, five species of insect pests are included in VIPS. Two of these five insects, codling moth (*Cydia pomonella*) and apple fruit moth (*Argyresthia conjugella*), are important pests in Norwegian apple orchards. For both insects species climatic data and biological observations are used in the forecasting models. For codling moth day degrees (temperature at sunset), pheromone traps and flowering (petal falls) are included in the model. Day degrees (optimal treatment timing), abundance of rowan berries, per cent of berries with larvae, level of parasitism of the larvae and flowering are parameters used in the model for forecasting of apple fruit moth.

Conclusions: The service is open and free of charge at www.vips-landbruk.no and is an important tool for implementing IPM in Norway.

Conclusion: Insect rearing education and training support for advancements in entomology?

Frank M. Davis[1], Norman C. Leppla[2]

[1]Mississippi State University, Department of Entomology and Plant Pathology, Mississippi State, MS, United States, [2]University of Florida, Department of Entomology and Nematology, Gainesville, FL, United States

Introduction: The evolution of the science of rearing insects in the laboratory from the 1940's to now have been phenomenal as we moved from table top rearing of a few hundred insects per week to mega facilities producing millions per week. As a result, a solid foundation of insect rearing information was generated in the last half of the 20th century. During this era we observed the birth of private enterprises in rearing insects for a multitude of purposes to go along with public ventures which have traditionally focused on rearing for education and research purposes. What was obviously missing during this period was the lack of formal education and training opportunities for insect rearers.

Methods: Some entomologists involved in rearing insects today have recognized the need for formal education and training of insect rearing personnel and are making efforts to address this problem.

Results: Education and training for those interested in rearing quality insects at the lowest cost possible is now available through workshops, symposiums, books generated by these efforts, and visits to respected rearing facilities. Plans are being made to develop the first ever college/university course in insect rearing and expand its utility by long distance educational means.

Conclusions: The 21st century can be the "The Golden Years" of insect rearing if personnel are properly educated and trained in the critical areas of rearing. This will require investment in funding, time and commitment with the result being continued significant advancements in insect rearing science.

We are one but not the same: Population and colony structure of the thelytokous ant *Platythyrea punctata* in Puerto Rico

Katrin Kellner, Juergen Heinze

University of Regensburg, Regensburg, Germany

Although all female Hymenoptera are capable of laying haploid eggs that develop parthenogenetically into males (arrhenotoky), very few are capable of laying unfertilised eggs that turn into diploid females (thelytoky). Once such species is the neotropical ponerine ant, *Platythyrea punctata*. This species appears to be primarily clonal on Caribbean islands and may be sexual on the American mainland. Because the presence or absence of a sexual process is thought to determine the genetic structure at both the colony and population level, *P. punctata* has become a model system for understanding the relationship between reproductive mode and population structure. This talk presents data on the population genetics of this species on Puerto Rico. Previous work indicated that all colonies are queenless and the dominant mode of reproduction is thelytokous parthenogenesis. We used high polymorphic microsatellite markers from several sample sites distributed over the island further determine the genetic composition of colonies and population structure. We found that colonies do not exclusively consist of a single clone, but rather a mixture of genotypes. Genetic variation was surprisingly high between colonies and sample sites. Some of this could be due to fusion events or recombination due to the thelytoky mechanism this species employs. However, a laboratory experiment designed to investigate this mechanism, suggested that colonies produce diploid eggs by apomixis (meiosis does not occur), therefore the observed variation would appear to come from fusion events.

New developments in the rearing and the management of quality control for tsetse flies for AW-IPM

Andrew Parker, Idrissa Kabore

International Atomic Energy Agency, Vienna, Austria

Following the successful eradication of *Glossina austeni* from Unguja Island, Zanzibar and the launching of the AU-PATTEC there has been a considerable increase in interest in developing area-wide integrated pest management (AW-IPM) programmes, including the use of the SIT, for the creation of tsetse free zones. The Joint FAO/IAEA Programme of Nuclear Techniques in Food and Agriculture through its Insect Pest Control sub-programme continues to develop the technology and procedures for tsetse mass rearing to meet this increasing demand.

Principle amongst these has been the development of the Tsetse Production Unit 3, a semi-automated system for tsetse holding and feeding. To complement this we are now working on the development of an automated system to sex tsetse in the late pupal stage. This will lead to easier male handling and irradiation.

A second area that we are actively developing is improved techniques for the decontamination of blood diet for tsetse feeding. Up to now this has been achieved using gamma irradiation, but with the withdrawal from the market of the commonest irradiator an alternative is required. We are investigating both pasteurization and UV irradiation.

The Joint Programme is also running a five year Co-ordinated Research Project (CRP) on “Improved and Harmonized Quality Control for Expanded Tsetse Production, Sterilization and Field Application”. Included under this CRP is work on quality control of rearing, flight muscle development and blood diet processing. The Joint Programme is also offering a dose inter-comparison service to allow projects to check their dosimetry systems.

Developing IRM strategies for the next generation of insect-resistant maize

Richard L. Hellmich[1], Jarrad R. Prasifka[1], Blair D. Siegfried[2]

[1]USDA-Agicultral Research Service, Corn Insects and Crop Genetics Research Unit and Department of Entomology, Iowa State University, Ames, Iowa, United States, [2]Department of Entomology, University of Nebraska, Lincoln, Nebraska, United States

The high-dose/refuge strategy is commonly used to manage insect resistance to *Bacillus thuringiensis* (Bt) crops. This strategy should be effective as long as plants express a high dose of the toxin, genes conferring resistance are rare, and there are many insects from a refuge (structured or unstructured) available to mate randomly with resistant insects. These assumptions are met with many lepidopteran pests of maize throughout the world, but certainly not all. A new generation of transgenic crops, however, that combines two or more toxins with different modes of action (stacks and pyramids) could increase the spectrum of insect control and at the same time allow reduced refuge size and the possibility of seed mixtures. Interplant movement of larvae has been recognized as an important factor that could violate high dose assumptions and thus has limited the use of seed mixtures. Experiments are underway with colonies of resistant corn borers, *Ostrinia nubilalis*, to determine how resistance alleles influence larval movement among Bt and non-Bt maize plants. These experiments could help determine whether “refuge in the bag” is possible for Bt maize and *O. nubilalis* and establish methods to similarly test other insect pests of transgenic crops.

Capacity building for tsetse and trypanosomosis control in Africa by the sterile insect technique

Andrew Parker, Marc Vreysen, Udo Feldmann, Jorge Hendrichs

International Atomic Energy Agency, Vienna, Austria

The Joint FAO/IAEA Programme of Nuclear Techniques in Food and Agriculture is supporting Member States in their efforts to generate progress towards the ultimate objectives of the Pan African Tsetse and Trypanosomiasis Eradication Campaign of the African Union (AU-PATTEC). Various resources of the FAO/IAEA are used to support methods development, technology transfer and capacity building relevant to the integration of the sterile insect technique (SIT) for tsetse and trypanosomosis control in Africa.

Our capacity building activities cover both training and assistance with facility design, construction and equipping. The training is organised under the Agency's Technical Cooperation programme by fellowships to develop the skills of individuals, by means of on the job training in specific fields, formal university courses and regional training courses. Recent training courses have covered baseline data collection, GIS and population genetics, and a course on tsetse rearing and sterile male handling will be held shortly. We are now working with the other mandated UN organizations and the AU-PATTEC to identify Regional Designated Centres (RDCs) for training relevant to addressing the tsetse and trypanosomosis problem. Selected RDCs will be assisted to develop their facilities and training capabilities, and to resolve any limitations in their capacities.

Another area of our assistance to capacity building is through Co-ordinated Research Projects (CRPs). CRPs bring together participants from developing and developed countries through a number of Research Coordination Meetings (RCMs) to plan and coordinate the work. Through these RCMs collaborations are set up between researchers in developing and developed countries.

Spiracular fluttering is not a steady state behaviour

Thomas D. Förster, Stefan K. Hetz

Humboldt Universität, Berlin, Germany

Using an automated perfusion system we investigated the steady state spiracle behaviour of diapausing *Attacus atlas* pupae in response to fixed enforced tracheal gas mixtures.

No mixture resulted in steady fluttering of the spiracles. We conclude that the intermittent opening of single spiracles during the flutter phase results from internal oscillations of the endotracheal gas composition caused by an on-off type feedback control of the spiracles.

The p_{CO2}/p_{O2} phase space consists of 2 distinct regions corresponding to fully open resp. closed spiracles. The boundary between the regions is bilinear. For small p_{CO2} values an oxygen partial pressure of approximately 1-2 kPa marks the trigger for spiracle opening. This terminal p_{O2} is positively correlated with carbon dioxide partial pressure. p_{CO2} values above 2.5 kPa resulted in spiracle opening regardless of the oxygen content of the tracheal air.

The bilinear nature of the regions boundary provides support to the emergent property hypothesis, which postulates discontinuous gas exchange as the result of two coupled feedback control systems.

Development of sex pheromones for management of cocoa mirids in West Africa

Joseph Sarfo[1], David Hall[2], Colin Campbell[2]

[1]Cocoa Research Institute of Ghana, New Tafo, Ghana, [2]Natural Resources Institute, Chatham Maritime, Kent, United Kingdom

Introduction: Approximately 70% of the world's cocoa comes from West Africa. Recent studies indicate that 25-30 % of cocoa in Ghana has significant mirid damage, the main species being *Sahlbergella singularis* and *Distantiella theobromae.* The mirids damage pods and attack young stems and branches with an annual crop loss estimated at 100,000 tonnes. Currently mirid control relies heavily on the use of insecticides, especially older, more toxic compounds, and the potential for use of pheromones and biopesticides in management of these pests is being explored. Two sex pheromone components produced by females were identified and blends of these shown to attract males of both species.

Methods: The pheromone components were synthesised on large scale by a two-step process at NRI. Experiments to optimise the pheromone lure and trap design and to develop the traps for monitoring and control by mass trapping are being carried out on-station and in growers' farms in Ghana.

Results: Experiments to optimise the pheromone lure and trap design have highlighted the difficulties in working with these pests because of their highly aggregated distribution. Both pheromone components are required for attraction of the main species, *S. singularis*, but the exact blend does not seem to be critical. Both sticky and water traps are effective and small-scale trials have shown an apparent effect on mirid populations at 150 traps/ha. A replicated trial is in progress to determine the effect of mass trapping on mirid damage.

Conclusions: Pheromone traps show promise for monitoring and control of the main cocoa mirid species in West Africa.

Molecular detection of predation: opportunities and challenges

William O.C. Symondson

Cardiff University, Cardiff, Wales, United Kingdom

Predator-prey interactions are fundamental to our understanding of invertebrate community dynamics. Whether we are interested in food webs, control of crop pests by natural enemies or the conservation of endangered species, an understanding of the mechanistic links driving change in populations, and of the many factors affecting prey choice by generalist predators, is of great value.

There is a long tradition of molecular analyses to determine the diets of insects using enzyme electrophoresis, polyclonal antisera and monoclonal antibodies. However, since 1999 this field has experienced a quantum leap forward with the utilisation of PCR-based analyses. It has now been clearly demonstrated that prey DNA can still be detected in the guts of arthropod predators after many hours (even days) of digestion. The precision and speed with which new DNA primers can be designed is leading inexorably to the extinction of earlier technologies. We can now simultaneously detect a broad range of different prey in the guts of predators using multiplexing with a library of prey-specific primers. As sequences databases expand, and primer information is published, this process is becoming ever simpler and more rapid. Great challenges lie ahead. How can predation rates using different primers, in the same or different predators, be compared? Can qPCR be used effectively to improve estimates of predation rates? Can new technologies (microarrays, pyrosequencing) help us? The important message is that these molecular techniques are simply tools; as entomologists and ecologists we now need to start using them to address exciting new questions.

Genomic analyses of behavior in *Polistes* wasps: Insights into social evolution

Amy L. Toth, Gene E. Robinson

University of Illinois, Urbana-Champaign, IL, United States

Genomic studies can provide a wealth of information for testing long-standing evolutionary hypotheses. We used 454 pyrosequencing to generate an EST (expressed sequence tag) set for the paper wasp *Polistes metricus*, a non-model genetic organism which is an important species for the study of social evolution. Using this genomic resource, we performed two studies of brain gene expression in *P. metricus*. First, quantitative PCR analyses of genes previously known to be associated with honey bee division of labor showed large expression differences between wasp queens, workers, maternal founding females, and future reproductive gynes. Expression patterns were most similar between workers and maternal females, supporting the idea that worker behavior evolved from maternal behavior. Second, we used the EST sequence data to develop *P. metricus* microarrays representing over 3000 different genes. We will present the results of ongoing brain microarray analyses comparing wasps in different behavioral castes. This study will allow us to identify major pathways and networks associated with wasp social behavior, and via comparison to honey bee transcriptomic data, to highlight conserved pathways underlying division of labor across multiple social insect lineages.

Changes in plant attributes: a possible cause for alterations in insect host-plant selection in laboratory host-specificity tests

Tsedal Ghebremariam[1], Kerstin Krüger[1], Carl Reinhardt[2], Arne Witt[3], Stefan Neser[3]

[1]Dept. of Zoology & Entomology, University of Pretoria, Pretoria, South Africa, [2]Department of Plant Production & Soil Science, University of Pretoria, Pretoria, South Africa, [3]ARC-Plant Protection Research Institute, Pretoria, South Africa

Introduction: The biocontrol programme against *Solanum mauritianum* (Solanaceae), an invasive alien weed from South America, has been hampered by unexpected host-plant selection behaviour of candidate insect biocontrol agents during quarantine laboratory evaluations, which is in conflict with the narrow host ranges observed in the native range of potential agents. It is suggested that changes in plant attributes are causing these differences.

Methods: The morphology and chemistry of four *Solanum* species (*S. lichtensteinii* (natural host)*, S. mauritianum, S. tuberosum* and *S. melongena*) grown in open air and under controlled environments (glasshouse, growth chamber and shade-net) were examined using microscopy, elemental analysis, reaction with stains and reagents, and other techniques. Multiple-choice trials with plants grown under different conditions was undertaken to compare host-plant choice by a native South African beetle (*Conchyloctenia hybrida* Boheman (Coleoptera: Chrysomelidae)) reared on its natural host plant, *S. panduriforme*.

Results: Considerable differences in the morphology and chemistry of plants grown in open-air and controlled environments were found in terms of plant height, leaf area, leaf thickness, cell-wall and cuticle thickness, trichome density, phenol-containing glands, CaCo3 cystoliths, silica, alkaloid and glycoside content. In line with this, multiple choice trials identified differences in feeding and oviposition behaviour between plants grown under different growth conditions.

Conclusions: Morphological and chemical differences between plants grown under controlled conditions and in the field may contribute to the alteration in host selection patterns of insect herbivores under laboratory vs. field conditions.

Plant-animal mutualistic networks: The architecture of biodiversity

Jordi Bascompte

Estación Biológica de Doñana, Sevilla, Spain

The mutualistic interactions between plants and their insect pollinators have molded the organization of Earths's biodiversity. Recently, it has been shown that these interactions can form complex networks involving dozens and even hundreds of species. These coevolutionary networks are highly heterogeneous, nested, and asymmetric**.** Some Hymenoptera and Diptera species act as network hubs and have an important role as the glue that keeps these networks together. These network patterns highly determine the robustness of the network to species extinctions or habitat destruction. I will follow by exploring to what extend past evolutionary history conveyed in the phylogenies of plants and insects can explain these network patterns and the robustness of the network to species extinctions. Because pylogenetically similar species tend to play similar roles in the network, extinction events trigger non-random coextinction cascades. This implies that taxonomic diversity is lost faster than expected if there was no relationship between phylogeny and network structure. These results illustrate how the simultaneous consideration of phylogenetic information and network structure can aid in the conservation of biodiversity.

Groundnut leafminer, *Aproaerema modicella* (Deventer) (Lepidoptera: Gelechiidae), a pest of groundnuts in South Africa

Hannalene du Plessis

ARC - Grain Crops Institute, Potchefstroom, South Africa

Introduction: The groundnut leafminer (GLM), *Aproaerema modicella* is an important pest of groundnut and soybean in South and South-east Asia. Since 1998, it has been reported from Uganda, Malawi, Mozambique and also South Africa. Since it is a new pest in this country and no integrated pest management programme (IPM) exists for this insect, it was, therefore, investigated.

Methods: Moth flight activity was monitored with pheromone traps at four localities over a period of two years. The efficacy of different insecticides for control of GLM on groundnut was evaluated as none is currently registered for this purpose in South Africa. To determine host plants of GLM, weed species with GLM infestations were collected inside and around groundnut fields at Tsiombo irrigation scheme. Parasitoids reared from GLM infested soybean and groundnut leaves (larvae and pupae) from one and four localities respectively, were identified.

Results: Flight activity patterns corresponded with the productive phase of groundnut. Differences in efficacy of insecticides for the control of GLM were determined. Eleven weed species infested with GLM were collected. Nine possible biological control agents of GLM were sampled from GLM larvae and pupae.

Conclusions: Timing of planting will largely affect both the severity and onset of GLM infestation, irrespective of locality. For effective chemical control of GLM, a high volume of water is essential for more efficient covering of plants. Host status of plants identified and the role it could play during the off-season survival of the pest still needs verification. Key components for an IPM strategy for GLM in South Africa were identified by this research. The next challenge is to put all these together in a sustainable and economical pest-control strategy.

G protein-coupled receptors and their signaling properties in flies and locusts

Jozef Vanden Broeck, Tom Van Loy, Heleen Verlinden, Boris Van Hiel, Hans Peter Vandersmissen, Pieter Van Wielendaele, Jeroen Poels

Animal Physiology and Neurobiology, Leuven, Belgium

For the analysis of insect G protein-coupled receptors (GPCRs), the *Drosophila* genome project represented a major breakthrough. Since then, the genomes of several other insect species, such as the malaria mosquito, *Anopheles gambiae*, the honeybee, *Apis mellifera*, the silkworm, *Bombyx mori*, and the red flour beetle, *Tribolium castaneum*, most of which are of economic (positive or negative) or medical value, have been sequenced; and more sequence information is becoming available from novel genome and EST data. Some insect receptors are even believed to be potential targets for pest control agents. *In silico* analyses revealed the presence of a few hundred genes coding for putative heptahelical transmembrane (7TM) proteins in these insect genomes. These can be classified into at least four distinct evolutionary conserved families. Insect genomes also encode a multitude of putative neuropeptide and peptide hormone precursor genes. In addition, an important fraction of the insect GPCRs shows sequence similarities with mammalian peptide receptors. Many of these receptors have been deorphanized in recent years, while others still remain orphans. *In vitro* (*e.g.* cell-based assays, reverse pharmacology) as well as *in vivo* (*e.g.* analysis of fruit fly mutants) approaches will further contribute to the discovery of specific receptor ligands and to the elucidation of insect GPCR signaling function(s), respectively. We will further discuss results we have obtained with fly and locust GPCRs.

Biogeography of the Tachinidae (Diptera) of China

James O'Hara, Hiroshi Shima, Chun-tian Zhang

[1]Invertebrate Biodiversity, Agriculture and Agri-Food Canada,, Ottawa, Ontario, Canada, [2]2-11-1-406 Kusagae, Chuo-ku, Fukuoka, Kyushu, Japan, [3]Liaoning Key Laboratory of Evolution and Biodiversity, Shenyang Normal University, Shenyang, Liaoning, China

The Tachinidae are a huge and cosmopolitan family of parasitic flies with an estimated 10,000 described species. There are believed to be thousands more undescribed species, mostly in the understudied Neotropical, Afrotropical, Australasian and Oriental regions. Within these understudied regions, tachinid research is progressing most rapidly in China. This vast country is uniquely positioned at the transition between the Palearctic and Oriental regions. We have reviewed all the primary literature and nearly all the regional faunal studies on the Tachinidae of China to catalogue the species and record their known distributions by province. The *Flies of China* (1998) documented a tachinid fauna of 754 species and 191 genera, but now ten years later those numbers have climbed to roughly 1100 species and 260 genera. The tachinid fauna of China consists of a mix of Palearctic and Oriental species, with the former dominating in the northern half and west of the country and the latter dominating in the south and southeast. There is also an endemic fauna comprising species of both limited and widespread distribution within China. The level of endemicity within China is currently 37% of the tachinid fauna but this level will undoubtedly decrease as more species described from China are discovered outside the country. Patterns of distribution, areas of endemicity, and the boundary between the Oriental and Palearctic regions are discussed in relation to earth history, the age of the Tachinidae, and the landforms and ecoregions of China.

Variation in induced plant responses and parasitoid foraging behaviour

Tibor Bukovinszky, Erik Poelman, Georgios Prekatsakis, Andre Kamp, Marcel Dicke

Laboratory of Entomology, Wageningen University, Wageningen, The Netherlands

Introduction: Trophic relationships between species can be indirectly mediated by other species, with consequences for species coexistence. Host-induced plant volatiles may aid parasitoids in host location, but indiscriminate use of host and non-host induced volatiles in a diverse community can reduce foraging efficiency. The behavioral mechanisms underlying parasitoid foraging efficiency when herbivore-related cues and plant volatiles are varied are poorly understood.

Methods: Parasitism rates were compared in a semi-field set-up, where parasitoids (*Cotesia glomerata*) were presented with a plot of plants that were (1) only infested by hosts (*Pieris rapae*), or also non-hosts (*Mamestra brassicae*) were placed (2) either on plants with the hosts, or (3) on plants next to host-infested plants. We studied parasitoid foraging behavior in a greenhouse bioassay, where the composition and density of hosts and non-hosts on plants were varied.

Results: When non-hosts were present on the same or on different plants as hosts, parasitism rates were lower than when only hosts were present. In bioassays parasitoids flew indiscriminately towards host and non-host infested plants. Upon encountering a non-host patch, parasitoids readily discriminated and left shortly. However, in mixed patches of hosts and non-hosts, parasitoids could not discriminate and left later.

Conclusions: Variation in induced plant responses may reduce parasitism, depending on whether long distance (infochemical) or short distance (patch related) cues are scrambled. This affects time-allocation of parasitoids in different ways with implications for the spatial distribution of attacks.

Forecasting tools for the management of the grapevine moth *Lobesia botrana* (Lepidptera, Tortricidae) in SW Spanish vineyards.

Antonio Gallardo Cano[1], Lara Maistrello[2], Rafael Ocete Rubio[1], M. Angeles Lopez Martinez[1], Francisco Javier Soria Iglesias[1]

[1]Laboratory of Applied Zoology, Department of Physiology and Zoology, Faculty of Biology, University of Seville, Seville, Spain, [2]Department of Agricultural & Food Sciences, University of Modena and Reggio Emilia, Reggio Emilia, Italy

Introduction: The European grapevine moth, *Lobesia botrana* (Denis & Schiffermüller) (Lepidoptera, Tortricidae), represents the main pest of vineyards in the Mediterranean area. The highest population levels and heaviest economic damages are recorded in areas with annual average temperature and relative humidity around 20ºC and 70%, respectively, which are the best eco-climatic conditions for this insect.

Methods: This study was developed during 12 years in the South West of Spain. Male flights of *L. botrana* were monitored using synthetic sex pheromone baited delta traps from the beginning of March to the end of October, checking all traps once a week. In order to achieve a reliable prediction model, data from temperature accumulations (degree-days) were plotted against conveniently transformed data from males captures.

Results: Correlation coefficients obtained from log-probit linear equations were high, especially for data related to the second generation. Results showed the existence of a linear relationship between temperature accumulations and male trap catches. Moreover, average linear regressions were calculated for the second and third generations and the obtained correlation coefficients were similar for both.

Conclusions: Obtained equations have shown to be acceptable in order to be considered as useful tools in the prediction of emergencies and in the future design of models to improve the effectiveness of the integrated management of *Lobesia botrana* in the studied area.

Link between the circadian clock and metabolism in *Drosophila melanogaster*

Kanyan Xu, Xiangzhong Zheng, Amita Sehgal

Howard Hughes Medical Institute, University of Pennsylvania School of Medicine, Philadelphia, PA, United States

Studies in mammals have indicated a relationship between circadian clocks and nutrient metabolism, but little is known about how circadian effects on metabolism impact overall physiology and behavior. Circadian regulation of metabolism has not been investigated in *Drosophila* although clock proteins are expressed in many metabolically important tissues in the fly, including the fat body. We have found that *Drosophila* feeding behavior exhibits a strong 24-hour circadian rhythm which is regulated by a clock in the fat body.. Flies lacking a fat body clock also display increased food consumption, but have decreased levels of energy stores, accompanied by a higher sensitivity to starvation, indicating that the clock in the fat body is required for the storage of energy reserves. At least some of these metabolic phenotypes may be mediated by effects of clock proteins on the expression of specific metabolic genes. Interestingly, the metabolic parameters mentioned above are also affected by clocks in neuronal cells but the effects of neuronal clocks oppose those of the fat body. We propose that the input of neuronal clocks and clocks in metabolic tissues is coordinated to provide effective energy homeostasis.

We have also identified effects of metabolic activity on the central clock that controls behavior. We previously showed that oxidative stress dampens molecular and behavioral rhythms driven by central clock cells, an effect that is manifest in flies lacking the *foxo* gene product. In recent work we have identified effects of other metabolic pathways on the periodicity and light response of behavioral rhythms.

Serotonin receptors in the control of circadian rhythms and sleep in *Drosophila*

Quan Yuan, Amanda Crocker, Amita Sehgal

Howard Hughes Medical Institute, University of Pennsylvania School of Medicine, Philadelphia, PA, United States

Despite the well-known role of monoamines in behavioral processes in mammals, there is limited information on how these molecules impact behavior in Drosophila. In part, this is because the basic characterization of Drosophila monoamines and their receptors has been relatively under-studied. We have identified effects of serotonin on both circadian rhythms and sleep in Drosophila. We find that serotonin modulates the light response of the circadian clock, thereby decreasing the ability of the clock to respond to light under normal day:night conditions. The mechanism underlying this effect involves the d5-HT1B receptor, which promotes the phosphorylation and thereby decreases the activity of GSK3-β. This leads to reduced phosphorylation of the clock protein TIM by GSK3-β and a decrease in the TIM response to light. In extended darkness, levels of serotonin are low in the fly head, which may account for increased light sensitivity under these conditions.

In other work, we found that serotonin acts through the d5-HT1A receptor to promote sleep in flies. In the absence of this receptor, flies have reduced sleep, but more strikingly, the sleep is fragmented. The mutant phenotype is rescued by driving expression of the receptor in mushroom bodies, supporting a role for this structure in Drosophila sleep. Interestingly, although the d5-HT1A and 1B receptors are quite similar, d5-HT1B can not substitute for 1A in rescue experiments. More recently we have also initiated studies of octopamine and octopamine receptors in the regulation of sleep in Drosophila.

Leafminer insects trigger the host plant physiology through an unexpected association with endosymbiotic bacteria

Wilfried Kaiser[1], Elisabeth Huguet[1], Nadine Imbault[2], Jérôme Casas[1], David Giron[1]

[1]CNRS - University of Tours, Tours, France, [2]University of Tours, Tours, France

Introduction: Gall-inducer arthropods are usually distinguished from other insect-generated shelters by the fact that they involve active differentiation of highly nutritive tissues. However, plant manipulation appears not to be restricted to gall-inducers only, as shown by the autumnal formation of 'green-islands' around mining caterpillars. This study aims at understanding the underlying mechanisms of the host-plant physiological manipulation.

Methods: Using ELISA assays and colorimetric techniques the amount of phytohormones and nutrients in mined areas were recorded. Isopentenyl transferase gene expression (key enzyme of the cytokinin biosynthetic pathway) was investigated using RT-PCR and the role played by endosymbionts was studied using antibiotic treatments.

Results: Our results show a large accumulation of cytokinins in the mined tissues which are responsible for the preservation of functional nutrient-rich green tissues at a time when leaves are otherwise turning yellow. All individuals analyzed so far are closely associated with *Wolbachia* and a key enzyme of the cytokinin biosynthetic pathway has been isolated, cloned and sequenced from the *Wolbachia* genome (tRNA-ipt Wo). This key enzyme is expressed in *Wolbachia*-infected insects leading to a clear alteration of the plant physiology. A manipulative study allowed us to show that insects cured of endosymbionts are not able to influence the host plant physiology showing the pivotal role played by endosymbionts in the host plant manipulation.

Conclusions: These results clearly show the ability of leafminer insects to manipulate their host plant physiology and to create an "optimal" nutritional micro-environment through cytokinin production by their endosymbiotic partners.

Phylogenetic analysis of Encyrtidae (Hymenoptera: Chalcidoidea): Are there un-concerted copies of 28S rDNA in Hymenoptera?

James B. Woolley[1], John S. Noyes[2], Donald Quicke[3], Joe Gillespie[4], Matt Yoder[5]

[1]Texas A&M University, College Station, Texas, United States, [2]Natural History Museum, London, United Kingdom, [3]Imperial College, Silwood Park, Ascot, United Kingdom, [4]University of Maryland, Baltimore, Maryland, United States, [5]Ohio State University, Columbus, Ohio, United States

Phylogenetic Analysis: D2 and D3 expansion segments of 28S ribosomal DNA were sequenced for 110 species in 69 genera of Encyrtidae and 11 outgroups from Tanaostigmatidae, Eupelmidae, Aphelinidae, Pteromalidae and Eulophidae. Data were partitioned into stem regions in which alignment was unambiguous due to base pair covariation, and loop regions, in which alignment was ambiguous. Data were also aligned using CLUSTAL. Data from both alignments were analyzed using parsimony and Bayesian methods, and POY in which optimization alignment and parsimony analyses were performed together. Results support monophyly of Encyrtidae, but not a sister group relationship to Tanaostigmatidae. Neither Encyrtinae nor Tetracneminae are consistently recovered as monophyletic, although some tribes are recovered as monophyletic under all analytical conditions. Other tribes are recovered under some conditions only or are either paraphyletic or polyphyletic.

Broader Significance: Of more general significance, results suggest the presence of two different, un-concerted copies of rDNA in Chalcidoidea. This was first apparent as a short insertion in the D2 region in sequences published by Heraty's lab not present in sequences from Quicke's lab. When analysis is restricted to unambiguously aligned regions only (mostly stems), sequences from congeneric species both with and without the insertion are grouped together. When regions of ambiguous alignment are included (for example using CLUSTAL), sequences with the insertion are not grouped with congeneric species without the insertion, indicating considerable sequence divergence between the two copies in the structurally less conserved loop regions. Thus, methods for sequence alignment are of paramount importance in data analysis.

Road-building and use in the western Amazon Basin, Part 1: Impacting the rainforest and its entomofauna, or not?

Terry L. Erwin[1], Christy Jo Geraci[1], Valeria Aschero[2]

[1]Smithsonian Institution, Washington, DC, United States, [2]Instituto Argentino de Investigaciones en Zonas Aŕidas, Mendoza, Argentina

Introduction: In the western Amazon Basin, oil deposits support local and regional economies, but certain methods of extraction can be harsh on the rainforest ecosystem and its fauna. We present data from the Ecuador Canopy Biodiversity Project (ECBP), a long-term study presently underway in an area of Yasuni National Park (Ecuador) that has been impacted by road construction for oil extraction. We compare data taken from impacted and control sites to examine the effects of road construction and use on canopy insect biodiversity.

Methods: Samples of the entomofauna were taken using standard canopy fogging protocols. Two macroplots of 1 km in length were established: one adjacent to the road, and one 21 km away. One-hundred sampling stations arrayed in 10 plots in each macroplot were each sampled 12 times over a period of 4 years. We examined changes in the abundances of target taxa across seasons and years, and compared data from the impact versus the control sites.

Results and Conclusions: Nearly 10 million specimens were collected, of which 3.8 million belonged to our target taxa. Each hectare of pristine Amazonian rainforest contains up to 3.2 x 10^{10} individuals of terrestrial arthropods representing some 100,000+ species. Relative abundances and adult-immature ratios did not significantly change over the course of the study (ANOVA: $F=0.39$, $P>0.05$). Our results suggest that management practices followed by oil extractors and road-building did not affect canopy entomofauna during the study period. Further research and monitoring will be needed to assure that this ecosystem will remain healthy and diverse.

Development of Spinetoram: A new spinosyn insecticide from Dow AgroSciences

Aris Chloridis, Paul Downard, James Dripps, Katsuya Kaneshi, Leng Choy Lee, Yi-Ki Min, Luis Pavan

Dow AgroSciences, Indianapolis, United States

Spinetoram (XDE-175) is a new spinosyn insecticide being developed by Dow AgroSciences. It is derived from two naturally occurring spinosyns that are chemically modified to increase insecticidal activity and duration of control. Spinetoram offers a unique mode of action and is effective against a broad spectrum of insect pests. It controls key top fruit and vine pests such as codling moth, *Cydia (Carpocapsa) pomonella*; oriental fruit moth, *Grapholita molesta*; pear psyllids, *Psylla (Cacopsylla*) spp; and grape berry moth, *Lobesia botrana*. In vegetable crops, spinetoram controls *Spodoptera* spp. and most other pest Lepidoptera. Spinetoram is also highly effective against thrips, (*Frankliniella* spp., *Thrips* spp., *Scirtothrips* spp.), dipterous leafminers (*Liriomyza* spp.) and certain coleopterans (*Leptinotarsa decemlineata*). Spinetoram conserves most beneficial arthropods in vegetables and tree fruits, and will be an effective and compatible control option for integrated pest management programs. In addition to fruits and vegetables, use in a number of other crops is being explored. Spinetoram was accepted for evaluation by US EPA under its reduced risk pesticide initiative and was granted US federal registration in October 2007. It is being marketed as Delegate WG (250 gai/kg) and Radiant SC (120 gai/L). It is also registered in Canada, New Zealand and in Pakistan for use in crops such as pome fruit, vegetables, and cotton. In EU, spinetoram is currently under evaluation for annex I inclusion. More registrations in other parts of the world are being pursued and anticipated from 2008 onwards.

Synomones induced by egg deposition in herbaceous plants.

Stefano Colazza[1], Ezio Peri[1], Eric Conti[2], Gianandrea Salerno[2], Ferdinando Bin[2]

[1]Department S.EN.FI.MI.ZO, Università di Palermo, Palermo, Sicilia, Italy, [2]Department of DSAA – Section of Entomology, Università di Perugia, Perugia, Umbria, Italy

The knowledge of the mechanisms of communication between plants, herbivores and parasitoids, mediated by volatile infochemicals, can provide more insights into the co-evolution of these tri-trophic systems. Recently, it has been demonstrated that egg parasitoids are able to detect plant synomones induced by egg deposition, indicating that these synomones are used to locate host eggs. Such "early alert" communication has been evidenced both in trees and in herbaceous plants. Relative to herbaceous plants, detailed evidences for defensive plant responses to oviposition, directed towards egg parasitoids, are available for the tri-trophic systems "bean plants – *Nezara viridula* – *Trissolcus basalis*" (bean system), "cabbage plants – *Murgantia histrionica* – *Trissolcus brochymenae*" (cabbage system) and "corn plants - *Sesamia nonagrioides* - *Telenomus busseolae*" (corn system). The bean system and the cabbage system present several analogies on the phenomenon of induction itself, its mechanisms, and its chemistry. However, females of *T. basalis* are able to perceive oviposition plant synomones as volatile compounds from a long/medium range, whereas *T. brochymenae* only after they have contacted the plant surface. The corn system shows more distinctive mechanisms, but it is also characterized by the emission of synomones that act on contact. The different strategies adopted by the egg parasitoids to explore these induced synomones are discussed, with respect to the possible manipulation of adult parasitoid behaviour, aiming at the enhancement of pest control, and to their implications for host selection by egg parasitoids.

Ancestral reconstruction of ancient insect allatostatins: a novel approach to the study of allatostatin function and evolution

Ekatarina Hult, C.J. Weadick, Belinda S.W. Chang, Stephen Tobe

University of Toronto, Toronto ON, Canada

Allatostatins (ASTs) are a class of regulatory neuropeptides, with diverse functions, found in an array of invertebrate phyla. ASTs have complex gene structure, in which individual ASTs are cleaved from a precursor peptide sequence. Little is known about the molecular evolution of AST peptides and functions, even in extensively studied groups such as cockroaches. We describe the application of a novel technique for the analysis of this system, using ancestral reconstruction, whereby ancestral amino acid sequences are resurrected in the laboratory. We inferred the ancestral sequences of a well-characterized peptide, AST7 at the insect ancestor and several cockroach ancestors. Peptides were assayed for *in vitro* inhibition of JH production in *Diploptera punctata* and *Periplaneta americana*. Our results, surprisingly, indicate that the ancestral insect peptide was a more potent inhibitor of JH production compared to ancient cockroach peptides in both species and peptides inferred at more recent cockroach ancestors had increased potency. We believe this decrease in potency at the cockroach ancestor is related to the increased copy number of peptide in these lineages. This model is supported by current physiological data and maybe linked to the increased role of ASTs in the regulation of reproductive processes in the cockroaches.

Does asymmetric specialization differ between mutualistic and trophic networks?

Colin Fontaine, Elisa Thebault

Center for Population Biology, Imperial College, London, United Kingdom

Introduction: Recently, plant-pollinator networks have been found to be highly structured in a nested pattern in which specialists interact with generalist species. This structure is often assumed to be particular to mutualistic interactions in opposition to the compartmentalized pattern expected for antagonistic networks.

Methods: We investigated the presence of asymmetric specialization in a data set assembled from the literature of 20 highly resolved plant-insect herbivore networks and compared them with 24 plant-pollinator networks.

Results: Our results indicate that these two types of networks differ, but not in the way it is generally assumed. Asymmetric specialization is present in plant-herbivore networks even if it appears less frequently than in plant-pollinator networks. Indeed, mean and median percentages of species showing asymmetric specialisation in herbivory webs are 33% and 14% respectively, compared to 57% and 60% in pollination webs. Furthermore, the amount of asymmetry is linked with species diversity and not to connectance in plant-pollinator networks whereas the opposite pattern is found in plant-herbivore networks.

Conclusion: Our results offer promising perspectives for understanding both the mechanisms that structure ecological communities and their impact on community dynamics depending on the type of interaction.

The role of juvenile hormone in parental care by burying beetles: A comparative perspective

Michelle Scott

University of New Hampshire, Durham, NH, United States

Introduction: Burying beetles (*Nicrophorus* spp.) provide lengthy biparental care. They bury and prepare small vertebrate carcasses as food for their young. Juvenile hormone (JH) in both males and females rises quickly upon the discovery of a suitable carcass and reaches high titers in females when larval care is most intense (e.g. *N. orbicollis* and *N. defodiens*).

The role of juvenile hormone: JH does not act primarily as a gonadotropin in burying beetles. It may regulate some parental behavior; it increases aggression directed toward conspecific competitors, and, in young larvae, appears to be correlated with begging intensity. Conversely, social stimuli affect JH titers. Males respond to the loss of a mate with increased JH and increased feeding behavior. JH of males caring for larger broods is higher than those with smaller broods. Both females and males respond physiologically to the intensity of larval begging.

Comparative endocrinology: In other carrion beetles, this hormone pattern varies and depends on life history. *Necrophila americana*, a species that uses large carcasses and provides no parental care, has no such hormonal response to the discovery of a carcass. *Ptomascopus morio*, a nicrophorine beetle, remain with their brood but provides only rudimentary care and has only a weak endocrine response to the arrival of larvae. *Nicrophorus pustulatus*, utilizes snake eggs as well as carcasses to provision their young and this host shift is reflected in JH titers. In burying beetles, the most dramatic changes in JH correlate with the most elaborate parental care.

Unusual challenges, unusual rewards: Introduction of insect-protected biotech cotton in Burkina Faso, West Africa

John Greenplate

Monsanto Company, St. Louis, Missouri, United States

Since 2003, Monsanto has been working with the government of Burkina Faso to assess the potential value of transgenic insect control technology in cotton, the country's leading export crop (>50% of export dollars), and its leading industry in terms of employment. Five years of confined field trials have determined that the technology can raise grower profits substantially, largely by increasing yields and saving caterpillar insecticide input costs. The road to commercial release of biotech cotton has been challenging, due mainly to the lack of enabling regulatory structures to assess, approve, and market biotechnology products. This presentation will describe the many partnerships forged and their efforts to build a robust regulatory framework to ensure grower access to the benefits of biotech cotton and to future safe, effective biotech products.

Augmentative biological control of sugarcane moth borers with *Cotesia flavipes* (Cameron) (Hymenoptera: Braconidae) in Thailand

Wiwat Suasaard, Kittiya Suksen, Oraphan Kernasa

[1]National Biological Control Research Center, Centsl Regional Center, Nakhon Pathom, Thailand, [2]Department of Entomology, Faculty of Agriculture at Kamphaeng Saen Kasetsart University, Kamphaeng Saen Campus, Nakhon Pathom, Thailand

Introduction: Investigation on biological control of sugarcane moth borers *Chilo infuscatellus* Snellen, *Chilo sacchariphagous* (Bojer), *Chilo tumidicostalis* Hampson and *Sesamia inferens* (Walker) with *Cotesia flavipes* (Cameron) was conducted in the central region of Thailand.

Methods: *Cotesia flavipes* were mass-reared at NBCRC-CRC. Augmentative field releases of *C. flavipes* (1000 per hectare) were made every month during 2003-2005 in Nakhon Pathom,Suphan Buri and Kanchanaburi provinces where were located in the central region of Thailand. Higher augmentative release rate (2000 per hectare) were made during 2006-2007 in the areas of heavy infestation occurred in Suphan Buri.

Results: Percent parasitization of sugarcane moth borers was higher in plots of cane where parasites were released than in plots of cane where parasites were not released in every year and every location. Overall parasitization averaged 18.33±8.42 and 4.4±3.12% in release plots and in non-release plots and overall percent infestation averaged 9.11±4.32 and 18.97±5.48 in release and non-released plots respectively during 2003-2005,. The infestation of sugarcane moth borers both in release and non-release plots was very high (23.98±13.61 and 42.98±6.73%) while percent parasitization was only 14.85±12.38 and 4.15±1.20 in release and non release plots during 2006-2007.

Conclusions: Augmentative release boosted biological control but the levels achieved were insufficient for reducing infestation of damage when heavy infestation occurred. Higher levels of control might be possible using higher release rate. This indicated that *C.flavipes* should be a key component in IPM program for sugarcane moth borers.

Heredity and fitness cost of resistance to granulosis virus in French populations of *Cydia pomonella*

Benoit Sauphanor, Marie Berling, Lionel Legros, Miguel Lopez Ferber, Antoine Bonhomme, Joel Chadoeuf

INRA, Avignon, France

Background: Control failures of the codling moth, *Cydia pomonella* , with the *Cydia pomonella* Granulovirus (CpGV) were recorded since 2004 in a few orchards of South-eastern and Centre France. Diapausing larvae of ten field populations were collected in these areas to be assessed in the laboratory for susceptibility to CpGV.

Results: Neonates of individual progenies of adult moths of these populations paired with a moth of a susceptible laboratory strain (Sv) were submitted to a diagnostic concentration of the virus, lethal for 95% of the Sv larvae. Over 90% survival was recorded in a part of individual progenies of field males paired with Sv females, while all individual progenies of field females paired with Sv males had only partial survival. The mortality distribution among these F1 progenies supported the hypothesis of a dominant and sex-linked resistance already demonstrated in German populations of *C pomonella*. Half of the ten analyzed French populations were proved to own a majority of resistant individuals. Inside each population, the resistant and susceptible moths did not significantly differ in weight, longevity, rate and numbers of mating, fecundity and fertility.

Conclusion: Due to its low reproductive cost, this resistance to CpGV is likely to be stable in time and also to spread easily out of the orchards under selection with virus formulations. Special attention has thus to be turned to resistance management strategies in organic orchards, in which CpGV is the only efficient way to control of the high *C pomonella* populations of southern Europe.

Cospeciation in the triplex symbiosis of termites, gut protists, and their bacterial endosymbionts

Osamu Kitade

Ibaraki Unibersity, Mito, Ibaraki, Japan

Introduction: A number of co-phylogenetic relationships between two organisms namely a host and a symbiont or parasite have been studied to date. However, biological interactions in nature usually involve multiple members. We investigated the cospeciation of a triplex symbiotic system comprising a hierarchy of three organisms - termites of the family Rhinotermitidae, cellulolytic protists of the genus *Pseudotrichonympha* in the guts of these termites, and intracellular bacterial symbionts of the protists.

Methods: The phylogeny was inferred based on two mitochondrial genes of the termites and nuclear ssu rRNA genes of the protists and their endosymbionts, and these were compared.

Results and Discussion: Although intestinal microorganisms are generally considered to have looser associations with the host than intracellular symbionts, the *Pseudotrichonympha* protists showed almost complete codivergence with the host termites, probably due to strict transmissions by proctodeal trophallaxis based on the social behavior of the termites. Except for one case, the endosymbiotic bacteria of the protists formed a monophyletic lineage in the order Bacteroidales, and the branching pattern was alsmost identical to those of the protists and the termites. However some non-codivergent evolutionary events were evident. The members of this triplex symbiotic system appear to have cospeciated during their evolution with minor exceptions.

Cospeciation in the triplex symbiosis of termites, gut protists, and their bacterial endosymbionts

Osamu Kitade

Ibaraki Unibersity, Mito, Ibaraki, Japan

Introduction: A number of co-phylogenetic relationships between two organisms namely a host and a symbiont or parasite have been studied to date. However, biological interactions in nature usually involve multiple members. We investigated the cospeciation of a triplex symbiotic system comprising a hierarchy of three organisms - ternites of the family Rhinotermitidae, cellulolytic protists of the genus *Pseudotrichonympha* in the guts of these termites, and intracellular bacterial symbionts of the protists.

Methods: The phylogeny was inferred based on two mitochondrial genes of the termites and nuclear ssu rRNA genes of the protists and their endosymbionts, and these were compared.

Results and Discussion: Although intestinal microorganisms are generally considered to have looser associations with the host than intracellular symbionts, the *Pseudotrichonympha* protists showed almost complete codivergence with the host termites, probably due to strict transmissions by proctodeal trophallaxis based on the social behavior of the termites. Except for one case, the endosymbiotic bacteria of the protists formed a monophyletic lineage in the order Bacteroidales, and the branching pattern was alsmost identical to those of the protists and the termites. However some non-codivergent evolutionary events were evident. The members of this triplex symbiotic system appear to have cospeciated during their evolution with minor exceptions.

Homology of the wing base sclerites and flight muscles of basal Pterygota

Jana Willkommen[2], Thomas Hoernschemeyer[1]

[1]Georg-August-University, Goettingen, Germany, [2]Staatliches Museum für Naturkunde, Stuttgart, Germany

Presently, there is no generally accepted hypothesis about the evolution of the different forms of the flight systems of Ephemeroptera, Odonata and Neoptera from a common winged ancestor. Usually, Ephemeroptera are regarded as the sistergroup of the remaining Pterygota, because they are the only insects moulting in a winged stage.

In this context we examined the flight apparatus of Ephemeroptera and compared it with those of Odonata and Neoptera. To be able to study as many species as possible, we supplemented dissections and serial sectioning with high resolution X-ray tomography. Finally, the ground plan of the wing base of Pterygota is reconstructed.

Our results show that most elements of the neopteran wing base are also present in Ephemeroptera and Odonata. Probably, the ground plan of the wing base of Pterygota was much more similar to the wing base of extant Neoptera than to that of extant Ephemeroptera. In the ground plan of Pterygota the wing base presumably is composed of three axillaries and the proximal median plate. Two muscles are attached to the first axillary and the third axillary is equipped with one short muscle. A most likely autapomorphic character of Neoptera is a second muscle that inserts on the third axillary and originates from the episternum. Consequently, the wing bases of Ephemeroptera and Odonata must be modified and stiffened secondarily and independently from each other. Nevertheless, the basalare of Ephemeroptera and Odonata is possibly not homologous to the basalare of Neoptera.

Land use intensity and landscape composition determine native bee diversity in agricultural landscapes

Andrea Holzschuh, Teja Tscharntke

Agroecology, Georg-August University, Göttingen, Germany

Introduction: Bees may connect noncrop habitats providing nesting sites and arable fields providing food resources via foraging. The agricultural intensification during the last decades may disrupt those bee movements thereby threatening biodiversity and ecosystem services.

M**ethods:** We studied effects of crop and noncrop habitats at local and landscape scales on bee diversity in 21 agricultural landscapes differing in land-use intensity.

Results: Organic farming of crop fields and heterogeneous landscapes both contributed to higher bee diversity. Our results suggest that organic farming may reach highest relative effectiveness in homogeneous landscapes with few remaining flower-rich habitats. Food subsidies from weeds in organic crop fields may have landscape-wide effects on bee communities even in noncrop habitats. An increase of the proportion of organic crop fields from now 5 % on average in Germany to 20 % as aimed by the government may enhance species richness of bees in fallow strips by 50 %.
Bee abundance in mass-flowering oil seed rape fields without seminatural habitats in the vicinity was low suggesting little contribution of bee pollination to seed set in isolated rape fields.

Conclusions: According to our data, cross-habitat fluxes between crop and noncrop habitats are important for maintaining high bee diversity in agricultural landscapes. Conservation management plans and studies assessing biodiversity patterns have to consider factors at both local and landscape scales, because they have the potential to modify or to complement effects of each other.

Density dependent effects of predator species-richness on herbivore supression

Georgianne Griffiths[1], Andrew Wilby[2], Michael Crawley[1], Matthew Thomas[3]

[1]Imperial College, London, United Kingdom, [2]University of Lancaster, Lancaster, United Kingdom, [3]Penn State University, Pennsylvania, United States

Introduction: Mechanisms driving the diversity-function relationship have implications for the optimal management of biodiversity for ecosystem services. With biological control, prevalence of the selection effect supports augmentation of the single most effective natural enemy, whilst dominance of complementarity supports augmentation of natural enemy richness. Few empirical studies however, explicitly consider changes in function with relative or absolute changes in abundance, and may confound the relative importance of richness and density through experimental designs (additive or substitutive).

Methods: Using the natural enemies of cereal aphids we test the relative contributions of predator richness and abundance on pest suppression to contrast accumulation of net effects between con- and heterospecifics. Mechanisms are identified by comparing observed patterns with those predicted by the additive and multiplicative risk model and their associated biological assumptions.

Results: We show that the effects of species richness are density-dependent, and mechanisms underlying those effects are diversity-dependent. We illustrate how density-dependent effects can be detected using a substitutive (or replacement) series design, but argue that greater understanding of mechanism and optimal management will be obtained by examining community assembly along a richness-abundance gradient from substitutive to additive.

Conclusion: Where natural enemy abundance is low, greater increases in function can be achieved by augmenting the most effective natural enemy. However, where natural enemy populations are intermediate or high, it may be more advantageous to increase the richness of functionally complementary species. This will reduce intraspecific interference between functionally equivalent species, and enable new species to occupy unique, and complementary niche space.

Studies on pediculosis in Poland

Aleksandra Gliniewicz[1], Bozena Sawicka[1], Elzbieta Kedra[2]

[1]National Institute of Public Health-National Institute of Hygiene, Warsaw, Poland, [2]Institute of Parasitology, Polish Academy of Sciences, Warsaw, Poland

Introduction: In XX century studies on occurrence of *Pediculus humanus capitis* (P.h.c.) were carried out in 60's and 70's in several localities in Poland. Infestation levels reached this time 0.6-11%. The goal of our study was the evaluation of pediculosis occurrence among schoolchildren in chosen localities and the comparison with the results from the past.

Methods: A questionnaire was elaborated to obtain data about: occurrence of pediculosis, pediculicides used, age of infested children, persistent infestation. Data were collected in 2006 and 2007 in a big city and a province in Poland.

Results: Data from 24 primary schools (9778 pupils), 9 orphanages (562 children) from a city and 100 schools (45235 pupils), 23 orphanages (1012 children) from province were analysed. The infestation levels ranged from 0.65% (primary schools, province) to 17.2% (orphanages, city). In the group of

7–12 yrs old children pediculosis was often observed than among different groups of age. In more than 65% schools from province it was necessary to use a pediculicide more than twice to eradicate infestation. In Poland most of pediculicides contained permethrin as active ingredient, numerous – herb extracts.

Conclusions: The occurrence of pediculosis among schoolchildren from chosen localities in 2006 and 2007 did not significantly differ from the previous data. Several difficulties in P.h.c. eradication could be resulted in improper use of pediculicides; possible development of permethrin resistance in P.h.c. populations could be also considered.

(This work was partly supported by Project No 40407232/2198 of Polish Ministry of Scientific Research and Information Technology)

Distribution of stress in beetle mandibles analysed with finite element analysis and µCT-data

Thomas Hoernschemeyer

Georg-August-University, Goettingen, Germany

The distribution of stress in the mandibles of a beetle (Coleoptera: Archostemata: *Priacma serrata*) was investigated with finite element analysis (FEA) of high resolution computed tomography data (µCT) under different load scenarios. The µCT-data allowed for reconstructing a very precise model of the mandible morphology. This model could be used for the finite element analysis. The investigation shows that the mandible-muscle apparatus of the species investigated is build very robust. The power that the muscles are able to generate is not sufficient to damage any part of the mandible or its attachment to the head capsule. The weakest part of the system is the point where the tendon of the adductor muscle is attachment to the mandible. If failure of the system should occur, it most likely would be at this point.

The design of the mandible maximises the pressure that is applied to the substrate. Thus, the species is enabled to cut even comparatively hard material. Since *P. serrata* always occurs in the vicinity of conifers, this material may be wood or conifer seeds and cone material. SEM investigation of the functional surfaces of the mandibles also shows that *P. serrata* really makes use of them. This example shows that the combination of µCT and FEA allows for reconstructing parameters of the biology even for species for which no real life observations are available.

How glyphosate pesticide residues affect the behaviour of agrobiont spiders and beetles

Veronika Michalkova, Stano Pekar, Stanislav Korenko

Masaryk University, Brno, Czech Republic

Introduction: Current production of GM corn includes application of high rates of non-selective herbicides. Aim of the study was to assess the effect of the glyphosate residues on the behaviour of epigeic spiders and carabid beetles under laboratory conditions.

Methods: Specimens of *Pardosa agricola* (Araneae: Lycosidae) and *Poecilus cupreus* (Coleoptera: Carabidae), collected in the field, were exposed for 2 hours to the fresh, 1-day or 5-day old residues of the herbicide glyphosate (Roundup Biaktiv, Monsanto, API 480 $g.l^{-1}$) applied on the dish surface. The control group of spiders and beetles were exposed to water. Specimens were kept at constant climate conditions and used in one of three behavioural experiments: consumption efficiency, avoidance and speed of locomotion.

Results: Consumption of prey (*D. hydei*) was similar for all treated specimens of both spiders and beetles. Neither spiders nor beetles avoided surface treated with herbicide residues more than the control surface. The speed of locomotion of spiders was not affected by herbicide residues. But in beetles exposed to residues the speed of locomotion was significantly lower than of those exposed to water, due to longer time spent grooming.

Conclusions: All types of herbicide residues studied here did not affect consumption and avoidance in both spiders and beetles. Speed of locomotion was, however, affected negatively in beetles.

Synthesis of information in phylogenetics, evolution, biogeography, and megadiverse taxa

Mark Westneat, Torsten Dikow

Biodiversity Synthesis Center, Field Museum of Natural History, Chicago, Iliinois, United States

Biodiversity informatics is changing the speed of problem solving and also the kinds of hypotheses that are testable in a wide range of biological disciplines. The Biodiversity Synthesis Center (BioSynC) of the Encyclopedia of Life (EOL) helps to facilitate scientific discovery in biodiversity, evolution, and conservation biology by hosting synthesis meetings. Funded by the MacArthur Foundation, synthesis meetings for the EOL can bring together experts on a wide range of scientific and public issues to encourage progress towards specific goals proposed by the scientific community. Meetings focus on biodiversity informatics involving large data sets, the formulation of novel scientific ideas, and building new bridges among disciplines. In particular, synthesis meetings deal with timely issues in biodiversity or conservation research that have a direct relation to the Encyclopedia of Life or develop new ways of using the growing content of the EOL web-pages for scientific discovery. Of particular interest are megadiverse groups such as many insect lineages, novel research questions in biogeography, evolution, systematics, and taxonomy, visualization of large data sets, and study of biodiversity hotspots. In addition, the BioSynC synthesis meetings can help to highlight public benefits to informatics such as new educational materials and citizen science approaches. Here we present the results of the first year of synthesis meetings, including advances in taxonomy and searchable web resources on insects, contributions to browsing insect phylogenies and related informatics, and a general tool for visualization of large data sets in taxonomy and phylogenetics.

The biology and impacts of Argentine ants: An overview

Andrew Suarez

University of Illinois, Urbana, IL, United States

Argentine ants are recognized as one of the world's most widespread and damaging invaders. Native to northern Argentina, Paraguay and southern Brazil, they have been spread by humans to over 30 countries on 6 continents. Research on Argentine ants has historically concentrated on their consequences and methods for their control. However, in addition to providing insight into the study of biological invasions, they are rapidly becoming a model system for understanding processes in a variety of fields in ecology, evolution and behavior. These include nestmate recognition, facilitation and mutualism, competition, population genetics, and sociality. In the introduction to the symposium, I discuss the history of Argentine ant research, introduce the speakers and suggest some future directions of study.

HIRA and the paternal chromatin assembly at fertilization in *Drosophila*

Benjamin Loppin, Emilie Bonnefoy, Guillermo Orsi, Pierre Couble

Université Claude Bernard Lyon 1, Villeurbanne, France

In sexually reproducing animals a crucial step of zygote formation is the decondensation of the fertilizing sperm nucleus into a replication-competent male pronucleus. In sperm DNA packaged with male germline specific chromosomal proteins, including protamines, these non histone proteins are replaced with maternally provided histones to form the male pronucleus. By studying a point mutation allele of the *Drosophila Hira* gene, we could show that HIRA, a conserved chromatin assembly factor, is essential for the assembly of paternal chromatin at fertilization. During this process, HIRA deposits nucleosomes containing the histone variant H3.3 on the decondensing male pronucleus, in agreement with its general role in assembly pathways independent of DNA synthesis that specifically involves this H3.3 histone variant. The exclusive H3.3 marking of paternal chromosomes could represent a primary epigenetic distinction between parental genomes in the zygote.

To further understand the functions of HIRA during early development, a loss-of-function allele of *Drosophila Hira* was generated by homologous recombination. Surprisingly, the phenotypic analysis of this mutant revealed that the only essential function of HIRA is the assembly of paternal chromatin during male pronucleus formation. Moreover, analysis of this mutant established that protamines are correctly removed at fertilization in the absence of HIRA, thus demonstrating that protamine removal and histone deposition are two functionally distinct processes. The observation that H3.3 deposition is apparently not affected in *Hira* mutant embryos and adults, suggests that different chromatin assembly machineries could deposit this core histone variant.

Transgenic crops, pest resistance, and outbreaks

Bruce Tabashnik[1], Aaron Gassmann[2], David Crowder[1], Yves Carrière[1]

[1]University of Arizona, Tucson, AZ, United States, [2]Iowa State University, Ames, IA, United States

Transgenic crops producing insecticidal proteins from the bacterium *Bacillus thuringiensis* (Bt) have grown on more than 200 million ha since 1996. Evolution of pest resistance to transgenic crops threatens the continued success of this approach. The theory and evidence regarding evolution of pest resistance to transgenic crops will be reviewed and evaluated for the potential of such resistance to cause pest outbreaks. Contrasts will be made with the effects on outbreaks of pest resistance to broad-spectrum insecticides. In principle, because transgenic crops producing Bt toxins have narrow specificity and cause little or no direct harm to natural enemies of pests, such crops are less likely than broad-spectrum insecticides to trigger outbreaks of insect pests.

The causes of outbreak dynamics: A life history perspective

Toomas Tammaru

University of Tartu, Tartu, Estonia

Populations of some insects frequently reach outbreak densities while others never do so. Among Lepidoptera, outbreak dynamics appears to be associated with capital breeding strategy (Oikos 77: 561-564). In capital breeders, as opposed to income breeders, reproduction completely relies on resources derived during the larval life of the insects. For various, reasonably well understood reasons females of capital breeding moths typically display simplified adult behaviors which involves lack of selectivity in oviposition substrate selection. As a consequence, ovipositing females of capital breeders are unable to evaluate the quality of resources available for their offspring. This implies no opportunity for density-dependent regulation of population density by the mechanisms of adult behavior. This allows for carrying capacity of the environment to be easily exceeded. Additionally, many outbreaking income breeders are spring feeders with the larvae being able to develop only on young, developing foliage of their host trees. The ways how such a life history may contribute to outbreaks, as well as to regular population dynamics is discussed using the ecologically well studied *Epirrita autumnata* (Lepidoptera: Geometridae) as an example. The key aspects may include insensitivity of reproduction to weather conditions, as well as the timing of the occurrence of different developmental stages in relation to the breeding cycle of insectivorous birds.

Spatial dynamics of ground beetle assemblage in a mosaic fragmented landscape

Irena Bertoncelj, Paul M. Dolman

University of East Anglia, Norwich, United Kingdom

Understanding dispersal and population persistence in fragmented habitat network is essential to conserving biodiversity in anthropogenic landscapes. We examined spatial and temporal dynamics of ground beetle populations in a mosaic landscape, comprising different growth stages of conifer plantations, patches and linear strips of permanent open habitats and ephemeral open areas created by clear-felling. Conservation interests in Breckland SPA (UK) focus on heathland species. We investigated effects of habitat quality, area and spatial location (proximity to source) for community composition and abundance of heathland ground beetles within this open habitat network in the forest landscape. Under current management regime narrow strips of suitable habitat between younger plantations (permanent linear refugia) provide a sufficient source of colonisers for clear-felled areas.

The impact of sulfur on spider mite and predatory mite populations on grapes and hops in the Pacific Northwest of the United States

David James[1], David Gent[2], Deirdre Prischmann[1], Lawrence Wright[1], Deborah Brooks[1], Oscar Garcia[1]

[1]Washington State University, Prosser, Washington, United States, [2]Oregon State University, Corvallis, Oregon, United States

Data collected from field studies and experiments conducted in vineyards and hop yards in Oregon and Washington State during 2001-2007 indicate that the multiple use of sulfur as a powdery mildew management tool, has an adverse impact on biological control of spider mites. In vineyards there appears to be a positive correlation between the frequency of sulfur applications and spider mite population densities. Multiple (> 4) applications of sulfur can result in spider mite population outbreaks requiring control. Similarly, in replicated vineyard and hop yard experiments, multiple applications of sulfur increased spider mite populations. Conversely, predatory mite (Phytoseiidae) populations are generally smaller on sulfur-exposed hops and grapes than on non-exposed plants, and it is likely that suppression of phytoseiid populations by multiple applications of sulfur contributes to spider mite population outbreaks in some instances. However, multiple applications of sulfur increase spider mite populations even in the absence of predatory mites suggesting a more complex mechanism than just elimination of natural enemies.

Gall-inducing insects can evade host-plant defences that are triggered by other insect herbivores

John Tooker, Consuelo De Moraes

Pennsylvania State University, University Park, PA, United States

Gall-inducing insects are accomplished plant parasites that can profoundly influence host-plant physiology. We recently reported that the caterpillar *Gnorimoschema gallaesolidaginis* failed to trigger emissions of host-plant volatiles that often recruit natural enemies of feeding insect herbivores. Only one other caterpillar species has been shown to circumvent some of the feeding-induced indirect defenses of its host plant, and does so by feeding on linolenate-deficient fruits. We initiated this study to determine whether the absence of volatile responses to the gall-inducing *G. gallaesolidaginis* could be explained by a lack of linolenic acid (LNA) in galls. We screened interior and exterior tissue of galls and control stems of the host plant *Solidago altissima* for LNA, jasmonic (JA) and salicylic (SA) acids. Linolenate is a precursor of the octadecanoid pathway, which produces JA, a phytohormone that triggers volatile releases. In some cases, SA can interact antagonistically with JA. We found unexpectedly that *G. gallaesolidaginis* strongly increased amounts of LNA in gall interiors without corresponding increases in JA or SA. These and similar findings with *Eurosta solidaginis*, a gall-inducing fly, suggest that gall insects can nutritionally enhance their food source without concomitant increases in phytohormones and associated defence responses.

Is DGC a result of a mismatch between spiracular conductance and metabolic demand?

Stefan K. Hetz, Thomas D. Förster

Humboldt Universität, Berlin, Germany

The insect tracheal system is a unique respiratory system in the animal kingdom. Oxygen is delivered directly to the tissues. Closable spiracles control the exchange of respiratory gases between tracheal system and atmosphere.

Discontinuous gas exchange cycles (DGC) are a result of discontinuous spiracle activity leading to huge fluctuations in oxygen and carbon dioxide partial pressures. Possible reasons for these DGCs are summarized by Chown et al. (2006). Recent investigations have shown that moth pupae use more spiracles in an opening period than needed in order to release the actually produced carbon dioxide (Hetz 2007). Even if all but one or two spiracles are artificially closed, the discontinuous release of carbon dioxide persists.

The huge spiracular conductance in some insect species may be an adaptation to changing metabolic demand e.g. during flight. Thus, in active insects, the tracheal system and the spiracles are designed for maximum gas exchange capability.

In inactive insects or insect stages, however, this design leads to effects comparable to a respiratory alkalosis caused by hyperventilation. The maximum flow rate of CO_2 through the spiracles in an opening period can exceed the average CO_2 production rate by a factor of 20 or more. The amount of CO_2 released in an opening period may thus reach up to 30 per cent of the total CO_2 stored within the insect body. This results in dramatic changes of the carbon dioxide partial pressure and the hemolymph pH.

The accumulation of CO_2 in the interburst period may be considered as a recovery from a respiratory alkalosis caused by the CO_2-burst.

Aversive conditioning in the monarch butterfly, *Danaus plexippus* (L.) (Lepidoptera: Nymphalidae)

Daniela Rodrigues[2], Martha Weiss[1]

[1]Georgetown University, Washington, DC, United States, [2]Universidade Estadual de Campinas, Campinas, SP, Brazil

Introduction: Learning ability allows insects to respond to a variable environment, and to adjust their behaviors in response to positive or negative experiences. Pollinating insects readily learn to associate floral characteristics, such as color or pattern, with the presence of a sugar reward. However, in nature, pollinators may also encounter flowers that present opportunities for aversive conditioning; the flowers may, for example, contain distasteful or toxic nectar, or offer highly variable nectar volumes. Whereas some bees learn to avoid flowers with unpalatable nectar or variable nectar rewards, little is known about how lepidopterans respond to these aversive stimuli.

Methods and Results: We determined that monarch butterflies learn to discriminate against model flowers that contain salt solution, decreasing probing time on models of a preferred color and altogether avoiding models of a non-preferred color. In addition, when we offered butterflies flower models of two different colors, both of which contained the same mean nectar volume but which differed in variance (models of one color all contained 2 µl of sucrose; models of the other color contained either 4 µl sucrose or none at all), the monarchs probed the constant flowers significantly more than the variable ones, regardless of flower color or butterfly gender.

Conclusions: These results, taken together, demonstrate that monarchs can respond to aversive as well as appetitive stimuli, allowing them to track positive and avoid negative stimuli as they forage in the field.

Financial Support: CAPES

Factors affecting the incidence of intraguild predation

Annie-Eve Gagnon[1], George, E. Heimpel[2], Jacques Brodeur[3]

[1]Département de Phytologie, Université Laval, Québec, Québec, Canada, [2]Department of Entomology, University of Minnesota, St-Paul, Minnesota, United States, [3]Institut de recherche en biologie végétale, Département des sciences biologiques, Université de Montréal, Montréal, Québec, Canada

Introduction: Understanding of guild interactions between natural enemies is of great interest for ecologists and biological control practitioners. Intraguild predation (IGP) occurs when two predators that compete for a shared prey species also engage in predator-prey interactions with each other.

Methods: We describe a method for the detection of intraguild prey in predator gut contents using a molecular approach. PCR primers were designed for four abundant predators in Quebec soybeans: *Coccinella septempunctata*, *Propylea quatuordecimpunctata, Harmonia axyridis* and *Coleomegilla maculata* (Coleoptera: Coccinellidae). Primer specificity and prey detectability half-life following a meal were determined for all coccinellid species interactions. We used these primers to evaluate the incidence of IGP between individuals collected in soybean fields during four years.

Results: Prey detectability half-life differed between species associations and was then considered to correct data from field-caught coccinellids. IGP was a very common interaction (~40%) within the coccinellid community. The interactions were symmetric (mutual intraguild predation) as each species may become prey or feed on each other and were influenced by factors inherent to the predator and prey species, predator-prey densities and seasonality.

Conclusion: This molecular technique is a powerful tool to disentangle and quantify poorly understood and complex interactions among natural enemies under field conditions.

Phylogeny of the Chalcidoidea

John Heraty[1], James Munro[1], Jean-Yves Rasplus[2], Roger Burks[1], Johan Liljeblad[1]

[1]University of California, Riverside, CA, United States, [2]INRA - Centre de Biologie et de Gestion des Populations, Montpellier, France

Economically and ecologically, Chalcidoidea are one of the most important groups of insects. More than 500,000 estimated species are grouped into 19 families, 81 subfamilies and over 2000 genera. Relationships among these mostly parasitic wasps have remained untested, and so far are based solely upon intuitive ideas or studies of only a few closely related groups. The Hymenoptera Tree-of-Life project was focused on three important aspects of Chalcidoidea: their monophyly, their sister group relationships within Hymenoptera, and relationships within the superfamily. These questions are being addressed using morphological and molecular characters, although only the later results will be discussed. The molecular phylogeny of Hymenoptera as based on four gene regions (28S, 18S, COI and EF-1alpha) supports both monophyly of Chalcidoidea and a sister group relationship with either Diapriidae or Mymarommatidae. A more directed study using 31 outgroup Proctotrupomorpha and 504 Chalcidoidea representing all families and 69 subfamilies for portions of 28S (D2-D5) and 18S (E17-35) has been completed. Alignment is optimized by eye across all taxa and also using secondary structure analysis with ambiguous regions optimized in MAFT. Data are analyzed using RAxML and CIPRES. Monophyly of Chalcidoidea is supported, as is a sister group relationship between Diapriidae and Chalcidoidea, and Mymaridae and the remaining Chalcidoidea. Several important and diverse family groups are monophyletic, including Agaonidae, Encyrtidae, Eulophidae and Trichogrammatidae, as are most subfamilies. Several family groups are polyphyletic, including Aphelinidae and Chalcididae. The implications of the phylogeny for understanding morphological and behavioral evolution in the group will be discussed.

Electrical Penetration Graph (EPG) monitoring of feeding by glassy-winged sharpshooter and potential application of EPG to other pathogen vectors

Elaine Backus

USDA Agricultural Research Service, Parlier, CA, United States

Introduction: Recent findings on feeding of the glassy-winged sharpshooter, *Homalodisca vitripennis*, and the mechanism of its transmission (acquisition and inoculation) of *Xylella fastidiosa* (*Xf*) to grape will be used as an example of the utility of Electrical Penetration Graph (EPG) monitoring for vector studies.

Methods: A recently designed Universal AC-DC EPG monitor provides updated, high-quality amplifiers with a wider range of user-selectable adjustments, to tailor the monitor to any new species.

Results: A model will be introduced of four critical steps to assure success in the acquisition and inoculation process (i.e. vector efficiency), however only the third step will be discussed in detail. This third step is performance of a specialized inoculation behavior that consists of salivation, ingestion of mixed saliva and plant fluid, followed by two different types of egestion, each from a different area of the anterior foregut. Thus, the mechanism of inoculation is a combination of salivation and egestion. Specific EPG waveforms are correlated with each of these behaviors, and are used to measure how often these behaviors are performed and their durations.

Conclusions: Our goal is to develop a resistance index using EPG waveforms alone, for use in development of host plant resistance to the vector. Possible applicability of EPG technology to studies of blood-sucking arthropod vectors will be discussed.

An evolutionary context for the Argentine ant

Alexander Wild

University of Arizona, Tucson, AZ, United States

The Neotropical ant genus *Linepithema* is known for the invasive Argentine ant *L. humile*, but the group contains an additional 18 species. These are distributed across a variety of habitats from Mexico to Argentina. A multi-locus molecular phylogeny suggests a southern South American origin for *Linepithema*, supports a recent morphology-based division into four monophyletic species groups, and demonstrates a sister-species relationship between *L. humile* and an obscure Andean species *L. oblongum*. Too little is understood about the biology of most species to elucidate the evolution of traits implicated in ecological invasiveness, but I discuss what is known and suggest avenues for future research.

Parasitoid communities attacking leaf chewing Lepidoptera in New Guinea rainforest

Jan Hrcek

Faculty of Science, University of South Bohemia and Institute of Entomology, Biology Center of the Czech Academy of Sciences, Ceske Budejovice, Czech Republic

Introduction: Natural leaf chewing caterpillar - parasitoid communities are overly complex, which often leads researchers to concentrate on Macrolepidoptera and neglect Microlepidoptera hosts. This study presents results from a mass rearing survey, where the caterpillars were sampled in proportion to their natural abundance.

Methods: Our group (www.entu.cas.cz/png/) studied a community of leaf chewing Lepidoptera and their parasitoids on 45 locally common tree species in primary and secondary tropical rainforest near Madang, Papua New Guinea over five years. All free-living and semi-concealed (leaf-rolling, web-tying) caterpillars were quantitatively sampled from 1500m^2 of foliage of every tree species, morphotyped and reared. Hatched insects were morphotyped by parataxonomists and later identified by taxonomists.

Results: The rearing of 49.000 caterpillars yielded 15.000 Lepidoptera adults from 274 species and 1.600 Hymenoptera and Diptera parasitoids from ~260 species.

Most of the caterpillars were semi-concealed (78%), only 22% were free-living. Two thirds of the parasitoids were Hymenoptera (mostly Ichneumonoidea) and one third were Diptera: Tachinidae.

Semi-concealed hosts had significantly higher parasitism rate than free-living hosts. While Hymenoptera strongly preferred semi-concealed hosts, Diptera parasitised both free-living and semi-concealed caterpillars with similar intensity. Free-living hosts seem to be prone to apparent competition from semi-concealed host via shared parasitoids, as majority of their parasitoids attack both types of hosts.

Conclusions: I suggest that semi-concealed caterpillars (in contrast to free-living ones) are main hosts of parasitoids because of numerical dominance in natural communities, concealment from predators and apparency for parasitoids.

Further quantitative studies are needed to evaluate the generality of these results.

Biodiversity hanging by a thread: the invertebrate community of fungal litter-trapping systems

Jake Snaddon[1], Paul Eggleton[2], William Foster[1]

[1]University Museum of Zoology, Department of Zoology, University of Cambridge, Cambridge, United Kingdom, [2]Department of Entomology, The Natural History Museum, Cromwell Road, London, United Kingdom

Introduction: Tropical rainforests are among the most diverse terrestrial ecosystems on the planet, and yet the rainforest canopy and understorey are hostile environments due to their extremely variable microclimatic conditions. Despite this, rhizomorph-forming fungi are abundant and efficient litter-trapping systems in moist tropical forest canopies.

Methods: We present research from a study in Sabah, Malaysia, where the influence of the fungal litter-trapping systems on the invertebrate community was experimentally assessed by removing the rhizomorph networks and associated leaf-litter from the forest understorey.

Results: The fungal litter-trapping systems were found to provide a valuable resource for a distinct invertebrate community within the forest. Affecting the diversity, abundance and composition of the invertebrate community.

Conclusion: The litter-trapping fungi and associated leaf-litter provide an important component of the forest structure and in doing so enhance invertebrate diversity within rainforest canopies.

Gene discovery and functional genomics in the Mediterranean fruit fly, *Ceratitis capitata*

Ludvik Gomulski[1], George Dimopoulos[2], Zhiyong Xi[2], Marcelo Soares[3], Maria Bonaldo[3], Anna Malacrida[1], Giuliano Gasperi[1]

[1]University of Pavia, Pavia, Italy, [2]Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States, [3]Northwestern University's Feinberg School of Medicine, Chicago, IL, United States

The medfly is a highly invasive agricultural pest that has become a model insect for the development of biological control programmes. Despite research into the behaviour and classical and population genetics of this organism, the quantity of sequence data available is limited. We used an expressed sequence tag (EST) approach to obtain detailed information on transcriptome signatures that relate to a variety of physiological systems in the medfly. Given that the study was based on normalized cDNA libraries from embryos and adult heads we have obtain information relating to reproduction, sex determination, and chemosensory perception.

Over 21,000 high-quality ESTs were obtained from the embryo and head libraries. Clustering analyses resulted in almost 12,000 unique sequences or transcripts. These assembled sequences represent a wide range of biological processes and molecular functions. Of particular interest are the sequences that share homology with *Drosophila* genes involved in sex determination, olfaction, and reproductive behaviour.

The sequences obtained in this study represent the first major dataset of expressed genes in a tephritid species of agricultural importance. This resource provides essential information to support the investigation of numerous questions regarding the biology of the medfly and other related species and also constitutes an invaluable tool for the annotation of complete genome sequences. Our study has revealed intriguing findings regarding the transcript regulation of sex determination genes, as well as insights into the comparative genomics of genes implicated in chemosensory reception and reproduction.

Production of *Bacillus thuringiensis* based biopesticide using a commercial lab medium and raw material rich in carbon and nitrogen

Fernando Valicente[1], Lucas Mendes[2], Leandro Carvalho[2]

Molecular biology and functional biochemistry of olfaction in *Anopheles gambiae* and *Aedes aegypti*

LJ Zwiebel

Vanderbilt University, Nashville, TN,, United States

The ability to sense and discriminate a large collection of chemical and visual cues is central for several behaviors of insects that act as vectors for the pathogens that are responsible for many important human diseases. In particular, olfaction plays a major role in host seeking and selection behaviors of blood feeding female anopheline mosquitoes. A long-term objective of our research is centered on an examination of the molecular genetics of the chemosensory system in anopheline and other mosquitoes and its role in determining anthropophilic host preference in malaria vector mosquitoes. We have identified and continue to characterize the complete repertoire of 79 odorant receptor (OR) genes *An. gambiae* as well the complete set of 117 functional OR genes from the Dengue and Yellow Fever virus vector mosquito A*edes aegypti*. Together with our collaborators, we have completed a detailed analysis of the olfactory physiology, molecular neurobiology and odorant-binding characteristics of ORs on the adult maxillary palp and proboscis as well as behavioral and molecular elements of the larval stage olfactory system of *An. gambiae* and *Ae. aegypti* to begin to define the functional "odor space" for these vector mosquitoes. Progress will also be presented on ongoing efforts to design novel anti-malarial programs that target chemosensory pathways and the behaviors they control in vector mosquitoes.

This work has received generous support by grants from the Foundation for the National Institutes of Health through the Grand Challenges in Global Health Initiative as well as the U.S. National Institutes of Health.

Progress in the management of maize streak virus and its leafhopper vectors in sub-Saharan Africa

Nilsa Bosque-Perez

Department of Plant, Soil and Entomological Sciences, University of Idaho, Moscow, ID, United States

Maize streak virus (MSV) is the causal agent of the most economically important and widespread disease of maize in sub-Saharan Africa. MSV is persistently transmitted by leafhoppers in the genus *Cicadulina.* Of the 22 species of *Cicadulina* known, 18 occur in Africa. Nine species of *Cicadulina* are confirmed vectors of MSV in Africa. MSV epidemiology is closely linked to the ecology of its vectors. Both MSV and its vectors evolved with African grasses and adapted to maize after its introduction into the continent. Several cultural practices have been suggested for MSV control, including avoiding maize plantings downwind from earlier-planted cereal crops, areas of bare ground between early and late-planted maize fields, and crop rotation, to reduce leafhopper movement and subsequent virus spread. While insecticides have been used also to control vectors, resistant varieties are recognized as the most effective method for MSV management. Several breeding programs are active in the development of resistant varieties. Maize varieties differ in disease severity and incidence and subsequent yield loss. Resistant varieties exhibit higher yields when diseased and lower disease incidence than susceptible ones. Low disease incidence is partly due to insect resistance and the potential for disease spread is lower on varieties exhibiting this character. Although MSV was first studied in the 1920's and resistance transferred into maize in the 1960's, many farmers in sub- Saharan Africa still grow MSV-susceptible maize and continue to experience yield losses. Advances in the management of MSV and its *Cicadulina* spp. vectors will be discussed.

Biogeographic factors that determine the distribution of the Exapiini Alonso-Zarazaga, 1990 (Coleoptera: Apionidae) in the Iberian Peninsula (Spain)

Mª Pilar Gurrea[1], Mª José Sanz[2], José Martin[1], Edgar Camero[3]

[1]Universidad Autónoma de Madrid, Madrid, Spain, [2]Universidad SEK, Segovia, Spain, [3]Universidad Nacional de Colombia, Bogotá, Colombia

Introduction: There are a great variety of methods to explain the distribution of the species. The techniques based on the use of presence data species try to identify the ranks of certain environmental variables in which these species appear comparing its distribution with a random one. In this work, we have analyzed the factors that affect the Iberian distribution of the weevil species of the tribe Exapiini, some of them well known for its economic interest because they have been used for the biological control of weeds. This tribe of Apionidae includes nearly 50 species, 22 of them known from the Iberian Peninsula.

Material and methods: The data of the distribution of these species of Exapiini have been obtained from UTM grids of 10x10 km. The presence or absence of each species has been analyzed to determine the influence of the geographic variables as such as latitude, length, distance to the Pyrenees, maxima altitude, minimum altitude, altitudinal rank, environmental (temperature, precipitations, pluviometric irregularity, types of ground) and food plants. The analysis has been repeated for the set of the species of Exapiini to estimate the variables of greater significance in the species density populations.

Results: The results show that the maxima altitude of the grids and the altitudinal rank are the factors with greater level of significance, as much for the density of species as for each one of them. The distribution model is predictive, and allows us to indicate areas of the Iberian Peninsula with greater probabilities of finding these species.

Photoperiodic diapause in mosquitoes: A link to insulin signaling

David Denlinger, Cheolho Sim

Ohio State University, Columbus, Ohio, United States

Introduction: Short daylength is used to program adult diapause in the mosquito, *Culex pipiens.* The downstream endocrine event that halts ovarian maturation is a shut-down in juvenile hormone (JH) production, but little is know about the molecular events that occur between perception of short daylength and the cessation of JH production. Here we explore a potential role for insulin signaling as an intermediary in this pathway.

Methods: Genes encoding the insulin receptor and a downstream gene, FOXO, were suppressed using RNAi and such attributes as ovarian maturation, fat accumulation and longevity were monitored. JH rescue experiments were also conducted to evaluate the capacity for JH to reverse the RNAi induced phenotype.

Results: Knocking down the insulin receptor with RNAi in nondiapausing mosquitoes results in a cessation of ovarian development akin to diapause. Mosquitoes could be rescued from this this developmental arrest with an application of JH. When RNAi was directed against FOXO in mosquitoes programmed for diapause, fat storage was dramatically reduced and the mosquito's life span was shortened, results suggesting that a shut-down of insulin signaling prompts activation of the downstream gene FOXO, leading to the diapause phenotype.

Conclusion: The results are consistent with a role for insulin signaling in the short-day response that ultimately leads to a cessation of juvenile hormone production.

Insulin signaling and juvenile hormone in metamorphic commitment of imaginal primordia and discs in the tobacco hornworm

Takashi Koyama[1], Lynn Riddiford[2]

[1]University of Washington, Seattle, WA, United States, [2]Janelia Farm Research Campus, HHMI, Ashburn, VA, United States

Juvenile hormone (JH) maintains morphostasis of the eye and leg primordia and the wing discs during the early larval life of *Manduca*, but in final instar fed larvae JH cannot prevent pupal commitment and subsequent morphogenetic growth. Normally *broad* (*br*) mRNA (indicative of pupal commitment) appears in both the eye primordia and the wing discs between 12 and 24 hr of feeding. In both tissues this up-regulation of *br* could be stimulated in a dose-responsive manner in starved 5th larvae by injection of either *Manduca* bombyxin or bovine insulin and inhibited in fed larvae by wortmannin, a specific inhibitor of phosphatidylinositide-3 kinase. *In vitro* wing discs from freshly ecdysed larvae showed a 4-fold increase in *br* mRNA by 24 hr in hormone-free medium which was prevented by the JH analog methoprene. Either bombyxin or insulin prevented the suppression by JH. The presence of either wortmannin or Insulin Receptor dsRNA in the culture medium prevented this action of insulin. These data show that feeding in the 5th instar causes bombyxin (insulin) release which in turn overcomes the JH inhibition of pupal commitment of the imaginal discs and primordia. This effect of insulin was not seen in 4th instar wing discs. Thus, the hypothesized nutrient-dependent Metamorphosis Initiating Factor that overcomes JH suppression of the discs and primordia in the 5th instar to allow pupal commitment and the subsequent morphogenetic growth (Truman *et al., Science,* 2006) is *Manduca* insulin. Factors involved in the subsequent growth are under study. Supported by NSF.

Forest management and the conservation of boreal forest arthropod biodiversity

Jan Volney, John Spence, David Langor

[1]Natural Resources Canada, Edmonton, Alberta, Canada, [2]University of Alberta, Edmonton, Alberta, Canada, [3]Natural Resources Canada, Edmonton, Albert6a, Canada

The EMEND (Ecosystem Management Emulating Natural Disturbance) Experiment is a large-scale, replicated comparison of variable retention forest harvesting and fire-dominated natural disturbance in the western Canadian boreal forest. The intent is to provide an empirical evaluation of the natural disturbance paradigm in designing forest management approaches. Outcomes of 5 levels of strip retention harvesting (75%, 50%, 20%, 10% and 2% residual structure) in 4 mixedwood canopy cover types (deciduous dominated, deciduous dominated with coniferous understory, mixedwood and coniferous dominated) are being compared with data collected after whole compartment burns and slash burns in 10-ha compartments. Residuals have been left evenly distributed in strips throughout compartments and as aggregated elliptical patches of two sizes (0.20 and 0.45 ha). The set of response variables is wide-ranging, including productivity, dynamics of coarse woody material, soil nutrient dynamics, hydrology, fire effects, harvesting costs and regeneration. Pre-treatment arthropod biodiversity estimates of forest canopy-feeding Lepidoptera, epigaeic fauna (Coleoptera and Arachnida), and saproxylic insects (both in coarse woody debris and fire-killed wood) were made and continued periodically post-treatment. These estimates allow comparisons of trade-offs among various distributed retention harvesting systems, clear-cutting, and prescribed fire in standing timber and slash burns. Results to date indicate that variation in the responses seems paramount. Future management indicators have to be tailored to account for this finding. Thus the use of ecosite indicators, the understory vegetation, and related sub-stand features become essential in designing practices that conserve biodiversity on forested landscapes.

Flea beetle diversity of the Sierra Tarahumara, Copper Canyon, Mexico (Chrysomelidae: Alticinae).

David Furth

Smithsonian Institution, Washington, D. C., United States

Introduction: This is the product of a 4 year study of the diversity of Alticinae of the Sierra Tarahumara a mountainous area of the Sierra Madre Oriental of northern Mexico, especially in the states of Chihuahua and Sonora. It is part of a multi-disciplinary bio-cultural survey of this region involving indigenous people, especially the Tarahumaras. Chihuahua is the largest, but biologically least known state in Mexico.

Methods: There are few recorded data of Alticinae from this region, thus almost all the data is from fieldwork collected by sweeping. Fieldwork was done by the author during 4 collecting trips at different seasons over a 5 year period.

Results: Thus far 24 genera and 71 species of Alticinae have been identified from the Sierra Tarahumara. At least 2 species are new to science, 6 new to Mexico, ca 40 new to Chihuahua, 10 new to Sonora, and there arenew host records for several species. Species diversity increases at lower elevations (below 2000m) with a complete turnover of the species composition every ca. 850 meters. Biogeographic affinities are Nearctic at higher elevations and Neotropical at lower.

Conclusions: Chihuahua is more species rich than previously recorded and the biogeographic affinities are primarily Nearctic.

Inquilinism in ants: ecology, social organization, phylogenetics, and speciation

Riitta Savolainen

University of Helsinki, Helsinki, Finland

Introduction: Eusociality involves cooperation in caring for the offspring, reproductive division of labour, and overlap of generations of different life stages. Ant social parasites have, however, lost all or some traits of eusociality. In particular, workerless social parasites, inquilines, have reverted to selfish behaviour that maximizes sexual reproduction on behalf of their host. Social parasites occur in six ant subfamilies, though the majority of parasites have been found in Formicinae and Myrmicinae, inquilines mostly in Myrmicinae. Here, I explore the origins of inquilines.

Methods: I will review the literature on inquiline ants and their hosts, weaving together patterns of their ecology, social organization of the colony, and phylogenetics.

Results: Phylogenetic analyses suggest multiple origins of inquiline ant species. Some inquiline-host pairs are sister species; this raises the question: could a species give rise to its own parasite?

Conclusions: Occurrence of inquilines mainly in temperate regions may be a real phenomenon resulting from relatively species-poor ant community structures that allow locally high nest densities of potential hosts. I suggest that the evolution of polygyny and polycaly as a highly successful adaptive tactic in specific ecological contexts has predisposed colonies to exploitation by cheating queens – a starting point for the evolution of inquilinism. By analysing morphological and behavioural changes accompanying the polygyny-polycaly syndrome, I will show how loss of sociality and speciation of inquilines through intraspecific parasitism in sympatry, within their host colonies, is possible.

The evolution on inbred social systems in spiders—causes and consequences

Leticia Avilés

University of British Columbia, Vancouver, Canada

Social spiders are notable among social organisms for being highly inbred—male and female colony members remain within the natal nest to mate generation after generation. Social spider colonies, therefore, constitute more or less isolated population lineages that grow, proliferate and become extinct without mixing with one another. We present recent evidence that confirms such strong population subdivision even at fast evolving microsatellite loci in the neotropical social spider *Anelosimus eximius*. We review data showing that the inbred social spiders originated from outbred subsocial ancestors, a transition that we suggest was associated with a switch from environments where costs of dispersal are high and benefits of group living low to environments where the reverse holds. That ecological and demographic factors can often be sufficiently strong to overcome inbreeding depression during the initial phases of the transition to inbreeding is suggested by the repeated phylogenetic origins of inbred spider sociality. Social spider species lineages, however, appear as isolated terminal branches of the phylogenetic tree of spiders. Such spindly phylogenetic distribution, reminiscent of that reported for asexual taxa, suggests that although social spiders may have overcome the initial costs of inbreeding, in the long run, inbred spider sociality may represent an evolutionary dead end.

Foraging activity in stingless bees depends on the reproductive state of a colony (*Plebeia remota*)

Patrícia Nunes-Silva[1], Pérsio de Souza Santos Filho[2], Vera Lucia Imperatriz-Fonseca[1]

[1]Faculty of Philosophy, Science and Letters of Ribeirão Preto, University of Sao Paulo, Ribeirão Preto/São Paulo, Brazil, [2]Institute of Bioscience, University of Sao Paulo, São Paulo/São Paulo, Brazil

Colonies of the Brazilian stingless bee *Plebeia remota* show a reproductive diapause in autumn and winter. During this period, the colonies do not build brood combs, and, in consequence, no new individuals are produced. Colonies of this bee species, therefore, present two distinct reproductive states (oviposition period and reproductive diapause), during which colony-needs are putatively different. Consequently, resource collection should be adapted to the different needs. We recorded the foraging activity of two colonies for 30 days in both reproductive states, registering the number of foragers entering the colony with different resources (nectar or pollen), and the time of collection. Indeed, the foraging activity of *P. remota* presented different patterns during the reproductive diapause and the queen oviposition period. In the course of the reproductive diapause, the resource predominantly collected by the foragers was nectar. Here, the majority of the bees were nectar foragers, and the peak of collecting activity occurred around noon. Instead, in the queen oviposition period, the predominantly collected resource was pollen, and the peak of activity occurred around 10:00am. Although the majority of the foragers was not specialized in this period, there was a larger number of pollen foragers compared to the period of reproductive diapause. The temperature and relative humidity also influenced the foraging activity. Apparently, the presence of new brood - during the queen oviposition period - is important for the "decision" of stingless bee colonies to collect pollen. Both internal and external conditions of the colonies influence the foraging behavior of this species.

Effects of international movement on populations of *Sirex noctilio* and its symbiotic fungus *Amylostereum areolatum*

Bernard Slippers, Brett P. Hurley, Magriet van der Nest, Osmond X. Mlonyeni, Brenda D. Wingfield, Michael J. Wingfield

Department of Genetics, Forestry and Agricultural Biotechnology Institute, Pretoria, South Africa

Genetic bottlenecks and environmental variability can have a substantial influence on populations of introduced insects and their microbial symbionts. We have used genetic, phenotypic and biological data to consider the influence of these factors on populations of the woodwasp, *Sirex noctilio*, and its homobasidiomycetes fungal symbiont, *Amylostereum areolatum*. The data show that these organisms have most likely been introduced a limited number of times into southern hemisphere pine plantations, but that they have spread widely after each introduction to other areas in the region. Each introduction has left an apparently clonal, and unique population of the fungus over vast areas, and even across continents. This lack of diversity is also evident in the wasp populations. Where introduced natural enemies are not compatible with the large, genetically uniform populations of *S. noctilio* and *A. areolatum,* the success of biological control programs may be retarded. This might account for the poor levels of parasitism achieved with the parasitic nematode, *Deladenus siricidicola*, in some areas. Furthermore, the lack of genetic diversity and population fluctuations in the wasp could also have contributed to the significant variation in sex ratio, often with a severe male bias, observed across invasive populations of *S. noctilio*. Apart from genetic influence, there are also dramatic life cycle changes associated with environmental differences in invaded areas. These influence the population dynamics of the mutualism and the establishment of biological control agents alike. A sound understanding of the genetic and environmental effects on population dynamics in an invasive insect such as *S. noctilio* and its fungal symbiont is clearly essential for a successful biological control program.

The cuckoo fungus "termite ball" mimicking termite eggs: a novel insect-fungal association

Kenji Matsuura, Takashi Tamura, Toshihisa Yashiro, Norimasa Kobayashi, Ken Shimizu

Okayama University, Okayama, Japan

Mimicry has evolved in a wide range of organisms encompassing diverse tactics for defense, foraging, pollination, and social parasitism. Here we report an extraordinary case of egg mimicry by a sclerotium-forming fungus, whereby the fungus gains competitor-free habitat in termite nests. Egg protection is one of the most fundamental social behaviours in social insects. When termite workers recognize the eggs laid by queens, they bring the eggs together and heap them up in nursery cells to take care of them. *Reticulitermes* termites frequently harbor brown fungal balls, called termite balls, alongside their eggs. The termite ball was identified as the sclerotium of a parasitic corticioid fungus, an undescribed species of genus *Fibularhizoctonia*, which mimics termite eggs physically and chemically so as to be protected in termite nests. This phenomenon has been found for seven *Reticulitermes* species in Japan and the US.

The discovery of the chemical camouflage by the egg-mimicking fungus indicated that termites can be manipulated by using the termite egg recognition pheromone (TERP), which strongly evokes the egg-carrying and -grooming behaviours of workers. We found that the TERP also provided antibacterial activity against a gram-positive bacterium. We isolated the target protein, determined the molecular size of 14.5kDa and identified the antibacterial protein lysozyme as the TERP. RT-PCR analysis confirmed that mRNA of termite lysozyme was expressed in both salivary glands and eggs. This novel function of lysozyme as a termite pheromone illuminates the profound influence of microbes on the evolution of social behaviour in termites. In addition to the mechanism of egg mimicry, we discuss the evolutionary processes of this novel insect-fungus interaction.

Are the determinants of ant diversity invariant across spatial and taxonomic scales?

Nathan Sanders[1], Robert Dunn[2], Michael Kaspari[1]

[1]University of Tennessee, Knoxville, TN, United States, [2]North Carolina State University, Raleigh, NC, United States, [3]University of Oklahoma, Norman, OK, United States

Macroecologists want to know whether and why biodiversity varies geographically. But the biotic and abiotic factors that shape biodiversity gradients may vary with spatial resolution – the factors that determine the number of insects in meter square quadrat might differ from the factors that determine why there are more insects in the tropics than in the tundra. Similarly, the factors that determine the number of species may not predict the number of genera, tribes, or subfamilies. In this study, we examined whether the determinants of ant diversity are invariant across spatial and taxonomic scales, using data from an extensively sampled elevational and latitudinal gradient and from a new global database on ant biodiversity. Along the elevational gradient, the determinants of species diversity varied with spatial scale: at the smallest 1-m2 scales, diversity was a function of abundance. At the largest scale, diversity was a function of temperature and energy availability. Surprisingly, the patterns and processes along the latitudinal gradient were qualitatively similar to those along the elevational gradient. This suggests that local interactions, such as competition, might operate at small spatial scales, but climatic, evolutionary, or historical factors might operate at larger spatial scales. When we asked whether diversity patterns of species mirrored generic and tribe-level diversity patterns, we found strikingly similar patterns. Generic diversity peaked at mid-latitudes and at low elevations. Together, these results suggest that gradients in ants are shaped by both evolutionary and ecological processes, but the relative importance of these processes varies with spatial and taxonomic scale.

Patterns of introduction of *Pinus* and *Eucalyptus* pests in South Africa compared using mitochondrial DNA sequence data

Bernard Slippers, Brett P. Hurley, Ryan Nadel, Derian Echeverri, Michael J. Wingfield

[1]Department of Genetics, Forestry and Agricultural Biotechnology Institute, University of Pretoria, Pretoria, South Africa, [2]Department of Microbiology and Plant Pathology, Forestry and Agricultural Biotechnology Institute, University of Pretoria, Pretoria, South Africa

During the past 100 years a number of invasive pests have had a significant negative impact on the productivity of commercial *Eucalyptus* and *Pinus* plantations in South Africa. In this study, mitochondrial cytochrome oxidase subunit I (CO I) sequences were used to characterize populations of some of these invasive insects in South Africa. These include *Sirex noctilio* (Hymenoptera), *Thaumastocoris peregrinus* (Hemiptera), *Bradysia difformis* (Diptera) and *Gonipterus scutellatus* (Coleoptera). Where possible, populations of these insects were compared with populations from potential regions of origin. *Sirex noctilio* showed very limited CO I diversity in the southern hemisphere as a whole, and appears to have been introduced into South Africa from South America. *Thaumastocoris peregrinus* also showed very limited CO I diversity, but seems to have been introduced into South Africa on two separate occasions over a short period, and independently once into South America. In contrast, *B. difformis* was highly diverse and has clearly been introduced in fairly large numbers or multiple times. In the case of *Gonipterus*, the South African populations are divided into two very distinct mitochondrial types. This might indicate that two distinct species occur in the country, contrary to previous reports. One of these types is shared between South African populations and those found in South America and Europe, while a third mitochondrial type only occurs in populations in South America. Where it was possible to examine these, the population diversity of biological control agents for *S. noctilio* (*Deladenus siricidicola*: Nematoda) and *G. scutellatus* (*Anaphes nitens*: Hymenoptera) display very limited genetic diversity. These studies have highlighted the fact that knowledge relating to genetic diversity in invasive forest pests in South Africa will be an important guide to predict future introductions and to manage associated biological control programs.

Genetic diversity, species phylogeny and historical biogeography of Lord Howe Island moss bugs (Hemiptera: Coleorrhyncha: Peloridiidae: *Howeria*)

Jakob Damgaard, Gerry Cassis

The Natural History Museum of Denmark, Copenhagen, Denmark

Introduction: Moss bugs are critical for understanding the basal evolution of Heteroptera, as well as for investigating the historical biogeography of the Southern Hemisphere continents and the supercontinent Gondwanaland. About 35 species are found in cool and humid habitats in Patagonia, New Zealand, New Caledonia and Australia. Among these, three species are found on the 27 hectare, plateau-like mountain-top of Mt. Gower of Lord Howe Island in the Tasman Sea. Lord Howe Island got considerable attention for hosting a possible case of sympatric speciation in palms (Howea), but the islands moss bugs may represent a comparable case.

Methods: The genetic diversity of the three species *Howeria coggeri* Evans, *H. kingsmilli* Evans, and *H. payteni* Evans are investigated on basis of body measurements and analyses of mitochondrial and nuclear DNA sequence data. A phylogenetic analysis of moss bugs from Australia, New Zealand and Patagonia is used to address the origin and diversification of the Lord Howe Island fauna.

Results: The results show a clear separation between the three species of *Howeria* on Lord Howe Island based on body size and DNA, and may indicate a sympatric speciation on the Mt. Gower plateau. Phylogenetic analyses of *Howeria* and other moss bugs give indices of the source and timing of the initial colonization of the island.

Conclusions: The presence of three congeneric species of moss bugs on Lord Howe Island is of great interest in understanding the evolution of biota on oceanic islands and specifically the historical biogeography of the southern Hemisphere.

Diversity and interactions of flower visitors of *Aechmea nudicaulis* and *Vriesea friburgensis* (Bromeliaceae)

Simone Grohme[1], Volker Schmid[2], Anne Zillikens[1], Josefina Steiner[3]

[1]Botanical Institute, University of Tuebingen, Tuebingen, Germany, [2]Department of Evolution, Behavior and Genetics, University of Regensburg, Regensburg, Germany, [3]Department of Embryology, Federal University of Santa Catarina, Florianópolis, SC, Brazil

Introduction: Bromeliads are terrestrial and epiphytic plants occurring almost exclusively in the neotropics. Although the most widespread bromeliad flower syndrome (ornithophily) favours bird visitation, inflorescences can be exploited by many insect species. We aimed to record spectrum and species richness of flower visitors and to document their temporal pattern, behaviour, and efficiency as pollinators.

Methods: In southern Brazil, the bromeliad species *Aechmea nudicaulis* and *Vriesea friburgensis* were observed throughout their flowering seasons from 2005 to 2008 to record flower visitors as well as interorganismic interactions. Flower bagging experiments allowed us to determine the pollinator efficiency of single species.

Results: 42 taxa were observed visiting *A. nudicaulis* flowers, 38 in *V. friburgensis*. Bees and ants appeared to be the most diverse groups, followed by butterflies in *A. nudicaulis* and beetles in *V. friburgensis*. Most visits were made by bees and hummingbirds; the latter were the most efficient pollinators. They patrolled inflorescences throughout the day, foraging for floral nectar. In contrast, bees were observed mainly in the morning, collecting first pollen and then nectar, while butterfly visits were recorded mostly in the afternoon. Further interactions comprise lycaenid caterpillars of the genus *Strymon*, eating *A. nudicaulis* fruits and associated to visiting ants, as well as eurytomid wasps parasitizing buds of *V. friburgensis*.

Conclusions: The bromeliad species *Aechmea nudicaulis* and *Vriesea friburgensis* are associated to a high diversity of animals, thus opening countless possibilities of interactions. This underpins the importance of bromeliads for tropical ecosystems, especially concerning insect-plant interactions.

Tribolium castaneum as a model organism for comparative pathology

Jeff Lord

GMPRC, USDA-ARS, Manhattan, Kansas, United States

The advantages of *Tribolium castaneum* as a model for host-pathogen interactions lie in the variety of disease organisms that may attack it and the apparent strength of its defenses against them. Unlike *Galleria mellonella*, which is a commonly used model that is highly susceptible to a wide array of opportunistic pathogens, *T. castaneum* is very tolerant of non-specific diseases. For example, we have found that the LC50 of *Beauveria bassiana* for larval *T. castaneum* is ca. 300 mg/kg of diet, approximately 10-fold of its LC50 for larvae of most stored-product beetles. Accordingly, it provides a system for assessing which defense mechanisms are most effective. Furthermore, it is subject to a small number of host-specific but slow developing pathogens, such as *Farinocystis tribolii*, a neogregarine, and *Paranosema whitei*, a microsporidium, to which it mounts no apparent defense reactions. This affords the opportunity to test evasive mechanisms of successful parasites and to do so on an experimentally advantageous schedule. The hardiness of this species is an advantage that should not be overlooked. Paucity of control mortality is a great aid in interpreting bioassay data.

Evidence of an interaction between host preference and endo/exophagy in the malaria mosquito *Anopheles arabiensis*

Inaki Tirados, Gabriella Gibson, Stephen Torr

Natural Resources Institute, University of Greenwich at Medway, Chatham Maritime, Kent, United Kingdom

Introduction: *Anopheles arabiensis* is variously described as 'more zoophilic than *An. gambiae s.s.*', 'opportunistic' (feeding on humans and cattle in proportion to availability), or 'anthropophilic', based mainly on bloodmeals and host-odour baited trap data. The effect of host availability on the behaviour of *An. arabiensis* was investigated experimentally in southern Ethiopia.

Methods: Human-landing catches and cattle-baited trap catches were used to assess the relative attractiveness of each of these hosts to *An. arabiensis* when the hosts were either on their own or surrounded by a ring of 5 cattle (5 m diameter ring), in a 4 X 4 Latin square design. The attractiveness of a human host indoors with and without a ring of cattle surrounding the dwelling was also tested.

Results: The ring of cattle had no significant effect on the human-landing catch or the cattle-baited trap catch, although > 10 times as many *An. arabiensis* were caught by the human bait than by the cattle bait, whether or not the bait was surrounded by cattle. When the human-landing catch was conducted indoors, however, significantly fewer *An. arabiensis* entered the dwelling when it was surrounded by a ring of cattle than when it was not.

Conclusions: *An. arabiensis* is more strongly attracted to humans than to cattle when there are no physical obstacles to reaching the host, but they are less likely to fly into an enclosure in response to human host cues if cattle are nearby, i.e. there is an interaction between host preference and endo-exophagy.

Using natural polymorphism and artificial selection to investigate the hormonal basis of phenotypic integration in a wing-dimorphic insect

Anthony Zera

School of Biological Sciences, University of Nebraska, Lincoln, Nebraska, United States

Wing polymorphism has been extensively discussed with respect to the evolution of systemic endocrine regulators that integrate the expression of suites of morphological, behavioral, and physiological traits to produce morphs adapted for flight versus reproduction. Detailed investigations of flightless/reproductive and flight-capable morphs of naturally-occurring wing polymorphisms have identified morph differences in both JH and ecdysteroid titers that potentially regulate aspects of morph development. The enzyme juvenile hormone esterase (JHE), a regulator of the blood JH titer, appears to play an important role in this process. Complementary artificial-selection studies on hemolymph JHE activity in a wing-monomorphic congener have provided experimental evidence concerning (1) the degree to which JHE activity must be changed to alter the JH titer sufficiently to modify the development of components of the flight apparatus, (2) the extent to which endocrine traits expressed in different life cycle stages are constrained to evolve in concert, and (3) the relative roles of JH and ecdysteroids in regulating variation in wing and flight muscle morphology. Recent molecular studies of JHE are identifying the mechanisms by which variation in JHE gene expression gives rise to variation in blood JHE activities, which, in turn regulate the expression of morphological traits involved in flight. Finally, recent studies of JH and ecdysteroid titers in adult wing morphs have demonstrated substantially more complex JH titer variation between morphs which necessitates a rethinking of basic models of the endocrine regulation of the expression of morph-specific traits in wing polymorphic insects.

Some challenges in modelling the potential distribution of invasive insects under climate change

Darren Kriticos

CSIRO Forest Biosciences, Kingston, ACT, Australia

CLIMEX is a modelling tool for exploring the relationship between a taxa and climate. This facility is useful for inferring a species response to climatic variables and for applying these relationships to novel climates to project the potential distribution and relative abundance of invasive organisms. In contrast to most habitat models, CLIMEX is process-oriented. This gives it an ability to project species ranges in novel climates with more confidence than regression based models like Bioclim or CLIMATE, which have a tendency to introduce range contractions under novel climates that are modelling artefacts that are inconsistent with observations or theoretical expectations. Many CLIMEX models have been developed for invasive insects, and many of these models have been well validated in terms of the range limiting factors. The performance of these models when projected into novel climates and compared with independent data in the exotic ranges gives us some confidence that the models will be robust under future climate scenarios. Thus, CLIMEX is fairly well adapted to projecting species ranges under future climate scenarios. However, a significant problem for all habitat models (including CLIMEX) that rely upon the known distribution of a species to infer its' habitat preferences is the decoupling of species ranges from the contemporaneous climate that gave rise to the distribution data. Species ranges are changing in relation to changes in climate. Lags in these range contractions and expansions in relation to a trending climate will inevitably give rise to projection errors.

Landscape structure and arthropod-mediated ecosystem services

Douglas A. Landis, Mary M. Gardiner, Anna K. Fiedler, J. Megan Woltz

Michigan State University, East Lansing, MI, United States

Introduction: Modern agricultural landscapes have been shaped by production systems aimed at maximizing crop yield and profitability and differ markedly in their ability to supply important Arthropod-Mediated Ecosystem Services (AMES) such as biological control and pollination. Highly simplified landscapes may lack critical infrastructure needed for some species and thus limit populations and diversity of beneficial arthropod communities. This in turn may limit the level of ecosystem services that can be garnered from such landscapes.

Methods: In a series of studies we have examined the impact of landscape structure on biological control of soybean aphid, *Aphis glycines* Matsumura, the role of native vegetation in promoting natural enemies and pollinators, and explored how directed versus unplanned landscape change may alter AMES. Using data from 23 sites across four states and two years, we calculated a biological control services index (BSI) based on relative suppression of soybean aphid populations relating it to landscape complexity and composition at multiple spatial scales.

Results: Landscape diversity and crop composition at a scale of 1.5 km surrounding the focal field explained the greatest proportion of the variation in BSI and predator abundance. We also identified 26 native plant species that show particular promise for use in habitat management to enhance AMES.

Conclusions: Our studies suggest that directed management of landscapes has the potential to stabilize or increase biocontrol services. In contrast, unplanned landscape changes driven by increasing demands for grain-based biofuel production have the potential to dramatically reduce biocontrol services in agricultural landscapes.

Phylogeny and evolution of Cynipoids

Matthew Buffington

Systematic Entomology Lab, USDA/ARS c/o NMNH, Smithsonian Institution, Washington DC, United States

The Cynipoidea (oak gall wasps and their allies) are a moderately speciose group of microhymenoptera that can be found world-wide. Of the five extant families, nearly all the species level diversity can be found within the Cynipidae and Figitidae. While the cynipids are fairly well known for their gall making abilities on plants such as the oaks and roses, the phylogenetics and taxonomy of the group are only now beginning to show some resolution. This, however, is confounded by the fact that molecular and morphological evidence are currently in disagreement over a few critical placements, even bringing into question the monophyly of the family as a whole. Relationships within the lesser-known Figitidae are also beginning to show signs of resolution. This group, largely endoparasites of cyclorrhaphous Diptera, plesiomorphically attack gall inducing Hymenoptera. This presentation highlights our current hypotheses of relationships and divergence estimates within Cynipoidea, providing novel insight into the evolution of the group.

The Encyclopedia of Life: A global, communal approach to arthropod systematics

David P. Shorthouse[1], David J. Patterson[1], Sarah Falwetter[2], Alexey Shipunov[1]

[1]Marine Biological Laboratory, Woods Hole, Massachusetts, United States, [2]Institute of Marine Biology and Genetics, Hellenic Centre for Marine Research, Heraklion, Crete, Greece

The Encyclopedia of Life (EOL) provides a vehicle for biodiversity information. EOL is committed to the Semantic Web. With the Global Biodiversity Information Facility (GBIF), EOL is exploring a Global Names Architecture that will assist machine to machine dialog about species. EOL is a member of CrossRef and will assign Digital Object Identifiers (DOIs) to its on-line species pages. Participation by experts will lead to a variety of new taxonomically intelligent and technically innovative tools and services to enhance appreciation for global biodiversity. EOL will also draw together distributed data from many partners inclusive of the millions of pages available through the Biodiversity Heritage Library and scholarly journals. We are developing new participatory tools that include on-line interfaces to help develop consensus taxonomies.

Gustatory and pheromone perception in *Drosophila*

Tetsuya Miyamoto, Jesse Slone, Hubert Amrein

Duke University Medical Center, Department of Molecular Genetics and Microbiology, Durham, North Carolina, USA

Introduction: In Drosophila, non-volatile chemicals are detected by a large number of 7 transmembrane receptors expressed in sensory neurons of taste sensilla located mainly in the labellum and the legs. Here, we investigate the role of several of these Gustatory receptors (GRs) necessary in the detection of food and pheromone compounds (sugars and long chain hydrocarbons, respectively), and we describe the behavioral phenotypes of flies lacking specific receptors.

Methods: Expression of individual Gr genes was performed using the Gal4/UAS expression system. Mutations in Gr genes were generated by homologous recombination or by PiggyBac/FRT mediated recombination. Behavioral analyses to measure the effects of *Gr* mutation included proboscis extension reflex, 2 –choice feeding assays and quantitative courtship analyses.

Results: Behavioral analyses of Gr64a-f mutant flies revealed that these six *Gr* genes are receptors for almost all sugars, including sucrose, glucose, trehalose and arabinose. Interestingly, the significant reduction of a behavioral response to trehalose is indicative of flies mutant for another Gr gene, Gr5a, and suggest multiple receptors may function as dimers or multimers for the detection of a single chemical. We also carried out a molecular genetic analysis of Gr32a, the closest homolog of the male-specifically expressed pheromone receptor Gr68a. Interestingly, Gr32a is not required for courtship of males towards females, but necessary to repress courtship among males.

Conclusions: The molecular-genetic characterization of several Gr genes and the behavioral analyses of mutant flies show that Gr genes have diverse functions in the perception of food chemicals and pheromones.

Impacts of CO_2 pollution on plant-insect interactions: A transcriptional and biochemical analysis of soybean defense signaling

Clare L. Casteel, Jorge A. Zavala, May R. Berenbaum, Evan H. DeLucia

Universtiy of Illinois - Urbana/Champaign, Urbana, IL, United States

Rising carbon dioxide (CO_2) levels are predicted to increase the productivity of ecosystems, however, growth in elevated CO_2 generally reduces the nutritional quality of plants for protein limited insects. Insects may increase food intake to compensate for reduced leaf nitrogen content, although this is not always the case. Incomplete understanding of the mechanisms governing plant-insect interactions under elevated CO_2 makes it difficult to predict how elevated CO_2 will influence ecosystems in the future. Based on previous studies examining global transcriptional profiles in soybean (*Glycine max*), elevated CO_2 exposure is hypothesized to modulate plant resistance through alterations in hormone signaling and defenses against herbivorous pests. To determine the impact of elevated CO_2 exposure on plant-insect interactions in soybean, magnitude and timing of three major hormone signaling pathways (jasmonic acid [JA], salicylic acid [SA], and ethylene [ET]) and related defenses were examined after Japanese beetle (JB; *Popillia japonica*) attack in controlled and open field environments under elevated CO_2. Elevated CO_2 exposure down-regulated the expression of transcripts related to JA and ET production and decreased accumulation of related metabolites (JA and protease inhibitors; PIs) in undamaged leaves. JB attack increased both transcripts and metabolite accumulation in ambient grown soybean leaves initially, but to a lesser extent over time or not at all in elevated CO_2. The modulation of JA and ET signaling transcripts and metabolites lowered plant chemical defense and can explain increases in damage observed in previous soybean studies that were not explained by changes in plant nutrition.

Neurochemicals in the mosquito chemosensory systems

KP Siju[1], Jan Bert Gramsbergen[2], Joachim Schachtner[3], Bill Hansson[4], Ignell Rickard[1]

[1]Swedish Agricultural University, Alnarp, Sweden, [2]University of Southern Denmark, Odense, Denmark, [3]Philipps University, Marburg, Germany, [4]Max Planck Institute for Chemical Ecology, Jena, Germany

Blood feeding insects, such as mosquitoes, primarily depend on their chemosensory systems to locate and identify blood hosts. In these insects, the need to fine tune the chemosensory systems, in order to adapt to complex environmental and behavioral conditions, is of paramount importance for their survival. Several putative neurochemicals present in the chemosensory system are believed to facilitate this modulation.

With the help of immunocytochemical and biochemical techniques we have studied the presence of neuromodulators, including biogenic amines and neuropeptides, in the chemosensory systems of disease vector mosquitoes. Immunocytochemical localization of the biogenic amine, serotonin, reveals the presence of a single serotonin-immunoreactive centrifugal neuron in the primary olfactory center or the antennal lobe (AL) that provide extensive serotonergic investment in the peripheral chemosensory organs, i.e. the antenna and the maxillary palp. In addition we find serotonergic neurons projecting into the labium. Titre analysis of all biogenic amines in the central nervous system using HPLC-ECD indicates a link between the titre of biogenic amines and the physiological state of the mosquitoes. To extend our analysis we also, for the first time, provide a detailed immunocytochemical map of neuropeptides such as FMRFamide, tachykinin, allatostatin and allatotropin in the AL of mosquitoes. Several of these neuropeptides are present in local interneurons as well as centrifugal neurons innervating the AL. The morphological data suggests a possible role of these neuropeptides in olfactory information processing. By using MALDI-TOF-MS analysis we are, furthermore, expanding our analysis to include all neuropeptides expressed in the AL of these mosquitoes.

Phylogeny and diversification of ants (Formicidae)

Sean Brady[1], Ted Schultz[1], Brian Fisher[2], Phil Ward[3]

[1]Smithsonian Institution, Washington, D.C., United States, [2]California Academy of Sciences, San Francisco, California, United States, [3]University of California, Davis, California, United States

Introduction: Resolving the phylogeny and timeline of major ant lineages is necessary to better understand the ecological dominance of ants and their coevolutionary relationships with other organisms.

Methods: We generated data from up to 10 nuclear genes from representatives of all extant ant subfamilies to address outstanding problems in ant phylogeny. Phylogenetic analyses were conducted using parsimony, likelihood, and Bayesian methods, including partitioned codon-model analyses. Divergence dating utilized penalized likelihood and Bayesian methods using evidence from the entire aculeate hymenopteran fossil record.

Results: Many relationships among major lineages were resolved robustly, but alternative hypotheses for early ant diversification could not be rejected. Estimates of the age of crown group ants ranged from ~115-135 million years ago. We explored the impact of these results on recently proposed ideas concerning codiversification between ants and angiosperms. Our sources of molecular data were also useful in resolving relationships at lower taxonomic levels. For example, we analyzed data from 26 of the 28 extant genera from the cosmopolitan subfamily Dolichoderinae. Our analyses revealed that the major Australian clade of dolichoderines is apparently of Neotropical origin and that this Australian radiation postdated the achievement of dolichoderine dominance in the northern hemisphere as judged by the fossil record.

Conclusions: Our molecular data robustly resolves many relationships at several taxonomic levels, but resolving early ant relationships with confidence will require additional data and taxon sampling. Robust phylogenies hold great potential for increasing our understanding of ant behavioral evolution, biogeography, and codiversification with other organisms.

Impact of green tree retention on boreal moths

Esther Kamunya[1], John Spence[1], Jan Volney[2]

[1]University of Alberta, Edmonton, Canada, [2]Canadian Forest Service, Edmonton, Canada

Introduction: Green tree retention (GTR) is a modification of traditional clear-cut harvesting whereby a proportion of a forest stand is left standing and alive at harvest to provide legacy elements. It is assumed that this promotes continuity and re-colonization of disturbed patches, thus mimicking natural processes of disturbance. However this assumption needs to be empirically tested. We used moth assemblages to monitor effects of GTR on biodiversity in experimentally harvested boreal forest stands at EMEND (Ecosystem Management Emulating Natural Disturbance) in NW Alberta, Canada. Forest lepidopterans play important ecological and environmental roles as primary insect herbivores and have potential to predict overall diversity of other taxa.

Methods: Using UV lights we trapped moths from two cover types (deciduous (ADOM) and coniferous (CDOM) both comprising two GTR treatments (20% and 50%) and unharvested controls. Moths were identified to species and their relative abundance was recorded. We estimated species richness by rarefaction and compared moth communities using multivariate techniques, including Non-Metric MultiDimentional Scaling (NMDS).

Results: Moth responses to harvesting varied with pre-harvest forest cover type. Species richness was higher in ADOM than CDOM stands. GTR decreased richness in ADOM stands, but retaining 50% forest structure maintained moth diversity close to that in undisturbed controls. In contrast, 80% reduction in forest cover increased diversity in coniferous stands which in turn grouped their lepidopteran assemblages together with those of ADOM stands, suggesting that forest moth assemblages were homogenized after harvesting. Most importantly, particular species-specific responses deviated from overall community response.

Conclusion: Maintaining a mosaic of habitat with varying disturbance intensity in each cover-type will better conserve moth assemblages of managed boreal forest ecosystems.

Long-distance gene flow among European corn borer populations in North America

Kyung-Seok Kim, Thomas Sappington

USDA-ARS, CICGRU, Ames, IA, United States

The European corn borer (ECB), *Ostrinia nubilalis,* is the main target of transgenic Bt corn expressing the Cry1Ab toxin. There is concern that strong selection pressure will lead to the evolution of resistance in ECB to Bt corn. Effective insect resistance management depends on knowledge of gene flow. We began a project in 2005 using 8 microsatellite DNA markers to measure gene flow spatially along two 450-mile transects through the central Corn Belt, and between years at a subset of locations. The results from both spatial and temporal population genetic analyses indicate that long-distance dispersal is very common in this insect. There is random mating within and between populations in the central Corn Belt, with no apparent barriers to gene flow, and per-generation dispersal is common out to 100s of km. This outcome was unexpected, based on circumstantial evidence suggesting maximum ECB movement of only about 80 km. However, this conclusion is consistent with recent field and laboratory behavior experiments in the U.S. and Europe that suggest long-distance dispersal is part of this insect's normal behavior. High gene flow over hundreds of km in the Corn Belt implies 1) that resistance to *Bt* corn will be slow to develop, but 2) if it does develop, it will spread geographically so quickly that local mitigation strategies likely will be ineffective. Thus, widely spaced sites, or pooling samples over widely spaced sites, for Bt-resistance monitoring is justified, at least for the common bivoltine Z-pheromone race in the Corn Belt.

Elucidation of the phylogenetic relationships and host-specificity of an oligophagous flea beetle (Coleoptera: Chrysomelidae: Galerucinae)

Tyler Eaton, S. Kristine Braman, Tracie Jenkins

University of Georgia, Griffin, Georgia, United States

Altica litigata is an economically important oligophagous flea beetle that is a pest on certain ornamental plants. Adult beetles are known to be aggregate feeders on the leaves of primroses of the genus *Oenothera* (Onagraceae) and opportunistic feeders on crape myrtles of the genus *Lagerstroemia* (Lythraceae). Gravid females oviposit on the leaves of *Oenothera* where the larvae feed until they pupate. *Altica litigata* is difficult to distinguish morphologically from other genera of *Altica*. Consequently, research into the species can lead to uncertainty. The purpose of this study was to illuminate the gene flow, genetic diversity, and population structure of *Altica litigata*.

Saproxylic insects in old hollow deciduous urban trees

Elina Peuhu[1], Meeri Mäki[2], Juha Siitonen[3], Kari Heliövaara[1]

[1]Department of Forest Ecology, Faculty of Agriculture and Forestry, University of Helsinki, Helsinki, Finland, [2]Department of Biological and Environmental Sciences, Faculty of Biosciences, University of Helsinki, Helsinki, Finland, [3]Finnish Forest Research Institute, Vantaa Research Unit, Vantaa, Finland

Introduction: Several rare and threatened saproxylic species occur in urban areas. Many of these species are specialized on temperate tree species, warm conditions and long-lasting habitats, which are found in old hollow trees. In Finland, saproxylic insects in urban areas have not been widely investigated. This study is a part of a larger project focusing on saproxylic insects living in old, hollow deciduous urban trees. The aim is to find out which species occur in urban parks and what kind of habitat characteristics they require.

Methods: We initiated a study on the occurrence of saproxylic Coleoptera, Hymenoptera and Diptera living in hollow deciduous trees in urban parks. The data were collected from linden, maple and elm trees in 2007. The trees were felled in April in a park located in southern part of Helsinki city. We took samples from wood mould and branches that seemed potential habitats for saproxylic insects. The samples were stored in a greenhouse for four months and then checked for saproxylic insects.

Preliminary results: *Stenostola dubia* (Cerambycidae) was abundant on linden branches. Predator species may have consumed some of the species before they were ever discovered. Tree species, and the specific part of the tree the sample was taken from, had an effect on the observed species assemblage. It seems that existence of a hole in a tree trunk affects species assemblage living inside the hollow in wood mould.

Pheromones and biodiversity - monitoring change in a changing world

Mattias Larsson[1], Glenn Svensson[2], Nils Ryrholm[3]

[1]Swedish University of Agricultural Sciences, Alnarp, Sweden, [2]Lund University, Lund, Sweden, [3]University of Gävle, Gävle, Sweden

Insect sex pheromones have been used extensively in integrated pest management but not yet for monitoring of rare and threatened insects, despite the growing concern for biodiversity and conservation. The legendary attractiveness of sex pheromones makes them an ideal tool for studying many insect species occurring at very low population densities, including newly established invasive species. We present two model systems that are likely the first to exploit pheromones in the context of conservation and biodiversity:

1) The sex pheromone-kairomone system of the threatened saproxylic scarab beetle *Osmoderma eremita* and its predator, the click beetle *Elater ferrugineus*, which breed in hollow trees in fragmented oak stands in pastoral landscapes.

2) Monitoring a whole range of tineid and clearwing moths in fragmented forest landscapes, using only a few single compounds from their phylogenetically restricted pheromone systems. Tineid moths breed in dead wood and/or associated fungi, making them potentially valuable indicators of mature forest with high levels of biodiversity.

Our investigations illustrate the versatility of pheromones for precise monitoring in space and time and include estimates of absolute population size by capture-recapture studies; estimates of presence/absence and population density on landscape and regional scales; monitoring of population fluctuations over several years, and studies of dispersal frequency and dispersal distance. We have shown that previous recapture models of *O. eremita* likely lead to severe underestimations of population size, and that patterns of disappearance for tineid moths appear to be very different from those of saproxylic beetles, which are studied more frequently.

In vivo models for exploring the molecular basis of tick feeding and pathogenesis

Deborah Jaworski[1], C. Jerry Bowen[1], Glen Needham[2]

[1]Oklahoma State University, Stillwater, OK, United States, [2]The Ohio State University, Columbus, OH, United States

Using in vivo models to study the molecular and physiological basis tick feeding and pathogenesis has become very tractable with immunological and RNAi technologies. Ticks are somewhat unique among blood feeding arthropods, because we can immunize hosts and subject them to tick feeding challenge. Through RNAi, we are able silence specific genes by injecting ticks with double-stranded RNA (RNAi) and feeding them on hosts. Some silenced genes lead to lowered fecundity, ablation of feeding or decreased pathogen transmission. For immunizations, we essentially produce hosts that are “immunological knockouts” of the tick protein. We discuss immunological- and RNAi-based tick-host models for tick feeding and pathogenesis; and their advantages and disadvantages for evaluating the function of a protein during tick feeding.

Variation in caterpillar chemical defense: Effects on predators versus parasitoids

Deane Bowers

University of Colorado, Boulder, Colorado, United States

The ability of insects to sequester defense compounds from host plants has evolved in many different groups of insects and involves a variety of different classes of chemical compounds. Most insect species that have this ability are specialists, but some are generalists and members of the Lepidoptera have been particularly well studied in this regard. Variation in the amounts and kinds of compounds sequestered by insects can be important for both predators and parasitoids of those insects. Using lepidopteran caterpillars as a model group, this talk will compare and contrast the effects of different groups of sequestered compounds on predators and parasitoids.

Whitefly Transmission of Sweet Potato Leaf Curl Virus

Alvin Simmons, Kai-Shu Ling, Howard Harrison, D. Michael Jackson

USDA, ARS, U. S. Vegetable Laboratory, Charleston, South Carolina, United States

Introduction: The sweetpotato whitefly, *Bemisia tabaci* (Gennadius) is highly adaptive and polyphagous on taxonomically diverse species of plants on a global scale. This whitefly transmits numerous plant viruses, including Begomoviruses (Geminiviridae). We recently found the *Sweet Potato Leaf Curl Virus* (SPLCV) in South Carolina and since conducted studies on the role of *B. tabaci* as a vector for this virus.

Methods: Laboratory, greenhouse, and field experiments were conducted on host range and on transmission, acquisition, and retention of SPLCV by *B. tabaci* on *Ipomoea setosa* and sweetpotato. Determination of SPLCV was made with symptom expression on indicator plants (*I. setosa*) and confirmed by Real-time PCR.

Results: Over 50 species of diverse taxa were identified as new hosts for *B. tabaci*, and over 40 species of *Ipomea* were identified as being susceptible to SPLCV. We did not detect SPLCV in over 70 species of other wild and cultivated plants. Data on transmission, acquisition, and retention will be presented.

Conclusions: Although individual *B. tabaci* appears to be moderately efficient in acquiring and transmitting SPLCV, the presence of the virus and an increasing population of the insect vector pose serious threat to sweetpotato production worldwide. These findings will help in the epidemiology of SPLCV in the sweetpotato field, and the resistant *Ipomea* may be useful in sweetpotato breeding programs.

Social life below ground: Colony breeding structure and inbreeding variation in subterranean termites

Edward Vargo

North Carolina State University, Raleigh, NC, United States

Introduction: Breeding systems of subterranean termites (Rhinotermitidae) are complex and poorly characterized. Colonies are founded by monogamous pairs of primary reproductives. Subsequently, colonies can be secondarily polygamous through production of neotenic reproductives that inbreed within the colony. To obtain a better understanding of colony breeding structure and how it varies among and within subterranean termite species, we conducted a comparative study of three species of *Reticulitermes* that are sympatric over much of the eastern U.S.: *R. flavipes*, *R. virginicus*, and *R. hageni*.

Methods: We used microsatellite markers to determine colony breeding structure and levels of inbreeding in several populations.

Results: We found important similarities and differences in breeding structures of these species. Most colonies of all species were simple families headed by monogamous pairs of reproductives. Nearly all of the remaining colonies contained low numbers of neotenic reproductives descended from simple families. In *R. flavipes*, a small number of colonies were mixed families, showing evidence of multiple unrelated same sex reproductives, probably arising from colony fusion. In general, inbreeding levels in all three species were low. In *R. flavipes*, for which we have the most extensive range samples, we found strong latitudinal variation in colony breeding structure with higher proportions of simple families in the south and progressively lower in the north.

Conclusions: Our results indicate that colonies of these subterranean termites are not as inbred as has been generally assumed, and that breeding structure is responsive to environmental factors that vary gradually across a latitudinal gradient.

Managing insect invasions: Lessons from biological control of weeds

Peter McEvoy, Eric Coombs, Fritzi Grevstad, Shon Schooler

[1]Oregon State University, Corvallis, Oregon, United States, [2]Oregon Department of Agriculture, Salem, Oregon, United States, [3]Olympic Natural Resources Center, Long Beach, Washington, United States, [4]CSIRO Entomology, Indooroopilly, Queensland, Australia

Introduction: Biological control introductions can provide more relevant information on the independent and dependent variables in the invasion processes of insects than is typical of most invasions. The introduction of two chrysomelid beetles, *Galerucella calmariensis* and *G. pusilla*, to North America for biological control of purple loosestrife (*Lythrum salicaria*) presented us with an opportunity to measure and model their rates of spread into new areas.

Methods: We compared spatial spread rates estimated by different methods; autonomous spread of different geographic populations; and autonomous and anthropogenic spread. We start with a basic reaction-diffusion model simplifying demography and movement.

Results: We compare observed spread with that predicted by the basic model; and we conclude that linear spread predicted by the basic model best describes autonomous spread by *Galerucella*. We evaluated the autonomous spread model based on both assumptions and predictions. Field observations closely matched model predictions: the radial distance increased linearly through time. However, field observations contradicted model assumptions by revealing that population growth is subject to Allee effects and stochastic variation and movement distances are leptokurtic.

Conclusions: Paradoxically, the data match the predictions of the basic model, but not the assumptions. A possible resolution to the paradox is that effects may be equal and offsetting: Allee and stochastic effects tend to slow the speed of an invasion, while leptokurtic dispersal tends to increase it.

Managing insect invasions: Lessons from biological control of weeds

Peter McEvoy, Eric Coombs, Fritzi Grevstad, Shon Schooler

[1]Oregon State University, Corvallis, Oregon, United States, [2]Oregon Department of Agriculture, Salem, Oregon, United States, [3]Olympic Natural Resources Center, Long Beach, Washington, United States, [4]CSIRO Entomology, Indooroopilly, Queensland, Australia

Intraguild predation in predatory Heteroptera

Éric Lucas

Université du Québec à Montréal, Montréal, Québec, Canada

Intraguild predation is an ubiquist interaction within predatory insect guilds. Heteropteran species, as predators of the main crop pests (aphids, whiteflies, mites …) in annual and perennial systems, are involved in the interaction either as intraguild preys or intraguild predators. The impact of their biological formula (morphology, physiology, behaviour, development) on the direction, symmetry and intensity of the intraguild predation is discussed. Many heteropteran predators also are considered as zoophytophagous organisms, able to complete their life cycle on animal, or on plant food source. According to this omnivorous behaviour, predation on a phytophagous organism may be considered as intraguild predation. This unique link between heteropteran predators, non-heteropteran intraguild natural enemies, crop pests and plants can generate singular direct and indirect effects. Finally, intraguild predation may disrupt or not biological control of pest, according to the nature of the different interactions in the system.

Life history and population dynamics of temperate waterstriders: lessons from a 24-year bug count

John Spence

University of Alberta, Edmonton, Alberta, Canada

Introduction: Long-term studies of populations are scarce but required to fully understand the adaptive value of insect life-history strategies. Selective pressures associated with regulation of voltinism and dispersal behavior are better understood in a long-term context.

Methods: I have conducted, over a 24 year period, weekly censuses of the populations of five co-occurring species of gerrids on a small pond in central Alberta, Canada. All adult individuals were collected and marked each week. Experiments embedded in this work estimate predation and dispersal rates and variation in female fertility over time.

Results: There is significant long term variation in the success of these species, suggesting that annual variation shifts selective advantages among species. Few overwintered bugs that completed development on the pond actually reproduced there in the subsequent year and this average proportion varies between c. 10% and <0.5%, depending on species. Flight is a highly significant aspect of local population dynamics, explaining more local changes in population than does depredation in the two main species. I identify at least 4 sorts of dispersal flights, each associated with a different range of selective pressures. Some bugs begin leaving the pond for overwintering diapause as early as mid-July.

Conclusion: Pond-dwelling gerrid populations in central Canada exist as structured demes with much connection among units traversing juvenile development on particular ponds. Dispersal by flight is a central aspect of life-history strategy and, in most species, this co-exists temporally with reproduction with only very weak expression of the oogenesis-flight syndrome.

Extensile oviscapts: enigmas in early Lepidoptera evolution

Niels Peder Kristensen, Frank Hünefeld

[1]*Natural History Museum of Denmark, University of Copenhagen, Copenhagen, Denmark,* [2]*Institut für Spezielle Zoologie und Evolutionsbiologie, Friederich-Schiller Universität, Jena, Germany*

A telescope-like extensile female postabdomen ('oviscapt') with two pairs of long rod-like apodemes arising, respectively, from the anterior margins of segments VIII and IX, is a putative ground pattern autapomorphy of the superorder Amphiesmenoptera. The non-glossatan Agathiphagidae have an extra apophysis pair, since one pair arises from tergum VIII and one from the ventral plate of the same segment. Expectedly, the musculature of this three-apophysis-pairs postabdomen is exceptionally complex: as many as 24 muscle sets were identified in our recently completed examination, while we find no more than 11 sets in the basal glossatan family Eriocraniidae. Muscle configuration does not clearly indicate whether the single anterior apophysis in the typical lepidopteran complement is homologous with the dorsal or the ventral set in *Agathiphaga*, and it remains a possibility that it actually represents a fusion product of the two. That the three-apophysis oviscapt could even represent the amphiesmenopteran ground pattern condition is another issue which deserves particular scrutiny in the light of this configuration being discovered in 1996 in the intriguing basal caddisfly *Fansipangana*.

The occurrence of overall very similar piercing oviscapts with a terminal 'saw' in the glossatan families Eriocraniidae, Acanthopteroctetidae and Lophocoronidae is enigmatic, since according to present understanding these families do not form a monophylum, but arose in three successive splitting events during initial glossatan evolution. Parsimony would indicate this postabdominal configuration to be plesiomorphic in Glossata, but then a scenario with the more unspecialized abdominal apex in higher Lepidoptera being due to character reversal is required.

Asilidae from the Cretaceous and Tertiary (Diptera: Brachycera): phylogenetic placement, biogeography, and faunal comparison

Torsten Dikow[1], David Grimaldi[2]

[1]Biodiversity Synthesis Center, Field Museum of Natural History, Chicago, Illinois, United States, [2]Division of Invertebrate Zoology, American Museum of Natural History, New York, New York, United States

The study of extinct species has enormous potential for an examination of the early evolution of a taxon, its biogeography, and species diversity because fossilized specimens preserve *in situ* stages of the evolutionary history otherwise undetected. This presentation reviews the extinct Asilidae (robber flies, assassin flies) from the Cretaceous and Tertiary with particular reference to Dominican amber. The oldest fossils that can be unambiguously assigned to the Asilidae are Cretaceous in origin and can be placed on a comprehensive phylogenetic hypothesis providing not only a minimum age for Asilidae itself, but for a clade composed of Asilidae excluding Asilinae, Laphriinae, and Ommatiinae (110 Mya) as well as the Leptogastrinae (94 Mya). The comprehensive study of the 20 Mya specimens preserved in Dominican amber from Hispaniola Island offers an insight into the faunal composition of the Caribbean Asilidae fauna in the Miocene. For this analysis, 26 amber specimens are available and the extinct diversity can be compared to recently published reviews of the extant robber-fly fauna of Central America and the Caribbean. The extant diversity is well represented by the extinct amber species particularly within Asilinae, Ommatiinae, and Stenopogoninae. A number of presently distributed Laphriinae and Trigonomiminae genera on Hispaniola have not been found in amber. On the other hand, four Neotropical genera (Laphriinae: *Lampria*, *Smeryngolaphria*; Leptogastrinae: *Leptopteromyia*, *Schildia*) have been preserved in amber, but do not presently occur on Hispaniola. An exceptionally surprising finding is the presence of the Old World Leptogastrinae genus *Lobus* in Dominican amber.

Deep splitting events in the mecopterid endopterygotes: a diversity of diversification modes

Niels Peder Kristensen

Natural History Museum of Denmark, Copenhagen University, Copenhagen, Denmark

The clade Mecopterida ('Panorpoid orders' of Hinton's benchmark 1958 review, 'Panorpida' of Grimaldi & Engel) can be traced back to the Permian. Its subgroup Amphiesmenoptera (Trichoptera + Lepidoptera) constitutes the only truly robustly supported sister-group pair among extant insect 'orders', while relationships within the Antliophora (Nannomecoptera + Neomecoptera + Siphonaptera + Pistillifera [Mecoptera *s.str.*] + Diptera) remain debatable, and the suggested assignment of the Strepsiptera to the latter is particularly contentious.

The megadiverse' orders Lepidoptera and Diptera both instructively exemplify the 'additive typogenesis' concept but exhibit starkly contrasting diversification modes. The numerous apomorphies characterizing 'typical flies' (schizophoran Cyclorrhapha) were acquired over a long time span, and sizable radiations occurred in a number of successive evolutionary grades; remarkably, however, resolving the deepest splitting events within the Diptera has proved singularly difficult. In contrast, it seems possible to resolve in detail the sequence in which the first lepidopteran families arose, and hence the sequence in which individual elements of the 'apomorphy syndrome' characterizing 'typical Lepidoptera' (Ditrysia) were acquired. The non-ditrysian lineages, harbouring the bulk of the structural diversity within the Lepidoptera, account for only 1-2% of the species diversity in the order. Resolving the ditrysian radiation is as problematical as resolving basal dipteran diversification.

The deepest splitting events within Trichoptera are not definitely resolved, but most extant caddisflies evolved during radiations of the Annulipalpia and Integripalpia. The recently suggested monophyly of a (Nannomecoptera + (Neomecoptera + Siphonaptera))-clade offers an interesting scenario for flea origin/evolution, but support from ongoing morphological work is ambiguous

Heavy metals alter interactions in a grass-leaf miner system

Luc De Bruyn, Jan Scheirs

University of Antwerp, Antwerp, Belgium

We studied the effects of heavy metal exposure on host plant growth and survival and subsequent host choice and performance of the grass miner *Chromatomyia milii* (Diptera, Agromyzidae). Cadmium decreased plant growth in a dose-dependent way. *C. milii* preferred the control to the cadmium-exposed plants for feeding and oviposition. Moreover, preference for the control plants increased with increasing cadmium exposure of the alternative choice. Adult and offspring performance decreased with increasing plant cadmium exposure. This suggests that, at least under our laboratory conditions, host choice of *C. milii* is adaptive under pollution stress. Foliar cadmium concentration increased and the soluble sugar concentration decreased with increasing cadmium exposure. Regression analysis showed that both latter components might be responsible for the decrease in performance of *C. milii* on cadmium-exposed plants. The protein and amino acid concentration of the leaves, the amount of structural defences, and water concentration were not affected by the cadmium treatment.

Electronic agricultural atlas of insect pests and other harmful organisms of the Former Soviet Union

Andrei Frolov[1], Igor Grichanov[1], Mikhail Saulich[1], Elena Ovsyannikova[1], Genrikh Davidyan[1], Marina Berim[1], Julia Malysh[1], Alexander Afonin[2], Stephanie Greene[3]

[1]All-Russian Institute of Plant Protection, St. Petersburg, Russian Federation, [2]Saint-Petersburg State University, St. Petersburg, Russian Federation, [3]USDA, ARS National Temperate Forage Legume Germplasm Unit, Prosser, WA 99350, United States

Modern geographic information system (GIS) tools allow spatially explicit data on living beings to be assembled, digitized, georeferenced and placed into a framework that can be accessed by a wide audience. As a result of international cooperation, the *Ecological Atlas of Russia and Neighboring Countries: Economic Plants and their Diseases, Pests and Weeds* is now nearing completion. This project is the first attempt to construct a bilingual information and decision support system on the economic plants and the organisms that harm them, across the territories of the Former Soviet Union. Three Russian institutes and the USDA Agricultural Research Service are cooperating to develop the Atlas, which consists of species distribution maps, biological descriptions, (including photographs), climate and agroecological maps, along with easy to use GIS exploratory software. Of interest to entomologists, the Atlas presents 222 maps reflecting the distribution of harmful insects and mites. There are a total of 640 maps describing the distribution of organisms harmful to economically important plants. The maps are based on an extensive review of literature, as well as original surveys of various national collections. Pest, disease and weed distribution zones reflect levels of severity, usually high, moderate and low. Maps can be reviewed at http://www.agroatlas.ru/. Because many of these species have trans-continental and even cosmopolitan distribution, it is of interest world-wide. Researchers, teachers, agronomists and amateurs are now using the freely available published data, maps and pictures to support their own activities. The Atlas is supported by a grant from the USDA, ARS Former Soviet Union Cooperation Program, managed by the ARS Office of International Research Programs, U.S. State Department Non-Proliferation/Proliferation Threat Reduction, and the International Science and Technology Center.

Phylogeography as a tool to trace the origin of expanding populations of the pine processionary moth in the Mediterranean area

Carole Kerdelhué[2], Mauro Simonato[1], Andrea Battisti[1], Lorenzo Zane[1], Jerome Rousselet[3], Alain Roques[3]

[1]University of Padova, Legnaro PD, Italy, [2]INRA Bordeaux, Pierroton, France, [3]INRA Orléans, Olivet, France

Introduction: Although native to large areas of southern Europe, northern Africa, and Middle East, the pine processionary moth *Thaumetopoea pityocampa* is behaving as an invasive species in new parts of the range that become available because of climate change or human introduction. We want to understand the history of this group of species in the Mediterranean and to know how much diversity is present in the range macrorefugia, as starting points of routes to colonize upper elevation and latitude areas.

Methods: Exploring the phylogeographic structure of the pine processionary moths in their whole range (74 populations) by using sequence of mitochondrial DNA, thus concerning the female lineage that is the only relevant for the knowledge of the colonization routes in this species.

Results: A considerable amount of genetic diversity has been found at all major range macrorefugia, that can be identified with mountain ridges located in southern Europe, northern Africa, and Middle East. Major islands showing ancient occurrence of pines, such as Crete, Cyprus, and Corsica, are also centres of diversity whereas the populations on other islands (e.g. Sardinia) are of recent origin, either natural or anthropogenic.

Conclusions: Range expansion is occurring within each major clade with the same pattern, i.e. nearest neighbour origin. Selection of haplotypes particularly adapted to dispersal can be envisaged for at least one clade. Assessment of expansion rates are available for continental France from Battisti et al. (2005) and mean values are around 2.7 km/year, a much faster rate than that observed for trees (most 0.2, few up to 2 km/year, Huntley 2005) and putatively close to that of mobile beetles according to Holocene fossil evidence.

Molecular targets for bark beetle pest management

Claus Tittiger[1], Gary Blomquist[1], Christopher Keeling[2], Tidiane Aw[1], Sharon Young[1], Rubi Figueroa-Teran[1], Pamela Sandstrom[1], Andrew Gorzalski[1], Anna Gilg[1]

[1]University of Nevada, Reno, Reno, United States, [2]University of British Columbia, Vancouver, BC, Canada

Introduction: Mitigation of pine forest destruction by bark beetles is difficult due in part to the geographic scale of outbreaks and the physical inaccessibility of the insects beneath the bark of their host trees. In an effort to develop focused management strategies applicable to high-value, relatively small area forests, we are using functional genomics tools to identify species-specific genes/enzymes to serve as targets.

Methods: In a preliminary "proof-of-concept" experiment, a small EST database representing pheromone-biosynthetic male midguts from the pine engraver, *Ips pini* was constructed and used to fabricate custom cDNA microarrays. The arrays were used to identify genes implicated in the *I. pini* pheromone-biosynthetic pathway. Similarly, a more extensive EST database and oligonucleotide microarray representing *Dendroctonus ponderosae* midguts has been constructed and queried. The biochemical roles of candidate enzymes were further investigated through functional assays of recombinant proteins produced using a baculoviral system.

Results: Enzymes involved in terminal steps in the *de novo* synthesis of the pheromone component ipsdienol were first tentatively identified by clustering microarray expression data and quantitative RT-PCR. Subsequent biochemical assays confirmed the identities of most, if not all of the enzymes involved in the terminal steps of ipsdienol production: geranyldiphosphate/myrcene synthase, myrcene hydroxylase, and ipsdienol dehydrogenase/reductase. Similarly, monoterpene-metabolizing enzymes are being identified from transcriptomic analyses of *D. ponderosae* midguts and fat bodies. Both EST pools have examples of "unknown," apparently Scolytidae-specific genes.

Summary: Functional genomics techniques rapidly identified novel pheromone-biosynthetic, monoterpene metabolizing, and other unique enzymes that may be targeted for future control strategies.

An overview of the Heteroptera of the Afrotropical Region with special reference to the fauna of southern Africa and the Aradidae

Dawid H Jacobs

University of Pretoria, Pretoria, South Africa

Worldwide the Heteroptera comprise about 80 families divided into about 5 500 genera and 40 000 described species. The Afrotropical Region (including Madagascar) has a rich Heteropteran diversity with about 60 families comprising approximately 1 700 genera and 9 000 described species. Notwithstanding the high diversity, few families or subfamilies are endemic to the Region. Only the families Medocostidae and Paraphrynoveliidae and the subfamilies Ocelloveliinae (Veliidae), Stenocorixinae (Corixidae) and Afrocimicinae (Cimicidae) occur exclusively in the Region.

From southern Africa about 55 families with approximately 720 genera and 2 100 described species have been recorded. More than 5% of the genera are endemic to the region. The greatest endemisity appears to be concentrated in the Cape Fynbos and the more xeric areas like Namaqualand, the Cedarberg mountains and the Karoo. Evergreen forests also harbours some endemic genera but not the Savanna.

The Aradidae are discussed as an example of the problems and the taxonomic challenges that the Afrotropical fauna poses. For example: the Carventinae are presently represented by 16 genera and 40 described species. They are associated with evergreen forests and most genera and species are apterous with very low vagility limited distributions. A few genera and species are distributed widely and occur in forests that are separated by large stretches of grassland or Savanna. It is uncertain when and how these taxa have spread. A further curiosity is that some populations are morphological indistinguishable but have vastly different chromosome numbers.

Vapor activity of essential oils extracted from fruit peels of two *Citrus* species against adults of *Callosobruchus maculatus* (F.) (Coleoptera: Bruchidae)

Gholamhossein Moravvej, Mohammad Hassanzadeh-Khayyat, Salehe Abbar

[1]Department of Plant Protection, Faculty of Agriculture, Ferdowsi University of Mashhad, Mashhad; [2]Department of Pharmaceutical Chemistry, School of Pharmacy, Mashhad University of Medical Sciences, Mashhad; [3]Department of Plant Protection, Faculty of Agriculture, Ferdowsi University of Mashhad, Mashhad, Islamic Republic of Iran

Introduction: The mixing of plant oils is traditionally practiced against stored-product insects in Asia and Africa. Due to the problems encountered with the use of modern synthetic insecticides, recently interest in the use of biocides from plants has been revived. The present study investigated the effects of volatile fractions of *Citrus limon* and *C. reticulata* peel essential oils on the cowpea adult bruchid, *Callosobruchus maculatus* (F.).

Methods: The essential oils were extracted from fresh rind tissue (albedo and flavedo) of fruits by water steam distillation using a Clevenger apparatus. The 2-cm-diameter pieces of filter paper were impregnated with different oil concentrations. The filter paper was attached to the undersurface of the screw cap of a glass vial containing one- to 2-day old adults of *C. maculatus*. Mortality was recorded after 3, 6, 9, 12 and 24 h from the commencement of exposure. Mortality data at 24 h exposure time were analysed with the probit model using a Maximum Likelihood Program.

Results: The citrus oils had high fumigant activity against adult beetles. There were positive and linear significant relationships between percent mortality of adults and duration of exposure to the essential oil vapors within all concentration levels and both plant oils, although not significantly within the concentration of 110 µl L^{-1} of *C. reticulata*. Within each essential oil, the slopes of regressions of mortality rates on exposure times were smaller in low concentrations than those in high concentrations. The oil of *C. reticulata* was significantly more toxic than that of *C. limon* based on both 24 h LC_{50} (33 and 45 µl L^{-1}, respectively) and 24 h LC_{90} (75 and 99 µl L^{-1}, respectively) values.

Conclusions: The citrus peel oils can be used as potential control measure against cowpea seed beetles. More investigations are needed for evaluation of their effects on other developmental stages.

Regulation of bark beetle pheromone biosynthesis by JH III

Claus Tittiger[1], Gary Blomquist[1], Christopher Keeling[3], Jeremy Bearfield[1], Sharon Young[1], Matthew Ginzel[2]

[1]University of Nevada, Reno, Reno, NV, United States, [2]Purdue University, West Lafayette, IA, United States, [3]University of British Columbia, Vancouver, BC, Canada

Pine bark beetles rely on aggregation pheromones for successful tree colonization and reproduction. For *Ips* spp., pheromone production begins when pioneer males arrive at a new host tree and is stimulated in part by elevated JH III titres. The mechanism by which this happens is unknown, but likely involves a newly-discovered gene, *Ipi10G08*, that has homologs in other insects.

JH III apparently coordinates *I. pini* and *Dendroctonus jeffreyi* pheromone-biosynthetic enzymes in the male anterior midgut, leading to the suggestion that JH mediates pheromone biosynthesis in pine bark beetles. However, other factors including developmental and environmental cues also influence pheromone biosynthesis. Comparisons between *I. pini* and the closely-related *I. confusus* further indicate that, while JH appears sufficient to induce pheromone biosynthesis in *I. pini*, its activity in *I. confusus* appears limited to elevating pheromone-biosynthetic gene expression, with other factors required post-transcriptionally to activate the necessary enzyme activities. Thus, JH III plays an important, but not exclusive role in regulating bark beetle pheromone biosynthesis.

Flying after Linnaeus: Dipteran names since Systema Naturae (1758)

Neal Evenhuis[1], Thomas Pape[2], Adrian Pont[3], Chris Thompson[4]

[1]B.P. Bishop Museum, Honolulu, Hawaii, United States, [2]Natural History Museum of Denmark, Copenhagen, Denmark, [3]Oxford University Museum of Natural History, Oxford, United Kingdom, [4]Systematic Entomology Laboratory, USDA, ARS, Washington, DC, United States

Since the start of zoological nomenclature, new names for flies (Diptera) have been proposed at an average of more than eight hundred names per year.

Linnaeus (1758: *Systema Naturae*) and Fabricius (1805: *Systema Antliatorum*) provided the first and the last comprehensive summaries of contemporary knowledge of extant flies respectively. Today, version 10 of the *BioSystematic Database of World Diptera* (BDWD) contains nomenclatural data for 156,599 extant and extinct species in 154 families and 11,671 genera, which is about 10% of the described diversity of the world biota. The BDWD is a nomenclator, which allows for the retrieval of the single correct name for each dipteran, and by providing a framework for organizing and integrating current and future knowledge it is a comprehensive portal to knowledge about all flies.

Various statistics are presented to assess the growth in knowledge, from species accumulation curves and regional patterns of taxonomic output, to the number of workers, their productivity and error rates. With an estimated 98% of all Diptera names entered in the BDWD, the challenge now is to assure the highest quality through appropriate community participation, particularly by specialists and peers. At present, 15% of the entries have been verified and peer-reviewed.

We also present our visions for how to build and maintain large nomenclators, and how these can be used to alleviate the critical need to summarize and make available existing knowledge about our biota.

Education and training in insect rearing for biological control purposes in Brazil

José Roberto Parra

University of Sao Paulo, ESALQ, Piracicaba-SP, Brazil

Brazil's beginnings in entomology were significantly influenced by agrochemicals, differently from other countries in Latin America, which were under strong influence from American Universities, especially the University of California. The first parasitoid was introduced in this country in 1921, and few satisfactory results were obtained until the 1970's, except for sporadic cases such as the successful control of *Antonina graminis* with the introduced parasitoid *Neodusmetia sangwani*. In 1968, formal graduate courses were introduced in Brazil. Presently, about 2000 professionals have been trained in Entomology in our country, in addition to those that were trained abroad; from those trained domestically, 25% received training in Biological Control, thus creating a Biological Control Culture, so difficult to implement in a country deeply rooted in the use of agrochemicals. The scenario today has changed, and there are many examples in the country comparable to the best biological control programs in the world, with 2,000,000 ha of soybean being treated with *Baculovirus anticarsia* to control *Anticarsia gemmatalis*, 1,700,000 ha covered with inundative releases of *Cotesia flavipes* to control *Diatraea saccharalis*, 1,000,000 ha receiving *Metarhizium anisopliae* to control *Mahanarva* spp. in sugarcane, and 200,000 ha being treated with *Trichogramma* spp. to control pests in sugarcane, tomato, corn, etc. The research data generated in Brazil allowed the publication of many books, contributing toward the implementation of the above-mentioned Biological Control culture. Extension courses have allowed the formation of BC research groups in different parts of the country. As BC awareness increases, classical BC has returned to the scene, such as the recent case in which *Ageniaspis citricola* was introduced to control *Phyllocnistis citrella*. Education, awareness, and training were essential for the success cases just mentioned, and there is a tendency for a steady increase in the use of BC in Brazil.

Biological control of the sugarcane borer, *Diatraea saccharalis*, using *Cotesia flavipes* and *Trichogramma galloi*

José Roberto Parra[1], Paulo Botelho[2]

[1]University of Sao Paulo, ESALQ, Piracicaba-SP, Brazil, [2]Universidade Federal de São Carlos, Araras-SP, Brazil

The sugarcane borer, *Diatraea saccharalis*, causes huge damages, with significant sugar and alcohol losses in Brazil. Since the 1970's, Brazil uses *Cotesia flavipes*, an introduced parasitoid, to control the pest, whose losses in the 1980's reached 100 million dollars annually in the State of São Paulo, which responds for most of the Brazilian production. As the parasitoid became adapted, losses dropped to 20 million dollars annually, decreasing infestation intensity levels from 10% to 2% in that state. Currently, insects reared on *D. saccharalis* maintained on artificial diet for inundative releases in 1,700,000 ha are produced by about 30 laboratories located in sugarcane mills, in addition to some 15 private laboratories. *T.galloi*, the pest's most important egg parasitoid, is produced by 2 private companies and is also released inundatively in about 150,000 ha, with very interesting results, significantly reducing infestation intensity levels, especially when reared on the factitious host *Corcyra cephalonica*. As the area cultivated with sugarcane in Brazil is expected to double in the next few years, the potential to increase the area where *D. saccharalis* Biological Control is adopted becomes increasingly higher.

Local gradients in stoichiometry and trophic level of an omnivorous ant

Terrence McGlynn

California State University Dominguez Hills, Carson, CA, United States

While the relative abundance of resources are known to affect dietary choices in omnivorous animals, less is known about dietary shifts in response to resource quality. In this study, we sampled colonies of the generalist gypsy ant *Aphaenogaster araneoides* across a known stoichiometric gradient. This gradient drives the relative carbon:nutrient ratios of the base of the food chain. We conducted stable isotope analyses to calculate delta N15 as a measure of relative omnivory. We found that the trophic level of gypsy ants responds to the environmental stoichiometric gradient. We suggest that undocumented patterns in the distribution of nutrients in soils, plants and leaf litter may explain, in part, diet selection and competition among ants.

The exploitation of insects as attraction at leisure farms in Taiwan

Ying-Sheue Wei

Kainan University, Taoyuan County, Taiwan

Introduction: As the vigorous development of leisure agriculture, the insect theme leisure farms are prevailing during recent decades in Taiwan. These farms provide leisure experiences as well as educational value to visitors by insect exhibition, watching activity, and observation. But some theme insects are not native species but introduced spectacular species. And go to leisure farms for observing insects is more and more popular among pupils. The exploitation of insects at leisure farms was investigated.

Methods: The study was conducted a survey using the integrity of field observation data, the results of interviews of leisure farmers and literature reviews. The insect exploiting measures, insect species, and native or not was recorded. And the activities that leisure farms provided would also analysis.

Results: Butterflies, fireflies and honey bees were the most famous theme insects of leisure farms. Tremendous exotic beetles were gradually popular insect resources. The farms would usually grow exotic plants or flowers to mass rear particular species butterflies, and built artificial ponds for aquatic fireflies. Main activities at leisure farms were only to introduce what were the insects, where to find them, and how they look like. Little information about the ecological role of insects was mentioned. And those activities always provided as outdoor educational opportunities for pupils.

Conclusions: Although insects could be attraction at leisure farms, the exploitation manners were required to be improved. The cooperation of leisure farmers and entomologist would make conditions much better.

Evaluation of *Podisus maculiventris* (Hemiptera: Pentatomidae) for biological control of viburnum leaf beetle, *Pyrrhalta viburni* (Coleoptera: Chrysomelidae), an emerging landscape pest in North America

Gaylord Desurmont, Paul Weston

Cornell University, Ithaca, NY, United States

Introduction: *Pyrrhalta viburni*, an invasive chrysomelid native to Europe first detected in the USA in Maine in 1994, is becoming a major landscape pest in North America and poses a serious threat to a large portion of the U.S. and Southern Canada. Both larvae and adults feed on shrubs in the genus *Viburnum*, and can kill susceptible plants within a few years. Plants in both managed landscapes and natural areas are at risk. Among the few natural enemies of viburnum leaf beetle native to North America, the spined soldier bug, *Podisus maculiventris* (Hemiptera: Pentatomidae), shows the greatest promise for biological control.

Results: In laboratory assays, nymphs consumed in average 100.6 larvae or 16.9 adults during their development. In field settings on both caged and open-grown plants, *Podisus maculiventris* nymphs developed successfully preying on *P. viburni* larvae. Predation efficacy was correlated with size of shrubs and pest density: defoliation due to pest populations was significantly reduced when the predator:prey ratio was greater than 1:100, but no effect was seen otherwise. Other parameters, such as temperature, presence of refugia, presence of other predators, and nature of the host plant also influence predatory efficiency.

Conclusions: These results suggest that *P. maculiventris* has potential for augmentation biological control programs against viburnum leaf beetle subject to several constraints of environment and release conditions.

A Late Triassic radiation of herbivorous insects in the Karoo Basin of South Africa

Conrad Labandeira[1], John Anderson[2], Heidi Anderson[2]

[1]Smithsonian Institution, Washington, DC, United States, [2]South African National Bioidiversity Institute, Pretoria, Gauteng, South Africa

Introduction: Cited examples of ancient insect radiations involve expansion of insect herbivory on emerging Early Cretaceous angiosperms. An equally impressive radiation of insect herbivores occurred on a dominantly gymnospermous flora 90 m.y. earlier, indicating an earlier, unrecognized chapter in plant-insect associations.

Methods: Damage type (DT) data were gathered for 177,301 individual plant-organ specimens from 106, stratigraphically ordinated localities representing 7 habitat types from the Molteno Formation of South Africa. (A DT is a distinctive, diagnosable pattern of insect herbivore feeding.) 79 DTs were scored from the following herbivore functional feeding groups: external foliage feeding (30 DTs), piercing-and-sucking (8), oviposition (10), leaf mining (7), galling (15), seed predation (4), boring (2) and unknown feeding (2). Plant hosts included liverworts, horsetails, ferns, and gymnosperm seed plants such as pinopsids, especially voltzialean and podocarpaceous conifers; diverse ginkgoopsids such as peltasperms, ginkgoaleans and umkomasialeans; bennettitopsids; gnetopsids, and several unaffiliated taxa.

Results: A matrix of DTs versus locality versus habitat versus plant host reveals a complex pattern of insect herbivory involving differential palatability of plants, favorable physical environments, and insect herbivore colonization patterns. Targeting of plant hosts ranged from leaf-miner (DT141) monophagy on *Equisetites*, gall (DT122) oligophagy widely occurring on *Sphenobaiera* but also on *Dicroidium* and *Kannaskoppifolia*, and rampant polyphagy from cuspate margin feeding (DT12). The greatest diversities and highest abundances of DTs occurred in intermediate successional habitats, particularly *Sphenobaiera* Closed Woodland and Immature *Dicroidium* Riparian Forest.

Conclusion: The primary associations of phytophagous insects are on ancient gymnospermous seed plants, rather than relatively recent angiosperms.

Aggregative oviposition of viburnum leaf beetle, *Pyrrhalta viburni* (Paykull): Mechanisms and benefits of an unusual social behavior

Gaylord Desurmont, Paul Weston

Cornell University, Ithaca, NY, United States

Introduction: *Pyrrhalta viburni*, an invasive chrysomelid native to Europe, is an emerging landscape pest in North America. Larvae and adults feed on shrubs in the genus *Viburnum* in both managed landscapes and natural areas. *P. viburni* females lay eggs in small groups in cavities they excavate in the twigs then cover with a frass-like protective secretion. Infested twigs sometimes produce wound tissue in response to oviposition as a defensive reaction.

Methods: In laboratory trials, we conducted several choice-tests to determine oviposition stimuli. Analysis of egg mass densities on field-collected infested twigs and rearing of larvae in groups of different sizes were also conducted.

Results: We found that females prefer to oviposit on branches already infested by other females, and will lay their eggs in close proximity to egg masses already present. Both the egg mass cap and the cavity acted as positional stimuli, but not the eggs themselves, and presence of plant wound tissue made the twigs more attractive to females. *P. viburni* larvae showed reduced mortality and produced heavier adults when reared in groups rather than individually, suggesting benefit of larval group feeding. Analysis of egg mass densities on field-collected infested twigs revealed that production of plant wound tissue was negatively correlated with magnitude of infestation, suggesting that egg survivorship is higher on heavily infested twigs by overcoming plant defensive reaction.

Conclusions: Results of this research shed light on a rare case of subsociality for a chrysomelid, and add to our understanding of the ecology of this important pest.

Feasibility of acoustic technology for canegrub detection and management

Richard Mankin[1], Peter Samson[2], Keith Chandler[3]

[1]USDA-ARS-CMAVE, Gainesville, FL, United States, [2]BSES Limited, Mackay, Queensland, Australia, [3]BSES Limited, Bundaberg, Queensland, Australia

Introduction: Several scarabaeid and melolonthinid canegrubs are important root-feeding pests of Australian sugarcane. Control methods are applied optimally in advance of infestations, so growers are encouraged to judge future risk by monitoring current infestations, past trends, and proximity to other infestations. To reduce costs of digging up large quantities of sugarcane, alternative methods of detecting and estimating canegrub populations are being considered, including acoustic detection.

Methods: Acoustic recordings were obtained from 59 sites in sugarcane fields near Mackay and Bundaberg in Queensland using either or both a Bruel and Kjaer accelerometer system and an AED-2000 acoustic detection system with a TEAC digital recorder. Recordings were assessed by listeners as they were being collected, and afterwards by custom-written signal processing software, which considered the spectral and temporal patterns of the detected sounds. The root systems of the sugarcane stools were examined after recording.

Results: Almost all of the recording sites were acoustically assessed as potentially infested. When the root systems were examined, we confirmed that canegrubs or other sound-producing, subterranean insects were present. Because only greyback (*Dermolepida albohirtum*) and Childers (*Antitrogus parvulus*) canegrubs were considered economically important in the fields examined, we attempted to develop spectral and temporal pattern analyses to identify these canegrubs specifically. Many of the sites containing greyback canegrubs were easily identifiable due to characteristic scraping and chewing behavior.

Conclusions: Greyback canegrub populations were rapidly identified using acoustic detection technology. Further studies are needed to assess the feasibility of these systems for detection of other canegrub species.

Effects of farm and landscape vegetational diversity on attack on coffee plants by leafcutting ants

Sanford Eigenbrode[1], Edgar Varón[2], Luko Hilje[3], Nilsa Bosque-Pérez[1]

[1]University of Idaho, Moscow, Idaho, United States, [2]CORPOICA, Tolima, Colombia, [3]Centro Agronómico Tropical de Investigación y Enseñanza (CATIE), Turrialba, Costa Rica

Introduction: Coffee agroforestry systems often include shade trees, which potentially protect the coffee from insect pests. In addition, vegetational diversity at the landscape scale could influence insects within coffee plantations. These effects were examined in coffee farms in Costa Rica, focusing on leaf-cutting ants, *Atta cephalotes*.

Methods: *Atta cephalotes* feeding on coffee and alternative host plants, and the densities of ant colonies in 15 coffee plantations differing in vegetational structure were compared based on visual surveys. The effect of different land use coverages on colony density at different buffer radii was analyzed for the 24 farms, and the effect of forest edge on ant colony density was analyzed in three farms.

Results: *Atta cephalotes* workers removed much less coffee as a proportion of their total diet in diversified coffee systems than in monocultures. This is related to a preference by the ants for a dominant shade tree (coral tree, *Erythrina poeppigiana*) as compared with coffee. Total ant colony density was significantly higher in monocultures, compared to the other systems, which should confer additional benefits in reduced attack by *A. cephalotes* in these systems. Ant colony densities were greater near forest edges than other edges of coffee farms. Effects of land use at a landscape scale on *A. cephalotes* colonies were detected but were negligible.

Conclusions: At the farm scale increased vegetational diversity reduces risks of *A. cephalotes* injury to coffee. Landscape scale effects appear to be of lesser importance for management of this insect pest.

ZooBank: The Official Registry of Zoological Names

M. Alonso-Zarazaga, D.J. Brothers, N.G. Bogutskaya, P. Bouchet, D.G. Fautin, M.J. Grygier, R.B. Halliday, I.M. Kerzhner, M. Kottelat, F. Krell, S.O. Kullander, G. Lamas, S. Lim, E. Macpherson, S.F. Mawatari, A. Minelli, P.K.L. Ng, T. Pape, L. Papp, D.J. Patterson, R. Pyle, G. Rosenberg, P. Stys, J.V. Tol, Z-Q Zhang

International Commission on Zoological Nomenclature, London, United Kingdom

The current scale of global taxonomic studies poses considerable challenges to a registry developed in the age of printing press and card files. Some 15,000 to 20,000 new nominal species are proposed every year in zoology, and together with thousands of other Code-compliant nomenclatural acts these are scattered in a bewildering number of journals, monograph series, books, and CD-based publications.

The ICZN Secretariat and Commissioners in 2005 proposed "ZooBank" - a central, web-based registry of zoological names and nomenclatural acts - as a mechanism for making information about all names and their nomenclatural status more accessible. ZooBank was launched as a functional prototype web site on January 1st, 2008, coinciding with the 250th anniversary of the official start of Zoological Nomenclature. At its launch, the ZooBank registry included all 4,819 names established in the 10th edition of Linnaeus' *Systema Naturae*, as well as five new fish species names established in an article published concurrently with the launch of ZooBank.

The goal of ZooBank is not to replace existing nomenclatural catalog databases, and it will make no assessment or judgement of the taxonomic content of any piece of published work. ZooBank will function as an archived index of zoological names and nomenclatural acts that affect names, and ultimately contain information regarding the availability or non-availability of all names in zoology. The complete implementation details of the ZooBank registry are currently being discussed, developed, and tested, with involvement from ICZN Commissioners, GBIF, TDWG, catalog and database managers, and the taxonomic community at large.

The initial radiation and environmental context of leaf-miners: Late Triassic Karoo floras of South Africa

Conrad Labandeira[1], John Anderson[2], Heidi Anderson[2], Tsepang Makholela[2]

[1]Smithsonian Institution, Washington, DC, United States, [2]South African National Biodiversity Institute, Pretoria, Gauteng, South Africa

Introduction: Leaf-mining insects presently target plant hosts and exhibit distinctive distributions among habitats. Little is understood about these two aspects of leaf-miner ecology during the Late Triassic, when leaf-mining was launched 90 m.y. before the appearance of angiosperms.

Methods: Leaf mines were identified and scored on 177,301 plant organs from the Karoo Basin of South Africa, representing 30 of 106 localities, 25 of 212 potential plant hosts, and all 7 habitats ranging from wetland to mature forest biomes. Mines were divided into 7 distinctive morphotypes, using the Damage Type (DT) system.

Results: Most specimens reveal superb frass-trail geometry, including fecal pellets, sidewall reaction rims, terminal areas and occasional oviposition sites. The commonest mine (DT71) represented 97.8 % of occurrences, in 22/30 localities, and targeted the broadleaved, parallel-veined voltzialean conifer, *Heidiphyllum elongatum*, at a frequency of 94.2 %. This mesophyll mine avoided major veins and venules, resembling modern polyphagan beetle mines on palms. At Aasvoëlberg 311, 6.3 % of all *H. elongatum* leaves were attacked, often multiply, suggesting outbreak levels. DT71 frequencies track plant-host occurrence rather than specific habitats, occurring in *Heidiphyllum* Thicket, but also *Dicroidium* Open Woodland and Mature *Dicroidium* Riparian Forest where *H. elongatum* is abundant. Rare mine morphotypes, including the thin, tubular, frass-filled, lepidopteran-like DT41, DT45, DT104, and DT141 preferred ferns and sphenopsids, but also occasional seed-plant leaves, occurring in all habitats.

Conclusion: Leaf-mining originated in southern Gondwana on a gymnospermous flora, replete with elevated host specificities, distinctive mine morphologies, and resource partitioning within and between habitats.

The effect of alternative plant production practices on predator-herbivore dynamics in ornamental nurseries

Paula Shrewsbury[1], Rebeccah Waterworth[2], Ellery Vodraska[1]

[1]University of Maryland, College Park, MD, United States, [2]University of California, Riverside, CA, United States

Introduction: In the production of ornamental plants, many plant management practices disrupt natural enemy - herbivore dynamics resulting in more frequent pest outbreaks. This study examines the effect of alternative plant management practices on natural enemy taxa and abundance, and ultimately on herbivore suppression.

Methods: Two alternative plant management practices, wood chip mulch as a groundcover and pot-in-pot planting method, were compared to conventional practices, weed cloth ground cover and above ground planting method for their influence on predator taxa and abundance, temporal and spatial dynamics, and herbivore suppression. A factorial design with 2 ground cover types and 2 pot positions was used. Natural enemies and survival of sentinel cohorts of black cutworm, *Agrotis ipsilon*, were sampled from the foliage and ground layers of container grown ornamental plants. Cutworm survival was compared between the day and night.

Results: Predator abundance did not differ on the foliage regardless of ground cover type or pot position. However, at the ground level predator abundance was greater in pot-in-pot containers. This effect was enhanced in plots with wood mulch. Ground cover type had no effect on cutworm survival and survival was lower at the ground level compared to foliar. This effect was enhanced at night in the pot-in-pot method. Predator species varied temporally and spatially.

Conclusion: The pot-in-pot system should increase predator activity and reduce the likelihood of outbreaks of soil dwelling insects compared to the conventional above ground system. The addition of wood mulch over weed cloth may enhance these effects.

Predators on the plantscape

Sanford Eigenbrode[1], Claire Rutledge[2]

[1]University of Idaho, Moscow, Idaho, United States, [2]Connecticut Agricultural Experiment Station, New Haven, Connecticut, United States

Introduction: Not only caterpillars and other insect herbivores, but also their natural enemies, must negotiate plant surfaces that vary morphologically on different spatial scales. Crystalline surface waxes on plants impair attachment and locomotion by predators. As a result, variable crystalline waxes in combination with plant architecture, can influence predator foraging behavior, potential interpredator interactions, and impacts on prey.

Methods: To explore the implications of waxy bloom for predators, simulation models were developed and parameterized based on observations of foraging *Hippodamia convergens* larvae (Coccinellidae) on individual plants and arrays of plants differing in waxy bloom.

Results: The models reveal the effects of varying interpredator interactions on the functional response of the predator. The models also can be adjusted to create refugia consistent with observed differences in parts of plant surfaces exploited depending upon the presence of wax bloom. Models of *H. convergens* larvae moving in arrays of plants differing in wax blooms reveal some non-intuitive effects of waxy bloom on predator aggregation to prey in the canopy.

Conclusions: Observations and simulation models show that wax bloom can influence interpredator interactions and interplant movement by predaceous coccinellids.

The Paleozoic and Mesozoic insect and mite gall record

Conrad Labandeira

Smithsonian Institution, Washington, DC, United States

Introduction: Reviews of gall-inducing insects suggest that the preangiospermous fossil gall record is sparse or nonexistent. However, recent fossil discoveries of anomalous plant structures indicate a rich gall record involving major insect and mite lineages.

Methods: Anatomically preserved coal-balls were sawn, acetate peeled, and mounted on slides for examination of histological and cellular-level detail similar to modern embedded sectioned material. Compression fossils were studied as surface views and fractures revealing inner gall structure. Explicit criteria for gall assignment include organoid or histioid structure, anomalous inner tissue, internal chambers, host-plant and tissue-type specificity, and evidence for arthropod inhabitation.

Results: Many interesting occurrences define the pre-Cenozoic gall record. (1), Spindle cone galls on horsetail fructifications (Early Pennsylvanian, Euramerica). (2), Holometabolan gall on fern rhachises with tufts of nutritive tissue invading an inner cavity (Late Pennsylvanian, Euramerica). (3), Adelgid-like bud galls mimicking cone morphology of a walchian conifer (Early Permian, Euramerica). (4), Swollen stem galls on an herbaceous voltzialean conifer (Middle Triassic, Laurasia). (5), Eriophyoid-like compound galls with submillimeter sized chambers on corystosperm pinnules (Late Triassic, Gondwana). (6), Small, spheroidal, clustered galls on bennettitalean leaves (Middle Jurassic, Europe). (7), Ellipsoidal, primary-vein galls on palmate sycamore leaves (Early Cretaceous, North America). (8), Varied galls assignable to modern galler clades (latest Cretaceous, North America).

Conclusion: Major lineages of galling insects currently correspond to highly stereotyped and recognizable external and internal features of galls, a condition that now extends to the late Paleozoic. Varied plant hosts, tissue types and habitats were colonized by early galling insects.

Fast acting insecticides: Novel utilization in vector control

Kamlesh Chauhan, Thanh Le, Ulrich Bernier, John Grieco

[1]USHUS, Bethesda, United States, [2]Walter Reed, Silver Spring, United States

Introduction: Fast acting pyrethroid insecticides like transfluthrin and metofluthrin are used in household and hygiene products, mainly for the control of flying insects such as mosquitoes and flies. While metofluthrin has only recently been registered, a related compound, transfluthrin, has been approved for use in about 50 countries worldwide. The main formulation types available are mosquito coils and aerosols. A high vapor pressure is the main physiochemical property of these and related fast acting pyrethroids.

Methods: In our study we designed and evaluated molecular properties of such pyrethroids for efficacy, commercial viability, as well as adaptation to new long lasting formulations. All newly designed fast acting pyrethroids were evaluated using K&D module to determine knockdown and feeding attributes of female mosquitoes.

Results: An interesting feature revealed for these candidate pyrethroids was their continued effect on several resistance strains of mosquitoes. Mosquitoes came in vicinity of vapor of most of these compounds were neither able to blood feed nor do they survive during test period of three minutes.

Conclusions and Future Work: We believe that these compounds induce desirable toxic effect to vectors in minutes with high vapor pressure.

Insecticide defenses in the salt marsh mosquito *Aedes sollicitans*

L. B. Brattsten, Debin Sun, Shaoming Huang

Rutgers University, Department of Entomology, New Brunswick, NJ, United States

Larval salt marsh mosquitoes are controlled in New Jersey by treatment with BTI, temephos, and methoprene. Data from about eight years showing LC50s of temephos indicate that despite sometimes heavy treatments for many years, the larvae are sensitive to the compounds and even become increasingly sensitive if the compound is discontinued for a year or two. The toxicity of BTI is variable between larval instars. Treatment with both methoprene and temephos can increase the toxicity of temephos in lab experiments. In vivo experiments with synergists indicate that the larvae use mainly esterases to detoxify temephos and methoprene but can detoxify synthetic pyrethroids with both enzyme systems. They have high esterase activities and medium to high microsomal monooxygenase activities. They have several P450 genes including CYP6P10 and CYP6BB1 each in at least five variants. The P450-NADPH-reductase gene from Aedes sollicitans most closely resembles that of the Asian Anopheles minimus.

Molecular phylogeny of the Platygastroidea: The big leap to a robust classification

Andy Austin[1], Norman Johnson[2], Hans Klompen[2], Andrew Polaszek[3], Alejandro Valerio[1], Matt Yoder[2]

[1]University of Adelaide, Adelaide, South Australia, Australia, [2]Ohio State University, Columbus, United States, [3]The Natural History Museum, London, United Kingdom

Introduction: The Platygastroidea and the two families it includes, the Scelionidae and Platygastridae, are a diverse assemblage of mostly small parasitic wasps comprising 4,500+ described species. All scelionids and some platygastrids are endoparasitoids of insect and spider eggs, while other platygastrids attack sessile Homoptera and gall-flies (Cecidomyiidae). Although the superfamily undoubtedly is monophyletic, recent phylogenetic studies strongly indicate that 1) the family Scelionidae is not a natural group unless Platygastridae is contained within it, and 2) several tribes of the largest subfamily, Scelioninae, and both subfamilies of Platygastridae seem not to be monophyletic.

Results and Discussion: Here we present our latest results toward a phylogeny of the Platygastroidea, based on a multi-gene analysis (using mitochondrial and nuclear coding genes) of an extensive taxon sampling representing most of the currently recognised tribes. The phylogeny is discussed in relation to the evolution of host associations, the role that morphological studies might play in future studies, and whether or not a more natural classification can yet be proposed.

Signaling interactions between axons and glial cells regulating olfactory receptor axon sorting and targeting in the developing moth olfactory pathway

Nicholas Gibson, Mark Higgina, Leslie Tolbert, Alan Nighorn, Lynne Oland

University of Arizona, Tucson, United States

Introduction: The olfactory pathway of the moth *Manduca sexta* presents an opportunity to study developmentally critical neuron-glia interactions involved in axon sorting and targeting. Axons of olfactory receptor neurons (ORNs) extending toward the olfactory lobe in the brain induce the formation of a glia-rich "sorting zone" (SZ). Later arriving ORN axons encountering SZ glia separate from their neighbors, dramatically change directions, and fasciculate according to their target glomerulus. These changes are dependent on the presence of SZ glial cells. Growth-cone interaction with SZ glia alters the shape and rate of movement of the growth cones (Tucker and Tolbert, 2003). In the SZ, fibroblast growth factor (FGFRs) receptors are activated on glia, epidermal growth factor receptors (EGFRs) are activated on ORN axons, and the cell adhesion molecule neuroglian (an L1 homolog) becomes tightly anchored in axonal membranes.

Methods and Results: We are using pharmacological approaches and RNAi to disrupt growth factor receptor (GFR) activation and expression of neuroglian *in vivo* and *in vitro*. The results of disruption include abnormal fasciculation, disrupted axon extension, and downstream effects on axon targeting and glomerulus formation, consistent with downstream effects of GFR activation in the SZ that include anchoring of neuroglian in the membrane, thus stabilizing fasciculation between axons, and possibly glial proliferation and migration.

Conclusions: Our data support a model of signaling interactions in which SZ glia alter axonal behavior by regulating interactions between IgCAMs. Homophilic binding between CAMs then activates the GFRs, and stabilizes CAM attachment to the cytoskeleton. Funded by NIH DC008597.

Arthropod decomposer communities in native forests in northern New Zealand

Anne Tomlinson[1], Robert Hoare[2], Jacqueline Beggs[1]

[1]University of Auckland, Auckland, New Zealand, [2]Landcare Research, Auckland, New Zealand

Introduction: Insects and other invertebrates play an important role in the decomposition of plant litter and numerous studies have highlighted their effect on decomposition rates. New Zealand has a rich and diverse litter fauna, but there is little understanding of the ecology of decomposer communities in different forest habitats. Litter fauna were studied in mixed conifer-angiosperm forests in northern New Zealand to determine whether: (1) community composition varied between different species of tree litter, and (2) invertebrate decomposers increased decomposition rates.

Methods: Pitfall trapping was undertaken beneath one conifer species, kauri (*Agathis australis*) and two angiosperm species, kanuka (*Kunzea ericoides*) and puriri (*Vitex lucens*). A complementary laboratory rearing study using litter samples from the same three tree species allowed accurate identification of Lepidoptera, Coleoptera and Diptera on maturity. Litterbags were used to study the effect of invertebrate decomposers on decomposition rates.

Results: Insect assemblages differed between the three litter types. A notable finding was the dominance of the introduced moth *Opogona omoscopa* (Lepidoptera: Tineidae) in puriri litter. Decomposition rates were significantly faster in litterbags accessible to invertebrates and, in the case of puriri litter, there was a correlation between invertebrate abundance and the rate of decomposition.

Conclusions: The finding that insect assemblages varied in different litter species has implications for conservation because it suggests a relationship between plant diversity and insect diversity. The abundance of introduced species in puriri litter suggests that further research is required to assess the impact of non-native species on nutrient cycling in New Zealand forests and their effects on endemic litter fauna.

.

Fine-scale pine scale intraspecific phylogeography across North America (Hemiptera: Diaspididae)

Rodger Gwiazdowski, Benjamin Normark

University of Massachusetts, Amherst, Amherst, Massachusetts, United States

Broad biogeographic sampling yields the best opportunity for identifying patterns of diversification and speciation within a taxon. *Chionaspis pinifoliae*, (Hexapoda: Hemiptera: Diaspididae), the pine needle scale insect, native to North America, appears to be omnipresent and morphologically similar on almost every species of *Pinus* in North America. Sampling from localities spanning southern Mexico to Canada reveal morphologically similar individuals with highly divergent mtDNA haplolotypes, potentially representing cryptic species, which show striking patterns of variation that accord with both geography and host use. We will explore plyolgeographic patterns of molecular variation in light of current Pinus biogeography.

Scale Insects are economically important pests and methods are currently being developed for molecular identification of pest species by non-specialists. We will explore the utility of current molecular methods of species identification given a dense sampling of this species throughout its native range.

A contrary perspective on native bee declines: The Oregon experience

Sujaya Rao, William Stephen

Oregon State University, Corvallis, United States

Worldwide, there are reports of declining populations of bumble bees and other native bee species. Habitat destruction and pesticide use are two agriculture-related factors that have been reported having negatively impacted bee diversity and abundance. However, cropping systems benefit bees by the abundance of foraging resources that they provide. In particular, agroecosystems adjacent to native habitats, that offer nesting sites for both solitary and social bee species, facilitate build-up of native bee pollinator populations. In 2004 we stumbled upon a new sampling device that caught an extraordinary number of bees. Census studies conducted with this trap have revealed remarkable diversity and abundance of native bees in both native and agricultural landscapes in Oregon on the west coast of the United States. In addition, we detected 6 specimens of the bumble bee, *Bombus occidentalis,* which was considered to be near extinction on the west coast. We believe that we are experiencing an increase in the numbers of native bees in Oregon, especially in western regions. Here, the increase in agricultural production is providing an abundance of food resources within flight distance of an abundance of nesting resources in adjacent native ecosystems. Consistency in sequential availability of foraging resources is likely to have been a key factor for conservation and build-up of native bees in western Oregon.

Pyrethroid resistance in *Culex pipiens* sensu lato: bridging the gap between bench-work and the field.

Anthony Cornel[1], Lisa Reimer[1], Adama Sacko[2], Rory McAbee[1], Etienne Fondjo[3], Gregory Lanzaro[1]

[1]UC Davis, Davis, California, United States, [2]Malaria Research Training Center, Bamako, Mali, [3]Ministry of Health, Yaounde, Cameroon

Introduction: Operationally meaningful interpretations of laboratory based assays used to detect insecticide resistance and to determine the mechanisms of resistance in mosquitoes remains a challenge.

Results: Comparisons between bottle bio-assay and cage field-trial mortality on *Culex pipiens* s.l. revealed that the bottle bio-assays underestimated the extent of expected operational failures for pyrethroid resistant mosquitoes when exposed to various ULV formulations of registered pyrethrum and permethrin. WHO test kit insecticide susceptibility assays were shown to perform well in predicting resistance to DDT in Cameroon populations of east and west African *kdr*-type *Anopheles gambiae* s.s genotypes. The assay, however, showed weak associations between resistance to type II pyrethroids and both *kdr* genotypes. Similar insignificant correlations between knock down times and recovery after three hours of pyrethroid exposure in a bottle bio-assay were found in both Mali *An. gambiae* s.s. and California *Cx. pipiens* s.l. *kdr* S/S, R/S and R/R genotypes.

Conclusion: For the most part, the interpretations and sensitivity of laboratory based susceptibility assays and role of *kdr* and other resistance mechanisms fall short of understanding the complexities of toxicological and irritancy/repellency responses particularly to pyrethroids . This in turn limits our ability to draw conclusions about expected mosquito survival in the field and impacts on disease transmission in areas where pyrethroid and other chemical vector control programs are applied.

Oxygen-water tradeoffs in eggs of *Manduca sexta*

H. Arthur Woods

University of Montana, Missoula, MT, United States

For terrestrial insect eggs, deciding what eggshell permeability to have constitutes a key physiological problem. High permeability supports high internal levels of oxygen while simultaneously allowing high rates of water loss. By contrast, low permeability conserves water while potentially depressing internal oxygen to low levels. Balancing this tradeoff is complicated because eggs experience changing environmental conditions and developmental demand for oxygen. I have shown that eggs of the sphingid moth *Manduca sexta* exert fine control over the tradeoff. During development, rates of metabolism and water loss are tightly correlated, suggesting that permeability is progressively increased to support higher metabolic rates. This effect can be induced experimentally by external hypoxia. External manipulation of relative humidity (RH) also alters eggshell permeability—high RH results in high-permeability eggshells and low RH in low-permeability eggshells. This pattern suggests that eggs do not simply attempt always to conserve water. Rather, they appear to increase permeability to dump water in humid conditions. Recent experiments in my lab have shown that water loss is a prerequisite for normal air filling of the pharate 1st instar tracheal system. Water loss deforms the eggshell, thereby spring-loading it, and the tension exerted by the spring is used to drive expansion of nucleated air bubbles in the developing tracheae. Together these experiments indicate that the oxygen-tradeoff is real and pressing for eggs of *M. sexta*, that eggs exert control over the tradeoff, and that control over eggshell permeability has functional consequences for multiple aspects of egg developmental biology.

Floral odour patterns and pollinator guilds in a New Zealand alpine plant community

Mascha L Bischoff[1], Andreas Juergens[3], Janice M Lord[1], Alastair W Robertson[2]

[1]Otago University, Dunedin, New Zealand, [2]Massey University, Palmerston North, New Zealand, [3]University of KwaZulu-Natal, Pietermaritzburg, South Africa

The New Zealand alpine flora is thought to be of relatively recent origin and appears to have evolved rapidly under highly changeable conditions. Much of the alpine habitat in New Zealand arose 2-3 million years ago and all of it has been repeatedly altered by extensive glaciation in the Pleistocene. These challenging environmental conditions seem to have provided unusual opportunities for plant evolution in response to a novel, isolated, and always changing environment. The story of New Zealand alpine plants is a story of success due to processes of adaptive radiation, interspecific hybridisation and recombination, and despecialisation of pollination systems. Historically it has been assumed that pollinator services in alpine New Zealand are imprecise, that plants are therefore often self-pollinating, and there is little pollinator specialisation amongst the pollinator-dependent species. However, the pollinator dependence of the alpine flora and the patterns of insect visitation are largely unknown and so the assumptions remain untested.

In general, the New Zealand alpine flower colours are rather uniform and the morphology simple and unspecialised so the plants appear to offer little in the way of visual cues to allow pollinator discrimination. However, many of the plants emit a noticeable scent. We surveyed floral odours for a total of 18 plant species using GC/MS and observed flower visitor spectra for each plant species. Here we present patterns of connectance between flowers and their insect visitors and test the idea that these might be created by patterns of floral odour advertisement acting at a community level.

The pollinator crisis: native bees in native habitats and agricultural landscapes

Sujaya Rao

Oregon State University, Corvallis, United States

Globally, biodiversity in native bee pollinators is threatened. Losses have been ascribed to several human-related activities such as habitat destruction and fragmentation, improper pesticide use, diseases, and competition with introduced species. In this symposium, we address the situation covering a range of species from bumble bees to stingless bees, and present case histories that address both new concerns and conservation practices for arresting further declines.

Morphogenesis in insect extraembryonic development

Kristen Panfilio

Department of Zoology, University of Cambridge, Cambridge, United Kingdom

Introduction: Almost all hemimetabolous insects undergo katatrepsis, a repositioning of the embryo in the egg by extraembryonic membranes. The *zen* gene has been implicated in effecting katatrepsis in the milkweed bug *Oncopeltus fasciatus*. However, the precise morphogenetic defect resulting from *zen* transcript depletion has been uncertain in this and in other species.

Methods: The dynamics of katatrepsis in wild type and *zen*-depleted (pRNAi) *Oncopeltus* embryos were analyzed from time-lapse movie data, supplemented by analysis of fixed samples.

Results: In *zen*-depleted embryos, preparatory tissue reorganization occurs but katatrepsis does not ensue. There is an increase in egg activity prior to the katatrepsis stage. Wild type activity is a quasi-periodic 'bouncing' movement that leads directly to extraembryonic membrane rupture, which is the initiation of katatrepsis. A similar phenomenon occurs in *zen*-depleted embryos, but it is delayed, reduced in amplitude, and ultimately subsides without membrane rupture.

Conclusions: These investigations identify a single point of failure in katatrepsis after depletion of *Oncopeltus zen*. The delay in activity suggests that there is a window of opportunity for membrane rupture. The reduced amplitude of activity corroborates a role for *zen* in membrane contraction. The lack of epithelial rupture supports a role for *zen* in alteration of intercellular structural integrity. Overall, *Oncopeltus zen* seems to have a highly specific role in morphogenesis at mid embryogenesis. Functional studies in other insect species suggest that this may reflect the ancestral role of *zen*, which implies that Zen function has changed in the holometabolous insect lineage.

Estimation of insect migration trajectories with flight parameters measured by Insect Monitoring Radar

Haikou Wang[1], V Alistair Drake[2]

[1]Australian Plague Locust Commission, Australian Government Department of Agriculture, Fisheries and Forestry, GPO Box 858, Canberra, ACT 2601, Australia, [2]School of Physical, Environmental and Mathematical Sciences, UNSW@ADFA, Australian Defence Force Academy, Canberra, ACT 2600, Australia

Introduction: Meteorological trajectory models have been widely used to simulate migration pathways of windborne insects, based on the assumption that migrating insects flow like air particles in the wind field. However, radar observations have revealed that migrating insects flap their wings actively during flight and many macro-insects demonstrate a capacity for orientation. Automated insect monitoring radars (IMRs), which can measure the ground speed, displacement direction and body alignment of insects flying through their vertically-pointing beam, have revealed mutual orientation by Australian plague locusts, *Chortoicetes terminifera* (Walker), during nocturnal migration. Therefore, to estimate insect migration pathways more accurately, the flight behaviours of the migrants must be taken into account.

Methods: Trajectories are calculated by three methods. First, simulated upper winds are linearly interpolated from the 6-hourly analysis grid output of the Australian Bureau of Meteorology's Limited Area Prediction System (LAPS). Second, the flight parameters of *C. terminifera* measured by the IMR are used alone to calculate trajectories for the nights when collective orientation is observed, on the assumption that migrating locusts some distance away made the same course changes, at the same time, as those flying over the IMR. Third, the simulated winds are used to estimate the airspeed and cross-wind angle of plague locusts passing over the IMR, and these are then combined vectorially with simulated winds to calculate modified wind trajectories. Python script language is used to program trajectory models and ArcGIS is used to plot the results.

Results: The plague locusts usually migrate under the influence of tropical troughs in eastern Australia. They migrate northwards with right-shifted headings but southwards with left-shifted headings. The comparison study shows that trajectories estimated using these three methods are significantly different in both direction and distance.

Conclusions: Insect flight behaviours affect the migration pathway significantly. To locate the source and destination of migrant insects, the orientation behaviour must be included along with the wind in the trajectory model.

Non-target impact of the use of fruit fly (Tephritidae) male lures and Biolure

Luc Leblanc[1], Daniel Rubinoff[1], Roger Vargas[2]

[1]University of Hawaii, Department of Plant and Environmental Protection Sciences, Honolulu, Hawaii, United States, [2]United States Department of Agriculture - Pacific Basin Agricultural Research Center, Hilo, Hawaii, United States

Introduction: Male lures and female attractants are widely used for fruit fly monitoring and more recently for their control as environmentally-friendly alternatives to insecticide cover sprays. Their potential non-target attraction impact should however also be minimal.

Methods: Traps baited with *Bactrocera* male lures (Cue-lure, methyl eugenol) and the Mediterannean fly attractant Biolure were maintained and emptied weekly in native and non-native forest and in orchards on the Hawaiian Islands. All non-target insects were counted and identified to species. Attraction to lure or to decaying fruit flies accumulating in traps was assessed by comparing lure trap catches with catches of unbaited control traps and traps artificially baited with decaying fruit flies.

Results: Cue-lure did not attract non-targets and methyl eugenol attracted limited numbers of non-native flower-associated insects and native plant bugs. Large numbers of saprophagous non-targets were however attracted whenever dead trapped fruit flies accumulated inside traps. These same non-target species were also attracted in traps baited with Biolure and with decaying fruit flies. Beneficial predatory or parasitoid insects were not attracted to lures or decaying flies. Numerous native species, especially Drosophilidae, were captured in traps set up in native forest, but not in orchards.

Conclusions: Most published past records of male lure attraction was actually attraction to decaying fruit flies caught by the lure. Non-target impact is minimal if traps are distant from native forest.

Effects of clearfell harvest area on beetle biodiversity

Stephen Pawson[1], Raphael Didham[2], Eckehard Brockerhoff[1]

[1]Scion, Christchurch, New Zealand, [2]University of Canterbury, Christchurch, New Zealand

Clearfelling remains the predominant forest harvesting model in most countries despite criticism of it environmental and aesthetic impacts. Comprehensive studies have previously compared the relative impacts of clearfelling and alternative harvesting systems, however, the impacts of clearfell harvest area remain largely unstudied. In this trial, the first large scale experimental trial, of different harvest areas (0.01 ha to 500 ha), we sampled all Coleoptera by pitfalling in transects between recent clearfells and adjacent mature *Pinus radiata* plantation stands.

Multivariate analyses of the 350 species sampled indicate that beetle assemblages were most strongly defined by the clearfell – mature-forest interface. Species composition was independent of clearfell size, once harvest area exceeded 0.05 ha, and there was no indication of a clearfell harvest area threshold response in beetle biodiversity. However, an edge mediated threshold response occurred in the community structure of non-harvested stands adjacent to clearfells. Beetle community composition at 125 m into forest stands changed significantly when neighbouring harvest areas exceeded a threshold area between 0.5 and 5 ha.

The changes in beetle composition we observed, in a temperate exotic monoculture plantation, would question the merit of prescriptive size restrictions for clearfelling; as minimum economically viable harvest areas have the same impact on beetle communities as larger harvest areas. Instead, harvesting strategies should focus on landscape-scale planning to ensure areas of core forest habitat and forest dispersal pathways are maintained whilst avoiding potential edge effects from regenerating clearfells.

Evaluation of a pheromone: Lure trap for monitoring distribution of the red palm weevil population in Egypt

Sadek Salem, Atef Abdel-Razek, Hussein Salama

National Research Centre, Cairo, Egypt

Introduction: The red palm weevil (RPM), *Rhynchophorus ferrugineus* (Olivier) is known as the most destructive insect pest of palm trees in the Middle East. As an internal tissue borer, detecting infested palms become extremely difficult in the early stage of attack.

Methods: A specially designed 5 liter plastic bucket with lid was used and 10 to 12 round holes (2–3 cm diameter) were made in each bucket at 10 cm height from its base for weevils entrance. Lures included general attractants for red palm weevil such as slices of sugarcane, slices of palm trunk, yeast, shredded date palm and Lannate (0.1%). The lid of the bucket has two holes: the first used to hang two bottles each containing 20 cm^3 of ethyl acetate. The second used to hang the pheromone capsule.

Results: The traps used in this study showed significant increase in weevils captured during the first year compared with that for the second year. Also, our investigations of captured weevils showed that the ratio of females to males captured was 1.07: 1.00 and the ratio of gravid females to non gravid ones was 2.24: 1.00 with maximum increase during May 2003. This indicating that they have been already mated before entering the traps. The synergistic effects of temperature and humidity with pheromone traps in capturing the red palm weevils were also recorded with more significant effects for the temperature regimes than the humidity.

Conclusions: The results recommended the use of trapping of red palm weevils in IPM strategies for control of red palm weevil, because of their benefit in reducing the population build up of red palm weevil in the field.

Understanding the factors that influence the geographical expansion of *Cactoblastis cactorum* in non-native habitats

Stephanie Bloem[1], Kenneth Bloem[2], Stephen Hight[3], James Carpenter[4], Silvia Dorn[5], Mark Sarvary[5], Helmuth Zimmermann[6], Joel Floyd[7]

[1]USDA-APHIS-PPQ-CPHST-Plant Epidemiology and Risk Analysis Laboratory, Raleigh, NC, United States, [2]USDA-APHIS-PPQ-CPHST, Raleigh, NC, United States, [3]USDA-ARS, Center for Medical, Agricultural, and Veterinary Entomology, Tallahassee, FL, United States, [4]USDA-ARS, Crop Protection Management and Research Unit, Tifton, GA, United States, [5]Institute of Plant Sciences, Applied Entomology, ETH Zurich, Switzerland, [6]HZ and Associates, Pretoria, South Africa, [7]USDA-APHIS-PPQ-EDP, Riverdale, MD, United States

Introduction: *Cactoblastis cactorum* is renowned for its role as a highly successful biological control agent for weedy Opuntia cactus, but more recently it is notorious as an invasive pest in North America. Interestingly, historical accounts of the geographical expansion of *C. cactorum* when deployed as a biological control agent suggest that dispersal ability is rather limited compared to the more robust dispersal documented for *C. cactorum* as a pest in the southeastern States of the USA and some offshore islands near Yucatan, Mexico.

Methods: Laboratory bioassays using a flight mill were used to examine the influence of age, gender, mating status, body size and seasonal generation on diel flight pattern and flight performance of adults. Direct evidence of dispersal was studied using release/recapture techniques.

Results: Both laboratory bioassays from ETH Zurich and field release/recapture trials in the USA and Mexico detected heterogeneity in the population with respect to dispersal behavior and ability, and measured differences associated with various parameters.

Conclusions: The factors that influence the geographical expansion of *C. cactorum* in non-native habitats are numerous and provide opportunity for complex interactions. Laboratory bioassays and field trials have provided some insights into this complicated area of study and have demonstrated the value of *C. cactorum* as a model system for future studies. This information is then used to design better control and management methods towards the insects' eradication and delimitation that would prevent its further invasion to sensitive cactus areas in the USA and Mexico.

Biology and conservation ecology of selected saproxylic beetles in Tasmania's southern forests

Belinda Yaxley[1], Simon Grove[2], Richardson Alastair[1], Simon Wotherspoon[1]

[1]University of Tasmania, Hobart, Tasmania, Australia, [2]Forestry Tasmania, Hobart, Tasmania, Australia

Studies worldwide have demonstrated that dead wood is a key habitat for forest insects. In Europe, many saproxylic species are red-listed, due to long-term changes in dead wood availability brought about by intensive forest management. Once species become this scarce, it is difficult to find practical and affordable ways to manage production forests that still allow for their recovery. In hindsight, it would have been preferable to have conducted forestry in a way that didn't threaten them in the first place. The philosophy behind the present study is that in Tasmania's commercially important lowland wet eucalypt forests, forestry is still at an early stage of intensification, presenting an opportunity to use a scientific approach to developing management regimes that not only generate forest products but also cater for biodiversity. The study involves developing an understanding of the ecology of several key saproxylic beetle species, and of their relationships with dead wood and with forest management. Multiple study sites have been selected to cover the range of forest ages and types present. In each study site, a suite of dead wood attributes has been measured. These are being compared with site-level and log-level data on populations and microhabitat associations of these beetle species. Findings show that particular species have very narrow habitat preferences, which will make them vulnerable to forestry in the absence of mitigation measures. The intention is to use these findings to help derive forest management approaches that will meet the twin needs of commercial forestry and conservation.

Will climate change alter the relationship between predator biodiversity and herbivore suppression?

William Snyder

Washington State University, Pullman, WA, United States

The dominant trend across terrestrial communities is for herbivore suppression to strengthen with greater predator biodiversity. However, widespread ecological disruption is likely to be triggered by global climate change, with complex implications for biodiversity-biocontrol relationships. In the state of Washington (USA), it is predicted that warming temperatures will foster invasion of agroecosystems by new, exotic arthropod and pathogen species. These new arrivals would change the species composition of natural enemy communities. We can use the extensive literature documenting the ecological impacts of previous predator invasions to predict likely effects of new invaders. Often, invasive predators displace similar native predator species, achieving far higher densities than natives and thus exerting far stronger impacts on prey. Thus, following successful invasion we would predict that species identity (sampling) effects will replace complementarity as the dominant factor underlying predator biodiversity effects. Because invaders are often dominant intraguild predators, negative predator-predator interactions may further dampen any benefits of predator diversity for herbivore suppression. Unlike predators, in the biodiversity-ecosystem functioning literature pathogens have rarely been considered as a component of natural enemy diversity. This relative dearth of information makes it difficult to predict the outcome(s) of invasion by new insect pathogens. However, because of clear ecological differences between predators and pathogens, these two natural enemy guilds might be particularly likely to complement one another. In summary, changing distributions of predator and pathogen species may form a key impact of global climate change, altering the relationship between biodiversity and biological control in many agroecosystems.

Evolution of the gustatory receptor (Gr) family in mosquitoes

Hugh Robertson, Lauren Kent

University of Illinois, Urbana, Illinois, United States

Introduction: Olfaction and gustation in insects is mediated by the insect chemoreceptor superfamily of proteins. The gustatory receptor or Gr family comprises most of the diversity of this superfamily, containing both gustatory and olfactory receptors. Mosquitoes are major vectors of diseases worldwide and are known to employ chemical cues in host-seeking behavior and might employ them in other behaviors.

Methods: We manually constructed gene models for the Grs in *Anopheles gambiae*, *Aedes aegypti*, and *Culex pipiens*, using the publicly available genome sequences, and analyzed their phylogenetic relationships using corrected distance methods.

Results: *An. gambiae* has 60 Gr genes encoding 89 Grs, through alternative splicing of the first long exon in four genes. *Ae. aegypti* has 79 Gr genes potentially encoding 114 Grs, however 19 of these are pseudogenic, so the Gr repertoire of this species is around 95 proteins. *C. pipiens* has 77 Gr genes potentially encoding 136 proteins, but 13 are pseudogenic, leaving 123 functional proteins. Phylogenetic analysis reveals the expected orthologous conservation of the three carbon dioxide receptors. Mosquitoes have nine sugar receptor lineages, with differential loss and duplication in each genus. There are several other simple conserved orthologs, some orthologs have been lost from one or more genus, and many gene lineages have duplicated in one or more genus. The alternatively-spliced loci show particular expansion in Aedes and Culex.

Conclusion: Although the expansion of the Gr family in culicines is enigmatic, these results provide the groundwork for functional work on the mosquito Grs, and expression studies are underway in *Anopheles gambiae.*

Biodiversity and host relationships of *Caenocholax fenyesi* sensu lato

Alexander Hayward, Dino McMahon, Jeyaraney Kathirithamby

University of Oxford, Oxford, United Kingdom

Male and female members of the strepsipteran species *Caenocholax fenyesi* have separate host preferences, with males parasitic in ants (Formicidae) and females parasitic in sword-tail crickets (Trigonidiinae). The species is Neotropical in distribution, with a large range extending from the southern USA to northern Argentina. Fossil specimens found in Baltic and Dominican amber suggest that the species has undergone little morphological change over the last 30-40 million years. In this study we investigated the molecular diversity and host range of the species using specimens gathered from across its range. Analysis of mitochondrial COI and nuclear 18S sequences revealed a high degree of variation indicative of a set of cryptic species, and molecular clock estimates suggest a relatively ancient date of divergence for the lineages. Male *C. fenyesi* was sampled from three different subfamilies of ant, with the same lineage sometimes found to parasitize different subfamilies at the same site.

Metamorphosis to the postgenomic era: RNA interference of neuropeptidergic systems in the red flour beetle *Tribolium castaneum*

Yoonseong Park, Richard Beeman

[1]Kansas State University, Manhattan, Kansas, United States, [2]USDA-ARS-GMPRC, Manhattan, Kansas, United States

The study of insect neuropeptides has experienced an immense change in the last decade with the development of whole-genome DNA sequencing technology. During the current postgenomics phase of red flour beetle research, our efforts are directed mainly towards the assignment of functions of neuropeptides and towards an understanding of evolutionary trends. RNA interference (RNAi) in *Tribolium* has become a versatile tool to investigate the functions of neuropeptidergic systems. The injection of dsRNA into the body cavity of postembryonic stages elicits systemic RNAi affecting tissues throughout the entire body, including target genes expressed in the central nervous system, such as neuropeptide and their receptors. We have been interested in the functions of neuropeptidergic systems involved in the control of water and ion regulation, and in insect ecdysis behavior. For example, RNAi of ecdysis triggering hormone and one of its receptor variants resulted in lethal deficiency in pre-ecdysis and ecdysis behavior. Postembryonic RNAi of ion transport peptide, which is known to be involved in water resorption in the hindgut of locust, resulted in mummification and death. We find that analysis of hypomorphic or amorphic phenotypes following injections of double stranded RNA provides critical information needed to understand the role(s) of particular neuropeptidergic signals in the biology of the organism.

Genetic differentiation and outbreak species in agroecosystems

Raul Medina

Texas A&M University, College Station, United States

Empirical evidence shows that morphologically cryptic genetic differentiation is more frequent than previously thought in plant feeding and parasitic insects. However, although genetic differentiation has been demonstrated in feral herbivorous insects, we still ignore under which conditions we can predict this differentiation to occur. If this phenomenon is as common in ago-ecosystems as it seems to be in feral habitats, then we need to consider it when designing IPM strategies. It has been postulated that morphologically cryptic genetic differentiation in predators and parasitoids may be crucial in determining the success or failure of biocontrol programs. For example, parasitoid populations that oviposit on the same herbivorous host species may differ genetically when their hosts are attacked on different plant species. Thus, introduced parasitoid populations associated with the same insect host but on different plant species might be ecologically and reproductively isolated. Similarly, in a transgenic crop scenario, if individuals from the same pest species are reproductively isolated when in association with crops or with adjacent feral vegetation, uncultivated plants cannot be considered as refuges to dilute resistance genes to transgenic plants. The purpose of this presentation is to motivate future researchers to gather information on HAD on their study systems so we can accumulate enough case studies to further our understanding of the relevance of evolutionary forces in agro-ecosystems.

The honey bee *Apis mellifera* genome: genes shared by bees and humans, but lost from Drosophila

Hugh Robertson

University of Illinois, Urbana, Illinois, United States

Introduction: An EST project on the honey bee brain was published in 2002, and a high-quality draft sequence of the honey bee genome in 2006. One interesting aspect of these two sequence resources is the presence of hundreds of genes that bees have that are highly conserved throughout most of animal evolution, including in our own genome, but are missing from Drosophila.

Methods: Examination of the honey bee brain ESTs revealed ~100 genes/proteins with strong matches to human proteins, but not Drosophila. These genes were examined in the draft genome assembly to provide full-length proteins for phylogenetic analysis. All available arthropod genomes were examined for these genes, and a few have been worked up extensively.

Results: Among these 100 genes are several known to be missing from Drosophila, such as telomerase and DNA methylase 1 and 3. Others include pteropsin and one of the cryptochromes. Examination of the pattern of loss on the phylogenetic tree of arthropods indicates that gene loss is mostly a background process at a reasonably steady rate, although there might be an acceleration in the Diptera.

Conclusion: Major aspects of insect and indeed general animal biology have been lost from the central insect molecular genetic model *Drosophila melanogaster*. In many cases these have been replaced or compensated for in some way in Drosophila flies, but others might underly significant differences between Drosophila and other insects.

Social evolution in paper wasps: natural history, genomics, and beyond

James H. Hunt

North Carolina State University, Raleigh, North Carolina, United States

Sociality in insects cannot be understood by a narrow focus on the origin and behavior of workers. For a clear understanding of the social evolutionary process, one must also know the origin and behavior of gynes. In paper wasps (*Polistes*), workers and gynes as sibling offspring are differentiated during larval development. One developmental pathway leads to hopeful reproductives trapped in a worker role through a combination of colony context and their own physiology. Another developmental pathway leads to future reproductives in a physiological state of diapause who, through their behavior, lead to the colony demise. Selection acts at the level of the colony to favor traits that engender this pattern. Recent genomics-based research provides gene expression data that constitute one of multiple lines of evidence that now are converging in strong support of the developmental components of this pattern. Those genomics data are presented and placed in evolutionary context. The evolution of sociality in paper wasps now can be clearly seen, and it points the way to understanding insect social evolution generally.

STEPP: spatio-temporal population probability models for delimiting pest incursions and monitoring eradication success, and a demonstration using painted apple moth

John M. Kean

AgResearch, Lincoln, New Zealand

Introduction: Successful incursion response relies on accurately delimiting the pest population, application of effective eradication treatments, and determining when the likelihood of continued pest presence becomes acceptably small. Here, I propose that spatio-temporal population probability (STEPP) models, which combine conventional population models with statistical probability approaches across space and time, can inform delimitation and eradication monitoring. A STEPP approach is demonstrated using painted apple moth (*Teia anartoides*) in Auckland, New Zealand.

Methods: A population model for daily temperature-determined male production was used in conjunction with spatially-explicit pheromone trap locations and attraction radii to determine the daily probability of detecting a wild population at a particular location. Over time, these probabilities multiply up to decrease the likelihood of presence given ongoing lack of detection. The model was parameterised for painted apple moth using data collected during the Auckland incursion response, allowing spatio-temporal risk maps to be produced.

Results: The model suggested that trapping in winter yields relatively little useful information on painted apple moth presence. Eradication was likely to have been successful in the main infestation areas by mid 2005, with subsequent catches likely to represent further small incursions, as corroborated by molecular evidence. It was plausible that a wild population was present in the Otahuhu area in 2005 but very unlikely that it remained by the end of 2006.

Conclusions: STEPP models can assist decision-making during incursion response, but depend on quantification of sampling efficacy and good data management. They show particular potential for use with future automated trapping systems.

Bombyx neuropeptide GPCR transcriptome reveals authentic neuroendocrine network

Naoki Yamanaka[1], Dusan Zitnan[2], Yu Kaneko[3], Kiyoshi Hiruma[3], Yoshiaki Tanaka[4], Tetsuro Shinoda[4], Hiroshi Kataoka[1]

[1]The University of Tokyo, Chiba, Japan, [2]Slovak Academy of Sciences, Bratislava, Slovakia, [3]Hirosaki University, Aomori, Japan, [4]National Institute of Agrobiological Sciences, Ibaraki, Japan

Background: Neuropeptides are among the most important class of molecules involved in diverse aspects of life history in metazoans. Insects have been one of the ideal model systems to investigate neuropeptide circuitry, but the systematic analysis of their signaling has been hampered by the small size of the best-studied model insect, *Drosophila melanogaster*.

Results: In this study, G protein-coupled receptors (GPCRs) for neuropeptides were comprehensively cloned and systematic expression analyses were performed in the large lepidopteran insect, *Bombyx mori*. In order to unequivocally demonstrate the effectiveness of this approach, we chose regulatory pathways of the juvenile hormone (JH) biosynthesis as a target of our detailed analysis, and characterized the long-sought allatotropin (AT) receptor. JH plays the pivotal role in many physiological events in insects, and AT is thought to stimulate JH biosynthesis in the corpora allata (CA). Surprisingly, however, the AT receptor was predominantly expressed not in the CA but in the corpora cardiaca (CC), an organ closely located to the CA. Indeed, by using reverse-physiological approach, we purified and characterized novel allatoregulatory peptides produced in the AT receptor-expressing CC cells, which may mediate indirect AT activity on the CA.

Conclusions: To our knowledge, this is the first report of the comprehensive cloning of neuropeptide GPCRs conducted in any organism. All of the above findings confirm the effectiveness of our systematic analyses, providing a solid framework for the combinational bioinformatic, molecular, biochemical and physiological approaches to tackle unsolved problems in neuropeptide research.

This work was supported by PROBRAIN.

The insect chemoreceptor superfamily

Hugh Robertson

University of Illinois, Urbana, Illinois, United States

Introduction: The insect chemoreceptor superfamily mediates the olfactory and gustatory senses of insects. It has now been described from several insects representing diverse orders. The evolutionary origins of these chemoreceptors remain unclear.

Methods: We manually annotated the superfamily from the available diverse insect genomes, as well as the crustacean *Daphnia pulex* and the tick *Ixodes scapularis*. Extensive searches for distant relatives in the Caenorhabditis nematode genomes reveals related receptors, known as GURs and SRRs. Membrane topology analysis support the assertion of the Vosshall laboratory that these are not GPCRs.

Results: The odorant receptor or Or family is a relatively recent expansion of one gene lineage within the superfamily. The remainder of the superfamily constitutes the so-called gustatory receptors or Grs, although some of these are olfactory in function, e.g. the carbon dioxide receptors. Amongst the Grs, the carbon dioxide receptors are the most conserved, however all available genomes below Tribolium on the phylogenetic tree do not have this gene lineage. The sugar receptors also show considerable conservation, but differential expansion in various insects. Most other Grs are species-specific lineages.

Conclusion: With a few exceptions, the insect chemoreceptor superfamily shows primarily lineage-specific expansions expected of ecologically-relevant genes when compared across orders of insects and classes of arthropods. Nevertheless, distant relatives are recognizable in nematodes, indicating that this novel superfamily of environmental sensors predates the Ecdysozoa.

Twelve years after the adoption of Bt maize in the U. S.: Impacts of landscape level suppression of European corn borer in several midwestern states

William Hutchison[1], Roger Moon[1], Tim Leslie[2], Shelby Fleischer[2], Mark Abrahamson[3], Krista Hamilton[4], Kevin Steffey[5], Mike Gray[5], Von Kaster[6], Rick Hellmich[7], Robert Wright[8], Thomas Hunt[8], Paul Mitchell[9]

[1]University of Minnesota, St. Paul, MN, United States, [2]Pennsylvania State Univ., State College, PA, United States, [3]Minn. Dept. of Agric., St. Paul, MN, United States, [4]Wisconsin Dept. of Agric., Madison, WI, United States, [5]University of Illinois, Urbana, IL, United States, [6]Syngenta Corp., Slater, IA, United States, [7]USDA-ARS, Ames, IA, United States, [8]University of Nebraska, Lincoln, NE, United States, [9]University of Wisconsin, Madison, WI, United States

Transgenic maize, transformed to express various Cry toxins from the bacterium, *Bacillus thuringiensis*, has been widely adopted by U.S. growers, particularly in the Midwestern states. Statewide adoption rates now exceed 55% in several states. Since commercialization in 1996, populations of the European corn borer (ECB), (*Ostrinia nubilalis*), have gradually declined. Although ECB has a broad host range, we hypothesized that the species could be affected by the vast area of Bt maize in the Midwest landscape (e.g., 7 million ha in 4 major states). We present evidence from autumn larval surveys (1943-2007) and moth flight data (light traps; since the 1980s), to examine the hypothesis of a regional suppression effect due to Bt maize over the past 12 years. Larval survey data for Minnesota, Illinois and Wisconsin indicated a 6-7 year cycle (periodicity) in ECB dynamics. We therefore examined the relationship between a 7-year moving average of fall larval density as a function of the annual and cumulative increase in proportional Bt maize use in each state, from 1996 to 2007. For Illinois and Wisconsin a significant linear reduction in larval populations was observed, relative to Bt maize use, with R^2 = 0.69 and 0.83, respectively. For Minnesota, with a higher cumulative Bt maize use rate, we found a non-linear significant reduction (R^2 = 0.83). Similar reductions were observed for annual moth flights in relation to Bt maize use. The impact of the landscape level suppression of ECB is discussed within the context of cyclical population dynamics and IPM implications.

Peptidergic and monoaminergic mechanisms regulating circadian rhythms in insects

Makio Takeda, Susumu Hiragaki, Qi-Miao Shao, Le Thi Dieu Trang, Hana Sehadova

Kobe University, Kobe, Hyogo, Japan

Recently, the molecular mechanism underlying circadian rhythm has been investigated in some model insects such as *Drosophila melanogaster,* cockroaches, and silkmoths. About a dozen of genes have been found in *D. melanogaster* .They form interlocked negative feedback loops. Homologous genes have been found in other insects but with some unique features to each species. The output pathways to regulate peripheral rhythms seem to vary. Unlike central cog mechanisms, the output pathway has not been worked out even in *D. melanogaster.* A convincing factor regulating this pathway is PDF, pigment dispersing factor in *D. melanogaster.* Since PDF-ir resides in the putative circadian pacemaker cells that express most of the clock gene products and that using mutants causing different degrees of optic lobe deformation, the number of PDF-expressing neurons and the strength of rhythmicity have a strong correlation. Also, a *pdf* mutant lost the rhythmicity. However, it is not likely that all output pathways are PDF-regulated, since *lark* mutant produces abnormal eclosion rhythms but locomotor activity rhythm is intact and pdf receptor is not expressed in neurosecretory cells.

Although surgical operations point to the accessory medulla region of the cockroach as the most critical locus to keep normal circadian rhythms, the IHCinvestigations have demonstrated that clock proteins-like antigens are not restricted to a particular part of the brain. We will show data indicating not only PDF but other factors are involved in circadian regulation. The classical scheme that the circadian pacemaker of the orthopteroid insects is located at the accessory medulla using PDF as an output messenger will be reappraised by focussing other factors, since this site expresses several other peptide-like immunochemical reactivities, such as BPP/NPF, glicentin, PHI, gastrin/CCK in *P. americana*, while some peptides like ATH, ASH and GABA caused phase shifts in *Leucopheae*. Melatonin and 5HT also are important in regulating circadian system in cockroaches and moths. There are several NAT genes but some have E-box in the regulatory region, and this is the access point of clock core mechanism to output pathway. I will show the neuroanatomical structure of peptides and indolamine mechanisms regulating circadian system and give its functional implications.

Building Sanitary/Phytosanitary (SPS) capacity in East Africa

Karl Suiter[1], Lloyd Garcia[2], Ronald Stinner[1]

[1]North Carolina State University, Raleigh, NC, United States, [2]USAID East Africa, Nairobi, Kenya

The East African Phytosanitary Information Committee (EAPIC) is a regional effort between Kenya, Tanzania, Uganda and Zambia to develop official country-specific and regional pest reporting tools in support of phytosanitary activities in East Africa. Through the efforts of EAPIC, a regional pest list encompassing species of concern found throughout all East African member countries has been developed. Additionally, the four EAPIC countries have deployed the Pest Information Management System (PIMS), an internet-based plant pest reporting database that supports SPS and pest reporting activities.

The PIMS software provides a mechanism for countries to create official country-specific pest lists, document pest status, generate distribution maps and archive related documents. This system will facilitate trade and permit trading partners the ability to harmonize border inspection protocols across the region. The outcome of these activities will in turn promote an increased flow of agricultural commodities across member borders and serve to guide future SPS activities and infrastructure building within the region.

The ability to share information relating to pest status among trading partners in the region will serve to satisfy international reporting obligations of contracting parties to the Food and Agriculture Organization's International Plant Protection Convention. Plans are underway to automate reporting of pest status to the IPP portal from the PIMS software through the creation of a dynamic data sharing link between these two systems.

Appropriate floral resources enhance biocontrol and obviate insecticide use against a major vineyard pest.

Marco Jacometti, Samantha Scarratt, Steve Wratten

Lincoln University, Canterbury, New Zealand

Introduction: Leafrollers (Lepidoptera: Tortricidae) are a major pest in New Zealand vineyards. They damage grapes directly and facilitate botrytis bunch rot, one of the world's most important vineyard diseases. Leafrollers are usually managed with insecticides, but these can become sub-optimal as pesticide resistance increases and international markets demand wine with low or no residues. Alternative methods for managing leafrollers are being sought, including conservation biological control techniques.

Methods: In this research, buckwheat (*Fagopyrum esculentum*) was sown in the inter-vine row space in two commercial vineyards in New Zealand.

Results: The nectar provided increased the efficacy of *Dolichogenidea tasmanica*, a parasitoid of leafroller caterpillars and parasitism rates increased to five times those in the control at harvest. As a result, the percentage of bunches infested with leafroller caterpillars reduced from 7% to 2%, the latter being below the economic threshold of 5% of bunches infested.

Conclusions: This research demonstrates how deploying appropriate floral resources in vineyards can obviate pesticide use, reduce variable costs and provide marketing advantages. The latter have been demonstrated through contingent valuation and other economics techniques, leading to the marketing of eco-tourism in working vineyard landscapes. This research is currently being adopted by commercial vineyards throughout New Zealand.

The role of the matrix in shaping ground-dwelling arthropod diversity and community composition of native remnants embedded within a pastoral and blue gum (*Eucalyptus globulus* Labill) plantation landscape

Chela Powell, Peter Ades, Nick Collett, Charlma Phillips

[1]*The University of Melbourne, Victoria, Australia,* [2]*Department of Primary Industries and Resources of South Australia, South Australia, Australia*

Introduction: Detailed information regarding the effects of monoculture plantation establishment on native plants and animals is limited and has usually concentrated on exotic soft wood plantations and higher level vertebrates such as marsupials and birds. The principal aim of this study was to investigate the role of the matrix in shaping epigeal arthropod diversity and community composition of native vegetation remnants embedded within a pastoral and blue gum (*Eucalyptus globulus.* Labill) plantation landscape. This study focuses on how the relatively recent change in the land use (from pasture to blue gum plantation) in the matrix surrounding native vegetation remnants affects local remnant arthropod communities.

Methods: Arthropods were sampled using both pitfall and flight intercept traps established within remnants surrounded by blue gum plantation (planted in 2000-2002), pasture and within continuous native forest in the Green Triangle region of south-east South Australia, and south-west Victoria. Pitfall sampling was carried out twice each season for 7 days over a 12 month period, while flight intercept trap sampling was conducted twice (summer and winter) during the study. All invertebrates were identified to ordinal level, while Coleopterans were identified to family level, and the 3 most abundant coleopteran families were identified to species level.

Results: Sampling results will presented and analysed using multiple regression through the statistical package SAS ©. The outcomes of this study will be used to aid in the development of management strategies aimed at maintaining and enhancing arthropod biodiversity in the Green Triangle region. Remnants of varying sizes and vegetation quality will be compared for their ability to support arthropod communities similar to that of regional contiguous native woodland, with the specific aim of identifying those remnants that should be targeted for conservation management by plantation owners.

The irresistible allure of an ant-eating assassin

Matthew Bulbert[1], Marie Herberstein[1], Gerasimos Cassis[2]

[1]Macquarie University, Sydney, NSW, Australia, [2]University of NSW, Sydney, NSW, Australia

Introduction: Members of the subfamily Holoptilinae (Insecta: Hemiptera: Reduviidae) are reputed to be obligate myrmecophages. Early accounts of two species suggest the bug uses an elaborate predatory tactic to deceive ants. The tactic culminates in ants compelled to interact with an extraordinary morphological adaptation known as the trichome. Recent characterisation of this structure revealed a complex arrangement of specialised hairs, unicellular glands and exaggerated cuticular modifications. My study aims to investigate the nature of this ant-true bug interaction using an Australian species of Holoptiline known as *Ptilocnemus lemur*.

Methods: The predatory behaviour of *P.lemur* was observed in the field and the laboratory. Chemical attractiveness of *P.lemur* towards foraging ants was experimentally tested using a Y-maze olfactometer; and the characterisation of chemicals, emitted at various behavioural states, was attempted using GC-MS and solid phase microextraction.

Results: *P.lemur* adults were regularly observed taking *Myrmecia pilosula;* an aggressive solitary forager. As expected, *P.lemur* presented the trichome to visiting ants by rising up on their hind legs. Ant-trichome interaction resulted in predatory success. However, unlike other species of Holoptilinae, it appears *P.lemur* initially attracts the ants' attention by waving its elaborately adorned tibia. Y-maze experiments, where visual signals were omitted, showed that foraging *M.pilosula* were attracted to adult *P.lemur* irrespective of sex; but only when *P.lemur* had entered its 'attacking' state. The chemical profile of the bug also varied accordingly.

Conclusions: *P.lemur* can be added to an incredibly small list of animals that lure and ultimately deceive prey through a multimodal signalling system.

Finishing the sequence of the *Bombyx mori* genome

Qingyou Xia[1], Kazuei Mita[2]

[1]Southwest University, Chongqing, China, [2]National Institute of Agrobiological Sciences, Tsukuba, Japan

We present a complete silkworm genome sequence obtained by the integration of data from two WGS projects performed independently in 2004. In the new assembly, sequence coverage of the merged WGS reads, together with a newly generated fosmid- and BAC-end data, reached 8.48x. The new assembly has the best continuity (> 3.7 Mb in N50 scaffold size, and 15.5 Kb in N50 contig, respectively) among the sequenced insect genomes. Using a high-density SNP linkage map consisting of 1,577 markers, about 87.4% of the scaffold sequences were anchored to all the 28 chromosomes. Comparison between the linkage map and the assembly indicated that both the assembly and the genetic map were reliable for subsequent analyses. The coverage of repeats in the *Bombyx* genome, 44%, is substantially higher than those in other insects, contributing larger genome size of *Bombyx*. *De novo* gene prediction was performed using gene finder BGF by pre-filtering classifiable TEs. It gave a gene count of 16,329. In conclusion, the new genome assembly made available a more precise annotation of the structure and function of the *B. mori* genome. The data presented and analyzed herein can facilitate us to explore evolutionary patterns of insect genomes and will serve as a useful tool for gleaning new insight into genetic, developmental and regulatory events.

BugWise, a programme providing opportunities for the community to work with invertebrates in a meaningful way

Matthew Bulbert, John Gollan, Helen Smith

Australian Museum, Sydney, NSW, Australia

Introduction: Invertebrates are generally undervalued by society and regularly overlooked in biodiversity surveys. *BugWise* was created to address the negative perceptions and the constraints that prevent the wider community from working with invertebrates in a meaningful way. In the process, *BugWise* aimed to involve community in the development of cost-effective and user-friendly reporting tools for interventions such as restoration.

Methods: Workshops were designed to show the link between invertebrates and the lifestyles of humans and to address common misconceptions. Reporting tools and associated resources were created and tested with the direct involvement of the community through both workshop and field activities. The foundations of the tools require the user to identify invertebrate signs or directly measure invertebrate processes.

Results: Volunteers provided feedback that significantly improved usability and accuracy of the resources. Field testing showed applicability of the methods to a wide variety of habitat types. The simplicity of the methods allowed rapid assessment of data quality and training needs. Volunteers gained value from the interaction with museum scientists and a sense of ownership in the products they helped refine. Moreover, participants gained greater appreciation of invertebrate diversity and the importance of the conservation of invertebrates. Appreciation has persisted beyond the workshops through the distribution of the *BugWise* methods through a dedicated website.

Conclusion: The *BugWise* model proved to be successful in developing practical applications through an interdisciplinary partnership of industry stakeholders, community volunteers, ecologists and taxonomists. The tools resulting from the programme alleviate the need for expensive laboratory processing.

Molecular cloning and characterization of *Tret1*-orthologs facilitating trehalose transport in insects

Takahiro Kikawada, Yasushi Kanamori, Ayako Saito, Yuichi Nakahara, Ken-ichi Iwata, Daisuke Tanaka, Kanako Mitsumasu, Masahiko Watanabe, Takashi Okuda

National Institute of Agrobiological Sciences, Tsukuba, Ibaraki, Japan

Introduction: Trehalose is the main hemolymph sugar in insects. Nevertheless, mechanisms of trehalose transport across cellular membrane in insects were unknown. Recently, we cloned a facilitated trehalose transporter, *Tret1*, from the sleeping chironomid, *Polypedilum vanderplanki*. We examined whether *Tret1*-orthologs from which deduced protein possess activity for trehalose transport exist in other insects.

Methods: *Tret1* orthologs were searched on public DNA databases such as FlyBase, AnoBase, BeeBase and SilkBase. Trehalose uptake activity of proteins translated from the obtained orthologs was investigated using *Xenopus* oocyte expression system. Subcellular localization of the deduced proteins was evaluated using the expression of a fusion protein with GFP in the oocyte. Tissue-specific expression pattern of *Tret1*-ortholog in *B. mori* was examined by quantitative RT-PCR (Q-PCR).

Results: *In silico*, candidates for *Tret1*-orthlogs were cloned from *Drosophila melanogaster, Anopheles gambiae, Apis mellifera* and *Bombyx mori*, and designated as *DmTret1, AgTret1, AmTret1* and *BmTret1*, respectively. Interestingly, *D. melanogaster* possesses another paralog for *DmTret1*, so further designated as *DmTret1-1* and *DmTret1-2*. All proteins deduced from these orthologs were localized in the cellular membrane. *Xenopus* oocyte expression system showed that all the orthologous proteins except DmTRET1-2 have activity for trehalose transport across the cellular membrane, indicating that *DmTret1-2* is a pseudogene of *Tret1*. Q-PCR revealed that *BmTret1* is mainly expressed in the fat body, which is consistent with the tissue-distribution of *Tret1* gene expression in *P. vanderplanki*. This result suggests that TRET1 would be involved in discharging trehalose from the fat body into hemolymph in many insect species.

Conclusion: Several dipteran, hymenopteran and lepidopteran species had TRET1 showing trehalose transport activity for across the cellular membrane in the fat body, indicating TRET1 is widespread among insects for blood sugar regulation.

Invasions and origins of *Quadrastichus erythrinae* (Hymenoptera: Eulophidae), and devastation of Pacific *Erythrina* species

Mark Wright, Daniel Rubinoff, Russell Messing

University of Hawaii at Manoa, Honolulu, Hawaii, United States

Introduction: In 2004, *Q. erythrinae* was described from Singapore, where is was causing severe damage to ornamental *Erythrina* (coral) trees. By 2005, it had further progressed to Taiwan, Japan, China, the Phillipines, and Hawaii. In Hawaii *Q. erythrinae* attacks endemic *Eyrthrina* in addition to ornamental species. Many trees are killed by these gall insects. This project aimed to seek biological control agents of this insect, and to elucidate its origin.

Methods: Wasps were collected from *Erythrina* spp. in South Africa, Mozambique, Tanzania and West Africa. Parasitoids were reared in quarantine, and gall wasps were kept for DNA extraction. A phylogeographic analysis of the samples was done to seek the origin of the invasive species. At least eight species of gall forming wasps were extracted from the sampled material.

Results: Numerous parasitoids were reared from the samples. Three species are currently being evaluated for biological control releases. Phylogeographic analysis based on mitochondrial and nuclear genes suggest a south-east African origin, but no match has yet been found that pinpoints the origin.

Discussion: The exact origin and route of escape that *Q. erythrinae* followed are not yet completely known. This species has demonstrated unprecedented invasive characteristics for an insect, and will have impacts on a broad geographical scale. The phylogeographic analysis revealed a complex of Eulophidae associated with *Erythrina* in Africa, which begs the question ‘why have no others become aggressively invasive’?

Alteration of social interactions with an immune-challenged nestmate in honeybees.

Freddie-Jeanne Richard[1], Arnaud Aubert[2], Christina Grozinger[1]

[1]North Carolina State University, Raleigh, NC, United States, [2]Université François Rabelais, Tours, France

Immune response pathways have been relatively well-conserved across animal species, with similar systems in both mammals and invertebrates. Social insects, such as honeybees and ants, provide ideal grounds for pathogens' dissemination, with controlled environmental conditions in the hive, high population densities, and frequent interactions. Interestingly, despite this theoretical vulnerability, honeybees have substantially reduced numbers of genes associated with immune function compared to solitary insect species. This suggests that honeybees may have developed complementary mechanisms - such as behavioural modifications - to deal with disease. Here, we demonstrate that activation of the immune system in honeybees (using a non-replicative bacterial coat protein: lipopolysaccharides, LPS), alters the responses of healthy nestmates toward the treated individuals. Furthermore, these altered behavioral responses of healthy bees match significant changes in the overall cuticular hydrocarbon profiles of immune-challenged bees. Since cuticular hydrocarbons play a critical role in nestmate recognition and other social interactions in a wide variety of insect species, modulation of such chemical profiles by the activation of the immune system could play a crucial role in the social regulation of pathogen dissemination within the colony.

DNA analysis to determine the origin of winter moth in North America and hybridization with its congener Bruce spanworm

Joseph Elkinton, George Boettner, Marinko Sremac, Rodger Gwiazdowski, Roy Hunkins, Adam Porter, Susan Schuefele

University of Massachusetts, Amherst, MA, United States

Introduction: The northeastern United States has experienced a novel outbreak of winter moth, *Operophtera brumata*, an invasive defoliator from Europe. We wished to map the extent of the infestation and to determine where the moths came from.

Methods: To map the infestation we deployed a grid of pheromone-baited traps. The traps also captured Bruce spanworm, *Operophtera bruceata,* a North American congener of winter moth. The adult males of these two species are difficult to distinguish based on wing characters. We dissected genitalia and sequenced the CO1 gene to distinguish the species. To detect hybrids between them, we looked for intermediate genitalia and we sequenced the nuclear gene G6PD.

Results: We found winter moth in coastal New England from Long Island to Maine. Further north and west we recovered only Bruce spanworm. Although many moths in the zone where the two species overlapped had intermediate genitalia, the G6PD sequences showed that hybrids occur but are rare. DNA analyses show that all winter moths from North America (Nova Scotia, British Columbia and New England) have an identical CO1 haplotype. In contrast populations of winter moth in Europe and Bruce spanworm in North America both show considerable sequence variation.

Conclusion: These facts may indicate a founder effect and a single introduction of winter moth to North America, However, the same haplotype that is ubiquitous in North America is also both dominant and widespread in Europe. Thus, at present, we cannot rule out multiple introductions of this haplotype to North America

The role of habitat structure on disease-infected insects invading Australia

Kylie Anderson[1], Mohamed Sallam[2], Bradley Congdon[1]

[1]James Cook University, Cairns, Queensland, Australia, [2]BSES Ltd, Gordonvale, Queensland, Australia

Introduction: Ramu Stunt disease of sugarcane and its vector, *Eumetopina flavipes*, are present in Papua New Guinea (PNG). Disease-free *E. flavipes* populations occur on the Torres Strait Islands (TSI) and northern peninsula area (NPA) of mainland Australia. Infected *E. flavipes* could disperse from PNG through the TSI and introduce Ramu Stunt into commercial Australian sugarcane. No data exists on *E. flavipes* habitat use when it colonises new regions. The effect of habitat structure (abundance and spatial distribution of hosts) on *E. flavipes* abundance was used to assess the likelihood of its successful establishment and population growth, and so determine likely TSI entry-points for Ramu Stunt infected *E. flavipes*.

Methods: The distribution of *Saccharum* host species, their occupancy by and abundance of *E. flavipes* if present was assessed at key locations in PNG, TSI and NPA.

Results: *E. flavipes* was always present in PNG, but not the TSI and NPA. When present, *E. flavipes* population size was extremely variable. In PNG, the abundance of *E. flavipes* varied considerably among four *Saccharum* host species. Of the PNG *Saccharum* species, two were present in the TSI and NPA. In contrast to PNG, *E. flavipes* abundance did not vary between them.

Conclusion: Habitat structure may affect the persistence of *E. flavipes* at some TSI and NPA sites. In PNG, hosts may provide a continuous habitat that is available for re-colonisation by *E. flavipes*. All PNG and particularly persistent TSI populations may be sources from which dispersal of Ramu Stunt disease infected *E. flavipes* could occur.

Field host range of *Melanagromyza eupatoriella* in Jamaica: implications for biological control of *Chromolaena odorata*

Marsha Robinson[1], Costas Zachariades[2], Dwight Robinson[1], Jane Cohen[1]

[1]University of the West Indies (Mona), Kingston 7, Jamaica, [2]ARC- Plant Protection Research Institute, Private Bag X6006, Hilton 3245, South Africa

Introduction: The neotropical shrub *Chromolaena odorata* (Asteraceae, has become one of the worst invasive alien weed species in the tropical and subtropical regions of Asia, Africa and Oceania. Biological control is critical in developing a successful management programme to control the spread of the weed. Previous studies in the neotropics highlighted the stem-tip killing fly, *Melanagromyza eupatoriella* (Agromyzidae), as a candidate for biological control of *C. odorata*.

Methods: Surveys were conducted in Jamaica to determine the field host range of the insect. Data was also collected on the prevalence of *M. eupatoriella* in relation to environmental parameters. Sites were selected based on the presence of *C. odorata* with shoot tips damaged by *M. eupatoriella* larvae, along with other species of Asteraceae.

Results: Damage by *M. eupatoriella* on *C. odorata* was observed at most sites, with over thirty species of Asteraceae being surveyed. To date, damage similar to that caused by *M. eupatoriella* larvae has been observed infrequently on four other Asteraceae, found growing alongside *C. odorata*, viz. *Bidens alba*, *Bidens reptans*, *Mikania micrantha* and *Calea jamaicensis*. Adult Agromyzidae were obtained only from *B. alba*. Taxonomic studies will determine if the damage is caused by *M. eupatoriella* or another species. Further research will establish the specificity of the insect in a controlled environment.

Conclusion: Although the presence of *M. eupatoriella*-like damage on other Asteraceae is a concern, it occurred at low levels and mines were often incomplete. This damaging fly thus still shows potential for biological control of *C. odorata.*

Development of a field-deployable chigger surveillance trap

Kriangkrai Lerdthusnee, James W. Jones, Jittawadee R. Murphy, Jason H. Richardson

Armed Forces Research Institute of Medical Sciences, Bangkok, Thailand

Introduction: Methods to assess relative risk in space and time are prerequisites for effective vector–borne disease control programs. However, there are no tools or methods specifically designed for conducting a rapid survey for ectoparasites such as chigger-mites, the vector for scrub typhus.

Methods: Several chigger trap models were designed (based on behavior and propensity of chiggers to climb upwards), made (by black-plastic sheet, paper or cloth), into several shapes, and tested against the black-plate, as the control trap. Traps were placed in the middle or spread-out in the testing platform area of 1x1 m^2. Ten to 40 live-chiggers (depending on number of traps tested) were randomly released into the platform. Numbers of chiggers approaching trap(s) were recorded through time, with 10 replications for each test. Evaluations on the difference between “Plastic-model” vs “Paper-model” were compared. Field trials of selected models were also conducted.

Results: Trap models with plastic base wrapped up with black cloth appeared to be more effective. Chiggers preferred the plastic model over the paper model. Preliminary field trials of the down-selected chigger trap model were initiated in order to evaluate their performance in the natural chigger-mite habitats.

Conclusions: Trap model with black cloth base captured more number of chiggers than the ones made from plastic or paper alone. Further evaluations are being conducted to improve trap attractiveness using attractants (CO_2, animal’s excreta, and commercially produced attractants).

Traversing a treacherous landscape: An overview

Myron Zalucki

University of Queensland, Brisbane, Queensland, Australia

Foraging behaviour of external feeding caterpillars; where they feed, “rest” and how often and where they move; will be influenced by many factors, both proximal and evolutionary. The former will pertain to internal and external ambient conditions. Internal factors comprise stage, age, nutritional balance, moisture and thermal balance. External factors include microclimate, surface waxes as well as plant and leaf “toughness”, trichomes and their constituents and internal plant attributes, such as, various constitutive allelochemicals, plant nutrients, plant exudates and changes in these as a result of feeding damage, so called induced defences. In addition, interaction with conspecifics and contact with natural enemies (predators and parasitoids) often causes drop off and other changes in behaviour, apart from mortality. The interactions among these factors at various spatial scales will likely result in complex movement patterns and distribution of damage to plants and plant parts. Obtaining nutrients whilst avoiding toxins in plants is not as simple as selecting a plant part and staying there. The plant part changes as a result of feeding and natural enemies are likely attracted to such damage. Moving is also likely to be hazardous as caterpillars may encounter both searching and sit-and-wait predators. The relative importance of these factors to the evolution of foraging strategies and what we might expect to be the distribution of damage and effects on survival are difficult to estimate but can be addressed experimentally within a modelling framework.

Progress in the development of a semiochemical-based system for managing *Lygus* spp. in an Arizona landscape

Jacquelyn Blackmer[1], Lynn Forlow Jech[1], David Hall[2], Jerry Hall[3], Michelle Fountain[3]

[1]US ALARC-ARS-USDA, Maricopa, Arizona, United States, [2]Natural Resources Institute, University of Greenwich, Chatham Maritime, Kent, United Kingdom, [3]East Malling Research, East Malling, Kent, United Kingdom

Introduction: Chemical attractants and repellents produced by insects and plants can be used to manipulate insect populations; however, a sound understanding of the mechanisms involved is needed to ensure effectiveness in the field. Trap design, placement, and insect activity levels must be taken into consideration.

Methods and Results: Through a combination of olfactometer bioassays and field-based experiments we have examined many of these factors for the *Lygus* species *L. lineolaris* and *L. hesperus* and found that in the laboratory females are more likely to respond to plant volatiles, especially in the presence of a green visual cue; however, in the field, males are more likely to be trapped. This difference is likely due to differences in flight activity relative to gender, as field populations, based on sweep samples, are usually at parity. Trap catches were enhanced by manipulating trap color, shape, height, orientation, and position in the field, but plant volatiles in combination with our traps have not been effective in trapping a higher number of *Lygus* spp. to date. Putatitve *Lygus* pheromones have also been examined, in combination with our most effective traps, and significantly higher numbers of male *L. lineolaris* were trapped with a binary combination. This response was short lived, but is the first report of significant attraction in the field by *L. lineolaris* to putative *Lygus* pheromones.

Conclusions: Ongoing studies are focusing on testing additional plant volatiles, confirmation of the response of *L. lineolaris* and other *Lygus* spp. to putative pheromone components in different cropping systems, and further refinement of our traps.

Why the browntail moth went extinct in much of its invasive range in North America

Joseph Elkinton[1], Dylan Parry[2], George Boettner[1]

[1]University of Massachusetts, Amherst, MA, United States, [2]State University of New York, Syracuse, NY, United States

Introduction: The browntail moth *Euproctis chrysorrhoea,* was introduced to North America near Boston from Europe in 1897. It became an important defoliator of many tree species throughout New England and was also a human health hazard due to severe skin rashes caused by urticating hairs from the larvae. Beginning around 1915, however, browntail populations receded gradually to coastal enclaves at the tip of Cape Cod, Massachusetts and on islands in Casco Bay in Maine, where high densities have persisted ever since. Until now no studies have explained why it declined and why it persists in coastal enclaves.

Methods: We analyzed historical data from the 1920s on levels of parasitism of browntail moth in New England and we created experimental populations of browntail moth at inland and coastal locations on Cape Cod.

Results: We present evidence that a major cause of the decline was the generalist tachinid parasitoid *Compsilura concinnata,* which was introduced to North America in 1906 to control gypsy moths. Analysis of historical data revealed high levels of parasitism of browntail moth by this species at inland sites, but low levels in coastal areas. We confirm this pattern in the experimentally created browntail populations at both inland and coastal locations on Cape Cod.

Conclusion: We conclude that *Compsilura concinnata,* was responsible for extirpation of browntail moth from most of its former range in North America.

Why the browntail moth went extinct in much of its invasive range in North America

Joseph Elkinton[1], Dylan Parry[2], George Boettner[1]

Tropical forests are both evolutionary cradles and museums of leaf beetle diversity

Duane McKenna

Harvard University Department of Organismic & Evolutionary Biology, Cambridge, MA, United States

Introduction: The extraordinary species richness of tropical forests is usually portrayed as a relatively recent and rapid development or as a result of the gradual accumulation or preservation of species over time. These explanations have led to alternative views of tropical forests as evolutionary 'cradles' or 'museums' of diversity. Biogeographic and fossil evidence implies that the history of diversification among tropical insects may be expected to exhibit features characteristic of both 'cradle' and 'museum' models. However, this possibility has not been explored in detail for any group of insects.

Methods: Using molecular phylogenetic and other data I reconstructed relationships and timing and patterns of taxonomic diversification in herbivorous Neotropical leaf beetles in the genus Cephaloleia (aka "rolled leaf hispine beetles").

Results: I present evidence for (i) comparatively ancient Paleocene–Eocene diversification associated with global warming and Cenozoic maximum global temperatures, (ii) moderately ancient lineage-specific diversification coincident with the Oligocene adaptive radiation of Cephaloleia host plants in the genus Heliconia, and (iii) relatively recent Miocene-Pliocene diversification coincident with the collision of the Panama island arc with South America and subsequent bridging of the Isthmus of Panama.

Conclusions: Taken together, these results demonstrate that for Cephaloleia and perhaps other groups of insects, tropical forests are at the same time both evolutionary cradles and museums of species diversity.

Colonizastion process of the threatened damselfly, *Mortonagrion hirosei*, inhabiting the artificially established reed community

Yuko Teramoto, Mamoru Watanabe

University of Tsukuba, Tsukuba, Ibaraki, Japan

Introduction: A new reed community was artificially established by transplanting reed rhizomes adjacent to the natural habitat of the threatened damselfly, *Mortonagrion hirosei*. The goal for the mitigation project was that the damselfly had immigrated and colonized the newly established habitat. The adult population size was considered to be one of the indicators for assessing the mitigation project.

Materials and Methods: During the flying season, from late May to early August, a weekly line census method was carried out. There was a good relationship between the daily number of adults detected per 10m along the transect line and the estimated daily number of adults per square mater calculated by the Manly & Parr method based on mark-and-recapture samplings.

Result and Discussion: In the original habitat, the estimated population size was stable at 15,000-18,000 for 4 years, that is about 20 adults per square meter. In the established habitat, a few adults was found daily in 2003 that is the 1st year of the establishment of the reed community. Adults seemed to be restricted near the original habitat because they have low flight activity throughout the life span. Then the population increased with year after year, but the growth rate decreased. Then, in 2007, the estimated population size was 79,000, 39 adults per square meter, probably due to result of the density dependent process. Although, the established reed community has not been fully grown up yet, the mitigation project for conservation of *M. hirosei* is now successful.

The mechanisms enabling movement of caterpillars on plants at the macro scale

Lynda Perkins, Bronwen Cribb, Jim Hanan, Ezekiel Glaze, Myron Zalucki

University of Queensland, Brisbane, Australia

Introduction: In order to model movement of an herbivorous insect on a plant we have divided interactions between plant and insect into two scales: macro and micro. At the macro scale, we have determined the affect of plant architecture and developmental stage using 1st instar *Helicoverpa armigera* on garden pea as our model.

Methods: Observations followed by targeted bioassays were used to determine how the architectural attributes of peas affected the movement of larvae. The results were used to create a set of 'rules' for the movement our model caterpillar. The simulated movement of the model caterpillar was compared to the movement of real caterpillars in glasshouse trials.

Results: Our modelling suggests that phototaxis and geotaxis as determined by the angle of plant structures are important mechanisms directing the movement of caterpillars. Plant attributes such as enclosed spaces, structural complexity, and the presence of flowers influence movement but not in a directional manner. The developmental stage of the larva affects its behavioural response to movement cues.

Conclusions: Phototaxis and geotaxis are mechanisms responsible for gross movement of early instar *H. armigera*, but these behaviours may be modified by plant attributes.

Plant-pollinator interactions in changing landscapes

Neal Williams[1], Elizabeth Crone[2], Rachael Winfree[3], Ramiro Aguilar[4], T'ai Roulston[5], Laurence Packer[6], Simon Potts[7], Robert Minckley[8]

[1]Bryn Mawr College, Bryn Mawr, PA, United States, [2]University of Montana, Missoula, MT, United States, [3]Princeton University, Princeton, NJ, United States, [4]UNAM, Morelia, Mexico, [5]University of Virginia, Boyce, VA, United States, [6]York University, Toronto, ON, Canada, [7]University of Reading, Reading, United Kingdom, [8]University of Rochester, Rochester, NY, United States

The loss and degradation of habitat resulting from human activities are among the greatest threats to biological diversity and to the ecological interactions and functions that depend on this diversity. Pollination is one such function that is a critical to plant and animal persistence, and which increases with the diversity and abundance of pollinators in the community. The tendency has been to consider natural habitats as good for pollinators and human-altered habitats as uniformly bad; however, recent studies call this generalization into question. We used a formal meta-analysis and hierarchical modelling to test the responses of native bee communities to different landscape changes and other anthropogenic disturbances. The meta-analysis revealed that habitat loss and fragmentation negatively affect abundance and diversity. Response to other disturbance types was variable, in part due to limited samples. The more detailed hierarchical model allows us to explore whether functional-traits help explain responses of bees within and among disturbance types. Here we define functional-trait groups as species with similar life histories (social vs. social), nesting strategies, body sizes, or trophic specialization. Preliminary results from different studies show that general nesting habit (e.g., ground-nesting vs. twig-nesting) and sociality can determine sensitivity to different land use changes. Less is known about the role of other functional traits.

Ecologically sustainable chemical recommendations for agricultural pest control?

Linda Thomson, Ary Hoffmann

University of Melbourne, Victoria, Australia

Introduction: Moves towards sustainability require a reduction in chemical toxicity loadings and conservation of natural enemies to maintain pest control. There is a lot of information based on laboratory and semi-field tests, such as that provided by the IOBC, on responses of natural enemies to chemicals but very few translations of these effects into field impacts particularly under commercial conditions.

Methods: We assessed the cumulative impact of chemical inputs across an entire season on the communities of natural enemies in vineyards. We calculated a chemical toxicity score for 19 commercial vineyards based on IOBC toxicity ratings and application number, and compared this to extensive field collections to determine if natural enemy populations can be related to predicted toxicity loadings. Invertebrates were sampled four times during the growing season using canopy sticky traps and ground level pitfall traps and abundance of natural enemies related to the toxicity score using ordination techniques. Further, we compared the metric used in this study to different approaches for assessing the impact of chemicals on agricultural ecosystems.

Results: Ordination analyses using non-metric multidimensional scaling indicated community structure in vineyards correlated to site chemical use. One ordination axis from canopy data and two axes from ground level data correlated to overall IOBC ratings for the vineyards and principal components analyses identified the taxa involved.

Conclusions: Our metric based IOBC toxicity ratings correlated with chemical effects on field populations of natural enemies in commercial vineyards where complexes of pesticides were applied. We proposed how effectiveness of metrics could be extended to include persistence and habitat features.

Factors in the establishment of boneseed leaf roller in New Zealand

Shaun Forgie[1], Darren Ward[1], Margaret Stanley[2]

[1]Landcare Research, Auckland, New Zealand, [2]University of Auckland, Auckland, New Zealand

Introduction: South African boneseed, *Chrysanthemoides monilifera monilifera,* naturalised in New Zealand in 1870. Boneseed threatens native biodiversity in coastal areas by shading out and preventing native seedling recruitment. Biocontrol of boneseed with the leaf roller *Tortrix s.l.* sp. *chrysanthemoides* began nationwide in 2007. This talk describes experiments to quantify the effect of generalist predators (especially Argentine ants, *Linepithema humile*) and parasitoids on invertebrate communities on boneseed, and their potential impact on establishment of the boneseed leaf roller.

Methods: We investigated boneseed plants with (control) and without (treatment) infestations of Argentine ants. Invertebrate assemblages on boneseed were determined by weekly foliage beating; placement/tethering observations and counts of defoliation, herbivory and sooty mould, all based on varying rates of ant traffic. To examine *Tortrix* establishment, 20 larvae on ten plants were monitored weekly for survivorship over several months.

Results: An increase in the proportion of Argentine ants visiting plants showed decreases in defoliation, herbivory and presence of predators; and increases in the proportion of sooty mould accumulation on stems and leaves. Ants removed significantly more invertebrates from leaves containing honeydew-providing homopterans than from leaves without homopterans. Significantly more *Tortrix* larvae were found developing on treatment plants than control plants. All but two larvae were subsequently killed with 14% per cent parasitism recorded.

Conclusions: Generalist predators (Argentine ants) and parasitoids (braconids and tachinids) play a significant role in shaping invertebrate community assemblages on boneseed, and combine to significantly effect successful establishment by biological control agents.

Operation Full Stop - 10 years of area-wide termite management

Claudia Riegel[1], Frank Guillot[2], Edgar Bordes[1]

[1]City of New Orleans Mosquito and Termite Control Board, New Orleans, LA, United States, [2]USDA/ARS, New Orleans, LA, United States

The French Quarter in New Orleans has had a long history of severe termite pressure from the Formosan subterranean termite (FST), *Coptotermes formosanus.* FST was accidentally introduced into New Orleans in the mid 1940's and its identity was first confirmed in 1966. Operation Full Stop began in 1998. It is the first project to apply area-wide management of subterranean termites in an expansive urban area with the aid of pest control professionals. The goal of the project was to reduce the termite pressure in the French Quarter. Therefore, they were required to utilize technologies such as termite baiting systems and non-repellent termiticides which are expected to eliminate termite colonies. This termite caused costly, reoccurring, structural damages to many buildings and trees including many of historic significance. Without intervention, the French Quarter was destined for destruction by FST. Green space such as parks with infested trees, railroad lines, and Mississippi river levee in the French Quarter were also included in the program. In-ground termite activity was evaluated monthly using independent monitoring stations and alate density was measured each April to July. A 15 city block section of the French Quarter (an area) was added to the program every two years. Since inception of the program, alate density across the French Quarter has been reduced from 44% to 75%. A 98% reduction in FST has been observed along the railroad and levee. An effort has been made to inspect every property in the program. Operation FullStop was a pioneer program that has reduced the overall termite activity in the French Quarter. Effort has been placed on identifying and treating above-ground infestations and infested trees. This project has also utilized improved termite detection tools and more thorough treatments to continue the effort to further reduce the subterranean termite population in the French Quarter.

Developing a systems approach for false codling moth on 'Hass' avocado

Tertia Grové, Marinda De Beer

ARC-Institute for Tropical and Subtropical Crops, Nelspruit, South Africa

Introduction: False codling moth, *Thaumatotibia leucotreta* Meyrick (Lepidoptera: Tortricidae) is a quarantine pest on avocado which prevent exportation of 'Hass' to new markets. A quarantine treatment needs to be developed before new markets can be exploited. A systems approach relies on knowledge of the pre- and postharvest biological factors that influence pest survivorship. The objective of the research is to obtain biological data that can be used in a systems approach.

Methods: The time frame for the development of visible lesions was determined. Fruits were artificially infested with eggs on the tree to determine if the larvae could develop. Male moths were monitored in 'Hass' orchards. The number of fruit with lesions was also determined. Fruit firmness was measured by using a densimeter and the correlation between firmness and the instars present in the fruit was determined. Insecticides and granulovirusses were evaluated for the control of *T. leucotreta*. Bagging of fruit to prevent infestation was also evaluated. Fruit infested with eggs in the orchard were picked 2, 4 and 6 weeks after infestation and the survival rate was determined. A survey was conducted to determine infestation levels in the field. A systems approach was evaluated during 2004, 2005 and 2006.

Results: Lesions were visible from two weeks after infestation of the larvae and therefore fruit with lesions can be sorted prior to entering the packhouse and again in the packline. Experiments done indicated that larvae could develop further than 1st instar. It also seemed that 'Hass' was partially resistant to the development of larvae when attached to the tree. As soon as the fruit were harvested, larvae started developing further. Field studies indicated that infestation usually started during January. Fifth instar larvae were only present in soft fruit. Fenpropathrin and the granulovirusses were effective in reducing the infestation rate of fruit. Bagging reduced the number of larvae present in the fruit but was a labour intensive method. Survival rate of larvae in fruit on the tree which were left to develop further after harvest, varied between 4.05% and 0.90% and depended on the time of infestation prior to harvest. Fruit that become infested shortly before harvest would be of higher risk. The survey conducted in the different production areas indicated that infestation levels in commercial orchards were usually <1%. Lower risk areas can be selected for export. No survival of larvae occurred in the systems approach tested.

Conclusion: A systems approach for *T. leucotreta* seemed to be a viable option to reach quarantine security on 'Hass' avocado.

Molecular phylogenetics and phylogeographic analysis of the Australian termite genus *Coptotermes*

Haidi Badawi

Melbourne University and Flinders University SA, Australia

This study will focus on the genus *Coptotermes* phylogeny, especially from Australian regions, by using 4 different genes which are 16S, COII, COI and H3 (the histone3 gene will be used for first time within *Coptotermes* phylogenies). The study will use different analyses of this combined data set of 3000 bp, to give a better phylogenetic model of Australian *Coptotermes* within the global *Coptotermes* view, moreover the study will focus on the phylogeographic status of *Coptotermes* by discussing the dispersal of haplotypes among the geographical localities by using NCPA nested Clade phylogeographic analysis.

Use of sequence data can provide some enormous advantages over other data types, including the ability to rapidly generate very large character suites and ease of analysis.

A simple approach to integrating insecticides into cotton IPM

Lewis Wilson, Simone Heimoana

CSIRO Plant Industry, Narrabri, New South Wales, Australia

Introduction: Insecticides are an important component of IPM systems. Establishing their ideal use in IPM systems requires information on efficacy against target pests, effects on beneficial populations and potential to induce secondary pest outbreaks. We developed a simple method which incorporates these variables and tested it by using it to compare several control options for the green mirid (*Creontiades dilutus*), a key pest in Australian Bt-cotton.

Methods: Field plots of irrigated cotton were either untreated or treated with petroleum spray oil (PSO), salt (NaCl), low rate fipronil alone or with salt, high rate fipronil, low rate indoxacarb alone or with salt or PSO and high rate indoxacarb. Insecticides were applied 4 times at 10 d intervals and plots sampled pre-spray and twice weekly thereafter. Key pests and a wide range of beneficials were recorded. Data were analysed for treatment effects, which were ranked according to the reduction in beneficial abundance compared with the untreated control; VL (very low), less than 10%; L (low), 10-20%; M (moderate), 20-40%; H (high), 40-60%; VH (very high), > 60% and risk of pest resurgence.

Results: All rates of fipronil provided effective control of green mirids. Reduced rates of fipronil were more selective than the full rate but all rates increased abundance of mites, *Helicoverpa* spp. and aphids. Indoxacarb was effective against mirids at the full rate but not at the lower rate unless salt or PSO were added. Indoxacarb at the full rate was as selective as low rate fipronil and at the low rate was even more selective. Indoxacarb did not induce mite outbreaks but had higher aphid numbers.

Conclusions: This approach has been used to evaluate the IPM fit of a wide range of insecticides. Meta-analysis of commercial crops managed with more selective insecticides had higher beneficial populations, confirming the value of rankings generated using this method.

Clock and photoreceptor in the photoperiodic regulation of diapause in the flesh fly *Sarcophaga similis*

Shin G. Goto

Osaka City University, Osaka, Japan

Introduction: Physiological processes underlying photoperiodism comprises 3 components, i.e., photoreceptor(s), photoperiodic clock(s) and hormonal effecter(s). Although our knowledge on the endocrinological details in the expression of photoperiodism has advanced, information on functional photoreceptor(s) and photoperiodic clock(s) are still limited. Here I approached the mechanisms of the photoperiodic clock and photoreception in the flesh fly *Sarcophaga similis*.

Results and Discussion: *Sarcophaga similis* enters pupal diapause in response to short days. Destination to diapause or nondiapause could be altered by a few long- or short-day cycles. Larvae discriminate photoperiods qualitatively and count the number of the photoperiodic cycles. Nanda-Hamner protocol revealed that the circadian oscillator is involved in the photoperiodic response. Experiments on 24h asymmetric skeleton photoperiods revealed that two phases (early and late) in the scotophase are sensitive to light for averting diapause. Experiments on non-24h asymmetric skeleton photoperiods revealed that the response at the early phase is reversible, but that at late phase is irreversible. Based on the external coincidence model which is verified in another *Sarcophaga* species, I suggest that the late phase is the photoinducible phase (Φ_i). Only light of short-wavelength (blue and UV) was effective in the early phase, whereas light of broad wavelength as well as that of short-wavelength successfully averted diapause in the late phase. From these results, I suggest that different photoreceptors are involved in the expression of photoperiodism in these phases.

Molecular phylogeny of the horse flies: a framework for renewing tabanid taxonomy

Shelah I. Morita[2], Keith M. Bayless[1], Brian M. Wiegmann[1]

[1]Department of Entomology, North Carolina State University, CB 7613, Raleigh, North Carolina, 27695-7613, United States, [2]Department of Botany and Zoology, University of Stellenbosch, Private Bag X1, Matieland, 7602, South Africa

Introduction: Horse flies (Diptera: Tabanidae) are an economically, medically, and ecologically important group containing bloodfeeding pests and long-proboscid pollinators. This group, with over 4,300 described species, has experienced a severe loss of taxonomic expertise. The TabanidPEET project will fill this gap by training at least four postgraduates. As a framework for student taxonomic revisions, we present here a new higher-level molecular phylogeny of the horse flies. This work will guide morphological character choice and focus student projects on evolutionary units. We also ask the following questions: 1) Are the three current subfamilies monophyletic? 2) Is pollinator morphology ancestral in Tabanidae? 3) When did the major tabanid clades diverge and radiate? 4) What are the morphological and life history features supporting tabanid clades?

Methods: Using exemplars from 10 of 11 tribes, we sampled two nuclear (CAD, AATS), and one mitochondrial (COI) gene. Phylogenetic inference was performed using Parsimony and Maximum Likelihood in Paup*, and using Bayesian Inference in Beast. Character reconstruction was optimized using BayesTraits and MacClade.

Results: Our phylogenetic hypothesis for Tabanidae is largely concordant with previous hypotheses, but also indicates several newly recognized groupings that will form the basis for focused taxonomic revisions. Divergence time estimates based on nucleotide data and fossil evidence reveal rapid radiations in the early history of horse fly diversification.

Conclusions: The current taxonomy of Tabanidae at the subfamily and tribal level needs to be revised based on new molecular evidence. Additionally, long-proboscides appear to be ancestral, suggesting that tabanids are ancient pollinators.

Elucidating cotton genotypes resistant to whitefly, *Bemisia tabaci* (Gennadius) (Homoptera: Aleyrodidae) by population build up studies under no choice conditions

Vikas Jindal, G.S. Dhaliwal

[1]Punjab Agricultural University, Regional Station, Faridkot/ Punjab, India, [2]Insect Biopesticide Research Centre, Jalandhar/Punjab, India

Introduction: Plant resistance has become an important component of cotton integrated pest management (IPM) for management of whitefly, *Bemisia tabaci,* an important pest of cotton in India. Therefore, cotton genotypes resistant/tolerant to whitefly were identified and evaluated.

Methods: Twelve cotton genotypes, *G hirsutum*(10) and *G. arboruem*(2), raised upto standardized (14-leaf) stage were released with five newly emerged pairs of whiteflies (F_1) under no choice conditions. After 25 days, eggs, immatures (nymphs+pupae) and adults were recorded to identify genotypes, not suitable for whitefly development. The experiment was repeated with F_2 and F_3 generation of whiteflies.

Results: In F_1 generation experiment, RS2098 recorded minimum eggs (2.17/6.5cm^2), immatures (12.00/6.5cm2) and adults (60.00/plant), however, F846 recorded maximum eggs (54.23/6.5cm^2), immatures (58.33/6.5cm^2) and adults (815.00/plant). In F_2 generation experiment, LD694, NHH44 and Supriya recorded minimum eggs (1.77/6.5cm^2), immatures (6.00/6.5cm^2) and adults (46.00/plant), respectively, while maximum eggs and immatures were found on F846. In F_3 generation experiment, RS2013 recorded lowest eggs (0.83/6.5cm^2) and LD694 recorded lowest immatures (0.83/6.5cm^2) and adults (22.67/plant). Genotypes IS-376/4/1/20/72, RS2098 and F846 recorded maximum eggs, immatures and adults, respectively.

Conclusions: LD694 was categorized as resistant; LK861, Supriya, RS2013, RS2098 and PA183 as moderately resistant; IS-376/4/1/20/72, NHH44, TxMaroon2-78, *Bt*6304, CNH911 as moderately susceptible and F846 as susceptible one. LD694 was found to be resistant in three consecutive generations of whitefly, hence, the chances of development of biotypes of whitefly are low for three generations, but detailed studies are further required.

Spatial analysis of the influence of adjacent vegetation on the abundance and distribution of natural enemies in a vineyard in south eastern Australia

Linda Thomson

University of Melbourne, Victoria, Australia

Introduction: Adjacent vegetation increases the relative abundance of natural invertebrate enemies on farmland and can assist in invertebrate pest control. The provision of vegetation either adjacent to the crop or within the crop can provide refuge from the effects of applied chemicals and sources of new populations.

Methods: We investigated the abundance and diversity of natural enemies in a range of vegetation types adjacent to vineyards in south eastern Australia. Invertebrates were sampled four times in 2 consecutive seasons at 10 sites, adjacent to either remnant native forests or shelterbelts, using canopy sticky traps and ground level pitfall traps. At one site we investigated the spatial distribution with 100 sampling points in a single vineyard and at 9, transects were set up from the vegetation into the vineyard. Distribution and abundance of natural enemies was mapped using spatial analysis by distance indices (SADIE) and ANOVAs. We also directly assessed impacts on predation and parasitism of eggs of an important vineyard lepidopteran pest.

Results: The abundance and distribution of vineyard natural enemies was influenced by adjacent vegetation, traps adjacent to vegetation with higher numbers of a range of natural enemies and sentinel eggs higher levels of parasitism. These results indicate that the abundance and distribution of vineyard natural enemies is influenced by adjacent vegetation and that there are direct beneficial effects on the control of a moth pest.

Conclusions: The conservation of remnant vegetation and planting of shelterbelts around vineyards may have direct economic benefits in terms of pest control which should promote the maintenance of vegetation by growers specifically for improving pest control.

Floral niche models best explain proboscis length evolution in long-tongued, bloodsucking pollinators (Diptera: Tabanidae)

Shelah I. Morita

[1]Population Biology Graduate Group, University of California, Davis, California 95616, United States, [2]Department of Botany and Zoology, University of Stellenbosch, Private Bag X1, Matieland, 7602, South Africa

Introduction: The relationship between plants and their pollinators has often been upheld as the best example of bioticaly mediated speciation, specialization, and co-divergence. Hypotheses regarding the mechanism of trait evolution in these relationships are focused on plants. They include two main hypotheses 1) plants and pollinators are in a coevolutionary race and 2) pollinators are relatively constant and plants evolve in response to pollinator shifts. Here I address the adaptive significance of pollinator morphology in species complex of long-tongued horse flies by asking: 1) Have long proboscides evolved multiple times? 2) Is their evolution consistent with a coevolutionary arms race (always increasing)? 3) Is pollinator morphology adapted to floral niches?

Methods: I sampled nuclear and mitochondrial genes from 9 of the 11 tabanid tribes with multiple geographic exemplars within the *Philoliche aethiopica* species complex. Twenty trees were randomly sampled from a Bayesian posterior distribution of 20 million generations, representing 13 unique topologies and branch lengths variation. For each tree, branch lengths in terms of time were estimated in r8s, character reconstruction was optimized using BayesTraits (Maximum Likelihood) and Mesquite (Max-Min Squared Changes Parsimony). Floral association models were tested using OUCH.

Results: Ancestral reconstruction supports multiple, independent evolutions of long proboscis morphology. Max-Min coding shows evolution of both longer and shorter proboscides. OUCH models strongly support the adaptive significance of Floristic Region and *Wastonia* floral morphology.

Conclusions: Proboscis length evolution seems labile and non-directional, incongruent with a coevolutionary arms race. However, proboscis length appears to evolve in response to floral niches.

Egg whites and whitegrubs - transgenic sugarcane for grub control

Kerry Nutt, Rachael Hassall, Peter Allsopp

BSES Limited, Brisbane, Australia

Major losses are inflicted on the Australian sugar industry by a complex of 19 species of whitegrubs (Scarabaeidae: Melolonthinae). The control of whitegrubs by insecticides is made difficult by their subterranean life style, but there are few alternatives for control and commercial sugarcane varieties lack natural resistance to whitegrub attack. Genetic modification of sugarcane cultivars to enhance resistance to whitegrubs has been investigated as an alternative method of control for whitegrubs. Artificial diet feeding trials conducted by Allsopp & McGhie (1996) found that avidin, a biotin binding protein from chicken egg white, could reduce larval growth and increase larval mortality of *Antitrogus parvulus* (Childers grub). A gene for vacuole-targeted avidin, under the control of the maize ubiquitin promoter, was introduced into sugarcane by microprojectile bombardment. Efficacy of avidin producing sugarcane was tested using cut leaf bioassays with late first instar (5d old) sugarcane armyworm (*Leucania* spp.). Larvae were fed transgenic sugarcane leaf sections from plants expressing avidin at average concentration ranging from 0.01-0.03 µM (µmoles/kg of fresh leaf tissue). Avidin expressed in sugarcane at this level had no significant effect on armyworm development or survival. Although avidin has conferred insect resistance to tobacco (Burgess et al. 2002), improvements in transgene expression in sugarcane need to be made if it is to become an effective whitegrub control method.

Analysing border interceptions and establishments of bark and ambrosia beetles: Can we identify traits of successful invaders?

Eckehard Brockerhoff[1], Jean-Claude Grégoire[2], Robert Haack[3], Milos Knizek[4], Andrew Liebhold[5], Robert Rabaglia[6]

[1]Scion / New Zealand Forest Research Institute, Christchurch, New Zealand, [2]Université libre de Bruxelles, Bruxelles, Belgium, [3]USDA-FS, East Lansing, Michigan, United States, [4]Forestry and Game Management Research Institute, Jiloviste, Czech Republic, [5]USDA-FS, Morgantown, West Virginia, United States, [6]USDA-FS, Arlington, Virginia, United States

Many bark and ambrosia beetles (Scolytinae) are highly destructive forest pests and they also include numerous successful invaders. Exports of logs and timber and the widespread use of wood packaging materials are recognised pathways for invasions of Scolytinae. We used information on border interceptions and records of establishments to improve our understanding of invasion pathways and the characteristics of successful invaders. By combining interceptions of true bark beetles in New Zealand and the United States we obtained data on species found in shipments from around the world. The probability of establishment somewhere in the world was positively correlated with interception rates of species, but interceptions alone can only partially explain the variation in this relationship. To identify other determinants of invasiveness of Scolytinae, we compiled a list of factors that could be correlated with invasiveness, such as body size, breeding behaviour, mating system, occurrence of outbreaks, etc. Results from a comparison of several prominent Scolytinae genera will be presented.

Phylogenetics of the *nasuta-albomicans* complex of *Drosophila*

H.A Ranganath

Bangalore University, Bangalore, Karnataka, India

Introduction: Inter-racial hybridizations between *Drosophila nasuta nasuta* and *D.n.albomicans* of the *nasuta* subgroup of *Drosophila* have resulted in the evolution of novel karyotypically stabilized hybrid lines.

Results: In each of the hybrid lines, called 'Cytorace', the chromosomes of parental races, namely, of *D. nasuta* and *D. albomicans* are differentially represented. These newly evolved hybrid cytoraces have gone through 600 generations under laboratory conditions. This assemblage of *D. nasuta*, *D. albomicans* and Cytoraces is named as '*nasuta-albomicans* complex'. The pattern and extent of anagenetic changes among these cytogenetically closely related members are evaluated and analyzed by adopting different sets of phenotypes, namely, karyotypes, mating behaviour, parameters of fitness, morpho-phenotypic components, Isozymes, Yolk Proteins, DNA markers etc.

Conclusion: Extent of genetic similarity and difference among members of this complex presents a complex profile and the implications of these studies will be discussed in relation to phylogenetic analysis of the group.

Microbial control of soil dwelling pests – progress and prospects

Trevor Jackson

AgResearch, Lincoln, New Zealand

Soil dwelling pests pose particular problems in insect control as they are protected by the soil and difficult to treat. The soil, however, acts as a reservoir for microorganisms, which can include insect pathogens. Insect disease usually occurs as a delayed-density-dependent response to pest build up and is often responsible for natural pest population collapses. Pathogenic microbes can be isolated from diseased insects, cultured, formulated and used as biopesticides for control of pest species. These include preparations of specific strains of bacteria, fungi and virus which have been used successfully for control of a range of soil dwelling pest problems. Most success has been achieved where the pathogens are able to persist within the host's environment. Use of pathogens in soil dwelling pest control has been limited by cost of production, application technology and specificity but, through efficient production processes and correct targeting of control, successful niche markets for microbial control products have been established. Current products provide models for analysis and future developments. The prospects for microbial control are improving with greater appreciation of soil ecosystems and the need to avoid disruptions with chemical pesticides.

Juvenile hormone and soldier-caste differentiation in the termite *Hodotermopsis sjostedti*

Richard Cornette[2], Shigeyuki Koshikawa[1], Hiroki Gotoh[1], Toru Miura[1]
